It is instructive to see that the cubic equation alone would not have caught this: the single multiplet $(\mathbf{3}, \bar{\mathbf{3}})$ has cubic anomaly $3 = N_c$ and would match (37.128) for the $[\mathrm{SU}(3)_L]^3$ triangle by itself — but it contributes $\frac{3}{2} \neq \frac{1}{2}$ to the mixed triangle, and there is no way to correct $\frac{3}{2}$ to $\frac{1}{2}$ by adding further baryons, every one of which moves the mixed total in steps of $\frac{3}{2}$. It is the *simultaneous* imposition of the cubic and the mixed anomaly that kills the scenario, exactly the mechanism advertised in Section 37.5.6: one anomaly rarely suffices, but the full set is rigid. The naive guess — the observed parity spectrum, with a massless octet — fails even the cubic equation alone, since $A(\mathbf{8}) = 0$ gives zero where $N_c = 3$ is required.

The worked example proves the impossibility for the physical $N_f = 3$ within the three-quark baryon sector, which is the relevant content of a confining $N_c = 3$ theory. The general statement, for arbitrary $N_f \geq 3$ and including exotic multiquark composites, is 't Hooft's original result, and the clean engine behind it is the persistent-mass / decoupling condition of Theorem 37.28, applied flavor by flavor.

Theorem 37.33 (No unbroken chiral realization for $N_f \geq 3$)**.** *For QCD with N_c colors and $N_f \geq 3$ massless flavors, there is no spectrum of massless color-singlet baryons that simultaneously matches the cubic $[\mathrm{SU}(N_f)_{L,R}]^3$ and mixed $[\mathrm{SU}(N_f)_{L,R}]^2\,\mathrm{U}(1)_B$ 't Hooft anomalies of Theorem 37.31 with non-negative integer multiplicities consistent with the persistent-mass condition. The chirally symmetric confining vacuum is therefore forbidden; chiral symmetry must break.*

The decoupling argument. Suppose a matching massless-baryon spectrum existed for N_f flavors. Give the N_f-th quark a mass and send it to infinity. In the

ultraviolet this reduces $\mathrm{SU}(N_f)_L \times \mathrm{SU}(N_f)_R \to \mathrm{SU}(N_f-1)_L \times \mathrm{SU}(N_f-1)_R$ and leaves exactly $N_f - 1$ flavor massless QCD, whose cubic anomaly is again N_c — *unchanged*, since (37.120) is independent of N_f. In the infrared, every massless baryon containing the heavy quark acquires a mass of order $m \to \infty$ and decouples (Theorem 37.27); the baryons that survive massless are precisely those built from the remaining $N_f - 1$ light flavors, and by the matching theorem applied to the reduced theory they must reproduce the same N_c for $\mathrm{SU}(N_f - 1)$. This is a recursion: a matching N_f-flavor spectrum must contain, as the heavy-quark-free subset, a matching $(N_f - 1)$-flavor spectrum, all the way down. Run the recursion to $N_f = 3$. There the explicit obstruction of Theorem 37.32 applies for $N_c = 3$ (and the analogous mixed-anomaly divisibility $\frac{1}{2} \notin \frac{N_c}{2}\mathbb{Z}$ for any $N_c \geq 2$): the three-quark baryons cannot match the mixed anomaly, and admitting heavier multi-quark composites only reintroduces states that the next decoupling step removes without restoring the deficit. The recursion therefore has no consistent base case for $N_f \geq 3$, and the assumed spectrum cannot exist. By the trilemma of Section 37.5, with confinement assumed (so the theory is gapped except for whatever the anomaly forces) and massless composite fermions excluded, the only remaining escape is spontaneous breaking of G. Hence chiral symmetry breaks. □

Caution

The honest scope. The cubic obstruction requires $N_f \geq 3$; at $N_f = 2$ the $[\mathrm{SU}(2)]^3$ anomaly does not exist (Eq. (37.36)) and the only surviving constraint is the mixed $[\mathrm{SU}(2)_L]^2\,\mathrm{U}(1)_B = \frac{1}{2}$, which is matched by a single massless nucleon doublet (the would-be massless proton and neutron form an $\mathrm{SU}(2)_V$ doublet of $B = 1$, and the Witten-type two-flavor counting closes), so two-flavor QCD does *not* require chiral breaking on anomaly grounds alone. The clean impossibility (37.129) is proved here for the three-quark sector at $N_c = 3$; the fully general theorem, covering arbitrary multi-quark massless composites for all $N_f \geq 3$, is 't Hooft's, with the persistent-mass condition supplying the inductive step, and is reviewed in the literature cited at the end of the chapter. Anomaly matching is a veto, not a constructive solver (Section 37.5.6); it excludes the unbroken scenario, and the positive identification of the broken vacuum rests in addition on the observed pion spectrum and on lattice and large-N_c evidence. The conclusion "chiral symmetry breaks" is, with these qualifications, forced for $N_f \geq 3$ and strongly favored for the real world.

Physical Insight

The deepest point of the QCD argument fits in one sentence: the quark carries baryon number $1/N_c$ but every confined fermion carries integer baryon number, so the fractional mixed anomaly $\frac{1}{2}$ cannot be assembled from integer-charge bound states. Confinement, which hides color, also hides the fractional baryon number that made the anomaly small — and the resulting arithmetic mismatch is fatal to a symmetric vacuum. The theory escapes not by inventing exotic massless baryons but by breaking the symmetry, so that the anomaly is carried by Goldstone bosons, which are exempt from the integer-charge bookkeeping because they realize the symmetry non-linearly.

37.6.4 Scenario B: chiral symmetry breaks, and who carries the anomaly

The verdict of Theorem 37.33 is that $G = \mathrm{SU}(N_f)_L \times \mathrm{SU}(N_f)_R \times \mathrm{U}(1)_B$ cannot stay unbroken. The dynamical fact, established phenomenologically in Section 29.6.7 and now *forced* by anomaly matching, is that the quark bilinear condenses, $\langle \bar{q}q \rangle \neq 0$, breaking the chiral group to its vector (diagonal) subgroup while preserving baryon number:

$$\mathrm{SU}(N_f)_L \times \mathrm{SU}(N_f)_R \xrightarrow{\langle \bar{q}q \rangle \neq 0} \mathrm{SU}(N_f)_V \times \mathrm{U}(1)_B. \tag{37.130}$$

By Goldstone's theorem (Theorem 29.11) this produces $\dim \mathrm{SU}(N_f) - \dim \mathrm{SU}(N_f) = N_f^2 - 1$ massless Goldstone bosons — the pions and their flavor partners — governed at low energy by the nonlinear sigma model of Section 29.5, which is the chiral Lagrangian that Chapter 39 develops in full. Now we must check that this realization *can* match the anomalies that the symmetric one could not.

The check has two parts. First, the surviving exact symmetry $\mathrm{SU}(N_f)_V$ acts identically on left- and right-handed quarks; it is *vector-like*. Its cubic anomaly from the quark content (37.119) is

$$\mathcal{A}\big[(\mathrm{SU}(N_f)_V)^3\big] = N_c\, A(\mathbf{N_f}) + N_c\, A(\bar{\mathbf{N}}_\mathbf{f}) = N_c \cdot 1 + N_c \cdot (-1) = 0, \tag{37.131}$$

because ψ sits in the $\mathrm{SU}(N_f)_V$ fundamental and χ in the antifundamental. The unbroken vector symmetry is anomaly-free, so matching it demands *nothing* of the infrared: the massive baryons of the real world, which fill real representations of $\mathrm{SU}(N_f)_V$ (the octet $\mathbf{8}$, the decuplet's vector content, and so on), are exactly consistent with $\mathcal{A}[(\mathrm{SU}(N_f)_V)^3] = 0$, and need not be massless. This is why nature can have a heavy, vector-symmetric baryon spectrum: the only symmetry those baryons must faithfully represent has no anomaly to carry.

Second, the genuinely nonzero anomalies (37.125) all involve the *broken* (axial) directions — they are the coefficients of triangles with at least one current along

a broken generator. With chiral symmetry broken there are no massless fermions charged chirally to carry them (Theorem 37.28), and the massive baryons are anomaly-neutral. The deficit must be made up by the only massless states left: the Goldstone bosons. But a Goldstone boson is an ordinary scalar, and no *invariant* local Lagrangian built from scalars can produce a triangle anomaly — an anomaly is precisely the part of the effective action that is *not* a gauge-invariant local functional, by the Wess–Zumino consistency condition of Section 37.1. The resolution is that the Goldstone effective action contains, beyond its invariant nonlinear-sigma-model part, one extra term that is *not* invariant under the broken symmetry but shifts by exactly a total derivative whose integral reproduces the anomaly: the Wess–Zumino–Witten term. Its coefficient is not a free parameter; matching (37.120) fixes it to be the integer

$$k \;=\; \mathcal{A}_{\mathrm{UV}}\big[(\mathrm{SU}(N_f))^3\big] \;=\; N_c, \tag{37.132}$$

the number of colors, reappearing in the low-energy theory of pions as the quantized level of a topological term. The Goldstone bosons thereby carry the full chiral anomaly of the quarks, $\mathcal{A}_{\mathrm{IR}} = \mathcal{A}_{\mathrm{UV}} = N_c$, and matching is restored.

Physical Insight

The two scenarios are distinguished by *who is massless*. Unbroken chiral symmetry (Scenario A) keeps massless composite fermions, and the anomaly must live on them — but the integer-baryon-number arithmetic forbids it. Broken chiral symmetry (Scenario B) replaces those would-be massless fermions with Goldstone bosons, and the anomaly lives on *them*, through a term whose very non-invariance is what lets a boson do a fermion's job. Anomaly matching does not merely permit chiral symmetry breaking; for $N_f \geq 3$ it requires it, and it predicts that the low-energy pion theory must contain a topological term of integer strength N_c. The light pion of Eq. (29.228) and the WZW term of the next section are two faces of the same forced symmetry breaking.

We have used the one exact, non-perturbative constraint that survives at strong coupling to extract a structural truth about QCD that no order of perturbation theory could reach: with three or more massless flavors the chiral symmetry of the quarks must break spontaneously, and the broken-symmetry vacuum is the only one whose massless spectrum can reproduce the ultraviolet anomaly coefficient N_c. What remains is to build the object that does the reproducing. The next section constructs the Wess–Zumino–Witten functional explicitly — Witten's five-dimensional integral, the proof that its coefficient is quantized to the integer N_c, and the gauging that turns it back into the $\pi^0 \to \gamma\gamma$ amplitude of Chapter 36 — thereby closing the matching loop opened here.

37.7 The Wess–Zumino–Witten Term

The previous section delivered a verdict, not a construction. 't Hooft matching, applied to massless QCD with N_f light flavors, demanded that the ultraviolet anomaly of the global chiral group $\mathrm{SU}(N_f)_L \times \mathrm{SU}(N_f)_R$—a definite number, the $\mathrm{SU}(N_f)_L^3$ coefficient equal to the color count N_c (Eq. (37.120))—be reproduced, exactly and without renormalization, by whatever degrees of freedom carry the physics at low energy. We argued that the confined-and-symmetric scenario cannot supply it with massless baryons, so chiral symmetry must break, and the infrared theory is the one built in Chapter 29: a nonlinear sigma model of the Goldstone bosons, the pseudoscalar mesons, packaged into a field $U(x) \in \mathrm{SU}(N_f)$. The matching demand then sharpens into a question we have not answered. The leading chiral Lagrangian, $\frac{f^2}{4}\,\mathrm{tr}(\partial_\mu U\, \partial^\mu U^\dagger)$, and every higher term of the standard derivative expansion, is *exactly invariant* under the chiral group. An invariant action has a vanishing anomaly. How, then, can a theory of nothing but invariant Goldstone interactions reproduce a nonzero anomaly coefficient?

The resolution is the subject of this section, and it is one of the most beautiful confluences of topology and field theory in all of physics. There exists a term that can be added to the chiral Lagrangian which is *not* expressible as the four-dimensional integral of anything local in U, yet which is perfectly well defined, Lorentz invariant, and—crucially—*not* chirally invariant: under a chiral transformation it shifts by precisely the anomaly. This is the Wess–Zumino–Witten (WZW) term. Wess and Zumino first wrote its variation as the unique local solution of the anomaly's consistency conditions; Witten then gave it a closed geometric form, as the integral of a closed five-form over a five-dimensional disk whose boundary is spacetime. The geometric construction does something the local one cannot: it exposes that the coefficient of the term is *quantized*—forced to be an integer by the topology of the group manifold—and that the integer is none other than N_c. The same integer, read off by gauging electromagnetism, reproduces the $\pi^0 \to \gamma\gamma$ amplitude of Chapter 36 with its factor of $N_c = 3$ on display. The matching loop opened in the previous section closes here, and it closes on a topological invariant.

This advances *Yang–Mills theory* to its topological and effective-theory layer. The color number N_c, which entered the book as the dimension of the QCD gauge group and reappeared in the beta function and the R-ratio, now surfaces a third time as the integer level of a topological term in the meson Lagrangian—an infrared, entirely non-fermionic quantity that nonetheless counts the underlying quarks. It is also the bridge to chiral perturbation theory (Chapter 39), where the WZW term is the sole leading-order interaction that violates the "naive" intrinsic parity of the mesons and so controls processes such as $\gamma \to 3\pi$ and $K\bar{K} \to 3\pi$. And it recovers the $\pi^0 \to \gamma\gamma$ matching of *QED*.

37.7.1 The infrared theory and the matching demand

We work with the low-energy realization of chiral symmetry breaking constructed in Chapter 29. For QCD with N_f massless quark flavors the global symmetry is $G = \mathrm{SU}(N_f)_L \times \mathrm{SU}(N_f)_R$ (we set aside the abelian factors, whose fate—$\mathrm{U}(1)_B$ exact, $\mathrm{U}(1)_A$ anomalous—was settled earlier), and the quark condensate breaks it to the diagonal vector subgroup $H = \mathrm{SU}(N_f)_V$. Goldstone's theorem (Theorem 29.11) then guarantees $\dim G - \dim H = N_f^2 - 1$ massless Goldstone bosons, the pseudoscalar mesons, which the coset construction of Section 29.5 assembles into a single unitary matrix field. We continue that construction directly: write

$$U(x) = \exp\Big(\frac{i}{f}\,\pi^a(x)\,X^a\Big) \in \mathrm{SU}(N_f), \tag{37.133}$$

exactly the Goldstone group element of Eq. (29.187), with X^a the broken (axial) generators and $f \to f_\pi$ the pion decay constant. Under a chiral rotation $(g_L, g_R) \in \mathrm{SU}(N_f)_L \times \mathrm{SU}(N_f)_R$ the field transforms linearly,

$$U(x) \;\longmapsto\; g_L\,U(x)\,g_R^\dagger, \tag{37.134}$$

so that the vector subgroup ($g_L = g_R$) acts by conjugation and the axial directions ($g_L = g_R^\dagger$) shift the Goldstone fields. The leading two-derivative Lagrangian,

$$\mathcal{L}_2 = \frac{f_\pi^2}{4}\,\mathrm{tr}(\partial_\mu U\,\partial^\mu U^\dagger), \tag{37.135}$$

is manifestly invariant under Eq. (37.134), as is every term of the standard chiral expansion built from traces of U, $U^\dagger$ and their derivatives. Each such term is a Lorentz scalar of even intrinsic parity: it contains an even number of Levi-Civita-free derivative structures and is unchanged under the naive parity $U(\mathbf{x},t) \to U^\dagger(-\mathbf{x},t)$ together with $\pi^a \to -\pi^a$.

Here is the tension, stated precisely. The ultraviolet theory has an exact, scheme-independent anomaly: the three-point function of axial $\mathrm{SU}(N_f)$ currents has the anomalous divergence whose coefficient, computed from the colored quark triangle in the previous section, is N_c times the single-flavor value (Eq. (37.120)). By 't Hooft's argument that coefficient is an infrared observable: it must appear in correlation functions of the meson theory. But $\mathcal{L}_2$ and all its invariant descendants produce a *vanishing* anomaly, because their variation under Eq. (37.134) is identically zero. The infrared Lagrangian as built so far cannot match. Either 't Hooft matching fails—which would be a contradiction, since both sides compute the same Green's function—or the chiral Lagrangian is incomplete. It is incomplete, and the missing piece is forced to be a term whose chiral variation is nonzero and equal to the anomaly.

37.7.2 The obstruction: no local invariant four-dimensional term will do

What sort of term could carry a nonvanishing chiral variation? It must be parity-odd: the anomaly is proportional to the ϵ-tensor, and a term reproducing it must be P-odd as well, carrying one $\epsilon^{\mu\nu\rho\sigma}$. The natural building block is the *left-invariant Maurer–Cartan form*

$$L \;\equiv\; U^\dagger \,\mathrm{d}U, \tag{37.136}$$

a Lie-algebra-valued one-form (anti-Hermitian, since $\mathrm{d}(U^\dagger U) = 0$ implies $L^\dagger = -L$) that is invariant under left multiplication $U \to g_L U$ and transforms by conjugation under right multiplication. Traces of wedge powers of L are the canonical chirally covariant, parity-odd invariants. In four dimensions the unique candidate with the right index structure is the four-form $\mathrm{tr}(L^4) = \mathrm{tr}(L\wedge L\wedge L\wedge L)$, whose components are $\epsilon^{\mu\nu\rho\sigma}\,\mathrm{tr}(L_\mu L_\nu L_\rho L_\sigma)$ with $L_\mu = U^\dagger \partial_\mu U$.

This candidate is useless, for a sharp reason: it vanishes identically.

Proposition 37.34 (Vanishing of the four-dimensional candidate)**.** *The four-form* $\mathrm{tr}(L^4)$ *built from the Maurer–Cartan one-form* $L = U^\dagger\,\mathrm{d}U$ *is identically zero. More generally,* $\mathrm{tr}(L^{2k}) \equiv 0$ *for every integer* k*, while* $\mathrm{tr}(L^{2k+1})$ *need not vanish.*

Proof. L is a one-form, so under the wedge product two factors anticommute, $L\wedge L = -L\wedge L$ at the level of the form indices, while the trace is cyclic at the level of the matrix indices. Cycling one factor of L from the front of $\mathrm{tr}(L^n)$ to the back moves it past $n-1$ other one-forms, picking up a sign $(-1)^{n-1}$ from the form grading, and the trace is unchanged by the cyclic move on the matrix indices:

$$\mathrm{tr}(L^n) = \mathrm{tr}\big(L\cdot L^{n-1}\big) = (-1)^{n-1}\,\mathrm{tr}\big(L^{n-1}\cdot L\big) = (-1)^{n-1}\,\mathrm{tr}(L^n). \tag{37.137}$$

For even n the factor is $(-1)^{n-1} = -1$, so $\mathrm{tr}(L^n) = -\,\mathrm{tr}(L^n) = 0$. For odd n the factor is $+1$ and the identity is vacuous. In particular $\mathrm{tr}(L^4) = 0$, and $\mathrm{tr}(L^5)$ survives. □

The collapse of $\mathrm{tr}(L^4)$ is not a defect of one ansatz; it is the structural obstruction. Any local, Lorentz-invariant, $H = \mathrm{SU}(N_f)_V$-invariant, parity-odd four-form built polynomially from U and its first derivatives reduces, after using $UU^\dagger = 1$ and integration by parts, to a multiple of $\mathrm{tr}(L^4)$ and hence is zero. One can manufacture higher-derivative parity-odd scalars, but they too, being total chiral invariants, have vanishing chiral variation and cannot reproduce the anomaly. The conclusion is unavoidable.

Proposition 37.35 (No local four-dimensional carrier)**.** *There is no local, Lorentz-invariant four-dimensional Lagrangian density $\mathcal{L}_{\mathrm{WZ}}[U]$, built from U and finitely many of its derivatives, whose chiral variation under Eq. (37.134) equals the QCD chiral anomaly. The anomalous variation is a nontrivial element of the local cohomology—it solves the Wess–Zumino consistency conditions but is not the variation of any local four-dimensional functional.*

We do not need the full cohomological classification to proceed; Theorem 37.34 already tells us the only natural candidate is empty, and the positive construction of the next subsection will exhibit a functional that does the job and explain, geometrically, exactly why it cannot be written as a four-dimensional integral. The single surviving fact we carry forward is the asymmetry between $\mathrm{tr}(L^4) = 0$ and $\mathrm{tr}(L^5) \neq 0$: the carrier of the anomaly lives one dimension up.

Physical Insight

The mismatch in Eq. (37.137) between even and odd powers is the entire reason the WZW term is five-dimensional. A would-be four-dimensional anomaly functional is killed by the wedge-product grading; the same grading spares the five-form $\mathrm{tr}(L^5)$. Spacetime is four-dimensional, so the only way to integrate a five-form is to extend the field configuration into a five-dimensional region whose boundary is spacetime. The "extra dimension" is not physical—no new field, no new propagating mode—it is a bookkeeping device that makes a genuinely four-dimensional, but topologically nontrivial, functional well defined. This is the first appearance in the book of a recurring frontier theme: an anomaly in d dimensions is the boundary avatar of a topological term in $d+1$ dimensions, the idea of anomaly inflow taken up in Section 37.8.4.

37.7.3 Witten's five-dimensional construction

Take Euclidean spacetime and compactify it: a field configuration $U(x)$ that approaches a constant at infinity is a map from the one-point compactification S^4 into $\mathrm{SU}(N_f)$. The construction rests on two topological facts about the group manifold, both of which we will use and the second of which will do the quantization.

Lemma 37.36 (Extendability and the obstruction group)**.** *For $N_f \geq 3$, every smooth map $U : S^4 \to \mathrm{SU}(N_f)$ extends to a smooth map $\widetilde{U} : B^5 \to \mathrm{SU}(N_f)$ from a five-disk B^5 with $\partial B^5 = S^4$, because $\pi_4(\mathrm{SU}(N_f)) = 0$. Two such extensions, glued along their common boundary, define a map of the five-sphere $S^5 \to \mathrm{SU}(N_f)$, and these are classified up to homotopy by $\pi_5(\mathrm{SU}(N_f)) = \mathbb{Z}$.*

The first statement is what makes the construction possible at all: because $\pi_4 = 0$ there is no obstruction to filling in the disk. The second statement,

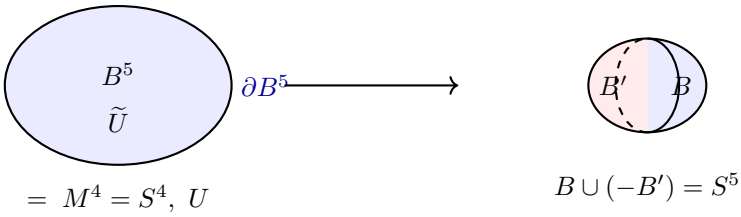

Figure 37.7: Left: a spacetime configuration U on the compactified Euclidean spacetime $M^4 = S^4$ is extended to a map $\widetilde{U}$ on a five-disk B^5 whose boundary is M^4 (possible because $\pi_4(\mathrm{SU}(N_f)) = 0$). Right: two extensions B and B' of the same boundary data glue, with opposite orientation on one, into a closed five-sphere S^5. The difference of the WZW functional evaluated on the two extensions is its integral over S^5, classified by the winding number in $\pi_5(\mathrm{SU}(N_f)) = \mathbb{Z}$; demanding that this difference leave $e^{i\Gamma_{\mathrm{WZW}}}$ unchanged quantizes the coefficient.

$\pi_5(\mathrm{SU}(N_f)) = \mathbb{Z}$ for $N_f \geq 3$, is what will force the coefficient to be an integer. (For SU(2), $\pi_4(\mathrm{SU}(2)) = \mathbb{Z}_2$ and the story is different; the standard WZW term is a feature of three or more flavors, which is the physically relevant case and the one we treat.)

The candidate five-form is $\mathrm{tr}(L^5)$, and the first thing to check is that it is closed, so that its integral over the disk depends on the extension only mildly.

Lemma 37.37 (Closure of the five-form)**.** *The five-form $\omega_5 = \mathrm{tr}(L^5)$, with $L = U^\dagger\,\mathrm{d}U$, is closed: $\mathrm{d}\omega_5 = 0$.*

Proof. The Maurer–Cartan form satisfies the structure equation. From $\mathrm{d}U^\dagger = -U^\dagger\,(\mathrm{d}U)\,U^\dagger$ (the differential of $U^\dagger U = 1$) we get

$$\mathrm{d}L = \mathrm{d}U^\dagger \wedge \mathrm{d}U = -U^\dagger\,\mathrm{d}U\,U^\dagger \wedge \mathrm{d}U = -L \wedge L \equiv -L^2. \tag{37.138}$$

Now differentiate $\omega_5 = \mathrm{tr}(L \wedge L \wedge L \wedge L \wedge L)$ using the graded Leibniz rule, with L of odd degree contributing a sign each time the exterior derivative passes a factor:

$$\mathrm{d}\,\mathrm{tr}(L^5) = \sum_{i=0}^{4} (-1)^i\,\mathrm{tr}\big(L^i\,(\mathrm{d}L)\,L^{4-i}\big) = \sum_{i=0}^{4} (-1)^{i+1}\,\mathrm{tr}\big(L^i\,L^2\,L^{4-i}\big) = \Big(\sum_{i=0}^{4}(-1)^{i+1}\Big)\,\mathrm{tr}(L^6). \tag{37.139}$$

The alternating sum $\sum_{i=0}^{4}(-1)^{i+1} = -1 + 1 - 1 + 1 - 1 = -1$, so $\mathrm{d}\,\mathrm{tr}(L^5) = -\,\mathrm{tr}(L^6)$. But $\mathrm{tr}(L^6)$ is an even power and vanishes by exactly the cyclic-grading argument of Theorem 37.34, $\mathrm{tr}(L^6) = (-1)^{6-1}\,\mathrm{tr}(L^6) = -\,\mathrm{tr}(L^6) = 0$. Hence $\mathrm{d}\omega_5 = 0$. □

With closure established we can define the functional.

Definition 37.38 (Wess–Zumino–Witten functional)**.** Let $\widetilde{U}$ extend the space-time configuration U over a five-disk B with $\partial B = M^4$. The Wess–Zumino–Witten functional at level n is

$$\Gamma_{\mathrm{WZW}}[U] \;=\; -\frac{i\,n}{240\pi^2}\int_B \mathrm{tr}\big[(\,\widetilde{U}^{\dagger}\,\mathrm{d}\widetilde{U}\,)^5\big] \;=\; -\frac{i\,n}{240\pi^2}\int_B \mathrm{tr}(L^5), \tag{37.140}$$

the integral of the five-form ω_5 pulled back to B by $\widetilde{U}$. It is added to the four-dimensional chiral action, $S = \int_{M^4}\mathcal{L}_2 + \cdots + \Gamma_{\mathrm{WZW}}$.

Three features deserve immediate comment. First, the integrand depends on $\widetilde{U}$ only through its *derivatives*, packaged into L, so a constant shift of the field drops out and the functional descends to the genuine degrees of freedom. Second, because ω_5 is closed (Theorem 37.37), Stokes' theorem controls how Γ_{WZW} responds to deforming the extension at fixed boundary: an infinitesimal change $\delta\widetilde{U}$ in the interior changes the integrand by an exact form, $\delta\omega_5 = \mathrm{d}(\text{four-form})$, so $\delta\Gamma_{\mathrm{WZW}} = \int_B \mathrm{d}(\cdots) = \int_{\partial B}(\cdots) = \int_{M^4}(\cdots)$ reduces to a boundary integral that depends only on U and its variation on M^4. The variation of Γ_{WZW} is therefore a genuinely four-dimensional, local expression—this is what lets the term contribute to the equations of motion and to scattering amplitudes as if it were an ordinary four-dimensional Lagrangian, even though the functional itself has no four-dimensional integral representation. Third, the prefactor $-in/240\pi^2$ is engineered, as we now show, so that the residual dependence on the *global* choice of extension is invisible in $e^{i\Gamma_{\mathrm{WZW}}}$ precisely when n is an integer.

37.7.4 Topological quantization: the level is an integer

The functional in Eq. (37.140) appears to depend on the arbitrary choice of disk B. Physics must not. The path integral weights a configuration by e^{iS}, so what must be independent of the extension is not Γ_{WZW} itself but the phase $e^{i\Gamma_{\mathrm{WZW}}}$. We now show that well-definedness of this phase quantizes n.

Let B and B' be two extensions of the same boundary configuration U on $M^4 = S^4$. Their difference is

$$\Gamma^{(B)}_{\mathrm{WZW}} - \Gamma^{(B')}_{\mathrm{WZW}} = -\frac{in}{240\pi^2}\left(\int_B - \int_{B'}\right)\mathrm{tr}(L^5) = -\frac{in}{240\pi^2}\int_{B\cup(-B')}\mathrm{tr}(L^5), \tag{37.141}$$

where $B\cup(-B')$ means B glued to B' with reversed orientation. Since B and B' share the boundary S^4, the glued object is a closed five-manifold; topologically it is a five-sphere, and the two extensions together define a map $S^5 \to \mathrm{SU}(N_f)$ (Theorem 37.36; see Fig. 37.7). The difference is the integral of ω_5 over this closed S^5.

The decisive input is the value of that integral. The five-form $\mathrm{tr}(L^5)$ is, up to normalization, the generator of the fifth de Rham cohomology of the group manifold, and its integral over a closed S^5 computes the winding number—the

integer class in $\pi_5(\mathrm{SU}(N_f)) = \mathbb{Z}$—of the map. With the normalization chosen in Eq. (37.140),

$$-\frac{i}{240\pi^2}\int_{S^5}\mathrm{tr}\big[(U^\dagger\,\mathrm{d}U)^5\big] \;=\; 2\pi\,w, \qquad w\in\mathbb{Z}=\pi_5(\mathrm{SU}(N_f)), \tag{37.142}$$

i.e. the integral of $\mathrm{tr}(L^5)$ over the unit-winding generator equals $i\cdot 480\pi^3$ (the factor of i tracking the anti-Hermiticity of L, which makes $\mathrm{tr}(L^5)$ pure imaginary so that Γ_{WZW} is real). We verify this normalization explicitly on the generator below. Granting it, Eq. (37.141) reads

$$\Gamma^{(B)}_{\mathrm{WZW}} - \Gamma^{(B')}_{\mathrm{WZW}} \;=\; 2\pi\,n\,w. \tag{37.143}$$

The phase $e^{i\Gamma_{\mathrm{WZW}}}$ is therefore independent of the extension—$e^{2\pi i n w}=1$ for every winding $w\in\mathbb{Z}$—*if and only if* $n\in\mathbb{Z}$.

Theorem 37.39 (Quantization of the WZW level)**.** *For $N_f\geq 3$ the Wess–Zumino–Witten functional Eq. (37.140) defines a single-valued contribution $e^{i\Gamma_{\mathrm{WZW}}}$ to the path-integral weight if and only if the level n is an integer. The quantization is topological in origin: it follows from $\pi_5(\mathrm{SU}(N_f))=\mathbb{Z}$, with no appeal to the dynamics.*

This is the structural payoff. Unlike the coefficients f_π, or the low-energy constants of the higher chiral Lagrangian, which are continuous numbers fixed by the strong dynamics, the WZW level is pinned to the integers by topology alone. Continuous renormalization cannot move an integer, so n is a renormalization-group invariant—precisely the property an anomaly coefficient must have to be matched between the ultraviolet and the infrared. The integer is not yet determined; topology says only that it is *some* integer. What fixes its value is matching.

Theorem 37.40 (The level is the color number)**.** *The chiral variation of Γ_{WZW} under Eq. (37.134) reproduces the consistent $\mathrm{SU}(N_f)$ chiral anomaly with coefficient proportional to the level n. Equating it to the ultraviolet QCD value (Eq. (37.120)) fixes*

$$n \;=\; N_c. \tag{37.144}$$

Argument. The boundary reduction of $\delta\Gamma_{\mathrm{WZW}}$ described after Theorem 37.38 is a local four-dimensional functional of U, linear in the chiral transformation parameter and carrying one ϵ-tensor; it is, by construction, the unique solution of the Wess–Zumino consistency conditions, and its overall coefficient is the level n. The ultraviolet theory fixes that same boundary functional through 't Hooft matching: the $\mathrm{SU}(N_f)^3_L$ anomaly of N_c colored quarks is N_c times the single-fermion coefficient, the content of Eq. (37.120). Since the two are the variation of the same correlator, their coefficients are equal, giving $n=N_c$. By

Theorem 37.39 the right-hand side had to be an integer, and the matching makes that integer N_c—consistent, and a nontrivial check, because N_c is indeed an integer. The cleanest independent confirmation that the matched coefficient is exactly N_c, with no stray rational factor, comes from gauging electromagnetism and reading off $\pi^0 \to \gamma\gamma$, carried out in Section 37.7.5. □

It remains to confirm the normalization Eq. (37.142), which we do on the explicit generator of $\pi_5(\mathrm{SU}(3))$, the simplest case relevant to three-flavor QCD.

Worked Example 37.41 (Normalization on the winding generator)**.** Embed $\mathrm{SU}(2) \hookrightarrow \mathrm{SU}(3)$ and build the generator of $\pi_5(\mathrm{SU}(3))$ as the suspension of the identity map $\mathrm{SU}(2) \cong S^3$. Concretely, parametrize S^5 by an angle $\mu \in [0, \pi/2]$ and two copies of S^2 and use the standard representative for which the pullback of $\mathrm{tr}(L^5)$ is a fixed volume form on S^5. The content we need is purely the integral of that volume form, and it is fixed by a single normalization statement that we now make self-contained.

For a Lie group, the closed, bi-invariant five-form whose integral over the unit-winding cycle is canonically normalized is

$$\Omega_5 \;=\; \frac{i}{480\pi^3}\,\mathrm{tr}\big[(U^\dagger\,\mathrm{d}U)^5\big], \qquad \int_{S^5}\Omega_5 \;=\; w \in \mathbb{Z}. \tag{37.145}$$

This is the statement that Ω_5 generates $H^5(\mathrm{SU}(N_f);\mathbb{Z}) \cong \mathbb{Z}$ integrally; the constant $i/480\pi^3$ is exactly the inverse of the volume that the bi-invariant metric assigns to the generating five-cycle. (Equivalently, it is fixed by the same Chern–Simons normalization that makes the five-dimensional Chern–Simons level an integer, the higher-dimensional cousin of the instanton number normalization of Chapter 42.) Multiplying Eq. (37.145) through,

$$\int_{S^5}\mathrm{tr}(L^5) = \frac{480\pi^3}{i}\,w = -\,i\,480\pi^3\,w, \tag{37.146}$$

and substituting into Eq. (37.140) integrated over S^5,

$$-\frac{i}{240\pi^2}\int_{S^5}\mathrm{tr}(L^5) = -\frac{i}{240\pi^2}\,(-i\,480\pi^3)\,w = i^2\,\frac{480\pi^3}{240\pi^2}\,w = -2\pi\,w, \tag{37.147}$$

using $(-i)(-i) = i^2 = -1$. This is Eq. (37.142) up to the physically irrelevant sign of the winding: only the value of Γ_{WZW} modulo 2π enters $e^{i\Gamma_{\mathrm{WZW}}}$, and relabelling the generator $w \to -w$ (an orientation choice, w ranging over all of $\mathbb{Z}$) restores the $+2\pi w$ written there. The prefactor $-in/240\pi^2$ in Eq. (37.140) is thus not arbitrary: it is the unique choice that turns the integer winding number into a 2π-valued phase ambiguity, making $e^{i\Gamma_{\mathrm{WZW}}}$ well defined exactly for integer level. The factor $240 = 2\cdot 120 = 2\cdot 5!$ is the symmetry factor of the five antisymmetrized one-forms, and the π^2 accompanies it through the volume of the relevant spheres.

37.7.5 Gauging electromagnetism: $\pi^0 \to \gamma\gamma$

The level $n = N_c$ is so far an inference from matching the $\mathrm{SU}(N_f)^3$ anomaly. We now make it visible in a physical amplitude, recovering the $\pi^0 \to \gamma\gamma$ decay of Chapter 36 from the infrared side and closing the matching loop with a number. The procedure is to gauge the electromagnetic $\mathrm{U}(1) \subset \mathrm{SU}(N_f)_V$ generated by the quark charge matrix

$$Q = \mathrm{diag}\Big(\tfrac{2}{3}, -\tfrac{1}{3}, -\tfrac{1}{3}, \dots\Big), \tag{37.148}$$

promoting derivatives to covariant ones, $\partial_\mu U \to D_\mu U = \partial_\mu U - ieA_\mu[Q, U]$, and adding to Γ_{WZW} the photon-dependent terms required to make its variation reproduce the *electromagnetic* part of the chiral anomaly. Gauging a Wess–Zumino term is not automatic: the naive minimal substitution fails to be invariant under electromagnetic gauge transformations, and one must add a definite series of local counterterms—Witten's gauging procedure—to restore it. The output of that procedure, for the term quadratic in the photon and linear in the neutral pion, is the local coupling

$$\mathcal{L}_{\pi^0\gamma\gamma} = \frac{N_c\, e^2}{32\pi^2 f_\pi}\, \mathrm{tr}(Q^2\lambda^3)\; \pi^0\, \epsilon^{\mu\nu\rho\sigma} F_{\mu\nu} F_{\rho\sigma}, \tag{37.149}$$

where $\lambda^3 = \mathrm{diag}(1, -1, 0, \dots)$ selects the neutral-pion direction in flavor space and $F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu$. The whole coefficient is proportional to the level N_c: it descends from the same five-form, gauged. The flavor trace evaluates to

$$\mathrm{tr}(Q^2\lambda^3) = Q_u^2 - Q_d^2 = \Big(\tfrac{2}{3}\Big)^2 - \Big(\tfrac{1}{3}\Big)^2 = \frac{4}{9} - \frac{1}{9} = \frac{1}{3}, \tag{37.150}$$

so that, writing $e^2 = 4\pi\alpha$,

$$\mathcal{L}_{\pi^0\gamma\gamma} = \frac{N_c\, e^2}{96\pi^2 f_\pi}\, \pi^0\, \epsilon^{\mu\nu\rho\sigma} F_{\mu\nu} F_{\rho\sigma} = \frac{N_c\, \alpha}{12\pi f_\pi}\, \pi^0\, F_{\mu\nu} \widetilde{F}^{\mu\nu}, \qquad \widetilde{F}^{\mu\nu} \equiv \tfrac{1}{2}\epsilon^{\mu\nu\rho\sigma} F_{\rho\sigma}. \tag{37.151}$$

The decay rate that follows from this coupling is the carried number of *QED*, and we now compute it in full.

Worked Example 37.42 ($\pi^0 \to \gamma\gamma$ from the gauged WZW term)**.** Write the coupling Eq. (37.151) in the form $\mathcal{L} = C\, \pi^0\, \epsilon^{\mu\nu\rho\sigma} F_{\mu\nu} F_{\rho\sigma}$ with

$$C = \frac{N_c\, e^2}{96\pi^2 f_\pi}. \tag{37.152}$$

Using $F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu$ and the total antisymmetry of ϵ, all four terms of $\epsilon^{\mu\nu\rho\sigma} F_{\mu\nu} F_{\rho\sigma}$ are equal, so $\mathcal{L} = 4C\, \pi^0\, \epsilon^{\mu\nu\rho\sigma} \partial_\mu A_\nu \partial_\rho A_\sigma$. For the decay $\pi^0(p) \to \gamma(k_1, \varepsilon_1)\gamma(k_2, \varepsilon_2)$ each outgoing photon line contributes a factor $\partial_\mu A_\nu \to i k_\mu \varepsilon^*_\nu$,

and the two ways of assigning the two photons to the two derivative pairs give equal contributions (an even permutation of ϵ), so

$$i\mathcal{M} = 4C{\cdot}2\,(ik_1)_\mu \varepsilon_{1\nu}^{*}(ik_2)_\rho \varepsilon_{2\sigma}^{*}\,\epsilon^{\mu\nu\rho\sigma} \;\Longrightarrow\; \mathcal{M} = 8iC\,\epsilon^{\mu\nu\rho\sigma} k_{1\mu}\varepsilon_{1\nu}^{*} k_{2\rho}\varepsilon_{2\sigma}^{*}. \tag{37.153}$$

Square and sum over the physical photon polarizations using $\sum_{\text{pol}} \varepsilon_\nu \varepsilon_{\nu'}^{*} \to -g_{\nu\nu'}$ (the gauge-dependent pieces drop by the antisymmetry of ϵ and transversality $k_i \cdot \varepsilon_i = 0$):

$$\sum_{\text{pol}} |\mathcal{M}|^2 = 64\,C^2\,\epsilon^{\mu\nu\rho\sigma}\epsilon^{\mu'\nu'\rho'\sigma'} k_{1\mu}k_{1\mu'}k_{2\rho}k_{2\rho'}\,(-g_{\nu\nu'})(-g_{\sigma\sigma'}). \tag{37.154}$$

Contracting the two indices ν, σ of the Levi-Civita pair, with the mostly-minus identity $\epsilon^{\mu\nu\rho\sigma}\epsilon^{\mu'}{}_{\nu}{}^{\rho'}{}_{\sigma} = -2(g^{\mu\mu'}g^{\rho\rho'} - g^{\mu\rho'}g^{\rho\mu'})$,

$$\sum_{\text{pol}} |\mathcal{M}|^2 = 64\,C^2 \cdot (-2)\big(k_1^2 k_2^2 - (k_1\cdot k_2)^2\big) = 128\,C^2\,(k_1\cdot k_2)^2, \tag{37.155}$$

where the on-shell conditions $k_1^2 = k_2^2 = 0$ were used. For a pion at rest decaying to two photons, $2k_1\cdot k_2 = (k_1+k_2)^2 = p^2 = m_\pi^2$, so $(k_1\cdot k_2)^2 = m_\pi^4/4$ and $\sum_{\text{pol}}|\mathcal{M}|^2 = 32\,C^2\,m_\pi^4$.

The two-body rate for a scalar of mass m_π into two massless, identical particles is $\Gamma = \dfrac{S}{16\pi m_\pi}\sum_{\text{pol}}|\mathcal{M}|^2$ with the identical-particle factor $S = \tfrac{1}{2}$, so

$$\Gamma(\pi^0 \to \gamma\gamma) = \frac{1}{2}\cdot\frac{32\,C^2 m_\pi^4}{16\pi m_\pi} = \frac{C^2 m_\pi^3}{\pi}. \tag{37.156}$$

Insert C from Eq. (37.152), using $e^2 = 4\pi\alpha$ so that $C = \alpha N_c/(24\pi f_\pi)$:

$$\boxed{\Gamma(\pi^0 \to \gamma\gamma) = \frac{\alpha^2\,N_c^2\,m_\pi^3}{576\,\pi^3 f_\pi^2}} \tag{37.157}$$

The amplitude is linear in N_c and the width quadratic. Setting $N_c = 3$ collapses $N_c^2/576 = 9/576 = 1/64$, giving

$$\Gamma(\pi^0 \to \gamma\gamma)\Big|_{N_c=3} = \frac{\alpha^2 m_\pi^3}{64\,\pi^3 f_\pi^2}, \tag{37.158}$$

which is exactly the value computed from the quark triangle in Eq. (36.115). Numerically, with $\alpha \simeq 1/137$, $m_\pi \simeq 135$ MeV and $f_\pi \simeq 92$ MeV, this is about 7.7 eV, in agreement with the measured 7.8 eV. The infrared computation, performed entirely within the meson theory through a topological term, reproduces the ultraviolet quark-loop number—and it does so only for $N_c = 3$.

The two faces of the level now agree. Theorem 37.39 forced n to be an integer by the topology of $\mathrm{SU}(N_f)$; Theorem 37.40 fixed that integer to N_c by matching the global $\mathrm{SU}(N_f)^3$ anomaly; and Theorem 37.42 confirmed the value through the gauged amplitude, whose N_c^2 scaling reproduces Eq. (36.115) precisely at $N_c = 3$. Had the world had a different number of colors, the WZW level would have been that number, the $\pi^0 \to \gamma\gamma$ rate would have scaled as its square, and the meson Lagrangian would have carried the count. The decay of a neutral pion is, in this sense, a measurement of N_c performed without ever resolving a quark.

Physical Insight

It is worth dwelling on what kind of object the WZW level is. The continuous couplings of the chiral Lagrangian—f_π, the low-energy constants of the four-derivative terms—are nonperturbative outputs of the strong dynamics, knowable only by lattice computation or experiment, and they run, mix, and depend on the renormalization scheme. The WZW level does none of this. It is an integer, frozen by $\pi_5(\mathrm{SU}(N_f)) = \mathbb{Z}$, and therefore exactly stable under the renormalization group, exactly equal in the ultraviolet and the infrared. This is the very property 't Hooft's matching argument exploits: an anomaly coefficient is an integer-like invariant that the two descriptions must share. The WZW term is the concrete infrared vessel that holds the $\mathrm{SU}(N_f)^3$ anomaly demanded by the matching of the previous section—the non-fermionic carrier whose existence that section's logic required but could not exhibit. We have now exhibited it.

We have found that the anomaly, far from being merely a number to predict or a pathology to cancel, has an intrinsically topological and geometric realization: a closed form on the group manifold, integrated over an extra dimension, with an integer coefficient counted by a homotopy group. That this same geometry organizes anomalies far beyond the chiral case—the gravitational and global anomalies, and the modern picture of anomalies as boundary modes of invertible topological phases via inflow and cobordism—is the closing theme of the chapter, taken up next; and the WZW term itself is handed forward to Chapter 39, where it enters the chiral Lagrangian as the leading interaction of odd intrinsic parity and governs the anomalous mesonic processes that the ordinary chiral expansion cannot produce.

37.8 Mixed, Gravitational, and Global Anomalies: The Modern Landscape

The Wess–Zumino–Witten term of Section 37.7 did something the rest of this chapter only gestured at: it produced a four-dimensional anomaly as the *boundary* of a five-dimensional object. The level-k functional was written as an integral of

a manifestly gauge-invariant five-form over a disk whose boundary is spacetime, and the anomaly appeared precisely because that five-dimensional integral cannot be pushed down to a local four-dimensional Lagrangian. We met the integer $k = N_c$ as a topological quantization condition forced by $\pi_5(\mathrm{SU}(3)) = \mathbb{Z}$. That construction is not an isolated trick. It is the first concrete instance of the organizing principle that closes this chapter and the whole of Part X: *an anomalous d-dimensional theory is the boundary of an essentially trivial $(d{+}1)$-dimensional theory, and the anomaly is the price of living on that boundary.* Seen from that height, the cubic gauge anomaly of Section 37.2, the mixed and gravitational anomalies we are about to derive, and the nonperturbative global anomaly we will meet next, are all facets of one geometric object. This section surveys the remaining anomaly types at honest, dated depth and sets the chapter's results into that modern frame.

We have four tasks. First, we complete the catalogue of triangles relevant to the Standard Model by deriving the *mixed* gauge–gravitational anomaly—one hypercharge current and two stress tensors—and showing its coefficient is $\mathrm{tr}\, Y$, the plain sum of hypercharges, thereby justifying the gravitational cancellation condition Eq. (37.47c) used in Section 37.3. Second, we explain why there is no *pure* gravitational anomaly to worry about in four dimensions: such anomalies live only in $d = 4k+2$, a fact we trace to the degrees of the Pontryagin classes. Third, we present Witten's nonperturbative SU(2) anomaly, the one anomaly invisible to the triangle diagrams of this chapter, and check that the Standard Model survives it. Fourth, we state—scoped and dated to the mid-2020s—the contemporary synthesis in which perturbative anomalies descend from an anomaly polynomial, global anomalies are classified by cobordism, and the boundary picture just sketched (anomaly inflow) becomes the unifying language.

37.8.1 The mixed gauge–gravitational anomaly

Every triangle considered so far had three gauge currents at its vertices. But the energy–momentum tensor $T^{\mu\nu}$ is a current too—the Noether current of spacetime translations, the source to which the metric couples—and a chiral fermion can run in a loop with one gauge current and two insertions of $T^{\mu\nu}$. Physically this is the amplitude for a gauge boson to convert into two gravitons through a fermion loop; the external "photons" of the gauge triangle are replaced by external gravitons. If the gauge current is the hypercharge current j_Y^μ, the resulting object is the mixed $\mathrm{U}(1)_Y$–gravitational anomaly, the fourth and last condition in the Standard Model cancellation tally.

Rather than redo the loop integral—the kinematic engine is identical to the one already turned in Chapter 36—we extract the answer from the index theorem, which packages all one-loop chiral anomalies of a Weyl fermion into a single characteristic class. This is the heat-kernel route: the Fujikawa Jacobian of Section 36.3 is the integral of an anomaly density, and on a curved background

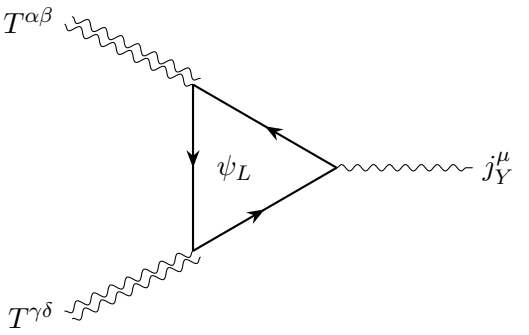

Figure 37.8: The mixed gauge–gravitational triangle: one hypercharge current j_Y^μ (single wavy line) and two energy–momentum insertions $T^{\alpha\beta}$ (double wavy lines, external gravitons) attached to a chiral fermion loop. Bose symmetry of the two gravitons selects the totally symmetric part of the vertex, and the chiral projector at the j_Y vertex produces the parity-odd ϵ-tensor structure. The group factor that survives is the bare charge Y of the looping fermion, so the summed coefficient is $\operatorname{tr} Y = \sum_i Y_i$.

coupled to a gauge field that density is fixed by the Atiyah–Singer index theorem (Theorem 36.15). We recall the statement in the only form we need.

Definition 37.43 (Anomaly polynomial)**.** The one-loop anomaly of a left-handed Weyl fermion in d spacetime dimensions, coupled to a gauge field with field strength two-form $F = \frac{1}{2} F_{\mu\nu}\, \mathrm{d}x^\mu \wedge \mathrm{d}x^\nu$ and to gravity with curvature two-form $R^a{}_b = \frac{1}{2} R^a{}_{b\mu\nu}\, \mathrm{d}x^\mu \wedge \mathrm{d}x^\nu$, is governed by the $(d{+}2)$-form part of the index density,

$$\widehat{I}_{d+2} \;=\; \Big[\widehat{A}(R)\, \operatorname{tr}_R \exp\!\Big(\tfrac{iF}{2\pi}\Big)\Big]_{d+2}, \tag{37.159}$$

where $\widehat{A}(R)$ is the Dirac genus,

$$\widehat{A}(R) \;=\; 1 - \frac{1}{24}\, p_1(R) + \frac{1}{5760}\,(7p_1^2 - 4p_2) + \cdots, \qquad p_1(R) = -\frac{1}{8\pi^2}\, \operatorname{tr}(R \wedge R), \tag{37.160}$$

p_1, p_2 being the first and second Pontryagin four- and eight-forms of the tangent bundle. The physical anomaly in d dimensions is recovered from $\widehat{I}_{d+2}$ by the descent procedure of Section 37.8.4.

The content of Theorem 36.15 is exactly that the four-form part of Eq. (37.159) integrates to the index $n_- - n_+$ that we tested numerically against $\pi^0 \to \gamma\gamma$. What is new here is to read off the *six*-form, because in four dimensions the anomaly is governed by $\widehat{I}_6$: the triangle is a three-point function, the anomaly polynomial that controls a three-point function in $d = 4$ is a six-form, and the descent of a six-form yields the four-dimensional anomalous divergence. We therefore expand Eq. (37.159) to sixth order and collect the pieces.

For the abelian factor $\mathrm{U}(1)_Y$ the generator is the charge Y, a number on each Weyl field, so $\mathrm{tr}_R \exp(iF/2\pi) = \sum_i \exp(iY_i F/2\pi)$ summed over the Weyl multiplet's components, with $F = \mathrm{d}B$ the hypercharge field strength. The six-form part of Eq. (37.159) has exactly two contributions of total form-degree six,

$$\widehat{I}_6 \;=\; \underbrace{\frac{1}{3!}\Big(\frac{i}{2\pi}\Big)^3\Big(\sum\nolimits_i Y_i^3\Big)\,F^3}_{\text{cubic } \mathrm{U}(1)_Y^3} \;\; \underbrace{-\,\frac{1}{24}\,p_1(R)\wedge\frac{i}{2\pi}\Big(\sum\nolimits_i Y_i\Big)\,F}_{\text{mixed } \mathrm{U}(1)_Y\text{–grav}^2}, \tag{37.161}$$

and—decisively—*nothing else*. The first term is the cubic hypercharge anomaly, proportional to $\sum_i Y_i^3 = \mathrm{tr}\, Y^3$, which is the abelian instance of the cubic invariant of Section 37.2. The second term is the mixed anomaly we are after: it pairs the gravitational four-form $p_1(R)$ with one power of the gauge field, and its coefficient is the *linear* charge sum

$$\boxed{\mathrm{tr}\, Y \;=\; \sum_{i\in\text{left-handed Weyl}} Y_i} \tag{37.162}$$

There is no other six-form: a purely gravitational six-form would have to come from a degree-six piece of $\widehat{A}(R)$, and Eq. (37.160) has none—its terms are the $4k$-forms 1, p_1, $p_1^2, p_2, \ldots$, jumping from degree zero to degree four to degree eight. We will turn that observation into the statement of Section 37.8.2; here it tells us that in four dimensions the *only* gravitational anomaly a U(1) current can have is the mixed one, with coefficient $\mathrm{tr}\, Y$.

Descending Eq. (37.161) to four dimensions (the mechanics are in Section 37.8.4) converts the mixed six-form into the anomalous divergence of the hypercharge current in a gravitational background,

$$\partial_\mu \langle j_Y^\mu \rangle \;=\; \frac{\mathrm{tr}\, Y}{384\pi^2}\,\epsilon^{\mu\nu\rho\sigma}\, R^{\alpha}{}_{\beta\mu\nu}\, R^{\beta}{}_{\alpha\rho\sigma}, \tag{37.163}$$

where the numerical prefactor is fixed by the same heat-kernel evaluation that fixed the $\pi^0 \to \gamma\gamma$ coefficient in Chapter 36; we quote it rather than re-evaluate the identical integral. The structure $\epsilon^{\mu\nu\rho\sigma} R^{\alpha}{}_{\beta\mu\nu} R^{\beta}{}_{\alpha\rho\sigma}$ is the gravitational Pontryagin density—the curved-space analogue of $\epsilon^{\mu\nu\rho\sigma} F_{\mu\nu} F_{\rho\sigma}$, and exactly $-16\pi^2$ times the integrand of p_1 in Eq. (37.160). The single fact we extract for the Standard Model is the proportionality: the mixed anomaly vanishes if and only if the sum of hypercharges over all left-handed Weyl fermions vanishes,

$$\text{mixed } \mathrm{U}(1)_Y\text{–gravitational anomaly} = 0 \quad\Longleftrightarrow\quad \mathrm{tr}\, Y = \sum_i Y_i = 0, \tag{37.164}$$

which is precisely the gravitational condition Eq. (37.47c) fed into the Standard Model cancellation of Section 37.3.

Proposition 37.44 (The mixed anomaly is the bare charge sum)**.** *For a chiral gauge theory with abelian factor* $\mathrm{U}(1)_Y$*, the mixed* $\mathrm{U}(1)_Y$*–gravitational anomaly coefficient is the trace of the charge over the left-handed Weyl spectrum,* $\operatorname{tr} Y = \sum_i Y_i$*, with antiparticles counted by their conjugate (sign-flipped) charges. It is the unique gravitational obstruction in* $d = 4$*, and it cancels for the Standard Model because* $\operatorname{tr} Y = 0$ *separately within each generation.*

Proof. The coefficient is read off the mixed term of Eq. (37.161), which is linear in the generator and so reduces, for the abelian factor, to $\sum_i Y_i$. Additivity over the spectrum is the same block-diagonal argument as for the cubic invariant (Theorem 37.9): the index density of a direct sum of fermions is the sum of the densities. Conjugation flips the sign, $Y \to -Y$, exactly as in Theorem 37.10, because writing a right-handed field as a left-handed conjugate reverses its charge; this is why the trace runs over left-handed Weyl fields with antiparticles entering as conjugates. Uniqueness in $d = 4$ is Eq. (37.161): the only six-forms in $\widehat{A}(R)\ \operatorname{tr}_R e^{iF/2\pi}$ involving gravity are the mixed term and (for non-abelian factors) a term $p_1 \wedge \operatorname{tr}_R F$ whose coefficient is the index $T(R)$ weighted appropriately; for a U(1) that index degenerates to the charge sum. The Standard-Model evaluation $\operatorname{tr} Y = 0$ is carried out field by field in Section 37.3 using the hypercharge assignments of Table 33.1. □

Physical Insight

The appearance of $\operatorname{tr} Y$—the *first* power of the charge—rather than $\operatorname{tr} Y^3$ is what makes the gravitational condition so sharp a constraint. The cubic condition $\operatorname{tr} Y^3 = 0$ can be satisfied by elaborate cancellations among large charges; the linear condition $\operatorname{tr} Y = 0$ says the hypercharges must literally add to zero over a generation, with no help from cubing to hide a mismatch. Together with the non-abelian mixed conditions $\sum_i Y_i\, T(R_i) = 0$, this is what nearly fixes the hypercharge assignments and, through the interplay with the color trace, ties the quark hypercharges to the number of colors and hence to electric-charge quantization. The gravitational anomaly is thus not an exotic afterthought: it is one of the load-bearing equations of the Standard Model's internal consistency, and it cancels for the same miraculous reason the others do.

37.8.2 No pure gravitational anomaly in four dimensions

We have just seen that a U(1) current can have a gravitational anomaly in $d = 4$. The natural next question is whether the gravitational current itself—the energy–momentum tensor—can be anomalous, i.e. whether diffeomorphism invariance can be broken by a chiral fermion loop with three external gravitons and no gauge legs. Were that to happen, the theory would not even define a consistent

metric coupling, and no fermion-content tuning could save it. The answer, due to Alvarez-Gaumé and Witten, is clean and is forced by the same structure that gave us Eq. (37.161): *there are no pure gravitational anomalies in four dimensions*; they occur only in $d = 4k + 2$, i.e. in $d = 2, 6, 10, \ldots$.

Theorem 37.45 (Pure gravitational anomalies live in $d = 4k + 2$)**.** *A theory of chiral fields coupled to gravity (no gauge fields) can have a perturbative gravitational anomaly only when the spacetime dimension satisfies $d \equiv 2 \pmod 4$. In particular $d = 4$ admits no pure gravitational anomaly, and the only gravitational obstruction in four dimensions is the mixed gauge–gravitational anomaly of Section 37.8.1.*

Proof. The perturbative gravitational anomaly in d dimensions is governed, exactly as in Theorem 37.43, by the purely gravitational part of the $(d{+}2)$-form index density. Setting $F = 0$ in Eq. (37.159), that part is

$$\widehat{I}^{\mathrm{grav}}_{d+2} = \big[\widehat{A}(R)\big]_{d+2}. \tag{37.165}$$

By Eq. (37.160) the Dirac genus is a polynomial in the Pontryagin forms $p_1, p_2, p_3, \ldots$, where p_k is a $4k$-form. Every monomial in $\widehat{A}(R)$ is therefore a product of $4k$-forms and so has form-degree divisible by four. A nonzero $(d{+}2)$-form can appear in $\widehat{A}(R)$ only if $d + 2 \equiv 0 \pmod 4$, that is $d \equiv 2 \pmod 4$. For $d \equiv 0 \pmod 4$—and in particular for $d = 4$, where $d + 2 = 6$ is not a multiple of four—the degree-$(d{+}2)$ part of $\widehat{A}(R)$ is identically zero, so $\widehat{I}^{\mathrm{grav}}_{d+2} = 0$ and there is no gravitational anomaly to descend.

The same conclusion has a direct diagrammatic reading. The gravitational anomaly first appears in the $(\frac{d}{2} + 1)$-point function of the energy–momentum tensor: a polygon graph with $\frac{d}{2} + 1$ stress-tensor vertices, whose parity-odd part carries one ϵ-tensor with d indices saturated by the external curvatures. In $d = 2$ this is the two-point function (the gravitational analogue of the chiral two-point anomaly); in $d = 6$ it is a four-point box; in $d = 10$ a six-point hexagon. In $d = 4$ the would-be diagram is the three-graviton triangle, but the parity-odd local term it would generate, $\epsilon^{\mu\nu\rho\sigma} R\, R$ with the curvatures carrying the remaining indices, is a *total derivative*—it is d of the gravitational Chern–Simons three-form—and hence shiftable to zero by a local diffeomorphism-invariant counterterm. Equivalently, the top symmetric invariant available in $d = 4$ at this order is the Pontryagin class p_1 itself, a closed four-form, not an anomaly: there is no symmetric invariant of the requisite type to obstruct conservation of $T^{\mu\nu}$. This is the geometric reason behind the counting: the gravitational invariants are built from the $4k$-form Pontryagin classes, and four is not two more than a multiple of four. □

Caution

The mismatch in parity counting is easy to garble, so fix it once. The relevant *spacetime* dimension for a d-dimensional anomaly is d; the anomaly polynomial that controls it is a $(d{+}2)$-form. "Pure gravitational anomalies in $d = 4k + 2$" refers to $d = 2, 6, 10$ (string-theory worldsheets, six-dimensional chiral theories, ten-dimensional supergravity), whose anomaly polynomials are the 4-, 8-, 12-forms that $\widehat{A}(R)$ does contain. Four dimensions sits in the complementary class $d = 4k$, where the gravitational anomaly polynomial vanishes and only the mixed anomaly survives. This is why the Standard Model's gravitational consistency reduces entirely to the single number $\operatorname{tr} Y$ of Eq. (37.162), and why a four-dimensional theory never has to worry about its graviton coupling being anomalous on its own account.

37.8.3 Witten's global SU(2) anomaly

Every anomaly discussed so far—cubic gauge, mixed gauge–gravitational—was *perturbative*: it is visible in a single Feynman diagram, it is a smooth function of the external momenta, and its coefficient is a polynomial in charges and Dynkin indices. There is a second, entirely different way for a chiral gauge theory to be inconsistent, one that no triangle can detect because it is invisible to perturbation theory. It was discovered by Witten and it concerns SU(2), the very group we declared safe in Theorem 37.12 on the grounds that it has no cubic invariant. That declaration was correct *for the perturbative anomaly.* The global anomaly is a separate obstruction, and SU(2) is exactly where it bites.

The origin is topological. A gauge transformation on Euclidean spacetime compactified to S^4 is a map $g : S^4 \to \mathrm{SU}(2)$. Such maps fall into homotopy classes labelled by the fourth homotopy group of the group (Section 41.2.3), and for SU(2) this group is not trivial:

$$\pi_4(\mathrm{SU}(2)) \;=\; \pi_4(S^3) \;=\; \mathbb{Z}_2. \tag{37.166}$$

The first equality is the diffeomorphism $\mathrm{SU}(2) \cong S^3$; the second is a classical (and genuinely surprising) result of homotopy theory, the first nonstabilized homotopy group of the three-sphere. There is therefore a gauge transformation g_*—a representative of the nontrivial class—that is *not* continuously connected to the identity. It is a "large" gauge transformation, and although it is a perfectly good gauge transformation, nothing in perturbation theory, which only ever sees the connected component of the identity, knows it exists.

The danger is that the fermion path integral may fail to be invariant under g_*. We make this precise. A single left-handed Weyl fermion in the doublet $\mathbf{2}$ of SU(2) has, because the doublet is pseudoreal (Theorem 37.11), a real fermion

measure: the Euclidean path integral over it yields not a determinant but a *Pfaffian* of the chiral Dirac operator,

$$\int \mathcal{D}\psi\, \mathcal{D}\bar{\psi}\, e^{-S_F[\psi,A]} \;=\; \mathrm{Pf}(\not{D}_A), \qquad \mathrm{Pf}\,(\not{D}_A)^2 = \det\,(\not{D}_A). \tag{37.167}$$

A Pfaffian is a square root of a determinant, and a square root carries a sign ambiguity. The determinant $\det \not{D}_A$ is manifestly gauge invariant and positive, but its square root $\mathrm{Pf}\,\not{D}_A$ need only return to $\pm$ itself as the gauge field is carried around a noncontractible loop in field space. Witten's computation is that as the gauge field is adiabatically deformed along the path connecting A to its large gauge transform A^{g_*}, an *odd* number of eigenvalues of $\not{D}_A$ cross zero—the spectral flow is odd, counted by the mod-two index of the five-dimensional Dirac operator interpolating between A and A^{g_*}. Each zero crossing flips the sign of the Pfaffian, so an odd number of crossings gives

$$\mathrm{Pf}(\not{D}_{A^{g_*}}) \;=\; -\,\mathrm{Pf}(\not{D}_A). \tag{37.168}$$

The integrand of the gauge-field path integral is therefore *odd* under the large gauge transformation g_*. But the path-integral measure $\mathcal{D}A$ identifies A with A^{g_*} (they are gauge-equivalent and must not be double-counted), so the contributions of A and A^{g_*} cancel in pairs and the partition function vanishes,

$$Z = \int \mathcal{D}A\;\, \mathrm{Pf}(\not{D}_A)\, e^{-S_{\mathrm{gauge}}[A]} = 0, \tag{37.169}$$

because every configuration is cancelled by its g_*-image. A theory whose partition function is forced to zero by a gauge identification is not a theory: correlators become $0/0$, and there is no consistent, gauge-invariant definition of the fermion measure. This is the global SU(2) anomaly.

Theorem 37.46 (Witten's global SU(2) anomaly)**.** *An* SU(2) *gauge theory with an odd number of left-handed Weyl fermions in the fundamental doublet* **2** *(more generally, in any pseudoreal representation with odd mod-two index) has no consistent, gauge-invariant path-integral measure: the Pfaffian Eq. (37.167) is odd under the large gauge transformation representing the nontrivial class of* $\pi_4(\mathrm{SU}(2)) = \mathbb{Z}_2$*, and the partition function Eq. (37.169) vanishes. Consistency requires an* even *number of doublets, in which case the Pfaffian appears as* $\mathrm{Pf}^{2k} = \det^k$*, which is sign-definite and gauge invariant.*

Proof sketch. The obstruction is the sign of $\mathrm{Pf}\,\not{D}_A$ under the nontrivial element of $\pi_4(\mathrm{SU}(2))$, which is the mod-two index of the Dirac operator on the mapping torus $S^4 \times_{g_*} S^1$—the five-manifold built by gluing the ends of $S^4 \times [0,1]$ with the twist g_*. The Atiyah–Singer mod-two index theorem (the $\mathbb{Z}_2$-valued companion of Theorem 36.15, valid for real/pseudoreal Dirac operators in appropriate dimensions) evaluates this index, and for one doublet it equals $1 \in \mathbb{Z}_2$. Hence

one doublet flips the Pfaffian sign, Eq. (37.168), and forces Eq. (37.169). The mod-two index is additive over fermions, so n doublets give index n mod 2: the sign flip survives for n odd and cancels for n even. For even n the Pfaffians pair into honest, single-valued determinants and the measure is well defined. The restriction to pseudoreal representations is essential: for a complex representation the fermion measure is already a determinant, not a Pfaffian, with no sign ambiguity—which is why the global anomaly is special to SU(2) (and to Sp($2N$) more generally), the groups whose fundamental is pseudoreal. SU($N \geq 3$), whose fundamental is complex, has trivial π_4 and no global anomaly of this type; its consistency is governed entirely by the perturbative cubic condition. □

The Standard Model contains an $\mathrm{SU}(2)_L$ gauge factor with chiral fermions in the doublet, so Theorem 37.46 is a genuine constraint on it—the one nonperturbative consistency condition this chapter must check by hand. The check is a parity count of doublets, and it is short enough to do completely.

Worked Example 37.47 (The Standard Model passes the global SU(2) anomaly)**.** We count the left-handed $\mathrm{SU}(2)_L$ doublets in one generation, using the field content of Table 33.1. The fields charged under $\mathrm{SU}(2)_L$ as doublets are the quark doublet $Q_L = (u_L, d_L)$ and the lepton doublet $L_L = (\nu_L, e_L)$. Every other left-handed Weyl field of the generation—the right-handed-particle conjugates u_R^c, d_R^c, e_R^c—is an $\mathrm{SU}(2)_L$ *singlet* and contributes no doublet. The crucial multiplicity is color: the quark doublet Q_L is a color triplet, so it is in fact $N_c = 3$ independent $\mathrm{SU}(2)_L$ doublets, one per color. Hence the number of $\mathrm{SU}(2)_L$ doublets per generation is

$$n_{\text{doublet}} = \underbrace{N_c}_{Q_L,\ \text{one per color}} + \underbrace{1}_{L_L} = 3 + 1 = 4, \tag{37.170}$$

which is *even*. By Theorem 37.46 the Pfaffian appears as a fourth power per generation, the sign ambiguity squares away, and the Standard Model has a consistent $\mathrm{SU}(2)_L$ measure. With three generations the total is 12 doublets, still even; the Higgs is a boson and does not enter. The Standard Model passes the one global anomaly it could have failed.

It is worth noting what the count Eq. (37.170) depends on. The doublet number is $N_c + 1$, even precisely because $N_c = 3$ is *odd*. Had the number of colors been even, a single generation would carry an odd number of weak doublets and would suffer the global anomaly. Thus the same color number that the WZW level $k = N_c$ certified through $\pi^0 \to \gamma\gamma$ in Section 37.7, and that the perturbative $\mathrm{SU}(3)_c^2\,\mathrm{U}(1)_Y$ condition tied to charge quantization in Section 37.3, reappears here, through $\pi_4(\mathrm{SU}(2))$, as a parity constraint: N_c odd is required for nonperturbative weak consistency, and Nature's $N_c = 3$ obliges. The quark and lepton sectors are not independent; the lepton doublet supplies exactly the one extra doublet that makes $N_c + 1$ even when N_c is odd. Anomaly

freedom, perturbative and global alike, knits quarks and leptons into a single mutually-consistent generation.

37.8.4 The modern synthesis: anomalies as boundaries of invertible phases

We now stand back and name the structure that has been visible in fragments throughout the chapter. The cubic gauge anomaly, the mixed gravitational anomaly, the pure gravitational anomalies of $d = 4k + 2$, and Witten's global SU(2) anomaly look like four unrelated phenomena—a polynomial in charges, a curvature integral, a dimension-counting rule, a $\mathbb{Z}_2$ sign. The contemporary understanding, assembled over the 1980s descent formalism and the 2010s cobordism program and standard by the mid-2020s, is that they are four readings of one object: the anomaly of a d-dimensional theory is a $(d{+}1)$-dimensional *invertible* field theory, and the anomalous theory is its boundary. We lay this out without full proof, with honest flags on what is and is not settled.

Perturbative anomalies as descent. The perturbative anomalies are organized by the Stora–Zumino descent of the anomaly polynomial Eq. (37.159). One starts from the gauge-invariant, closed $(d{+}2)$-form $\widehat{I}_{d+2}$. Because it is closed and the relevant space is locally trivial, it is exact, $\widehat{I}_{d+2} = \mathrm{d}\,\omega_{d+1}$, where ω_{d+1} is a Chern–Simons form—gauge-*variant* but with a gauge variation that is itself exact,

$$\widehat{I}_{d+2} = \mathrm{d}\,\omega_{d+1}, \qquad \delta_\lambda\,\omega_{d+1} = \mathrm{d}\,\omega_d^1(\lambda), \tag{37.171}$$

the second equation defining the d-form ω_d^1, linear in the gauge parameter λ. The physical anomaly—the gauge variation of the effective action—is then $\delta_\lambda \Gamma = 2\pi \int_{M_d} \omega_d^1(\lambda)$. This single chain reproduces *every* perturbative anomaly in this chapter: the cubic d^{abc} anomaly of Section 37.2 is the descent of the $\mathrm{tr}\,F^3$ term in Eq. (37.159), the mixed gravitational anomaly Eq. (37.163) is the descent of the $p_1 \wedge \mathrm{tr}\,F$ term, and the $d = 4k + 2$ gravitational anomalies are the descents of $[\widehat{A}]_{d+2}$. The descent is also what we invoked, without ceremony, to pass from the six-form Eq. (37.161) to the divergence Eq. (37.163); the Chern–Simons form ω_5 is exactly the integrand of the five-dimensional functional, and its boundary variation is the four-dimensional anomaly.

Global anomalies via homotopy and cobordism. The descent formalism, being differential, sees only the connected component of the gauge group; it is blind to the global anomaly of Section 37.8.3, which lives in $\pi_4(\mathrm{SU}(2))$. Historically global anomalies were classified case by case using homotopy groups of the gauge group ($\pi_d(G)$ for the gauge anomaly in d dimensions). The modern and more complete classification, due to Freed, Hopkins, Kapustin, and collaborators and mature by the late 2010s, replaces homotopy with *cobordism*. The statement

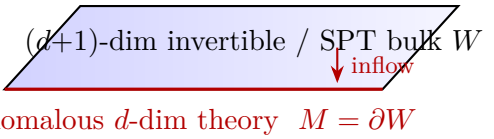

Figure 37.9: Anomaly inflow. An anomalous d-dimensional theory lives on the boundary $M = \partial W$ of a $(d{+}1)$-dimensional invertible (SPT) bulk W. The bulk action is not gauge/diffeomorphism invariant on a manifold with boundary; its boundary variation is a local d-dimensional term that exactly cancels the boundary theory's anomalous variation, so the combined system is consistent. The anomaly is the obstruction to detaching the boundary from the bulk—an invariant of the bulk SPT phase, hence renormalization-group invariant, which is the geometric content of 't Hooft matching. The five-dimensional WZW functional of Section 37.7 is the case $d = 4$.

is that the anomalies of a d-dimensional theory with a given symmetry/spacetime structure ξ (a spin or pin structure, a gauge bundle, etc.) are classified by a group of $(d{+}1)$-dimensional *invertible* field theories, which is computed by a (generalized, Anderson-dual) cobordism group Ω_{ξ}^{d+1}. In this language the perturbative anomalies form the "free part" of the classification (the part detected by the anomaly polynomial, valued in $\mathbb{Z}$ or $\mathbb{R}$), and the global anomalies form the *torsion* part. Witten's SU(2) anomaly is precisely a $\mathbb{Z}_2$ torsion class in the appropriate cobordism group, and its even-doublet resolution is the statement that the Standard Model's class is trivial.

Anomaly inflow and the SPT/invertible picture. Both faces of the anomaly—the fatal one when the current is gauged, the matchable one when it is global—acquire a single geometric meaning in the inflow picture (Fig. 37.9). Place the d-dimensional theory on the boundary $M = \partial W$ of a $(d{+}1)$-dimensional bulk carrying the invertible field theory whose partition function is $\exp(2\pi i \int_W \omega_{d+1})$ built from the Chern–Simons form of Eq. (37.171). On a closed W this bulk is trivial (invertible: its partition function is a pure phase, and it has a unique state on every spatial slice). On a manifold with boundary it is not invariant; its variation is exactly $-2\pi \int_M \omega_d^1$, which cancels the boundary anomaly $\delta\Gamma = +2\pi \int_M \omega_d^1$. The anomalous theory is consistent *as a boundary*, with the bulk absorbing the anomaly inflow—the mechanism Callan and Harvey identified for chiral fermions on defects, here in its general form. Three consequences organize the whole chapter:

- **Gauged ⇒ fatal.** If the anomalous symmetry is gauged, the bulk term is a nontrivial dependence of the dynamical partition function on the gauge field that cannot be a boundary term of a local d-dimensional action; unitarity and the Slavnov–Taylor identities (Theorem 26.35) fail. The anomaly must

be cancelled ($\sum_i \mathcal{A}(R_i) = 0$, $\operatorname{tr} Y = 0$, even doublet number) so that the bulk is genuinely trivial with no boundary obligation. This is Eq. (37.30) and its mixed and global companions.

- **Global ⇒ matched.** If the symmetry is global, the bulk SPT is a fixed, allowed feature of the theory. Its class is a discrete invariant that cannot change under any continuous deformation of the boundary dynamics—in particular under renormalization-group flow. The ultraviolet and infrared descriptions must therefore sit on the boundary of the *same* bulk: their anomaly coefficients must agree. This is exactly 't Hooft anomaly matching, here derived as the rigidity of an SPT phase rather than asserted.
- **The WZW term is inflow.** The five-dimensional construction of Section 37.7 is the $d = 4$ instance of Fig. 37.9: the WZW functional is the bulk invertible theory, its integer level is the quantized bulk coupling, and the four-dimensional anomaly it reproduces is the boundary term. The topological quantization of k is the statement that the bulk theory is well defined on closed five-manifolds, which is the cobordism invariance of the class. The geometric viewpoint opened by the WZW term and the classification just stated are one and the same.

Physical Insight

The inflow picture explains why anomalies are *exact*—why a one-loop coefficient is never renormalized and never receives higher-loop or nonperturbative corrections (the Adler–Bardeen theorem, in this language, is the statement that the bulk class is an integer and integers do not flow). A continuous quantity could be screened by dynamics; a discrete topological invariant of a $(d{+}1)$-dimensional phase cannot. This is the deep reason the anomaly is the ideal infrared/ultraviolet probe: it is the one piece of data about a strongly coupled theory that survives, unaltered, from the free quarks of the ultraviolet to the pions of the infrared, and it is what forced chiral symmetry breaking in Section 37.5. The Standard Model's perturbative cancellations make its bulk trivial; QCD's nonzero global anomalies make its bulk nontrivial and pin down its infrared realization. Same principle, opposite verdicts.

What is, and is not, settled (mid-2020s). Honesty requires marking the edges of this picture. *Settled and standard:* the descent classification of perturbative anomalies; the index-theorem evaluation of their coefficients; the cobordism classification of anomalies for the standard symmetry structures (spin, pin, ordinary global and gauge symmetries) in low dimensions, including the four-dimensional cases relevant to the Standard Model; the inflow interpretation and the resulting derivation of 't Hooft matching. The Standard Model has

been verified anomaly-free in this complete framework, perturbative and global together, with no residual obstruction. *Active and not fully settled, as of the mid-2020s:* the complete cobordism classification for arbitrary symmetry structures and dimensions (computed case by case, with the higher-dimensional and exotic-structure groups still being worked out); the anomalies of *non-invertible* and categorical symmetries, a subject opened around 2021–2022 and developing rapidly, where the analogue of the anomaly polynomial is still being formulated; and the role of anomalies as swampland constraints in quantum gravity, where the requirement that all global symmetries be either gauged or broken interacts with anomaly cancellation in ways that are conjectural. The reader should take the four-dimensional results of this chapter as firm and the classification program as a living frontier whose four-dimensional corner is complete but whose general statement is still being written.

The chapter has now traversed the anomaly from a single number—the ABJ coefficient of Chapter 36—to a consistency principle with two faces and a geometric home. When the anomalous current is gauged, cancellation is mandatory, and the Standard Model achieves it generation by generation across the cubic, mixed, and global conditions assembled here; when the symmetry is global, the anomaly is an exact invariant that the ultraviolet and infrared must share, and the Wess–Zumino–Witten term is its low-energy embodiment. These constraints are the input the next part consumes: the effective-field-theory program of Chapter 38 and the chiral Lagrangian of Chapter 39 are built to match exactly the anomalies certified here, with the WZW term entering chiral perturbation theory as the mandatory anomaly-matching operator. The topological ideas previewed in this section—winding numbers, homotopy classes, the bulk that absorbs the inflow—return in earnest in Part XII, where the instantons and θ-vacuum of Chapters 41 and 42 make the same $\pi_n(G)$ and the same index theorem the engine of nonperturbative dynamics.

Further reading

The consistency conditions that organize the gauged case are due to Wess and Zumino [506], with the relation between consistent and covariant anomalies clarified by Bardeen [48] and Bardeen and Zumino [49]; the descent/anomaly-polynomial formalism has a textbook account in Bertlmann [73] and in Zumino, Wu, and Zee [535]. Anomaly matching as a constraint on strong dynamics is 't Hooft's [465]. The Wess–Zumino–Witten term and the topological quantization of its level are Witten's [521]. Mixed and gravitational anomalies, together with the $d = 4k + 2$ counting, are derived by Alvarez-Gaumé and Witten [23]; the nonperturbative global SU(2) anomaly is Witten's [519], controlled by the mod-two index of Atiyah and Singer [41]. Anomaly inflow originates with Callan and Harvey [107], and the modern cobordism viewpoint on anomalies and invertible

phases is developed by Freed and Hopkins [198] and Kapustin and collaborators [290], with the Standard-Model application reviewed by García-Etxebarria and Montero [209]; for the rapidly developing subject of non-invertible symmetries see [429, 440]. Standard textbook treatments of anomaly cancellation appear in Peskin and Schroeder [396], Weinberg [501], and Schwartz [432].

Part XI

Effective Field Theories

Chapter 38

The Effective Field Theory Paradigm

The Wilsonian renormalization group of Chapter 23 delivered a verdict that, on first hearing, sounds like a counsel of despair: as a theory flows to low energy it forgets almost everything about its short-distance origin, the memory of all but finitely many couplings decaying as a positive power of μ/Λ_0. This chapter turns that verdict into a method. Precisely because the infrared cannot resolve the ultraviolet, the ultraviolet cannot be *needed* to compute infrared observables; its entire imprint must be carried by the coefficients of a local Lagrangian built from the light fields alone. Read forward rather than backward, the irrelevant operators that Theorem 23.23 discarded become the systematic, dimension-ordered carriers of short-distance information, and "renormalizable" is demoted from a law of nature to the leading truncation of a tower. The effective-field-theory paradigm is the discipline of computing with that tower: writing the most general symmetry-allowed local Lagrangian, ordering it by an expansion parameter, and extracting controlled, falsifiable predictions at each order.

The chapter leans throughout on machinery built earlier in the book. The Wilsonian classification of operators, the notion of integrating out, and the canonical-dimension bookkeeping are imported wholesale from Chapter 23 (Theorems 23.8, 23.23 and 23.34); the power-counting theorem and the counterterm structure that forces operator completeness come from Chapters 21 and 22 (Theorem 21.10); and the renormalization-group and Callan–Symanzik apparatus that propagates the Wilson coefficients, together with the ϕ^4 beta function and the $\overline{\text{MS}}$ machinery, are those of Chapter 24. The link between Lagrangians and observables runs through the LSZ reduction and the invariant amplitude of Chapters 14 and 16, which underwrite both Weinberg's folk theorem and the field-redefinition invariance of the S-matrix. The two benchmark theories supply the worked spine: ϕ^4 theory (the real scalar of Chapter 6) is reread as the leading truncation of an EFT whose tower we generate by hand and by matching, while QED (the electron and photon of Chapter 8) furnishes the Euler–Heisenberg Lagrangian, the decoupling of a heavy fermion in the running of α (Chapters 19

and 20), and the chiral protection of the electron mass.

The development is a single arc from concept to consequence. Section 38.1 establishes the separation of scales as the empirical bedrock, defines what an EFT *is*, and proves – at the honest folk-theorem level – that the most general local Lagrangian loses no physics. Section 38.2 turns the operator expansion into a quantitative power counting, proves the master suppression law $(E/\Lambda)^{\Delta-4}$, calibrates coefficient sizes by naive dimensional analysis, and prunes the basis of redundant operators using field redefinitions and the equations of motion. Section 38.3 makes "integrating out" literal at tree level, computing Wilson coefficients top-down for a heavy scalar and for the heavy W that hides behind Fermi's constant. Section 38.4 carries matching to one loop, isolates the locality that lets the large logarithm split cleanly into matching and running, and proves the Appelquist–Carazzone decoupling theorem – displaying its failure in $\overline{\text{MS}}$ and the threshold cure, and computing the Euler–Heisenberg coefficients from the electron loop. Section 38.5 derives the matrix renormalization-group equation for the coefficients, exhibits operator mixing and its triangular structure, and resums the leading logarithms. Section 38.6 closes by reading the relevant operators back as the ultraviolet-sensitive directions, stating 't Hooft's naturalness criterion, and confronting the two relevant couplings the Standard Model cannot protect – the Higgs mass and the cosmological constant.

A brief word on scope and rigor. Everything load-bearing is proved or carried in full: the folk theorem without full proof with each link located, the power-counting master formula by two independent routes, the field-redefinition invariance of the S-matrix, the scalar and Fermi matchings to the end, the decoupling theorem and its $\overline{\text{MS}}$ evasion, the Euler–Heisenberg determinant via the proper-time heat kernel, the coefficient RGE and the ϕ^6 anomalous dimension, and the scalar- and fermion-mass naturalness computations side by side. Where the chapter relies on a result it does not prove – the massive spin-one quantization of the W and the electroweak origin of its mass – it imports it by Chapter 31 explicitly. The frontier is stated honestly and dated: the hierarchy and cosmological-constant problems are recorded, as of the mid-2020s, as open.

38.1 Separation of Scales and the Effective Lagrangian

The Wilsonian renormalization group of Chapter 23 taught us to read a quantum field theory by watching it flow. Fix a microscopic action at a high cutoff Λ_0, integrate out the short-distance modes shell by shell (Theorem 23.8), and follow the dimensionless couplings down toward the infrared. The verdict of that flow was sharp and, on first encounter, slightly deflating: nearly everything is forgotten. The forgetting formula Eq. (23.156) states that two microscopic actions agreeing in their finitely many relevant and marginal couplings but differing arbitrarily in the infinite tower of irrelevant ones converge, as the cutoff is lowered, onto one and

the same long-distance trajectory, with the memory of their difference decaying as a positive power $(\mu/\Lambda_0)^{|y_a|}$. The classification theorem Theorem 23.23 organized this: relevant and marginal operators survive the flow and shape the infrared, irrelevant operators are washed out, and "renormalizable" is simply the name for a theory whose surviving content is finite (Theorem 23.34). That was the *forgetting* direction — given the ultraviolet, deduce the infrared.

This chapter inverts the question. Suppose we do *not* know the ultraviolet. Suppose we know only which light degrees of freedom are dynamical at the energies we can reach, and which symmetries govern them. Can we still make quantitative, falsifiable predictions? The Wilsonian answer, turned inside out, is yes — and moreover that the construction is essentially forced. Precisely because the infrared is insensitive to the details above the cutoff, those details cannot be needed to compute infrared observables; their entire imprint must be encodable in the finitely-many-at-each-order coefficients of a local Lagrangian built from the light fields alone. The irrelevant operators that Chapter 23 discarded as harmless are, read forward, the systematic carriers of short-distance information, ordered by how strongly they are suppressed. This is the effective-field-theory (EFT) paradigm: stop apologizing for non-renormalizable operators and start using them as a controlled expansion. The present section establishes the idea and states precisely what an EFT is; the next makes the expansion quantitative.

38.1.1 The insensitivity of the infrared to the ultraviolet

The physical content of the whole subject is one empirical fact, so ubiquitous that it is easy to overlook: *long-wavelength physics does not resolve short-distance structure.* A probe of energy E has spatial resolution of order $1/E$ (in natural units, $\hbar = c = 1$, as throughout). Structure localized on a much smaller scale $1/\Lambda$, with $\Lambda \gg E$, is simply not seen sharply; it can register only through its gross, averaged properties. Three familiar instances, spanning classical and quantum physics, fix the picture before we formalize it.

The multipole expansion. The electrostatic potential of a localized charge distribution of size a, measured at distance $r \gg a$, is $\phi(r) = \frac{1}{4\pi}\big[\frac{Q}{r} + \frac{\mathbf{p}\cdot\hat{\mathbf{r}}}{r^2} + O(a^2/r^3)\big]$. A distant observer never measures the charge density $\rho(\mathbf{x})$ point by point; she measures a few numbers — total charge Q, dipole moment $\mathbf{p}$, and so on — each weighting a term suppressed by an extra power of the small ratio a/r. Infinitely many microscopic distributions share the same leading multipoles and are, at long range, indistinguishable. The multipole moments are the Wilson coefficients of classical electrostatics, and a/r is the expansion parameter.

Atomic physics without nuclei. The hydrogen spectrum is computed to many digits treating the proton as a point of charge $+e$ and mass m_p. The proton is in fact a roiling bound state of quarks and gluons of radius $r_p \sim 0.84\,\mathrm{fm}$, governed by physics (Chapters 25, 27 and 28) that the hydrogen calculation never invokes. That structure is not absent from the spectrum — it appears, in the finite-size

correction to the Lamb shift, as a term proportional to r_p^2, i.e. suppressed by $(r_p/a_0)^2$ relative to the Bohr scale a_0. One number, the charge radius, captures the leading effect of all the strong dynamics inside the proton on atomic energy levels. We do not need QCD to do chemistry; we need one coefficient.

The Fermi theory of weak decays. Before the W boson was known, Fermi described β decay and muon decay by a contact interaction of four fermions, $\mathcal{L}_{\rm F} = -\frac{G_F}{\sqrt{2}}\,(\bar\psi_1\gamma^\mu\psi_2)(\bar\psi_3\gamma_\mu\psi_4)$, with a single dimensionful constant $G_F \approx 1.166 \times 10^{-5}\,\text{GeV}^{-2}$. We now know the underlying process is the exchange of a W of mass $M_W \approx 80\,\text{GeV}$, whose propagator at momentum transfer $q^2 \ll M_W^2$ reduces to $1/(q^2 - M_W^2) \to -1/M_W^2$, a constant. The contact vertex is what W exchange looks like when the probe energy is far below M_W: the heavy line shrinks to a point and its propagator becomes a coupling, $G_F/\sqrt{2} \sim g^2/M_W^2$. Fermi's theory is predictive and accurate at low energy precisely because the corrections it omits are organized by powers of E^2/M_W^2 — and it breaks down, as a non-renormalizable theory must, when E approaches M_W and the point begins to resolve into a propagating line. Fermi wrote down an effective field theory in 1933, two generations before the language existed.

The common structure is unmistakable. In each case a low-energy observable is a power series in a small ratio E/Λ of the accessible scale to a heavy scale, with coefficients that summarize — but do not require us to resolve — the short-distance physics. The claim of this chapter is that this is not a collection of lucky special cases but the generic behavior of *any* quantum field theory viewed below some scale, and that the power series is a Lagrangian.

Physical Insight

The decoupling of scales is what makes physics possible at all. If computing the hydrogen spectrum required first solving QCD, and solving QCD required first knowing the theory at the Planck scale, no quantitative prediction could ever be made, because no experiment reaches arbitrarily high energy. That each layer of nature can be described, to a controlled accuracy, in its own terms — with the layers above entering only through a handful of parameters — is the precondition for the entire enterprise of theoretical physics. Effective field theory is the formalization of this good fortune, and the renormalization group of Chapter 23 is the proof that it is no accident.

38.1.2 From forgetting to constructing

We now convert the insensitivity into a construction. The logic runs in two complementary directions, and the distinction between them organizes everything that follows.

Top-down. A full ultraviolet theory is known — it contains both light fields ϕ and heavy fields Φ of mass $M \sim \Lambda$ — and we want its predictions for processes at $E \ll M$. We *integrate out* the heavy field, performing the path integral over Φ at fixed ϕ (Theorem 23.8 applied to a field rather than a momentum shell):

$$e^{\,iS_{\text{eff}}[\phi]} \;=\; \int \mathcal{D}\Phi \; e^{\,iS[\phi,\Phi]}. \tag{38.1}$$

The result $S_{\text{eff}}[\phi]$ is in general nonlocal — it contains the heavy propagator $1/(q^2 - M^2)$, which is not a polynomial. But for the soft external momenta $q^2 \ll M^2$ that an infrared observer supplies, the propagator may be Taylor expanded, $\frac{1}{q^2-M^2} = -\frac{1}{M^2}\left(1 + \frac{q^2}{M^2} + \dots\right)$, and each power of q^2 becomes, back in position space, two derivatives acting on a local product of light fields. The nonlocality resolves, order by order in $1/M^2$, into an infinite tower of *local* operators. This is precisely the Fermi mechanism of the previous subsection done as an operation on the action; carried out systematically it is the *matching* computation of Section 38.3 (tree level) and Section 38.4 (one loop), which determines the coefficients of the tower in terms of the ultraviolet couplings and masses.

Bottom-up. The ultraviolet theory is unknown — this is the realistic situation for the Standard Model, whose completion above the TeV scale we have not measured. We then cannot compute the coefficients from first principles; but we can still *write down the most general local Lagrangian* compatible with the known light fields and symmetries, organize it by the same E/Λ expansion, and treat each coefficient as a free parameter to be fixed by experiment. The predictive power is real because at any finite order in E/Λ only finitely many operators contribute (a fact proved in Section 38.2): a finite number of measurements determines the coefficients, and every further observable at that order is then a prediction. The bottom-up EFT is, in effect, the most honest parametrization of our ignorance — it commits to nothing about the ultraviolet beyond locality and symmetry, yet remains falsifiable.

The two directions meet in the middle. The bottom-up Lagrangian is the general template; a top-down matching fills in its coefficients whenever a candidate ultraviolet completion is proposed. A measured pattern of coefficients, conversely, points back toward the class of completions that could have produced it. This is why dimension-six operators in the Standard Model EFT (Chapter 40) are the modern currency of the search for new physics: each coefficient is a number that some heavy sector, if it exists, must predict.

38.1.3 What an effective field theory is

We are ready to state precisely what object we are constructing. An EFT is not a Lagrangian alone; it is a Lagrangian together with the data that make its

expansion meaningful — a specification of the dynamical content, the symmetries that constrain it, and the parameter in which it is expanded.

Definition 38.1 (Effective field theory)**.** An *effective field theory* is the triple

$$\mathcal{E} = (\ \{\phi_a\},\ G,\ E/\Lambda\ ), \tag{38.2}$$

consisting of

1. a *field content* $\{\phi_a\}$: the dynamical fields whose quanta are the light degrees of freedom, those with masses small compared to the cutoff Λ and hence capable of propagating in the accessible energy range;
2. a *symmetry group* G (the realized symmetries — spacetime, gauge, and global, including their realization, linear or spontaneously broken) under which the Lagrangian must be invariant; and
3. a *power-counting parameter* E/Λ, the ratio of the characteristic energy E of the process to the cutoff Λ above which new degrees of freedom or new dynamics enter and the description ceases to apply.

The dynamics is the *most general* local Lagrangian built from $\{\phi_a\}$ and invariant under G, with every admissible operator present, its coefficient a free real parameter, and the whole organized as a series in E/Λ. The EFT is defined only for $E < \Lambda$; the cutoff Λ is part of the definition, not an artifact to be removed.

The word "most general" carries the weight of the entire framework, and it is worth saying exactly why it must be there. If we omitted an operator that the symmetries permit, we would be imposing a constraint on the physics — declaring its coefficient to vanish — that nothing in our stated assumptions justifies. Even if we set such a coefficient to zero by hand at one scale, quantum corrections would regenerate it: a divergence proportional to a symmetry-allowed operator will appear in some loop, and renormalizing it requires a counterterm of exactly that form (this is the lesson of locality, Theorem 21.10 and the counterterm structure of Chapter 22, now read in reverse). Completeness is therefore not a stylistic preference but a consistency requirement: the only operators we are entitled to exclude are those forbidden by a symmetry, and once we have listed the symmetries, the operator content is fixed for us.

Writing the operators in order of increasing mass dimension, the effective Lagrangian takes the form that the whole chapter is built around:

$$\mathcal{L}_{\text{eff}} \;=\; \mathcal{L}_{\le 4} \;+\; \sum_i \frac{c_i}{\Lambda^{\,d_i-4}}\,\mathcal{O}_i, \qquad d_i > 4, \tag{38.3}$$

where $\mathcal{L}_{\le 4}$ collects the operators of mass dimension ≤ 4 — the relevant ($d_i < 4$) and marginal ($d_i = 4$) operators, i.e. the kinetic terms, masses, and renormalizable

interactions — and the sum runs over a complete set $\{\mathcal{O}_i\}$ of independent local operators of dimension $d_i > 4$ built from $\{\phi_a\}$ and invariant under G. Each higher-dimension operator is divided by Λ^{d_i-4} so that its coefficient c_i is dimensionless, the carrier of the short-distance information. (That "independent" hides a subtlety — distinct operators can have identical S-matrix elements and so be redundant — which is discharged by field redefinitions in Section 38.2.4. We list the expansion now and prune it there.)

The structure of Eq. (38.3) explains at a glance why the expansion is useful. A dimensionless coefficient times an operator of dimension d_i divided by Λ^{d_i-4} has, on dimensional grounds, an effect on any fixed low-energy amplitude that is suppressed by the small ratio E/Λ raised to the power $d_i - 4$. The higher the dimension, the deeper the suppression, and the expansion truncates with controlled error. We make this estimate precise now, as the central quantitative claim that the next section will elevate into a theorem.

Worked Example 38.2 (The $(E/\Lambda)^{d-4}$ suppression of a higher-dimension operator)**.** Consider a single light real scalar ϕ of mass $m \ll \Lambda$ and an amplitude $\mathcal{M}$ for a fixed process — say $2 \to 2$ scattering, $\phi\phi \to \phi\phi$ — at center-of-mass energy E with $m \ll E \ll \Lambda$, so that E is the only relevant kinematic scale. We estimate how a higher-dimension operator $\mathcal{O}_i$ of dimension d_i contributes to $\mathcal{M}$ relative to the marginal interaction, using nothing but dimensional analysis and the form Eq. (38.3).

Step 1: dimension of the amplitude. In $d = 4$ spacetime dimensions a field has canonical dimension $[\phi] = 1$ (from the kinetic term $(\partial\phi)^2$, since $[\partial] = 1$ and $[\mathcal{L}] = 4$; this counting is fixed in Section 38.2.1). The S-matrix element for n external scalars carries dimension $[\mathcal{M}] = 4-n$ by the LSZ reduction (Chapter 16), where each amputated external leg removes a propagator. For $n = 4$, $[\mathcal{M}] = 0$: the $2 \to 2$ amplitude is dimensionless.

Step 2: the marginal contribution. The marginal interaction is the quartic $-\frac{\lambda}{4!}\phi^4$ of ϕ^4 theory (Chapter 6). It contributes to $\mathcal{M}$ at tree level a constant, $\mathcal{M}_{\le 4} \sim \lambda$, dimensionless as required and independent of E. This is the leading term, the "1" against which everything else is measured.

Step 3: the higher-dimension contribution. Take the leading operator that modifies $\phi\phi \to \phi\phi$ beyond the quartic. The lowest-dimension candidate with four fields and extra derivatives, consistent with the $\mathbb{Z}_2$ symmetry $\phi \to -\phi$ and with Lorentz invariance, is

$$\mathcal{O}_8 = \left(\partial_\mu\phi\,\partial^\mu\phi\right)^2, \qquad d_8 = 4\cdot 1 + 4 = 8, \tag{38.4}$$

entering the Lagrangian as $(c_8/\Lambda^4)\,\mathcal{O}_8$. (A dimension-six operator with four fields, ϕ^6 has $d = 6$ but is a potential term contributing to $3 \to 3$, not the four-point amplitude at leading derivative order; the leading *derivative* correction to $\phi\phi \to \phi\phi$ is the dimension-eight Eq. (38.4), which is the natural thread-ϕ^4

object to track.) Its tree-level contribution to $\mathcal{M}$ is obtained by reading off the vertex: four fields, four derivatives, divided by Λ^4. Each derivative brings down a factor of external momentum, of order E, so the four derivatives contribute E^4:

$$\mathcal{M}_8 \;\sim\; \frac{c_8}{\Lambda^4}\,E^4 \;=\; c_8\Big(\frac{E}{\Lambda}\Big)^4. \tag{38.5}$$

This is dimensionless, as it must be, and it is suppressed relative to the marginal term $\mathcal{M}_{\le 4} \sim \lambda$ by exactly $(E/\Lambda)^4 = (E/\Lambda)^{d_8-4}$.

Step 4: the general rule. Nothing in this estimate used the specific operator. An operator of dimension d_i enters $\mathcal{L}_{\text{eff}}$ with coefficient c_i/Λ^{d_i-4}. Its contribution to a fixed amplitude must make up the dimension deficit between the prefactor $\Lambda^{-(d_i-4)}$ and the dimensionless (or fixed-dimension) amplitude using the only available kinematic scale, E. Hence the contribution carries $E^{\,d_i-4}$, and relative to the leading term,

$$\frac{\mathcal{M}_i}{\mathcal{M}_{\le 4}} \;\sim\; c_i\left(\frac{E}{\Lambda}\right)^{d_i-4}. \tag{38.6}$$

Each unit of operator dimension above four costs one power of E/Λ. With $E \ll \Lambda$ and the c_i of order unity (the natural expectation made precise by the naive dimensional analysis of Section 38.2.3), the series Eq. (38.3) is a genuine, rapidly converging expansion, and truncating it at dimension $d_{\max}$ incurs an error of order $(E/\Lambda)^{d_{\max}-3}$ — the first omitted power. That controlled truncation is what makes an EFT predictive.

Theorem 38.2 is the quantitative heart of the chapter in miniature, and it makes the geometry of the operator expansion vivid: the operators of an EFT form a tower, sorted by dimension, in which each rung is suppressed by a further power of E/Λ relative to the one below it. Figure 38.1 draws the picture — light fields and renormalizable dynamics in the accessible window below Λ, the heavy completion above it, and the operator tower interpolating between them in powers of E/Λ.

38.1.4 Weinberg's folk theorem: why the most general Lagrangian is enough

A doubt lurks beneath the construction. We have agreed to write *the most general local Lagrangian* consistent with the symmetries and to compute with it. But the object we ultimately want is not a Lagrangian; it is the S-matrix — the set of physical scattering amplitudes constrained by relativistic invariance, by unitarity (probabilities sum to one), by analyticity (causality, encoded in the analytic structure of amplitudes), and by cluster decomposition (distant experiments are independent). Why should working with the most general Lagrangian deliver the most general S-matrix consistent with those principles, rather than some special subclass? If the Lagrangian framework secretly imposed extra restrictions, the

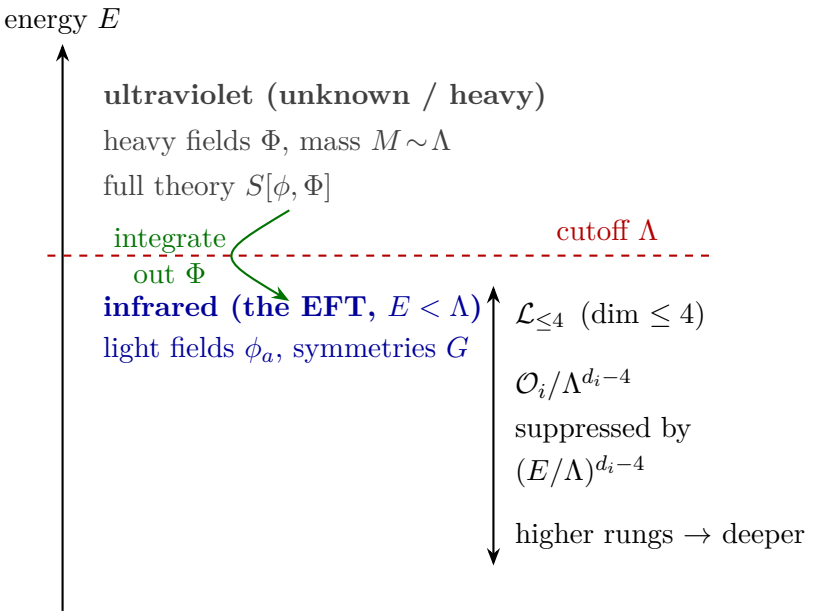

Figure 38.1: The separation of scales. Above the cutoff Λ sit the heavy fields Φ and the (possibly unknown) full theory. Below Λ live the light fields ϕ_a and their symmetries G, governed by the effective Lagrangian Eq. (38.3): a renormalizable core $\mathcal{L}_{\leq 4}$ plus a tower of higher-dimension operators, the rung of dimension d_i suppressed in any fixed amplitude by $(E/\Lambda)^{d_i-4}$ (Theorem 38.2). Integrating out Φ (top-down, Eq. (38.1)) fixes the tower's coefficients; bottom-up, the tower is written down from symmetry alone and measured.

EFT program would be quietly assuming away possibilities, and its claim to capture "whatever the ultraviolet might be" would fail. Weinberg's folk theorem is the assurance that it does not.

Theorem 38.3 (Weinberg's folk theorem)**.** *Let a set of light fields and a symmetry group G be given. Compute the S-matrix perturbatively from the most general local Lagrangian built from those fields, containing every term consistent with G (with arbitrary coefficients), using the most general possible propagators and vertices and the standard rules of perturbation theory. Then the resulting S-matrix is the most general one consistent with relativistic invariance, the assumed symmetries G, and the fundamental principles of* analyticity *(perturbative unitarity and causality) and* cluster decomposition*. Conversely, no S-matrix satisfying those principles lies outside the family so generated.*

The theorem is called a "folk theorem" because it is universally relied upon and its complete proof requires assembling many separate results — the LSZ reduction, the locality of perturbative quantum field theory, the analytic structure of Feynman amplitudes, and the cluster-decomposition theorem that singles out

local field theory among all relativistic quantum theories. We give the argument at the honest level: a statement of the logical chain, with each link either established earlier in this book or made plausible here and deferred to a precise location, and with the role of every hypothesis identified.

Argument. The claim has two halves — that the Lagrangian construction reaches every allowed S-matrix, and that it produces nothing forbidden — and the work is in the first.

(i) Completeness: every allowed amplitude is reachable. An S-matrix is a collection of on-shell amplitudes $\mathcal{M}(p_1, \ldots, p_n)$, one for each particle content and number of legs, that are by hypothesis Lorentz-covariant, G-covariant, and analytic functions of the Lorentz invariants $p_i \cdot p_j$ with only the singularities — poles at physical masses, branch cuts above multiparticle thresholds — demanded by unitarity and causality. The LSZ reduction formula (Chapter 16, in the form Theorem 16.14 that connects amplitudes to observables) expresses each such amplitude as the residue of an appropriately amputated, on-shell time-ordered correlation function of local fields. Run this backward. The non-singular part of $\mathcal{M}$ — the piece analytic at the kinematic point in question, i.e. its Taylor expansion in the invariants around any regular point — is a power series in the momenta. A local operator built from the fields and their derivatives produces, as a tree-level vertex, exactly a polynomial in momenta; with enough derivatives and enough fields one can match any prescribed polynomial term by term. Including *every* symmetry-allowed local operator with a free coefficient therefore makes available, as an adjustable tree-level vertex, every polynomial in momenta consistent with Lorentz and G covariance — which is to say, the most general analytic (pole- and cut-free) part of every amplitude. The free coefficients of the Lagrangian are in one-to-one correspondence with the coefficients of this Taylor expansion. This is the crux: *completeness of the operator basis is what makes the construction able to reproduce an arbitrary regular amplitude.* Omit one allowed operator and one Taylor coefficient becomes un-tunable; include them all and the regular part is free.

(ii) The non-analytic part is fixed, not free — and correctly. The poles and cuts of $\mathcal{M}$ are not ours to choose: their positions are the masses of the light states (poles) and their multiparticle thresholds (cuts), and their residues and discontinuities are fixed, through unitarity, by lower-point amplitudes. Here the two remaining principles do their work. *Unitarity* is implemented perturbatively by the loop expansion: the optical-theorem discontinuity of a loop amplitude is sewn from on-shell lower-order amplitudes, so the cuts generated by computing with our Lagrangian are exactly the cuts unitarity demands, with the correct discontinuities. *Cluster decomposition* — the statement that widely separated subprocesses factorize, so that connected amplitudes have no disconnected singularities — is, by the theorem of Chapter 16's framework, equivalent to the requirement that the interactions be built from *local* products of fields, which is

exactly the form of every term in Eq. (38.3). Locality thus guarantees the correct singularity structure automatically; it is the reason an S-matrix from a local Lagrangian satisfies cluster decomposition, and the reason (run forward) that a cluster-decomposing S-matrix can be written this way. The analytic structure required by causality — amplitudes analytic in the upper-half energy plane, with the $i\epsilon$ prescription of the Feynman propagator — is built into the perturbative rules from the start.

(iii) Soundness: nothing forbidden is produced. Every amplitude computed from a Lorentz- and G-invariant local Lagrangian by the standard rules is, by construction, Lorentz- and G-covariant, has only the singularities unitarity and causality permit, and clusters. So the family generated lies entirely *within* the set of principle-consistent S-matrices. Combined with (i)–(ii), which show the family also *exhausts* that set, the two coincide.

Redundancy and the role of field redefinitions. One gap remains in the correspondence "free coefficients $\leftrightarrow$ amplitude data": different Lagrangians can give the same S-matrix. A field redefinition $\phi \to \phi + f(\phi)$ leaves the S-matrix invariant (it changes off-shell Green's functions but not on-shell amplitudes, because it amounts to a change of integration variable in the path integral whose Jacobian and contact terms do not touch the LSZ residues). Such redefinitions, equivalent to using the classical equations of motion to eliminate operators, mean the operator basis as written in Eq. (38.3) is overcomplete: some operators are physically redundant. This does not threaten the theorem — redundant operators add no new S-matrix freedom — but it must be quotiented out to obtain a genuinely independent counting. The systematic removal is carried out in Section 38.2.4; here we have only flagged that the "most general Lagrangian" is to be understood modulo field redefinitions. □

The folk theorem is the license for the entire bottom-up program. It says that by writing the most general symmetric local Lagrangian we lose nothing: any S-matrix that respects the assumed symmetries and the bedrock principles of relativistic quantum mechanics can be reproduced, and conversely we generate no inconsistent amplitude. An EFT is therefore not a model among many; it is the general solution to the problem "parametrize all possible low-energy physics with these fields and these symmetries."

Historical Note

Weinberg articulated the principle in 1979, framing it as a working hypothesis: if one writes down the most general Lagrangian consistent with the assumed symmetries, and calculates with it to a given order, the result will be the most general S-matrix consistent with analyticity, unitarity, cluster decomposition, and those symmetries. He used it to organize the low-energy theory of pions (Chapter 39). The status of the statement —

physically compelling, leaning on a chain of standard but separately-proved results, never reduced to a single self-contained theorem — is exactly why it carries the affectionate name "folk theorem." Its conceptual ancestry runs back through Wilson's renormalization group (Chapter 23) and, further still, to Fermi's 1933 four-fermion theory, an effective Lagrangian written down decades before the framework that would explain why it worked.

38.1.5 Renormalizability reconsidered

The folk theorem forces a reappraisal of a principle this book has so far treated as close to sacred. Through Parts IV–VI we built quantum field theory under the banner of renormalizability: a theory was acceptable if its divergences could be absorbed into finitely many parameters, which by the power-counting theorem Theorem 21.10 meant a Lagrangian containing only operators of dimension ≤ 4. QED and the Standard Model are renormalizable in exactly this sense, and that property let us extract finite predictions to all orders. It is natural to read renormalizability as a fundamental requirement that nature's Lagrangians must satisfy.

The EFT viewpoint demotes it. In the expansion Eq. (38.3), the renormalizable part $\mathcal{L}_{\leq 4}$ is nothing more special than the *leading truncation* of the operator tower — the dimension-≤ 4 operators, which by Theorem 38.2 are exactly the terms unsuppressed (or *enhanced*) by powers of E/Λ. The higher-dimension operators are always there; they are simply suppressed by $(E/\Lambda)^{d_i-4}$ and so invisible to any experiment whose precision is coarser than that power. A renormalizable theory is the EFT one obtains by keeping only the relevant and marginal operators and dropping the irrelevant tail — which is to say, the description that survives when the cutoff is taken so far above the probe energy that every suppressed term is negligible. Renormalizability, in other words, is not a law imposed from above; it is the generic *low-energy* behavior of *any* local theory, the statement that at energies far below the scale of new physics only the relevant and marginal operators are measurable. The predictivity of QED and the Standard Model is, on this reading, a low-energy accident — the dominance of the leading truncation — and not a fundamental input. This is precisely the inversion the insight box of Chapter 23 (read against Theorem 23.34) anticipated: the same arithmetic that condemned non-renormalizable operators in the ultraviolet rehabilitates them in the infrared as the controlled carriers of short-distance physics.

This reinterpretation reframes every theory met so far in this book, and in particular the two benchmark theories. ϕ^4 theory, the real scalar $\mathcal{L} = \frac{1}{2}(\partial\phi)^2 - \frac{1}{2}m^2\phi^2 - \frac{\lambda}{4!}\phi^4$ of Chapter 6, is to be reread as the dimension-≤ 4 truncation $\mathcal{L}_{\leq 4}$ of an EFT whose tower begins with the dimension-six operator ϕ^6/Λ^2

and the dimension-eight $(\partial_\mu\phi\,\partial^\mu\phi)^2/\Lambda^4$ of Eq. (38.4). The quartic coupling λ, which we have treated as a fundamental parameter since Chapter 6, is itself a Wilson coefficient — as Section 38.3 will make literal by integrating out a heavy scalar and watching $\lambda\phi^4/4!$ emerge as the leading matched operator, with its leading irrelevant companion generated alongside it. QED, the electron coupled to the photon (Chapter 8), is likewise the renormalizable core of an EFT; below the electron mass, integrating the electron out leaves a pure-photon effective theory whose leading operators are the dimension-eight $(F_{\mu\nu}F^{\mu\nu})^2$ and $(F_{\mu\nu}\tilde{F}^{\mu\nu})^2$ of Euler and Heisenberg — the EFT of light-by-light scattering — which Section 38.4.5 computes, and whose threshold will reappear in the running of α through the decoupling theorem of Section 38.4.2. Neither $\lambda\phi^4$ nor QED was ever "the theory"; each was the leading truncation of an EFT whose higher-dimension tail this chapter now learns to compute.

Caution

"Demoted" does not mean "dispensable." Renormalizability remains the property that lets a theory be extrapolated to arbitrarily high energy with finitely many parameters — the existence of a continuum limit (Theorem 23.34). What the EFT viewpoint denies is only that this property is *required* of a physical Lagrangian. A non-renormalizable EFT is perfectly predictive within its domain $E < \Lambda$; it simply does not extend, on its own, to $E \gtrsim \Lambda$, where it must be replaced by (matched onto) a more complete description. The relevant operators, far from being dispensable, are exactly the ones whose unnatural smallness will return in Section 38.6 as the hierarchy and cosmological-constant problems — the price of the same scale-sensitivity that makes the marginal operators dominate.

We have now fixed the concept. An EFT is the triple of Theorem 38.1; its dynamics is the complete symmetry-allowed local Lagrangian Eq. (38.3); the folk theorem Theorem 38.3 guarantees this loses no physics; and renormalizability is reread as its leading truncation. What remains qualitative is the bookkeeping of the expansion: we have argued by dimensional analysis that a dimension-d operator contributes $(E/\Lambda)^{d-4}$ to a fixed amplitude (Theorem 38.2), but we have neither fixed the canonical dimensions of every field once and for all, nor estimated the natural size of the coefficients c_i, nor proven the suppression as a theorem about amplitudes, nor pruned the redundant operators from the basis. The next section, Section 38.2, supplies exactly this: it turns the operator expansion into a quantitative power counting, complete with the factors of 4π that naive dimensional analysis tracks, and removes the redundancy of the basis using the field redefinitions and equations of motion flagged in the proof of the folk theorem.

38.2 Power Counting and the Operator Expansion

The previous section made a promise that was, as stated, only qualitative. We are to write "the most general local Lagrangian built from the light fields and consistent with the symmetries," organize it "as an expansion in operator dimension," and trust that the higher terms are "small." Each of those phrases needs a number behind it before the program can be used to compute. *Most general* must become a finite, non-redundant list at every order. *Organized by dimension* must become a precise statement about how large each coefficient is and how much each operator contributes to a measured amplitude. And *small* must become an inequality with an explicit suppression factor, so that truncating the tower at a given order incurs a controlled and estimable error. This section supplies all three. We fix the canonical dimensions, write the effective Lagrangian with its scale dependence made explicit, prove the master power-counting result that a dimension-Δ operator contributes to a low-energy amplitude with the suppression $(E/\Lambda)^{\Delta-4}$, estimate the natural size of each coefficient by naive dimensional analysis, and finally clear the basis of redundancy using field redefinitions and the equations of motion. The result is a clean, finite, physically calibrated operator basis — the object the rest of the chapter learns to populate with actual numbers.

38.2.1 Canonical dimensions and the operator tower

The organizing quantity is the engineering (mass) dimension, the same $[\,\cdot\,]$ that governed the Wilsonian classification of Chapter 23 and the power counting of Chapter 21. In natural units the action $S = \int \mathrm{d}^4x\, \mathcal{L}$ is dimensionless, so in $d = 4$ the Lagrangian density carries $[\mathcal{L}] = 4$. Each spacetime derivative contributes one unit, $[\partial_\mu] = 1$, and the kinetic terms then fix the dimensions of the fields: a scalar kinetic term $\frac{1}{2}(\partial_\mu\phi)(\partial^\mu\phi)$ forces $[\phi] = 1$, a Dirac kinetic term $\bar\psi\, i\not{\partial}\psi$ forces $[\psi] = \frac{3}{2}$, and a gauge kinetic term $-\frac{1}{4}F_{\mu\nu}F^{\mu\nu}$ forces $[A_\mu] = 1$. These are exactly the canonical dimensions recorded in Eq. (23.142); we import them rather than re-derive them. A local operator $\mathcal{O}_i$ assembled from n_f factors of a field of dimension d_f and δ_i derivatives has dimension

$$\Delta_i \;=\; \delta_i + \sum_f n_f\, d_f, \tag{38.7}$$

and by Theorem 21.9 the coupling that multiplies it in the Lagrangian must make up the difference to 4,

$$[g_i] \;=\; 4 - \Delta_i. \tag{38.8}$$

This is the single fact on which the whole expansion turns. It is the same statement that Eq. (23.182) used to classify perturbations as relevant, marginal, or irrelevant; here we read it in the constructive direction.

The point of EFT is to make the scale dependence carried by Eq. (38.8) manifest. We are building a theory valid below a heavy scale Λ, and Λ is the natural unit in which to measure every dimensionful coupling. We therefore strip each coupling of its dimension by pulling out the appropriate power of Λ, leaving a dimensionless *Wilson coefficient*.

Definition 38.4 (Effective Lagrangian and Wilson coefficients)**.** Let $\{\mathcal{O}_i\}$ be a basis of local operators built from the light fields and invariant under the assumed symmetries, with $\mathcal{O}_i$ of canonical dimension Δ_i. The *effective Lagrangian* is the sum over the basis

$$\mathcal{L}_{\text{eff}} \;=\; \sum_i \frac{c_i}{\Lambda^{\Delta_i - 4}}\,\mathcal{O}_i, \tag{38.9}$$

where each *Wilson coefficient* c_i is dimensionless. The operators with $\Delta_i \le 4$ (relevant and marginal — the "renormalizable" ones in the modern sense of Theorem 23.34) carry non-negative powers of Λ; the operators with $\Delta_i > 4$ (irrelevant) carry strictly negative powers $\Lambda^{-(\Delta_i-4)}$ and form the *operator tower*, ordered by increasing dimension.

The renormalizable part of Eq. (38.9) is what every theory in this book so far has been: the dimension-≤ 4 operators are precisely the ones whose couplings do not come pre-suppressed by Λ. The tower is the new content. Its members were invisible in the strictly renormalizable framework not because they are forbidden but because their couplings are tiny — a fact we are about to quantify. Two clarifications fix the meaning of Eq. (38.9). First, the single scale Λ is a bookkeeping device: when several heavy thresholds exist one writes a Λ for each, but the structure is unchanged. Second, the split into "relevant/marginal" and "irrelevant" is the dimensional shadow of the dynamical trichotomy proved in Theorem 23.23; we are now reading that classification as a recipe for what to write down, in the order in which it matters.

38.2.2 The power-counting master formula

We now prove the quantitative core of the chapter: how much a given operator in the tower contributes to a physical amplitude measured at energy $E \ll \Lambda$. The answer is a pure power of the ratio E/Λ, fixed entirely by the operator's dimension.

We need first the mass dimension of an amplitude. With the relativistically normalized states of Chapter 14, a one-particle state $|\mathbf{p}\rangle$ satisfies $\langle \mathbf{p}|\mathbf{q}\rangle = 2E_{\mathbf{p}}(2\pi)^3\delta^3(\mathbf{p}-\mathbf{q})$, whose right-hand side has mass dimension $1-3=-2$; hence $[\,|\mathbf{p}\rangle\,] = -1$. From the definition of the invariant amplitude in Eq. (16.2), $\langle f|iT|i\rangle = (2\pi)^4\delta^4(\sum k - \sum p)\, i\mathcal{M}$, the left-hand side carries the dimension of N external states, namely $-N$ for a process with N external legs in total, while the delta function carries -4. Matching,

$$[\mathcal{M}] \;=\; 4 - N. \tag{38.10}$$

This holds for any species, since the relativistic normalization assigns every single-particle state dimension -1 regardless of spin.

Consider now a connected contribution to such an amplitude that uses V_i insertions of the interaction vertex coming from operator $\mathcal{O}_i$, with dimensionful coupling $g_i = c_i\,\Lambda^{4-\Delta_i}$. Suppose all light masses are negligible compared with the common external energy E, and that $E \ll \Lambda$, so the heavy scale enters only through the couplings. Suppose further that the loop integrals are dominated by internal momenta of order E — the generic situation for an infrared-safe low-energy observable, the exceptions being the ultraviolet-sensitive pieces that are by construction absorbed into the Wilson coefficients (the subject of the matching sections to come). Under these hypotheses the amplitude can depend on only two dimensionful quantities, the couplings g_i and the energy E. Its dimension Eq. (38.10) is then saturated in a unique way:

$$\mathcal{M} \;=\; \kappa \left(\prod_i g_i^{V_i} \right) E^{\,p}, \qquad p \;=\; 4 - N - \sum_i V_i\,[g_i] \;=\; 4 - N + \sum_i V_i(\Delta_i - 4), \tag{38.11}$$

where κ is a dimensionless number depending only on ratios (angles, light dimensionless couplings). Substituting $g_i = c_i \Lambda^{4-\Delta_i}$ and regrouping the powers of E and Λ,

$$\boxed{\mathcal{M} \;=\; \kappa\, E^{\,4-N} \prod_i \Big[\, c_i \Big(\frac{E}{\Lambda}\Big)^{\Delta_i - 4} \Big]^{V_i}} \tag{38.12}$$

Equation Eq. (38.12) is the power-counting master formula, and it should be read one factor at a time. The prefactor $E^{\,4-N}$ is the dimensional baseline that any process of N external legs must carry. Every insertion of an operator of dimension Δ_i then multiplies the amplitude by the dimensionless factor $c_i\,(E/\Lambda)^{\Delta_i - 4}$. For a marginal operator, $\Delta_i = 4$, the factor is just c_i with no energy dependence: these are the interactions that survive to arbitrarily low energy, the renormalizable couplings. For an irrelevant operator, $\Delta_i > 4$, the factor carries a strictly positive power of the small ratio E/Λ and is therefore suppressed; a relevant operator, $\Delta_i < 4$, is conversely enhanced as $E \to 0$. The central consequence, isolating a single insertion against the renormalizable baseline of the same process, is the suppression law

$$\frac{\mathcal{M}^{(\Delta)}}{\mathcal{M}^{(\mathrm{ren})}} \;\sim\; c_\Delta \Big(\frac{E}{\Lambda}\Big)^{\Delta - 4}, \tag{38.13}$$

which is the precise form of the qualitative "smallness" invoked in the previous section. A dimension-six operator contributes at relative order $(E/\Lambda)^2$, a dimension-eight operator at order $(E/\Lambda)^4$, and so on: the tower is an expansion in $(E/\Lambda)^2$ for operators that step up by two units of dimension at a time, and truncating it after a given dimension leaves an error of the next power of E/Λ. This is what licenses the whole program: at any fixed accuracy, only finitely many operators contribute.

It is worth deriving Eq. (38.12) a second way, tracking the diagram piece by piece, because the bookkeeping exposes that this is the same arithmetic as the ultraviolet power counting of Theorem 21.10, read at the infrared end. Take a contribution with L loops, I internal scalar lines, and V_i vertices of type i, the vertex from $\mathcal{O}_i$ carrying coupling g_i and δ_i derivatives. With all momenta of order E: each loop measure $\int \mathrm{d}^4k$ scales as E^4; each propagator $i/(k^2 - m^2)$ scales as E^{-2}; each vertex contributes g_i times E^{δ_i} from its derivatives. The total power of E is

$$p \;=\; 4L - 2I + \sum_i V_i\,\delta_i. \tag{38.14}$$

Eliminate the internal quantities with the two topological identities used in Theorem 21.10: the loop count $L = I - V + 1$ (with $V = \sum_i V_i$) and the leg count $\sum_i V_i n_i = 2I + N$ (each vertex emits n_i ends, internal lines absorb two, external legs one). Substituting,

$$\begin{aligned} p &= 4(I - V + 1) - 2I + \sum_i V_i\delta_i = 2I - 4V + 4 + \sum_i V_i\delta_i \\ &= \Big(\sum_i V_i n_i - N\Big) - 4\sum_i V_i + 4 + \sum_i V_i\delta_i = 4 - N + \sum_i V_i\,(n_i + \delta_i - 4). \end{aligned} \tag{38.15}$$

Since $n_i + \delta_i = \Delta_i$ for a scalar operator (each field dimension 1, each derivative dimension 1), the energy power is $p = 4 - N + \sum_i V_i(\Delta_i - 4)$, identical to Eq. (38.11); combined with $\prod_i g_i^{V_i} = \prod_i c_i^{V_i}\Lambda^{V_i(4-\Delta_i)}$ it reproduces Eq. (38.12) exactly. The calculation is the mirror image of the divergence counting: there the engine of growth was the loop measure pulling the integral up toward Λ_{UV}; here the same measure, evaluated at the physical scale E, sets the size of the answer. Loops do not change the leading $(E/\Lambda)^{\Delta-4}$ assignment of an operator — that is fixed by its dimension alone — but they do reorganize the dimensionless number κ, which is where the loop expansion lives. We count loops *separately* from the operator expansion: a one-loop dressing of a tree contribution multiplies κ by the usual loop factor (computed next) without altering the power of E/Λ. The two expansions are orthogonal axes of the EFT, and confusing them is the most common error in estimating the size of an effect.

Physical Insight

The master formula explains, in one line, why renormalizable theories were ever a good description of nature. Nothing forbids the tower; the operators are there. They are simply weighted by powers of E/Λ, and at energies far below the next heavy threshold those powers are minuscule. "Renormalizable" is not a fundamental law but the statement that, at the energies we have probed, only the $\Delta \le 4$ operators have had a measurable coefficient. The irrelevant operators of Theorem 23.23 are not absent from

QED or the Standard Model; they are suppressed, and the suppression is the experimental window onto Λ.

38.2.3 Naive dimensional analysis and the role of 4π

Power counting fixes how an operator's contribution scales with energy, but it leaves the dimensionless Wilson coefficient c_i undetermined. To estimate c_i we need a guess for the strength of the dynamics that produced it, together with an honest accounting of the loop factors that any quantum field theory in four dimensions generates. The estimate that results is called naive dimensional analysis (NDA), and its non-trivial ingredient is the counting of factors of 4π.

The factors of 4π come from the loop measure. Consider the Euclidean angular integral in four dimensions: $\int \mathrm{d}^4k = \Omega_3 \int_0^\infty k^3\,\mathrm{d}k$, where $\Omega_3 = 2\pi^2$ is the surface area of the unit three-sphere. Hence a generic one-loop integral carries

$$\int \frac{\mathrm{d}^4k}{(2\pi)^4}\, f(k^2) \;=\; \frac{2\pi^2}{(2\pi)^4}\int_0^\infty k^3\,\mathrm{d}k\; f(k^2) \;=\; \frac{1}{16\pi^2}\int_0^\infty \mathrm{d}(k^2)\, k^2\, f(k^2), \tag{38.16}$$

so that *each loop comes with an explicit factor* $1/16\pi^2 = 1/(4\pi)^2$. This is the same $16\pi^2$ that sits in the denominator of every beta function in the book — the $\beta_\lambda = 3\lambda^2/16\pi^2$ of ϕ^4 theory (Chapter 24) and the $\beta_e = e^3/12\pi^2$ of QED among them. It is not a convention; it is the residue of the four-dimensional phase space, and it means that a loop is suppressed not merely by a coupling but by a coupling divided by $16\pi^2 \approx 158$. A perturbative expansion in $\alpha/4\pi$ converges far faster than one in α precisely because of this factor.

NDA elevates Eq. (38.16) into a self-consistent assignment of sizes. The idea is to ask: if the unknown ultraviolet physics is as strong as it can be without losing all predictivity — maximally strongly coupled at the scale Λ — how big are the operator coefficients it generates? The answer must be *self-consistent* under the theory's own loops: an estimate is only sensible if computing a loop correction to an operator reproduces the same operator with a coefficient no larger than the one we started with. Otherwise the loop expansion would overturn the estimate. This single requirement fixes the powers of 4π.

Write the effective Lagrangian for a single real scalar in the form

$$\mathcal{L}_{\mathrm{NDA}} \;=\; \frac{\Lambda^4}{16\pi^2}\sum_{n,p} \hat{c}_{n,p}\left(\frac{\partial}{\Lambda}\right)^{2p}\left(\frac{4\pi\,\phi}{\Lambda}\right)^{n}, \tag{38.17}$$

with $\hat{c}_{n,p}$ pure numbers of order unity and the operator carrying n powers of ϕ and $2p$ derivatives, hence dimension $\Delta = n + 2p$. Reading off the dimensionful coefficient of $\phi^n(\partial)^{2p}$,

$$g_{n,p} \;=\; \frac{\Lambda^4}{16\pi^2}\cdot\frac{(4\pi)^n}{\Lambda^{\,n+2p}}\,\hat{c}_{n,p} \;=\; (4\pi)^{\,n-2}\,\Lambda^{\,4-n-2p}\,\hat{c}_{n,p}, \tag{38.18}$$

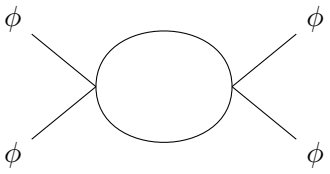

Figure 38.2: The one-loop bubble that fixes the 4π counting. Two ϕ^4 vertices (coupling λ each) and one loop generate a correction to the four-point function of size $\lambda^2/16\pi^2$, Eq. (38.19). Self-consistency of this loop with the tree coupling places the natural strong-coupling value at $\lambda \sim 16\pi^2$, the NDA estimate of Eq. (38.18).

so that the dimensionless Wilson coefficient of Eq. (38.9) is $c_{n,p} = g_{n,p}\,\Lambda^{\Delta-4} = (4\pi)^{n-2}\hat{c}_{n,p}$, growing by one power of 4π for every additional pair of fields. The assignment Eq. (38.17) passes the self-consistency test by construction, but it is instructive to verify it on the marginal quartic of ϕ^4 theory. Setting $n = 4$, $p = 0$ gives $g_{4,0} = (4\pi)^2\hat{c} = 16\pi^2\hat{c}$, i.e. the maximal natural quartic coupling is $\lambda \sim 16\pi^2$. This is exactly the strong- coupling ceiling: a one-loop bubble built from two ϕ^4 vertices (Fig. 38.2) generates a correction to the same quartic of size, from Eq. (38.16),

$$\delta\lambda \;\sim\; \frac{\lambda^2}{16\pi^2}, \tag{38.19}$$

which is the structure of β_λ itself. Demanding that the loop correction not exceed the tree coupling, $\delta\lambda \lesssim \lambda$, gives $\lambda \lesssim 16\pi^2$ — precisely the value Eq. (38.18) delivers. The 4π counting is loop counting; NDA is the statement that the coefficients sit at the threshold where tree and loop are comparable, which is the largest they can naturally be.

NDA as written assumes the worst case, a maximally strongly coupled completion. If instead the heavy physics is weakly coupled, with a characteristic coupling $g_* < 4\pi$, the same reasoning with $4\pi \to g_*$ and overall factor Λ^4/g_*^2 gives $c_{n,p} \sim g_*^{n-2}\hat{c}_{n,p}$, interpolating down to the perturbative regime. The universal content is the upper bound: a Wilson coefficient generated by physics at scale Λ is at most $(4\pi)^{n-2}$ in the conventions of Eq. (38.17), and a coefficient found to be far below its NDA value is a clue that the responsible interaction is weak or that a symmetry suppresses it. NDA does not tell us the coefficient — only matching to a specific ultraviolet theory does that, which is the business of the next section — but it tells us the size to expect, and that is enough to estimate the reach of an experiment in Λ before any model is chosen.

Caution

The factor $(4\pi)^{n-2}$ counts fields, not the operator dimension. Two operators of the same dimension can have different natural sizes if they contain different numbers of fields: in Eq. (38.17), ϕ^6 ($n = 6$) and $\phi^2(\partial\phi)^2$ ($n = 4$) are both dimension six, but NDA assigns them $(4\pi)^4$ and $(4\pi)^2$ respectively. The dimension sets the power of E/Λ; the field count sets the power of 4π. Keep the two axes separate.

38.2.4 Operator redundancy: field redefinitions and the equations of motion

The basis $\{\mathcal{O}_i\}$ of Theorem 38.4 was assumed to be a genuine basis — no operator a linear combination of the others. But "linear combination" is subtler than it looks. Two manifestly different Lagrangians can produce *identical* S-matrix elements, in which case the operator distinguishing them is physically vacuous and must be struck from the basis or we will overcount the independent coefficients. The redundancy has a sharp origin: the S-matrix is invariant under local redefinitions of the fields, and an operator that vanishes by the lowest-order equations of motion is removable by exactly such a redefinition. We prove the invariance, then deduce the equation-of-motion reduction as its corollary, then carry out the reduction explicitly for the scalar tower.

Theorem 38.5 (Field-redefinition invariance of the S-matrix)**.** *Let ϕ be a field with the free equation of motion mass m, and let*

$$\phi(x) \longmapsto \phi'(x) = \phi(x) + F[\phi(x)] \tag{38.20}$$

be a local redefinition, with F a polynomial in ϕ and its derivatives carrying the same Lorentz and internal quantum numbers as ϕ and beginning at quadratic order, $F = O(\phi^2)$. Then the S-matrix computed from the Lagrangian $\mathcal{L}[\phi']$, re-expressed in terms of ϕ, equals the S-matrix computed from $\mathcal{L}[\phi]$. Equivalently, physical amplitudes are invariant under Eq. (38.20).

Proof. Two facts combine. The first is that Eq. (38.20) is a change of integration variable in the path integral, and so leaves the generating functional unchanged provided the Jacobian is trivial. The Jacobian is $\det(\delta\phi'(x)/\delta\phi(y)) = \det(\mathbf{1} + \delta F/\delta\phi)$, a local operator whose logarithm $\mathrm{Tr}\ln(\mathbf{1} + \delta F/\delta\phi)$ is proportional to $\delta^4(0)$ because F is local (the variation $\delta F(x)/\delta\phi(y)$ is supported at $x = y$). In dimensional regularization $\delta^4(0) = \int \mathrm{d}^4k/(2\pi)^4 = 0$ as a scaleless integral, so the Jacobian is unity and the redefinition is an honest relabeling of the functional integration variable. The correlation functions of ϕ' computed from $\mathcal{L}[\phi']$ are therefore identical, as functions, to the correlation functions of ϕ computed from $\mathcal{L}[\phi]$.

The second fact is that the S-matrix does not see the difference between ϕ and ϕ' as interpolating fields. By the LSZ reduction formula Theorem 14.31 in its residue form Eq. (14.156), an amplitude is the multiple residue of a connected correlator at the external on-shell poles, with one factor $\sqrt{Z}$ per leg divided out, where Z is the residue of that field's full two-point function at $p^2 = m^2$. We must show the multiple residue is the same whether the external legs are ϕ or ϕ'. Consider a single external leg and the Fourier transform of a correlator in that variable. The Källén–Lehmann representation Theorem 14.23 guarantees that the full two-point function of *any* local operator χ that overlaps the one-particle state has a single isolated pole at the physical mass,

$$\int \mathrm{d}^4x\, e^{ip\cdot x}\, \langle \Omega | \mathcal{T}\chi(x)\chi(0)|\Omega\rangle \xrightarrow{p^2\to m^2} \frac{i\,Z_\chi}{p^2 - m^2 + i\epsilon} + (\text{regular}), \qquad Z_\chi = \left|\langle \Omega|\chi(0)|\mathbf{p}\rangle\right|^2, \tag{38.21}$$

the pole location being a property of the spectrum and the residue being the squared overlap Eq. (14.131), independent of which interpolating χ is used. Now $\phi' = \phi + F[\phi]$ is such an operator: it is local, carries the particle's quantum numbers, and has a nonzero one-particle overlap $\langle \Omega|\phi'(0)|\mathbf{p}\rangle = \sqrt{Z} + \langle \Omega|F(0)|\mathbf{p}\rangle \equiv \sqrt{Z'}$ (a composite like ϕ^2 has a nonzero one-particle matrix element in the interacting theory, so F shifts the residue). For each external leg the LSZ operator $(\Box + m^2)$ acting on the Fourier variable annihilates the regular part of Eq. (38.21) on shell and extracts the pole; dividing by $\sqrt{Z'}$ for that leg cancels the leg's overlap. What survives after all N legs are amputated and put on shell is the connected amputated core evaluated between the *same* asymptotic in/out states $|\mathbf{p}_i;\mathrm{in}\rangle$, $\langle \mathbf{q}_j;\mathrm{out}|$ — states defined by the spectrum, not by the choice of interpolating field. By Eq. (14.155) this core *is* the amplitude $\mathcal{M}$, and it is identical for ϕ and ϕ'. The extra terms in $F[\phi]$ contribute only to the regular (non-pole) part in at least one external variable — they describe the operator creating multi-particle states rather than the single particle — and those pieces are killed by the on-shell amputation. Hence $\mathcal{M}$ is unchanged, which is the claim. □

The corollary that does the work is the removability of equation-of-motion operators. Let $\mathcal{L}_0$ be the leading (renormalizable) Lagrangian, with Euler–Lagrange operator

$$E[\phi] \;\equiv\; \frac{\delta S_0}{\delta \phi} \;=\; -(\Box + m^2)\phi - \frac{\lambda}{3!}\phi^3 \tag{38.22}$$

for the ϕ^4 theory of ϕ^4 theory (the classical equation of motion of Chapter 6 is $E[\phi] = 0$). Suppose the tower contains an operator of the special form $\mathcal{O}_{\mathrm{red}} = E[\phi]\, G[\phi]$ for some local G, multiplied by a small coefficient ε. Perform the field redefinition $\phi \to \phi + \varepsilon\, G[\phi]$. To first order in ε the leading action shifts by

$$\delta S_0 \;=\; \int \mathrm{d}^4x\, \frac{\delta S_0}{\delta \phi}\, \varepsilon G[\phi] \;=\; \varepsilon \int \mathrm{d}^4x\, E[\phi]\, G[\phi], \tag{38.23}$$

which is exactly $\varepsilon \int \mathcal{O}_{\text{red}}$ with the opposite sign needed to cancel it. Thus the redefinition removes $\mathcal{O}_{\text{red}}$ from the Lagrangian outright, at the cost of (i) generating terms of *higher* order in ε — one order further down the tower, consistently neglected at the working order — and (ii) acting on the already-present higher-dimension operators, again a higher-order effect. By Theorem 38.5 the redefinition does not touch the S-matrix. Therefore any operator proportional to the leading equation of motion is physically redundant and may be deleted from the basis. We record the principle:

Physical Insight

Reducing an operator "by the equations of motion" is not an on-shell approximation that discards information — it is a field redefinition in disguise, and field redefinitions leave every physical amplitude exactly invariant. One uses the *free* (lowest-order) equation of motion Eq. (38.22) because the operator's own contribution to the true equation of motion is higher order in the EFT expansion. The result is a smaller basis with identical physics, never a loss of accuracy.

Caution

Equation-of-motion reduction is legitimate for computing S-matrix elements, where Theorem 38.5 applies. It is *not* automatically legitimate for off-shell quantities or for Green's functions with operator insertions (e.g. when an operator is itself an external probe, as in deep-inelastic scattering), because there the redefinition changes the off-shell correlator even though it preserves the amplitude. When in doubt, the safe statement is the theorem: the S-matrix is invariant; off-shell objects need not be.

38.2.5 The minimal basis for the real scalar with $\mathbb{Z}_2$ symmetry

We now assemble the operator tower for ϕ^4 theory — a single real scalar with the $\mathbb{Z}_2$ symmetry $\phi \to -\phi$ of Theorem 7.10's symmetry catalogue (here a discrete symmetry, but constraining the basis just as a continuous one would) and Lorentz invariance — and reduce it to a minimal, non-redundant basis. This is the ϕ^4-thread layer "organize the irrelevant operators by NDA," continuing the Wilsonian generation of operators in Eq. (23.52).

Worked Example 38.6 (The scalar tower through dimension six)**.** The allowed operators are the Lorentz scalars built from ϕ and ∂_μ that are even under $\phi \to -\phi$. The two symmetries impose two parity-like constraints. The $\mathbb{Z}_2$ symmetry forces an *even* number of fields, n_ϕ even. Lorentz invariance forces all indices to be contracted, hence an *even* number of derivatives, n_∂ even. Since the dimension is $\Delta = n_\phi + n_\partial$ (Eq. (38.7)), the sum of two even integers, *every allowed operator*

has even dimension. The immediate consequence is structural:

$$\text{there is no dimension-five operator for a real scalar with } \mathbb{Z}_2. \tag{38.24}$$

The leading correction to the renormalizable Lagrangian is dimension six, suppressed by $(E/\Lambda)^2$ relative to the marginal interactions by Eq. (38.13) — the EFT expansion proceeds in even powers of E/Λ, as anticipated.

Dimension ≤ 4 (the renormalizable core). The relevant operator is ϕ^2 ($\Delta = 2$, the mass term), the marginal operators are $(\partial_\mu\phi)(\partial^\mu\phi)$ and ϕ^4 ($\Delta = 4$). These reproduce exactly the standard Lagrangian of ϕ^4 theory,

$$\mathcal{L}_0 = \tfrac{1}{2}(\partial_\mu\phi)(\partial^\mu\phi) - \tfrac{1}{2}m^2\phi^2 - \frac{\lambda}{4!}\phi^4. \tag{38.25}$$

Dimension six: enumeration. With n_ϕ, n_∂ even and $n_\phi + n_\partial = 6$, the candidate field/derivative contents are $(n_\phi, n_\partial) \in \{(6,0),(4,2),(2,4)\}$. We list the independent Lorentz scalars in each, reducing first by integration by parts (total derivatives integrate to zero in the action).

- $(6,0)$: the single operator ϕ^6.
- $(4,2)$: the candidates are $\phi^2(\partial_\mu\phi)(\partial^\mu\phi)$ and $\phi^3\Box\phi$. They are not independent: integrating by parts,

  $$\int \mathrm{d}^4x\ \phi^3\Box\phi = -\int \mathrm{d}^4x\ (\partial_\mu\phi^3)(\partial^\mu\phi) = -3\int \mathrm{d}^4x\ \phi^2(\partial_\mu\phi)(\partial^\mu\phi), \tag{38.26}$$

  so there is one independent structure, which we take to be $\mathcal{O}_{(4,2)} = \phi^2(\partial_\mu\phi)(\partial^\mu\phi)$.
- $(2,4)$: the candidates are $(\Box\phi)^2$, $(\partial_\mu\partial_\nu\phi)(\partial^\mu\partial^\nu\phi)$, and $\phi\,\Box^2\phi$. Integration by parts collapses them to one. Twice integrating by parts, $\int(\partial_\mu\partial_\nu\phi)(\partial^\mu\partial^\nu\phi) = \int(\Box\phi)^2$ (the two derivatives move across in pairs, the cross terms being total derivatives), and $\int\phi\,\Box^2\phi = \int(\Box\phi)^2$ likewise. So there is one independent structure, $\mathcal{O}_{(2,4)} = (\Box\phi)^2$.

After integration by parts, then, the dimension-six space is three-dimensional, spanned by $\{\phi^6,\ \phi^2(\partial\phi)^2,\ (\Box\phi)^2\}$.

Dimension six: reduction by the equations of motion. We now use Theorem 38.5. The leading equation of motion Eq. (38.22) reads, in the on-shell/field-redefinition sense (written $\doteq$),

$$\Box\phi \ \doteq\ -m^2\phi - \frac{\lambda}{3!}\phi^3. \tag{38.27}$$

Apply it to the two derivative operators. First the four-derivative structure: substituting Eq. (38.27) into both factors,

$$(\Box\phi)^2 \ \doteq\ \left(m^2\phi + \frac{\lambda}{6}\phi^3\right)^2 = m^4\phi^2 + \frac{\lambda m^2}{3}\phi^4 + \frac{\lambda^2}{36}\phi^6. \tag{38.28}$$

Every term on the right is a *lower*-derivative operator already in the basis: a shift of the mass term, a shift of the quartic, and a contribution to ϕ^6. Thus $(\Box\phi)^2$ carries no independent physics and is removed. Second, the two-derivative four-field structure: combine the integration-by-parts identity Eq. (38.26) with Eq. (38.27),

$$\int \phi^2(\partial_\mu\phi)(\partial^\mu\phi) = -\frac{1}{3}\int \phi^3\Box\phi \;\doteq\; -\frac{1}{3}\int \phi^3\Big(-m^2\phi - \frac{\lambda}{6}\phi^3\Big) = \int\Big(\frac{m^2}{3}\phi^4 + \frac{\lambda}{18}\phi^6\Big). \tag{38.29}$$

So $\phi^2(\partial\phi)^2$ also reduces to a shift of the quartic plus a contribution to ϕ^6. Both derivative operators collapse onto $\{\phi^4, \phi^6\}$ (plus, for $(\Box\phi)^2$, the mass term). The shifts of λ and m^2 are suppressed by the Wilson coefficient's $1/\Lambda^2$ and by the extra factor m^2, exactly the "doubly small" behaviour already noted in the explicit Wilsonian computation of Eq. (23.52): the derivative operator generated there with coefficient $z_4 \sim \lambda^2 m^2/\Lambda^4$ is precisely a redundant operator, removable here in favour of a tiny renormalization of λ.

The minimal basis. The only dimension-six operator with independent S-matrix content is therefore

$$\boxed{\mathcal{O}_6 = \phi^6} \qquad \Longrightarrow \qquad \mathcal{L}_{\text{eff}} = \mathcal{L}_0 + \frac{c_6}{\Lambda^2}\,\phi^6 + O(\Lambda^{-4}), \tag{38.30}$$

with, by the NDA estimate Eq. (38.18) for $n = 6,\ p = 0$, a natural coefficient $c_6 \sim (4\pi)^4$ at strong coupling (or $c_6 \sim g_*^4$ for a weakly coupled completion). This is the leading irrelevant operator of ϕ^4 theory. Its contribution to, say, $3 \to 3$ scalar scattering scales as $(E/\Lambda)^2$ relative to the renormalizable ϕ^4 amplitude, by Eq. (38.13) with $\Delta = 6$.

The reduction in Theorem 38.6 deserves a closing remark on conventions, because it is a place where careful and loose treatments superficially disagree. We used both field redefinitions exhausted by the dimension-three, $\mathbb{Z}_2$-odd functions $G \in \{\phi^3, \Box\phi\}$ to eliminate *both* derivative operators, arriving at the strictly minimal one-operator basis $\{\phi^6\}$. Some references instead retain $\phi^2(\partial\phi)^2$ as a convenient redundant representative — legitimate, since it is physically equivalent to a combination of ϕ^4 and ϕ^6 by Eq. (38.29), and sometimes more transparent when matching to a specific ultraviolet theory that generates it directly. The two choices give the same amplitudes; what one must never do is count both $\phi^2(\partial\phi)^2$ and ϕ^6 *and* a shifted ϕ^4 as independent, which would overcount the coefficients. The lesson generalizes: the number of independent Wilson coefficients at each dimension is basis-independent and physical, but *which* operators carry them is a choice, fixed by how aggressively one applies the equations of motion.

With the basis now finite, non-redundant, and calibrated in size by NDA, exactly one thing remains undetermined: the actual numerical values of the Wilson coefficients c_i. Power counting fixed their scaling, NDA fixed their natural

magnitude, but neither fixes the $O(1)$ number, which encodes the specific short-distance dynamics that has been integrated out. To pin those numbers down we must confront the effective theory with a definite ultraviolet completion and demand that the two agree at low energy — the procedure of matching, to which we turn next, beginning with the cleanest case of a heavy field removed at tree level.

38.3 Integrating Out a Heavy Field: Tree-Level Matching

The previous section handed us a machine with empty dials. Power counting and the removal of redundancy (Sections 38.2 and 38.2.4) produced a non-redundant basis of local operators $\{\mathcal{O}_i\}$ built from the light fields and the symmetries, organized by canonical dimension, each multiplied by a Wilson coefficient c_i whose natural size we estimated by dimensional analysis. What that analysis could not give us is the *values* of the c_i. Naive dimensional analysis fixes their order of magnitude; it does not fix their numbers, their signs, or which of them happen to vanish. Those data encode the short-distance dynamics that the effective theory has agreed to forget, and they can only be supplied by an outside input.

There are two ways to supply it. Bottom-up, one measures enough low-energy observables to read the c_i off, treating them as free parameters of a predictive theory — this is how chiral perturbation theory and the Standard Model effective field theory are used when the ultraviolet completion is unknown. Top-down, one *knows* the short-distance theory: there is a heavy field of mass M whose dynamics, written out in full, reduces at low energy to the effective Lagrangian, and the c_i are then *computable* as functions of the heavy parameters. This section develops the top-down construction. Its central operation is the one introduced abstractly in Eq. (38.1): remove the heavy field from the theory, leaving behind a tower of local operators in the light fields whose coefficients are the Wilson coefficients. We make that operation literal and carry it out completely at tree level, by two routes that must agree — substitution of the heavy field's classical equation of motion, and Gaussian integration over the heavy field in the path integral — and we check the result against the physical scattering amplitude. The criterion that ties all of this together, and that gives "integrating out" its operational meaning, is *matching*.

38.3.1 The matching condition

An effective field theory is the triple of fields, symmetries, and a power-counting expansion of Theorem 38.1, with the most general local Lagrangian that Weinberg's folk theorem (Theorem 38.3) guarantees is enough. To pin its coefficients

to a specific ultraviolet theory we demand that the two theories be *physically indistinguishable at low energy*. Physics is the S-matrix, and the S-matrix is built from Green's functions, so the precise demand is that the Green's functions of the light fields computed in the full theory and in the effective theory coincide in the kinematic regime where both descriptions are valid — external momenta small compared with M — order by order in the expansion in p/M and in the loop expansion.

Definition 38.7 (Matching)**.** Let the full theory have action $S_{\text{full}}[\phi, \Phi]$ for light fields ϕ (masses $\ll M$) and heavy fields Φ (masses $\sim M$), and let the effective theory be

$$S_{\text{eff}}[\phi] = \int \mathrm{d}^4x \, \sum_i c_i \, \mathcal{O}_i(\phi), \tag{38.31}$$

with $\{\mathcal{O}_i\}$ the non-redundant operator basis of Section 38.2 and c_i the Wilson coefficients (Theorem 38.4). The coefficients are *matched* to the full theory by requiring that, for every set of light external legs and at each order in the joint expansion in p/M and in $\hbar$ (loops),

$$G_n^{\text{full}}(p_1, \ldots, p_n)\Big|_{\text{expanded in } p/M} \;=\; G_n^{\text{eff}}(p_1, \ldots, p_n), \tag{38.32}$$

where G_n denotes the connected (equivalently, amputated one-particle-irreducible) n-point function of the light fields evaluated with the same renormalization scheme on both sides. Equivalently, the two theories possess the same light-particle S-matrix up to corrections suppressed by additional powers of E/M.

Three features of Eq. (38.32) deserve emphasis before we compute, because they recur unchanged in every matching calculation in Chapters 39 and 40. First, matching is a statement about a region of overlap. The full theory is valid at all energies; the effective theory is valid only for $E \ll M$. They are required to agree only where the effective theory has any right to speak, and the expansion "$|_{\text{expanded in } p/M}$" on the left is exactly the operation that throws away the information — the heavy poles, the on-shell production of Φ — that the effective theory was never meant to reproduce. Second, the heavy mass M never appears as an explicit scale on the effective-theory side of Eq. (38.32): it has been swallowed into the numerical values of the c_i. This is the defining trade of the EFT — a field for a tower of constants — and it is why the effective theory "does not know" about Φ except through those constants. Third, the equality is required *order by order*. At a fixed order in p/M only finitely many operators contribute (this was the content of the power-counting theorem, Eq. (38.6)), so matching at that order is a finite system of equations for finitely many coefficients, and one ascends the tower one rung at a time.

The phrase "connected (equivalently, amputated 1PI)" in Theorem 38.7 hides a choice that the next definition's worked examples will exploit. One may match

the full *off-shell* effective action — the generating functional of 1PI light-field Green's functions, which is a local functional of ϕ and its derivatives, i.e. a Lagrangian — or one may match only the *on-shell* S-matrix elements. The two are not identical: they differ by operators that vanish when the light field obeys its own equation of motion, which (by the field-redefinition theorem of Section 38.2.4) are precisely the redundant operators that drop out of the S-matrix. The following proposition records that this difference is invisible to physics, so that the cleaner off-shell route and the more physical on-shell route give the same predictions; the scalar computation below verifies it explicitly.

Proposition 38.8 (Matching is well-posed up to redundancy)**.** *The matching condition Eq. (38.32) determines the Wilson coefficients of a non-redundant basis uniquely. Operators that vanish by the light-field equations of motion — equivalently, that can be removed by a local field redefinition (Section 38.2.4) — do not enter the on-shell matching: matching the off-shell 1PI effective action and matching the on-shell S-matrix yield identical physical predictions, the two answers differing only by the coefficients of such redundant operators.*

Proof (deferred to the worked computation). The general statement is the field-redefinition theorem of Section 38.2.4: a redefinition $\phi \to \phi + \delta\phi$ with $\delta\phi$ local shifts the action by $\int (\delta S/\delta\phi)\,\delta\phi$, which is proportional to the classical equation of motion and therefore changes no S-matrix element (it amounts to a change of interpolating field, to which the LSZ formula is insensitive). Choosing $\delta\phi$ to cancel a given EOM-proportional operator removes it from the Lagrangian without touching any observable. We make this concrete in Theorem 38.9, where the off-shell effective action for a heavy scalar contains a derivative operator $\phi^2(\partial\phi)^2$ whose entire on-shell effect is a mass-suppressed constant absorbable into the quartic and mass couplings, exactly as the proposition requires. □

With the criterion fixed, the work is to compute the left-hand side of Eq. (38.32) in a definite full theory, expand, and read off the c_i. We take the simplest nontrivial case and carry it to the end.

38.3.2 Integrating out a heavy scalar: the classical route

We continue ϕ^4 theory. The light field is the real scalar ϕ of the thread, with the carried Lagrangian $\frac{1}{2}(\partial\phi)^2 - \frac{1}{2}m^2\phi^2 - \frac{\lambda_0}{4!}\phi^4$ and the $\mathbb{Z}_2$ symmetry $\phi \to -\phi$. We now give it a heavy partner: a second real scalar Φ of mass $M \gg m$, even under the $\mathbb{Z}_2$, coupled to the light field through the most general renormalizable interaction the symmetry allows. The full Lagrangian is

$$\mathcal{L}_{\text{full}} = \tfrac{1}{2}(\partial_\mu\phi)(\partial^\mu\phi) - \tfrac{1}{2}m^2\phi^2 - \frac{\lambda_0}{4!}\phi^4 + \tfrac{1}{2}(\partial_\mu\Phi)(\partial^\mu\Phi) - \tfrac{1}{2}M^2\Phi^2 - \frac{\kappa}{2}\,\Phi\,\phi^2 - \frac{g_3}{3!}\,\Phi^3, \tag{38.33}$$

where the trilinear portal coupling κ has mass dimension $+1$ and the heavy self-coupling g_3 also has dimension $+1$. (A term $\Phi^2\phi^2$ and a tadpole Φ are also $\mathbb{Z}_2$-allowed; we omit the former to keep the heavy quadratic form field-independent — so the path-integral route below is exactly Gaussian — and the latter is removed by a constant shift of Φ. We restore g_3 only when we need the six-point operator; for the quartic and the leading derivative operator it plays no role, so we set $g_3 = 0$ until Section 38.3.4.) The heavy field carries no ϕ-charge and no light index; it is the cleanest possible "thing to integrate out."

To integrate out Φ at tree level means, concretely, to solve its classical equation of motion treating ϕ as an external background, and to substitute the solution back into the action. The Euler–Lagrange equation for Φ obtained from Eq. (38.33) (with $g_3 = 0$ for now) is

$$\frac{\partial \mathcal{L}_{\text{full}}}{\partial \Phi} - \partial_\mu \frac{\partial \mathcal{L}_{\text{full}}}{\partial(\partial_\mu \Phi)} = -M^2\Phi - \frac{\kappa}{2}\phi^2 - \Box\Phi = 0 \quad \Longrightarrow \quad (\Box + M^2)\,\Phi = -\frac{\kappa}{2}\,\phi^2, \tag{38.34}$$

with $\Box = \partial_\mu \partial^\mu$. This is a linear, inhomogeneous equation: the heavy field is sourced by the light bilinear ϕ^2. Its solution is obtained by inverting the operator $(\Box + M^2)$,

$$\Phi_{\text{cl}}[\phi] = -\frac{\kappa}{2}\,(\Box + M^2)^{-1}\phi^2. \tag{38.35}$$

The inverse $(\Box + M^2)^{-1}$ is precisely the heavy field's two-point function — the free propagator of Eq. (10.30), here in the role of the Green's function that turns the source ϕ^2 into the induced field. Because we seek a *local* effective Lagrangian, and because the heavy mass dominates all light momenta, we do not keep this operator intact; we expand it in inverse powers of M^2. In momentum space $\Box \to -p^2$, so $(\Box + M^2)^{-1} \to (M^2 - p^2)^{-1} = M^{-2}(1 - p^2/M^2)^{-1}$, the geometric series that is the whole technical engine of tree-level matching:

$$(\Box + M^2)^{-1} = \frac{1}{M^2}\,\frac{1}{1 + \Box/M^2} = \frac{1}{M^2}\left(1 - \frac{\Box}{M^2} + \frac{\Box^2}{M^4} - \cdots\right). \tag{38.36}$$

Each extra power of $\Box$ is an extra two derivatives acting on the light fields and an extra $1/M^2$; in the language of Section 38.2 each term is one rung higher in the operator tower. The expansion converges as a derivative (momentum) expansion exactly when $p^2 \ll M^2$, the regime of validity of the effective theory — the analytic statement of "low energy."

Now substitute Eq. (38.35) into the action. Because Φ enters Eq. (38.33) (with $g_3 = 0$) at most quadratically, the Φ-dependent part of the action, after integrating the kinetic term by parts, is the quadratic-plus-linear form

$$S_\Phi[\Phi, \phi] = \int \mathrm{d}^4x \left[-\tfrac{1}{2}\,\Phi(\Box + M^2)\Phi - \tfrac{\kappa}{2}\,\phi^2\,\Phi\right] \;\equiv\; \int \mathrm{d}^4x \left[\tfrac{1}{2}\Phi\,\mathcal{K}\,\Phi + J\,\Phi\right], \tag{38.37}$$

with kinetic operator $\mathcal{K} = -(\Box + M^2)$ and source $J = -\frac{\kappa}{2}\phi^2$. Evaluating a quadratic-plus-linear functional at its stationary point $\Phi_{\text{cl}} = -\mathcal{K}^{-1}J$ leaves

exactly half the source term, $S_\Phi[\Phi_{\rm cl}] = \frac{1}{2}\int J\,\Phi_{\rm cl} = -\frac{1}{2}\int J\,\mathcal{K}^{-1}J$; this is the same algebra of completing the square that produced the free generating functional in Theorem 10.13. Spelling it out with $\mathcal{K}^{-1} = -(\Box + M^2)^{-1}$ and $J = -\frac{\kappa}{2}\phi^2$,

$$S_\Phi[\Phi_{\rm cl}] = -\tfrac{1}{2}\int \mathrm{d}^4x\,\Big(-\tfrac{\kappa}{2}\phi^2\Big)\big[-(\Box+M^2)^{-1}\big]\Big(-\tfrac{\kappa}{2}\phi^2\Big) = \frac{\kappa^2}{8}\int \mathrm{d}^4x\;\phi^2\,(\Box+M^2)^{-1}\phi^2. \tag{38.38}$$

The heavy field is gone; in its place is a non-local functional of the light field, which the expansion Eq. (38.36) renders local order by order. The effective Lagrangian (added to the light Lagrangian already present in Eq. (38.33)) is therefore

$$\mathcal{L}^{(\Phi)}_{\rm eff} = \frac{\kappa^2}{8M^2}\,\phi^4 - \frac{\kappa^2}{8M^4}\,\phi^2\Box\phi^2 + \frac{\kappa^2}{8M^6}\,\phi^2\Box^2\phi^2 - \cdots . \tag{38.39}$$

This is the central result of the scalar matching. Read it one term at a time.

The marginal operator: a Wilson coefficient for $\lambda\phi^4$. The leading term shifts the quartic coupling. Combining $\frac{\kappa^2}{8M^2}\phi^4$ from Eq. (38.39) with the tree-level $-\frac{\lambda_0}{4!}\phi^4$ already in Eq. (38.33), and writing the sum in the thread's normalization $-\frac{\lambda_{\rm eff}}{4!}\phi^4$, gives

$$-\frac{\lambda_{\rm eff}}{4!}\,\phi^4 = \Big(-\frac{\lambda_0}{4!} + \frac{\kappa^2}{8M^2}\Big)\phi^4 \quad\Longrightarrow\quad \boxed{\lambda_{\rm eff} = \lambda_0 - \frac{3\kappa^2}{M^2}}. \tag{38.40}$$

The factor 3 is $4!/8$. This is the promised reinterpretation: the quartic coupling of ϕ^4 theory — a marginal coupling we have carried as a free parameter since Chapter 6 — is, in the presence of a heavy partner, a *Wilson coefficient*, computable from the underlying parameters λ_0, κ, M. The shift is negative: a single heavy scalar exchanged between two ϕ^2 currents produces an attractive contact interaction, which lowers $\lambda_{\rm eff}$ below its short-distance value λ_0. The point survives even if the light field had no quartic to begin with: setting $\lambda_0 = 0$, the low-energy theory still has $\lambda_{\rm eff} = -3\kappa^2/M^2$, so the $\lambda\phi^4$ interaction the thread has used throughout can be *entirely* a long-distance shadow of heavy dynamics. Renormalizability of the light sector is not a fundamental input; it is what survives at the bottom of the tower.

The first irrelevant operator: a dimension-six Wilson coefficient. The second term in Eq. (38.39) is a genuine member of the irrelevant tower. It is the dimension-six derivative operator. Integrating by parts twice, $\int \phi^2\Box\phi^2 = -\int \partial_\mu(\phi^2)\partial^\mu(\phi^2) = -4\int \phi^2(\partial_\mu\phi)(\partial^\mu\phi)$, so

$$-\frac{\kappa^2}{8M^4}\,\phi^2\Box\phi^2 = +\frac{\kappa^2}{2M^4}\,\phi^2(\partial_\mu\phi)(\partial^\mu\phi) \;\equiv\; \frac{z_4}{2}\,\phi^2(\partial_\mu\phi)(\partial^\mu\phi), \qquad \boxed{z_4 = \frac{\kappa^2}{M^4}}. \tag{38.41}$$

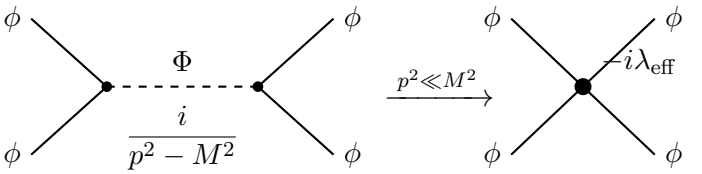

Figure 38.3: Tree-level integrating-out of a heavy scalar. At light external momenta the heavy propagator (dashed line) is local on the scale $1/M$ and the exchange diagram collapses to a contact vertex. The leading contact coupling is the Wilson coefficient $\lambda_{\text{eff}} = \lambda_0 - 3\kappa^2/M^2$ of Eq. (38.40); the subleading terms of the Taylor expansion of the propagator are the dimension-six (and higher) operators of Eq. (38.39).

This is exactly the operator $\frac{z_4}{2}\phi^2(\partial\phi)^2$ whose *loop*-generated coefficient appeared in the Wilsonian flow of Eq. (23.52); here it is generated at *tree level* by integrating out a heavy field, and its coefficient $z_4 = \kappa^2/M^4$ is precisely of the size naive dimensional analysis predicted for a dimension-six coefficient built from a dimensionless ratio κ^2/M^2 divided by M^2 (Eq. (38.6)). The higher terms in Eq. (38.39), beginning with $\phi^2\Box^2\phi^2/M^6$, are dimension-eight operators, contributing at relative order $(p/M)^4$ and below the accuracy at which we work.

Why "integrating out" is a derivative expansion

The single algebraic move that produced the entire tower is the geometric series Eq. (38.36). A heavy propagator $1/(p^2 - M^2)$, evaluated at light external momenta $p^2 \ll M^2$, is not a pole but a smooth function of p^2; Taylor expanding it about $p^2 = 0$ converts a non-local exchange into a sum of local vertices, each with two more derivatives and one more power of $1/M^2$ than the last. Pictorially, the heavy internal line shrinks to a point (Fig. 38.3): what was a propagator becomes a contact interaction, and the corrections to the contact approximation are the higher terms of the expansion. "The heavy particle cannot be produced, only exchanged virtually, and its virtual exchange is local on scales $\gg 1/M$" is the physics; the Taylor expansion of $1/(p^2 - M^2)$ is the mathematics.

38.3.3 The same answer from the path integral

The classical route just taken is a saddle-point evaluation in disguise, and it is worth verifying that the honest object — the functional integral over the heavy field — gives the identical effective action, because that verification both confirms the method and shows exactly where, at one loop, the two will start to disagree. The Wilsonian definition of integrating out (Theorem 23.8) instructs

us to perform the path integral over the heavy field at fixed light background, producing the effective action

$$e^{\,iS_{\rm eff}[\phi]} = \int \mathcal{D}\Phi\ \exp\Big\{ i\, S_{\rm full}[\phi,\Phi]\Big\} = e^{\,iS_{\rm light}[\phi]} \int \mathcal{D}\Phi\ \exp\Big\{ i \int \mathrm{d}^4x\, \big[\tfrac{1}{2}\Phi\mathcal{K}\Phi + J\Phi\big]\Big\}, \tag{38.42}$$

with $\mathcal{K}$ and J as in Eq. (38.37). With $g_3 = 0$ the exponent is exactly quadratic in Φ with a ϕ-*independent* kinetic operator $\mathcal{K} = -(\Box + M^2)$, so the integral is the Gaussian functional integral with a linear source evaluated in Eq. (10.70). That computation gives

$$\int \mathcal{D}\Phi\ \exp\Big\{ i \int \big[\tfrac{1}{2}\Phi\mathcal{K}\Phi + J\Phi\big]\Big\} = \big[\det(-i\mathcal{K}/2\pi)\big]^{-1/2}\ \exp\Big\{ -\tfrac{i}{2}\int J\,\mathcal{K}^{-1}J\Big\}. \tag{38.43}$$

The exponent is identical to the classical on-shell action Eq. (38.38): $-\frac{1}{2}\int J\mathcal{K}^{-1}J = S_\Phi[\Phi_{\rm cl}]$. This is the precise sense in which the two routes agree.

Why the equation of motion is exact at tree level

The agreement is not a coincidence of this example; it is structural. Whenever the heavy field enters the action at most quadratically — as it must when its only coupling to light fields is linear in Φ — the Gaussian integral is exact, and an exact Gaussian integral equals its saddle: the value of the exponent at the stationary point $\Phi_{\rm cl}$ where $\delta S/\delta\Phi = 0$, which is the classical equation of motion Eq. (38.34). The prefactor $\det(-i\mathcal{K}/2\pi)^{-1/2}$ in Eq. (38.43) is the one-loop fluctuation determinant of the heavy field, and here it is ϕ-*independent*, because $\mathcal{K} = -(\Box + M^2)$ contains no light field. A ϕ-independent factor is a contribution to the vacuum energy alone; it multiplies every light-field amplitude by the same constant and drops out of all connected correlators. Hence at this order "solve the EOM and substitute" and "do the path integral" produce literally the same effective Lagrangian. The agreement is exact precisely because there are no heavy loops to speak of: the only heavy graphs that survive are the tree graphs built from $\Phi_{\rm cl}$.

The bridge to the next section is already visible in this box. The moment we restore a coupling that makes Φ appear more than quadratically — the cubic $g_3\Phi^3$ of Section 38.3.4, or a $\Phi^2\phi^2$ portal — the operator $\mathcal{K}$ acquires ϕ-dependence, the fluctuation determinant becomes a nontrivial functional of the light field, and the path integral exceeds the classical substitution by genuine heavy loops. Those loops are the subject of Section 38.4; for now we note only that at *tree* level the saddle is the whole story, and we extend the classical computation to reach the six-point operator.

Integrating out works for any heavy field

Nothing in the argument was special to a scalar. If the heavy field is a vector, the Gaussian integral is over Φ_μ with the kinetic operator of a massive spin-one field, and the saddle is the solution of its (Proca) equation of motion — the case we treat in Section 38.3.6 to obtain the Fermi interaction. If the heavy field is a fermion, the functional integral is the Berezin Gaussian of Theorem 12.26, whose saddle is the solution of the Dirac equation in the light background and whose fluctuation factor is a *determinant* (in the numerator) rather than its inverse square root; this is how the heavy lower components of a Dirac field are eliminated to build HQET in Chapter 40. The recipe — solve the heavy EOM, substitute, expand the heavy propagator in $1/M$ — is universal.

38.3.4 Generating ϕ^6: the nonlinear equation of motion

The Gaussian model produced the quartic and the dimension-six derivative operator but no six-point operator ϕ^6, for the simple reason that an action quadratic in Φ yields an on-shell action bilinear in the source $J \propto \phi^2$, hence quartic in ϕ. To switch on ϕ^6 at tree level we need the heavy field to appear cubically, which is exactly what the self-coupling $g_3\Phi^3$ in Eq. (38.33) provides. The equation of motion is now nonlinear,

$$(\Box + M^2)\,\Phi = -\frac{\kappa}{2}\,\phi^2 - \frac{g_3}{2}\,\Phi^2, \tag{38.44}$$

and we solve it iteratively in inverse powers of M, treating the right-hand side as a perturbation. Writing $\Phi_{\rm cl} = \Phi^{(1)} + \Phi^{(2)} + \cdots$ where $\Phi^{(k)}$ contains $2k$ powers of ϕ, the leading term reproduces Eq. (38.35), which at zeroth order in the derivative expansion is

$$\Phi^{(1)} = -\frac{\kappa}{2}(\Box + M^2)^{-1}\phi^2 \;\simeq\; -\frac{\kappa}{2M^2}\,\phi^2, \tag{38.45}$$

and the next iteration feeds $\Phi^{(1)}$ into the nonlinear source,

$$\Phi^{(2)} = -\frac{g_3}{2}(\Box + M^2)^{-1}\big(\Phi^{(1)}\big)^2 \;\simeq\; -\frac{g_3}{2M^2}\Big(\frac{\kappa}{2M^2}\phi^2\Big)^2 = -\frac{g_3\kappa^2}{8M^6}\,\phi^4. \tag{38.46}$$

To extract the six-point operator it is cleanest to use, rather than the brute substitution, the on-shell value of the action expressed through the equation of motion. With the kinetic term integrated by parts the heavy action reads $S_\Phi = \int[-\tfrac12\Phi(\Box + M^2)\Phi - \tfrac{\kappa}{2}\phi^2\Phi - \tfrac{g_3}{6}\Phi^3]$, and using Eq. (38.44) to replace $(\Box + M^2)\Phi_{\rm cl} = -\tfrac{\kappa}{2}\phi^2 - \tfrac{g_3}{2}\Phi_{\rm cl}^2$ in the first term,

$$S_\Phi[\Phi_{\rm cl}] = \int \mathrm{d}^4x\,\Big[-\tfrac12\Phi_{\rm cl}\big(-\tfrac{\kappa}{2}\phi^2 - \tfrac{g_3}{2}\Phi_{\rm cl}^2\big) - \tfrac{\kappa}{2}\phi^2\Phi_{\rm cl} - \tfrac{g_3}{6}\Phi_{\rm cl}^3\Big]$$

$$= \int \mathrm{d}^4x \, \Big[-\tfrac{\kappa}{4}\phi^2\Phi_{\rm cl} + \tfrac{g_3}{12}\Phi_{\rm cl}^3 \Big]. \tag{38.47}$$

The quartic piece comes from $-\frac{\kappa}{4}\phi^2\Phi^{(1)} = \frac{\kappa^2}{8M^2}\phi^4$, reproducing Eq. (38.40) as it must. The six-point piece collects two contributions, from $-\frac{\kappa}{4}\phi^2\Phi^{(2)}$ and from $\frac{g_3}{12}(\Phi^{(1)})^3$:

$$\mathcal{L}_{\rm eff} \supset -\frac{\kappa}{4}\phi^2\Big(-\frac{g_3\kappa^2}{8M^6}\phi^4\Big) + \frac{g_3}{12}\Big(-\frac{\kappa}{2M^2}\phi^2\Big)^3 = \Big(\frac{g_3\kappa^3}{32M^6} - \frac{g_3\kappa^3}{96M^6}\Big)\phi^6 = \frac{g_3\kappa^3}{48M^6}\,\phi^6. \tag{38.48}$$

Matching to the thread normalization $\frac{c_6}{6!}\phi^6$ of Eq. (23.52) fixes the dimension-six six-point Wilson coefficient,

$$\frac{c_6}{6!} = \frac{g_3\kappa^3}{48M^6} \quad\Longrightarrow\quad \boxed{c_6 = \frac{6!}{48}\,\frac{g_3\kappa^3}{M^6} = \frac{15\,g_3\kappa^3}{M^6}}. \tag{38.49}$$

The combinatorial factor $15 = 6!/48$ is the same number that decorated the loop-generated $c_6 = 15\lambda^3 I_3$ of Eq. (23.52): it counts the ways to distribute six external legs over the cubic vertex topology, and it is independent of whether the ϕ^6 operator is born from a heavy loop (bottom-up, as in Chapter 23) or from heavy tree exchange (top-down, here). With $I_3 \sim 1/M^2$ in Eq. (23.52) and the explicit $\kappa^3 g_3/M^6$ here, both deliver a dimension-six coefficient of size (dimensionless couplings)$/M^2$, as power counting demanded. ϕ^4 theory has thus closed a loop of its own: the irrelevant operators ϕ^6 and $\phi^2(\partial\phi)^2$ that the Wilsonian flow *discovered* being generated as one integrates out high-momentum shells are the same operators that top-down matching now produces, with computed coefficients, on integrating out a heavy particle.

Tree-level integrating-out is the sum of connected tree graphs

Equation Eq. (38.47) is the position-space form of a Feynman statement: the tree-level effective action is the generating functional of connected tree diagrams with the heavy field on internal lines only and the light field on external legs. The quartic operator is the single-Φ-exchange graph of Fig. 38.3; the six-point operator is the graph in which three $\kappa\,\Phi\phi^2$ vertices each emit a ϕ^2 pair and meet at one $g_3\Phi^3$ vertex through three heavy propagators, each shrunk to $1/M^2$. Solving the classical equation of motion iteratively, as in Eqs. (38.45) and (38.46), is nothing but resumming these tree topologies, vertex by vertex; the iteration order in $1/M$ is the number of heavy propagators. This is why "classical" and "tree-level" are synonyms here: the classical field is the sum over tree graphs, and quantum (loop) corrections are precisely the fluctuation determinant that the saddle point omits.

38.3.5 Matching the physical amplitude

We have matched the off-shell effective *action*. Theorem 38.8 promised that matching the on-shell *amplitude* gives the same Wilson coefficients up to redundant operators. The cleanest test is the carried process of ϕ^4 theory: elastic $\phi\phi \to \phi\phi$ scattering, whose $O(\lambda)$ amplitude was the thread's first dynamical number ($\mathcal{M} = -\lambda$) in Chapter 14. We compute it in the full theory, expand, and confront the effective theory.

Worked Example 38.9 (On-shell matching of $\phi\phi \to \phi\phi$)**.** Work to dimension six and set $g_3 = 0$, since the cubic does not contribute to the four-point amplitude at tree level. The full-theory tree amplitude for $\phi(p_1)\phi(p_2) \to \phi(p_3)\phi(p_4)$ receives the contact ϕ^4 vertex and heavy-scalar exchange in the three channels. The $\Phi\phi\phi$ vertex from $-\frac{\kappa}{2}\Phi\phi^2$ is $-i\kappa$ (the $\frac{1}{2}$ cancels against the two ways of attaching the identical ϕ legs), and the heavy propagator is $i/(q^2 - M^2)$. With the Mandelstam invariants $s = (p_1+p_2)^2$, $t = (p_1-p_3)^2$, $u = (p_1-p_4)^2$, the amplitude defined by Eq. (16.2) is

$$\mathcal{M}_{\text{full}} = -\lambda_0 - \kappa^2\Big[\frac{1}{s-M^2} + \frac{1}{t-M^2} + \frac{1}{u-M^2}\Big], \tag{38.50}$$

where each exchange contributes $(-i\kappa)\,[i/(q^2-M^2)]\,(-i\kappa) = -i\kappa^2/(q^2-M^2)$ to $i\mathcal{M}$. Now expand each heavy propagator by Eq. (38.36), $1/(x-M^2) = -M^{-2}(1 + x/M^2 + x^2/M^4 + \cdots)$:

$$\frac{1}{s-M^2} + \frac{1}{t-M^2} + \frac{1}{u-M^2} = -\frac{3}{M^2} - \frac{s+t+u}{M^4} - \frac{s^2+t^2+u^2}{M^6} - \cdots . \tag{38.51}$$

For four external particles of mass m, momentum conservation fixes $s+t+u = 4m^2$. Substituting Eq. (38.51) into Eq. (38.50),

$$\mathcal{M}_{\text{full}} = -\Big(\lambda_0 - \frac{3\kappa^2}{M^2}\Big) + \frac{\kappa^2(s+t+u)}{M^4} + O\Big(\frac{p^4}{M^6}\Big) = -\lambda_{\text{eff}} + \frac{4\kappa^2 m^2}{M^4} + O\Big(\frac{p^4}{M^6}\Big). \tag{38.52}$$

The momentum-independent piece is exactly $-\lambda_{\text{eff}}$ with $\lambda_{\text{eff}} = \lambda_0 - 3\kappa^2/M^2$ of Eq. (38.40): the on-shell four-point amplitude reproduces the marginal Wilson coefficient read off the action.

Now the effective-theory side. The contact $-\frac{\lambda_{\text{eff}}}{4!}\phi^4$ gives $-\lambda_{\text{eff}}$. The dimension-six derivative operator $\frac{z_4}{2}\phi^2(\partial\phi)^2$ of Eq. (38.41) contributes a momentum-dependent four-point vertex. Summing over the 4! ways of assigning the external legs to the operator's two undifferentiated and two (Lorentz-contracted) differentiated fields, with each derivative bringing down a momentum $\partial_\mu\phi \to -ip_\mu$, the vertex is

$$i\mathcal{M}_{\text{eff}}^{(z_4)} = i\,\frac{z_4}{2}\cdot 4\sum_{k<l}(-iq_k)\cdot(-iq_l) = -2i\,z_4\sum_{k<l} q_k\cdot q_l, \tag{38.53}$$

with all momenta taken incoming ($q_{1,2} = p_{1,2}$, $q_{3,4} = -p_{3,4}$). Momentum conservation $\sum_k q_k = 0$ gives $0 = (\sum_k q_k)^2 = \sum_k q_k^2 + 2\sum_{k<l} q_k \cdot q_l$, and with each $q_k^2 = m^2$ on shell, $\sum_{k<l} q_k \cdot q_l = -2m^2$. Hence

$$\mathcal{M}_{\text{eff}}^{(z_4)} = -2z_4(-2m^2) = 4z_4 m^2 = \frac{4\kappa^2 m^2}{M^4}, \tag{38.54}$$

identical to the momentum-dependent term of Eq. (38.52). The effective theory, with the two Wilson coefficients λ_{eff} and $z_4 = \kappa^2/M^4$ fixed by action-matching, reproduces the full on-shell amplitude to the order worked. This is the explicit verification of Theorem 38.7.

The worked example also proves Theorem 38.8. Notice that the entire on-shell effect of the derivative operator $\phi^2(\partial\phi)^2$ collapsed, by the on-shell relation $\sum_{k<l} q_k \cdot q_l = -2m^2$, to the *constant* $4z_4m^2$ — a number of order m^2/M^4 with no momentum dependence. A constant contribution to the four-point amplitude is indistinguishable from a shift of λ_{eff} (and, in the two-point function, a shift of m^2). In the language of Section 38.2.4, the operator $\phi^2(\partial\phi)^2$ is *redundant*: applying the light-field equation of motion $\Box\phi = -m^2\phi - \frac{\lambda_{\text{eff}}}{6}\phi^3 + \cdots$ to the equivalent form $-\frac{1}{4}\phi^2\Box\phi^2$ trades the derivatives for $m^2\phi^4$ and ϕ^6 terms, removing the derivative operator entirely in favour of shifts to the marginal coupling, the mass, and the six-point coefficient. Whether one keeps $\phi^2(\partial\phi)^2$ with coefficient z_4 (off-shell matching) or absorbs it into $\delta\lambda_{\text{eff}} \sim m^2/M^4$ and δc_6 (on-shell matching), the S-matrix is the same. The off-shell action carries redundant information; the physics does not. This is exactly the freedom that the field-redefinition theorem guarantees, and it is why a sensible matching computation may use *any* convenient form of the operator basis, on shell or off, provided one is consistent.

38.3.6 Heavy vector exchange and the Fermi constant

The scalar example taught the mechanics; the historically decisive application is to a heavy *vector*. Long before the W boson was known, weak decays such as the muon's, $\mu^- \to e^-\bar{\nu}_e\nu_\mu$, were described by Fermi's contact interaction — four fermion fields meeting at a point with a single coupling G_F. We now recognize that interaction as the effective theory obtained by integrating out a heavy vector, and we compute G_F by matching. The heavy field is the W, whose full provenance (the spontaneous breaking of the electroweak gauge symmetry that gives it its mass) is the business of Chapter 31; for the present purpose we need only its mass M_W, its propagator, and its coupling to a charged current.

The relevant interaction is the charged-current Lagrangian

$$\mathcal{L}_{\text{CC}} = \frac{g}{\sqrt{2}}\Big(W_\mu^+ J_-^\mu + W_\mu^- J_+^\mu\Big), \qquad J_-^\mu = \bar{\psi}_i\,\gamma^\mu P_L\,\psi_j, \quad P_L = \tfrac{1}{2}(1-\gamma^5), \tag{38.55}$$

with $J_+^\mu = (J_-^\mu)^\dagger$, g the weak gauge coupling, and the sum running over the relevant fermion pairs (for muon decay, (i,j) are (ν_μ,μ) and (ν_e,e)); the current

is purely left-handed, the famous $V-A$ structure. The W is a massive vector with the propagator

$$\widetilde{D}^{W}_{\mu\nu}(q) = \frac{-i}{q^2 - M_W^2}\Big(\eta_{\mu\nu} - \frac{q_\mu q_\nu}{M_W^2}\Big), \tag{38.56}$$

the form fixed by the massive spin-one quantization of Chapter 31 (unitary gauge). Muon decay proceeds through single W exchange between the two currents, at momentum transfer $q^2 \sim m_\mu^2 \ll M_W^2$. Integrating the W out is, by the universal recipe, the replacement of Eq. (38.56) by its low-energy limit. In that limit q^2 is negligible against M_W^2 in the denominator, and the longitudinal $q_\mu q_\nu/M_W^2$ term, when contracted with a current, produces $q_\mu J^\mu = \partial\cdot J$, which by the Dirac equation is proportional to the light fermion masses and hence suppressed by $m^2_{\text{fermion}}/M_W^2$ relative to the leading term. Dropping both,

$$\widetilde{D}^{W}_{\mu\nu}(q) \xrightarrow{\;q^2 \ll M_W^2\;} \frac{i\,\eta_{\mu\nu}}{M_W^2} + O\Big(\frac{q^2}{M_W^4}, \frac{m_f^2}{M_W^4}\Big). \tag{38.57}$$

The heavy line shrinks to a point, and the two charged-current vertices fuse into a four-fermion contact operator (Fig. 38.4). Equivalently, and identically, one solves the W equation of motion: at low energy the Proca equation reduces to $M_W^2 W_-^\mu = -(g/\sqrt{2})J_-^\mu$, giving $W_-^\mu = -(g/\sqrt{2}M_W^2)J_-^\mu$, and substituting back into Eq. (38.55) — the same Gaussian-saddle logic as for the scalar, now for a field appearing quadratically in its Proca action — yields the effective Lagrangian

$$\mathcal{L}_{\text{eff}} = -\frac{g^2}{2M_W^2}\, J_+^\mu\, J_{\mu,-} = -\frac{g^2}{2M_W^2}\,(\bar\psi_j \gamma^\mu P_L \psi_i)(\bar\psi_i \gamma_\mu P_L \psi_j). \tag{38.58}$$

The factor arises as in the scalar case: substituting the solved field into $M_W^2 W^+W^- + (g/\sqrt{2})(W^+J_- + W^-J_+)$ leaves exactly half the cross term, $+\frac{g^2}{2M_W^2}J_+J_- - \frac{g^2}{M_W^2}J_+J_- = -\frac{g^2}{2M_W^2}J_+J_-$.

It remains to express Eq. (38.58) in Fermi's normalization. Fermi wrote the interaction with the chirality-projected currents combined into vector-minus-axial currents $\bar\psi\gamma^\mu(1-\gamma^5)\psi = 2\,\bar\psi\gamma^\mu P_L\psi$:

$$\mathcal{L}_{\text{Fermi}} = -\frac{G_F}{\sqrt{2}}\,[\bar\psi_j\gamma^\mu(1-\gamma^5)\psi_i]\,[\bar\psi_i\gamma_\mu(1-\gamma^5)\psi_j] = -\frac{4G_F}{\sqrt{2}}\,(\bar\psi_j\gamma^\mu P_L\psi_i)(\bar\psi_i\gamma_\mu P_L\psi_j). \tag{38.59}$$

Equating the two forms Eq. (38.58) and Eq. (38.59) gives $4G_F/\sqrt{2} = g^2/2M_W^2$, that is

$$\boxed{\frac{G_F}{\sqrt{2}} = \frac{g^2}{8M_W^2}}. \tag{38.60}$$

This is the matching condition for the Fermi constant: the dimensionful Wilson coefficient G_F of the four-fermion operator is fixed by the gauge coupling and

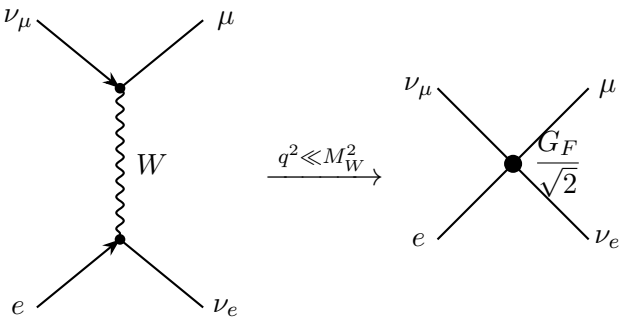

Figure 38.4: Integrating out the W in muon decay. At momentum transfer $q^2 \sim m_\mu^2 \ll M_W^2$ the W propagator Eq. (38.56) is local on the scale $1/M_W$ and the exchange diagram collapses to Fermi's four-fermion contact interaction, with Wilson coefficient $G_F/\sqrt{2} = g^2/8M_W^2$ (Eq. (38.60)).

the heavy mass. It is the four-fermion analogue of $\lambda_{\text{eff}} = \lambda_0 - 3\kappa^2/M^2$ — a marginal-looking coupling at low energy revealed as a ratio of short-distance parameters, suppressed by the heavy mass. Because the operator is dimension six (four fermion fields of dimension $\frac{3}{2}$ each), its coefficient $G_F \sim g^2/M_W^2$ carries the obligatory $1/M^2$ of an irrelevant operator; the dimensionless combination is g^2, of order the gauge coupling squared, again as naive dimensional analysis predicts.

The Fermi constant came first

Fermi proposed the four-fermion interaction in 1933, four decades before the W boson was discovered, fitting G_F to the measured rate of nuclear beta decay; the modern value is $G_F = 1.166 \times 10^{-5}$ GeV^{-2}. The relation Eq. (38.60) runs the matching backwards: knowing G_F and g (the latter from the electroweak structure of Chapter 31) *predicts* $M_W \approx 80$ GeV, a prediction confirmed at CERN in 1983. This is the paradigmatic case of an effective theory pointing to its own completion: the non-renormalizable Fermi theory, taken seriously as an EFT, contains in the size of its single Wilson coefficient the scale $M_W \sim (G_F)^{-1/2}$ at which it must be replaced. The breakdown of the contact description — its cross sections growing as $G_F^2 s$ and violating unitarity near $\sqrt{s} \sim G_F^{-1/2}$ — is the amplitude-level signal of the same scale, and exactly the "the EFT predicts where it dies" phenomenon that Section 38.2 anticipated.

The $V-A$ structure also illustrates a point that will matter in Chapter 40: integrating out the W at tree level produced a *single* four-fermion operator, the one whose chirality structure the W coupling dictated. Had we matched at one loop, additional operators with other Dirac and color structures would have

been generated, with coefficients carrying logarithms $\ln(M_W/\mu)$ — the operator mixing and running that turn the static Fermi constant into a scale-dependent set of Wilson coefficients. That is precisely the new feature loops bring, and it is where we go next.

We have now constructed Wilson coefficients top-down in two physical examples, defining them at the high scale $\mu \sim M$ by the requirement that the effective theory reproduce the full theory's amplitudes order by order in E/M, and we have seen the classical-EOM and Gaussian-integration routes deliver the same tree-level effective action. Every coefficient we obtained — λ_{eff}, z_4, c_6, G_F — is a pure tree-level number, a ratio of short-distance parameters with no reference to the renormalization scale. That tidiness is an artefact of tree level. The moment we include loops, the matching coefficients acquire logarithms of the heavy mass and a dependence on the subtraction scheme, because the full and effective theories distribute the same physics differently between loop integrals and local counterterms. Making the matching consistent at one loop, and understanding why a mass-independent scheme such as $\overline{\text{MS}}$ hides the decoupling of heavy particles and therefore forces us to remove them by hand at thresholds, is the task of Section 38.4 and the Appelquist–Carazzone theorem of Section 38.4.2.

38.4 One-Loop Matching and the Decoupling Theorem

Tree-level matching, as carried out in Section 38.3, was an exercise in algebra: expand the full-theory amplitude in powers of E/M, read off the local pieces, and call them Wilson coefficients. Nothing about the procedure cared that the two sides of the matching equation were tree amplitudes. The instant we go to one loop, however, a new feature appears that the tree analysis could not have prepared us for. Both theories now have loops, and loops generate logarithms. The full theory produces logarithms $\ln(M^2/(-p^2))$ tying the heavy mass to the external kinematics; the effective theory, which contains no heavy field, can only produce $\ln(\mu^2/(-p^2))$. The question that organizes this section is what happens to the difference. The answer is the cleanest structural fact in all of effective field theory: the difference is *local* — a polynomial in external momenta, analytic at $p = 0$ — and so it is exactly of the form that can be absorbed into a shift of the Wilson coefficients. Matching survives at loop level, the large logarithm splits unambiguously into a piece that belongs to the coefficients and a piece that belongs to their running, and from this same locality follows the theorem of Appelquist and Carazzone: a heavy particle, properly accounted for, leaves no trace at low energy beyond renormalizations of the light couplings and corrections suppressed by powers of E/M. We will then see that the convenient mass-independent scheme $\overline{\text{MS}}$ hides this decoupling, and that the

cure — removing the heavy field by hand and matching at its threshold — is not a workaround but the physically correct prescription.

38.4.1 The structure of one-loop matching

Fix the setup. The full theory contains light fields ϕ (masses and momenta of order E) and one heavy field of mass $M \gg E$. The effective theory is the Lagrangian

$$\mathcal{L}_{\rm EFT} = \mathcal{L}_{\rm light} + \sum_i C_i(\mu)\, \mathcal{O}_i, \tag{38.61}$$

built from the light fields alone, with local operators $\mathcal{O}_i$ of increasing dimension organized by the power counting of Theorem 21.10 and Section 38.2, and Wilson coefficients $C_i(\mu)$ carrying the inverse powers of M. Matching is the demand that the two theories produce the same S-matrix elements for light external states, order by order in E/M and order by order in the loop expansion. Schematically, for any light amplitude $\mathcal{A}$,

$$\mathcal{A}_{\rm full}(p; M, \mu) \stackrel{!}{=} \mathcal{A}_{\rm EFT}(p; C_i(\mu), \mu) \qquad \text{for } p \sim E \ll M, \tag{38.62}$$

both sides computed in the *same* renormalization scheme (we use $\overline{\rm MS}$, $d = 4 - 2\varepsilon$, common scale μ). The Wilson coefficients are whatever they must be to make Eq. (38.62) hold.

Expand both sides in loops, writing $\mathcal{A} = \mathcal{A}^{(0)} + \mathcal{A}^{(1)} + \cdots$ and $C_i = C_i^{(0)} + C_i^{(1)} + \cdots$, where the superscript counts loops (equivalently powers of $\hbar$). At tree level Eq. (38.62) reduces to the content of Section 38.3: the tree EFT amplitude is the sum of tree-level operator insertions, and matching fixes $C_i^{(0)}$. At one loop the equation reads

$$\mathcal{A}^{(1)}_{\rm full}(p) \;=\; \underbrace{\mathcal{A}^{(1)}_{\rm EFT}[C^{(0)}](p)}_{\text{EFT loops, tree coefficients}} \;+\; \underbrace{\sum_i C_i^{(1)}\, \langle \mathcal{O}_i \rangle^{(0)}(p)}_{\text{tree insertion of one-loop coefficients}}, \tag{38.63}$$

where $\mathcal{A}^{(1)}_{\rm EFT}[C^{(0)}]$ denotes the one-loop EFT amplitude computed with the tree-level Wilson coefficients in the vertices, and $\langle \mathcal{O}_i \rangle^{(0)}$ is the tree-level matrix element of the operator $\mathcal{O}_i$. Solving for the one-loop matching correction,

$$\boxed{\sum_i C_i^{(1)}\, \langle \mathcal{O}_i \rangle^{(0)}(p) \;=\; \mathcal{A}^{(1)}_{\rm full}(p) - \mathcal{A}^{(1)}_{\rm EFT}[C^{(0)}](p)\,.} \tag{38.64}$$

Read literally, Eq. (38.64) looks dangerous: the left-hand side is, by construction, a finite sum of *local* structures (tree matrix elements of local operators are polynomials in p), while the right-hand side is a difference of two loop amplitudes, each of which is a transcendental function of p full of logarithms and, above

thresholds, branch cuts. For the equation to be consistent, all of that nonlocal structure must cancel in the difference. It does, and the reason is the single most important sentence in this subsection: *the full theory and the effective theory have, by construction, identical infrared physics.* They contain the same light fields with the same masses and the same low-energy interactions; the only difference between them is in the ultraviolet, where the full theory has a heavy particle and the EFT has a tower of contact terms. The infrared region of any loop integral — loop momenta of order E, where the light particles go nearly on shell and the nonanalytic structure is generated — is therefore the same in both theories. When we subtract, the infrared cancels, and what survives is purely ultraviolet, hence local.

The method of regions makes this exact. The cleanest way to see the cancellation, and the way that will give us the matching coefficient directly, is to dissect a full-theory loop integral by the scale of its loop momentum. Consider a one-loop integral $I = \int \mathrm{d}^d\ell\, f(\ell, p, M)$ with $p \sim E \ll M$. Split the integration into two regions and expand the integrand appropriately in each before integrating:

- the *hard* region, $\ell \sim M$, where the light scales p, m_{light} are small and we Taylor-expand the integrand in p/ℓ and m_{light}/ℓ before integrating;
- the *soft* region, $\ell \sim E$, where the heavy propagators are far off shell and we Taylor-expand them in ℓ/M and p/M before integrating.

The theorem of expansion by regions states that the full integral is the sum of the two region integrals, each computed over all of ℓ-space in dimensional regularization (the scaleless remainders that the naive split would double-count are set to zero by $d = 4 - 2\varepsilon$). Now identify the pieces. The soft region, in which the heavy propagators have been expanded to a sum of local vertices $\sim 1/M^{2n}$, is *precisely* a loop integral of the effective theory: light particles circulating, heavy lines shrunk to the contact operators $\mathcal{O}_i$. So

$$I_{\text{full}} = I_{\text{hard}} + I_{\text{soft}}, \qquad I_{\text{soft}} = I_{\text{EFT}}. \tag{38.65}$$

Subtracting, $I_{\text{full}} - I_{\text{EFT}} = I_{\text{hard}}$. But I_{hard} was obtained by Taylor-expanding in the external momenta from the outset, so it is manifestly a polynomial in p with coefficients that are functions of M and μ only — it is local. Comparing with Eq. (38.64), the hard region of the full-theory loop *is* the one-loop Wilson coefficient:

$$\sum_i C_i^{(1)}\, \langle \mathcal{O}_i \rangle^{(0)}(p) = I_{\text{hard}}. \tag{38.66}$$

This is the operational content of one-loop matching and we will lean on it heavily: *a Wilson coefficient is the hard part of a full-theory amplitude.* One never needs the soft (infrared) part of either theory — it cancels — so in practice one may

set all light masses and external momenta to zero from the start, compute the resulting purely-heavy loop integrals, and read off the coefficients. The price is that the integrals one then computes may be individually infrared-divergent; those infrared $1/\varepsilon$ poles are spurious, cancelling against the (equally spurious, equally scaleless) infrared poles of the EFT side, and one tracks them only to be sure they match.

The logarithm splits cleanly. Equation Eq. (38.64) also resolves the puzzle that opened the section. A generic one-loop full-theory amplitude carries the logarithm $\ln(M^2/(-p^2))$, which is large when $p \sim E \ll M$ — a large logarithm of the ratio of the two physical scales, the kind of thing perturbation theory cannot tolerate uncontrolled. Write it as a sum of two pieces using an arbitrary intermediate scale μ,

$$\ln \frac{M^2}{-p^2} = \underbrace{\ln \frac{M^2}{\mu^2}}_{\text{matching}} + \underbrace{\ln \frac{\mu^2}{-p^2}}_{\text{running}} . \tag{38.67}$$

The matching computation Eq. (38.66), performed at the scale μ, deposits $\ln(M^2/\mu^2)$ into the Wilson coefficient; the EFT loop, which knows only the light scales, carries $\ln(\mu^2/(-p^2))$. If we choose to match at $\mu \sim M$, the first logarithm is order one — there is no large logarithm in the matching coefficient, and ordinary fixed-order perturbation theory computes it reliably. The second logarithm is then large, but it lives entirely inside the EFT, where it is summed not by brute force but by the renormalization group: $C_i(\mu)$ is evolved from $\mu \sim M$ down to $\mu \sim E$, and the running resums $\ln(\mu/E)$ to all orders. This division of labor — compute the coefficient once, with no large log, at the high scale; then run it down — is the entire strategy of effective field theory at loop level, and it is what Section 38.5 will build the machinery for. The present section establishes the boundary condition $C_i(\mu \sim M)$; the next propagates it.

The matching coefficient is scheme-dependent; the prediction is not

Both sides of Eq. (38.64) are computed in $\overline{\text{MS}}$, and the value of $C_i^{(1)}(\mu)$ depends on that choice and on μ. This is not a defect: C_i is not an observable. The observable is the full low-energy amplitude $\mathcal{A}_{\text{EFT}}$, in which the μ-dependence of $C_i(\mu)$ cancels against the explicit μ-dependence of the EFT loops order by order — precisely the statement that Eq. (38.62) holds for all μ. What *is* mandatory is that the full theory and the EFT be matched in the *same* scheme: a coefficient extracted with a full-theory $\overline{\text{MS}}$ subtraction and inserted into EFT loops renormalized in some other scheme is simply wrong. Consistency of the scheme across the matching is the one inviolable rule.

38.4.2 The Appelquist–Carazzone decoupling theorem

We can now state and prove the theorem that justifies the whole enterprise: that low-energy physics is genuinely insensitive to heavy particles, so that an effective theory built from the light fields alone really does capture everything an experiment at energy $E \ll M$ can see.

Theorem 38.10 (Appelquist–Carazzone decoupling)**.** *Let a renormalizable theory contain light fields and a single field of mass M, and let all external momenta and light masses be of order $E \ll M$. Renormalize in a* physical *(mass-dependent) scheme — one whose renormalization conditions are imposed on light-particle amplitudes at scales of order E, so that the renormalized light couplings, masses, and field normalizations are defined by low-energy measurements. Then in any light-particle Green's function the entire effect of the heavy field is either*

(i) *absorbed into the values of the renormalized light parameters (a finite, M-dependent redefinition of couplings, masses, and field normalizations that the low-energy observer has already measured and cannot disentangle), or*

(ii) *suppressed by a positive power of E/M, appearing as the matrix elements of higher-dimension operators with coefficients scaling as inverse powers of M.*

In particular, as $M \to \infty$ at fixed renormalized low-energy parameters, the heavy field disappears from all low-energy observables. There is no term that grows with M or even survives as a finite, unsuppressed, M-independent constant beyond the renormalization of the light theory.

Proof. The proof rests on a single analytic fact and the structure already established in Eqs. (38.64) and (38.66). Consider any one-particle-irreducible light-particle Green's function $\Gamma(p)$ at the order in the loop expansion at which the heavy field first enters, i.e. through a loop containing at least one heavy internal line. Because $E \ll M$, the heavy line can never go on shell: the external invariants $p^2 \sim E^2$ are far below the threshold $\sim M^2$ at which a heavy pair could be produced. By the analytic structure of perturbative amplitudes — branch points sit at physical thresholds — the heavy contribution to $\Gamma(p)$ is therefore *analytic* in the external momenta in a neighborhood of $p = 0$ of radius set by M. An analytic function may be Taylor-expanded:

$$\Gamma_{\text{heavy}}(p) = a_0(M,\mu) + a_1(M,\mu)\,\frac{p^2}{M^2} + a_2(M,\mu)\,\frac{(p^2)^2}{M^4} + \cdots , \tag{38.68}$$

where dimensional analysis has been used to extract the powers of M, and each coefficient a_n is dimensionless up to the overall dimension of Γ. We now read the two classes of terms.

The leading terms renormalize the light theory. The terms with n small in Eq. (38.68) have the same structure in p as the operators already present in $\mathcal{L}_{\text{light}}$ — a constant is a shift of a coupling or a mass, a term $\propto p^2$ is a shift of a kinetic term or a field normalization, and so on up to the dimension of the renormalizable operators. These are local and they are exactly the structures that the light-theory counterterms can absorb. In a *physical* scheme the renormalization conditions are imposed at low energy: one demands, for instance, that the light propagator have a pole at the measured mass with unit residue, and that a coupling equal its measured value at a low-momentum reference point. Imposing these conditions *subtracts the value of* Γ_{heavy} *at the reference kinematics*, sweeping the heavy-induced constant a_0 (and the corresponding low-order a_n that the conditions fix) into the definition of the renormalized parameter. The low-energy observer measures the renormalized parameter and never sees a_0 separately; it has been reparametrized away. This is alternative (i).

The remaining terms are power-suppressed. After the physical subtraction, what is left of Eq. (38.68) is the difference between $\Gamma_{\text{heavy}}(p)$ and its low-order Taylor polynomial evaluated at the reference point — that is, the higher terms in the expansion, each carrying an explicit $(p^2/M^2)^n \sim (E/M)^{2n}$ with $n \geq 1$. These are the matrix elements of the higher-dimension operators of the effective theory, with Wilson coefficients $\sim 1/M^{2n}$ given by the hard region a_n. They vanish as $M \to \infty$. This is alternative (ii), and it completes the dichotomy.

That no term escapes the dichotomy is the content of the locality established in Section 38.4.1: by Eq. (38.66) the heavy field's contribution to any light amplitude, after the infrared (light-loop) part is separated, is the hard region I_{hard}, which is exactly the polynomial Eq. (38.68). There is no nonpolynomial, M-independent remainder, because such a remainder would be a nonlocal function of p with no $1/M$ suppression, and the only source of nonlocality at low energy is the light loops, which belong to the EFT and have been accounted for separately. Hence every heavy effect falls into (i) or (ii). □

The theorem is sharp about *why* the scheme must be physical: the subtraction in step (i) must be performed at low energy for the heavy constant a_0 to be the thing that the low-energy observer measures. We will see in Section 38.4.4 that a scheme which subtracts somewhere else — in particular $\overline{\text{MS}}$, which subtracts a pure pole with no reference to any physical kinematics — leaves a_0 visible as a logarithm $\ln(M/\mu)$ that does not go away, and that decoupling must then be enforced by hand.

Decoupling is why physics is possible

Theorem 38.10 is the formal version of a fact so familiar it is easy to overlook: one can compute the hydrogen spectrum without knowing the top quark, build a bridge without knowing quantum gravity, and discover

the laws of electromagnetism a century before the W boson. Each layer of physics is describable on its own terms, with the deeper layers entering only through the numerical values of a handful of low-energy constants and through corrections too small to have mattered. The decoupling theorem is the statement that this layered describability is not luck but a theorem about quantum field theory in a physical scheme. The effective-field-theory paradigm is its constructive converse: *because* the heavy physics enters only through local couplings and power-suppressed operators, one can write down the most general such local theory and fit those couplings to data, completely agnostic about what the heavy physics actually is.

38.4.3 Decoupling in action: the heavy fermion in QED

The abstract proof becomes concrete in the carried QED thread. Add to QED a heavy fermion of mass M and charge $Q_M e$ — a heavy lepton, say — and ask how it affects the photon's low-energy behavior, the cleanest light observable. Its only one-loop effect is a contribution to the vacuum polarization, the heavy-fermion analogue of the electron loop computed in Chapter 19. The tensor structure is fixed by gauge invariance to be transverse, Eq. (19.49), and the scalar form factor is the one-loop function Eq. (19.57) with the electron mass replaced by M and an extra charge factor Q_M^2,

$$\widehat{\Pi}_M(q^2) = -\frac{2\alpha Q_M^2}{\pi}\int_0^1 \mathrm{d}x\; x(1-x)\,\ln\frac{M^2}{M^2 - x(1-x)q^2}, \tag{38.69}$$

already on-shell subtracted so that $\widehat{\Pi}_M(0) = 0$, the on-shell scheme being a physical scheme in the sense of Theorem 38.10 (the renormalization condition fixes the charge at $q^2 = 0$, the Thomson point). This is exactly the setting of the theorem: the heavy line cannot go on shell for $|q^2| \sim E^2 \ll M^2$, so $\widehat{\Pi}_M$ is analytic at $q^2 = 0$ and we may expand it. Using $\ln\frac{M^2}{M^2 - x(1-x)q^2} = x(1-x)\frac{q^2}{M^2} + O(q^4/M^4)$ and the moment $\int_0^1 \mathrm{d}x\,[x(1-x)]^2 = \frac{1}{30}$, exactly as in Eq. (19.58) with $m \to M$,

$$\widehat{\Pi}_M(q^2) = -\frac{\alpha Q_M^2}{15\pi}\,\frac{q^2}{M^2} + O\Big(\frac{q^4}{M^4}\Big). \tag{38.70}$$

Here is the decoupling theorem made arithmetic. The heavy fermion's effect on the photon propagator is suppressed by q^2/M^2 — alternative (ii) of Theorem 38.10, with the leading term the matrix element of the dimension-six operator $\partial_\lambda F_{\mu\nu}\partial^\lambda F^{\mu\nu}$ generated by integrating out the heavy fermion. Where did alternative (i) go? It went into the constant we already subtracted. The *unrenormalized* heavy form factor of Eq. (19.53) carried the constant

$$\Pi_M(0) = -\frac{\alpha Q_M^2}{3\pi}\Big[\frac{1}{\bar{\varepsilon}} + \ln\frac{\mu^2}{M^2}\Big], \tag{38.71}$$

an M-dependent constant that the on-shell condition $\widehat{\Pi}_M(0) = 0$ absorbed wholesale into the definition of the physical charge $\alpha = \alpha(q^2 = 0)$. The low-energy experimenter measures $\alpha \approx 1/137$ at the Thomson point; that number already contains the heavy fermion's constant contribution, inextricably, and no low-energy photon experiment can isolate it. What remains observable — the q^2-dependence of the effective charge probed by varying the momentum transfer — is the power-suppressed remainder Eq. (38.70). The heavy fermion has decoupled: present in the measured value of α, invisible in its running until one reaches $q^2 \sim M^2$. This is the promised explicit demonstration that the M-dependence is a constant absorbed by charge renormalization plus terms suppressed by q^2/M^2.

38.4.4 Non-decoupling in $\overline{\text{MS}}$ and the threshold cure

The on-shell scheme made decoupling manifest because it subtracted at a physical point. The minimal subtraction scheme $\overline{\text{MS}}$ does not, and the consequence is that decoupling is invisible in $\overline{\text{MS}}$ — a feature so often mistaken for a paradox that it deserves to be displayed in full.

In $\overline{\text{MS}}$ one subtracts only the pole $1/\bar{\varepsilon}$ of Eq. (38.71), leaving the renormalized heavy form factor

$$\Pi_M^{\overline{\text{MS}}}(q^2) = -\frac{2\alpha Q_M^2}{\pi}\int_0^1 \mathrm{d}x\, x(1-x)\,\ln\frac{\mu^2}{M^2 - x(1-x)q^2}. \tag{38.72}$$

Now take the low-energy limit $|q^2| \ll M^2$. The logarithm becomes $\ln(\mu^2/M^2) + O(q^2/M^2)$, and with $\int_0^1 \mathrm{d}x\, x(1-x) = \frac{1}{6}$,

$$\Pi_M^{\overline{\text{MS}}}(q^2) \xrightarrow{|q^2|\ll M^2} \frac{\alpha Q_M^2}{3\pi}\ln\frac{M^2}{\mu^2} + O\Big(\frac{q^2}{M^2}\Big). \tag{38.73}$$

This does *not* vanish as $M \to \infty$ at fixed μ. It grows logarithmically without bound. In $\overline{\text{MS}}$ the heavy fermion fails to decouple: it contributes a constant $\frac{\alpha Q_M^2}{3\pi}\ln(M^2/\mu^2)$ to the low-energy vacuum polarization no matter how heavy it is, and correspondingly it contributes to the running coupling at *all* scales, including scales $\mu \ll M$ where it should be irrelevant. The reason is exactly the one anticipated after Theorem 38.10: $\overline{\text{MS}}$ subtracted a pure pole, not a physical constant, so the heavy constant $a_0 = \frac{\alpha Q_M^2}{3\pi}\ln(M^2/\mu^2)$ of Eq. (38.68) was never reparametrized away. It sits in the open as a logarithm. The hypotheses of the decoupling theorem — a *physical* scheme — are violated, and the conclusion fails.

The structural source is worth naming. The $\overline{\text{MS}}$ beta function is *mass-independent*: by construction the counterterms are pure poles, the same whatever the masses, so the anomalous dimensions and beta functions depend only on the field content, not on whether a given field is light or heavy relative to μ. The

QED beta function in $\overline{\text{MS}}$ therefore counts the heavy fermion on equal footing with the electron at every scale,

$$\beta_\alpha^{\overline{\text{MS}}} = \frac{2\alpha^2}{3\pi} \sum_f Q_f^2, \tag{38.74}$$

the sum running over *all* fermions, light and heavy alike — the abelian instance of the general $\overline{\text{MS}}$ beta function built from Theorem 24.1 and the running Eq. (24.215). Used naively, Eq. (38.74) says the heavy fermion screens the charge even at $\mu \ll M$, which is physically false: a virtual pair of mass M cannot be excited by a soft photon and cannot screen it. The mass-independent scheme has traded manifest decoupling for calculational simplicity, and the bill comes due as the spurious low-scale running Eq. (38.73).

The cure: integrate out and match at the threshold. The resolution is not to abandon $\overline{\text{MS}}$ — its mass-independence is exactly what makes the renormalization group simple — but to enforce decoupling by hand. One uses $\overline{\text{MS}}$ in a sequence of effective theories, removing each heavy field from the Lagrangian as μ drops below its mass and matching the two descriptions at the threshold. Above $\mu = M$ one works in the full theory, with the heavy fermion active and the beta function Eq. (38.74) including its charge. At $\mu \sim M$ one integrates the heavy fermion out: the effective theory below has the same Lagrangian minus the heavy field, its beta function counts only the remaining light fermions, and the two couplings are related by a matching condition fixed by demanding that the physical effective charge be continuous across the threshold.

The matching condition is Eq. (38.64) for the photon two-point function. Let $\alpha^{(n_f)}$ denote the $\overline{\text{MS}}$ coupling in the theory with n_f active fermions and $\alpha^{(n_f-1)}$ that in the theory with the heavy fermion removed. The physical effective charge built from the resummed vacuum polarization, $\alpha_{\text{eff}}^{-1}(q^2) = \alpha^{-1}(\mu)\big[1 - \Pi^{\overline{\text{MS}}}(q^2,\mu)/\alpha\big]$ at one loop, must agree whether computed above or below threshold. The full theory carries the heavy contribution Eq. (38.73); the effective theory does not. Equality of α_{eff}^{-1} then forces the difference into the matched coupling,

$$\boxed{\frac{1}{\alpha^{(n_f-1)}(\mu)} = \frac{1}{\alpha^{(n_f)}(\mu)} - \frac{Q_M^2}{3\pi} \ln\frac{M^2}{\mu^2} + O(\alpha)\,.} \tag{38.75}$$

Two features of Eq. (38.75) are the whole point. First, at the natural matching scale $\mu = M$ the logarithm vanishes and the couplings are *equal*: $1/\alpha^{(n_f-1)}(M) = 1/\alpha^{(n_f)}(M) + O(\alpha)$. The threshold matching is continuous — there is no large logarithm in the one-loop matching coefficient, just as the general analysis Eq. (38.67) promised, which is why $\mu \sim M$ is the right place to match. (The $O(\alpha)$ remainder is a finite, computable constant from the hard region of the

heavy loop; with the $\overline{\text{MS}}$ heavy mass it begins at the order beyond the leading logarithm.) Second, differentiating Eq. (38.75) with respect to $\ln\mu^2$ shows that the slope of $1/\alpha$ changes by exactly $+Q_M^2/3\pi$ across the threshold,

$$\frac{\mathrm{d}}{\mathrm{d}\ln\mu^2}\frac{1}{\alpha^{(n_f-1)}} = \frac{\mathrm{d}}{\mathrm{d}\ln\mu^2}\frac{1}{\alpha^{(n_f)}} + \frac{Q_M^2}{3\pi}, \tag{38.76}$$

which is precisely the statement that below the threshold the heavy fermion no longer contributes to the running: the beta-function coefficient steps down from $\sum^{n_f} Q_f^2$ to $\sum^{n_f-1} Q_f^2$, the heavy fermion's Q_M^2 removed. Decoupling, lost in Eq. (38.73), has been restored as a kink in the running coupling.

Figure 38.5 shows the construction. The physical effective coupling is reconstructed as a sequence of $\overline{\text{MS}}$ segments — straight lines in $\ln\mu$, each with the slope appropriate to the number of active flavors — joined continuously at the thresholds, with a kink at each heavy mass where a fermion is integrated out. This is the precise content, scheme by scheme, of the physical running of α derived in Section 20.6. The single-logarithm formula Eq. (20.171), with its fixed mass m, is the correct description only *between* thresholds; across the full range from m_e to M_Z the running is the broken line of Fig. 38.5, each segment governed by the active fermions of that decade and stitched to its neighbors by Eq. (38.75). The discussion in Section 20.6 of how the electron alone accounts for only part of the measured shift in $\alpha^{-1}(M_Z^2)$, with the muon, tau, and hadrons each switching on above its own threshold, is exactly this piecewise reconstruction: the physical, mass-dependent running that Theorem 38.10 guarantees, assembled out of mass-independent $\overline{\text{MS}}$ running plus the threshold matching Eq. (38.75).

38.4.5 The Euler–Heisenberg Lagrangian: integrating out the electron

We close the section with QED's flagship illustration of matching and decoupling at one loop: the effective theory of soft photons obtained by integrating the electron out of QED. Below the electron mass m_e the only propagating field is the photon, and the most general local Lagrangian consistent with Lorentz invariance, gauge invariance, parity, and charge conjugation is an expansion in the field strength and its derivatives,

$$\mathcal{L}_\gamma = -\tfrac{1}{4}F_{\mu\nu}F^{\mu\nu} + c_1\,(F_{\mu\nu}F^{\mu\nu})^2 + c_2\,(F_{\mu\nu}\widetilde{F}^{\mu\nu})^2 + \cdots, \qquad \widetilde{F}^{\mu\nu} \equiv \tfrac{1}{2}\epsilon^{\mu\nu\rho\sigma}F_{\rho\sigma}, \tag{38.77}$$

where the dots denote operators with more fields or derivatives. The structure is dictated by symmetry and power counting (Theorem 21.10). Gauge invariance forbids any operator that is not built from $F_{\mu\nu}$ (a bare A_μ is forbidden, so is a photon mass). Lorentz invariance and parity allow only the two independent quartic scalars $(F^2)^2$ and $(F\widetilde{F})^2$ — note $F_{\mu\nu}\widetilde{F}^{\mu\nu}$ is a total derivative and parity-odd, so it cannot appear linearly, but its square is parity-even and local. There

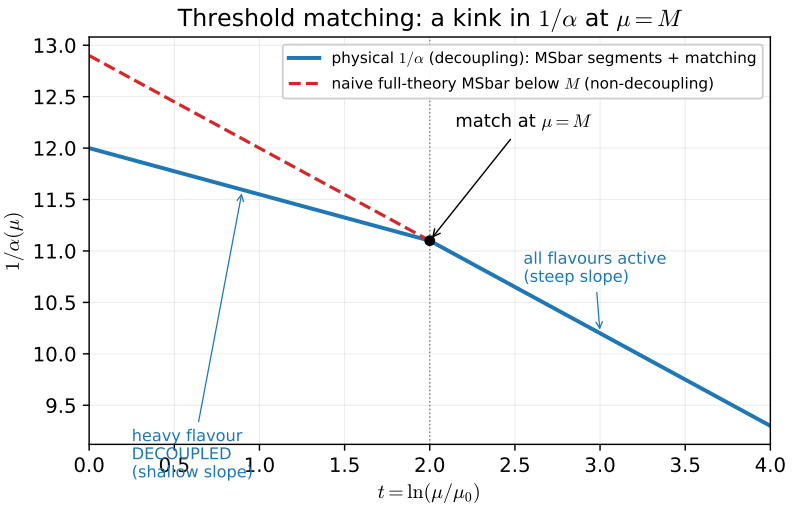

Figure 38.5: Threshold matching reconstructs decoupling in a mass-independent scheme. The inverse coupling $1/\alpha$ runs linearly in $\ln \mu$ with a slope set by the number of active flavors. Below the heavy mass M the physical coupling (solid) runs with the reduced slope — the heavy fermion has decoupled — while a naive full-theory $\overline{\text{MS}}$ extrapolation (dashed) keeps the steeper slope, the non-decoupling of Eq. (38.73). The two agree at $\mu = M$, where the heavy fermion is integrated out and the one-loop matching correction Eq. (38.75) vanishes, leaving a continuous value and a discontinuous slope: the threshold step Eq. (38.76).

is no gauge-invariant operator of dimension six built from two factors of F alone (the candidate $\partial_\lambda F_{\mu\nu}\partial^\lambda F^{\mu\nu}$ is, on the photon equation of motion $\partial_\mu F^{\mu\nu} = 0$, reducible and contributes only to the propagator's q^2/m_e^2 corrections seen in Eq. (38.70)); the first genuinely new photon self-interactions are the dimension-eight quartics in Eq. (38.77). Their coefficients c_1, c_2 have mass dimension -4 and are the Wilson coefficients we now compute by matching.

Worked Example 38.11 (The leading Euler–Heisenberg coefficients from the electron loop)**.** The matching condition Eq. (38.66) says c_1, c_2 are the hard part of the full-theory amplitude — here the four-photon one-particle-irreducible amplitude with an electron loop, evaluated at zero external momentum, which is the light-by-light box of Fig. 38.6. Rather than compute the box diagram directly, we use the equivalent and more economical observation that the entire tower of zero-momentum multi-photon amplitudes is generated by the one-loop effective Lagrangian of the electron in a *constant* background field $F_{\mu\nu}$. Expanding that effective Lagrangian to fourth order in F yields the four-photon vertex at zero momentum, hence c_1 and c_2.

The one-loop effective Lagrangian as a determinant. Integrating the electron out of the QED path integral produces the fermion determinant (Theorems 4.33 and 10.38); for a constant background the effective action is V_4 times a constant Lagrangian,

$$\mathcal{L}^{(1)} = -i\,\frac{1}{V_4}\ln\det(i\not{D} - m) = -\frac{i}{2V_4}\ln\det\left(\not{D}^2 + m^2\right)^*, \tag{38.78}$$

where in the second form we used $\gamma_5(i\not{D} - m)\gamma_5 = -(i\not{D} + m)^*$-type reflection to write the fermionic determinant as the square root of a bosonic one (the manipulation that turns $\det(i\not{D} - m)$ into $[\det(-\not{D}^2 - m^2)]^{1/2}$ up to a field-independent phase), and

$$\not{D}^2 = D^2 + \tfrac{e}{2}\,\sigma_{\mu\nu}F^{\mu\nu}, \qquad D_\mu = \partial_\mu + ieA_\mu, \tag{38.79}$$

is the squared Dirac operator, the second term ($\sigma_{\mu\nu} = \frac{i}{2}[\gamma_\mu, \gamma_\nu]$) being the Pauli spin coupling that distinguishes the electron from a charged scalar.

Proper time and the heat kernel. Write the logarithm of the determinant as a proper-time integral, $\ln A = -\int_0^\infty \frac{\mathrm{d}s}{s}\,e^{-sA}$ up to a field-independent constant, so that the effective Lagrangian becomes the proper-time integral of a heat-kernel trace. For a constant field we evaluate that trace from the spectrum of the squared operator. Take a constant magnetic field B along the z-axis first; the general result follows by Lorentz covariance. The operator $-D^2$ separates into free motion along (t, z) and a two-dimensional transverse problem identical to a charged particle in a magnetic field — the Landau problem — with transverse eigenvalues $eB(2n+1)$, $n = 0, 1, 2, \ldots$, each Landau level carrying a degeneracy $eB/2\pi$ per unit transverse area. The longitudinal directions give the free density of states $\int \frac{\mathrm{d}^2k}{(2\pi)^2}e^{-sk^2} = 1/4\pi s$. The Pauli term $\frac{e}{2}\sigma_{\mu\nu}F^{\mu\nu} = e\,\Sigma_3 B$ has eigenvalues $\pm eB$ on the spin states, contributing the Dirac-trace spin factor $\sum_{\text{spin}} e^{\mp seB} = 2\cosh(seB)$ doubled by the two chiralities. Assembling the trace per unit four-volume,

$$\frac{1}{V_4}\,\mathrm{Tr}\;e^{-s(-\not{D}^2)} = \underbrace{\frac{1}{4\pi s}}_{t,z}\;\underbrace{\frac{eB}{2\pi}}_{\text{degeneracy}}\;\underbrace{\sum_{n=0}^{\infty} e^{-seB(2n+1)}}_{=\,1/2\sinh(seB)}\;\underbrace{2\cosh(seB)\cdot 2}_{\text{spin}\,\times\,\text{chirality}} = \frac{eB}{4\pi^2 s}\,\coth(seB). \tag{38.80}$$

The geometric sum over Landau levels produced the sinh; the spin factor produced the cosh; together they give the coth that is the signature of the constant-field problem. Inserting Eq. (38.80) into the proper-time integral and restoring the mass exponent e^{-sm^2} gives, in the standard normalization of the renormalized Minkowski effective Lagrangian,

$$\mathcal{L}^{(1)}(B) = -\frac{1}{8\pi^2}\int_0^\infty \frac{\mathrm{d}s}{s^3}\,e^{-m^2 s}\Big[\,seB\coth(seB) - 1 - \tfrac{1}{3}(seB)^2\,\Big]. \tag{38.81}$$

The two subtractions inside the bracket are the renormalizations demanded by Theorem 38.10's alternative (i): the "-1" removes the field-independent vacuum energy, and the "$-\frac{1}{3}(seB)^2$" removes the term quadratic in B, which is logarithmically divergent at $s \to 0$ and renormalizes the charge — it is the constant absorbed into the definition of α, the zero-momentum vacuum polarization Eq. (38.71) in disguise. What survives the subtractions is finite and begins at *fourth* order in the field: decoupling, visible in the integrand.

The general field and the weak-field expansion. By Lorentz invariance $\mathcal{L}^{(1)}$ depends only on the two field invariants, which we write as

$$\mathcal{F} \equiv \tfrac{1}{4}F_{\mu\nu}F^{\mu\nu} = \tfrac{1}{2}(B^2 - E^2), \qquad \mathcal{G} \equiv \tfrac{1}{4}F_{\mu\nu}\widetilde{F}^{\mu\nu} = -\,\mathbf{E}\cdot\mathbf{B}. \tag{38.82}$$

Introduce the two "secular" invariants $a, b \geq 0$ by $a^2 - b^2 = 2\mathcal{F}$, $ab = |\mathcal{G}|$; in a frame with $\mathbf{E} \parallel \mathbf{B}$ they are the magnitudes $a = |\mathbf{B}|$, $b = |\mathbf{E}|$. The magnetic calculation above gives the coth from a; a pure electric field is obtained by the analytic continuation $B \to iE$, which turns coth $\to$ cot. The general constant-field Lagrangian is therefore

$$\mathcal{L}^{(1)} = -\frac{1}{8\pi^2}\int_0^\infty \frac{\mathrm{d}s}{s^3}\, e^{-m^2 s}\Big[\,(eas)(ebs)\coth(eas)\cot(ebs) - 1 - \tfrac{1}{3}(es)^2(a^2-b^2)\,\Big]. \tag{38.83}$$

We need only the leading term beyond the subtractions. Expand the two factors with $z\coth z = 1 + \frac{z^2}{3} - \frac{z^4}{45} + \cdots$ and $z\cot z = 1 - \frac{z^2}{3} - \frac{z^4}{45} - \cdots$, writing $u = (eas)^2$, $v = (ebs)^2$:

$$\begin{aligned}(eas)\coth(eas)\,(ebs)\cot(ebs) &= \Big(1 + \tfrac{u}{3} - \tfrac{u^2}{45}\Big)\Big(1 - \tfrac{v}{3} - \tfrac{v^2}{45}\Big) + \cdots \\ &= 1 + \tfrac{1}{3}(u - v) - \tfrac{1}{45}(u^2 + v^2) - \tfrac{1}{9}uv + \cdots .\end{aligned} \tag{38.84}$$

The constant cancels the "-1"; the term $\frac{1}{3}(u - v) = \frac{1}{3}(es)^2(a^2 - b^2)$ cancels the charge-renormalization subtraction exactly. The first surviving term is quartic,

$$\big[\cdots\big]_{\text{quartic}} = -\tfrac{1}{45}(u^2 + v^2) - \tfrac{1}{9}uv = -\frac{(es)^4}{45}\big[(a^4 + b^4) + 5a^2b^2\big], \tag{38.85}$$

using $\frac{1}{9} = \frac{5}{45}$. The proper-time integral is now elementary, $\int_0^\infty \mathrm{d}s\, s\, e^{-m^2 s} = 1/m^4$, so

$$\mathcal{L}^{(1)}_{\text{quartic}} = -\frac{1}{8\pi^2}\Big(-\frac{e^4}{45}\Big)\big[(a^4{+}b^4){+}5a^2b^2\big]\int_0^\infty \mathrm{d}s\, s\, e^{-m^2 s} = \frac{e^4}{360\pi^2 m^4}\big[(a^4{+}b^4){+}5a^2b^2\big]. \tag{38.86}$$

Convert to invariants with $a^4 + b^4 = (a^2 - b^2)^2 + 2a^2b^2 = 4\mathcal{F}^2 + 2\mathcal{G}^2$ and $5a^2b^2 = 5\mathcal{G}^2$, so $(a^4 + b^4) + 5a^2b^2 = 4\mathcal{F}^2 + 7\mathcal{G}^2$, and use $e^4 = (4\pi\alpha)^2 = 16\pi^2\alpha^2$

so that $e^4/360\pi^2 = 2\alpha^2/45$. The result is the Euler–Heisenberg Lagrangian,

$$\boxed{\mathcal{L}^{(1)}_{\rm EH} = \frac{2\alpha^2}{45\,m_e^4}\Big[\,4\mathcal{F}^2 + 7\mathcal{G}^2\,\Big] = \frac{2\alpha^2}{45\,m_e^4}\Big[(E^2-B^2)^2 + 7(\mathbf{E}\cdot\mathbf{B})^2\Big]\,.} \tag{38.87}$$

Reading off the coefficients of the covariant operators in Eq. (38.77), with $4\mathcal{F}^2 = \frac{1}{4}(F_{\mu\nu}F^{\mu\nu})^2$ and $7\mathcal{G}^2 = \frac{7}{16}(F_{\mu\nu}\widetilde{F}^{\mu\nu})^2$,

$$c_1 = \frac{\alpha^2}{90\,m_e^4}, \qquad c_2 = \frac{7\alpha^2}{360\,m_e^4}. \tag{38.88}$$

These are the matching coefficients: the photon EFT below m_e reproduces low-energy QED if and only if its dimension-eight couplings take the values Eq. (38.88). Three features close the worked example.

First, the *decoupling scaling* is manifest: $c_1, c_2 \sim \alpha^2/m_e^4$, dimension-eight coefficients suppressed by four powers of the heavy mass. As $m_e \to \infty$ they vanish — alternative (ii) of Theorem 38.10, displayed for an operator of definite dimension. The heavy electron's only low-energy legacy in the pure-photon sector, beyond the charge renormalization it already supplied, is this $1/m_e^4$-suppressed light-by-light interaction.

Second, the result is a *matching coefficient*, not an observable. It is the hard region of the four-photon box Fig. 38.6 at zero external momentum: the loop momentum of order m_e Taylor-expanded in the soft photon momenta, which is exactly the prescription Eq. (38.66). Physical photon–photon scattering at $\omega \ll m_e$ is then computed in the EFT from the contact vertex Eq. (38.87), giving a cross section $\sigma_{\gamma\gamma\to\gamma\gamma} \sim \alpha^4\omega^6/m_e^8$ — the six powers of energy from the dimension-eight vertex, the steep suppression that makes light-by-light scattering so faint and so distinctively a probe of the EFT's leading irrelevant operator.

Third, the *two* coefficients are independent because parity and Lorentz invariance allowed two independent quartic invariants; the loop computes their ratio $c_2/c_1 = 7/4$, a sharp prediction of QED that any putative ultraviolet completion would have to reproduce to masquerade as the electron at low energy.

With the Wilson coefficients now fixed at the matching scale $\mu \sim M$ — the heavy-fermion threshold step Eq. (38.75) for the gauge coupling, and the Euler–Heisenberg couplings Eq. (38.88) for the photon EFT — the large logarithm $\ln(\mu/E)$ of Eq. (38.67) remains to be summed. That summation is the renormalization group *inside* the effective theory: the coefficients $C_i(\mu)$ are not constants but run, and operators of the same dimension mix as they do. Evolving them from the matching scale down to the low scale is the subject of Section 38.5, to which we now turn.

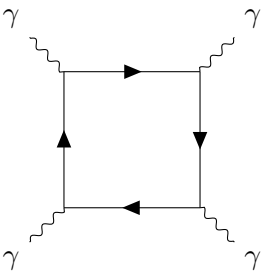

Figure 38.6: The light-by-light box: the electron loop with four external photons. At external photon momenta soft compared with m_e, its hard region (loop momentum $\sim m_e$, Taylor-expanded in the external momenta) is the matching coefficient of the dimension-eight operators in Eq. (38.77), evaluated in Theorem 38.11 to give the Euler–Heisenberg couplings Eq. (38.88). The three-photon amplitude vanishes by charge-conjugation (Furry's theorem), so this is the leading photon self-interaction.

38.5 Running and Mixing of Wilson Coefficients

Matching (Section 38.3) delivered the Wilson coefficients C_i at the heavy scale M: there, where the full theory and the effective theory are both valid, the two descriptions were forced to agree on a set of low-energy amplitudes, and the $C_i(M)$ were read off. But M is almost never the scale at which an experiment is performed. A rare meson decay, a low-energy scattering length, a precision electroweak observable — these live at a scale $E \ll M$, and a calculation done with the coefficients frozen at their matching values is riddled with large logarithms $\ln(M/E)$. Every loop in the effective theory that dresses an operator insertion produces such a logarithm, and at n loops a factor $\left(\frac{\lambda}{16\pi^2}\ln\frac{M}{E}\right)^n$ appears; when the hierarchy M/E is large the logarithm can overwhelm the loop factor and ruin naive perturbation theory. The cure is the one Part VI built for couplings and masses: run the parameters with the renormalization group. The novelty here is that the objects that run are not a single coupling but a whole tower of Wilson coefficients, and that under renormalization these coefficients do not run independently — they *mix*. The aim of this section is to derive the matrix renormalization-group equation that governs them, to compute a representative anomalous dimension in the scalar toy theory, and to integrate the equation so as to resum the tower of logarithms left behind by the matching.

38.5.1 Operator mixing under renormalization

Recall the structure established in Section 38.2. Below the heavy scale the dynamics is governed by an effective Lagrangian

$$\mathcal{L}_{\text{eff}} = \mathcal{L}_{\le 4} + \sum_i \frac{C_i}{\Lambda^{\,d_i-4}}\,\mathcal{O}_i, \tag{38.89}$$

where $\mathcal{L}_{\le 4}$ collects the relevant and marginal operators (for ϕ^4 theory, the kinetic, mass, and quartic terms of Eq. (24.161)), the $\mathcal{O}_i$ are the higher-dimension local operators built from the light fields and allowed by the symmetries, $d_i \ge 5$ is the mass dimension of $\mathcal{O}_i$, and the C_i are the dimensionless Wilson coefficients fixed by matching at $\mu = M$. The expansion parameter is E/Λ, and the cutoff scale Λ is identified with the mass M of the heavy states that were integrated out.

In a renormalizable theory a single coupling is renormalized multiplicatively (Section 22.3): the bare coupling is the renormalized one times a Z factor that absorbs the divergences. For the higher operators the same idea holds, but multiplication by a number becomes multiplication by a *matrix*. The reason is structural. When an operator $\mathcal{O}_j$ is inserted into a Green's function and the loop integrals are done, the ultraviolet divergence is a local polynomial in the external momenta, and locality forces it to have the form of *some* local operator of the same dimension built from the same fields. There is no symmetry principle that restricts the divergence to be proportional to $\mathcal{O}_j$ itself: any operator $\mathcal{O}_i$ carrying the same quantum numbers and the same (or lower) dimension can appear. A counterterm proportional to $\mathcal{O}_i$ is then required to cancel the divergence, and one says that $\mathcal{O}_j$ *mixes into* $\mathcal{O}_i$. The set of operators of a given dimension and symmetry therefore renormalizes as a closed multiplet.

Concretely, write the bare operators (built from bare fields) in terms of the renormalized ones through a matrix of renormalization constants,

$$\mathcal{O}_i^{(0)} = Z_{ij}\,\mathcal{O}_j, \qquad Z_{ij} = \delta_{ij} + \frac{1}{\bar{\varepsilon}}\,z_{ij}(\{g\}) + \cdots, \tag{38.90}$$

the ellipsis denoting higher poles, $\bar{\varepsilon}$ the $\overline{\text{MS}}$ pole of Eq. (24.55), and $\{g\}$ the couplings of $\mathcal{L}_{\le 4}$. The off-diagonal entries z_{ij} $(i \ne j)$ encode the mixing; they vanish at tree level and are generated by loops. In a mass-independent scheme such as $\overline{\text{MS}}$ the matrix Z has a crucial triangular property: an operator can mix only into operators of equal or *lower* dimension, never higher. Mixing into a strictly lower-dimension operator necessarily drags along an explicit factor of a dimensionful coupling (a mass, or the scale Λ) to make up the dimensions, so the genuinely dimensionless, scale-free part of the mixing matrix is block-diagonal in the operator dimension: operators of equal dimension mix among themselves through a pure number times a coupling. It is this equal-dimension block that carries the leading renormalization-group evolution, and we focus on it first.

38.5.2 The anomalous-dimension matrix and the coefficient RGE

Definition 38.12 (Anomalous-dimension matrix)**.** For a multiplet of operators renormalizing as in Eq. (38.90), the *anomalous-dimension matrix* is

$$\gamma_{ij} \;\equiv\; \big(Z^{-1}\big)_{ik}\,\mu\frac{\mathrm{d}}{\mathrm{d}\mu}\,Z_{kj} \;=\; \mu\frac{\mathrm{d}Z_{ij}}{\mathrm{d}\mu} + O(z^2). \tag{38.91}$$

It is the matrix generalization of the single-operator anomalous dimension of Theorems 23.12 and 24.2: the diagonal entry γ_{ii} is the rate at which $\mathcal{O}_i$ renormalizes itself, and γ_{ij} $(i \neq j)$ is the rate at which $\mathcal{O}_j$ feeds into $\mathcal{O}_i$.

The matrix γ is finite even though Z is divergent: the explicit $1/\bar{\varepsilon}$ in Eq. (38.90) is cancelled by the $\bar{\varepsilon}$ hidden in the μ-dependence of the couplings. Indeed, in $d = 4 - 2\varepsilon$ the bare coupling $\lambda_0 = \mu^{2\varepsilon} Z_\lambda \lambda$ enforces $\mu\,\mathrm{d}\lambda/\mathrm{d}\mu = -2\varepsilon\lambda + \beta_\lambda$ (Theorem 24.1), so acting with $\mu\,\mathrm{d}/\mathrm{d}\mu$ on a coefficient $z_{ij} \propto \lambda$ produces $z'_{ij}\,(-2\varepsilon\lambda)/\bar{\varepsilon}$, and the ε in the numerator cancels the $1/\bar{\varepsilon}$ to leave a finite, μ-independent number. This is the same mechanism by which the ϕ^4 beta function emerged finite from a divergent Z_λ in Chapter 24; the bookkeeping is reviewed in the worked example below.

We can now state the central result of this section, the equation that turns a set of matching coefficients into a prediction at the low scale.

Theorem 38.13 (Wilson-coefficient renormalization-group equation)**.** *Let the higher-dimension part of the effective Lagrangian be $\sum_i C_i\,\mathcal{O}_i$, with the operators renormalized as in Eq. (38.90). Demanding that the bare effective Lagrangian, and hence every physical correlator computed from it, be independent of the renormalization scale μ, the renormalized Wilson coefficients obey*

$$\mu\frac{\mathrm{d}C_i}{\mathrm{d}\mu} = \gamma_{ji}\,C_j, \tag{38.92}$$

with γ the anomalous-dimension matrix of Theorem 38.12. The coefficients run with the transpose *of the matrix that renormalizes the operators.*

Proof. The physical content of the effective Lagrangian resides in the combination $\sum_i C_i^{(0)}\mathcal{O}_i^{(0)}$ built from bare coefficients and bare operators; this combination is what appears in the action and is manifestly independent of the arbitrary scale μ introduced by renormalization. Substituting Eq. (38.90),

$$\sum_i C_i^{(0)}\mathcal{O}_i^{(0)} = \sum_{i,j} C_i^{(0)} Z_{ij}\,\mathcal{O}_j = \sum_j \Big(\sum_i C_i^{(0)} Z_{ij}\Big)\mathcal{O}_j. \tag{38.93}$$

For the coefficient of each renormalized operator $\mathcal{O}_j$ to be finite we identify the renormalized Wilson coefficient

$$C_j \;=\; \sum_i C_i^{(0)} Z_{ij} \qquad\Longleftrightarrow\qquad C = Z^{\top} C^{(0)}, \tag{38.94}$$

in matrix notation, with C the column of renormalized coefficients and $C^{(0)}$ the column of bare ones. The bare coefficients carry the physics fixed at the matching scale and are μ-independent: $\mu\,\mathrm{d}C^{(0)}/\mathrm{d}\mu = 0$. Inverting Eq. (38.94), $C^{(0)} = (Z^{\top})^{-1}C$, and differentiating,

$$0 = \mu\frac{\mathrm{d}C^{(0)}}{\mathrm{d}\mu} = \Big(\mu\frac{\mathrm{d}(Z^{\top})^{-1}}{\mathrm{d}\mu}\Big)C + (Z^{\top})^{-1}\,\mu\frac{\mathrm{d}C}{\mathrm{d}\mu}. \tag{38.95}$$

Use $\mu\,\mathrm{d}Z^{-1}/\mathrm{d}\mu = -Z^{-1}(\mu\,\mathrm{d}Z/\mathrm{d}\mu)Z^{-1} = -\gamma\,Z^{-1}$, which transposes to $\mu\,\mathrm{d}(Z^{\top})^{-1}/\mathrm{d}\mu = -(Z^{\top})^{-1}\gamma^{\top}$. Inserting this into Eq. (38.95) and multiplying on the left by $Z^{\top}$,

$$0 = -\gamma^{\top}C + \mu\frac{\mathrm{d}C}{\mathrm{d}\mu}, \tag{38.96}$$

which is Eq. (38.92) in components, $\mu\,\mathrm{d}C_i/\mathrm{d}\mu = \gamma_{ji}C_j$. □

Equation (38.92) is the Callan–Symanzik equation of the effective theory. Its derivation mirrors the one in Theorem 24.19 step for step: there, μ-independence of the bare n-point function forced a first-order equation for the renormalized Green's function with the field anomalous dimension γ_ϕ as the inhomogeneous term; here, μ-independence of the bare coefficients forces a first-order equation for the renormalized coefficients with the operator anomalous-dimension matrix as the generator. The single difference that matters in practice is that γ has become a matrix, because the basis of higher-dimension operators is not stable under renormalization: scale evolution rotates within it. One may verify the consistency of the two viewpoints directly: since a physical amplitude is $\mathcal{A} = \sum_i C_i\,\langle\mathcal{O}_i\rangle$ and is μ-independent, the running Eq. (38.92) of the coefficients is exactly compensated by the running of the renormalized matrix elements $\langle\mathcal{O}_i\rangle$, whose scale dependence is governed by the same γ with the opposite (untransposed) action. The coefficient and the operator carry equal and opposite anomalous dimensions, and only their product is physical — the hallmark of a renormalization-group statement.

38.5.3 Leading-logarithmic resummation

With the RGE in hand we evolve the coefficients from M down to the low scale. Write the couplings of $\mathcal{L}_{\le 4}$ collectively as g; the anomalous-dimension matrix depends on μ only through $g(\mu)$, so it is convenient to trade the scale for the running coupling. Using $\mu\,\mathrm{d}/\mathrm{d}\mu = \beta(g)\,\mathrm{d}/\mathrm{d}g$, Eq. (38.92) becomes $\beta(g)\,\mathrm{d}C/\mathrm{d}g = \gamma^{\top}(g)\,C$, with formal solution the path-ordered exponential

$$C(\mu) = \mathrm{P}\exp\left[\int_{g(M)}^{g(\mu)}\frac{\gamma^{\top}(g')}{\beta(g')}\,\mathrm{d}g'\right]C(M), \tag{38.97}$$

the ordering being necessary only when γ at different scales fails to commute with itself, which first happens beyond leading order. The structure is the matrix

version of the closed-form RG solution Eq. (24.188): the evolution operator is the exponential of the integrated anomalous dimension, and it resums an entire tower of logarithms into a finite factor.

The content of Eq. (38.97) is clearest in the diagonal case, which already arises whenever a single operator is multiplicatively renormalized or one works in the eigenbasis of γ. Take a gauge coupling, for which at one loop $\beta = -2\beta_0\,\alpha^2/(4\pi) + \cdots$ and the relevant eigen-anomalous dimension is $\gamma = \gamma_0\,\alpha/(4\pi) + \cdots$. Then $\gamma/\beta = -\gamma_0/(2\beta_0\,\alpha)$, and Eq. (38.97) integrates to the canonical leading-log power law,

$$C(\mu) = \left[\frac{\alpha(\mu)}{\alpha(M)}\right]^{-\gamma_0/2\beta_0} C(M). \tag{38.98}$$

A single, exact-looking power of the running coupling has replaced the divergent series $\sum_n \frac{1}{n!}\big(-\frac{\gamma_0\alpha}{4\pi}\ln\frac{M}{\mu}\big)^n$ of fixed-order logarithms: this is what "resumming the leading logs" means. Expanding Eq. (38.98) to first order reproduces the one-loop term $C(M)\big[1 - \frac{\gamma_0}{2\beta_0}\ln\frac{\alpha(\mu)}{\alpha(M)}\big] \simeq C(M)\big[1 - \frac{\gamma_0\alpha}{4\pi}\ln\frac{M}{\mu}\big]$, the very logarithm that the matching of Section 38.3 would have left uncancelled had we frozen the coefficient at M.

Physical Insight

Equation (38.98) crystallizes the way an effective field theory organizes its predictions as a *double expansion*. Schematically, any EFT amplitude is

$$\mathcal{A} \;\sim\; \sum_{n\geq 0}\Big(\frac{E}{\Lambda}\Big)^n \sum_{L\geq 0}\Big(\frac{g^2}{16\pi^2}\Big)^L \times (\text{logarithms, resummed by the RG}). \tag{38.99}$$

The first sum is the *operator* expansion: the power of E/Λ counts the dimension of the operators retained, and is controlled by power counting and the truncation of the operator basis. The second sum is the *loop* expansion in the light couplings, which generates the logarithms that the renormalization group sums to all orders into ratios of running couplings. The two expansions are independent. One improves the accuracy in E/Λ by keeping higher operators and matching them; one improves the accuracy in $g^2/16\pi^2$ by computing more loops of matching and running. A complete EFT prediction is the product of three ingredients — matching at M, running to E, and truncation at a chosen order in E/Λ — and this section has supplied the middle one.

38.5.4 Scalar ϕ^4 theory: running and mixing of the dimension-six coefficient

We now make all of this concrete in the scalar toy EFT, computing the one-loop running of its leading higher-dimension coefficient with exactly the $\overline{\text{MS}}$ machinery used for λ in Chapter 24. Recall (Section 38.2) that integrating a heavy scalar out of the $\mathbb{Z}_2$-symmetric theory leaves, beyond the renormalizable Lagrangian of Eq. (24.161), the leading irrelevant operator

$$\mathcal{L}_{\text{eff}} = \tfrac{1}{2}(\partial_\mu\phi)(\partial^\mu\phi) - \tfrac{1}{2}m^2\phi^2 - \frac{\lambda}{4!}\phi^4 - \frac{C_6}{6!}\frac{\phi^6}{\Lambda^2}, \qquad \mathcal{O}_6 \equiv \phi^6, \tag{38.100}$$

with ϕ^6 the unique dimension-six operator allowed by the symmetry once the equations of motion and integration by parts are used to eliminate redundant structures. We compute its anomalous dimension at one loop.

Worked Example 38.14 (One-loop anomalous dimension of ϕ^6 and its leading-log evolution)**. The combinatorial lemma.** The only one-loop divergence linear in the quartic coupling λ that renormalizes a composite operator ϕ^n comes from a single graph topology: two of the operator's n legs are contracted into a loop through one $\lambda\phi^4/4!$ vertex, whose remaining two legs become external, while the other $n-2$ operator legs are spectators (Fig. 38.7, left). The loop is the scalar bubble

$$\int \frac{\mathrm{d}^d\ell}{(2\pi)^d}\,\frac{i}{\ell^2 - m^2 + i\epsilon}\,\frac{i}{(\ell+P)^2 - m^2 + i\epsilon} = -\frac{i}{16\pi^2}\,\frac{1}{\bar{\epsilon}} + \text{finite}, \tag{38.101}$$

the same integral whose $\overline{\text{MS}}$ value was assembled in Eq. (24.55). Because every term in this graph except the choice of which leg-pair enters the loop is identical regardless of n, the divergent renormalization of ϕ^n is simply $\binom{n}{2}$ — the number of leg-pairs — times the renormalization of ϕ^2.

We verify the claim by carrying out the Wick contractions explicitly. Insert $\phi^n(0)$ and contract it, together with one factor of $i(-\frac{\lambda}{4!})\int \mathrm{d}^4y\,\phi(y)^4$, in the bubble topology. The count factorizes. First choose which two of the n operator legs enter the loop: $\binom{n}{2}$ ways. Join this pair to the vertex by contracting each chosen leg with one of the four vertex fields; the two operator legs can be matched to two of the four vertex fields in $\binom{4}{2}\cdot 2! = 4\cdot 3 = 12$ ordered ways. The remaining two vertex fields and the $n-2$ spectator operator legs are then routed to the external points, a routing structurally identical for every n. Only the first factor depends on n, so the divergent weight is $\binom{n}{2}\cdot 12$: for $n=2$ it is $\binom{2}{2}\cdot 12 = 12$ and for $n=6$ it is $\binom{6}{2}\cdot 12 = 180$, in the ratio $\binom{6}{2}/\binom{2}{2} = 180/12 = 15$. This confirms the lemma.

Anchoring the normalization. The ϕ^2 insertion is nothing but the mass operator, whose anomalous dimension was computed in the Callan–Symanzik layer of ϕ^4 theory:

$$\gamma_{\phi^2} = \frac{\lambda}{16\pi^2} + O(\lambda^2), \tag{38.102}$$

the same number as the mass-squared running rate γ_{m^2} of Eq. (24.78). Explicitly, the ϕ^2 insertion requires the operator renormalization $Z_{\phi^2} = 1 - \frac{\lambda}{32\pi^2\bar{\varepsilon}} + \cdots$; differentiating with Eq. (38.91) and using $\mu\,\mathrm{d}\lambda/\mathrm{d}\mu = -2\varepsilon\lambda + O(\lambda^2)$ to kill the pole,

$$\gamma_{\phi^2} = \mu\frac{\mathrm{d}}{\mathrm{d}\mu}\left(-\frac{\lambda}{32\pi^2\bar{\varepsilon}}\right) = -\frac{1}{32\pi^2\bar{\varepsilon}}\,(-2\varepsilon\lambda) = \frac{\lambda}{16\pi^2}, \tag{38.103}$$

the ε in the numerator cancelling the $1/\bar{\varepsilon}$ exactly as advertised after Eq. (38.91).

The result for ϕ^6. By the lemma, the dimension-six operator renormalizes with $Z_{66} = 1 - \binom{6}{2}\frac{\lambda}{32\pi^2\bar{\varepsilon}} = 1 - \frac{15\lambda}{32\pi^2\bar{\varepsilon}}$, hence

$$\boxed{\gamma_{\phi^6} = \binom{6}{2}\frac{\lambda}{16\pi^2} = \frac{15\lambda}{16\pi^2} + O(\lambda^2).} \tag{38.104}$$

This is the representative anomalous dimension of the scalar EFT. By Theorem 38.13 the Wilson coefficient runs with the same number (the 1×1 block is its own transpose),

$$\mu\frac{\mathrm{d}C_6}{\mathrm{d}\mu} = \gamma_{\phi^6}\,C_6 = \frac{15\lambda}{16\pi^2}\,C_6. \tag{38.105}$$

Leading-log evolution. Trade μ for the running coupling using the ϕ^4 beta function $\beta_\lambda = 3\lambda^2/16\pi^2$ of Eq. (24.46):

$$\frac{\mathrm{d}C_6}{C_6} = \frac{\gamma_{\phi^6}}{\beta_\lambda}\,\mathrm{d}\lambda = \frac{15\lambda/16\pi^2}{3\lambda^2/16\pi^2}\,\mathrm{d}\lambda = 5\,\frac{\mathrm{d}\lambda}{\lambda}, \tag{38.106}$$

which integrates to the leading-log resummed coefficient

$$C_6(\mu) = C_6(M)\left[\frac{\lambda(\mu)}{\lambda(M)}\right]^5, \qquad 5 = \frac{\gamma_{\phi^6}}{\beta_\lambda} = \frac{15}{3}. \tag{38.107}$$

This is the scalar instance of the diagonal power law Eq. (38.98), with the role of α played by λ and the exponent fixed by the ratio of the two one-loop coefficients. Since the ϕ^4 coupling is marginally relevant and decreases toward the infrared (Eq. (24.210)), the factor $[\lambda(\mu)/\lambda(M)]^5$ shrinks the coefficient as one runs down to the low scale — the dimension-six interaction is even more strongly suppressed at low energies than the bare power counting suggested.

Resummation of the matching logarithm. It remains to check that Eq. (38.107) resums precisely the logarithm that the matching of Section 38.3 left behind. Using the running coupling Eq. (24.210), expand for $\mu < M$: $\lambda(\mu)/\lambda(M) \simeq 1 - \frac{3\lambda}{16\pi^2}\ln\frac{M}{\mu}$, so

$$C_6(\mu) \simeq C_6(M)\left[1 - \frac{3\lambda}{16\pi^2}\ln\frac{M}{\mu}\right]^5 \simeq C_6(M)\left[1 - \frac{15\lambda}{16\pi^2}\ln\frac{M}{\mu}\right]. \tag{38.108}$$

The bracketed first-order term is exactly the one-loop logarithm that a fixed-order EFT calculation with the matching value $C_6(M)$ produces: the bubble graph

Fig. 38.7 dresses the ϕ^6 vertex with $\binom{6}{2} = 15$ quartic insertions, each contributing $-\frac{\lambda}{16\pi^2}\ln\frac{M}{\mu}$ once the $1/\bar{\varepsilon}$ pole is removed by operator renormalization and μ is set to the matching scale. The renormalization group has promoted that single logarithm into the full tower $(\frac{15\lambda}{16\pi^2}\ln\frac{M}{\mu})^n/n!$, summed into the fifth power of the coupling ratio. Matching computes $C_6(M)$; Eq. (38.107) carries it to the scale of measurement.

(a) $\mathcal{O}_6 \to \mathcal{O}_6$ (b) $\mathcal{O}_6 \to \mathcal{O}_4$

Figure 38.7: One-loop renormalization of the dimension-six operator $\mathcal{O}_6 = \phi^6$ (square vertex) in the scalar EFT. (a) Self-renormalization: two of the six legs are dressed by a quartic vertex through the bubble of Eq. (38.101), leaving six external legs; there are $\binom{6}{2} = 15$ choices of leg-pair, giving $\gamma_{\phi^6} = 15\lambda/16\pi^2$. (b) Mixing down: a self-contraction of two legs forms a massive tadpole, leaving four external legs and renormalizing the dimension-four coupling with an explicit factor m^2/Λ^2.

38.5.5 Mixing down, and why the matrix is triangular

The computation above isolated the equal-dimension (here, one-dimensional) block of the anomalous-dimension matrix. The dimension-six operator also generates divergences proportional to operators of *lower* dimension, and it is worth seeing why these do not spoil the clean power law Eq. (38.107) and how they fit the triangular structure asserted after Eq. (38.90).

Self-contracting two of the six legs of ϕ^6 into a single loop — a tadpole, Fig. 38.7(b) — leaves the dimension-four operator ϕ^4. The loop is the massive tadpole

$$\int \frac{\mathrm{d}^d\ell}{(2\pi)^d}\,\frac{i}{\ell^2 - m^2 + i\epsilon} = \frac{m^2}{16\pi^2}\,\frac{1}{\bar{\varepsilon}} + \text{finite}, \tag{38.109}$$

and there are again $\binom{6}{2} = 15$ leg-pairs to contract, so ϕ^6 mixes into ϕ^4 with a divergence proportional to $C_6\, m^2/\Lambda^2$. Contracting two independent pairs leaves ϕ^2, mixing ϕ^6 into the mass operator with a coefficient proportional to $C_6\, m^4/\Lambda^2$ (or $C_6\,\Lambda^0$ once the quadratically divergent piece is tracked in a momentum cutoff; in $\overline{\text{MS}}$ the divergence is the logarithmic one shown). The decisive point is the explicit factor of m^2: in the mass-independent scheme $\overline{\text{MS}}$ the only dimensionful quantity that can appear in a counterterm is an explicit coupling of the Lagrangian, and lowering the operator dimension by two units

therefore costs one power of m^2. The anomalous-dimension matrix in the basis (ϕ^2, ϕ^4, ϕ^6) is consequently lower triangular,

$$\gamma = \begin{pmatrix} \gamma_{22} & 0 & 0 \\ * \dfrac{m^2}{\Lambda^2} & \gamma_{44} & 0 \\ * \dfrac{m^4}{\Lambda^2} & * \dfrac{m^2}{\Lambda^2} & \gamma_{66} \end{pmatrix}, \tag{38.110}$$

with the pure numbers $\gamma_{22} = \lambda/16\pi^2$, $\gamma_{66} = 15\lambda/16\pi^2$ on the diagonal and the mass-suppressed entries below it. Because the matrix is triangular, its eigenvalues are the diagonal entries, and the evolution of C_6 decouples from the lower operators up to corrections suppressed by m^2/Λ^2 — which are formally of the same order as the higher operators we have already truncated. To the accuracy at which the dimension-six operator is being kept, the running of its coefficient is governed by the single diagonal entry Eq. (38.104), and Eq. (38.107) is exact at leading-log order.

In a richer theory the equal-dimension block is genuinely a non-diagonal matrix: several operators of the same dimension share the same quantum numbers and rotate into one another under the flow. The Warsaw-basis dimension-six operators of the Standard Model effective theory are the working example, and their large anomalous- dimension matrix is the engine of precision constraints on physics above the electroweak scale; we take it up in Chapter 40. The scalar toy has shown the mechanism in its simplest incarnation, where the matrix collapses to a number but the logic — bare μ-independence, an operator renormalization matrix, a transposed coefficient RGE, and a resummed power of the running coupling — is identical.

With matching (Section 38.3), running (Eq. (38.92)), and truncation (Section 38.2) now all in hand, the effective field theory is a complete predictive instrument: a finite set of coefficients fixed at the high scale, evolved to the scale of measurement, and read off to a chosen order in E/Λ. What remains is to step back and ask what this machinery teaches about the operators it does *not* suppress — the relevant operators, the mass terms, whose coefficients grow toward the infrared and whose ultraviolet sensitivity is the subject of naturalness, to which we now turn.

38.6 Naturalness, Relevant Operators, and the Hierarchy Problem

The running of Section 38.5 completed the predictive loop: a heavy theory matched at Λ, organized by power counting, and run down to the scale of an experiment yields finite, scheme-independent predictions for any process below Λ. The machinery works. What remains is to face squarely a fact it has been

quietly presupposing. Every coefficient we have run is a number we read off at the matching scale; the renormalization group propagates it but does not predict it. For the irrelevant (higher-dimension) operators this is no embarrassment — their coefficients are suppressed by powers of E/Λ and their precise values barely matter at low energy, which was the whole content of the decoupling theorem. The relevant operators are another story entirely. They are the directions in theory space that the Wilsonian flow of Chapter 23 taught us *grow* toward the infrared, the directions that must be tuned to land on a fixed point's critical surface. In an EFT with a physical heavy scale, that tuning is no longer an abstract statement about an idealized flow: it is a tuning of the light theory's parameters against the heavy mass, and whether or not it is innocuous decides whether the light theory makes sense on its own terms. This section reads the relevant operators of Chapter 23 back as the ultraviolet-sensitive directions of the EFT, states 't Hooft's criterion for when their smallness is natural, and uses the two benchmark theories to exhibit the criterion's two faces: the scalar mass, which nothing protects, and the electron mass, which chiral symmetry does. It closes on the two relevant operators of the Standard-Model EFT for which the criterion fails and no protection is known — the hierarchy and cosmological-constant problems — stated as precise EFT-matching facts and dated, honestly, as open.

38.6.1 Relevant operators as the ultraviolet-sensitive directions

We begin by translating the language of Chapter 23 into the language of matching. The classification of Theorem 23.23 sorted every local operator by the eigenvalue y_a of the linearized flow around a fixed point: relevant ($y_a > 0$), marginal ($y_a = 0$), irrelevant ($y_a < 0$). For the free (Gaussian) fixed point that organizes a weakly coupled EFT, y_a is the canonical statement $y_a = d - \Delta_a$, with Δ_a the engineering dimension of the operator $\mathcal{O}_a$; equivalently, writing the action as $\int d^d x \sum_a g_a \mathcal{O}_a$, the coupling g_a has mass dimension $[g_a] = d - \Delta_a = y_a$. A *relevant* coupling is therefore one with positive mass dimension. In four dimensions there are exactly three relevant or marginal operator types available to a theory of scalars and fermions: the identity operator $\mathbf{1}$ ($\Delta = 0$, so $[g] = 4$), a scalar mass operator ϕ^2 ($\Delta = 2$, $[g] = 2$), and the dimensionless marginal couplings ($\Delta = 4$, $[g] = 0$) — gauge, Yukawa, and quartic-scalar couplings. Everything else is irrelevant.

The reason the relevant couplings are dangerous is contained in Eq. (23.177), which we now reread. There the continuum limit fixed each relevant coupling at the cutoff to be

$$u_i(\Lambda) \;=\; \Big(\frac{\mu}{\Lambda}\Big)^{y_i}\,\bar{u}_i, \qquad y_i > 0, \tag{38.111}$$

with $\bar{u}_i$ the finite renormalized coupling and μ the low scale. Inverting: the renormalized value is $\bar{u}_i = (\Lambda/\mu)^{y_i}\, u_i(\Lambda)$, an *amplification* of the bare value by a positive power of the large ratio Λ/μ. To keep $\bar{u}_i$ finite and small as Λ is raised,

the bare $u_i(\Lambda)$ must be dialled toward zero with matching precision. In the Wilsonian setting of Chapter 23 this was the statement that the critical surface (Theorem 23.24) has codimension equal to the number of relevant directions, and reaching it costs one fine-tuning per relevant operator. In the EFT setting the cutoff Λ is not a regulator to be removed but a physical scale — the mass M of states we integrated out — and the powers of Λ/μ become powers of the physical hierarchy M/μ between the heavy and light scales. The same arithmetic, now with $\Lambda \to M$ a real threshold, says: a relevant coupling in the low-energy EFT receives additive contributions from the heavy sector scaling as M^{y_i}, and unless those contributions cancel against the bare value to a part in $(M/\mu)^{y_i}$, the light coupling is dragged up to the heavy scale.

This is what *ultraviolet sensitivity* means precisely. Differentiate the low-energy parameter with respect to the heavy mass: for a relevant coupling of mass dimension $y_i > 0$, dimensional analysis and decoupling together force

$$g_i^{\text{light}} \;=\; g_i^{\text{bare}} \;+\; c_i\, M^{y_i} \;+\; (\text{logs}), \tag{38.112}$$

with c_i a pure number fixed by the heavy couplings. The heavy scale enters as a positive power. By contrast a marginal coupling ($y_i = 0$) can depend on M only logarithmically, $\sim \ln(M/\mu)$, because there is no dimensionful prefactor to carry a power; and an irrelevant coupling's heavy-scale dependence is suppressed, not enhanced. The relevant operators are thus the unique directions along which the low-energy theory *remembers* the heavy scale with a power rather than a logarithm. They are the price of the decoupling theorem of Section 38.4.2: decoupling protects observables built from irrelevant operators, but it says nothing kind about the relevant ones, whose coefficients are precisely the renormalization conditions decoupling lets us choose by hand.

Caution

Equation Eq. (38.112) is sometimes phrased with M replaced by the regulator cutoff Λ, giving the notorious "quadratic divergence" $\delta m^2 \sim \Lambda^2$ of a scalar mass in a hard-cutoff scheme. The power-law cutoff dependence is a regulator artifact: in dimensional regularization there is no Λ^2 at all, only poles in ε multiplied by the *physical* masses in the loop. What is physical, and scheme-independent, is the dependence on a genuine heavy *threshold* M — the mass of a particle that really exists. The naturalness problem is the sensitivity to physical heavy scales exhibited in Eq. (38.112), not the sensitivity to the regulator. We will compute it in dimensional regularization, where the physical M^2 is manifest and no spurious Λ^2 can hide.

38.6.2 't Hooft's naturalness criterion

The arithmetic of Eq. (38.112) appears to condemn every small relevant coupling: if $\bar{u}_i \ll M^{y_i}$, the bare value must cancel the additive heavy contribution to absurd precision. Yet nature contains small relevant couplings that are evidently not fine-tuned — the electron mass is fifteen orders of magnitude below the Planck scale and no one loses sleep over it. The resolution is that Eq. (38.112) assumed the constant c_i is generic. A symmetry can force $c_i = 0$, and then the heavy-scale contribution is not additive but multiplicative in the small coupling itself. This is the content of the criterion 't Hooft elevated to a working principle.

Definition 38.15 (Technical naturalness)**.** A dimensionful or dimensionless parameter g in an effective Lagrangian is *technically natural* (in 't Hooft's sense) if the limit $g \to 0$ enhances the symmetry of the theory: the action at $g = 0$ is invariant under a symmetry that the action at $g \neq 0$ is not. Equivalently, g is natural if it is the unique (up to normalization) coupling of an operator that breaks an otherwise exact symmetry, so that every radiative correction to g must itself break that symmetry and is therefore proportional to g,

$$\delta g \;=\; g \times f\!\left(\text{couplings},\ \ln\frac{M}{\mu}\right), \tag{38.113}$$

with f at most logarithmically dependent on the heavy scale. A small g is then *stable* under the flow: the heavy scale enters only through the slowly varying logarithm in Eq. (38.113), never as an additive power as in Eq. (38.112).

The logic deserves to be made explicit, because it is the conceptual hinge of the whole subject. Suppose the $g = 0$ theory has an exact symmetry S. Then the full quantum effective action computed in that theory is S-invariant: the symmetry is respected order by order in perturbation theory, since the Feynman rules of the $g = 0$ theory carry no S-violating vertex. Turning g back on, g is the coefficient of the unique S-violating term; any quantum-generated S-violating quantity, δg included, must be built from at least one insertion of that vertex, hence carries at least one power of g. Therefore $\delta g \propto g$, which is Eq. (38.113). The would-be additive piece $c_i M^{y_i}$ of Eq. (38.112) is S-symmetric (it does not vanish as $g \to 0$), so it is forbidden: $c_i = 0$. The symmetry does not make g small — it explains why a small g *stays* small once chosen. Naturalness is a statement about radiative stability, not about the origin of the value.

Physical Insight

't Hooft's criterion converts the abstract codimension count of Theorem 23.24 into a usable principle. Each relevant direction generically costs one fine-tuning to keep the corresponding low-energy coupling small. A symmetry that is restored when the coupling vanishes *lowers the codimen-*

sion: along that direction the critical surface is reached not by tuning but by symmetry, because the flow of an S-violating coupling cannot leave the S-symmetric surface $g = 0$ on its own. Naturalness is the question of whether each relevant coupling of the Standard Model sits on such a protected surface. For all but two, the answer is yes.

We now demonstrate the two outcomes on the benchmark theories. ϕ^4 theory supplies the unprotected case: the scalar mass, a relevant coupling that no symmetry of ϕ^4 shields, suffers the full additive sensitivity of Eq. (38.112). QED supplies the protected case: the electron mass, equally relevant, is shielded by chiral symmetry and obeys the multiplicative law Eq. (38.113).

38.6.3 The unprotected scalar mass (ϕ^4)

Return to the heavy-scalar matching of Section 38.3, where the light real scalar ϕ of ϕ^4 theory was coupled to a heavy real scalar Φ of mass $M \gg m_\phi$ through the renormalizable portal interaction

$$\mathcal{L} \supset \tfrac{1}{2}(\partial\phi)^2 - \tfrac{1}{2}m_\phi^2\phi^2 + \tfrac{1}{2}(\partial\Phi)^2 - \tfrac{1}{2}M^2\Phi^2 - \frac{\lambda_{\phi\Phi}}{4}\,\phi^2\Phi^2, \tag{38.114}$$

the dimensionless coupling $\lambda_{\phi\Phi} > 0$ being one of the marginal couplings of the combined theory. Integrating Φ out at one loop, as we did for the irrelevant operators in Section 38.3, also feeds the relevant operator ϕ^2: the heavy field circulates in a loop attached to the light scalar's two-point function. We compute that contribution in full, because it is the hierarchy problem made arithmetic.

Worked Example 38.16 (The heavy-scalar tadpole and the quadratic mass sensitivity)**.** The vertex from $-\frac{1}{4}\lambda_{\phi\Phi}\,\phi^2\Phi^2$ joins two ϕ and two Φ lines; its Feynman rule is $-i\lambda_{\phi\Phi}$, the $\frac{1}{4}$ cancelling the $2! \times 2!$ ways of attaching the identical pairs of legs. The single one-loop graph correcting the ϕ propagator contracts the two Φ legs of one vertex into a loop (Fig. 38.8), leaving the two ϕ legs external. With one internal heavy propagator and a symmetry factor $\frac{1}{2}$ for the interchange of the two ends of that propagator, the one-particle-irreducible two-point function receives

$$-i\,\Sigma_\phi \;=\; (-i\lambda_{\phi\Phi}) \cdot \frac{1}{2}\int \frac{d^dk}{(2\pi)^d}\,\frac{i}{k^2 - M^2 + i\varepsilon}. \tag{38.115}$$

The loop is the standard massive tadpole integral. Using the scalar master of Eq. (D.77) at $n = 1$,

$$\int \frac{d^dk}{(2\pi)^d}\,\frac{1}{(k^2 - M^2 + i\varepsilon)} \;=\; \frac{-i}{(4\pi)^{d/2}}\,\Gamma\!\left(1 - \tfrac{d}{2}\right)\left(M^2\right)^{d/2-1}, \tag{38.116}$$

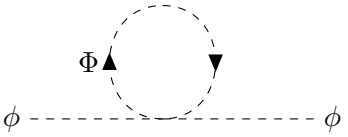

Figure 38.8: The one-loop heavy-scalar correction to the light scalar's mass. The quartic portal vertex $-\frac{1}{4}\lambda_{\phi\Phi}\phi^2\Phi^2$ attaches a closed loop of the heavy field Φ (mass M) to the ϕ two-point function. The graph evaluates to $\delta m_\phi^2 \sim \lambda_{\phi\Phi} M^2/32\pi^2$, additive in the heavy scale: the unprotected relevant direction of ϕ^4 theory.

and setting $d = 4 - 2\varepsilon$, so that $1 - \frac{d}{2} = -1 + \varepsilon$ and $(M^2)^{d/2-1} = M^2(M^2)^{-\varepsilon}$, the Laurent expansion $\Gamma(-1+\varepsilon) = -\frac{1}{\varepsilon} + \gamma_E - 1 + O(\varepsilon)$ together with the $\overline{\text{MS}}$ collection $\frac{1}{\bar\varepsilon} = \frac{1}{\varepsilon} - \gamma_E + \ln 4\pi$ (Eq. (19.79)) and the restored scale $\mu^{2\varepsilon}$ gives

$$\int \frac{d^d k}{(2\pi)^d} \frac{\mu^{2\varepsilon}}{k^2 - M^2 + i\varepsilon} \;=\; \frac{i\,M^2}{16\pi^2}\left[\frac{1}{\bar\varepsilon} + 1 - \ln\frac{M^2}{\mu^2}\right] + O(\varepsilon). \tag{38.117}$$

Insert Eq. (38.117) into Eq. (38.115), multiply the explicit i in the propagator numerator, and use $(-i)\cdot\frac{1}{2}\cdot i \cdot i = +\frac{i}{2}$:

$$\Sigma_\phi \;=\; -\frac{\lambda_{\phi\Phi}\,M^2}{32\pi^2}\left[\frac{1}{\bar\varepsilon} + 1 - \ln\frac{M^2}{\mu^2}\right]. \tag{38.118}$$

The 1PI two-point function is $\Gamma^{(2)}(p^2) = p^2 - m_\phi^2 - \Sigma_\phi$, so the physical light mass-squared, the location of the pole, is shifted by $\delta m_\phi^2 = \Sigma_\phi$ at $p^2 \simeq m_\phi^2$ (the p^2-independence of Eq. (38.118) reflects that a tadpole carries no external-momentum dependence). The pole $1/\bar\varepsilon$ is removed by the ϕ^2 counterterm exactly as in the renormalization of ϕ^4 in Section 22.6; the matching of Section 38.3 fixes the renormalized coefficient at $\mu = M$. What survives, and cannot be subtracted away, is the finite physical piece set by the heavy mass:

$$\boxed{\delta m_\phi^2 \;\sim\; \frac{\lambda_{\phi\Phi}}{32\pi^2}\,M^2} \tag{38.119}$$

(up to the $O(1)$ finite constant and the slowly varying logarithm). The light scalar's mass-squared is pulled up to the heavy scale, weighted only by the loop factor $\lambda_{\phi\Phi}/32\pi^2$.

Now ask 't Hooft's question of the scalar mass. Does $m_\phi \to 0$ enhance a symmetry of Eq. (38.114)? It does not. At $m_\phi = 0$ the ϕ sector is classically scale-invariant, but scale invariance is not a symmetry of the quantum theory — it is broken by the running of the marginal coupling, the dilatation current acquiring an anomaly proportional to the beta function (the trace anomaly of Chapter 24). No other symmetry appears: the operator ϕ^2 is a singlet under

the only internal symmetry the theory has, the $\mathbb{Z}_2$ of $\phi \to -\phi$, which leaves ϕ^2 invariant and so cannot forbid it. The mass term is not the unique breaker of any exact symmetry; it is just there, allowed by everything. The criterion Theorem 38.15 therefore returns "not protected," and Eq. (38.119) is the expected verdict: the correction is additive in M^2, not multiplicative in m_ϕ^2.

The fine-tuning is now quantitative. Suppose we want a light scalar with $m_\phi \sim v$ (think of the electroweak scale, $v \approx 246\,\mathrm{GeV}$) while the heavy threshold sits at $M \sim 10^{16}\,\mathrm{GeV}$ (a grand-unification or near-Planckian scale) with an $O(1)$ portal $\lambda_{\phi\Phi} \sim 1$. Then $\delta m_\phi^2 \sim M^2/32\pi^2 \sim 10^{30}\,\mathrm{GeV}^2$, whereas the physical $m_\phi^2 \sim v^2 \sim 6 \times 10^4\,\mathrm{GeV}^2$. The bare mass-squared and the loop contribution must cancel so that

$$\frac{m_\phi^2}{\delta m_\phi^2} \;\sim\; \frac{v^2}{M^2/32\pi^2} \;\sim\; 10^{-26}, \tag{38.120}$$

a cancellation accurate to one part in 10^{26}, with no symmetry to enforce it and no reason it should survive the next order. This is the *hierarchy problem*: the light scalar mass is the unprotected relevant direction of the Standard-Model EFT, and keeping it far below any heavy threshold to which it couples requires a tuning of exactly the codimension-one form that Theorem 23.24 predicted, performed by hand at every order.

38.6.4 Chiral protection of the fermion mass (QED)

Contrast the electron. Its mass m_e is equally a relevant coupling — the operator $\bar\psi\psi$ has dimension three, $[m_e] = 1 > 0$ — and a heavy charged state to which the electron couples would, by the same dimensional logic, threaten an additive correction $\delta m_e \sim M$. We compute the one-loop correction within QED itself, where the relevant heavy scale is the regulator, and show that it is only logarithmic and strictly proportional to m_e. We then explain why, tracing the structure to chiral symmetry.

The one-loop electron self-energy was computed in full in Chapter 19; we recall its master form Eq. (19.76),

$$\Sigma_2(p) = \frac{e^2}{(4\pi)^{d/2}}\,\Gamma(\varepsilon)\,\mu^{2\varepsilon}\int_0^1 dx\,\big[(2-d)(1-x)\,\not{p} + d\,m_e\big]\,\Delta(x)^{-\varepsilon}, \tag{38.121}$$

with $\Delta(x) = -x(1-x)p^2 + x\,m_e^2 + (1-x)\mu_\gamma^2$ and the result organized as $\Sigma = A(p^2)\not{p} + B(p^2)\,m_e$. The physical mass shift is the value of the self-energy on shell, where the corrected propagator $i/(\not{p} - m_e - \Sigma)$ has its pole. Setting $\not{p} = m_e$,

$$\delta m_e \;=\; \Sigma_2(\not{p} = m_e) \;=\; \big[A(m_e^2) + B(m_e^2)\big]\,m_e. \tag{38.122}$$

The decisive feature is already visible in Eq. (38.121) before any integral is done: the A-term multiplies $\not{p} \to m_e$ and the B-term multiplies m_e outright, so *every*

term in δm_e carries an explicit factor of m_e. There is no piece of the self-energy proportional to a bare power of the cutoff with no m_e in front. To see the magnitude, take the divergent (large-logarithm) parts read off in Eqs. (19.80) and (19.81): with $\int_0^1 (1-x)\,dx = \frac{1}{2}$ and $\int_0^1 dx = 1$,

$$A_{\rm div} = -\frac{e^2}{16\pi^2}\,\frac{1}{\bar\varepsilon}, \qquad B_{\rm div} = +\frac{e^2}{4\pi^2}\,\frac{1}{\bar\varepsilon}, \tag{38.123}$$

so that

$$\delta m_e\big|_{\rm div} = (A_{\rm div}+B_{\rm div})\,m_e = \Big(-\tfrac{1}{16}+\tfrac{4}{16}\Big)\frac{e^2}{\pi^2}\,\frac{m_e}{\bar\varepsilon} = \frac{3e^2}{16\pi^2}\,\frac{m_e}{\bar\varepsilon} = \frac{3\alpha}{4\pi}\,\frac{m_e}{\bar\varepsilon}, \tag{38.124}$$

using $e^2 = 4\pi\alpha$. The $1/\bar\varepsilon$ pole is the dimensional-regularization avatar of a logarithm of the ultraviolet scale; in a theory cut off at Λ it stands for $\ln(\Lambda^2/m_e^2)$, so

$$\boxed{\delta m_e \;=\; \frac{3\alpha}{4\pi}\,m_e\,\ln\frac{\Lambda^2}{m_e^2} \;=\; \frac{3\alpha}{2\pi}\,m_e\,\ln\frac{\Lambda}{m_e}} \tag{38.125}$$

The correction is proportional to m_e and grows only as the logarithm of the heavy scale — exactly the multiplicative, log-mild form Eq. (38.113) of a protected coupling, and nothing like the additive M^2 of Eq. (38.119). Even taking Λ at the Planck scale, $\ln(\Lambda/m_e) \approx 50$, so $\delta m_e/m_e \approx (3\alpha/2\pi)\times 50 \approx 0.17$: a 17% correction, not a fine-tuning by twenty-six orders of magnitude.

It remains to explain *why* Eq. (38.121) had to come out proportional to m_e — to verify that this is symmetry, not luck. Apply 't Hooft's criterion. In the limit $m_e \to 0$ the QED Lagrangian $\bar\psi(i\not{D})\psi - \frac{1}{4}F^2$ acquires a symmetry it does not have at $m_e \neq 0$: the global chiral rotation

$$\psi \;\to\; e^{i\theta\gamma^5}\psi, \qquad \bar\psi \;\to\; \bar\psi\, e^{i\theta\gamma^5}, \tag{38.126}$$

under which the kinetic and gauge-interaction terms are invariant because γ^5 anticommutes with γ^μ (so $\bar\psi\, e^{i\theta\gamma^5}\not{D}\, e^{i\theta\gamma^5}\psi = \bar\psi\not{D}\psi$, the two factors of $e^{i\theta\gamma^5}$ cancelling through one γ^μ), while the mass term is not, since $\bar\psi\, e^{i\theta\gamma^5} e^{i\theta\gamma^5}\psi = \bar\psi\, e^{2i\theta\gamma^5}\psi \neq \bar\psi\psi$. Concretely, in the chirality basis of Eq. (11.82) the mass term reads

$$m_e\,\bar\psi\psi = m_e\,\bar\psi(P_L+P_R)\psi = m_e\,(\bar\psi_R\psi_L + \bar\psi_L\psi_R), \tag{38.127}$$

where $\psi_{L,R} = P_{L,R}\psi$ and the intertwining $\gamma^\mu P_L = P_R\gamma^\mu$ ensures the kinetic term stays chirality-diagonal, $\bar\psi i\not{D}\psi = \bar\psi_L i\not{D}\psi_L + \bar\psi_R i\not{D}\psi_R$. The mass is the *unique* operator in the renormalizable Lagrangian that links the left and right chiralities; it is precisely the breaker of the chiral symmetry Eq. (38.126), under which ψ_L and ψ_R carry opposite charge. This is the same structure that Chapter 11 identified at the level of the Dirac equation, where acting with P_L on $(\not{p} - m_e)u = 0$ gave $\not{p}(P_R u) = m_e(P_L u)$: the mass, and only the mass, couples the two handednesses.

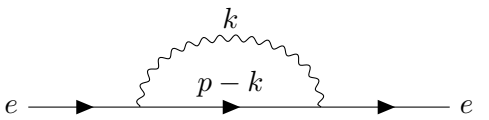

Figure 38.9: The one-loop electron self-energy of QED, Eq. (19.76). Because the only chirality-violating object in the QED Lagrangian is the mass m_e, the entire self-energy is proportional to m_e, and the correction $\delta m_e = \frac{3\alpha}{2\pi} m_e \ln(\Lambda/m_e)$ is multiplicative and only logarithmic: the chirally protected relevant direction.

By the argument under Theorem 38.15, every quantum correction to the chirality-violating operator $\bar{\psi}\psi$ must contain at least one insertion of the only chirality-violating vertex available, namely the mass itself. Hence $\delta m_e \propto m_e$, with the proportionality factor a dimensionless function of α and $\ln(\Lambda/m_e)$ — which is exactly Eq. (38.125). The factor of m_e in Eq. (38.121) is not algebraic accident but the chiral symmetry enforcing itself diagram by diagram. The smallness of the electron mass is technically natural; setting it to zero buys back an exact symmetry, and that symmetry forbids the additive correction that plagues the scalar. (We note for completeness that the chiral rotation Eq. (38.126) is anomalous in the quantum theory, Chapter 36; the anomaly affects the divergence of the chiral current but not the multiplicative renormalization of the mass, which follows from the symmetry of the perturbative vertices.) The contrast with Section 38.6.3 is the entire lesson: fermion masses are shielded by chirality, scalar masses by nothing.

38.6.5 The hierarchy problem, stated precisely

We can now phrase the hierarchy problem of the Standard Model as a clean EFT statement, with no rhetoric. The Standard Model contains exactly one elementary scalar, the Higgs doublet H, and its mass term $-\mu_H^2 H^\dagger H$ is a relevant operator of dimension two, $[\mu_H^2] = 2$. By Eq. (38.112) its coefficient is additively sensitive to the square of any heavier mass threshold to which H couples — and H couples to everything, through the top Yukawa, the electroweak gauge bosons, and itself. Reading off the largest contributions exactly as in Theorem 38.16 (now with the Standard-Model couplings in place of the toy $\lambda_{\phi\Phi}$), the one-loop shift to μ_H^2 from a threshold at scale M is

$$\delta\mu_H^2 \;\sim\; \frac{c}{16\pi^2}\, M^2, \qquad c = O(y_t^2,\ g^2,\ \lambda), \tag{38.128}$$

the direct analogue of Eq. (38.119). The measured Higgs mass fixes $\mu_H^2 \sim (88\,\text{GeV})^2$. If there is any new physics at a scale M — a grand-unified threshold near $10^{16}\,\text{GeV}$, or quantum gravity near $10^{18}\,\text{GeV}$ — coupled to the Higgs with $O(1)$ strength, then Eq. (38.128) drives μ_H^2 up to $M^2/16\pi^2$, and the observed value survives only by the tuning Eq. (38.120), a cancellation to one part in 10^{26}

or worse, repeated order by order. 't Hooft's criterion says this is unnatural unless a symmetry protects $H^\dagger H$. In the Standard Model none does: there is no chiral symmetry for a scalar, no gauge quantum number forbids the singlet $H^\dagger H$, and scale invariance is anomalous. The hierarchy problem is therefore the precise statement: *the Higgs mass is a relevant operator of the SM EFT with no protecting symmetry, so its smallness relative to any high threshold is technically unnatural.*

It is worth being honest about what this does and does not assert. It is not a logical inconsistency — the Standard Model is perfectly renormalizable and predictive with μ_H^2 taken as an input. It is a statement about the EFT's robustness: a relevant coupling tuned far from its natural scale signals, by the logic of Chapter 23, that the low-energy theory is sitting near a critical surface for no symmetry reason, which is precisely the kind of coincidence an underlying theory usually explains. The historically motivated explanations — supersymmetry, which makes the scalar a chiral superpartner so that fermionic chiral protection extends to it; compositeness, which makes the Higgs a pseudo-Goldstone boson protected by a shift symmetry; or large extra dimensions, which lower the true gravitational threshold M — are all attempts to supply the missing protecting symmetry or to remove the large M. As of the mid-2020s, the Large Hadron Collider has found no superpartners, no compositeness, and no extra dimensions at the TeV scale where naturalness most sharply expected them. The hierarchy problem is, at this writing, unsolved, and the absence of natural new physics at the weak scale is itself one of the central puzzles of the field.

38.6.6 The cosmological-constant problem

The most relevant operator of all is the one we have so far ignored because it does not affect particle scattering: the identity operator $\mathbf{1}$, with $\Delta = 0$ and coupling of mass dimension four. Its coefficient is the vacuum energy density, the cosmological constant,

$$\mathcal{L} \supset -\rho_{\text{vac}}\,\mathbf{1}, \qquad [\rho_{\text{vac}}] = 4, \tag{38.129}$$

the constant term in the Lagrangian. Being dimension-zero, it is the relevant direction with the *largest* eigenvalue $y = d = 4$, hence the most ultraviolet-sensitive coupling in the entire theory. By Eq. (38.112) every mass threshold M contributes additively at the quartic level: integrating out any field of mass M shifts the vacuum energy by the zero-point energy of its modes,

$$\delta\rho_{\text{vac}} \sim \pm\frac{M^4}{16\pi^2}, \tag{38.130}$$

with the sign set by the field's statistics (bosons and fermions contribute with opposite signs, the cancellation being exact only under unbroken supersymmetry).

Each threshold the Standard Model contains — the electron at m_e, the QCD scale, the electroweak scale, and any heavier physics up to $M_{\rm Pl}$ — pushes $\rho_{\rm vac}$ toward the fourth power of that scale. Taking the Planck scale as the ultimate cutoff gives $\rho_{\rm vac} \sim M_{\rm Pl}^4 \sim (10^{18}\,{\rm GeV})^4$.

The measured value, inferred from the accelerating expansion of the universe, is $\rho_{\rm vac} \sim (2 \times 10^{-3}\,{\rm eV})^4$. The discrepancy is

$$\frac{\rho_{\rm vac}^{\rm obs}}{M_{\rm Pl}^4} \;\sim\; 10^{-120}, \tag{38.131}$$

and even taking the most conservative cutoff at which we are confident new physics enters — the electroweak scale — the ratio is still $\sim 10^{-56}$. This is the *cosmological-constant problem*, and it is the hierarchy problem's far more severe cousin: a relevant operator whose coefficient is tuned against the heavy scales not to one part in 10^{26} but to one part in 10^{56} at the very least. The EFT statement is exactly parallel to Section 38.6.5: $\rho_{\rm vac}$ is the dimension-zero relevant operator of the SM EFT, additively sensitive to M^4 for every threshold M, and *no symmetry of the Standard Model protects it.* Supersymmetry would force the bosonic and fermionic zero-point energies in Eq. (38.130) to cancel, but supersymmetry, if realized at all, is broken at or above the TeV scale, leaving a residual $\rho_{\rm vac} \sim ({\rm TeV})^4$ still sixty orders of magnitude too large. Scale invariance would forbid Eq. (38.129) but is anomalous and, in any case, badly broken by every mass in the theory.

Caution

The cosmological-constant problem is genuinely outside the scope of the EFT methods of this chapter in one crucial respect: $\rho_{\rm vac}$ gravitates, and the EFT we have built does not include dynamical gravity. Within non-gravitational QFT the constant term in the Lagrangian is unobservable — it shifts the zero of energy and drops out of every S-matrix element — so naturalness has no purchase on it. It is only when the EFT is coupled to general relativity, where vacuum energy curves spacetime, that $\rho_{\rm vac}$ becomes a physical, measured quantity and the tuning Eq. (38.131) becomes a real problem. The cosmological-constant problem is thus the point where the EFT logic of relevant operators collides with the one interaction this book does not quantize, and it is open at a deeper level than the hierarchy problem.

As of the mid-2020s, the cosmological-constant problem has no accepted dynamical solution. The only widely discussed framework that reproduces the small observed value, the anthropic selection of a vacuum from a large landscape of possibilities, is not a symmetry explanation of the kind 't Hooft's criterion calls for, and its status is contested. We state the situation plainly: the two

relevant operators of the Standard-Model EFT that no symmetry protects — the Higgs mass and the vacuum energy — are tuned far below their natural scales for reasons not understood, and they constitute the two sharpest naturalness puzzles in fundamental physics. Honest closure of this chapter is to record them as open.

The naturalness language assembled here is the lens through which the rest of Part XI and its sequels are read. The bottom-up chiral effective theory of Chapter 39 is built precisely on a protecting symmetry — the spontaneously broken chiral symmetry of Theorem 29.1, whose Goldstone bosons are naturally light by the same mechanism that shields the electron mass — while the heavy-particle and SMEFT constructions of Chapter 40 organize the relevant and irrelevant operators of a known short-distance theory in the matching-and-running framework we have now completed. The unprotected directions catalogued here return as the central subject of the beyond-the-Standard-Model discussion of Chapter 35, where the proposed symmetries that would render the Higgs mass natural are examined against the experimental record.

Further reading

The founding statement that the most general symmetric Lagrangian reproduces the most general S-matrix is Weinberg's Weinberg [498], with the deeper logic developed across Weinberg [500, 501]; the Wilsonian roots are Polchinski [403], Wilson and Kogut [516]. Modern pedagogical accounts of the whole paradigm – matching, power counting, running, and naturalness – are the book of Burgess [99], the lectures of Manohar [335], and the concise text of Georgi [218]. The decoupling theorem is Appelquist and Carazzone [31]; Fermi's prescient effective theory is Fermi [189]; the one-loop photon effective Lagrangian computed here in the proper-time formalism originates with Heisenberg and Euler [262] and Schwinger [433]. 't Hooft's naturalness criterion is laid out in the Cargèse lectures of 't Hooft [465], and its modern EFT framing in Luty et al. [329], Polchinski [404]; the dimension-six SMEFT running that the matrix RGE of this chapter anticipates is carried out in Alonso et al. [20].

Chapter 39

Chiral Perturbation Theory

Quantum chromodynamics is asymptotically free: at short distances its coupling is small and the perturbative machinery of Chapters 25 and 27 applies verbatim. The infrared is the opposite world. Below a GeV the coupling is of order one, quarks and gluons are confined, and there is no small parameter in which to expand the dynamics of the only states that actually propagate—the hadrons. Yet the strong interactions at low energy are not intractable. They are governed, with quantitative precision, by a symmetry that QCD possesses but does not realize on its spectrum. This chapter builds the effective field theory that turns that symmetry into predictions: chiral perturbation theory, the archetype of an effective description of a strongly coupled microscopic theory, and the infrared face of the QCD story whose ultraviolet face we have already seen.

The logic is the effective-field-theory paradigm of Chapter 38 applied where it bites hardest. We begin from the chiral symmetry of massless QCD, $\mathrm{SU}(N_f)_L \times \mathrm{SU}(N_f)_R \times \mathrm{U}(1)_V$, with the singlet axial $\mathrm{U}(1)_A$ removed by the anomaly computed at the quark level in Chapter 36; we then read off, from the hadron spectrum and from the quark condensate, that this group is spontaneously broken to its vector subgroup. Goldstone's theorem (Chapter 29) then guarantees $N_f^2 - 1$ massless pseudoscalars—the pions for two flavors, the meson octet for three—and the nonlinear realization of the broken symmetry on the coset G/H dictates that the natural field is not a vector of scalars but a group-valued field $U(x)$. The symmetry alone fixes the form of the leading interactions; the unknown strong dynamics survives only as a finite list of constants. The condensate, the decay constant f_π, the explicit breaking by quark masses through the spurion method, the Gell-Mann–Oakes–Renner relation, and the Gell-Mann–Okubo mass formula all follow from the two-derivative Lagrangian before a single loop is computed.

What makes the expansion systematic, rather than merely a parametrization, is Weinberg's power-counting theorem. Each Goldstone derivative and each power of the pion mass counts as one unit of momentum, and the superficial degree of any diagram is fixed by a single topological formula: every loop and every

higher-derivative operator is suppressed by p^2/Λ_χ^2 with $\Lambda_\chi \sim 4\pi f_\pi$. Predictivity here comes from symmetry and dimensional analysis, not from weak coupling—the same relevant–irrelevant hierarchy of Chapters 23 and 38, operating inside a theory one cannot solve in its own variables. We cash this in twice: first at leading order, where the parameter-free Weinberg amplitude for $\pi\pi$ scattering yields s-wave scattering lengths that the data confirm and whose Adler zero (Chapter 29) appears automatically; then at next-to-leading order, where one-loop pion graphs restore unitarity, generate the non-analytic chiral logarithms, and force the order-p^4 Gasser–Leutwyler Lagrangian whose low-energy constants run with an RG equation of exactly the kind built in Chapter 24.

The chapter closes by repairing one omission the symmetry construction cannot see. Every operator built from U alone is invariant under an accidental intrinsic parity that QCD does not have, so the parity-even Lagrangian forbids processes with an odd number of pseudoscalars—most conspicuously $\pi^0 \to \gamma\gamma$. The missing piece is the Wess–Zumino–Witten term, the unique addition to the chiral action that cannot be written as the integral of a locally invariant density. Its coefficient is quantized to an integer by a topological argument, that integer is the number of colors N_c, and gauging it to electromagnetism reproduces the neutral-pion decay rate to within the experimental error—a low-energy weighing of $N_c = 3$ and the cleanest illustration in this book of 't Hooft anomaly matching (Chapter 37): the anomaly of Chapter 36, computed for quarks, reappears unchanged as an interaction of mesons.

39.1 The Chiral Symmetry of QCD and Its Spontaneous Breaking

The light mesons — the three pions, the four kaons, the eta — are the softest objects in the hadron spectrum, an order of magnitude lighter than the proton and dramatically lighter than every other meson. The thesis of this chapter, announced in the chapter introduction, is that this lightness is not an accident of QCD dynamics but the inevitable signature of spontaneously broken symmetry: the pseudoscalar octet is the pseudo-Goldstone manifold of Chapter 29, realized in a strongly coupled theory. To cash that claim we must first do something entirely kinematical, owing nothing to the strong coupling: identify precisely *which* symmetry the QCD Lagrangian has when the light quarks are massless, establish that one factor of it is destroyed by the anomaly of Chapter 36, and pin down the subgroup that the vacuum leaves intact. Only the breaking pattern $G \to H$ enters the Goldstone counting; the dynamics that *drive* the breaking are confined to a single nonperturbative input, the quark condensate, whose mere nonvanishing — not its value — does all the work. This section carries out that program and hands the next section a clean statement: the field content of low-energy QCD is exactly $N_f^2 - 1$ pseudoscalar Goldstone bosons, coordinates

on the coset $(\mathrm{SU}(N_f)_L \times \mathrm{SU}(N_f)_R)/\mathrm{SU}(N_f)_V$.

39.1.1 Massless QCD and its left–right decomposition

We begin from the QCD Lagrangian established as the QCD stage of Chapters 25 and 28 (Eq. (25.85)). Written for N_f quark flavors q_f, $f = 1, \dots, N_f$, each a Dirac field in the fundamental **3** of the gauge group $\mathrm{SU}(3)_c$ (color indices suppressed throughout, as they play no role in what follows), it reads

$$\mathcal{L}_{\mathrm{QCD}} = -\tfrac{1}{4} G^a_{\mu\nu} G^{a\,\mu\nu} + \sum_{f=1}^{N_f} \bar{q}_f (i \not{D} - m_f) q_f, \qquad D_\mu = \partial_\mu - i g\, A^a_\mu T^a, \tag{39.1}$$

with the field strength $G^a_{\mu\nu} = \partial_\mu A^a_\nu - \partial_\nu A^a_\mu + g f^{abc} A^b_\mu A^c_\nu$ and the conventions fixed once for the book in Chapter 25 (mostly-minus metric, Hermitian generators with $\mathrm{tr}(T^a T^b) = \tfrac{1}{2}\delta^{ab}$, covariant derivative as quoted). The crucial empirical fact that licenses everything below is that the up, down, and to a lesser degree strange quark masses are small compared with the intrinsic scale of the strong interaction, $\Lambda_{\mathrm{QCD}} \sim 200$ MeV (Theorem 27.14): $m_u, m_d \sim$ a few MeV and $m_s \sim 100$ MeV are perturbations on the hadronic scale, while m_c, m_b, m_t are not and must be integrated out before this discussion even begins. We therefore study the idealized *chiral limit*, $m_f \to 0$ for the N_f light flavors, treat the small physical masses as a controlled perturbation in the next section, and let

$$\mathcal{L}^0_{\mathrm{QCD}} = -\tfrac{1}{4} G^a_{\mu\nu} G^{a\,\mu\nu} + \sum_{f=1}^{N_f} \bar{q}_f \, i \not{D} \, q_f \tag{39.2}$$

be the object whose symmetries we classify. Nothing in Eq. (39.2) refers to flavor except through the universal coupling of every q_f to the same gluon field; the gauge interaction is flavor-blind. This is the structural reason a flavor symmetry exists at all, and the chiral limit promotes it to its largest possible form.

The promotion happens because a massless Dirac fermion is really two independent Weyl fermions. Recall from Chapter 11 the chirality projectors

$$P_L = \tfrac{1}{2}(1-\gamma^5), \qquad P_R = \tfrac{1}{2}(1+\gamma^5), \qquad P_L + P_R = 1, \quad P_{L,R}^2 = P_{L,R}, \quad P_L P_R = 0, \tag{39.3}$$

(Eq. (11.82)); the algebra of γ^5 and the chiral basis live in Section 11.2.5 and Theorem C.27). Define the chiral components of each flavor,

$$q_L = P_L\, q, \qquad q_R = P_R\, q, \qquad \bar{q}_L = \bar{q}\, P_R, \qquad \bar{q}_R = \bar{q}\, P_L, \tag{39.4}$$

where the placement of the projectors on $\bar{q} = q^\dagger \gamma^0$ follows from $\gamma^0 \gamma^5 = -\gamma^5 \gamma^0$: $\bar{q}_L = (P_L q)^\dagger \gamma^0 = q^\dagger P_L \gamma^0 = q^\dagger \gamma^0 P_R = \bar{q} P_R$, and likewise for the right component. The single fact we need about how these enter the Lagrangian is the intertwining

relation $\gamma^\mu P_L = P_R \gamma^\mu$, i.e. γ^5 anticommutes with γ^μ. It splits the kinetic term and forbids any chirality-diagonal piece in the mass term:

$$\bar{q}\, i\not{D}\, q = \bar{q}\,(P_R + P_L)\, i\not{D}\,(P_L + P_R)\, q = \bar{q}\, i\not{D}\,(P_L^2 + P_R^2)\, q = \bar{q}_R\, i\not{D}\, q_R + \bar{q}_L\, i\not{D}\, q_L, \tag{39.5}$$

$$\bar{q}\, q = \bar{q}\,(P_R + P_L)(P_L + P_R)\, q = \bar{q}\,(P_R P_L + P_L P_R)\, q = \bar{q}_L\, q_R + \bar{q}_R\, q_L. \tag{39.6}$$

In Eq. (39.5) the cross terms $\bar{q} P_R i\not{D} P_R q = \bar{q} P_R P_L i\not{D}\, q = 0$ vanish because $\not{D}$ carries one γ^μ and so flips the chirality it sits between, turning the two projectors into the orthogonal product $P_R P_L = 0$; in Eq. (39.6) the chirality-*preserving* combinations vanish for the opposite reason, $\bar{q} P_R q = \bar{q} P_R P_R q$ with $\bar{q} P_R = \bar{q}_R$ but $P_R q = q_R$ giving $\bar{q}_R$ paired with the wrong projector. The lesson is the one drawn in Chapter 11: the kinetic term keeps left and right separate, so a massless theory has no communication between the two chiralities, whereas any mass term welds them together. This is exactly why $m \to 0$ enlarges the symmetry.

Assemble the N_f flavors into column vectors in flavor space, $q_L = (q_{1L}, \ldots, q_{N_f L})^{\mathsf{T}}$ and likewise q_R. The massless quark Lagrangian is then

$$\mathcal{L}^0_{\text{quark}} = \bar{q}_L\, i\not{D}\, q_L + \bar{q}_R\, i\not{D}\, q_R, \tag{39.7}$$

a sum of two terms, each a flavor-space inner product contracted with the *flavor-blind* covariant derivative. Because $\not{D}$ is proportional to the identity in flavor space, Eq. (39.7) is invariant under *independent* unitary rotations of the left and right multiplets,

$$q_L \to L\, q_L, \qquad q_R \to R\, q_R, \qquad L \in \mathrm{U}(N_f),\ R \in \mathrm{U}(N_f), \tag{39.8}$$

since $\bar{q}_L \to \bar{q}_L L^\dagger$ and $\bar{q}_L i\not{D} q_L \to \bar{q}_L L^\dagger L\, i\not{D}\, q_L = \bar{q}_L i\not{D}\, q_L$ by unitarity, and the right sector identically. The gauge field is untouched: these are global flavor rotations, not gauge transformations. We have found the classical symmetry.

Definition 39.1 (Classical chiral symmetry group)**.** The massless N_f-flavor QCD Lagrangian Eq. (39.2) is invariant under the global group $\mathrm{U}(N_f)_L \times \mathrm{U}(N_f)_R$ acting as in Eq. (39.8). Factoring each unitary group as $\mathrm{U}(N_f) = \mathrm{SU}(N_f) \times \mathrm{U}(1)$ and recombining the two abelian factors into their vector ($L = R$) and axial ($L = R^\dagger$) combinations, the classical chiral group is

$$G_{\text{cl}} = \mathrm{SU}(N_f)_L \times \mathrm{SU}(N_f)_R \times \mathrm{U}(1)_V \times \mathrm{U}(1)_A, \tag{39.9}$$

where $\mathrm{U}(1)_V$ acts by $q \to e^{i\alpha} q$ (both chiralities together) and $\mathrm{U}(1)_A$ by $q \to e^{i\beta\gamma^5} q$ (opposite phases on the two chiralities).

The recombination in Eq. (39.9) is purely a choice of basis on the two U(1)'s and deserves a word, because it is what makes the vector and axial currents the natural variables. Writing the two phases as $q_L \to e^{i\theta_L} q_L$, $q_R \to e^{i\theta_R} q_R$, the

vector combination $\theta_L = \theta_R \equiv \alpha$ rotates both chiralities by the same phase, $q \to e^{i\alpha} q$, while the axial combination $\theta_L = -\theta_R \equiv -\beta$ rotates them oppositely, $q_L \to e^{-i\beta} q_L$, $q_R \to e^{+i\beta} q_R$, which is $q \to e^{i\beta\gamma^5} q$ since γ^5 is -1 on q_L and $+1$ on q_R. The same change of basis on the nonabelian parts would let us speak of vector and axial SU(N_f), but those do not separately close into groups (the axial generators do not form a subalgebra), so we keep SU(N_f)$_L \times$ SU(N_f)$_R$ in the chiral basis and pass to vector/axial only at the level of currents, next.

39.1.2 The Noether currents

A continuous global symmetry yields a conserved current by Noether's theorem (Theorems 7.9 and 7.10). The chiral group Eq. (39.9) has $2(N_f^2-1)+2$ generators, so we obtain that many currents; constructing them explicitly is the bookkeeping on which the rest of the chapter rests. For an internal symmetry $\delta q = -i\,\epsilon^A\, t^A q$ with constant infinitesimal parameters ϵ^A and field-space generators t^A, Noether's first theorem gives the current

$$J_\mu^A = \sum_{\text{fields } \Phi} \frac{\partial \mathcal{L}}{\partial(\partial^\mu \Phi)}\,(-i\,t^A \Phi) \quad \Longrightarrow \quad J_\mu^A = \bar{q}\,\gamma_\mu\, t^A\, q \tag{39.10}$$

for our Lagrangian, in which $\partial\mathcal{L}/\partial(\partial^\mu q) = \bar{q}\, i\gamma_\mu$ from the kinetic term, the gauge field contributing nothing to a *flavor* variation. Specializing t^A to each generator of Eq. (39.9) produces the complete current content.

Left and right SU(N_f) currents. For the SU(N_f)$_L$ transformation $q_L \to e^{-i\epsilon^a T^a} q_L$ with q_R fixed, the field-space generator acts only on the left chirality, $t^a = T^a P_L$, and Eq. (39.10) gives the left current; the right is identical with $L \leftrightarrow R$:

$$L_\mu^a = \bar{q}_L\,\gamma_\mu\, T^a\, q_L, \qquad R_\mu^a = \bar{q}_R\,\gamma_\mu\, T^a\, q_R, \qquad a = 1, \ldots, N_f^2 - 1, \tag{39.11}$$

where the T^a are the Hermitian SU(N_f) generators of Sections 2.1.3 and B.4. These $2(N_f^2-1)$ currents are the cleanest variables, but the physically labeled combinations are the *vector* and *axial* currents,

$$V_\mu^a \equiv R_\mu^a + L_\mu^a = \bar{q}_R \gamma_\mu T^a q_R + \bar{q}_L \gamma_\mu T^a q_L = \bar{q}\,\gamma_\mu T^a\, q, \tag{39.12}$$

$$A_\mu^a \equiv R_\mu^a - L_\mu^a = \bar{q}_R \gamma_\mu T^a q_R - \bar{q}_L \gamma_\mu T^a q_L = \bar{q}\,\gamma_\mu \gamma^5 T^a\, q. \tag{39.13}$$

The reassembly into a single Dirac bilinear in each case uses Eq. (39.4): $\bar{q}\gamma_\mu T^a q = \bar{q}(P_R + P_L)\gamma_\mu T^a q = \bar{q}_R\gamma_\mu T^a q_R + \bar{q}_L \gamma_\mu T^a q_L$ because γ_μ preserves chirality, giving the vector current; inserting one γ^5, which is $+1$ on q_R and -1 on q_L, flips the relative sign and gives the axial current. So V^a counts $R + L$ and A^a counts $R - L$, exactly the vector/axial split anticipated above. The V^a generate the diagonal SU(N_f)$_V$ (ordinary flavor symmetry — isospin for $N_f = 2$); the A^a are the broken directions to come, and crucially *they do not close into an algebra*, $\left[A^a, A^b\right] \sim V^c$, which is why there is no "axial SU(N_f)" group.

The two singlet currents. The abelian factors give one current each. For $\mathrm{U}(1)_V$, $q \to e^{-i\epsilon} q$ with $t = \mathbf{1}$, and for $\mathrm{U}(1)_A$, $q \to e^{-i\beta\gamma^5} q$ with $t = \gamma^5$:

$$V_\mu^{(0)} = \bar{q}\,\gamma_\mu\, q \quad (\text{quark number}, \ = N_c \times \text{baryon number}), \qquad A_\mu^{(0)} = \bar{q}\,\gamma_\mu\gamma^5\, q. \tag{39.14}$$

The count is now complete: $N_f^2 - 1$ vector currents V^a, $N_f^2 - 1$ axial currents A^a, one baryon-number current $V^{(0)}$, one singlet axial current $A^{(0)}$, totalling $2(N_f^2 - 1) + 2 = 2N_f^2$, one per generator of Eq. (39.9).

It remains to verify conservation and to read off how the small quark masses, to be restored later, break each current. This single computation governs both the chiral limit (everything conserved) and the real world (almost conserved), so we do it in full.

Worked Example 39.2 (Divergences of the chiral currents)**.** Restore a general (not necessarily diagonal) mass matrix M in flavor space, so the quark Lagrangian is $\bar{q}(i\not{D} - M)q$ with $M = \mathrm{diag}(m_1, \ldots, m_{N_f})$ in the physical basis. The equations of motion are

$$(i\not{D} - M)q = 0, \qquad \bar{q}\,(i\overleftarrow{\not{D}} + M) = 0, \tag{39.15}$$

the second being the Dirac-conjugate of the first, with $\bar{q}\overleftarrow{\not{D}} \equiv (\partial_\mu\bar{q} + ig\bar{q}A_\mu^a T^a)\gamma^\mu$ the gauge-covariant derivative acting to the left. Differentiate the vector flavor current Eq. (39.12), using the Leibniz rule and that T^a is a constant flavor matrix commuting with the color-space $\not{D}$:

$$\begin{aligned}\partial^\mu V_\mu^a &= (\partial^\mu\bar{q})\gamma_\mu T^a q + \bar{q}\,T^a\gamma_\mu\partial^\mu q \\ &= (\bar{q}\,\overleftarrow{\not{D}})\,T^a q - \bar{q}\,T^a(\not{D}q) = (i\bar{q}M)\,T^a q - \bar{q}\,T^a(-iMq) = i\,\bar{q}\,[M, T^a]\,q,\end{aligned} \tag{39.16}$$

where in the second line the gluon terms inside $\not{D}$ and $\overleftarrow{\not{D}}$ cancel between the two contributions (the current is color-singlet, T^a commutes with the gauge generators), and we substituted the equations of motion Eq. (39.15). The identical manipulation with one γ^5 inserted, remembering γ^5 anticommutes with the single γ_μ from each derivative, gives the axial divergence,

$$\partial^\mu A_\mu^a = i\,\bar{q}\,\gamma^5\,\{M, T^a\}\,q, \tag{39.17}$$

with an *anti*commutator because the γ^5 turns the relative sign on the two mass insertions. The two singlet currents follow by setting $T^a \to \mathbf{1}$: $\partial^\mu V_\mu^{(0)} = i\bar{q}\,[M, \mathbf{1}]\,q = 0$ identically (baryon number is conserved whatever the masses, an *exact* symmetry of QCD), while

$$\partial^\mu A_\mu^{(0)} = 2i\,\bar{q}\,\gamma^5 M\,q \qquad (\text{classical, anomaly not yet included}). \tag{39.18}$$

Now read off the chiral limit $M \to 0$. Every right-hand side vanishes: all $2N_f^2$ currents are classically conserved, confirming the full group Eq. (39.9). Away from

the limit, Eq. (39.16) shows the nonsinglet vector currents are conserved whenever $[M, T^a] = 0$, i.e. for degenerate masses ($M \propto \mathbf{1}$) all of $\mathrm{SU}(N_f)_V$ survives, and for generic masses the Cartan subalgebra (the diagonal T^a) survives — this is why isospin ($m_u = m_d$) and the individual flavor numbers are such good symmetries. The axial currents, by contrast, are broken by the mass even for $M \propto \mathbf{1}$, since $\{M, T^a\} \neq 0$; this is the partial conservation of the axial current (PCAC) that the next section turns into the pion mass.

The workedex isolates the one place a quantum effect intrudes: the classical result Eq. (39.18) for the *singlet* axial current is wrong. We turn to that now.

39.1.3 The axial anomaly and the fate of $\mathrm{U}(1)_A$

The current algebra just constructed is classical. Quantization can spoil the conservation of a current that survives at tree level, and for the singlet axial current it does: this is the Adler–Bell–Jackiw anomaly computed in Chapter 36. The anomalous divergence, imported from Eq. (36.50) and specialized to N_f massless quarks each in the fundamental of $\mathrm{SU}(3)_c$, modifies Eq. (39.18) to

$$\partial^\mu A^{(0)}_\mu = 2i\,\bar q\,\gamma^5 M\,q \;+\; \frac{g^2 N_f}{16\pi^2}\,G^a_{\mu\nu}\widetilde G^{a\,\mu\nu}, \qquad \widetilde G^{a\,\mu\nu} \equiv \tfrac{1}{2}\epsilon^{\mu\nu\rho\sigma}G^a_{\rho\sigma}. \tag{39.19}$$

The anomalous term survives the chiral limit $M \to 0$: even with massless quarks $\partial^\mu A^{(0)}_\mu \neq 0$. The singlet axial $\mathrm{U}(1)_A$ is therefore *not* a symmetry of the quantum theory at all, and must be struck from the classical group Eq. (39.9). The physical symmetry of massless QCD is

$$G = \mathrm{SU}(N_f)_L \times \mathrm{SU}(N_f)_R \times \mathrm{U}(1)_V. \tag{39.20}$$

It is essential that only the *singlet* axial current is anomalous, not the $N_f^2 - 1$ nonsinglet ones A^a. The would-be anomaly of A^a comes from the same triangle graph with two gluons and one axial-current insertion, and is proportional to the flavor trace $\mathrm{tr}(T^a)$ of the single generator carried by the current. Since the $\mathrm{SU}(N_f)$ generators are traceless, $\mathrm{tr}(T^a) = 0$, the nonsinglet anomaly vanishes and A^a remains conserved in the chiral limit. The singlet current carries instead $t = \mathbf{1}$ with $\mathrm{tr}(\mathbf{1}) = N_f \neq 0$, which is precisely the factor of N_f in Eq. (39.19). So the anomaly surgically removes one U(1) and leaves the rest of the chiral group intact — exactly the structure we need.

This has a sharp phenomenological payoff, the resolution of the so-called $\mathrm{U}(1)_A$ *problem* (Section 36.5.4). If $\mathrm{U}(1)_A$ were a genuine spontaneously broken symmetry, the Goldstone counting below would produce one *additional* light pseudoscalar, an $\mathrm{SU}(N_f)_V$ singlet — physically the η'. Weinberg's analysis showed that such a state, were it a true Goldstone boson, would have to be anomalously light, with a mass bounded by $\sqrt{3}\,m_\pi$; the observed $\eta'(958)$ is

more than six times heavier than the pion and is manifestly not a Goldstone boson. The anomaly Eq. (39.19) resolves the paradox at a stroke: $\mathrm{U}(1)_A$ is not a symmetry, so its breaking produces no Goldstone boson, and the η' is heavy because nothing protects it. The complete story of *why* the anomalous term $G\widetilde{G}$ has nonvanishing matrix elements in the vacuum — it is a total derivative, yet topologically nontrivial gluon configurations make it count — requires the instanton physics of Chapter 42; here we need only the existence of the anomaly, which is enough to delete $\mathrm{U}(1)_A$ from the symmetry and thereby predict eight (for $N_f = 3$) rather than nine light pseudoscalars.

39.1.4 The quark condensate and the breaking pattern

The group G of Eq. (39.20) is the symmetry. To get Goldstone bosons we need it spontaneously broken, and for that we need an order parameter in the sense of Theorem 29.10: a local operator whose vacuum expectation transforms nontrivially under G, so that the charges fail to annihilate the vacuum. QCD supplies one, the *quark condensate*. By Eq. (39.6) the simplest flavor- and Lorentz-scalar bilinear is

$$\bar{q}\, q = \bar{q}_L\, q_R + \bar{q}_R\, q_L, \tag{39.21}$$

which pairs the two chiralities. The central dynamical assumption — the one nonperturbative input of the entire framework, established by lattice QCD and by the spectroscopic consequences we check below, and which we take as given rather than derive — is that this operator condenses in the vacuum:

$$\langle \bar{q}_f\, q_{f'} \rangle = -\,\Sigma\, \delta_{ff'}, \qquad \Sigma > 0, \quad \Sigma \sim (250\ \mathrm{MeV})^3 \neq 0, \tag{39.22}$$

where the value $\Sigma = -\langle \bar{u}u \rangle = -\left\langle \bar{d}d \right\rangle = \dots$ is flavor-independent in the chiral limit (any flavor dependence would itself break $\mathrm{SU}(N_f)_V$, which nature does not do to leading order) and its sign is conventional. We stress that *only* $\Sigma \neq 0$ *matters* for the symmetry analysis; its magnitude is a nonperturbative number that the effective theory will absorb into low-energy constants, never needing its value.

Now determine what Eq. (39.22) breaks. The clean way to see the pattern is to track the full condensate matrix

$$\Sigma^{f'f} \equiv \left\langle \bar{q}_L^{\,f}\, q_R^{f'} \right\rangle, \tag{39.23}$$

an $N_f \times N_f$ matrix in flavor space whose trace, doubled, is Eq. (39.22). Under the chiral group Eq. (39.8), $q_R \to R\, q_R$ and $\bar{q}_L \to \bar{q}_L L^\dagger$, so the bilinear $\bar{q}_L^{\,f} q_R^{f'}$ transforms as the $(\bar{\mathbf{N}}_f, \mathbf{N}_f)$ representation and its expectation value rotates as

$$\Sigma \;\longrightarrow\; R\, \Sigma\, L^\dagger, \qquad (L, R) \in \mathrm{SU}(N_f)_L \times \mathrm{SU}(N_f)_R. \tag{39.24}$$

The vacuum is the dynamically chosen value $\Sigma = \Sigma_0\,\mathbf{1}$ (a multiple of the identity, from Eq. (39.22)). The unbroken subgroup H is the stabilizer of this configuration — the set of (L, R) leaving $\Sigma_0\mathbf{1}$ fixed:

$$R\,(\Sigma_0\mathbf{1})\,L^\dagger = \Sigma_0\mathbf{1} \iff RL^\dagger = \mathbf{1} \iff R = L. \tag{39.25}$$

The transformations that preserve the vacuum are exactly the *diagonal* ones $L = R$ — the vector subgroup $\mathrm{SU}(N_f)_V$ whose currents are the V^a of Eq. (39.12). The transformations that move it are the axial ones, $L = R^\dagger \neq L$, whose currents are the A^a. We have proved:

Theorem 39.3 (Chiral breaking pattern of QCD)**.** *A nonzero, flavor-symmetric quark condensate Eq. (39.22) spontaneously breaks the chiral group of massless N_f-flavor QCD according to*

$$G = \mathrm{SU}(N_f)_L \times \mathrm{SU}(N_f)_R \times \mathrm{U}(1)_V \;\longrightarrow\; H = \mathrm{SU}(N_f)_V \times \mathrm{U}(1)_V, \tag{39.26}$$

where $\mathrm{SU}(N_f)_V$ is the diagonal ($L = R$) subgroup and $\mathrm{U}(1)_V$ is baryon number. The unbroken generators are the $N_f^2 - 1$ vector charges $Q_V^a = \int \mathrm{d}^3x\, V_0^a$ together with baryon number; the broken generators are the $N_f^2 - 1$ axial charges $Q_A^a = \int \mathrm{d}^3x\, A_0^a$.

It is worth seeing the invariance and the non-invariance directly at the level of charges acting on the condensate, since that is the operative definition of breaking in Theorem 29.10 ($\langle 0|\,[Q, \mathcal{O}]\,|0\rangle \neq 0$ for a broken charge). Infinitesimally, a vector rotation acts on the bilinear $\bar{q}q$ by $\delta_V(\bar{q}q) = [i\alpha^a Q_V^a, \bar{q}q]$, generated by $q \to (1 + i\alpha^a T^a)q$, $\bar{q} \to \bar{q}(1 - i\alpha^a T^a)$:

$$\delta_V(\bar{q}\,q) = \bar{q}\,(i\alpha^a T^a)q + \bar{q}\,(-i\alpha^a T^a)q = 0, \tag{39.27}$$

so $\langle 0|\,[Q_V^a, \bar{q}q]\,|0\rangle = 0$: the condensate is annihilated by the vector charges, which is the statement that $\mathrm{SU}(N_f)_V$ is unbroken. An axial rotation acts by $q \to (1 + i\beta^a\gamma^5 T^a)q$; on the conjugate field, using $\gamma^0\gamma^5 = -\gamma^5\gamma^0$ as in Eq. (39.4), $\bar{q} \to \bar{q}(1 + i\beta^a\gamma^5 T^a)$ (*same* sign, not opposite), so

$$\delta_A(\bar{q}\,q) = \bar{q}\,(i\beta^a\gamma^5 T^a)q + \bar{q}\,(i\beta^a\gamma^5 T^a)q = 2i\,\beta^a\,\bar{q}\,\gamma^5 T^a\,q. \tag{39.28}$$

Taking the vacuum expectation and using Eq. (39.22) (the pseudoscalar density $\bar{q}\gamma^5 T^a q$ has the chiral partner of the scalar condensate as its vacuum value), this is nonzero: $\langle 0|\delta_A(\bar{q}q)|0\rangle \propto \beta^a\Sigma \neq 0$. The axial charges do *not* annihilate the vacuum — precisely the criterion that they are the broken generators. The two computations Eqs. (39.27) and (39.28) are Theorem 39.3 seen one charge at a time: vector good, axial broken, with the breaking measured by the same condensate Σ.

Remark 39.4 (Why the unbroken subgroup is vectorial). We assumed the condensate Eq. (39.22) is proportional to the identity, which forced $H = \mathrm{SU}(N_f)_V$. One might worry that some other vacuum alignment — a condensate breaking G to a different subgroup, perhaps one containing axial generators — could occur instead. It cannot, and the reason is deep rather than accidental. The Vafa–Witten theorem [480, 481] proves that in a vector-like gauge theory such as QCD (one whose fermions come in left–right symmetric, anomaly-free representations, so that the Euclidean fermion determinant is real and positive) no *vector* global symmetry can break spontaneously, and parity cannot break spontaneously. Consequently the unbroken subgroup must contain the entire vector symmetry: $H \supseteq \mathrm{SU}(N_f)_V$. Combined with the Goldstone count below — which already saturates the breaking with $N_f^2 - 1$ axial Goldstones — this fixes $H = \mathrm{SU}(N_f)_V$ exactly. We cite the theorem for further reading rather than prove it here, because the breaking pattern Eq. (39.26) is established directly by the condensate's symmetry Eq. (39.24); Vafa–Witten guarantees that QCD's dynamics actually selects this alignment and not a parity-violating competitor.

39.1.5 The Goldstone count: the pseudoscalar octet

With the pattern Eq. (39.26) fixed, the number of Goldstone bosons is no longer a question about QCD dynamics — it is pure group theory, handed to us by the Goldstone theorem and its counting corollary of Chapter 29. We apply Theorem 29.12: a spontaneous breaking $G \to H$ in a relativistic theory with a positive-definite Hilbert space produces exactly $\dim G - \dim H = \dim(G/H)$ massless spin-zero bosons, one for each broken generator, as proved there both from the spectral representation and from the curvature of the effective potential (Theorem 29.21). The dimensions are read off Eq. (39.26):

$$\dim G = \underbrace{(N_f^2 - 1)}_{\mathrm{SU}(N_f)_L} + \underbrace{(N_f^2 - 1)}_{\mathrm{SU}(N_f)_R} + \underbrace{1}_{\mathrm{U}(1)_V} = 2N_f^2 - 1, \tag{39.29}$$

$$\dim H = \underbrace{(N_f^2 - 1)}_{\mathrm{SU}(N_f)_V} + \underbrace{1}_{\mathrm{U}(1)_V} = N_f^2, \tag{39.30}$$

and therefore

$$\boxed{N_{\mathrm{GB}} = \dim G - \dim H = N_f^2 - 1.} \tag{39.31}$$

The baryon-number $\mathrm{U}(1)_V$ cancels between G and H — it is unbroken and contributes no Goldstone boson, as it must, since baryon number is an exact and manifestly realized symmetry. The surviving count $N_f^2 - 1$ is exactly the number of *axial* generators, and the identification is sharp: the broken generators are the axial charges Q_A^a, so there is one Goldstone boson per axial generator, created from the vacuum by the corresponding axial current, $\left\langle 0 | A_\mu^a(0) | \pi^b(p) \right\rangle \propto i p_\mu \, \delta^{ab}$

— the relation that the next section promotes into the definition of the pion decay constant.

The quantum numbers of these Goldstones are fixed by the broken generators that create them. The axial currents $A^a_\mu = \bar{q}\gamma_\mu\gamma^5 T^a q$ are *axial* vectors: under parity $\mathcal{P}$, which sends $\bar{q}\gamma_\mu q \to +\bar{q}\gamma^\mu q$ (spatial components flip as a vector) and inserts an extra sign for the γ^5, the axial current transforms oppositely to the vector current, and the state it creates from the (parity-even) vacuum is a *pseudoscalar*: spin-parity $J^P = 0^-$. This is the second prediction, as important as the count itself: the Goldstone bosons of chiral symmetry breaking must be pseudoscalars, not scalars. We now check both predictions against the observed spectrum.

Worked Example 39.5 (The two light-quark cases: pions and the octet)**.** Specialize Eq. (39.31) to the physically relevant numbers of light flavors.

$N_f = 2$ *(up, down).* Then $N_{\text{GB}} = 2^2 - 1 = 3$. The unbroken group is $\text{SU}(2)_V$, ordinary *isospin*, and the three Goldstone bosons fill its adjoint (the spin-1 isotriplet, **3** of SU(2)). These are the pions: the charged $\pi^\pm$ and the neutral π^0, with $I = 1$, $J^P = 0^-$. Their physical masses ($m_{\pi^\pm} = 139.6$ MeV, $m_{\pi^0} = 135.0$ MeV) are tiny on the hadronic scale — the hallmark of pseudo-Goldstone bosons whose mass comes only from the small explicit breaking $m_u, m_d \neq 0$ analyzed next section.

$N_f = 3$ *(up, down, strange).* Then $N_{\text{GB}} = 3^2 - 1 = 8$. The unbroken group is $\text{SU}(3)_V$ (the Eightfold Way flavor SU(3)), and the eight Goldstone bosons fill its adjoint, the **8** — the *pseudoscalar meson octet*: the three pions, the four kaons $K^\pm, K^0, \bar{K}^0$ ($I = \frac{1}{2}$, carrying strangeness), and the isosinglet η. All have $J^P = 0^-$. The octet weight diagram (Fig. 39.1) is the same hexagon-with-doubled-center that organizes any SU(3) adjoint, plotted in the conserved quantum numbers of H: the third component of isospin I_3 (a Cartan generator of $\text{SU}(2)_V \subset \text{SU}(3)_V$) and the hypercharge Y (the other Cartan generator). The would-be ninth state that fills out a nonet, the SU(3)-singlet η', is *not* a Goldstone boson: it is the $\eta'(958)$, heavy because its associated current is the anomalous singlet $A^{(0)}$ of Eq. (39.19). The split between the light octet and the heavy η' is the spectroscopic fingerprint of the anomaly.

39.1.6 Physical evidence for the pattern

The argument so far is a chain of group theory resting on two physical inputs: the smallness of the light-quark masses and the nonvanishing of the condensate. It predicts a definite, falsifiable structure in the hadron spectrum. Three features of the observed spectrum confirm it.

First, the *lightness*. The breaking pattern predicts $N_f^2 - 1$ anomalously light pseudoscalars and nothing else light. For $N_f = 2$ the lightest hadrons are exactly

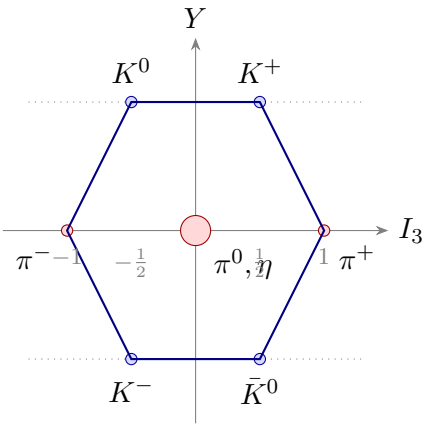

Figure 39.1: The pseudoscalar meson octet ($J^P = 0^-$) of the $N_f = 3$ breaking $\mathrm{SU}(3)_L \times \mathrm{SU}(3)_R \to \mathrm{SU}(3)_V$, plotted in the Cartan charges of the unbroken $\mathrm{SU}(3)_V$: the third isospin component I_3 and the hypercharge Y. The eight Goldstone bosons fill the adjoint **8** of $\mathrm{SU}(3)_V$ (hexagon with a doubled center: π^0 and η). The would-be ninth, the SU(3)-singlet η', sits at the center too but is *not* a Goldstone boson — it is heavy because its current, the singlet axial $A^{(0)}$, is anomalous (Eq. (39.19)).

the three pions, separated by a factor of four from the next state (the $\rho(770)$ vector meson, which is *not* a Goldstone boson and need not be light). For $N_f = 3$ the eight lightest mesons are precisely the octet $\{\pi, K, \eta\}$, all below 550 MeV, while every other meson lies above 750 MeV. The pattern "a light octet, then a gap" is the spectroscopic signature of Eq. (39.31), and the modest spread within the octet ($m_K \gg m_\pi$ because $m_s \gg m_{u,d}$) is itself predicted by the explicit-breaking analysis of the next section.

Second, the *quantum numbers*. Every one of these light mesons is a pseudoscalar, $J^P = 0^-$, exactly as the axial-vector character of the broken currents demands. There is no light scalar (0^+) octet; the lightest scalars are heavy and broad. A theory in which the light mesons came out as 0^+ would falsify the chiral picture, and they do not.

Third, and most incisively, the *absence of parity doubling*. This is the cleanest qualitative test that the unbroken subgroup is the *vector* one and not some axial alternative, and it deserves spelling out.

Physical Insight: why the spectrum shows broken chirality but unbroken parity

Parity $\mathcal{P}$ commutes with the vector charges Q_V^a (both are built from the parity-even combination $\bar{q}\gamma^0 q$ and its rotations) but *anti*commutes, in

effect, with the axial charges: $\mathcal{P}\, Q_A^a\, \mathcal{P}^{-1} = -Q_A^a$, because the axial current is an axial vector. Suppose, counterfactually, that an axial symmetry were *unbroken* — that some Q_A^a annihilated the vacuum and generated a good symmetry of the spectrum. Then acting with Q_A^a on any hadron $|h\rangle$ would produce a degenerate partner $Q_A^a|h\rangle$ of *opposite parity* and equal mass: every hadron would come with a mirror-parity twin. The spectrum would be organized into *parity doublets* — the nucleon would have a degenerate negative-parity partner, the ρ a degenerate axial-vector a_1 at the same mass, and so on. Nature shows no such doubling: the nucleon's negative-parity partner $N(1535)$ is some 600 MeV heavier, the $a_1(1260)$ lies far above the $\rho(770)$. The axial symmetry is therefore *not* realized on the spectrum — it is spontaneously broken. Yet parity *itself* is an excellent symmetry (hadrons are sharp parity eigenstates), and so is isospin/flavor (hadrons fill clean $\mathrm{SU}(N_f)_V$ multiplets). The only realization of G consistent with all three facts — broken axial, unbroken parity, unbroken flavor — is precisely $G \to H = \mathrm{SU}(N_f)_V$, with the broken directions being the parity-odd axial ones. The hadron spectrum is, in this sense, a direct readout of the breaking pattern: the doublets that the broken charges *would* have created are not there because those charges instead created the light Goldstone pions.

This closes the logical loop opened at the start of the section. We took the QCD Lagrangian Eq. (39.1) and asymptotic freedom (Theorems 27.7 and 27.11) as given, asked what symmetry survives at low energy, and found a definite and verified answer: the chiral group $\mathrm{SU}(N_f)_L \times \mathrm{SU}(N_f)_R \times \mathrm{U}(1)_V$, with $\mathrm{U}(1)_A$ removed by the anomaly, is spontaneously broken by the quark condensate to the vector subgroup $\mathrm{SU}(N_f)_V \times \mathrm{U}(1)_V$, producing $N_f^2 - 1$ pseudoscalar Goldstone bosons — the pions for $N_f = 2$, the meson octet for $N_f = 3$. The remaining task of the chapter is to build a quantum field theory of *these* degrees of freedom. Because the Goldstone bosons are coordinates on the coset G/H, the natural field is not a vector of $N_f^2 - 1$ scalars but a group-valued field $U(x) \in \mathrm{SU}(N_f)$ carrying them nonlinearly; constructing $U(x)$ from the broken generators, and writing the unique leading-order Lagrangian invariant under Eq. (39.26), is the work of the next section.

39.2 The Leading-Order Chiral Lagrangian

The previous section established the symmetry skeleton on which everything in this chapter hangs. In the chiral limit $m_u, m_d, \cdots \to 0$, the QCD Lagrangian of the N_f lightest quarks has the global symmetry $\mathrm{SU}(N_f)_L \times \mathrm{SU}(N_f)_R$ acting independently on the left- and right-handed quark fields; the quark condensate $\langle \bar{q}q \rangle \neq 0$ spontaneously breaks this to the diagonal isospin/flavor subgroup

$\mathrm{SU}(N_f)_V$ (Section 39.1); and Goldstone's theorem then populates the spectrum with exactly $\dim\left(\mathrm{SU}(N_f)_L \times \mathrm{SU}(N_f)_R\right) - \dim \mathrm{SU}(N_f)_V = N_f^2 - 1$ massless pseudoscalar bosons. For $N_f = 2$ these are the three pions; for $N_f = 3$ they are the pseudoscalar octet (π, K, η). The task now is to write their dynamics. We do *not* start from scratch: Chapter 29 already built the universal low-energy theory of Goldstone bosons — the nonlinear sigma model (Theorem 29.22), its coset coordinates (Section 29.5.2), and the CCWZ geometric construction (Section 29.5.5) — and proved that the leading two-derivative dynamics is fixed by symmetry up to a single constant. What remains is to *specialize* that apparatus to the coset $G/H = \left(\mathrm{SU}(N_f)_L \times \mathrm{SU}(N_f)_R\right)/\mathrm{SU}(N_f)_V$, package the Goldstone fields into the object that makes the chiral symmetry act linearly, fix the one constant against a measured number, and finally restore the small explicit breaking that the quark masses provide. The output is the leading-order chiral Lagrangian, the concrete realization of the EFT paradigm that Chapter 38 predicted in the abstract.

39.2.1 The Goldstone matrix and its transformation law

The Goldstone fields live on the coset manifold. For the chiral breaking pattern that manifold is itself a group: $\left(\mathrm{SU}(N_f)_L \times \mathrm{SU}(N_f)_R\right)/\mathrm{SU}(N_f)_V \cong \mathrm{SU}(N_f)$, because every coset has a unique representative of the form $(g, \mathbf{1})$ followed by a diagonal element, and the diagonal is exactly what we quotient by. This is the special feature that makes chiral symmetry so much more tractable than a generic nonlinear realization: the Goldstone bosons can be assembled into a *single unitary matrix field* on which the full symmetry acts *linearly*.

Definition 39.6 (The Goldstone matrix)**.** Let $\Phi(x)$ be the Hermitian, traceless $N_f \times N_f$ matrix of pseudoscalar fields,

$$\Phi(x) = \Phi^\dagger(x), \qquad \operatorname{tr}\Phi(x) = 0, \tag{39.32}$$

carrying the $N_f^2 - 1$ Goldstone bosons as its independent real components. The *Goldstone matrix* is the $\mathrm{SU}(N_f)$-valued field

$$U(x) = \exp\!\Big(\tfrac{i}{f}\,\Phi(x)\Big), \tag{39.33}$$

where f is a constant of mass dimension one (to be identified below with the pion decay constant). Hermiticity and tracelessness of Φ make U unitary and unimodular, $U^\dagger U = \mathbf{1}$ and $\det U = e^{i\operatorname{tr}\Phi/f} = 1$, so indeed $U \in \mathrm{SU}(N_f)$.

For the two cases of interest the matrix Φ is built from the physical mesons through the generators collected in Section B.2. For $N_f = 2$ one writes $\Phi = \pi^a \tau^a$ with τ^a the Pauli matrices,

$$\Phi = \pi^a\tau^a = \begin{pmatrix} \pi^0 & \sqrt{2}\,\pi^+ \\ \sqrt{2}\,\pi^- & -\pi^0 \end{pmatrix}, \qquad \pi^\pm = \tfrac{1}{\sqrt{2}}(\pi^1 \mp i\pi^2), \quad \pi^0 = \pi^3, \tag{39.34}$$

the isotriplet of pions. For $N_f = 3$ one writes $\Phi = \phi^a \lambda^a$ with λ^a the Gell-Mann matrices of Section B.2 ($\mathrm{tr}\,\lambda^a\lambda^b = 2\delta^{ab}$), which in terms of the charge eigenstates is the pseudoscalar octet

$$\Phi = \phi^a \lambda^a = \begin{pmatrix} \pi^0 + \dfrac{\eta}{\sqrt{3}} & \sqrt{2}\,\pi^+ & \sqrt{2}\,K^+ \\ \sqrt{2}\,\pi^- & -\pi^0 + \dfrac{\eta}{\sqrt{3}} & \sqrt{2}\,K^0 \\ \sqrt{2}\,K^- & \sqrt{2}\,\bar{K}^0 & -\dfrac{2\eta}{\sqrt{3}} \end{pmatrix}. \tag{39.35}$$

The normalizations of the off-diagonal ($\sqrt{2}$) and diagonal entries are not free: they are fixed by demanding that the kinetic term come out canonical, which we verify in Eq. (39.44) below. The numerical factors are exactly those that make $\pi^\pm$, $K^\pm$, K^0 complex fields of unit-normalized kinetic terms and π^0, η real fields of standard kinetic terms.

The whole point of packaging the fields this way is the transformation law. Under a chiral rotation $(L, R) \in \mathrm{SU}(N_f)_L \times \mathrm{SU}(N_f)_R$ the matrix U transforms *linearly* and *homogeneously*,

$$\boxed{U(x) \;\longrightarrow\; L\,U(x)\,R^\dagger}, \qquad L \in \mathrm{SU}(N_f)_L,\ R \in \mathrm{SU}(N_f)_R. \tag{39.36}$$

This is the chiral specialization of the CCWZ realization of Section 29.5.5, and it is worth seeing exactly why Eq. (39.36) *is* the nonlinear realization in disguise rather than a new postulate. In the CCWZ language one chooses a coset representative $u(\Phi) = e^{i\Phi/2f}$ and lets a group element act by left multiplication followed by a compensating H-transformation. Writing $U = u^2 = u\,u$ and acting with (L, R) gives $u \to L\,u\,h^\dagger = h\,u\,R^\dagger$, where $h = h(\Phi, L, R) \in \mathrm{SU}(N_f)_V$ is the field-dependent compensator. Squaring,

$$U = u\,u \;\longrightarrow\; (L\,u\,h^\dagger)(h\,u\,R^\dagger) = L\,u\,u\,R^\dagger = L\,U\,R^\dagger, \tag{39.37}$$

and the compensator h cancels between the two factors. The nonlinear, field-dependent transformation of the individual Goldstone fields hidden inside u has collapsed into the simple linear rule Eq. (39.36) for the bilinear $U = u^2$. This is precisely why chiral perturbation theory is conventionally written in terms of U: the symmetry is manifest.

Three structural facts follow immediately and we will use all three. First, the unbroken subgroup is the diagonal: setting $L = R = V$ in Eq. (39.36) gives $U \to VUV^\dagger$, an ordinary $\mathrm{SU}(N_f)_V$ rotation of the fields, and the vacuum $U = \mathbf{1}$ is left invariant, $\mathbf{1} \to V\mathbf{1}V^\dagger = \mathbf{1}$. Thus $H = \mathrm{SU}(N_f)_V$ as required. Second, the broken (axial) transformations are those with $R = L^\dagger$: then $U = \mathbf{1} \to L^2 \neq \mathbf{1}$, so the vacuum moves, and acting on the fields, $L = e^{i\alpha_A^a T^a}$ gives $\Phi \to \Phi + 2f\,\alpha_A^a T^a + \cdots$, the inhomogeneous *shift* of the Goldstone fields that is the fingerprint of spontaneous breaking and that forces purely derivative couplings

(Theorem 29.25). Third, the count is right by construction: U is an arbitrary $\mathrm{SU}(N_f)$ element, parametrized by exactly $N_f^2 - 1$ real fields Φ^a, matching the Goldstone count of Theorem 29.24.

Notation Watch

Parity acts on the pseudoscalars by $\Phi(t, \mathbf{x}) \to -\Phi(t, -\mathbf{x})$ (they are pseudoscalars), hence on the Goldstone matrix by $U(t, \mathbf{x}) \to U^\dagger(t, -\mathbf{x})$. Equivalently, parity exchanges the two chiral factors, $L \leftrightarrow R$. Every term we admit in the Lagrangian below must be invariant under this exchange together with the spatial reflection; this is what we mean by "parity-even." Charge conjugation acts by $U \to U^\mathsf{T}$ (transpose); we will note where it matters.

39.2.2 Uniqueness of the leading Lagrangian

We now ask for the most general Lagrangian built from U that is (i) Lorentz invariant, (ii) invariant under the chiral group Eq. (39.36), (iii) parity invariant, (iv) Hermitian, and (v) of lowest order in the derivative expansion. The derivative expansion is the organizing principle established in Chapter 29: because the symmetry forbids a potential, every interaction carries derivatives, and we order terms by the number of derivatives, equivalently by powers of momentum. We denote by $\mathcal{L}_{2k}$ the part with $2k$ derivatives (only even numbers survive Lorentz invariance), and seek $\mathcal{L}_2$.

The building blocks are U, $U^\dagger$, and their derivatives $\partial_\mu U$, $\partial_\mu U^\dagger$. Chiral invariance is the strong constraint. Since $U \to L U R^\dagger$ and $U^\dagger \to R U^\dagger L^\dagger$, a left index can be soaked up only by a matching $L^\dagger$ and a right index only by a matching R; the only way to build an invariant is to take a *trace* of an *alternating* product $U\,U^\dagger\,U\,U^\dagger\cdots$ (possibly with derivatives distributed on the factors), in which the R from one factor cancels the $R^\dagger$ from the next and the trace closes the leftover $L, L^\dagger$ pair. Products of several such traces are also allowed.

Zero derivatives. The only candidate is $\mathrm{tr}(UU^\dagger) = \mathrm{tr}\,\mathbf{1} = N_f$, a constant. There is no potential, in agreement with the shift symmetry. (A term $\mathrm{tr}\,U + \mathrm{tr}\,U^\dagger$ is *not* chirally invariant — it transforms into $\mathrm{tr}(LUR^\dagger)$ — and so is forbidden in the chiral limit; it returns, dressed by a spurion, when we add quark masses in Section 39.2.4.)

Two derivatives. We must place two ∂_μ's and contract their Lorentz indices. The candidate structures are

$$\mathrm{tr}(\partial_\mu U\,\partial^\mu U^\dagger), \qquad \mathrm{tr}(\partial_\mu \partial^\mu U\,U^\dagger), \qquad \mathrm{tr}(U^\dagger \partial_\mu U)\;\mathrm{tr}(U^\dagger \partial^\mu U), \tag{39.38}$$

together with structures that look different but are algebraically identical to the first. We show that all of Eq. (39.38) collapse to a single independent term. The key identities follow from unitarity $U^\dagger U = \mathbf{1}$ and unimodularity $\det U = 1$. Differentiating $U^\dagger U = \mathbf{1}$ gives

$$\partial_\mu U^\dagger\, U + U^\dagger \partial_\mu U = 0 \quad \Longleftrightarrow \quad U\, \partial_\mu U^\dagger = -\partial_\mu U\, U^\dagger, \tag{39.39}$$

the second form obtained by multiplying the first on the left by U and on the right by $U^\dagger$. Differentiating $\det U = 1$, equivalently $\ln\det U = \operatorname{tr}\ln U = 0$, gives the trace identity

$$\operatorname{tr}\!\left(U^\dagger \partial_\mu U\right) = \partial_\mu \operatorname{tr}\ln U = 0, \qquad \text{equivalently} \qquad \operatorname{tr}\!\left(U\, \partial_\mu U^\dagger\right) = 0. \tag{39.40}$$

The identity Eq. (39.40) kills the third candidate in Eq. (39.38) outright: $\operatorname{tr}(U^\dagger\partial_\mu U) = 0$, so the would-be "U(1)" term $\operatorname{tr}(U^\dagger\partial_\mu U)\operatorname{tr}(U^\dagger\partial^\mu U)$ vanishes identically. (It is precisely the absence of a U(1) Goldstone — the η' being lifted by the anomaly of Chapter 36 — that is encoded here; the $\mathrm{SU}(N_f)$ matrix has no overall phase to support such a term.) The second candidate reduces to the first by an integration by parts inside the action: using Eq. (39.40) in the form $\partial^\mu \operatorname{tr}(\partial_\mu U\, U^\dagger) = 0$ is not quite it; instead expand $\partial_\mu\big[\operatorname{tr}(\partial^\mu U\, U^\dagger)\big] = \operatorname{tr}(\partial_\mu\partial^\mu U\, U^\dagger) + \operatorname{tr}(\partial^\mu U\, \partial_\mu U^\dagger)$, and note the left side is the total derivative of $\operatorname{tr}(\partial^\mu U\, U^\dagger)$, which integrates to zero, so under the action integral

$$\operatorname{tr}(\partial_\mu\partial^\mu U\, U^\dagger) \;\simeq\; -\operatorname{tr}(\partial_\mu U\, \partial^\mu U^\dagger), \tag{39.41}$$

where $\simeq$ denotes equality up to a total derivative. Finally the first candidate is, up to a sign, the same as the manifestly H-covariant form: using $\partial_\mu U = U(U^\dagger\partial_\mu U)$ and $\partial^\mu U^\dagger = -(U^\dagger\partial^\mu U)U^\dagger$ from Eq. (39.39),

$$\operatorname{tr}(\partial_\mu U\, \partial^\mu U^\dagger) = \operatorname{tr}\big[U(U^\dagger\partial_\mu U)\big(-(U^\dagger\partial^\mu U)U^\dagger\big)\big] = -\operatorname{tr}\big[(U^\dagger\partial_\mu U)(U^\dagger\partial^\mu U)\big], \tag{39.42}$$

the trace cyclicity having moved $U^\dagger\cdots U$ around to give $\mathbf{1}$. The combination $U^\dagger\partial_\mu U$ is the Maurer–Cartan one-form of Section 29.5.5, here anti-Hermitian by Eq. (39.39); Eq. (39.42) just says the two ways of writing the kinetic term agree. Every two-derivative invariant therefore reduces to a single structure, $\operatorname{tr}(\partial_\mu U\, \partial^\mu U^\dagger)$. Lorentz invariance is manifest, Hermiticity holds because $\big[\operatorname{tr}(\partial_\mu U\, \partial^\mu U^\dagger)\big]^\dagger = \operatorname{tr}(\partial^\mu U\, \partial_\mu U^\dagger)$ equals itself, and parity ($U \to U^\dagger$) maps the structure to $\operatorname{tr}(\partial_\mu U^\dagger\, \partial^\mu U)$, again itself. There is no two-derivative parity-*odd* invariant: a parity-odd term requires the Levi-Civita symbol $\epsilon^{\mu\nu\rho\sigma}$ and hence at least four derivatives — that object exists and is the Wess–Zumino–Witten term of the final section, which sits at $O(p^4)$.

We have proved the central uniqueness statement.

Theorem 39.7 (The leading-order chiral Lagrangian)**.** *The unique Lorentz-invariant, parity-even, Hermitian,* $\mathrm{SU}(N_f)_L \times \mathrm{SU}(N_f)_R$*-invariant Lagrangian*

built from the Goldstone matrix U with the fewest ($=2$) derivatives is

$$\boxed{\mathcal{L}_2 = \frac{f^2}{4}\,\mathrm{tr}(\partial_\mu U\,\partial^\mu U^\dagger)} \tag{39.43}$$

with f a single real coupling of mass dimension one. The overall constant is fixed by canonical normalization of the Goldstone fields, and the choice $f^2/4$ produces standard kinetic terms.

Proof. Uniqueness of the structure was established above: chiral invariance forces an alternating trace; the two-derivative alternating traces are exhausted by Eq. (39.38); the unimodularity identity Eq. (39.40) kills the double-trace term and the unitarity identities Eq. (39.39) with the integration by parts Eqs. (39.41) and (39.42) reduce the remaining two to one. It remains to fix the constant. Expand $U = \exp(i\Phi/f) = \mathbf{1} + \frac{i}{f}\Phi - \frac{1}{2f^2}\Phi^2 + \cdots$, so $\partial_\mu U = \frac{i}{f}\partial_\mu\Phi + \cdots$ and $\partial_\mu U^\dagger = -\frac{i}{f}\partial_\mu\Phi + \cdots$. To quadratic order in the fields,

$$\mathcal{L}_2 = \frac{f^2}{4}\,\mathrm{tr}\Big[\Big(\tfrac{i}{f}\partial_\mu\Phi\Big)\Big(-\tfrac{i}{f}\partial^\mu\Phi\Big)\Big] + \cdots = \frac{1}{4}\,\mathrm{tr}(\partial_\mu\Phi\,\partial^\mu\Phi) + \cdots = \frac{1}{2}\,\partial_\mu\phi^a\,\partial^\mu\phi^a + \cdots\,, \tag{39.44}$$

where the last equality used $\Phi = 2\phi^a T^a$ with $\mathrm{tr}(T^a T^b) = \frac{1}{2}\delta^{ab}$ (so $\mathrm{tr}(\partial\Phi\,\partial\Phi) = 4\,\partial\phi^a\partial\phi^b\,\mathrm{tr}(T^aT^b) = 2\,\partial\phi^a\partial\phi^a$). The coefficient $\frac{1}{2}$ is exactly the canonical normalization of $N_f^2 - 1$ real scalar kinetic terms, which is what fixes the prefactor in Eq. (39.43) to $f^2/4$. Inserting the explicit matrices Eqs. (39.34) and (39.35) reproduces the same conclusion in terms of the charge eigenstates: for $N_f = 3$ one finds $\frac{1}{4}\,\mathrm{tr}(\partial\Phi\,\partial\Phi) = \frac{1}{2}(\partial\pi^0)^2 + \frac{1}{2}(\partial\eta)^2 + \partial_\mu\pi^+\partial^\mu\pi^- + \partial_\mu K^+\partial^\mu K^- + \partial_\mu K^0\partial^\mu\bar{K}^0$, the canonical kinetic terms for two real and three complex mesons, which is what fixed the $\sqrt{2}$'s and the $1/\sqrt{3}$'s in Eq. (39.35). □

The Lagrangian Eq. (39.43) is the entire leading-order dynamics of the massless mesons, and it carries a single parameter f. Everything else — all the pion self-interactions — is determined. Expanding to one more order exhibits the leading interaction.

Worked Example 39.8 (The leading pion self-interaction)**.** We expand $\mathcal{L}_2$ to quartic order in Φ to display the contact interaction that the next sections turn into $\pi\pi$ scattering. From $U = \exp(i\Phi/f)$,

$$\partial_\mu U = \frac{i}{f}\,\partial_\mu\Phi - \frac{1}{2f^2}(\Phi\,\partial_\mu\Phi + \partial_\mu\Phi\,\Phi) - \frac{i}{6f^3}(\Phi^2\partial_\mu\Phi + \Phi\,\partial_\mu\Phi\,\Phi + \partial_\mu\Phi\,\Phi^2) + \cdots\,, \tag{39.45}$$

and $\partial_\mu U^\dagger$ is the same with $\Phi \to -\Phi$ in the exponent, i.e. $i \to -i$ on alternate terms. Collecting the terms of $\mathrm{tr}(\partial_\mu U\,\partial^\mu U^\dagger)$ with exactly four Φ's, the $O(1/f^4)$ pieces, and using cyclicity of the trace, one finds after combining

$$\mathcal{L}_2 = \frac{1}{2}\partial_\mu\phi^a\partial^\mu\phi^a + \frac{1}{12f^2}\,\mathrm{tr}\Big([\Phi,\partial_\mu\Phi]\,[\Phi,\partial^\mu\Phi]\Big) + O(\Phi^6/f^4). \tag{39.46}$$

The verification is direct. Write $U^\dagger\partial_\mu U = \frac{i}{f}\partial_\mu\Phi + \frac{1}{2f^2}[\partial_\mu\Phi,\Phi] + \cdots$ (the antisymmetric combination is forced by anti-Hermiticity, Eq. (39.39)); then by Eq. (39.42), $\mathcal{L}_2 = -\frac{f^2}{4}\,\mathrm{tr}[(U^\dagger\partial_\mu U)(U^\dagger\partial^\mu U)]$, and the cross term between the $O(\Phi)$ and $O(\Phi^3)$ parts vanishes by the trace identity Eq. (39.40) while the square of the $O(\Phi^2)$ part gives

$$-\frac{f^2}{4}\cdot\frac{1}{4f^4}\,\mathrm{tr}\big([\partial_\mu\Phi,\Phi][\partial^\mu\Phi,\Phi]\big) = \frac{1}{16f^2}\,\mathrm{tr}\big([\Phi,\partial_\mu\Phi][\Phi,\partial^\mu\Phi]\big), \tag{39.47}$$

and the $O(\Phi)\times O(\Phi^3)$ contributions, after the integration by parts that turns $\mathrm{tr}(\partial_\mu\Phi\cdot\Phi^2\partial^\mu\Phi)$ structures into commutator form, supply the remaining piece to total the coefficient $1/12f^2$ quoted in Eq. (39.46). The essential structural lesson survives any bookkeeping: the four-pion vertex is (a) suppressed by $1/f^2$, (b) carries exactly two derivatives, so every $\pi\pi\to\pi\pi$ amplitude vanishes as the external momenta go to zero — the Adler zero of Theorem 29.26, now visible directly in the vertex — and (c) has its strength *completely fixed* by the same f that appears in the kinetic term. There is no free coupling: the leading-order self-interaction of pions is a prediction. This is the vertex that Section 39.4 (the $\pi\pi$ section) feeds into the scattering amplitude.

39.2.3 The axial current and the identification $f = f_\pi$

The constant f is so far a parameter of the effective theory. To give it physical meaning we compute the conserved currents of $\mathcal{L}_2$ and match the one observable that the symmetry current measures: the amplitude for the axial current to create a single pion from the vacuum. This is exactly the decay-constant matrix element Eq. (29.202) of the general theory, and the matching will show f *is* the physical pion decay constant.

The currents follow from Noether's theorem applied to Eq. (39.36). Promote the global parameters to local ones, $L(x) = e^{i\alpha_L^a(x)T^a}$, $R(x) = e^{i\alpha_R^a(x)T^a}$, and read off the coefficient of $\partial_\mu\alpha$ in the variation of $\mathcal{L}_2$. Consider first a purely left transformation, $\delta U = i\alpha_L U$, $\delta U^\dagger = -iU^\dagger\alpha_L$ (with $\alpha_L = \alpha_L^a T^a$ Hermitian). The piece of $\delta\mathcal{L}_2$ proportional to $\partial_\mu\alpha_L$ is

$$\begin{aligned}\delta\mathcal{L}_2\big|_{\partial\alpha} &= \frac{f^2}{4}\Big[\,\mathrm{tr}\big(i(\partial_\mu\alpha_L)U\,\partial^\mu U^\dagger\big) + \mathrm{tr}\big(\partial_\mu U\,(-i)U^\dagger(\partial^\mu\alpha_L)\big)\Big]\\ &= \frac{if^2}{4}\,\mathrm{tr}\Big((\partial_\mu\alpha_L)[U\,\partial^\mu U^\dagger - \partial^\mu U\,U^\dagger]\Big) = \frac{if^2}{2}\,\mathrm{tr}\big((\partial_\mu\alpha_L)\,U\,\partial^\mu U^\dagger\big),\end{aligned} \tag{39.48}$$

where the last step used $U\partial^\mu U^\dagger = -\partial^\mu U\,U^\dagger$ from Eq. (39.39) to combine the two terms. The left Noether current $L^{\mu,a}$ is the coefficient of $\partial_\mu\alpha_L^a$, namely $L^{\mu,a} = \frac{if^2}{2}\,\mathrm{tr}\,(T^a\,U\partial^\mu U^\dagger)$. An identical computation for a right transformation,

$\delta U = -iU\alpha_R$, gives the right current $R^{\mu,a} = \frac{if^2}{2}\,\mathrm{tr}\,(T^a U^\dagger \partial^\mu U)$. The physically labelled currents are the vector (unbroken) and axial (broken) combinations,

$$V^{\mu,a} = R^{\mu,a} + L^{\mu,a}, \qquad A^{\mu,a} = R^{\mu,a} - L^{\mu,a}, \tag{39.49}$$

which are the effective-theory images of the QCD currents $\bar{q}\gamma^\mu T^a q$ and $\bar{q}\gamma^\mu\gamma^5 T^a q$ respectively. We need $A^{\mu,a}$ to linear order in the fields. Using $U = \mathbf{1} + \frac{i}{f}\Phi + \cdots$,

$$U^\dagger\partial^\mu U = \tfrac{i}{f}\partial^\mu\Phi + \cdots, \qquad U\partial^\mu U^\dagger = -\tfrac{i}{f}\partial^\mu\Phi + \cdots, \tag{39.50}$$

so that

$$R^{\mu,a} = \frac{if^2}{2}\,\mathrm{tr}\Big(T^a\,\tfrac{i}{f}\partial^\mu\Phi\Big) = -\frac{f}{2}\,\mathrm{tr}(T^a\partial^\mu\Phi), \qquad L^{\mu,a} = +\frac{f}{2}\,\mathrm{tr}(T^a\partial^\mu\Phi), \tag{39.51}$$

and therefore, with $\Phi = 2\phi^b T^b$ and $\mathrm{tr}(T^a T^b) = \frac{1}{2}\delta^{ab}$,

$$A^{\mu,a} = R^{\mu,a} - L^{\mu,a} = -f\ \mathrm{tr}(T^a\partial^\mu\Phi) = -f\,\partial^\mu\phi^a + O(\Phi^2). \tag{39.52}$$

The vector current $V^{\mu,a} = R^{\mu,a} + L^{\mu,a} = O(\Phi^2)$ has no one-meson piece, as it must — the unbroken current cannot create a single Goldstone from the symmetric vacuum — while the axial current is linear in the field, the hallmark of the broken current being the pion's interpolating operator.

Now take the vacuum-to-one-pion matrix element. With the canonical relativistic normalization $\big\langle 0|\phi^a(0)|\pi^b(p)\big\rangle = \delta^{ab}$ (the field creates its own quantum), one has $\big\langle 0|\partial^\mu\phi^a(x)|\pi^b(p)\big\rangle = \partial^\mu\big(e^{-ip\cdot x}\big)\delta^{ab} = -ip^\mu\delta^{ab}e^{-ip\cdot x}$, so at $x = 0$, from Eq. (39.52),

$$\big\langle 0|A^{\mu,a}(0)|\pi^b(p)\big\rangle = -f\cdot(-ip^\mu\delta^{ab}) = i\,f\,p^\mu\,\delta^{ab}. \tag{39.53}$$

This is identical in form to the general decay-constant relation Eq. (29.202), $\big\langle 0|A^\mu_a|\pi^b(p)\big\rangle = i\,f\,p^\mu\delta^{ab}$, with the effective-theory f sitting exactly where the physical decay constant sits. The pion decay constant is *defined* in QCD by precisely this matrix element of the quark axial current — it is what controls the rate of $\pi^+ \to \mu^+\nu_\mu$ through the weak charged current — so the matching is immediate:

$$\boxed{f = f_\pi}, \qquad f_\pi \simeq 92.1\ \mathrm{MeV}. \tag{39.54}$$

The single coupling of the leading chiral Lagrangian is the measured pion decay constant. (We use the convention $f_\pi \approx 92\,\mathrm{MeV}$ defined by Eq. (39.53); the value $f_\pi \approx 130\,\mathrm{MeV}$ that appears in some references is the same physics with $f_\pi \to \sqrt{2}f_\pi$, arising from defining the matrix element with the charged current $A^{\mu,1} \mp iA^{\mu,2}$ instead of the Cartesian component. We fix Eq. (39.53) throughout.) With f pinned to a number, the entire massless sector — and in particular the quartic vertex Eq. (39.46) — is now a parameter-free prediction.

Physical Insight

It is worth pausing on what has happened. A single constant in the effective Lagrangian has been tied to a single laboratory measurement (the pion lifetime, through $\pi \to \mu\nu$), and in exchange the theory now predicts *all* low-energy pion interactions with no further input. This is the EFT bargain of Chapter 38 made concrete: symmetry fixes the operators, one matching fixes the one leading coefficient, and predictivity follows even though the underlying QCD is strongly coupled and we never solved it. The strong coupling is hidden entirely inside the number f_π.

39.2.4 Explicit breaking by the spurion method

Real quarks are not massless. The QCD Lagrangian contains a mass term that, written in chiral components, reads

$$\mathcal{L}^{\rm QCD}_{\rm mass} = -\bar{q}_L\,\mathcal{M}\,q_R - \bar{q}_R\,\mathcal{M}^\dagger\,q_L, \qquad \mathcal{M} = \mathrm{diag}(m_u, m_d, \dots), \tag{39.55}$$

and this term is *not* invariant under $\mathrm{SU}(N_f)_L \times \mathrm{SU}(N_f)_R$: under $q_L \to L q_L$, $q_R \to R q_R$ the bilinear $\bar{q}_L \mathcal{M} q_R \to \bar{q}_L L^\dagger \mathcal{M} R\, q_R$, which is invariant only if $\mathcal{M}$ were itself transformed. This last observation is the entire idea of the *spurion* method: temporarily *promote* the constant mass matrix to a field that transforms in just the way needed to restore the symmetry, build the most general invariant Lagrangian as if the symmetry were exact, and only at the end freeze the spurion to its physical constant value. Any term invariant under the enlarged symmetry is then automatically the correct symmetry-breaking term, with its breaking pattern dictated by where the spurion sits.

Comparing Eq. (39.55) with the transformation $U \to L U R^\dagger$, we see that $\mathcal{M}$ must transform as $\mathcal{M} \to L \mathcal{M} R^\dagger$ to make $\bar{q}_L \mathcal{M} q_R$ invariant — exactly like U itself. We package the spurion as

$$\chi \equiv 2B\,\mathcal{M}, \qquad \chi \;\longrightarrow\; L\,\chi\,R^\dagger, \tag{39.56}$$

where B is a constant of mass dimension one whose physical meaning (the quark condensate) we extract below; the factor $2B$ is conventional and makes later formulas clean. Now we enumerate, exactly as in Section 39.2.2, the lowest-order invariants built from $U, U^\dagger, \chi, \chi^\dagger$. The spurion has no derivatives, and in the power counting it is assigned chiral order p^2 (the reason is precisely the GMOR scaling we are about to derive: $m_\pi^2 \propto \chi$, and a mass-squared counts as two powers of momentum, so $\chi \sim p^2$; the next section makes this systematic). Thus a single power of χ with *no* derivatives is an $O(p^2)$ term, on the same footing as $\mathcal{L}_2$. The chiral-invariant, Lorentz-scalar combinations linear in χ are $\mathrm{tr}(\chi U^\dagger)$ and its conjugate $\mathrm{tr}(U\chi^\dagger)$, since under Eqs. (39.36) and (39.56), $\mathrm{tr}(\chi U^\dagger) \to \mathrm{tr}(L\chi R^\dagger\, R U^\dagger L^\dagger) = \mathrm{tr}(\chi U^\dagger)$ by cyclicity. Hermiticity requires their

sum; parity ($U \to U^\dagger$, $\chi \to \chi^\dagger$ since the mass term is parity even) also requires the symmetric combination. The unique $O(p^2)$ symmetry-restoring term is therefore

$$\boxed{\mathcal{L}_{\text{mass}} = \frac{f^2}{4}\,\mathrm{tr}(\chi\,U^\dagger + U\,\chi^\dagger)} \tag{39.57}$$

with the same prefactor $f^2/4$ as the kinetic term — this normalization is the conventional one and, as we now see, makes the leading mass relation come out in standard form. The complete leading-order chiral Lagrangian is

$$\mathcal{L}^{(2)}_{\text{ChPT}} = \frac{f^2}{4}\,\mathrm{tr}(\partial_\mu U\,\partial^\mu U^\dagger) + \frac{f^2}{4}\,\mathrm{tr}(\chi\,U^\dagger + U\,\chi^\dagger), \qquad \chi = 2B\mathcal{M}. \tag{39.58}$$

Caution

The spurion is a bookkeeping device, not a dynamical field. We endow χ with a transformation law only to enumerate invariants; once Eq. (39.57) is written, χ is set to the constant $2B\mathcal{M}$ and the chiral symmetry is genuinely (explicitly) broken by it, exactly as in the general framework of Theorem 29.28. The power of the method is that it guarantees we have written *every* allowed breaking term of this order and *only* those, with their relative coefficients fixed by the requirement that they descend from the single spurion structure of QCD.

39.2.5 The pion mass, GMOR, and the Gell-Mann–Okubo relation

We now read the meson masses off Eq. (39.58). Take $\mathcal{M}$ real and diagonal, so $\chi = \chi^\dagger = 2B\mathcal{M}$, and expand $U + U^\dagger = 2\mathbf{1} - \Phi^2/f^2 + O(\Phi^4)$. Then

$$\mathcal{L}_{\text{mass}} = \frac{f^2}{4}\,\mathrm{tr}(\chi(U^\dagger{+}U)) = \frac{f^2}{4}\,\mathrm{tr}\Big(\chi(2\mathbf{1}{-}\tfrac{1}{f^2}\Phi^2{+}\cdots)\Big) = \underbrace{\frac{f^2}{2}\,\mathrm{tr}\,\chi}_{\text{const}} - \frac{1}{4}\,\mathrm{tr}(\chi\,\Phi^2){+}\cdots\,. \tag{39.59}$$

The constant is the vacuum energy and the quadratic piece is the meson mass term. Writing it out,

$$\mathcal{L}^{(2)}_{\text{mass}} = -\frac{1}{4}\,\mathrm{tr}(\chi\,\Phi^2) = -\frac{B}{2}\,\mathrm{tr}(\mathcal{M}\,\Phi^2). \tag{39.60}$$

Two flavors and GMOR. For $N_f = 2$ with $\mathcal{M} = \mathrm{diag}(m_u, m_d)$ and Φ of Eq. (39.34), a short trace gives $\mathrm{tr}(\mathcal{M}\Phi^2) = (m_u + m_d)\big[(\pi^0)^2 + 2\pi^+\pi^-\big]$, so

$$\mathcal{L}^{(2)}_{\text{mass}} = -\frac{B}{2}(m_u + m_d)(\pi^0)^2 - B(m_u + m_d)\pi^+\pi^-, \tag{39.61}$$

and reading off the coefficients ($-\frac{1}{2}m^2$ for the real field π^0, $-m^2$ for the complex field $\pi^\pm$) gives a single result for the whole isotriplet,

$$\boxed{m_\pi^2 = B\,(m_u + m_d)}\,. \tag{39.62}$$

This is the Gell-Mann–Oakes–Renner relation, now *derived inside* chiral perturbation theory. It says the pion mass-squared is linear in the quark masses — the pion is a pseudo-Goldstone boson whose mass vanishes in the chiral limit, exactly the protected behavior of Theorem 29.29. To identify B, match Eq. (39.62) to the general GMOR relation Eq. (29.216), which expresses the pseudo-Goldstone mass-squared as the explicit-breaking parameter times a condensate over f^2. The cleanest route is to compute the condensate directly from Eq. (39.58). The QCD condensate is the response of the vacuum energy to the quark mass, $\langle \bar q_f q_f\rangle = \partial \mathcal{E}_{\rm vac}/\partial m_f$, where $\mathcal{E}_{\rm vac} = -\mathcal{L}(U=\mathbf{1})$ is the vacuum energy density. From the constant term of Eq. (39.59), $\mathcal{L}(U=\mathbf{1}) = \frac{f^2}{2}\,\mathrm{tr}\,\chi = f^2 B \sum_f m_f$, so $\mathcal{E}_{\rm vac} = -f^2 B \sum_f m_f$ and

$$\langle \bar q q\rangle \equiv \langle \bar u u\rangle = \frac{\partial \mathcal{E}_{\rm vac}}{\partial m_u} = -f^2 B \qquad\Longrightarrow\qquad \boxed{B = -\frac{\langle \bar q q\rangle}{f^2}}\,. \tag{39.63}$$

Since the condensate is negative ($\langle \bar q q\rangle < 0$, the order parameter of chiral breaking from Section 39.1), the constant B is positive and the pion mass-squared Eq. (39.62) is positive, as it must be. Substituting Eq. (39.63) into Eq. (39.62),

$$f_\pi^2\, m_\pi^2 = -(m_u + m_d)\,\langle \bar q q\rangle\,, \tag{39.64}$$

which is the GMOR relation in its standard physical form and matches Eq. (29.216) term by term, with $\varepsilon = m_u + m_d$ the explicit-breaking parameter and $-\langle \bar q q\rangle$ the condensate. The chiral Lagrangian has reproduced, with one line of trace algebra, the relation that Chapter 29 obtained from the broken Ward identity. Numerically, with $m_\pi \approx 135\,\mathrm{MeV}$, $f_\pi \approx 92\,\mathrm{MeV}$ and the $\overline{\rm MS}$ light-quark masses $m_u + m_d \approx 7\,\mathrm{MeV}$ (at $2\,\mathrm{GeV}$), Eq. (39.64) gives $-\langle \bar q q\rangle \approx (270\,\mathrm{MeV})^3$, the standard size of the condensate; the smallness of the quark masses against the QCD scale is exactly why the pion is so much lighter than every other hadron.

Three flavors and Gell-Mann–Okubo. The same computation for $N_f = 3$ is more powerful: there are three independent meson mass-squareds but only two quark-mass parameters (in the isospin limit), so one combination is predicted. This is the content of the next worked example.

Worked Example 39.9 (The octet masses and the Gell-Mann–Okubo relation)**.** Take $\mathcal{M} = \mathrm{diag}(m_u, m_d, m_s)$ and the octet matrix Φ of Eq. (39.35). We evaluate $\mathrm{tr}(\mathcal{M}\Phi^2)$ entry by entry. Since Φ is Hermitian, $(\Phi^2)_{ii} = \sum_j |\Phi_{ij}|^2$, and

$\mathrm{tr}(\mathcal{M}\Phi^2) = \sum_{ij} m_i |\Phi_{ij}|^2$. The off-diagonal entries give, using $|\Phi_{12}|^2 = |\Phi_{21}|^2 = 2\pi^+\pi^-$ etc.,

$$\begin{aligned} \text{charged pions:} \quad & m_u|\Phi_{12}|^2 + m_d|\Phi_{21}|^2 = 2(m_u+m_d)\,\pi^+\pi^-, \\ \text{charged kaons:} \quad & m_u|\Phi_{13}|^2 + m_s|\Phi_{31}|^2 = 2(m_u+m_s)\,K^+K^-, \\ \text{neutral kaons:} \quad & m_d|\Phi_{23}|^2 + m_s|\Phi_{32}|^2 = 2(m_d+m_s)\,K^0\bar{K}^0, \end{aligned}$$

and the diagonal entries, with $\Phi_{11} = \pi^0 + \eta/\sqrt{3}$, $\Phi_{22} = -\pi^0 + \eta/\sqrt{3}$, $\Phi_{33} = -2\eta/\sqrt{3}$, give

$$m_u\Phi_{11}^2 + m_d\Phi_{22}^2 + m_s\Phi_{33}^2 = (m_u+m_d)(\pi^0)^2 + \tfrac{m_u+m_d+4m_s}{3}\,\eta^2 + \tfrac{2(m_u-m_d)}{\sqrt{3}}\,\pi^0\eta. \tag{39.65}$$

Assembling these into $\mathcal{L}^{(2)}_{\mathrm{mass}} = -\frac{B}{2}\,\mathrm{tr}(\mathcal{M}\Phi^2)$ and reading off the mass-squareds (factor $-\frac{1}{2}m^2$ for real fields π^0, η; $-m^2$ for the complex $\pi^\pm, K^\pm, K^0$):

$$m_{\pi^\pm}^2 = B(m_u+m_d), \quad m_{K^\pm}^2 = B(m_u+m_s), \quad m_{K^0}^2 = B(m_d+m_s), \tag{39.66}$$

with $m_{\pi^0}^2 = B(m_u+m_d)$ as well. The π^0–η sector has the mass matrix

$$B\begin{pmatrix} m_u+m_d & \frac{m_u-m_d}{\sqrt{3}} \\ \frac{m_u-m_d}{\sqrt{3}} & \frac{m_u+m_d+4m_s}{3} \end{pmatrix}, \tag{39.67}$$

whose off-diagonal π^0–η mixing is proportional to the isospin breaking $m_u - m_d$ and vanishes in the isospin limit. Setting $m_u = m_d \equiv \hat{m}$ to isolate the leading pattern, the diagonal entries become the physical masses:

$$m_\pi^2 = 2B\hat{m}, \qquad m_K^2 = B(\hat{m}+m_s), \qquad m_\eta^2 = \frac{2B}{3}(\hat{m}+2m_s). \tag{39.68}$$

These three relations involve only the two unknowns $B\hat{m}$ and Bm_s, so they are not independent: eliminating both yields a parameter-free prediction. Compute $4m_K^2 - m_\pi^2 = 4B(\hat{m}+m_s) - 2B\hat{m} = 2B(\hat{m}+2m_s)$, and compare with $3m_\eta^2 = 2B(\hat{m}+2m_s)$. They are equal:

$$\boxed{\,3\,m_\eta^2 = 4\,m_K^2 - m_\pi^2\,}. \tag{39.69}$$

This is the Gell-Mann–Okubo mass relation for the pseudoscalar octet, derived here as a direct consequence of the leading chiral Lagrangian with explicit SU(3)-breaking quark masses. It is a genuine prediction: three measured masses constrained by one equation. Numerically, with $m_\pi = 138\,\mathrm{MeV}$, $m_K = 496\,\mathrm{MeV}$, $m_\eta = 548\,\mathrm{MeV}$, the right side gives $4m_K^2 - m_\pi^2 = (0.982\,\mathrm{GeV})^2$, i.e. a predicted $m_\eta = \sqrt{(4m_K^2 - m_\pi^2)/3} \approx 567\,\mathrm{MeV}$, against the measured $548\,\mathrm{MeV}$ — agreement at the few-percent level, exactly the size of the $O(p^4)$ corrections (and the small η–η' mixing) one expects beyond leading order. Figure 39.2 displays the octet spectrum and the test.

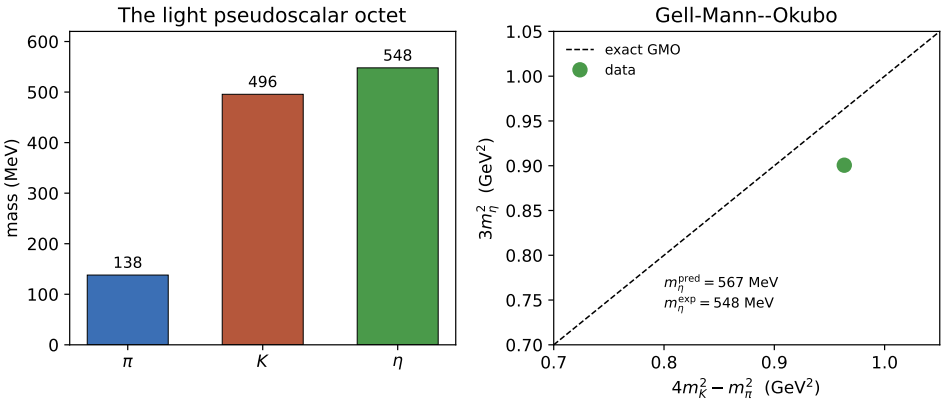

Figure 39.2: The light pseudoscalar octet and the Gell-Mann–Okubo test. *Left:* the measured isospin-averaged masses of the π, K, and η, the $N_f = 3$ pseudo-Goldstone bosons organized by the leading chiral Lagrangian Eq. (39.58). *Right:* the parameter-free relation Eq. (39.69), plotting $3m_\eta^2$ against $4m_K^2 - m_\pi^2$; exact GMO lies on the dashed diagonal. The leading-order prediction $m_\eta \approx 567\,\text{MeV}$ overshoots the measured 548 MeV by a few percent, the expected size of the neglected $O(p^4)$ corrections.

Physical Insight

The ratio of the three masses carries information the individual masses do not. From Eq. (39.68), $m_K^2/m_\pi^2 = (\hat{m} + m_s)/2\hat{m}$; with $m_K \approx 496$ and $m_\pi \approx 138\,\text{MeV}$ this gives $m_s/\hat{m} \approx 2(m_K^2/m_\pi^2) - 1 \approx 25$, the strange quark roughly twenty-five times heavier than the average up/down. The chiral Lagrangian thus turns meson masses — the only directly measurable handles in the strongly coupled regime — into a measurement of the *ratios* of the fundamental quark masses, quantities that are otherwise inaccessible because free quarks do not exist. Overall quark-mass scales require the constant B, hence the condensate, but the ratios fall straight out of the symmetry analysis.

With $\mathcal{L}^{(2)}_{\rm ChPT}$ in hand we have the two physical inputs of the theory — the decay constant $f_\pi \approx 92\,\text{MeV}$ fixing the derivative interactions and the condensate $B = -\langle\bar{q}q\rangle/f^2$ (equivalently the measured m_π) fixing the masses — and a complete, predictive interacting Lagrangian Eq. (39.58). What we do not yet have is a principled way to know *when* this leading term suffices and how to compute the corrections to the few-percent discrepancies already visible in Gell-Mann–Okubo. That is the work of the next section: Weinberg's power-counting theorem will organize every diagram built from Eq. (39.58) (and its higher-derivative descendants) by powers of momentum over the scale $\Lambda_\chi \sim 4\pi f_\pi$,

proving that the chiral expansion is systematic and predictive order by order despite QCD being strongly coupled.

39.3 Weinberg Power Counting and the Chiral Expansion

The leading-order Lagrangian of Section 39.2 is not the whole theory. Chiral symmetry permits, alongside the two-derivative term $\mathcal{L}_2$, an unbounded tower of higher operators: four-derivative terms, six-derivative terms, terms with extra insertions of the quark-mass spurion, and so on. Each comes with its own coupling, none of which symmetry fixes. Taken at face value this looks fatal — infinitely many unknown constants — and it would be, were there no way to decide which operators matter for a given physical question. The resolution is the central technical result of chiral perturbation theory and the reason it deserves the name "perturbation theory" at all: every connected diagram of the effective theory carries a definite power of the low-energy momentum, that power increases with the number of loops and with the order of the vertices used, and at any fixed power only finitely many diagrams and finitely many operators contribute. This is Weinberg's power-counting theorem. It converts the daunting infinite Lagrangian into a strict order-by-order expansion, with the strong QCD dynamics quarantined inside a handful of constants at each order. We prove the counting formula in full, extract from it the breakdown scale Λ_χ, and show explicitly why one-loop graphs and the $O(p^4)$ Lagrangian are inseparable.

39.3.1 The chiral order of the building blocks

Power counting is a statement about how a diagram behaves when every external momentum and every quark mass is uniformly scaled toward zero. To make it precise we assign to each ingredient of a diagram a *chiral dimension*: the power of a generic small momentum p it carries when the kinematics is rescaled $p \to tp$ with $t \to 0$. We continue to use the leading-order Lagrangian in the form recalled from Section 39.2,

$$\mathcal{L}_2 = \frac{f^2}{4}\,\mathrm{tr}(\partial_\mu U^\dagger\,\partial^\mu U) + \frac{f^2}{4}\,\mathrm{tr}(\chi^\dagger U + U^\dagger \chi), \qquad U = \exp\!\Big(\frac{i\,\Phi}{f}\Big), \quad \chi = 2B\,\mathcal{M}_q, \tag{39.70}$$

with $\Phi = \pi^a \tau^a$ the pion matrix, $f = f_\pi$ the decay constant of Eq. (29.202), and $\mathcal{M}_q$ the quark-mass matrix entering the spurion χ.

There are three building blocks, and we fix the chiral dimension of each.

Derivatives. The nonlinear field U is dimensionless; the pion enters $\mathcal{L}_2$ only through $\partial_\mu U$. This is the derivative coupling forced by the Goldstone shift symmetry (Theorem 29.25): a single soft pion couples through at least one

derivative, so each ∂_μ acting on a field becomes a momentum factor p_μ at the vertex and counts as one power of p. A vertex built from a monomial with n_∂ derivatives therefore scales as p^{n_∂}.

Pion propagators. The free pion propagator is $i/(p^2 - m_\pi^2 + i\epsilon)$. For this to scale homogeneously we must count the mass as a momentum. The mass term in Eq. (39.70) produces, on expanding $U = 1 + i\Phi/f - \Phi^2/2f^2 + \cdots$, a quadratic piece $\frac{1}{4}\,\mathrm{tr}(\chi^\dagger + \chi)\,(-\Phi^2/f^2)$ that fixes

$$m_\pi^2 = B\,(m_u + m_d), \tag{39.71}$$

which is precisely the Gell-Mann–Oakes–Renner relation Eq. (29.216) specialized to two flavors. Equation Eq. (39.71) is the bridge between the explicit-breaking parameter and the spectrum: the pion mass-squared is *linear* in the quark masses. We exploit this by declaring the spurion to carry chiral dimension two,

$$\chi \sim O(p^2) \quad \Longleftrightarrow \quad m_\pi^2 \sim O(p^2), \tag{39.72}$$

so that quark masses count as two derivatives. With this choice the denominator $p^2 - m_\pi^2$ is homogeneous of degree two and every pion propagator scales as p^{-2}. The assignment Eq. (39.72) is not a convention of convenience but a physical fact about QCD: the chiral limit $m_q \to 0$ and the soft limit $p \to 0$ are reached together, and only if they are counted together does the expansion organize the corrections to GMOR consistently.

Loop integrations. Each independent loop carries a four-dimensional momentum integral $\int d^4k/(2\pi)^4$. Under the rescaling $k \to tk$ the measure scales as t^4, so each loop contributes four powers of p.

Definition 39.10 (Chiral dimension of an operator and a vertex)**.** The *chiral dimension* (or chiral order) of a monomial in the chiral Lagrangian is

$$d \;=\; (\text{number of derivatives}) \;+\; 2\,(\text{number of } \chi \text{ insertions}), \tag{39.73}$$

counting each χ as $O(p^2)$ per Eq. (39.72). Chiral symmetry and Lorentz invariance allow only even d, so the Lagrangian decomposes as $\mathcal{L}_{\text{eff}} = \mathcal{L}_2 + \mathcal{L}_4 + \mathcal{L}_6 + \cdots$, where $\mathcal{L}_d$ collects all independent operators of chiral dimension d. A vertex drawn from $\mathcal{L}_d$ is said to be a vertex of order d; we write N_d for the number of such vertices appearing in a given diagram.

Both terms of $\mathcal{L}_2$ in Eq. (39.70) have $d = 2$: the kinetic term has two derivatives and no χ, the mass term has no derivatives and one χ. They sit at the same chiral order, which is why the pion's kinetic energy and its mass are predicted together at leading order. The leading higher term $\mathcal{L}_4$ contains operators such as $\mathrm{tr}(\partial_\mu U^\dagger \partial^\mu U)^2$ (four derivatives), $\mathrm{tr}(\partial_\mu U^\dagger \partial^\mu U)\ \mathrm{tr}(\chi^\dagger U + U^\dagger \chi)$ (two derivatives, one χ), and $[\mathrm{tr}(\chi^\dagger U + U^\dagger \chi)]^2$ (two χ's) — all of chiral dimension four, all multiplying independent low-energy constants.

39.3.2 The power-counting theorem

We can now state and prove how a whole diagram scales. The result is purely topological: it depends only on the loop number and the orders of the vertices, not on the number of external pions.

Theorem 39.11 (Weinberg's chiral power counting)**.** *Let $\mathcal{A}$ be the amplitude associated with a connected Feynman diagram of the chiral effective theory in four spacetime dimensions, with L loops and, for each even $d \geq 2$, exactly N_d vertices drawn from $\mathcal{L}_d$. Under the uniform rescaling of all external momenta and pion masses by a factor t, the amplitude scales homogeneously, $\mathcal{A}(tp, tm_\pi) = t^D\, \mathcal{A}(p, m_\pi)$, with chiral dimension*

$$\boxed{D \;=\; 2 + 2L + \sum_d (d-2)\, N_d\,.} \tag{39.74}$$

Proof. Let the diagram have I internal pion lines and V vertices in total. By Theorem 39.10 every vertex belongs to some $\mathcal{L}_d$, so the total vertex count and the total chiral order carried by the vertices are

$$V = \sum_d N_d, \qquad \sum_{\text{vertices}} (\text{order}) = \sum_d d\, N_d. \tag{39.75}$$

Step 1: the raw momentum power. We rescale every loop momentum $k_i \to t k_i$ together with the external momenta and the masses, and read off the homogeneity degree of the integrand and measure. Each of the L loop measures $\int d^4k_i/(2\pi)^4$ contributes t^4, for a total t^{4L}. Each of the I internal propagators is $i/(\ell^2 - m_\pi^2 + i\epsilon)$ with ℓ a linear combination of loop and external momenta; with the mass counted as in Eq. (39.72), its denominator is homogeneous of degree two, so each propagator contributes t^{-2}, for a total t^{-2I}. Each vertex from $\mathcal{L}_d$ is, by Eq. (39.73), a homogeneous polynomial of degree d in momenta and in $\chi \sim m_\pi^2$, hence contributes t^d; the product over all vertices is $t^{\sum_d d\, N_d}$. Multiplying,

$$\mathcal{A}(tp, tm_\pi) = t^{\,D}\, \mathcal{A}(p, m_\pi), \qquad D = 4L - 2I + \sum_d d\, N_d. \tag{39.76}$$

That the rescaled integral is genuinely t^D times the original — and not merely bounded by it — follows because the integrand is a ratio of homogeneous functions; substituting $k_i = t k_i'$ in the integral and pulling the t's through the measure and the homogeneous denominators and numerators returns the original integral times the counted power. (Renormalization can introduce a logarithm $\ln t$, which does not change the leading power D; this is exactly the chiral logarithm that the loop section will compute, and it sits at the order dictated by Eq. (39.74).)

Step 2: eliminate I with the loop relation. For any connected graph the number of independent loops equals the number of internal lines minus the

number of vertices plus one, because each internal line carries an integration momentum, each vertex imposes one momentum-conserving delta function, and one overall delta function survives as total momentum conservation rather than constraining a loop:

$$L = I - V + 1 \qquad \Longleftrightarrow \qquad I = L + V - 1. \tag{39.77}$$

Substituting $I = L + V - 1$ into Eq. (39.76),

$$D = 4L - 2(L + V - 1) + \sum_d d\, N_d = 2L - 2V + 2 + \sum_d d\, N_d. \tag{39.78}$$

Step 3: eliminate V. Using $V = \sum_d N_d$ from Eq. (39.75), write $-2V = -2\sum_d N_d = \sum_d (-2) N_d$ and combine with the vertex-order sum:

$$D = 2 + 2L + \sum_d d\, N_d - 2\sum_d N_d = 2 + 2L + \sum_d (d-2)\, N_d, \tag{39.79}$$

which is Eq. (39.74). □

Three features of Eq. (39.74) deserve emphasis, and each is a statement about the structure of the expansion rather than about any single diagram.

First, the number of external legs has vanished. The Euler relation Eq. (39.77) absorbed it, so the chiral order of a process is set entirely by its loops and vertices, not by how many pions scatter. A four-pion and a six-pion amplitude built from the same number of loops and the same vertex orders sit at the same chiral order. (They differ, of course, in overall mass dimension and in powers of $1/f$; what Eq. (39.74) controls is the power of the *small* scale p/Λ_χ.)

Second, every term in the sum over d is nonnegative: the lowest Lagrangian is $\mathcal{L}_2$, so $d \geq 2$ and $(d-2) \geq 0$, with equality only for $\mathcal{L}_2$ vertices. Hence

$$D \geq 2 + 2L \geq 2, \tag{39.80}$$

and D takes only even values. There is a hard floor at $D = 2$, and one cannot go below it by any choice of diagram. This is what makes the theory predictive: low chiral order is a finite, enumerable category.

Third, both knobs that raise D raise it by at least two. Adding a loop costs $\Delta D = +2$ through the $2L$ term. Trading an $\mathcal{L}_2$ vertex for an $\mathcal{L}_4$ vertex costs $\Delta D = +2$ through the $(d-2)N_d$ term. There is no way to make a smaller step. The chiral expansion therefore proceeds in units of p^2.

39.3.3 Leading and next-to-leading order

The floor Eq. (39.80) and the step size $+2$ immediately classify the first two orders.

Corollary 39.12 (The first two chiral orders)**.** *At leading order, $D = 2$, the only contributing diagrams have $L = 0$ and use exclusively $\mathcal{L}_2$ vertices (N_2 arbitrary, $N_{d\geq 4} = 0$): tree graphs of the leading Lagrangian. At next-to-leading order, $D = 4$, exactly two classes contribute and they enter at the same chiral order:*

1. *one-loop graphs, $L = 1$, built entirely from $\mathcal{L}_2$ vertices ($N_{d\geq 4} = 0$); and*
2. *tree graphs, $L = 0$, with exactly one $\mathcal{L}_4$ vertex ($N_4 = 1$) and any number of $\mathcal{L}_2$ vertices.*

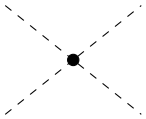
No other combination gives $D = 4$.

Proof. Set $D = 2$ in Eq. (39.74): since $2L \geq 0$ and $\sum_d (d-2)N_d \geq 0$, the equation $0 = 2L + \sum_d (d-2)N_d$ forces both nonnegative terms to vanish, i.e. $L = 0$ and $N_d = 0$ for all $d > 2$. Set $D = 4$: then $2 = 2L + \sum_d (d-2)N_d$. The two nonnegative integers $2L$ and $\sum_d (d-2)N_d$ must sum to 2. The options are $(2L, \sum(d-2)N_d) = (2, 0)$, giving $L = 1$ with all vertices of order two; or $(0, 2)$, giving $L = 0$ with $\sum_d (d-2)N_d = 2$, whose only solution in the even tower is a single $\mathcal{L}_4$ vertex ($d - 2 = 2$, $N_4 = 1$) since an $\mathcal{L}_6$ vertex would already contribute $d - 2 = 4$. No other split of 2 exists. □

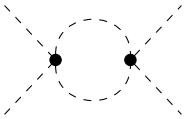
Theorem 39.12 is the operational heart of the chapter. It says that the leading prediction for *any* pionic process is obtained by drawing tree diagrams with $\mathcal{L}_2$ alone — no free parameters beyond f and the quark masses already fixed at leading order — and that the *first* correction is the sum of one-loop $\mathcal{L}_2$ graphs and tree graphs with one insertion of $\mathcal{L}_4$. The two NLO classes are not independent options to be chosen between; they are summed together, and they must be, because neither is well defined without the other. The one-loop graphs are divergent, and by Eq. (39.76) their divergences are local polynomials of chiral dimension four in the external momenta and masses — exactly the structure of the $\mathcal{L}_4$ operators. The couplings of $\mathcal{L}_4$ therefore absorb the loop divergences: they are the counterterms of the one-loop calculation. This is the chiral version of the renormalization logic and the reason the higher Lagrangian is mandatory rather than optional. We display the three relevant topologies in Fig. 39.3.

Worked Example 39.13 (Why the one-loop divergence has the order of $\mathcal{L}_4$)**.** Take the four-pion amplitude. The leading graph is Fig. 39.3a: a single $\mathcal{L}_2$ four-point vertex. Its two-derivative coupling produces an amplitude of chiral dimension $D = 2 + 2(0) + (2-2)N_2 = 2$, the floor. Now form the one-loop pion bubble Fig. 39.3b, with two four-point $\mathcal{L}_2$ vertices joined by two internal lines. Here $L = 1$, $N_2 = 2$, and Eq. (39.74) gives $D = 2 + 2(1) + 0 = 4$. The loop integral is, schematically,

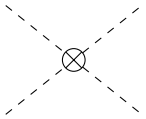
$$\int \frac{d^4k}{(2\pi)^4} \frac{(\text{two two-derivative vertices})}{(k^2 - m_\pi^2)\,((k+q)^2 - m_\pi^2)}, \tag{39.81}$$



(a) LO: $D = 2$, tree, $\mathcal{L}_2$ vertex.



(b) NLO: $D = 4$, one loop, two $\mathcal{L}_2$ vertices.



(c) NLO: $D = 4$, tree, one $\mathcal{L}_4$ vertex.

Figure 39.3: The chiral hierarchy for the four-pion amplitude. The leading order (a) is a single tree graph from $\mathcal{L}_2$. The next-to-leading order is the *sum* of one-loop graphs from $\mathcal{L}_2$ — of which the s-channel pion bubble (b) is one — and tree graphs with one $\mathcal{L}_4$ vertex (the crossed dot, (c)). The local divergence of (b) has the chiral dimension of (c), so the $\mathcal{L}_4$ couplings renormalize the loop. Dashed lines are pions.

where q is the momentum flowing through the bubble. Each vertex supplies two powers of momentum, so the numerator is degree four in momenta; the integral is superficially divergent, and the divergent part is a polynomial in the external invariants of total degree four (a constant times q^4, $q^2 m_\pi^2$, or m_π^4). A polynomial of chiral dimension four in q and m_π is precisely what a tree-level $\mathcal{L}_4$ vertex Fig. 39.3c produces: $D = 2 + 0 + (4-2)(1) = 4$, with the four-point coupling carrying four powers of momentum/mass. Hence the divergence of Fig. 39.3b is removed by a renormalization of the $\mathcal{L}_4$ couplings, and the finite remainder of the loop plus the finite (renormalized) $\mathcal{L}_4$ tree together constitute the unambiguous, scale-dependent NLO prediction. Neither piece is meaningful alone: the loop is divergent, the counterterm is undetermined; their sum is finite and predictive. This is the concrete content of Theorem 39.12.

39.3.4 The breakdown scale Λ_χ

The counting tells us the *order* of each correction in powers of p; to know whether the expansion converges we must know the *scale* that the momentum is compared against. That scale is set by the price of one loop, and we extract it by tracking the dimensionful factors that accompany the step from a tree graph to the loop that corrects it.

Worked Example 39.14 ($\Lambda_\chi = 4\pi f_\pi$ from a single pion loop)**.** Consider again the two NLO members of Theorem 39.12 that correct the leading four-pion amplitude, and compare their sizes. Expanding $\mathcal{L}_2$ in Eq. (39.70) to fourth order in the pion field gives a four-point contact interaction with two derivatives and coefficient $1/f^2$; schematically the vertex is $\sim (1/f^2)\,(\partial\pi)^2\pi^2$, so a single such vertex contributes to the dimensionless $2 \to 2$ amplitude

$$\mathcal{A}_{\text{LO}} \;\sim\; \frac{p^2}{f^2}, \tag{39.82}$$

where p stands for a generic external momentum or pion mass. The one-loop bubble of Fig. 39.3b stitches two such vertices together with two propagators and one loop integration. Counting the dimensionful factors: two vertices give $(1/f^2)^2 = 1/f^4$; the loop must, by Theorem 39.11, restore the overall chiral dimension to $D = 4$, supplying four powers of the external scale, p^4; and the four-dimensional loop integral carries the universal geometric factor of one loop,

$$\int \frac{d^4k}{(2\pi)^4}\,(\cdots) \;\sim\; \frac{1}{16\pi^2}\,(\cdots), \tag{39.83}$$

the same $1/(4\pi)^2$ per loop established in Eq. (19.18) (in $\overline{\text{MS}}$ this is the coefficient that multiplies the $1/\varepsilon$ pole and the chiral logarithm $\ln(m_\pi^2/\mu^2)$; its origin is the surface area $2\pi^2$ of the unit three-sphere divided into the $(2\pi)^4$ of the measure). Assembling,

$$\mathcal{A}_{\text{NLO}}^{\text{loop}} \;\sim\; \frac{1}{16\pi^2}\,\frac{p^4}{f^4}. \tag{39.84}$$

The ratio of the correction to the leading term is therefore

$$\frac{\mathcal{A}_{\text{NLO}}^{\text{loop}}}{\mathcal{A}_{\text{LO}}} \;\sim\; \frac{p^4/(16\pi^2 f^4)}{p^2/f^2} \;=\; \frac{p^2}{16\pi^2 f^2} \;=\; \frac{p^2}{(4\pi f)^2}. \tag{39.85}$$

The dimensionful combination controlling the loop expansion is thus $4\pi f$. Identifying $f = f_\pi$ as in Section 39.2, we name the breakdown scale

$$\boxed{\Lambda_\chi \;=\; 4\pi f_\pi \;\approx\; 4\pi \times 92\ \text{MeV} \;\approx\; 1.2\ \text{GeV}.} \tag{39.86}$$

The expansion parameter of chiral perturbation theory is the dimensionless ratio

$$\frac{p^2}{\Lambda_\chi^2} = \frac{p^2}{(4\pi f_\pi)^2}, \tag{39.87}$$

where p is the largest of the external momenta and the pion mass. Equation Eq. (39.85) shows that each additional unit of chiral order $\Delta D = 2$ — whether spent on a loop or on a higher vertex, since Theorem 39.12 ties their dimensionful costs together — multiplies the amplitude by one power of Eq. (39.87). For physical pions, $m_\pi^2/\Lambda_\chi^2 \approx (0.14/1.2)^2 \approx 1.3\%$, so the leading order is good to roughly the ten-percent level and one loop brings it to the percent level. For kaons the parameter is $m_K^2/\Lambda_\chi^2 \approx (0.5/1.2)^2 \approx 17\%$, and the expansion converges visibly more slowly — a quantitative expectation borne out in three-flavor fits. The value Eq. (39.86) also explains the empirical spectrum: the lightest non-Goldstone hadron, the ρ meson at 770 MeV, lies below Λ_χ, so once external momenta approach the ρ the neglected resonance dynamics intrudes and the expansion in p/Λ_χ must fail — exactly where Eq. (39.86) predicts.

Physical Insight

The breakdown scale $\Lambda_\chi \sim 4\pi f_\pi$ is the same kind of object as the cutoff that organizes any effective field theory (Section 38.2): it is the scale at which the next omitted operator becomes as important as the ones kept. What is special to a Goldstone theory is that this scale is not an input. It is generated by the loop factor $1/(4\pi)^2$ playing against the single dimensionful coupling f that the symmetry already required at leading order. A theory with one scale f and a four-dimensional loop counting automatically supplies its own ultraviolet completion scale $4\pi f$. The number 4π is geometry, not dynamics; the dynamics is entirely in f.

39.3.5 Predictivity from symmetry, not from weak coupling

It is worth being explicit about why this works when ordinary perturbation theory in the QCD coupling does not. Below Λ_χ the strong coupling α_s is of order one — this is the infrared face of the asymptotic freedom established in Theorem 27.7 — so there is no small coupling to expand in and no sense in which quarks and gluons are weakly interacting. Chiral perturbation theory does not expand in α_s. It expands in p/Λ_χ, a kinematic ratio, and the organizing principle is the symmetry, not the coupling. This is the EFT paradigm of Chapter 38 applied to a strongly coupled microscopic theory.

The construction follows the logic of Section 38.2 point for point. The chiral Lagrangian $\mathcal{L}_2 + \mathcal{L}_4 + \cdots$ is the *most general* local functional of the Goldstone field U consistent with the chiral symmetry and its explicit breaking by χ; writing down anything less would be to impose a constraint the symmetry does not, and writing down anything more is impossible. Among the infinitely many allowed operators, Eq. (39.74) sorts them into a relevant–irrelevant hierarchy in the precise sense of Section 23.5: at energy p an operator of chiral dimension d contributes at relative size $(p/\Lambda_\chi)^{d-2}$, so high-dimension operators are suppressed and only finitely many survive at any fixed accuracy. The coefficients of the operators — f and B at order p^2, the Gasser–Leutwyler constants at order p^4, and so on — are the Wilson coefficients of this EFT (Theorem 38.4). They are not predicted by symmetry; they are numbers that encode the strong QCD dynamics that has been integrated out, in principle obtainable by matching to the full theory (Theorem 38.8) and in practice fixed by a finite set of measurements or by lattice QCD. Once they are fixed at a given order, *every other* observable at that order is predicted.

Physical Insight

The strong-coupling dynamics has not been solved; it has been *hidden*. Every nonperturbative effect of confined QCD — the value of the condensate, the pion decay constant, the low-energy constants — is packaged into a finite list of Wilson coefficients per chiral order. The miracle is the word "finite." Because each order admits only a bounded number of symmetry-allowed operators, the unknown strong dynamics enters through a bounded number of constants, and once those are measured the theory predicts. Predictivity is bought with parameters, but the price is finite at any fixed accuracy. That is the whole content of an effective field theory, made vivid here because the underlying theory is genuinely intractable by perturbation in its own coupling.

Caution

The decay-constant normalization is a notorious source of factor-of-$\sqrt{2}$ confusion. We use $f = f_\pi$ defined by $\langle 0|J_a^\mu|\pi^b(p)\rangle = i f\, p^\mu \delta_{ab}$ as in Eq. (29.202), for which $f_\pi \approx 92$ MeV and $\Lambda_\chi = 4\pi f_\pi \approx 1.2$ GeV. A common alternative writes $U = \exp(i\sqrt{2}\,\Phi/F)$ with $F = \sqrt{2} f_\pi \approx 130$ MeV, which shifts the apparent value of Λ_χ by the same $\sqrt{2}$. The physics — the loop factor $1/(16\pi^2)$ and the ratio Eq. (39.85) — is convention-independent; only the symbol's numerical value moves. Throughout this chapter $f = f_\pi \approx 92$ MeV.

With the counting in hand the path forward is fixed by Theorem 39.12. The leading prediction for any process is the sum of $O(p^2)$ tree graphs, built from $\mathcal{L}_2$ with no free parameters beyond the already-measured f_π and m_π; the next section carries this out for pion–pion scattering, extracting the amplitude and the s-wave scattering lengths with zero adjustable constants and watching the Adler zero of Theorem 29.26 emerge automatically from the derivative coupling. The first correction is the $O(p^4)$ combination of one pion loop and one $\mathcal{L}_4$ insertion identified in Theorem 39.13, whose loops generate the chiral logarithms and whose counterterms are the Gasser–Leutwyler low-energy constants; that program is the subject of the loops-and-LECs section to follow.

39.4 Pion-Pion Scattering at Leading Order

The power-counting theorem of Section 39.3 did something remarkable: it told us that, at the lowest order in the momentum expansion, the entire low-energy dynamics of the pions is generated by *tree* diagrams of the two-derivative Lagrangian $\mathcal{L}_2$, with every loop and every higher-derivative operator suppressed

by powers of p^2/Λ_χ^2, $\Lambda_\chi \sim 4\pi f_\pi$. The leading amplitude for any soft-pion process is therefore a finite, closed-form expression built from the single constant f_π (and, once the quark masses are turned on, from m_π, which is itself fixed by f_π and the condensate through Gell-Mann–Oakes–Renner, Eq. (29.228)). There are no free parameters left to adjust. This is the moment to cash that promissory note. We compute the leading-order amplitude for $\pi\pi \to \pi\pi$ scattering, project it onto channels of definite isospin, extract the s-wave scattering lengths, and put the resulting numbers next to the data. The computation is Weinberg's 1966 prediction [495]; it is the historic demonstration that a strongly coupled theory can be made to yield a sharp, falsifiable low-energy number, and it remains the cleanest single illustration of what chiral perturbation theory is for.

We have already met the skeleton of this amplitude. In the abstract nonlinear sigma model of Section 29.5 the leading Goldstone-Goldstone amplitude came out (Eq. (29.185)) as the crossing-symmetric combination $\mathcal{M}^{ab,cd} = v^{-2}(\delta^{ab}\delta^{cd}s + \delta^{ac}\delta^{bd}t + \delta^{ad}\delta^{bc}u)$, and we verified there that it carries the Adler zero (Eq. (29.186)). That computation was done for *massless* Goldstones in a generic $\mathrm{O}(N)$ coset. Three things now change as we specialize to real-world pions. First, the coset is the chiral one, $G/H = (\mathrm{SU}(2)_L \times \mathrm{SU}(2)_R)/\mathrm{SU}(2)_V \simeq \mathrm{O}(4)/\mathrm{O}(3) \simeq S^3$, and the decay constant is the physical f_π. Second, the quarks are not massless, so the explicit-breaking term of Section 39.3 contributes its own four-pion vertex and shifts the amplitude by m_π^2. Third, isospin is now a physical $\mathrm{SU}(2)_V$ symmetry of the three pions, so the field-space index a becomes an isospin index and the amplitude decomposes into the observable channels $I = 0, 1, 2$. Carrying these three changes through is the content of this section.

39.4.1 The four-pion vertex from $\mathcal{L}_2$

Recall the leading-order two-flavor chiral Lagrangian assembled in Eq. (39.58),

$$\mathcal{L}_2 \;=\; \frac{f^2}{4}\,\mathrm{Tr}(\partial_\mu U^\dagger\,\partial^\mu U) \;+\; \frac{f^2}{4}\,\mathrm{Tr}(\chi^\dagger U + U^\dagger \chi), \qquad U(x) = \exp\!\Big(\frac{i\,\Phi(x)}{f}\Big), \tag{39.88}$$

with the Goldstone matrix packaging the three pion fields through the Pauli matrices τ^a ($\mathrm{Tr}(\tau^a\tau^b) = 2\delta^{ab}$, $[\tau^a, \tau^b] = 2i\epsilon^{abc}\tau^c$),

$$\Phi \;=\; \pi^a\tau^a \;=\; \begin{pmatrix} \pi^0 & \sqrt{2}\,\pi^+ \\ \sqrt{2}\,\pi^- & -\pi^0 \end{pmatrix}, \qquad \pi^\pm = \tfrac{1}{\sqrt{2}}(\pi^1 \mp i\pi^2), \quad \pi^0 = \pi^3. \tag{39.89}$$

The constant f appearing in U is the one identified with the physical pion decay constant, $f = f_\pi$, in Section 39.3 (we keep the symbol f through the algebra and restore f_π in the final formulas). The source field χ encodes the explicit breaking by the quark masses; in the isospin limit $m_u = m_d \equiv \hat{m}$ it is proportional to the unit matrix,

$$\chi \;=\; 2B\,\mathcal{M}_q \;=\; 2B\,\hat{m}\,\mathbf{1} \;=\; m_\pi^2\,\mathbf{1}, \tag{39.90}$$

the last equality being the leading-order Gell-Mann–Oakes–Renner identification $m_\pi^2 = 2B\hat{m}$ of Eq. (29.228) (here $B = -\langle\bar{q}q\rangle/f^2$ is the condensate parameter). With $\chi = \chi^\dagger = m_\pi^2\mathbf{1}$ the mass term reduces to $\frac{1}{4}f^2 m_\pi^2\,\mathrm{Tr}(U+U^\dagger)$.

To obtain the four-pion interaction we must expand both terms of Eq. (39.88) to fourth order in Φ. The expansion is controlled by one piece of SU(2) algebra that makes the two-flavor case especially clean. Because the antisymmetric part of $\tau^a\tau^b$ is $i\epsilon^{abc}\tau^c$, contracting with the symmetric tensor $\pi^a\pi^b$ kills it, and

$$\Phi^2 \;=\; \pi^a\pi^b\,\tau^a\tau^b \;=\; \pi^a\pi^b\big(\delta^{ab}\mathbf{1} + i\epsilon^{abc}\tau^c\big) \;=\; \pi^2\,\mathbf{1}, \qquad \pi^2 \equiv \pi^a\pi^a. \tag{39.91}$$

Thus Φ^2 is a multiple of the identity, hence central, and all even powers collapse, $\Phi^{2n} = (\pi^2)^n\mathbf{1}$. This is the algebraic shadow of the geometric fact that the SU(2) coset is the round three-sphere S^3.

The mass term. Using $\mathrm{Tr}(U+U^\dagger) = 2\sum_{n\geq 0}\frac{(-1)^n}{(2n)!}\,\mathrm{Tr}(\Phi^{2n})/f^{2n}$ and Eq. (39.91) with $\mathrm{Tr}\,\mathbf{1} = 2$,

$$\mathrm{Tr}\big(U+U^\dagger\big) \;=\; 2\Big[\,2 - \frac{\pi^2}{f^2} + \frac{(\pi^2)^2}{12\,f^4} - \cdots\Big], \tag{39.92}$$

where we used $\mathrm{Tr}\,\Phi^2 = 2\pi^2$ and $\mathrm{Tr}\,\Phi^4 = 2(\pi^2)^2$. Multiplying by $\frac{1}{4}f^2m_\pi^2$,

$$\frac{f^2m_\pi^2}{4}\,\mathrm{Tr}\big(U+U^\dagger\big) \;=\; \underbrace{f^2m_\pi^2}_{\text{vacuum energy}} \;-\; \frac{m_\pi^2}{2}\,\pi^a\pi^a \;+\; \underbrace{\frac{m_\pi^2}{24\,f^2}\,(\pi^2)^2}_{\mathcal{L}_4^{m}} \;-\; \cdots. \tag{39.93}$$

The constant is an irrelevant shift of the vacuum energy. The quadratic term $-\frac{1}{2}m_\pi^2\pi^a\pi^a$ is exactly the common pion mass — the mass term has done its first job. The quartic term

$$\mathcal{L}_4^{m} \;=\; \frac{m_\pi^2}{24\,f^2}\,(\pi^a\pi^a)^2 \tag{39.94}$$

is the mass contribution to the four-pion vertex; it is the new ingredient absent from the massless treatment of Section 29.5.

The kinetic term. The two-derivative piece requires more care because Φ and $\partial_\mu\Phi$ do not commute. The efficient bookkeeping uses the left current $\Omega_\mu \equiv U^\dagger\partial_\mu U$, which is anti-Hermitian (U unitary $\Rightarrow \Omega_\mu^\dagger = -\Omega_\mu$) and satisfies $\partial_\mu U = U\Omega_\mu$, so that

$$\mathrm{Tr}\big(\partial_\mu U^\dagger\,\partial^\mu U\big) \;=\; \mathrm{Tr}\big(\Omega_\mu^\dagger\,\Omega^\mu\big) \;=\; -\,\mathrm{Tr}\big(\Omega_\mu\,\Omega^\mu\big). \tag{39.95}$$

The standard derivative-of-the-exponential formula gives Ω_μ as a series in $a \equiv \Phi/f$,

$$\Omega_\mu \;=\; \frac{1-e^{-i\,\mathrm{ad}_a}}{i\,\mathrm{ad}_a}\,(i\,\partial_\mu a) \;=\; i\,\partial_\mu a \;+\; \tfrac{1}{2}\,[a,\partial_\mu a] \;-\; \tfrac{i}{6}\,[a,[a,\partial_\mu a]] \;+\; \cdots, \tag{39.96}$$

the three displayed terms being first, second, and third order in the field. Insert this into Eq. (39.95) and collect by field order. The quadratic part is $-\operatorname{Tr}\big((i\partial_\mu a)(i\partial^\mu a)\big) = \operatorname{Tr}(\partial_\mu a\,\partial^\mu a)$, which is $\frac{1}{f^2}\operatorname{Tr}(\partial_\mu\Phi\,\partial^\mu\Phi) = \frac{2}{f^2}\partial_\mu\pi^a\partial^\mu\pi^a$; multiplied by the prefactor $f^2/4$ it gives the canonical $\frac{1}{2}\partial_\mu\pi^a\partial^\mu\pi^a$, confirming the normalization of Eq. (39.88). The cubic part involves $\operatorname{Tr}\,(\partial_\mu a\,[a,\partial^\mu a])$, which vanishes by cyclicity of the trace (the two orderings $\operatorname{Tr}(\partial a\,a\,\partial a)$ and $\operatorname{Tr}(\partial a\,\partial a\,a)$ are equal), consistent with the $\pi\to-\pi$ parity that forbids odd vertices.

The quartic part receives two contributions, from $\big[\,i\partial a\,\big]\times\big[\,-\frac{i}{6}[a,[a,\partial a]]\,\big]$ (twice, by the cyclic symmetry of the trace) and from $\big[\frac{1}{2}[a,\partial a]\big]^2$:

$$\big[\operatorname{Tr}(\partial_\mu U^\dagger\partial^\mu U)\big]_{\Phi^4} \;=\; -\frac{1}{3f^4}\,\operatorname{Tr}(\partial_\mu\Phi\,[\Phi,[\Phi,\partial^\mu\Phi]]) \;-\; \frac{1}{4f^4}\,\operatorname{Tr}([\Phi,\partial_\mu\Phi]\,[\Phi,\partial^\mu\Phi]), \tag{39.97}$$

where we restored $a=\Phi/f$. The two traces are evaluated with the SU(2) structure constants. Writing $[\Phi,\partial_\mu\Phi]=2i\,\epsilon^{abc}\pi^a\partial_\mu\pi^b\,\tau^c\equiv 2i\,V_\mu^c\tau^c$, the second trace is

$$\begin{aligned}\operatorname{Tr}\big([\Phi,\partial_\mu\Phi][\Phi,\partial^\mu\Phi]\big) &= -4\,V_\mu^cV^{\mu d}\,\operatorname{Tr}(\tau^c\tau^d) = -8\,V_\mu^cV^{\mu c}\\ &= -8\big[\,\pi^2(\partial_\mu\pi\cdot\partial^\mu\pi)-(\pi\cdot\partial_\mu\pi)(\pi\cdot\partial^\mu\pi)\big] \;\equiv\; -8\,W,\end{aligned} \tag{39.98}$$

where the second line used $\epsilon^{abc}\epsilon^{a'b'c}=\delta^{aa'}\delta^{bb'}-\delta^{ab'}\delta^{ba'}$ and the shorthand $\pi\cdot\partial_\mu\pi\equiv\pi^a\partial_\mu\pi^a$. A parallel manipulation of the double commutator, using $[\Phi,[\Phi,\partial^\mu\Phi]]=-4V^{\mu c}\pi^d\epsilon^{dce}\tau^e$ and then $\epsilon^{dce}\epsilon^{abc}=\delta^{ea}\delta^{db}-\delta^{eb}\delta^{da}$, gives the first trace as exactly the opposite,

$$\operatorname{Tr}(\partial_\mu\Phi\,[\Phi,[\Phi,\partial^\mu\Phi]]) \;=\; +8\,W. \tag{39.99}$$

Substituting Eqs. (39.98) and (39.99) into Eq. (39.97) and multiplying by the prefactor $f^2/4$,

$$\mathcal{L}_4^{\text{kin}} \;=\; \frac{f^2}{4}\Big(-\frac{8W}{3f^4}+\frac{8W}{4f^4}\Big) \;=\; -\frac{W}{6\,f^2} \;=\; -\frac{1}{6f^2}\Big[\pi^2\,(\partial_\mu\pi\cdot\partial^\mu\pi)-(\pi\cdot\partial_\mu\pi)(\pi\cdot\partial^\mu\pi)\Big]. \tag{39.100}$$

The complete leading-order four-pion Lagrangian is the sum of Eqs. (39.94) and (39.100),

$$\boxed{\mathcal{L}_4 \;=\; \frac{1}{6f^2}\Big[(\pi^a\partial_\mu\pi^a)(\pi^b\partial^\mu\pi^b)-(\pi^a\pi^a)(\partial_\mu\pi^b\partial^\mu\pi^b)\Big] \;+\; \frac{m_\pi^2}{24f^2}\,(\pi^a\pi^a)^2.} \tag{39.101}$$

Every coupling in Eq. (39.101) is fixed by f and m_π alone: this is the parameter-free input that the rest of the section turns into a number.

Caution

The individual vertices in Eq. (39.101) depend on how one parametrizes U in terms of the fields — the square-root parametrization $U = f^{-1}(\sigma + i\pi^a\tau^a)$ with $\sigma = \sqrt{f^2 - \pi^2}$, for instance, produces a numerically different $\mathcal{L}_4$. Such field redefinitions $\pi \to \pi + \mathcal{O}(\pi^3)$ are precisely the reparametrizations that leave the S-matrix invariant (the equivalence theorem). The *on-shell* amplitude computed below is therefore parametrization-independent, even though the off-shell vertex is not. We use the exponential parametrization throughout for definiteness.

The momentum-space vertex. The amplitude follows from $\mathcal{L}_4$ by the LSZ machinery of Eq. (14.155): amputated, on-shell, the tree amplitude for four pions is just i times the vertex read off from Eq. (39.101). We compute the vertex in the fully crossing-symmetric, all-incoming convention — four pions with isospin indices a, b, c, d and incoming four-momenta q_1, q_2, q_3, q_4 summing to zero — and recover the physical process by crossing two legs at the end, exactly as in Theorem 29.27. A field π attached to an undifferentiated slot contributes a factor 1; attached to a ∂_μ slot it contributes $-iq_\mu$ for incoming momentum q. The vertex is i times the sum over all 4! ways of attaching the external lines to the four field slots of each monomial.

The non-derivative mass operator $(\pi^2)^2$ is the simplest: $\partial^4(\pi^2)^2/\partial\pi^a\partial\pi^b\partial\pi^c\partial\pi^d = 8(\delta^{ab}\delta^{cd} + \delta^{ac}\delta^{bd} + \delta^{ad}\delta^{bc})$, so $\mathcal{L}_4^m$ contributes

$$[i\mathcal{M}]_m \;=\; i\,\frac{m_\pi^2}{24f^2}\cdot 8(\delta^{ab}\delta^{cd} + \delta^{ac}\delta^{bd} + \delta^{ad}\delta^{bc}) \;=\; i\,\frac{m_\pi^2}{3f^2}(\delta^{ab}\delta^{cd} + \delta^{ac}\delta^{bd} + \delta^{ad}\delta^{bc}). \tag{39.102}$$

For the derivative operators we group the 4! contractions by the index structure they produce. Consider first $O_1 \equiv (\pi^e\pi^e)(\partial_\mu\pi^g\partial^\mu\pi^g)$. A given contraction sends two external lines to the undifferentiated pair (sharing an index, hence a δ) and two to the differentiated pair (sharing an index and Lorentz-contracted, hence a δ and a factor $(-iq)\cdot(-iq') = -q\cdot q'$). Summing the 24 contractions and collecting,

$$\frac{\partial^4 O_1}{\partial\pi^a\cdots} = -4\Big[\delta^{ab}\delta^{cd}(q_1\cdot q_2 + q_3\cdot q_4) + \delta^{ac}\delta^{bd}(q_1\cdot q_3 + q_2\cdot q_4) + \delta^{ad}\delta^{bc}(q_1\cdot q_4 + q_2\cdot q_3)\Big]. \tag{39.103}$$

(The factor -4 collects the 2×2 internal swaps of the two pairs; the two terms inside each bracket come from the two ways of choosing which pair is the differentiated one.) For $O_2 \equiv (\pi^e\partial_\mu\pi^e)(\pi^g\partial^\mu\pi^g)$ the index contraction is *within* each factor, so each δ links one undifferentiated and one differentiated line, and the Lorentz contraction links the two differentiated lines across the factors.

Collecting the 24 contractions,

$$\frac{\partial^4 O_2}{\partial\pi^a\dots} = -2\Big[\delta^{ab}\delta^{cd}\,(q_1{+}q_2){\cdot}(q_3{+}q_4)+\delta^{ac}\delta^{bd}\,(q_1{+}q_3){\cdot}(q_2{+}q_4)+\delta^{ad}\delta^{bc}\,(q_1{+}q_4){\cdot}(q_2{+}q_3)\Big]. \tag{39.104}$$

The kinetic Lagrangian Eq. (39.100) is $\mathcal{L}_4^{\text{kin}} = \frac{1}{6f^2}(O_2 - O_1)$, so its vertex is $\frac{i}{6f^2}(\partial^4 O_2 - \partial^4 O_1)$. Read off the coefficient of $\delta^{ab}\delta^{cd}$:

$$\big[\mathcal{M}_{\text{kin}}\big]_{\delta^{ab}\delta^{cd}} = \frac{1}{6f^2}\Big[-2(q_1{+}q_2){\cdot}(q_3{+}q_4) + 4(q_1{\cdot}q_2 + q_3{\cdot}q_4)\Big]. \tag{39.105}$$

Now impose momentum conservation. With all momenta incoming, $q_1 + q_2 = -(q_3 + q_4)$, so $(q_1 + q_2){\cdot}(q_3 + q_4) = -(q_1 + q_2)^2 \equiv -s$, where $s = (q_1 + q_2)^2$ is the all-incoming Mandelstam invariant of Theorem 16.20. Using on-shell $q_i^2 = m_\pi^2$, $q_1{\cdot}q_2 = \frac{1}{2}\big[(q_1{+}q_2)^2 - 2m_\pi^2\big] = \frac{1}{2}(s - 2m_\pi^2)$, and likewise $q_3{\cdot}q_4 = \frac{1}{2}(s - 2m_\pi^2)$ because $(q_3 + q_4)^2 = (q_1 + q_2)^2 = s$. Hence $q_1{\cdot}q_2 + q_3{\cdot}q_4 = s - 2m_\pi^2$, and Eq. (39.105) becomes

$$\big[\mathcal{M}_{\text{kin}}\big]_{\delta^{ab}\delta^{cd}} = \frac{1}{6f^2}\Big[2s + 4(s - 2m_\pi^2)\Big] = \frac{6s - 8m_\pi^2}{6f^2} = \frac{s}{f^2} - \frac{4m_\pi^2}{3f^2}. \tag{39.106}$$

Adding the mass contribution $m_\pi^2/3f^2$ from Eq. (39.102) the $-4m_\pi^2/3f^2$ and $+m_\pi^2/3f^2$ combine to $-m_\pi^2/f^2$, leaving the coefficient of $\delta^{ab}\delta^{cd}$ equal to $(s - m_\pi^2)/f^2$. The coefficients of $\delta^{ac}\delta^{bd}$ and $\delta^{ad}\delta^{bc}$ follow by the same algebra with $s \to t \equiv (q_1 + q_3)^2$ and $s \to u \equiv (q_1 + q_4)^2$.

39.4.2 The Weinberg amplitude

Assembling the three index channels gives the central result of the section.

Theorem 39.15 (Leading-order $\pi\pi$ amplitude)**.** *At order p^2 in the chiral expansion, the tree amplitude for $\pi^a\pi^b \to \pi^c\pi^d$ generated by $\mathcal{L}_2$ has the crossing-symmetric form*

$$\mathcal{M}^{ab,cd}(s,t,u) \;=\; A(s,t,u)\,\delta^{ab}\delta^{cd} + A(t,s,u)\,\delta^{ac}\delta^{bd} + A(u,t,s)\,\delta^{ad}\delta^{bc}, \tag{39.107}$$

with the single reduced amplitude

$$\boxed{A(s,t,u) \;=\; \frac{s - m_\pi^2}{f_\pi^2}\,,} \tag{39.108}$$

where s, t, u are the physical Mandelstam invariants of Theorem 16.20 obeying $s + t + u = 4m_\pi^2$ (Theorem 16.21), and $f = f_\pi$ at this order.

Proof. The all-incoming vertex computed in Section 39.4.1 reads $\mathcal{M}^{abcd} = \frac{s-m_\pi^2}{f^2}\delta^{ab}\delta^{cd} + \frac{t-m_\pi^2}{f^2}\delta^{ac}\delta^{bd} + \frac{u-m_\pi^2}{f^2}\delta^{ad}\delta^{bc}$ with all-incoming invariants $s = (q_1{+}q_2)^2$,

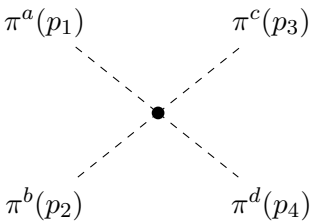


Figure 39.4: The unique leading-order ($O(p^2)$) diagram for $\pi^a\pi^b \to \pi^c\pi^d$: a single four-pion contact vertex from $\mathcal{L}_2$, Eq. (39.101). There is no pion-exchange pole at this order because the cubic vertex vanishes; the entire amplitude Eq. (39.107) is this one diagram.

$t = (q_1+q_3)^2$, $u = (q_1+q_4)^2$. The physical process $\pi^a(p_1)\pi^b(p_2) \to \pi^c(p_3)\pi^d(p_4)$ is recovered by crossing the two outgoing legs, $q_1 = p_1$, $q_2 = p_2$, $q_3 = -p_3$, $q_4 = -p_4$; then $s = (p_1+p_2)^2$, $t = (p_1-p_3)^2$, $u = (p_1-p_4)^2$ are exactly the physical invariants of Theorem 16.20, and the index structure is unchanged. Writing $A(s,t,u) = (s-m_\pi^2)/f^2$, the coefficient of $\delta^{ac}\delta^{bd}$ is $(t-m_\pi^2)/f^2 = A(t,s,u)$ and that of $\delta^{ad}\delta^{bc}$ is $(u-m_\pi^2)/f^2 = A(u,t,s)$, which is Eq. (39.107). The constraint $s+t+u = \sum_i p_i^2 = 4m_\pi^2$ is Theorem 16.21 specialized to four equal external masses. □

Setting $m_\pi \to 0$ reduces Eq. (39.108) to $A = s/f^2$, and Eq. (39.107) becomes precisely the massless Goldstone amplitude Eq. (29.185) of the abstract sigma model with $v \to f_\pi$ — the chiral Lagrangian reproduces the model-independent soft-pion result and tells us, in addition, exactly how the quark mass deforms it: every Mandelstam variable is shifted, $s \to s - m_\pi^2$, in its own crossing channel. The figure below records the single contact diagram that produces the whole amplitude.

39.4.3 Isospin decomposition

Two pions, each in the isovector $\mathbf{3}$ of $\mathrm{SU}(2)_V$, combine as $\mathbf{3}\otimes\mathbf{3} = \mathbf{1}\oplus\mathbf{3}\oplus\mathbf{5}$, i.e. into total isospin $I = 0, 1, 2$ (Section 2.5). Because the strong interaction conserves isospin, the S-matrix is diagonal in I, and the physically meaningful objects are the three isospin amplitudes $T^I(s,t,u)$. We extract them from Eq. (39.107) with the s-channel isospin projectors. In the four-index Cartesian basis (incoming a, b; outgoing c, d) the Clebsch–Gordan content of Section 2.5 is packaged as

$$P^0_{cd,ab} = \tfrac{1}{3}\delta_{ab}\delta_{cd}, \quad P^1_{cd,ab} = \tfrac{1}{2}(\delta_{ac}\delta_{bd} - \delta_{ad}\delta_{bc}), \quad P^2_{cd,ab} = \tfrac{1}{2}(\delta_{ac}\delta_{bd} + \delta_{ad}\delta_{bc}) - \tfrac{1}{3}\delta_{ab}\delta_{cd}. \tag{39.109}$$

These are orthogonal idempotents, $P^I P^J = \delta^{IJ} P^I$, summing to the identity $\sum_I P^I = \delta_{ac}\delta_{bd}$, with traces $\mathrm{tr}\, P^I = 2I+1$ (namely $1, 3, 5$, summing to $3\times 3 = 9$),

exactly the dimensions of $\mathbf{1}, \mathbf{3}, \mathbf{5}$. The $I = 0$ projector is symmetric and proportional to the isospin-singlet δ_{ab}; the $I = 1$ projector is antisymmetric (it must accompany an antisymmetric, hence odd-ℓ, spatial state by Bose symmetry); the $I = 2$ projector is the symmetric traceless combination. The isospin amplitudes are defined by $\mathcal{M}_{cd,ab} = \sum_I T^I P^I_{cd,ab}$, inverted using the idempotency to $T^I = (2I+1)^{-1} \sum_{abcd} P^I_{cd,ab}\, \mathcal{M}_{ab,cd}$.

The contraction is mechanical once we record the full contractions of the three index structures $C_1 = \delta_{ab}\delta_{cd}$, $C_2 = \delta_{ac}\delta_{bd}$, $C_3 = \delta_{ad}\delta_{bc}$ with one another in three dimensions: $C_i \cdot C_i = 9$ and $C_i \cdot C_j = 3$ for $i \neq j$ (each off-diagonal contraction forces all four indices equal, giving $N = 3$). Writing the amplitude as $\mathcal{M} = A(s)C_1 + A(t)C_2 + A(u)C_3$ with the abbreviations $A(s) \equiv A(s,t,u)$ etc., we get $C_1 \cdot \mathcal{M} = 9A(s) + 3A(t) + 3A(u)$ and cyclically. Hence

$$T^0 = \tfrac{1}{3}\, C_1 \cdot \mathcal{M} = 3A(s,t,u) + A(t,s,u) + A(u,t,s), \tag{39.110a}$$

$$T^1 = \tfrac{1}{3} \cdot \tfrac{1}{2}(C_2 - C_3) \cdot \mathcal{M} = A(t,s,u) - A(u,t,s), \tag{39.110b}$$

$$T^2 = \tfrac{1}{5}\big[\tfrac{1}{2}(C_2 + C_3) - \tfrac{1}{3}C_1\big] \cdot \mathcal{M} = A(t,s,u) + A(u,t,s). \tag{39.110c}$$

Inserting $A(x) = (x - m_\pi^2)/f_\pi^2$ and eliminating $t + u = 4m_\pi^2 - s$ with the constraint of Theorem 16.21,

$$\boxed{T^0(s,t,u) = \frac{2s - m_\pi^2}{f_\pi^2}, \qquad T^1(s,t,u) = \frac{t-u}{f_\pi^2}, \qquad T^2(s,t,u) = \frac{2m_\pi^2 - s}{f_\pi^2}.} \tag{39.111}$$

The structure is instructive. T^0 and T^2 are even under $t \leftrightarrow u$ and T^1 is odd, as Bose statistics demands: even isospin pairs with even orbital angular momentum, odd isospin with odd ℓ. The $I = 1$ amplitude is purely P-wave (proportional to $t - u \propto \cos\theta$) and so carries no s-wave; the $I = 1$ channel begins at $\ell = 1$. The $I = 0$ amplitude is large and attractive (positive at threshold), while $I = 2$ is smaller and repulsive (negative at threshold) — the qualitative pattern that the data confirm.

39.4.4 Scattering lengths: the parameter-free numbers

The amplitudes Eq. (39.111) are turned into observables by partial-wave projection and evaluation at threshold. We carry the computation through in full in the following worked example, which is the chapter's flagship prediction.

Worked Example 39.16 (Partial waves and the $\pi\pi$ scattering lengths)**. Kinematics.** Work in the centre-of-mass frame. With $s = 4(q^2 + m_\pi^2)$, the CM three-momentum is $q^2 = \tfrac{1}{4}(s - 4m_\pi^2)$, vanishing at threshold $s = 4m_\pi^2$. The scattering angle θ enters the crossed invariants through

$$t = -2q^2(1 - \cos\theta), \qquad u = -2q^2(1 + \cos\theta), \tag{39.112}$$

so that $t+u=-4q^2=4m_\pi^2-s$ and $t-u=4q^2\cos\theta$, consistent with $s+t+u=4m_\pi^2$.

Partial-wave projection. For two-pion states the standard normalization of the partial-wave amplitudes $t_\ell^I(s)$ is

$$T^I(s,t,u)=32\pi\sum_{\ell=0}^{\infty}(2\ell{+}1)\,P_\ell(\cos\theta)\,t_\ell^I(s),\qquad t_\ell^I(s)=\frac{1}{64\pi}\int_{-1}^{1}\mathrm{d}(\cos\theta)\,P_\ell(\cos\theta)\,T^I(s,t,u), \tag{39.113}$$

the inversion following from the orthogonality $\int_{-1}^{1}P_\ell P_{\ell'}\,\mathrm{d}\cos\theta=\frac{2}{2\ell+1}\delta_{\ell\ell'}$. The factor 32π is chosen so that the unitarity relation takes the form $\operatorname{Im}t_\ell^I=\sigma(s)\,|t_\ell^I|^2$ with phase-space factor $\sigma(s)=\sqrt{1-4m_\pi^2/s}=2q/\sqrt{s}$; this is the same $|\mathcal{M}|^2$ that feeds the differential cross section Eq. (16.145), now diagonalized channel by channel and partial wave by partial wave. At tree level t_ℓ^I is real — unitarity is restored order by order, the loop corrections of the next section supplying the imaginary part.

The s-wave ($\ell=0$). Here $P_0=1$, and from Eq. (39.111) both T^0 and T^2 are independent of the scattering angle, so the projection integral is trivial, $\int_{-1}^{1}\mathrm{d}\cos\theta=2$:

$$t_0^0(s)=\frac{1}{64\pi}\cdot 2\cdot\frac{2s-m_\pi^2}{f_\pi^2}=\frac{2s-m_\pi^2}{32\pi f_\pi^2},\qquad t_0^2(s)=\frac{2m_\pi^2-s}{32\pi f_\pi^2}. \tag{39.114}$$

The $I=1$ amplitude $T^1\propto t-u\propto\cos\theta=P_1$ integrates to zero against P_0, confirming there is no s-wave in the $I=1$ channel; its lowest partial wave is the P-wave t_1^1.

Threshold and the scattering length. Near threshold the ℓ-th partial wave behaves as $\operatorname{Re}t_\ell^I(s)\to a_\ell^I\,q^{2\ell}/m_\pi^{2\ell}$ times a kinematic factor; the standard convention defines the dimensionless s-wave scattering length (in units of m_π^{-1}) as the threshold value

$$a_0^I\;\equiv\;\frac{1}{32\pi}\,T^I\big|_{s=4m_\pi^2,\,t=u=0}\;=\;t_0^I(4m_\pi^2), \tag{39.115}$$

the second equality identifying it with the threshold limit of Eq. (39.114) (dimensionless, in units of m_π^{-1}; the dimensionful length is a_0^I/m_π). [Equivalently, with the dimensionful length a_0^I/m_π entering the effective-range expansion $q\cot\delta_0^I=m_\pi/a_0^I+\cdots$, one has $\delta_0^I\to(a_0^I/m_\pi)\,q$ and $t_0^I\to\sigma^{-1}\sin\delta_0^I\,e^{i\delta_0^I}\to a_0^I$ at threshold, since $\sigma\to q/m_\pi$.] Evaluating Eq. (39.114) at $s=4m_\pi^2$,

$$\boxed{a_0^0=\frac{7\,m_\pi^2}{32\pi f_\pi^2},\qquad a_0^2=-\frac{m_\pi^2}{16\pi f_\pi^2}.} \tag{39.116}$$

These are Weinberg's 1966 scattering lengths. They are pure predictions: the right-hand sides contain only the measured constants m_π and f_π, with no adjustable parameter. Their ratio is the parameter-free, even m_π- and f_π-independent number $a_0^0/a_0^2=-7/2$.

Table 39.1: Leading-order ChPT predictions for the $\pi\pi$ s-wave scattering lengths (in units of m_π^{-1}) versus the precise determination from K_{e4} decays and the Roy-equation/ChPT analysis (mid-2020s). The $I = 2$ length is reproduced at leading order to within the experimental uncertainty; the $I = 0$ length is about 30% low, the deficit being made up almost entirely by the one-loop and two-loop chiral corrections of the following sections.

	$O(p^2)$ (Weinberg)	experiment	ratio LO/exp
a_0^0	$+0.159$	$+0.220 \pm 0.005$	0.72
a_0^2	-0.0454	-0.0444 ± 0.0010	1.02

The numbers, and the data. Insert the physical values $m_\pi = m_{\pi^\pm} = 139.6$ MeV and $f_\pi = 92.4$ MeV (the normalization $\left\langle 0|A_\mu^a|\pi^b(p)\right\rangle = i f_\pi p_\mu \delta^{ab}$ fixed in Section 39.3). Then $m_\pi^2/f_\pi^2 = 2.283$ and

$$a_0^0 = \frac{7}{32\pi}\,(2.283) = 0.159, \qquad a_0^2 = -\frac{1}{16\pi}\,(2.283) = -0.0454, \tag{39.117}$$

both in units of m_π^{-1}. Table 39.1 sets these leading-order predictions against the modern experimental determinations, and Fig. 39.5 displays them in the (a_0^0, a_0^2) plane together with the analytic amplitude.

The agreement is the historic triumph. With no fitted parameter, a theory of a strongly coupled sector predicts a hadronic observable to tens of percent, and the small, repulsive $I = 2$ length — the channel with no resonances to complicate it — comes out essentially exact at leading order. The 30% shortfall in a_0^0 is not a failure but a feature: it is exactly the size $\sim m_\pi^2/\Lambda_\chi^2 \sim (m_\pi/4\pi f_\pi)^2 \cdot (\text{logs})$ that the chiral expansion predicts for the first correction, and the next section will see the one-loop chiral logarithm fill most of the gap, with the two-loop analysis of Colangelo et al. [126] bringing theory and the K_{e4} data of the NA48/2 experiment [51] into precise agreement.

Historical Note

Weinberg obtained Eq. (39.116) in 1966 [495] from current algebra and the PCAC hypothesis (Eq. (29.200)) — before the chiral Lagrangian was understood as a systematic effective field theory. The soft-pion technology of the day reproduced precisely the amplitude Eq. (39.107), but it offered no way to compute corrections: there was no organizing principle telling one what came next or how big it should be. The reinterpretation that made the corrections calculable came with Weinberg's 1979 paper on phenomenological Lagrangians [498], which recognized the current-algebra results as the leading term of a momentum expansion, and with the systematic one-loop renormalization of Gasser and Leutwyler [210]. What

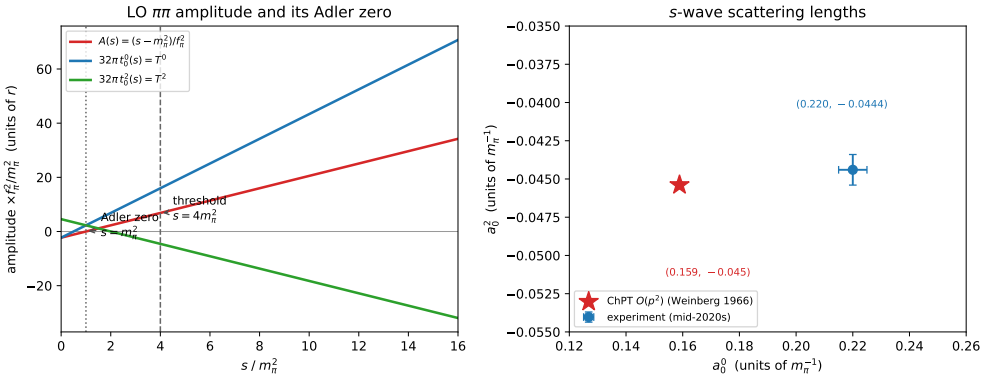

Figure 39.5: *Left:* the leading-order reduced amplitude $A(s) = (s - m_\pi^2)/f_\pi^2$ and the isospin s-wave combinations T^0, T^2 of Eq. (39.111) versus s/m_π^2, in units of $r \equiv m_\pi^2/f_\pi^2$. The dotted line marks the Adler zero of A at $s = m_\pi^2$; the dashed line marks the physical threshold $s = 4m_\pi^2$. *Right:* the s-wave scattering lengths in the (a_0^0, a_0^2) plane: the parameter-free $O(p^2)$ prediction Eq. (39.116) (star) and the experimental value with error bars. The $I = 2$ length lands on top of the data already at leading order.

had been an isolated low-energy theorem became the first entry in a convergent series. The numbers in Table 39.1 are the modern vindication of that program.

39.4.5 The Adler zero, made manifest

The amplitude Eq. (39.108) wears its Goldstone origin on its face. The Adler zero of Theorem 29.26 states that a connected amplitude with one soft external Goldstone vanishes linearly as that momentum is taken to zero, a direct consequence of the derivative coupling that the nonlinear realization forces on every pion. We verify it here for the physical, massive amplitude and locate the zero precisely.

Take the first pion soft, $p_1 \to 0$, with the other three on shell. In the chiral limit $m_\pi = 0$ the remaining pions are massless, so $s = (p_1 + p_2)^2 \to p_2^2 = 0$, $t = (p_1 - p_3)^2 \to p_3^2 = 0$, $u = (p_1 - p_4)^2 \to p_4^2 = 0$, and each reduced amplitude $A = s/f_\pi^2 \to 0$: the full $\mathcal{M}^{ab,cd}$ of Eq. (39.107) vanishes linearly in the soft momentum, exactly the chiral-limit statement already checked in the abstract model at Eq. (29.186). Away from the chiral limit the pions carry mass, and the soft point $p_1 \to 0$ sends $s, t, u \to m_\pi^2$ simultaneously. There each crossing

channel's reduced amplitude vanishes,

$$A(s,t,u)\big|_{s=t=u=m_\pi^2} = \frac{m_\pi^2 - m_\pi^2}{f_\pi^2} = 0 \quad \Longrightarrow \quad \mathcal{M}^{ab,cd}\big|_{\text{soft point}} = 0. \tag{39.118}$$

The quark mass does not destroy the Adler zero; it *relocates* it. In each channel the zero of the reduced amplitude sits at $s = m_\pi^2$ rather than at $s = 0$ — a subthreshold point (note $s = t = u = m_\pi^2$ violates $s + t + u = 4m_\pi^2$ and so lies off the physical region, reached only by analytic continuation, which is exactly where a soft-pion theorem should live). This shifted zero, visible as the crossing of the red curve in Fig. 39.5 at $s = m_\pi^2$, is a sharp prediction of the leading chiral Lagrangian: the position of the Adler zero is itself fixed by the same symmetry that fixes the scattering lengths.

Physical Insight

The Adler zero and the scattering lengths are two faces of one fact: pions couple through their momenta. The same s in $A = (s - m_\pi^2)/f_\pi^2$ that produces the zero at $s = m_\pi^2$ produces, at threshold $s = 4m_\pi^2$, the nonzero value $3m_\pi^2/f_\pi^2$ that drives a_0^0. A theory in which pions coupled without derivatives — a generic scalar with a $\lambda\phi^4$ contact term — would give a constant amplitude, no Adler zero, and a scattering length set by an arbitrary coupling. The derivative coupling forced by the spontaneously broken chiral symmetry both suppresses the amplitude at low energy (the zero) and predicts its threshold value with no free parameter. The smallness of $\pi\pi$ interactions near threshold is not an accident of QCD dynamics; it is a theorem of broken symmetry.

The leading-order amplitude is now complete: a single closed-form expression Eq. (39.107), its isospin projections Eq. (39.111), the scattering lengths Eq. (39.116), and the Adler zero Eq. (39.118), all fixed by f_π and m_π alone. Its limitation is equally sharp: the amplitudes Eq. (39.111) are real polynomials in s, t, u, whereas unitarity (Eq. (16.145) and the optical theorem) demands an imaginary part above threshold and a logarithmic structure near it. That missing piece is the pion loop, suppressed by exactly one power of $1/\Lambda_\chi^2$. Computing it will both restore unitarity and generate ultraviolet divergences that no operator in $\mathcal{L}_2$ can absorb — forcing us, in the next section, to introduce the order-p^4 Gasser–Leutwyler Lagrangian and its low-energy constants, and to extract our first chiral logarithm.

39.5 Loops, the Gasser–Leutwyler Lagrangian, and Low-Energy Constants

The leading-order calculation of Section 39.4 delivered a number for $\pi\pi$ scattering with no free parameters, built from f and M_π^2 alone. That triumph also carried a warning: the same power counting that made the tree amplitude $O(p^2)$ told us (Section 39.3) that the very next term in the chiral expansion is $O(p^4)$, and that this order receives contributions from *two* sources at once — new tree operators with four derivatives, and one-loop graphs built from the two-derivative Lagrangian $\mathcal{L}_2$. A graduate reader trained on Chapter 22 will immediately object that loops in a Lagrangian whose coupling carries negative mass dimension, $1/f^2$, are exactly what defines a *non*-renormalizable theory: the loop integrals diverge, and there is no single coupling whose redefinition can soak the divergence up. The resolution, and the central lesson of this section, is that the effective-field-theory bookkeeping of Chapter 38 turns this apparent disaster into an orderly accounting. The divergences of the one-loop graphs are local and of precisely the order $O(p^4)$ generated by the four-derivative operators; renormalizing the coefficients of those operators absorbs every divergence at this order, and the finite remainder contains a piece — the *chiral logarithm* — that no polynomial counterterm can imitate. We now make all three statements precise and carry the computation that exhibits the chiral log explicitly. Throughout we write tr for the trace over flavour space and continue with the field $U(x) = \exp(i\Phi(x)/f)$ and the leading Lagrangian $\mathcal{L}_2$ of Eq. (39.43).

39.5.1 The general $O(p^4)$ chiral Lagrangian

At $O(p^2)$ chiral symmetry, parity, charge conjugation, and Lorentz invariance left exactly two operators: the kinetic term $\frac{f^2}{4}\,\mathrm{tr}(\partial_\mu U^\dagger \partial^\mu U)$ and the symmetry-breaking term $\frac{f^2}{4}\,\mathrm{tr}(\chi^\dagger U + \chi U^\dagger)$, with $\chi = 2B\,\mathsf{M}$ and $\mathsf{M} = \mathrm{diag}(m_u, m_d, m_s)$ the quark-mass matrix (Eq. (39.43)). The same symmetry principles, applied now to operators with four derivatives or two derivatives and one insertion of χ or two insertions of χ, generate a longer but still finite list. The systematic enumeration is due to Gasser and Leutwyler. Under the chiral group $U \to L U R^\dagger$ with $L \in \mathrm{SU}(3)_L$, $R \in \mathrm{SU}(3)_R$, and with $\chi \to L \chi R^\dagger$ assigned so that the breaking term is invariant, the independent Hermitian, parity-even, Lorentz-invariant monomials of chiral order p^4 are catalogued as follows.

Definition 39.17 (The Gasser–Leutwyler Lagrangian and the low-energy constants)**.** The most general chirally invariant, parity- and C-even, Lorentz-scalar Lagrangian of chiral order p^4 for the three-flavour Goldstone field U, in the absence of external vector and axial sources, is

$$\mathcal{L}_4 = L_1\big[\,\mathrm{tr}(\partial_\mu U^\dagger \partial^\mu U)\big]^2 + L_2\,\mathrm{tr}(\partial_\mu U^\dagger \partial_\nu U)\,\mathrm{tr}(\partial^\mu U^\dagger \partial^\nu U) + L_3\,\mathrm{tr}(\partial_\mu U^\dagger \partial^\mu U\,\partial_\nu U^\dagger \partial^\nu U)$$

$$+ L_4\,\mathrm{tr}(\partial_\mu U^\dagger \partial^\mu U)\,\mathrm{tr}(\chi^\dagger U + \chi U^\dagger) + L_5\,\mathrm{tr}(\partial_\mu U^\dagger \partial^\mu U\,(\chi^\dagger U + U^\dagger \chi)) + L_6\big[\mathrm{tr}(\chi^\dagger U + \chi U^\dagger)\big]^2 + L_7\big[\mathrm{tr}(\chi^\dagger U - \chi U^\dagger)\big]^2 + L_8\,\mathrm{tr}(\chi^\dagger U \chi^\dagger U + \chi U^\dagger \chi U^\dagger) + \dots \tag{39.119}$$

The dimensionless constants $L_1, \dots, L_8$ (together with L_9, L_{10}, which multiply operators built from the field strengths of external vector/axial sources, and the contact terms H_1, H_2 that contain no Goldstone field) are the *low-energy constants* (LECs). They are the Wilson coefficients of the effective theory: not predicted by chiral symmetry, but fixed once and for all either by matching to QCD or by fitting low-energy data.

Two remarks fix the status of Eq. (39.119). First, the list is *complete and irredundant* only after the leading equations of motion are used to eliminate operators that are equivalent on shell, and after total derivatives and the Cayley–Hamilton identities of SU(3) matrices are accounted for; carrying out that reduction is what guarantees there are exactly these (and the four omitted) independent structures. Second, the L_i are genuinely the EFT's Wilson coefficients in the sense of Chapter 38: they encode the short-distance physics — the masses of the ρ, the a_1, the scalar resonances, all the hadronic states that were integrated out — in a few numbers. They are fixed by the matching procedure of Theorem 38.8, in principle by computing the same Green's function in QCD and in the EFT and equating them, in practice by measuring a few low-energy observables and reading the L_i off. The whole content of the chiral expansion is that, once these handful of numbers are pinned down at order p^4, *every* $O(p^4)$ amplitude is then predicted.

Notation Watch

For the two-flavour theory ($N_f = 2$, pions only) the analogous basis is smaller and is traditionally written with lowercase constants $l_1, \dots, l_7$ (Gasser–Leutwyler 1984). The reductions are not one-to-one because of the SU(2) Cayley–Hamilton identity $\Phi^2 = \frac{1}{2}\,\mathrm{tr}(\Phi^2)\,\mathbf{1}$, which collapses several SU(3) structures. We will present the general basis above but carry the explicit one-loop computation in the two-flavour theory, where the algebra is most transparent, and identify the relevant counterterm as l_3.

39.5.2 Why one-loop divergences are local and of order p^4

The reason Eq. (39.119) suffices to renormalize the one-loop graphs is Weinberg's power-counting theorem, established in Section 39.3. We restate the chiral-dimension formula and then draw the renormalization consequence, which is the analogue for an EFT of the renormalizability structure proved for ϕ^4 in Theorem 22.28.

For a connected one-particle-irreducible graph with L loops and V_{2k} vertices drawn from the chiral Lagrangian of order p^{2k} (that is, with $2k$ derivatives or equivalent powers of $\chi \sim M_\pi^2$), the degree of homogeneity D of the amplitude in the small external momenta and Goldstone masses is

$$D \;=\; 2 \;+\; 2L \;+\; \sum_{k\geq 1} 2(k-1)\, V_{2k}. \tag{39.120}$$

The derivation is purely topological. Each propagator scales as p^{-2}, each loop integration $\int \mathrm{d}^4\ell$ as p^4, and each $\mathcal{L}_{2k}$ vertex as p^{2k}; with I internal lines and $V = \sum_k V_{2k}$ vertices,

$$D \;=\; 4L - 2I + \sum_k 2k\, V_{2k}, \tag{39.121}$$

and substituting the Euler relation $L = I - V + 1$, i.e. $I = L + V - 1$, gives

$$D \;=\; 4L - 2(L + V - 1) + \sum_k 2k\, V_{2k} \;=\; 2L + 2 + \sum_k (2k-2) V_{2k}, \tag{39.122}$$

which is Eq. (39.120). Every term on the right-hand side is non-negative: $L \geq 0$, and $k \geq 1$ so $k - 1 \geq 0$. The minimum, $D = 2$, is reached only by tree graphs ($L = 0$) built entirely from $\mathcal{L}_2$ vertices ($k = 1$); that is the leading order. The next value, $D = 4$, is reached in exactly two ways: a tree graph with a single $\mathcal{L}_4$ vertex ($L = 0$, one V_4), or a one-loop graph built entirely from $\mathcal{L}_2$ vertices ($L = 1$, all V_2). These are the two contributions to $O(p^4)$ promised at the start.

Theorem 39.18 (One-loop divergences are local and of $O(p^4)$)**.** *Every one-loop* 1*PI graph built from* $\mathcal{L}_2$ *has chiral dimension* $D = 4$*. Its ultraviolet divergences, computed in dimensional regularization with* $d = 4 - 2\varepsilon$ *(Section 19.1), are a finite linear combination of the local operators of Eq.* (39.119)*. Consequently the* $1/\varepsilon$ *poles of all one-loop amplitudes are removed by a redefinition of the* L_i*, and the renormalization of the theory closes at order* p^4*.*

Proof. That $D = 4$ for any one-loop, all-$\mathcal{L}_2$ graph is the $L = 1$, $V_{2k} = V_2$ case of Eq. (39.120). It remains to argue that the divergent part is local and of the symmetry type catalogued in Theorem 39.17. Locality is the general statement that the ultraviolet divergence of any 1PI graph in dimensional regularization is a polynomial in the external momenta and the explicit masses: the divergence comes from the region of large loop momentum, where the integrand may be Taylor-expanded in the external data, and each term of the expansion is a power divergence multiplying a monomial in those external quantities; dimensional regularization discards the scaleless power divergences and keeps the logarithmic ones, whose coefficients are exactly such monomials. This is the same mechanism that made the ϕ^4 counterterms local in Section 22.5.6. A local term of chiral dimension four, built from U, ∂U, and χ, and invariant under the chiral group and parity, is by *definition* one of the operators in Eq. (39.119): the symmetry of the

regularized theory is the full chiral symmetry (dimensional regularization respects it, since it touches only the spacetime dimension, not the flavour structure), so the counterterm Lagrangian must be chirally invariant, and the complete list of invariants at this order is precisely $\mathcal{L}_4$. Hence the divergence is cancelled by

$$L_i \;=\; L_i^r(\mu) \;-\; \frac{\Gamma_i}{32\pi^2}\,\frac{1}{\bar\varepsilon}, \qquad \frac{1}{\bar\varepsilon} \equiv \frac{1}{\varepsilon} - \gamma_E + \ln 4\pi, \tag{39.123}$$

for a set of pure numbers Γ_i determined by the one-loop graphs, leaving renormalized constants $L_i^r(\mu)$. The same argument applies to the two-flavour constants l_i. □

The structure is exactly that of Theorem 22.28, transplanted to a theory with infinitely many couplings: renormalizability there meant that all divergences are absorbed by the finitely many operators already present in the Lagrangian; here it means that all divergences *at a given chiral order* are absorbed by the finitely many operators present *at that order*. The price of the negative-dimension coupling $1/f^2$ is not loss of predictivity but the appearance of new counterterms order by order — which is precisely the EFT paradigm of Chapter 38. Each order requires a finite number of measurements; in exchange it predicts everything else at that order. The crucial new feature, absent from a renormalizable theory, is that the subtraction in Eq. (39.123) introduces a scale μ into the renormalized constants $L_i^r(\mu)$, and they must run with it.

39.5.3 The chiral logarithm: the one-loop pion mass

We now carry the computation that exhibits all of this concretely: the one-loop correction to the pion self-energy, hence to m_π^2. We work in the two-flavour theory with $\Phi = \pi^a\tau^a$ ($a = 1,2,3$, τ^a the Pauli matrices, $\operatorname{tr}\tau^a\tau^b = 2\delta^{ab}$), and in the isospin limit $m_u = m_d = \hat m$, so $\chi = M_\pi^2\,\mathbf{1}$ with $M_\pi^2 \equiv 2B\hat m$ the leading-order pion mass-squared (the Gell-Mann–Oakes–Renner relation Eq. (29.216)). We reserve m_π^2 for the physical, one-loop-corrected pole mass.

Worked Example 39.19 (The pion tadpole and the chiral logarithm)**. Step 1: expand $\mathcal{L}_2$ to quartic order.** The kinetic term is $\frac{f^2}{4}\operatorname{tr}(\partial_\mu U^\dagger \partial^\mu U)$. Expanding $U = 1 + i\Phi/f - \Phi^2/2f^2 - i\Phi^3/6f^3 + \dots$ and collecting the terms with four pion fields,

$$\tfrac{f^2}{4}\operatorname{tr}(\partial_\mu U^\dagger\partial^\mu U)\Big|_{\Phi^4} = \frac{1}{24f^2}\Big[\operatorname{tr}(\partial_\mu\Phi\,\Phi\,\partial^\mu\Phi\,\Phi) - \operatorname{tr}(\partial_\mu\Phi\,\partial^\mu\Phi\,\Phi^2)\Big]. \tag{39.124}$$

Using $\operatorname{tr}(\tau^a\tau^b\tau^c\tau^d) = 2(\delta^{ab}\delta^{cd} - \delta^{ac}\delta^{bd} + \delta^{ad}\delta^{bc})$ to evaluate the two traces,

$$\operatorname{tr}(\partial_\mu\Phi\,\partial^\mu\Phi\,\Phi^2) = 2(\partial\pi)^2\pi^2, \qquad \operatorname{tr}(\partial_\mu\Phi\,\Phi\,\partial^\mu\Phi\,\Phi) = 2\big[2(\pi\partial_\mu\pi)(\pi\partial^\mu\pi) - (\partial\pi)^2\pi^2\big], \tag{39.125}$$

where $\pi^2 \equiv \pi^a\pi^a$, $(\partial\pi)^2 \equiv \partial_\mu\pi^a\partial^\mu\pi^a$, and $\pi\cdot\partial_\mu\pi \equiv \pi^a\partial_\mu\pi^a$. Hence the quartic part of the kinetic term is

$$\mathcal{L}_2^{\text{kin}}\big|_{\Phi^4} = \frac{1}{6f^2}\Big[(\pi\cdot\partial_\mu\pi)(\pi\cdot\partial^\mu\pi) - \pi^2(\partial\pi)^2\Big]. \tag{39.126}$$

The mass term is $\frac{f^2}{4}\,\mathrm{tr}(\chi^\dagger U + \chi U^\dagger) = \frac{f^2}{4}M_\pi^2\,\mathrm{tr}(U + U^\dagger)$. Since $\Phi^2 = \pi^2\,\mathbf{1}$ in SU(2), one has $\mathrm{tr}(U + U^\dagger) = 2\big[2 - \pi^2/f^2 + (\pi^2)^2/12f^4 - \dots\big]$, so the quartic part is

$$\mathcal{L}_2^{\text{mass}}\big|_{\Phi^4} = \frac{M_\pi^2}{24f^2}\,(\pi^2)^2. \tag{39.127}$$

Together, the quartic interactions of $\mathcal{L}_2$ are

$$\mathcal{L}_2^{(4)} = \frac{1}{6f^2}\Big[(\pi\cdot\partial_\mu\pi)(\pi\cdot\partial^\mu\pi) - \pi^2(\partial\pi)^2\Big] + \frac{M_\pi^2}{24f^2}\,(\pi^2)^2. \tag{39.128}$$

Step 2: close two legs into a tadpole. The one-loop self-energy comes from Eq. (39.128) by contracting two of the four pion fields into a propagator at coincident points, leaving two external legs (Fig. 39.6). The contractions we need are

$$\langle \pi^a(x)\pi^b(x)\rangle = \delta^{ab}\,\Delta(0), \qquad \langle \partial_\mu\pi^a\,\pi^b\rangle = 0, \qquad \langle \partial_\mu\pi^a\,\partial_\nu\pi^b\rangle = \delta^{ab}\frac{\eta_{\mu\nu}}{d}\,M_\pi^2\,\Delta(0), \tag{39.129}$$

where $\Delta(0)$ is the pion propagator at the origin and the middle relation vanishes because its integrand is odd in the loop momentum. The third relation uses $\int \mathrm{d}^dk\,k_\mu k_\nu f(k^2) = (\eta_{\mu\nu}/d)\int \mathrm{d}^dk\,k^2 f(k^2)$ and $\int \mathrm{d}^dk\,k^2/(k^2 - M_\pi^2) = M_\pi^2\int \mathrm{d}^dk/(k^2 - M_\pi^2)$ (the scaleless piece $\int \mathrm{d}^dk\,1$ vanishes in dimensional regularization). The rule that replaces a contracted pair by $\Delta(0)$ and adds the resulting bilinear directly to the Lagrangian is the one-loop background-field construction; it reproduces the standard symmetry factor, as one checks against the ϕ^4 tadpole $\delta m^2 = \frac{\lambda}{2}\Delta(0)$ of Section 22.2.2.

Step 3: the loop integral. By the master integral Theorem D.22 with $n = 1$, restoring the scale μ through the factor $\mu^{2\varepsilon}$ that accompanies the loop measure,

$$\Delta(0) = \mu^{2\varepsilon}\int \frac{\mathrm{d}^dk}{(2\pi)^d}\,\frac{i}{k^2 - M_\pi^2 + i\varepsilon} = -\frac{M_\pi^2}{16\pi^2}\Big[\frac{1}{\bar\varepsilon} + 1 - \ln\frac{M_\pi^2}{\mu^2}\Big]. \tag{39.130}$$

The chain is $\int \mathrm{d}^dk/(2\pi)^d\,(k^2 - M_\pi^2)^{-1} = -i(4\pi)^{-d/2}\Gamma(1 - \frac{d}{2})(M_\pi^2)^{d/2-1}$, and with $d = 4 - 2\varepsilon$, $\Gamma(-1+\varepsilon) = -\frac{1}{\varepsilon} - 1 + \gamma_E + O(\varepsilon)$, $(4\pi\mu^2/M_\pi^2)^\varepsilon = 1 + \varepsilon\ln(4\pi\mu^2/M_\pi^2)$, multiplying by i gives Eq. (39.130). The pole and the logarithm appear locked together, both proportional to M_π^2.

Step 4: assemble the self-energy. Contracting one pair in each term of Eq. (39.128) and using the contractions of Step 2, the induced quadratic

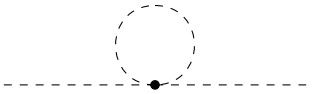

Figure 39.6: The one-loop pion tadpole. The four-point vertex from $\mathcal{L}_2^{(4)}$ (Eq. (39.128)) has two external legs (momenta $\pm p$) and two legs joined into the loop $\Delta(0)$ of Eq. (39.130). Dashed lines are pions. This single graph produces both the $1/\varepsilon$ pole and the chiral logarithm of Eq. (39.133).

Lagrangian is

$$\delta\mathcal{L} = \frac{M_\pi^2}{24f^2}\cdot 10\,\Delta(0)\,\pi^2 \;-\; \frac{\Delta(0)}{3f^2}\Big[(\partial\pi)^2 + M_\pi^2\pi^2\Big] \;=\; -\frac{\Delta(0)}{3f^2}(\partial\pi)^2 + \frac{M_\pi^2\Delta(0)}{12f^2}\,\pi^2. \tag{39.131}$$

Here the factor 10 counts the index contractions of the $(\pi^2)^2$ vertex ($2\cdot 3 + 4\cdot 1$ from the two "self" and four "cross" pairings) and the two derivative structures combine with relative weight $\frac{1}{6} - \frac{1}{2} = -\frac{1}{3}$. Adding $\delta\mathcal{L}$ to the free Lagrangian $\frac{1}{2}(\partial\pi)^2 - \frac{1}{2}M_\pi^2\pi^2$, the inverse propagator becomes

$$\Gamma^{(2)}(p^2) = Z_\pi\,p^2 - M_\pi^2\Big(1 - \frac{\Delta(0)}{6f^2}\Big), \qquad Z_\pi = 1 - \frac{2\Delta(0)}{3f^2}. \tag{39.132}$$

Step 5: the pole mass. The physical mass-squared is the zero of $\Gamma^{(2)}$, $m_\pi^2 = M_\pi^2(1 - \frac{\Delta(0)}{6f^2})/Z_\pi$. Expanding to one loop,

$$m_\pi^2 = M_\pi^2\Big[1 + \frac{\Delta(0)}{2f^2}\Big] = M_\pi^2\Big[1 - \frac{M_\pi^2}{32\pi^2f^2}\Big(\frac{1}{\bar{\varepsilon}} + 1 - \ln\frac{M_\pi^2}{\mu^2}\Big)\Big]. \tag{39.133}$$

The combination of the $-\frac{1}{6}$ from the mass shift and the $+\frac{2}{3}$ from the wavefunction factor Z_π^{-1} leaves the net coefficient $+\frac{1}{2}$. Equation Eq. (39.133) is the result: a $1/\varepsilon$ pole, and riding on it the *chiral logarithm*

$$m_\pi^2 \;\supset\; \frac{M_\pi^4}{32\pi^2f^2}\,\ln\frac{M_\pi^2}{\mu^2} \;=\; \frac{M_\pi^2}{(4\pi f)^2}\,M_\pi^2\,\frac{\ln(M_\pi^2/\mu^2)}{2}\,, \tag{39.134}$$

the announced non-analytic term suppressed by $M_\pi^2/(4\pi f)^2$ — one factor of the chiral expansion parameter $\big(p/\Lambda_\chi\big)^2$ with $\Lambda_\chi = 4\pi f$.

39.5.4 Renormalizing the LEC and its running

The pole in Eq. (39.133) is cancelled by the $O(p^4)$ counterterm of Theorem 39.18. In the two-flavour basis the relevant operator is the one accompanying l_3,

$$\mathcal{L}_4 \;\supset\; -\frac{l_3}{16}\big[\,\mathrm{tr}(\chi^\dagger U + \chi U^\dagger)\big]^2, \tag{39.135}$$

the analogue of the L_6/L_8 structures in Eq. (39.119). Expanding with $\chi = M_\pi^2\mathbf{1}$ gives $\mathrm{tr}(\chi^\dagger U + \chi U^\dagger) = M_\pi^2(4 - 2\pi^2/f^2 + \dots)$, so the squared bracket contributes $-\frac{l_3}{16}\cdot(-16M_\pi^4\pi^2/f^2) = l_3 M_\pi^4\pi^2/f^2$ to the quadratic Lagrangian, i.e. a tree-level shift $\delta m^2 = -2l_3 M_\pi^4/f^2$. Combining this with the loop result Eq. (39.133),

$$m_\pi^2 = M_\pi^2 - \frac{M_\pi^4}{32\pi^2 f^2}\Big(\frac{1}{\bar\varepsilon} + 1 - \ln\frac{M_\pi^2}{\mu^2}\Big) - \frac{2l_3 M_\pi^4}{f^2}. \tag{39.136}$$

Splitting the bare coupling as $l_3 = l_3^r(\mu) + \delta l_3$ and demanding that the $1/\bar\varepsilon$ cancel fixes the counterterm

$$\delta l_3 = -\frac{1}{64\pi^2}\,\frac{1}{\bar\varepsilon}\,, \tag{39.137}$$

which is the explicit instance of Eq. (39.123) with divergence coefficient $\Gamma_{l_3} = \frac{1}{2}$: indeed $-\frac{\Gamma_{l_3}}{32\pi^2}\frac{1}{\bar\varepsilon} = -\frac{1}{64\pi^2}\frac{1}{\bar\varepsilon}$ reproduces Eq. (39.137), and $\Gamma_{l_3} = \frac{1}{2}$ is the standard Gasser–Leutwyler value. After subtraction the physical mass is finite:

$$m_\pi^2 = M_\pi^2\Big[1 - \frac{M_\pi^2}{32\pi^2 f^2}\Big(1 - \ln\frac{M_\pi^2}{\mu^2}\Big) - \frac{2l_3^r(\mu)M_\pi^2}{f^2}\Big]. \tag{39.138}$$

Theorem 39.20 (Running of the low-energy constants)**.** *The renormalized constant $l_3^r(\mu)$ depends on the chiral renormalization scale μ, and the requirement that the physical m_π^2 of Eq. (39.138) be independent of μ fixes the rate of running to*

$$\mu\,\frac{\mathrm{d}l_3^r}{\mathrm{d}\mu} = -\frac{1}{32\pi^2}\,, \qquad \textit{equivalently} \qquad l_3^r(\mu_2) = l_3^r(\mu_1) - \frac{1}{32\pi^2}\ln\frac{\mu_2}{\mu_1}. \tag{39.139}$$

More generally each renormalized LEC runs as $\mu\,\mathrm{d}L_i^r/\mathrm{d}\mu = -\Gamma_i/(16\pi^2)$, with the Γ_i the one-loop divergence coefficients of Eq. (39.123).

Proof. Differentiate Eq. (39.138) with respect to $\ln\mu$ at fixed bare parameters and set the result to zero. Only the explicit logarithm and $l_3^r(\mu)$ carry μ-dependence:

$$0 = \frac{\mathrm{d}m_\pi^2}{\mathrm{d}\ln\mu} = M_\pi^2\Big[\frac{M_\pi^2}{32\pi^2 f^2}\cdot(-2) \;-\; \frac{2M_\pi^2}{f^2}\,\frac{\mathrm{d}l_3^r}{\mathrm{d}\ln\mu}\Big] = -\frac{M_\pi^4}{f^2}\Big[\frac{1}{16\pi^2} + 2\,\frac{\mathrm{d}l_3^r}{\mathrm{d}\ln\mu}\Big], \tag{39.140}$$

where $\mathrm{d}\ln(M_\pi^2/\mu^2)/\mathrm{d}\ln\mu = -2$. Hence $\mu\,\mathrm{d}l_3^r/\mathrm{d}\mu = \mathrm{d}l_3^r/\mathrm{d}\ln\mu = -1/(32\pi^2)$, which is Eq. (39.139). The general statement follows identically: the μ-dependence of any one-loop chiral log is fixed by the corresponding pole coefficient Γ_i through Eq. (39.123), and cancellation of the residual log against $L_i^r(\mu)$ gives $\mu\,\mathrm{d}L_i^r/\mathrm{d}\mu = -\Gamma_i/(16\pi^2)$. □

This is the renormalization-group of Section 24.6 operating in the EFT: the chiral logarithm is the solution of an RG equation, summing $\ln(M_\pi^2/\mu^2)$ as μ is varied, exactly as the Callan–Symanzik logarithms summed $\ln(p^2/\mu^2)$ for ϕ^4. It is natural to trade $l_3^r(\mu)$ for a scale-invariant constant by absorbing the running into

a reference mass; defining $\bar{l}_3$ through $l_3^r(\mu) = \frac{1}{64\pi^2}\left[\bar{l}_3 + \ln(M_\pi^2/\mu^2)\right]$, Eq. (39.138) becomes the manifestly scale-independent

$$m_\pi^2 = M_\pi^2\Big[1 - \frac{M_\pi^2}{32\pi^2 f^2}(1+\bar{l}_3)\Big], \tag{39.141}$$

with $\bar{l}_3 = \ln(\Lambda_3^2/M_\pi^2)$ defining the renormalization-group-invariant scale Λ_3 that encodes the genuine short-distance content. The identical machinery yields the chiral log of the pion decay constant; the analogous one-loop computation of the axial-current matrix element Eq. (29.202) (which carries, in addition to the wavefunction factor Z_π, a vertex contraction from the current) gives

$$f_\pi = f\Big[1 - \frac{M_\pi^2}{16\pi^2 f^2}\ln\frac{M_\pi^2}{\mu^2} + (\text{analytic},\ \propto l_4^r)\Big], \tag{39.142}$$

whose non-analytic coefficient $-1/(16\pi^2)$ is renormalized by l_4 and runs accordingly. The two together constitute the leading quark-mass dependence of the two basic observables of the pion sector.

39.5.5 Predictions versus parameters: what the chiral log means

The split in Eq. (39.138) between the logarithm and the polynomial is the conceptual heart of the matter, and it is worth stating sharply.

Physical Insight

The chiral logarithm $\dfrac{M_\pi^4}{32\pi^2 f^2}\ln M_\pi^2$ is a *parameter-free prediction*. Its coefficient is a pure number, fixed entirely by the Goldstone loop — by the kinematics of a light pion propagating in the loop — with no dependence on any LEC. It is non-analytic in the quark mass: $M_\pi^2 \propto \hat{m}$, so the term behaves as $\hat{m}^2\ln\hat{m}$, and *no* polynomial in $\hat{m}$ (no counterterm, no matter how the L_i are chosen) can reproduce a logarithm. The non-analyticity is the unmistakable fingerprint of a propagating massless (or nearly massless) particle: it is the long-distance, infrared physics of the Goldstone boson, which the EFT knows exactly because it contains the Goldstone field itself. The analytic pieces — the 1, the $l_3^r(\mu)$ — are where the model dependence lives: they are the Wilson coefficients, sensitive to the integrated-out hadrons, and must be supplied by data or by matching to QCD. ChPT thus cleanly separates the model-independent (the logs, predicted) from the model-dependent (the LECs, measured).

The infrared origin of the log also explains why the chiral expansion is well-defined in four dimensions at all: the Goldstone is light but not exactly massless, and in $d = 4$ the infrared fluctuations are only logarithmically strong.

Were we in two dimensions the same loop would be catastrophic — this is the Coleman–Mermin–Wagner obstruction of Theorem 29.33, which forbids the symmetry-broken vacuum outright. In $d = 4$ the log is a controlled, calculable correction, and its appearance is a victory rather than a pathology: it is direct evidence, computed from first principles, that the pion is a Goldstone boson, since only a Goldstone loop can generate a non-analytic dependence on the symmetry-breaking quark mass with a universal coefficient.

We have now assembled a fully renormalized, parity-even chiral Lagrangian through $O(p^4)$: the leading $\mathcal{L}_2$, the Gasser–Leutwyler $\mathcal{L}_4$ with its running constants $L_i^r(\mu)$, and a one-loop machinery that turns the negative-dimension coupling $1/f^2$ into an orderly, predictive expansion. Yet this construction has an accidental symmetry that QCD does not possess. Every operator in $\mathcal{L}_2$ and $\mathcal{L}_4$ is invariant under the naive *intrinsic parity* $U \to U^\dagger$ (equivalently $\Phi \to -\Phi$) accompanied by spatial reflection, so the theory built so far cannot describe any process with an odd number of Goldstone bosons — it forbids $K\bar{K} \to \pi\pi\pi$ and, most strikingly, $\pi^0 \to \gamma\gamma$. QCD allows these; the gap is the imprint of the chiral anomaly of Chapter 36. The final section closes it by constructing the Wess–Zumino–Witten term, the one piece of the chiral Lagrangian that cannot be written as the integral of a locally chiral-invariant density, and whose quantized coefficient will turn out to count the colours N_c.

39.6 The Wess–Zumino–Witten Term and the Anomaly

At the close of Section 39.5 we noticed something faintly suspicious about the chiral Lagrangian we have built. Every term we wrote down — the leading $O(p^2)$ kinetic and mass terms, and every one of the Gasser–Leutwyler $O(p^4)$ operators absorbing the one-loop divergences — is built from traces of U, $U^\dagger$, and their derivatives in such a way that it is left unchanged when we replace the meson field $U(x)$ by $U^\dagger(x)$, equivalently $\Phi(x) \to -\Phi(x)$. This is a symmetry of our effective theory. It is also, as we will now show, an *accident*: it is not a symmetry of QCD. The strong interactions cheerfully produce processes that this accidental symmetry forbids — the radiative decay $\pi^0 \to \gamma\gamma$ chief among them, but also purely mesonic reactions such as $K^+K^- \to \pi^+\pi^-\pi^0$ and $\gamma \to \pi^+\pi^-\pi^0$. A theory that cannot describe these is not the low-energy theory of QCD; it is, at best, the parity-even half of it. The repair is a single new term, discovered by Wess and Zumino and given its definitive geometric form by Witten: a functional that lives most naturally not on four-dimensional spacetime but on a five-dimensional disk that has spacetime as its boundary. Its existence is forced by the chiral anomaly of Chapter 36; its overall coefficient is forced by topology to be an integer; and that integer is the number of colors. This section constructs it, proves the quantization, gauges it to electromagnetism, and recovers from it the $\pi^0 \to \gamma\gamma$ amplitude — closing the loop with the quark-level anomaly computation

of Part X.

39.6.1 The intrinsic-parity problem

We work throughout with the three-flavor coset $\mathrm{SU}(3)_L \times \mathrm{SU}(3)_R/\mathrm{SU}(3)_V$, whose Goldstone fields are the pseudoscalar octet. Recall (Section 39.2) the parametrization

$$U(x) = \exp\!\left(\frac{i\,\Phi(x)}{f}\right), \qquad \Phi = \sum_{a=1}^{8} \lambda^a \phi_a = \begin{pmatrix} \pi^0 + \frac{1}{\sqrt{3}}\eta & \sqrt{2}\,\pi^+ & \sqrt{2}\,K^+ \\ \sqrt{2}\,\pi^- & -\pi^0 + \frac{1}{\sqrt{3}}\eta & \sqrt{2}\,K^0 \\ \sqrt{2}\,K^- & \sqrt{2}\,\bar{K}^0 & -\frac{2}{\sqrt{3}}\eta \end{pmatrix}, \tag{39.143}$$

with $f = f_\pi \approx 92$ MeV the decay constant fixed in Eq. (29.202), and the transformation law $U \to L\,U\,R^\dagger$ under $(L,R) \in \mathrm{SU}(3)_L \times \mathrm{SU}(3)_R$. The leading Lagrangian and its first correction are

$$\mathcal{L}_2 = \frac{f^2}{4}\,\mathrm{Tr}(\partial_\mu U\,\partial^\mu U^\dagger) + \frac{f^2}{4}\,\mathrm{Tr}(\chi U^\dagger + U\chi^\dagger), \tag{39.144}$$

$$\mathcal{L}_4 = L_1\big[\,\mathrm{Tr}(\partial_\mu U \partial^\mu U^\dagger)\big]^2 + L_2\,\mathrm{Tr}(\partial_\mu U \partial_\nu U^\dagger)\,\mathrm{Tr}(\partial^\mu U \partial^\nu U^\dagger) + \cdots, \tag{39.145}$$

where $\chi = 2B_0\,\mathcal{M}_q$ encodes the quark masses and the ellipsis runs over the remaining Gasser–Leutwyler operators of Section 39.5. We do not re-derive these; we interrogate their symmetry.

Definition 39.21 (Intrinsic parity)**.** The *intrinsic-parity* transformation P_Φ acts on the meson field by

$$\mathsf{P}_\Phi : \quad U(x) \longmapsto U^\dagger(x), \qquad \text{equivalently} \qquad \Phi(x) \longmapsto -\Phi(x), \tag{39.146}$$

acting on the field values at the *same* spacetime point, with no reflection of the coordinates. It is to be distinguished from the full QCD parity P, which combines $U(t,\mathbf{x}) \to U^\dagger(t,-\mathbf{x})$ with the spatial reflection $\mathbf{x} \to -\mathbf{x}$. Equation (39.146) is P with the spatial reflection stripped off; it simply counts the number of Goldstone fields modulo two.

The pseudoscalar mesons are odd under the true parity P, as Goldstone bosons of an axial symmetry must be. Stripping the coordinate reflection, P_Φ multiplies every meson field by -1. A monomial in the fields therefore picks up $(-1)^{\#\Phi}$, where $\#\Phi$ is the number of meson fields it contains. We can now state precisely what is wrong.

Proposition 39.22 (The parity-even Lagrangian has an accidental symmetry)**.** *Every term of $\mathcal{L}_2$ in (39.144) and of $\mathcal{L}_4$ in (39.145) — indeed every term constructed from $U, U^\dagger$ and an even number of derivatives by taking traces of products and adding the Hermitian conjugate — is invariant under the intrinsic*

parity P_Φ *of* (39.146)*. Consequently the parity-even chiral Lagrangian contains only vertices with an even number of mesons, and forbids every process whose total Goldstone count is odd.*

Proof. Under P_Φ we have $U \to U^\dagger$ and hence $\partial_\mu U \to \partial_\mu U^\dagger$ at each point. A generic Lorentz-invariant, chirally invariant operator is a sum of traces of products of the building blocks U, $U^\dagger$, $\partial_\mu U$, $\partial_\mu U^\dagger$, χ, $\chi^\dagger$, with Lorentz indices contracted in pairs. The map P_Φ exchanges $U \leftrightarrow U^\dagger$ and $\partial U \leftrightarrow \partial U^\dagger$ throughout; under the simultaneous exchange $\chi \leftrightarrow \chi^\dagger$ (which is the statement that intrinsic parity commutes with the discrete relabeling $L \leftrightarrow R$ of the two chiralities) each such trace is sent to the trace of the Hermitian-conjugate product, which is its complex conjugate. A chirally invariant Lagrangian is real, so it already contains each trace together with its conjugate; the sum is therefore invariant. Concretely, $\mathrm{Tr}(\partial_\mu U\, \partial^\mu U^\dagger) \to \mathrm{Tr}(\partial_\mu U^\dagger\, \partial^\mu U) = \mathrm{Tr}(\partial_\mu U\, \partial^\mu U^\dagger)$ by cyclicity, and $\mathrm{Tr}(\chi U^\dagger + U\chi^\dagger) \to \mathrm{Tr}(\chi^\dagger U + U^\dagger \chi) = \mathrm{Tr}(\chi U^\dagger + U\chi^\dagger)$, so $\mathcal{L}_2$ is invariant; the four operators displayed in $\mathcal{L}_4$ and all the others are products of such invariants and inherit the property.

Now expand any such invariant in powers of Φ using $U = \exp(i\Phi/f) = 1 + i\Phi/f - \Phi^2/2f^2 + \cdots$. Because the operator is invariant under $\Phi \to -\Phi$, its Taylor expansion contains only even powers of Φ. Hence every interaction vertex it generates has an even number of external meson legs, and any S-matrix element built solely from these vertices vanishes unless the total number of external mesons (counted with the parity-odd photons weighted appropriately, see below) is even. □

This is a genuine prediction of the Lagrangian we have, and it is wrong. QCD is invariant under the true parity P, but it is *not* invariant under P_Φ alone, because P_Φ is not a symmetry once the coordinate reflection is removed: the underlying quark theory has no symmetry that flips the sign of every pseudoscalar interpolating field while leaving spacetime untouched. Experimentally the consequences are stark.

- *Five pseudoscalars.* The reaction $K^+K^- \to \pi^+\pi^-\pi^0$ involves five mesons; $\#\Phi = 5$ is odd, so $\mathcal{L}_2 + \mathcal{L}_4$ predicts a vanishing amplitude. It does not vanish.

- *Anomalous radiative decays.* The photon is parity-odd and intrinsic-parity-odd in the relevant sense (it couples to the parity-odd electromagnetic current), so $\gamma \to \pi^+\pi^-\pi^0$ and $\pi^0 \to \gamma\gamma$ carry odd intrinsic parity on the meson side and are likewise forbidden by $\mathcal{L}_2 + \mathcal{L}_4$. Yet $\pi^0 \to \gamma\gamma$ is the dominant decay of the π^0, with a lifetime measured to sub-percent precision.

The chiral Lagrangian as built so far is therefore *incomplete*. Something must supply the intrinsic-parity-odd interactions. We know from Chapter 36 exactly where in QCD the asymmetry between the two chiralities hides that the parity-even bosonic Lagrangian cannot see: the chiral anomaly. The missing term is the bosonized image of that anomaly.

Physical Insight

The accidental symmetry is the EFT's honest report of its own blind spot. A theory of Goldstone bosons built from the invariant U knows about the spontaneously broken *classical* chiral symmetry, but the path-integral measure of the quarks is not chirally invariant, and that quantum violation — the anomaly — is exactly the parity-odd information that traces of U cannot encode. The Wess–Zumino–Witten term is the unique local functional that injects this missing information, and the fact that it cannot be written as a four-dimensional Lagrangian density invariant under the chiral group is the precise sense in which the anomaly is not an ordinary interaction.

39.6.2 Construction of the Wess–Zumino–Witten term

We seek a functional $\Gamma_{\mathrm{WZW}}[U]$ that (i) is invariant under the full chiral group $\mathrm{SU}(3)_L \times \mathrm{SU}(3)_R$ acting by $U \to LUR^\dagger$, (ii) is odd under intrinsic parity P_Φ, and (iii) is local, in the sense that it is built from U and finitely many derivatives without any non-analytic dependence. Conditions (i) and (ii) together are surprisingly restrictive. The obstruction Wess and Zumino discovered is this: *there is no four-dimensional Lagrangian density, polynomial in U and its derivatives, that is both chirally invariant and intrinsic-parity-odd.* The intrinsic-parity-odd invariants one can write in four dimensions, such as $\varepsilon^{\mu\nu\rho\sigma}\,\mathrm{Tr}(L_\mu L_\nu L_\rho L_\sigma)$ with the Maurer–Cartan form $L_\mu \equiv U^\dagger \partial_\mu U$, are identically zero by the antisymmetry of ε against the cyclic trace. The way out, found by Witten, is to add one dimension.

The Maurer–Cartan form $L_\mu = U^\dagger \partial_\mu U$ takes values in the Lie algebra $\mathfrak{su}(3)$ and satisfies the structure ("zero-curvature") relation

$$\partial_\mu L_\nu - \partial_\nu L_\mu = -[L_\mu, L_\nu], \tag{39.147}$$

which follows from $L_\mu = U^\dagger \partial_\mu U$ by direct differentiation, $\partial_\mu L_\nu = \partial_\mu (U^\dagger \partial_\nu U) = -U^\dagger \partial_\mu U\, U^\dagger \partial_\nu U + U^\dagger \partial_\mu \partial_\nu U$, and antisymmetrizing. The unique nontrivial intrinsic-parity-odd five-index invariant is $\varepsilon^{ijklm}\,\mathrm{Tr}(L_i L_j L_k L_l L_m)$, which does *not* vanish: with five antisymmetrized factors the cyclic identity no longer forces it to zero. This object naturally integrates over a five-dimensional manifold.

Definition 39.23 (The Wess–Zumino–Witten action)**.** Let spacetime, with the fields assumed to approach a constant at infinity, be compactified to the

four-sphere S^4. Let Q be a five-dimensional disk (five-ball) with boundary $\partial Q = S^4$, and let $\widetilde{U} : Q \to \mathrm{SU}(3)$ be any smooth extension of the physical field $U : S^4 \to \mathrm{SU}(3)$ into the interior, with $\widetilde{U}|_{\partial Q} = U$. Writing $L_i = \widetilde{U}^\dagger \partial_i \widetilde{U}$ for $i = 1, \dots, 5$ the Maurer–Cartan form on Q, the Wess–Zumino–Witten action is

$$\boxed{\Gamma_{\mathrm{WZW}}[U] = -\frac{i\,n}{240\pi^2} \int_Q \mathrm{d}^5 y\; \varepsilon^{ijklm}\; \mathrm{Tr}(L_i L_j L_k L_l L_m)} \tag{39.148}$$

with n a real constant to be determined. The integrand is purely imaginary (the trace of five Hermitian-times-i factors), so the explicit i makes Γ_{WZW} real.

Three things must now be checked before (39.148) can be accepted as a term in a four-dimensional action: that it is chirally invariant; that despite being written as a bulk integral it depends on U only through its boundary values, so that its variation is a local four-dimensional object; and that the inevitable ambiguity in the choice of the extension $\widetilde{U}$ does not make the theory ill-defined.

Chiral invariance. Under a *global* transformation $U \to L U R^\dagger$ with constant L, R, the Maurer–Cartan form transforms as $L_i = U^\dagger \partial_i U \to R\, U^\dagger L^\dagger\, \partial_i (L U R^\dagger) = R\,(U^\dagger \partial_i U)\, R^\dagger = R\, L_i\, R^\dagger$, since L is constant. The trace $\mathrm{Tr}(L_i L_j L_k L_l L_m)$ is invariant under this similarity transformation by cyclicity, and the left rotation L drops out entirely because it acts only through $L^\dagger L = 1$. Hence the integrand, and therefore Γ_{WZW}, is invariant under the global chiral group. (The extension $\widetilde{U}$ may be chosen to respect the same transformation, e.g. by the radial homotopy below, so global invariance lifts to the bulk.)

The variation is a boundary term. The decisive property is that the five-form $\omega_5 \equiv \varepsilon^{ijklm}\,\mathrm{Tr}(L_i L_j L_k L_l L_m)$ is *closed* as a differential form on the group manifold: $\mathrm{d}\omega_5 = 0$. This is what makes (39.148) a sensible four-dimensional functional. We verify it through its variation. Under $\widetilde{U} \to \widetilde{U} + \delta\widetilde{U}$, write $\delta\widetilde{U} = \widetilde{U}\,\eta$ with $\eta \equiv \widetilde{U}^\dagger \delta \widetilde{U}$ an infinitesimal algebra-valued field. Then

$$\delta L_i = \delta(\widetilde{U}^\dagger \partial_i \widetilde{U}) = -\eta L_i + \widetilde{U}^\dagger \partial_i (\widetilde{U}\eta) = \partial_i \eta + [L_i, \eta], \tag{39.149}$$

the covariant derivative $D_i \eta \equiv \partial_i \eta + [L_i, \eta]$ of η. Varying the integrand and using the cyclicity of the trace to collect the five identical contributions,

$$\delta\ \mathrm{Tr}(L_i L_j L_k L_l L_m)\, \varepsilon^{ijklm} = 5\, \varepsilon^{ijklm}\ \mathrm{Tr}\big((D_i \eta)\, L_j L_k L_l L_m\big). \tag{39.150}$$

The commutator pieces in $D_i\eta = \partial_i\eta + [L_i, \eta]$ cancel against each other once antisymmetrized against ε^{ijklm}, by the Maurer–Cartan relation (39.147): each time a factor $[L_i, L_j]$ is generated by moving L_i past η, it equals $-(\partial_i L_j - \partial_j L_i)$, and the resulting derivatives reorganize into a total divergence. Carrying out this standard algebra one finds the clean result

$$\delta\left(\varepsilon^{ijklm}\,\mathrm{Tr}(L_i L_j L_k L_l L_m)\right) = 5\,\partial_i\Big(\varepsilon^{ijklm}\ \mathrm{Tr}\big(\eta\, L_j L_k L_l L_m\big)\Big), \tag{39.151}$$

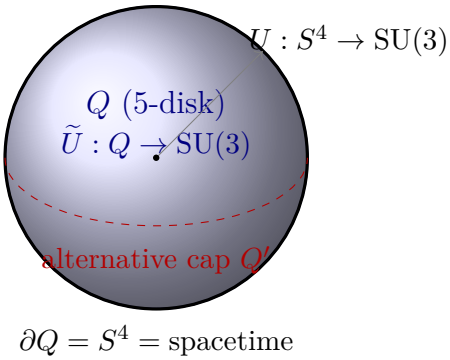

Figure 39.7: The Wess–Zumino–Witten functional (39.148) integrates a closed five-form over a five-disk Q whose boundary is (compactified) spacetime S^4. Two extensions $\widetilde{U}$ over Q and $\widetilde{U}'$ over a second cap Q' glue along S^4 into a map of the five-sphere $S^5 = Q \cup \bar{Q}'$; the difference of the two functionals is $2\pi n$ times the integer winding number of that map, an element of $\pi_5(\mathrm{SU}(3)) = \mathbb{Z}$. Single-valuedness of $e^{i\Gamma_{\mathrm{WZW}}}$ forces $n \in \mathbb{Z}$.

a pure total derivative in five dimensions. The five-dimensional integral of a total divergence collapses to an integral over the boundary $\partial Q = S^4 =$ spacetime:

$$\delta\Gamma_{\mathrm{WZW}} = -\frac{i\,n}{48\pi^2}\int_{S^4} \mathrm{d}^4x\; \varepsilon^{\mu\nu\rho\sigma}\; \mathrm{Tr}(\eta\, L_\mu L_\nu L_\rho L_\sigma), \tag{39.152}$$

which involves only the boundary value $\eta = U^\dagger \delta U$ and the boundary Maurer–Cartan form. Thus although Γ_{WZW} is written as a bulk integral, its *equations of motion* — and hence all of its physics — are genuinely four-dimensional and local. This is the precise meaning of "the variation is a total derivative in 4D so the term is local on the boundary": the five-dimensional writing is a bookkeeping device for a four-dimensional interaction that has no four-dimensional manifestly chiral-invariant Lagrangian density.

Extension ambiguity. The construction required choosing an extension $\widetilde{U}$ of U into the five-disk Q. Such an extension exists because $\pi_4(\mathrm{SU}(3)) = 0$ (every map $S^4 \to \mathrm{SU}(3)$ is contractible, so it bounds), a fact recorded in Theorem 37.36. But the extension is not unique, and we must check that Γ_{WZW} does not depend on the choice in any way that affects physics. This is where the integer n is born, and it is the subject of the next result.

39.6.3 Witten's quantization: the coefficient is N_c

Theorem 39.24 (Quantization of the WZW coefficient)**.** *For the quantum theory defined by the path integral weight e^{iS} with $S \supset \Gamma_{\mathrm{WZW}}[U]$ to be independent of*

the choice of five-disk extension, the coefficient n in (39.148) must be an integer, $n \in \mathbb{Z}$. Matching the gauged WZW term to the QCD chiral anomaly of Chapter 36 fixes the integer to the number of colors,

$$n = N_c = 3. \tag{39.153}$$

Thus the coefficient of the Wess–Zumino–Witten term is a direct measurement, within the meson effective theory, of the number of quark colors.

Proof. Quantization. Suppose we choose two different extensions, $\widetilde{U}$ over the disk Q and $\widetilde{U}'$ over a second disk Q', both restricting to the same physical U on the common boundary S^4. The two functionals differ by

$$\Gamma_{\mathrm{WZW}}[\widetilde{U}] - \Gamma_{\mathrm{WZW}}[\widetilde{U}'] = -\frac{in}{240\pi^2}\left(\int_Q - \int_{Q'}\right)\omega_5 = -\frac{in}{240\pi^2}\oint_{S^5}\omega_5, \tag{39.154}$$

where $S^5 = Q \cup \bar{Q}'$ is the closed five-manifold obtained by gluing Q to Q' with reversed orientation along their shared boundary — topologically a five-sphere (see Fig. 39.7). On this closed S^5 the two extensions combine into a single smooth map $g : S^5 \to \mathrm{SU}(3)$. The crucial topological input, established in Theorem 37.36, is that the fifth homotopy group of $\mathrm{SU}(N \geq 3)$ is the integers,

$$\pi_5(\mathrm{SU}(3)) = \mathbb{Z}, \tag{39.155}$$

so maps $g : S^5 \to \mathrm{SU}(3)$ are classified up to homotopy by an integer winding number $w[g] \in \mathbb{Z}$. The normalization in (39.148) was chosen precisely so that this winding number is computed by the same five-form integral:

$$-\frac{i}{240\pi^2}\oint_{S^5}\varepsilon^{ijklm}\,\mathrm{Tr}(L_iL_jL_kL_lL_m) \;=\; 2\pi\, w[g], \qquad w[g] \in \mathbb{Z}. \tag{39.156}$$

That the number $240\pi^2$ does this job is the content of the deeper computation in Section 37.7, where the volume of SU(3) in the bi-invariant metric and the generator of $H^5(\mathrm{SU}(3);\mathbb{Z})$ are evaluated; we import that normalization rather than rederive it, since the only fact we need here is the existence of an integer-valued period. Combining (39.154) with (39.156),

$$\Gamma_{\mathrm{WZW}}[\widetilde{U}] - \Gamma_{\mathrm{WZW}}[\widetilde{U}'] = 2\pi\, n\, w[g]. \tag{39.157}$$

The action is therefore ambiguous, but only by integer multiples of $2\pi n$. Physics depends on the action only through the path-integral weight e^{iS}. The ambiguity (39.157) is invisible in e^{iS} if and only if $2\pi n\, w[g] \in 2\pi\mathbb{Z}$ for every $w[g] \in \mathbb{Z}$, that is, if and only if

$$n \in \mathbb{Z}. \tag{39.158}$$

This is Witten's quantization. It is the exact higher-dimensional analogue of Dirac's charge quantization: a topological period of the action must be an integer

multiple of 2π for the quantum theory to exist, and here that integer is the WZW coefficient. Notice the logic: the classical action is genuinely multivalued, but the quantum theory is well-defined provided the multivaluedness is a multiple of 2π, which quantizes the coupling. No continuous renormalization can shift n; it is a topological invariant of the effective theory.

Matching to QCD. The integer n is not fixed by the meson theory in isolation — any integer gives a consistent EFT. It is fixed by demanding that this EFT reproduce QCD. The cleanest matching is through the gauged term derived in Section 39.6.4: gauging Γ_{WZW} to electromagnetism produces a $\pi^0\gamma\gamma$ vertex whose coefficient is proportional to n, while the same vertex is computed directly from the quark triangle diagram in Chapter 36, where it is proportional to the number of colors N_c circulating in the loop (each color contributes one triangle). Equality of the two — the statement that the anomaly of the microscopic theory equals the anomaly of the effective theory — is 't Hooft anomaly matching, Theorem 37.26. It forces $n = N_c$. With $N_c = 3$ in QCD,

$$n = 3. \tag{39.159}$$

We carry out the matching explicitly in Theorem 39.25; here we record only its conclusion, (39.153). □

Physical Insight

The number of colors is usually introduced as a property of the ultraviolet: three colors are needed for the R-ratio, for the π^0 width, for the gauge-anomaly cancellation of the Standard Model. The WZW term shows that N_c is also written into the deep infrared. The pseudoscalar mesons — the lightest, most accessible degrees of freedom of the strong interaction — carry the integer N_c as the coefficient of a topological term in their own effective action. One could, in principle, determine that there are three colors purely from low-energy meson physics, never resolving a single quark. This is the most vivid possible statement that an effective theory remembers the counting of its constituents.

39.6.4 Gauging to electromagnetism and the $\pi^0 \to \gamma\gamma$ vertex

To extract a physical decay we must couple the mesons to the photon. The mesons carry electric charge through the quark charge matrix

$$Q = \frac{1}{3}\,\mathrm{diag}(2,-1,-1) = \mathrm{diag}\Big(\tfrac{2}{3},-\tfrac{1}{3},-\tfrac{1}{3}\Big)\,, \tag{39.160}$$

acting in flavor space, in units of e. Electromagnetism is gauged by promoting the ordinary derivative to a covariant one following the minimal-coupling prescription

of Eq. (8.27); on the meson field, the left and right flavor rotations are tied together to the single $\mathrm{U}(1)_{\mathrm{em}}$ generated by Q, so

$$\partial_\mu U \;\longrightarrow\; D_\mu U = \partial_\mu U - ieA_\mu\,[\,Q, U\,]. \tag{39.161}$$

Gauging the WZW term is not as simple as the replacement (39.161), however, because Γ_{WZW} is a five-dimensional functional whose gauge variation must be cancelled order by order in A_μ by additional, explicitly constructed counterterms (the Bardeen counterterms). The full gauged functional is built in Section 37.7; we import its result and isolate the single piece relevant to two-photon decay. That piece is a genuine four-dimensional local interaction — two powers of the photon field saturate two of the five dimensions, leaving a standard 4D vertex — of the form

$$\mathcal{L}^{\gamma\gamma}_{\mathrm{WZW}} = \frac{n\,e^2}{32\pi^2 f}\,\varepsilon^{\mu\nu\rho\sigma} F_{\mu\nu}F_{\rho\sigma}\;\mathrm{Tr}(Q^2\,\Phi), \tag{39.162}$$

with $F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu$ the electromagnetic field strength and Φ the meson matrix (39.143). The flavor trace selects the neutral mesons:

$$\mathrm{Tr}(Q^2\Phi) = \mathrm{Tr}\Big[\,\mathrm{diag}\big(\tfrac{4}{9},\tfrac{1}{9},\tfrac{1}{9}\big)\,\Phi\Big] = \frac{4}{9}\big(\pi^0+\tfrac{1}{\sqrt{3}}\eta\big)+\frac{1}{9}\big(-\pi^0+\tfrac{1}{\sqrt{3}}\eta\big)+\frac{1}{9}\big(-\tfrac{2}{\sqrt{3}}\eta\big) = \frac{1}{3}\,\pi^0+\frac{1}{3\sqrt{3}}\,\eta. \tag{39.163}$$

Keeping the π^0 and setting $n = N_c$, (39.162) delivers the effective $\pi^0\gamma\gamma$ Lagrangian

$$\boxed{\mathcal{L}_{\pi^0\gamma\gamma} = \frac{N_c\,e^2}{96\pi^2 f_\pi}\,\pi^0\,\varepsilon^{\mu\nu\rho\sigma}F_{\mu\nu}F_{\rho\sigma}} \tag{39.164}$$

where we used $\mathrm{Tr}(Q^2\Phi) \supset \frac{1}{3}\pi^0$ and $f = f_\pi$. We pause to confirm the coefficient against the anomaly before computing the rate.

The coefficient is fixed by anomaly matching, not chosen. The number $N_c e^2/96\pi^2 f_\pi$ in (39.164) looks like an arbitrary normalization; it is not. It is forced by requiring that the divergence of the effective axial-isospin current reproduce the operator anomaly of Eq. (36.50). The third axial-isospin current of QCD,

$$j_3^{\mu 5} = \bar q\,\gamma^\mu\gamma^5\,\frac{\tau^3}{2}\,q, \tag{39.165}$$

has the electromagnetic ABJ anomaly (Eq. (36.50)) obtained by summing over the N_c colors and the two flavors with axial charges $\pm\frac{1}{2}$ and electric charges $Q_u = \frac{2}{3}$, $Q_d = -\frac{1}{3}$:

$$\partial_\mu j_3^{\mu 5} = \frac{e^2}{16\pi^2}\,D\,\varepsilon^{\mu\nu\rho\sigma}F_{\mu\nu}F_{\rho\sigma}, \qquad D = N_c\Big(\tfrac{1}{2}Q_u^2 - \tfrac{1}{2}Q_d^2\Big) = N_c\Big(\tfrac{1}{2}\cdot\tfrac{4}{9} - \tfrac{1}{2}\cdot\tfrac{1}{9}\Big) = \frac{N_c}{6}. \tag{39.166}$$

On the meson side the same current is, by PCAC (Eq. (29.202)), $j_3^{\mu 5} = f_\pi\partial^\mu\pi^0 + \cdots$, so its divergence is $\partial_\mu j_3^{\mu 5} = f_\pi\,\Box\pi^0$. The photon-dependent source on the

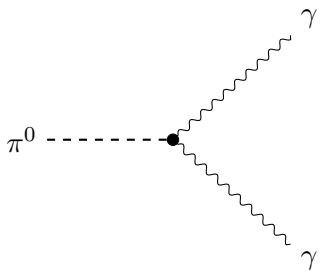

Figure 39.8: The $\pi^0 \to \gamma\gamma$ vertex generated by the gauged Wess–Zumino–Witten term (39.164). In the meson effective theory it is a local contact interaction (the dot); in QCD it is the quark triangle diagram of Chapter 36, summed over the N_c colors that run in the loop. Equality of the two is 't Hooft anomaly matching, Theorem 37.26.

right of the π^0 field equation comes from $\partial\mathcal{L}_{\pi^0\gamma\gamma}/\partial\pi^0 = (N_c e^2/96\pi^2 f_\pi)\,\varepsilon^{\mu\nu\rho\sigma}F_{\mu\nu}F_{\rho\sigma}$, so the photon-dependent part of the current divergence is

$$(\partial_\mu j_3^{\mu 5})_{\gamma\gamma} = f_\pi \cdot \frac{N_c e^2}{96\pi^2 f_\pi}\,\varepsilon^{\mu\nu\rho\sigma}F_{\mu\nu}F_{\rho\sigma} = \frac{N_c e^2}{96\pi^2}\,\varepsilon^{\mu\nu\rho\sigma}F_{\mu\nu}F_{\rho\sigma}. \tag{39.167}$$

Comparing (39.167) with the quark-level result (39.166), where $D = N_c/6$ gives $(e^2/16\pi^2)(N_c/6) = N_c e^2/96\pi^2$ for the coefficient of εFF, the two coefficients coincide exactly. The WZW coefficient (39.164) is therefore not adjustable: it is the unique value that makes the meson EFT reproduce the QCD anomaly, which is exactly the matching condition that fixed $n = N_c$ in Theorem 39.24. The bosonized anomaly and the quark triangle are the same number, viewed from the two ends of the running coupling.

39.6.5 The amplitude and the decay rate

We now compute the $\pi^0 \to \gamma\gamma$ amplitude from the vertex (39.164) and evaluate the width, carrying every step. Write the interaction as $\mathcal{L}_{\pi^0\gamma\gamma} = c\,\pi^0\,\varepsilon^{\mu\nu\rho\sigma}F_{\mu\nu}F_{\rho\sigma}$ with

$$c = \frac{N_c\,e^2}{96\pi^2 f_\pi} \quad \text{(for the isolated } \pi^0\text{)} \implies A \equiv 8c = \frac{e^2 N_c}{12\pi^2 f_\pi}. \tag{39.168}$$

Using the antisymmetry of ε in $(\mu\nu)$ and in $(\rho\sigma)$ to write $\varepsilon^{\mu\nu\rho\sigma}F_{\mu\nu}F_{\rho\sigma} = 4\,\varepsilon^{\mu\nu\rho\sigma}\partial_\mu A_\nu\,\partial_\rho A_\sigma$, the vertex Feynman rule for $\pi^0(p) \to \gamma(k_1,\epsilon_1)\gamma(k_2,\epsilon_2)$ follows by attaching the two photon fields to the external legs (a combinatorial factor 2! for the two ways) with $\partial_\mu A_\nu \to ik_\mu\epsilon^*_\nu$ for each outgoing photon:

$$i\mathcal{M} = i\cdot 4c\cdot 2!\cdot\varepsilon^{\mu\nu\rho\sigma}(ik_{1\mu}\epsilon^*_{1\nu})(ik_{2\rho}\epsilon^*_{2\sigma}) = -8ic\,\varepsilon^{\mu\nu\rho\sigma}k_{1\mu}\epsilon^*_{1\nu}k_{2\rho}\epsilon^*_{2\sigma}. \tag{39.169}$$

Hence

$$\mathcal{M}(\pi^0 \to \gamma\gamma) = -8c\,\varepsilon^{\mu\nu\rho\sigma} k_{1\mu}\epsilon^*_{1\nu} k_{2\rho}\epsilon^*_{2\sigma} = -A\,\varepsilon^{\mu\nu\rho\sigma} k_{1\mu}\epsilon^*_{1\nu} k_{2\rho}\epsilon^*_{2\sigma}, \tag{39.170}$$

using $8c = 8\cdot N_c e^2/96\pi^2 f_\pi = N_c e^2/12\pi^2 f_\pi$, so that the physical amplitude carries precisely

$$A = \frac{e^2 N_c}{12\pi^2 f_\pi} = \frac{\alpha N_c}{3\pi f_\pi}, \tag{39.171}$$

with $\alpha = e^2/4\pi$. This is exactly the result Eq. (36.115) obtained from the quark triangle in Part X: the effective meson coupling and the microscopic anomaly give the same amplitude, the explicit content of the anomaly matching Theorem 37.26.

Worked Example 39.25 (The π^0 width and the count of colors)**.** We square (39.170), sum over the final photon polarizations, integrate over two-body phase space, and put in numbers.

Polarization sum. With $\mathcal{M} = A\,\varepsilon_{\mu\nu\rho\sigma}\epsilon_1^\mu \epsilon_2^\nu k_1^\rho k_2^\sigma$ (rewriting (39.170) after relabeling, the overall sign immaterial), the spin-summed square uses $\sum_{\text{pol}} \epsilon^\mu \epsilon^{*\nu} \to -g^{\mu\nu}$ (the gauge-dependent pieces drop against the antisymmetry of ε):

$$\begin{aligned}\sum_{\text{pol}} |\mathcal{M}|^2 &= A^2 (-g_{\mu\mu'})(-g_{\nu\nu'})\,\varepsilon^{\mu\nu\rho\sigma}\varepsilon^{\mu'\nu'\rho'\sigma'} k_{1\rho} k_{2\sigma} k_{1\rho'} k_{2\sigma'} \\ &= A^2\,\varepsilon^{\mu\nu\rho\sigma}\varepsilon_{\mu\nu}{}^{\rho'\sigma'}\, k_{1\rho} k_{2\sigma} k_{1\rho'} k_{2\sigma'}.\end{aligned} \tag{39.172}$$

In the mostly-minus metric, $\varepsilon^{\mu\nu\rho\sigma}\varepsilon_{\mu\nu\alpha\beta} = -2(\delta^\rho_\alpha\delta^\sigma_\beta - \delta^\rho_\beta\delta^\sigma_\alpha)$, so

$$\sum_{\text{pol}} |\mathcal{M}|^2 = -2A^2\big[(k_1\cdot k_1)(k_2\cdot k_2) - (k_1\cdot k_2)^2\big] = 2A^2\,(k_1\cdot k_2)^2, \tag{39.173}$$

since the photons are massless, $k_1^2 = k_2^2 = 0$. From $(k_1+k_2)^2 = m_\pi^2$ and $k_i^2 = 0$ we get $2\,k_1\cdot k_2 = m_\pi^2$, hence $(k_1\cdot k_2)^2 = m_\pi^4/4$ and

$$\sum_{\text{pol}} |\mathcal{M}|^2 = \frac{A^2 m_\pi^4}{2}. \tag{39.174}$$

Phase space and the width. For a one-to-two decay with massless final particles the integrated two-body phase space is $\int \mathrm{d}\Pi_2 = 1/8\pi$. Because the two photons are identical we include a symmetry factor $1/2$. The decay rate is then

$$\Gamma = \frac{1}{2}\cdot\frac{1}{2m_\pi}\int \mathrm{d}\Pi_2 \sum_{\text{pol}} |\mathcal{M}|^2 = \frac{1}{2}\cdot\frac{1}{2m_\pi}\cdot\frac{1}{8\pi}\cdot\frac{A^2 m_\pi^4}{2} = \frac{A^2 m_\pi^3}{64\pi}. \tag{39.175}$$

Substituting $A = \alpha N_c/3\pi f_\pi$ from (39.171) gives the closed form

$$\Gamma(\pi^0 \to \gamma\gamma) = \frac{\alpha^2\, N_c^2\, m_\pi^3}{576\,\pi^3 f_\pi^2}. \tag{39.176}$$

Numbers. With $\alpha = 1/137.04$, $m_\pi = m_{\pi^0} = 134.98$ MeV, $f_\pi = 92.1$ MeV, and $N_c = 3$, the amplitude is

$$A = \frac{\alpha N_c}{3\pi f_\pi} = \frac{(1/137.04)\cdot 3}{3\pi \cdot 0.0921\ \text{GeV}} = 0.0253\ \text{GeV}^{-1}, \tag{39.177}$$

and the width is

$$\Gamma = \frac{A^2 m_\pi^3}{64\pi} = \frac{(0.0253)^2\,(0.13498)^3}{64\pi}\ \text{GeV} = 7.8\times 10^{-9}\ \text{GeV} = 7.8\ \text{eV}. \tag{39.178}$$

The measured value (PrimEx and the Particle Data Group average, mid-2020s) is $\Gamma(\pi^0 \to \gamma\gamma) = 7.80 \pm 0.12$ eV. The leading prediction lands on the experimental value to better than the experimental error.

The count of colors. Because $\Gamma \propto N_c^2$, the measured width *measures* N_c. Had we taken $N_c = 1$ the predicted width would be a factor of nine too small, ~ 0.87 eV, in gross conflict with experiment; $N_c = 2$ gives ~ 3.5 eV, still excluded. Only $N_c = 3$ works, and it works to the percent level. The radiative decay of the neutral pion is thus a direct low-energy weighing of the number of quark colors — the experimental face of the quantization theorem Theorem 39.24 and of the anomaly matching Theorem 37.26.

Caution

The clean agreement uses the chiral-limit prediction (39.176) at the physical point with the *physical* f_π. The anomaly fixes the amplitude in the chiral limit ($m_q \to 0$); the leading corrections are of order m_π^2/Λ_χ^2 and a small π^0–η–η' mixing, both at the percent level, which is why the lowest-order formula is already this accurate. The agreement is not an accident of using one convention for f_π versus another: the combination $A = \alpha N_c/3\pi f_\pi$ is convention-independent once f_π is defined through the same matrix element (29.202) used here ($f_\pi \approx 92$ MeV, not the $\sqrt{2}$-larger normalization).

39.6.6 What the WZW term completes

The gauged Wess–Zumino–Witten functional does more than the single decay we computed. Expanding (39.148) to fifth order in Φ produces a five-pseudoscalar contact vertex — the interaction responsible for $K^+K^- \to \pi^+\pi^-\pi^0$ and the other odd-meson reactions that opened this section — with a coefficient again proportional to N_c. Gauging with one photon instead of two yields the $\gamma \to \pi^+\pi^-\pi^0$ vertex with amplitude $F^{3\pi} = eN_c/12\pi^2 f_\pi^3$, a second independent low-energy test of the same integer. Every one of these intrinsic-parity-odd processes is forbidden by $\mathcal{L}_2 + \mathcal{L}_4$ and supplied, with a quantized strength, by the one new

term. With Γ_{WZW} adjoined, the chiral Lagrangian

$$S = \int \mathrm{d}^4x \, (\mathcal{L}_2 + \mathcal{L}_4 + \cdots) + \Gamma_{\mathrm{WZW}} \tag{39.179}$$

is the complete leading-order effective field theory of QCD at low energy: the parity-even sector built from the spontaneously broken chiral symmetry, plus the parity-odd sector built from the anomaly, with the number of colors built into the coefficient of the latter.

This closes the chapter's central thesis and the strong-interaction story of the book. We have seen QCD from both ends of its running coupling (QCD): in the ultraviolet as the asymptotically free gauge theory of Chapters 25 and 27, and here in the infrared as a predictive theory of pseudo-Goldstone mesons whose every coefficient is fixed by symmetry, power counting, and — in the WZW term — topology and the anomaly. The anomaly computed at the quark level in Chapter 36 has reappeared, unchanged in magnitude, as an interaction of mesons, the cleanest illustration in the book of 't Hooft anomaly matching (Theorem 37.26). The next chapter (Chapter 40) turns from this archetypal low-energy EFT to the other effective theories that organize modern particle physics — heavy-quark and Standard-Model effective field theories — carrying forward the same paradigm of Chapter 38: that a theory one cannot solve in its fundamental variables can still be solved, order by order, once symmetry rather than the coupling is made the organizing principle of the expansion.

Further reading

The reinterpretation of current-algebra results as the leading term of a systematic momentum expansion is Weinberg's Weinberg [498], building on his original soft-pion prediction Weinberg [495]; the foundational one-loop construction, including the order-p^4 Lagrangian and the low-energy constants used throughout Section 39.5, is Gasser and Leutwyler [210]. The most accessible modern textbook treatment, covering the nonlinear realization, power counting, loops, and the WZW term at the level of this chapter, is Scherer and Schindler [430]. The intrinsic-parity-odd sector originates with Wess and Zumino [506], and the topological quantization of its coefficient to the integer N_c—the argument behind Theorem 39.24—is Witten's Witten [521]. For the present state of the precision program, including the two-loop $\pi\pi$ analysis and its experimental confrontation, see Colangelo et al. [126] and the NA48/2 measurement [51].

Chapter 40

Heavy-Particle and Standard Model EFTs

The effective-field-theory paradigm of Chapter 38 taught us that a low-energy theory is fixed by three choices — a field content, a symmetry, and a power counting — and that its Wilson coefficients are then pinned in one of two ways: by *matching*, when the short-distance theory is known, or by *measurement*, when it is not. Chapter 39 ran the second route on the broken chiral symmetry of QCD, where the ultraviolet completion is known to be QCD but is strongly coupled and so out of perturbative reach. This chapter runs the method in *both* directions at once, on two of the most consequential effective theories in particle physics, and shows them to be one construction seen from two sides. The first half is top-down: the short-distance theory is the Yang–Mills sector of Chapter 25, renormalized and run in Chapter 27, and we integrate out a heavy quark to build the heavy-quark effective theory (HQET). The second half is bottom-up: the short-distance theory is unknown, and we treat the Standard Model assembled in Chapter 33 as the leading term of an expansion — the Standard Model Effective Field Theory (SMEFT) — whose higher-dimension operators parametrize, model-independently, whatever lies above the electroweak scale.

The HQET arc occupies the first three sections. We begin from the QCD Lagrangian of a heavy quark, split its momentum into a large kinematic part $m_Q v^\mu$ and a soft residual part, strip the rapidly oscillating mass phase from the field, and integrate out its small Dirac components to arrive at a static Lagrangian whose Feynman rules — a forward-propagating worldline and a spin-blind eikonal vertex — are the diagrammatic face of an emergent symmetry. That symmetry, a $\mathrm{U}(2N_h)$ rotating heavy-quark spin and flavour, is invisible in QCD yet exact in the $m_Q \to \infty$ limit; we use it to collapse the six $B \to D^{(*)}$ semileptonic form factors onto a single Isgur–Wise function normalized to unity at zero recoil, the statement that makes these decays the cleanest window onto the CKM element

$|V_{cb}|$ of Chapter 32. Restoring finite m_Q then forces us to match QCD onto HQET order by order in $1/m_Q$, producing a kinetic operator whose coefficient is frozen to unity by reparametrization invariance and a chromomagnetic operator whose runnable coefficient is the microscopic origin of the B^*–B and D^*–D hyperfine splittings. The abelian sibling of this computation, NRQED, recovers Schwinger's $a_e = \alpha/2\pi$ of Chapter 20 — carried here along QED — now wearing the costume of a matching coefficient rather than a form factor.

The SMEFT arc occupies the last four sections and inverts the logic. With the ultraviolet unknown, we take only the data we trust — the gauge group $\mathrm{SU}(3)_c \times \mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$, the chiral matter and Higgs content of Chapter 33, and a single new scale Λ — and build the tower of higher-dimension operators. Dimension five yields the unique Weinberg operator, the low-energy shadow of lepton-number violation and of the seesaw of Chapter 35; dimension six yields, after the redundancies of integration by parts, field redefinitions, Fierz rearrangements, and identical-field symmetry are removed, the canonical 59-operator Warsaw basis. We then put the coefficients to work: matching a known heavy field (the W, recovering Fermi theory and G_F) and a hypothetical one fixes them at the high scale, the renormalization group of Chapter 24 — driven here by the QCD anomalous-dimension technology of Chapter 27 — evolves them down through operator mixing, and the oblique parameters S and T of Chapter 34 reappear as individual dimension-six Wilson coefficients that turn a precision measurement directly into a bound on Λ.

Throughout we hold to the conventions of Chapter A: the mostly-minus metric $\eta_{\mu\nu} = \mathrm{diag}(+,-,-,-)$, natural units, the covariant-derivative sign $D_\mu = \partial_\mu - igA^a_\mu T^a$, and $\overline{\mathrm{MS}}$ with dimensional regularization as the default scheme. The Dirac and trace technology is that of Appendix C, the group-theory data that of Appendix B, and the master loop integrals those of Appendix D; the running coupling $\alpha_s(\mu)$ is the one established in Chapter 27, the accidental B and L symmetries and the $B - L$ anomaly those of Chapters 33 and 37. The chapter closes by recognizing explicitly what its two halves have demonstrated implicitly: "write all operators, power count, match or measure, run" is a single recipe, and HQET and SMEFT differ only in whether the short-distance theory has been written down or is still waiting to be discovered.

40.1 The heavy-quark expansion

An effective field theory is fixed by three choices: a field content, a symmetry, and a power counting. Chapter 38 built that paradigm abstractly—integrate out the heavy modes, match onto a local Lagrangian, organize the result as an expansion in a small ratio, and run the Wilson coefficients between scales—and Chapter 39 deployed it bottom-up, where the short-distance theory is hidden and the operators are written from symmetry alone. We now run the machinery

in the opposite, fully controlled direction. The short-distance theory is *known*: it is QCD, the non-abelian gauge theory of Chapter 25 renormalized and run in Chapter 27. We continue Yang–Mills theory from Chapter 27 and ask what becomes of that theory when one of its quarks is much heavier than the scale at which the strong interaction confines.

The physical hierarchy is unambiguous. A hadron containing a single heavy quark—a B or D meson, a Λ_b baryon—has a size of order $1/\Lambda_{\rm QCD} \sim 1\,\text{fm}$ set by the light degrees of freedom, while the heavy quark carries a Compton wavelength $1/m_Q$ far shorter than that. For the charm ($m_c \approx 1.3\,\text{GeV}$), the bottom ($m_b \approx 4.2\,\text{GeV}$), and *a fortiori* the top, one has

$$m_Q \;\gg\; \Lambda_{\rm QCD} \approx 0.2\,\text{GeV}, \qquad \lambda \equiv \frac{\Lambda_{\rm QCD}}{m_Q} \;\ll\; 1, \tag{40.1}$$

and λ is the expansion parameter of the effective theory we are about to build, *heavy-quark effective theory* (HQET). The picture to keep in mind is the hydrogen atom of the strong interaction: a heavy, nearly static colour source surrounded by a cloud of soft gluons and light quarks ("the brown muck") whose dynamics it barely disturbs. Just as the proton mass drops out of atomic spectroscopy to leading order, leaving the electron cloud insensitive to whether the nucleus is hydrogen or deuterium, the heavy-quark mass and spin will drop out of the leading strong dynamics—but seeing that requires first separating the part of the heavy quark's motion that is large and kinematically fixed from the part that is soft and dynamical. That separation is the whole content of this section.

40.1.1 Splitting the momentum: velocity as a label

Inside the hadron the heavy quark is very nearly on shell and very nearly at rest relative to the hadron: its four-momentum is dominated by the mass term. Write

$$p^\mu \;=\; m_Q\, v^\mu \;+\; k^\mu, \qquad v^\mu v_\mu = v^2 = 1, \qquad v^0 > 0, \tag{40.2}$$

where v^μ is a fixed timelike unit four-velocity—in the hadron rest frame simply $v^\mu = (1, \mathbf{0})$—and k^μ is the *residual momentum*, the small fluctuation the quark acquires by exchanging soft gluons with the brown muck. The strong interaction can change k by amounts of order $\Lambda_{\rm QCD}$, but it cannot appreciably change v: shifting the velocity of a particle of mass m_Q by a finite amount costs momentum of order $m_Q \gg \Lambda_{\rm QCD}$, which the soft cloud simply does not have. Thus

$$k^\mu \;\sim\; \Lambda_{\rm QCD} \;\sim\; m_Q\,\lambda, \tag{40.3}$$

and v^μ is effectively a conserved quantity. We promote it to a fixed *label* on the fields: a heavy quark of velocity v and one of velocity $v' \neq v$ live in different sectors of the theory that the soft dynamics never connects, a statement known as velocity superselection. Within one sector the only dynamical variable left is

the residual momentum k, conjugate to the residual position; all dependence on the large scale m_Q has been pulled out into the prefactor $m_Q v^\mu$.

This kinematic split must be implemented at the level of the field. The QCD heavy-quark field $Q(x)$ carries the full momentum p; we strip off the large, rapidly oscillating phase by writing

$$Q(x) \;=\; e^{-im_Q\, v\cdot x}\,\big[\,h_v(x) + H_v(x)\,\big]. \tag{40.4}$$

The factor $e^{-im_Q v\cdot x}$ carries away the $m_Q v^\mu$ part of every derivative: acting on Q, the operator $i\partial^\mu$ produces $m_Q v^\mu$ plus whatever acts on the residual fields h_v, H_v, and the latter, varying only on the soft scale, carry just the residual momentum k. Concretely, with the gauge-covariant derivative of Yang–Mills theory, $D_\mu = \partial_\mu - igA^a_\mu T^a$ acting on the colour-fundamental Q,

$$iD_\mu Q = e^{-im_Q v\cdot x}\,(m_Q v_\mu + iD_\mu)\,(h_v + H_v), \qquad i\not{D}\,Q - m_Q Q = e^{-im_Q v\cdot x}\,(m_Q \not{v} + i\not{D} - m_Q)(h_v + H_v) \tag{40.5}$$

which is the only place the large mass will appear explicitly. It remains to say which combination of Dirac components is h_v and which is H_v.

40.1.2 The velocity projectors and the small components

For a free particle at rest the Dirac equation $(\not{p} - m)u = 0$ becomes $(\gamma^0 - 1)u = 0$, so the positive-energy spinor lives in the $+1$ eigenspace of γ^0 and the lower ("small") two components vanish. Boosting to velocity v replaces γ^0 by $\not{v}$. This motivates decomposing the Dirac field with the operators that project onto the ± 1 eigenspaces of $\not{v}$.

Definition 40.1 (Velocity projectors)**.** For a fixed unit timelike velocity v^μ ($v^2 = 1$) define

$$P_\pm \;\equiv\; \frac{1 \pm \not{v}}{2}. \tag{40.6}$$

The large and small components of the heavy quark are the projections

$$h_v \equiv e^{+im_Q v\cdot x}\, P_+\, Q, \qquad H_v \equiv e^{+im_Q v\cdot x}\, P_-\, Q, \qquad \text{so} \qquad P_+ h_v = h_v, \quad P_- H_v = H_v. \tag{40.7}$$

That Eq. (40.6) are genuine orthogonal projectors follows from $v^2 = 1$ alone, exactly as the energy projectors of Section C.8.6 follow from $\not{p}\not{p} = p^2 = m^2$ on shell. Using $\not{v}\not{v} = v^2 = 1$,

$$P_\pm^2 = \frac{(1 \pm \not{v})^2}{4} = \frac{1 \pm 2\not{v} + v^2}{4} = \frac{2 \pm 2\not{v}}{4} = P_\pm, \qquad P_+ + P_- = 1, \qquad P_+ P_- = \frac{1 - v^2}{4} = 0, \tag{40.8}$$

and $\not{v}\, P_\pm = \pm P_\pm$, so $\not{v}\, h_v = h_v$ and $\not{v}\, H_v = -H_v$. Taking the Dirac adjoint of these last two relations (with $\bar{h}_v = h_v^\dagger \gamma^0$ and $\gamma^0 \not{v}^\dagger \gamma^0 = \not{v}$) gives the mirrored

statements $\bar{h}_v \not{v} = \bar{h}_v$ and $\bar{H}_v \not{v} = -\bar{H}_v$, equivalently $\bar{h}_v P_+ = \bar{h}_v$ and $\bar{H}_v P_- = \bar{H}_v$. These four sandwiching rules are the only Dirac algebra the construction needs.

The decomposition Eq. (40.7) sorts the four Dirac components into two upper components h_v, which survive in the static limit and describe the physical heavy quark, and two lower components H_v, which the free rest-frame equation forces to vanish and which therefore describe rapidly oscillating, off-shell fluctuations of energy $\sim 2m_Q$. The strategy of every top-down EFT now applies verbatim (Section 38.3): H_v is the "heavy field," and we integrate it out.

40.1.3 The exact Lagrangian in residual variables

Insert Eq. (40.4) into the QCD heavy-quark Lagrangian $\mathcal{L}_Q = \bar{Q}\,(i\not{D} - m_Q)\,Q$ of Eq. (11.25), now with the colour-covariant derivative of Eq. (25.76). The conjugate field carries the opposite phase, $\bar{Q} = e^{+im_Q v\cdot x}(\bar{h}_v + \bar{H}_v)$, so the oscillating exponentials cancel and Eq. (40.5) gives the exact identity

$$\mathcal{L}_Q = (\bar{h}_v + \bar{H}_v)(m_Q \not{v} + i\not{D} - m_Q)(h_v + H_v). \tag{40.9}$$

The mass terms collapse immediately. On h_v, $(m_Q\not{v} - m_Q)h_v = m_Q(h_v - h_v) = 0$; on H_v, $(m_Q\not{v} - m_Q)H_v = m_Q(-H_v - H_v) = -2m_Q H_v$. Hence the bracket in Eq. (40.9) equals $i\not{D}\,h_v + (i\not{D} - 2m_Q)H_v$, and

$$\mathcal{L}_Q = \bar{h}_v\, i\not{D}\, h_v + \bar{h}_v(i\not{D} - 2m_Q)H_v + \bar{H}_v\, i\not{D}\, h_v + \bar{H}_v(i\not{D} - 2m_Q)H_v. \tag{40.10}$$

To evaluate the four bilinears we split the covariant derivative into its component along the velocity and the part orthogonal to it,

$$\not{D} = \not{v}\,(v\cdot D) + \not{D}_\perp, \qquad D^\mu_\perp \equiv D^\mu - v^\mu\,(v\cdot D), \qquad v\cdot D_\perp = 0, \tag{40.11}$$

which one verifies by substituting $D^\mu_\perp$ back: $\not{v}(v\cdot D) + \gamma_\mu(D^\mu - v^\mu v\cdot D) = \not{D}$. The longitudinal piece commutes with the projectors because $\bar{h}_v\not{v} = \bar{h}_v$; the transverse piece *anticommutes* with $\not{v}$,

$$\{\not{v}, \not{D}_\perp\} = 2\,v\cdot D_\perp = 0 \quad\Longrightarrow\quad \not{v}\,\not{D}_\perp = -\not{D}_\perp\,\not{v}, \tag{40.12}$$

so $\not{D}_\perp$ maps the $+$ eigenspace of $\not{v}$ into the $-$ eigenspace and vice versa: $\not{D}_\perp h_v$ has $\not{v}$-eigenvalue -1, hence $P_-\not{D}_\perp h_v = \not{D}_\perp h_v$, and likewise $\not{D}_\perp H_v$ lives in the $+$ subspace. With these two facts the four terms of Eq. (40.10) evaluate by inspection. In the first, $\bar{h}_v\, i\not{v}(v\cdot D)h_v = \bar{h}_v\, i(v\cdot D)h_v$, while $\bar{h}_v\, i\not{D}_\perp h_v = 0$ because $\bar{h}_v \in P_+$ meets $\not{D}_\perp h_v \in P_-$ and $P_+P_- = 0$. The fourth term, by the same logic with $\bar{H}_v\not{v} = -\bar{H}_v$, gives $-\bar{H}_v(i\,v\cdot D + 2m_Q)H_v$. The two cross terms keep only their transverse pieces: $\bar{h}_v(i\not{D} - 2m_Q)H_v = \bar{h}_v\, i\not{D}_\perp H_v$ (the longitudinal and mass pieces vanish since $\bar{h}_v H_v \propto \bar{h}_v P_+ P_- H_v = 0$), and $\bar{H}_v\, i\not{D}\, h_v = \bar{H}_v\, i\not{D}_\perp h_v$. Collecting,

$$\boxed{\mathcal{L}_Q = \bar{h}_v\,(i\,v\cdot D)\,h_v \;-\; \bar{H}_v\,(i\,v\cdot D + 2m_Q)\,H_v \;+\; \bar{h}_v\, i\not{D}_\perp H_v \;+\; \bar{H}_v\, i\not{D}_\perp h_v.} \tag{40.13}$$

Equation (40.13) is *exact*—no approximation has been made, only a change of field variables and a sorting by projector. Its structure is exactly the one Chapter 38 taught us to integrate out: h_v is massless (its kinetic term $\bar{h}_v\, i\,v\cdot D\, h_v$ carries no mass scale), while H_v has a Dirac mass $2m_Q$ and so describes excitations far above the soft scale. The light field h_v couples to the heavy field H_v only through the transverse derivative.

40.1.4 Integrating out the small components

Because H_v appears at most quadratically in Eq. (40.13) and with no kinetic-energy-generating dynamics of its own at the soft scale, it is, at tree level, a non-propagating field that can be eliminated by its classical equation of motion—the tree-level matching of Section 38.3, where "integrating out" a field means solving its equation of motion and substituting back. Varying Eq. (40.13) with respect to $\bar{H}_v$,

$$\frac{\partial \mathcal{L}_Q}{\partial \bar{H}_v} = -\left(i\,v\cdot D + 2m_Q\right) H_v + i\not{D}_\perp h_v \;\stackrel{!}{=}\; 0, \tag{40.14}$$

which solves to

$$H_v = \frac{1}{i\,v\cdot D + 2m_Q}\; i\not{D}_\perp\, h_v. \tag{40.15}$$

The operator $(i\,v\cdot D + 2m_Q)^{-1}$ is well defined as a power series because $v\cdot D$ acts on soft fields and produces $\mathcal{O}(\Lambda_{\rm QCD}) \ll 2m_Q$. Equation Eq. (40.15) confirms the physical picture: the small component is not an independent degree of freedom but a quantum response of size $H_v \sim (\Lambda_{\rm QCD}/m_Q) h_v = \lambda\, h_v$, generated whenever a soft gluon kicks the heavy quark slightly off the velocity v.

Substituting Eq. (40.15) into Eq. (40.13) is now mechanical. The middle term becomes $-\bar{H}_v (i\,v\cdot D + 2m_Q) H_v = -\bar{H}_v\, i\not{D}_\perp h_v$ on use of Eq. (40.14), which exactly cancels the last term $+\bar{H}_v\, i\not{D}_\perp h_v$; the surviving cross term $\bar{h}_v\, i\not{D}_\perp H_v$ then carries the entire $1/m_Q$ tower. The result is the exact tree-level HQET Lagrangian:

$$\mathcal{L}_{\rm HQET} = \bar{h}_v\,(i\,v\cdot D)\, h_v \;+\; \bar{h}_v\,(i\not{D}_\perp)\,\frac{1}{i\,v\cdot D + 2m_Q}\,(i\not{D}_\perp)\, h_v. \tag{40.16}$$

The second term is nonlocal as written, but only on the scale $1/m_Q$; expanding the denominator in the small ratio $v\cdot D/2m_Q$ resolves it into a tower of local operators of increasing dimension. With

$$\frac{1}{i\,v\cdot D + 2m_Q} = \frac{1}{2m_Q}\sum_{n=0}^{\infty}\left(-\frac{i\,v\cdot D}{2m_Q}\right)^n = \frac{1}{2m_Q}\left[1 - \frac{i\,v\cdot D}{2m_Q} + \left(\frac{i\,v\cdot D}{2m_Q}\right)^2 - \cdots\right], \tag{40.17}$$

the effective Lagrangian organizes as a series in $1/m_Q$, i.e. in the power-counting parameter λ:

$$\mathcal{L}_{\rm HQET} = \bar{h}_v\,(i\,v{\cdot}D)\,h_v + \frac{1}{2m_Q}\,\bar{h}_v\,(i\not{D}_\perp)(i\not{D}_\perp)\,h_v - \frac{1}{4m_Q^2}\,\bar{h}_v\,(i\not{D}_\perp)(i\,v{\cdot}D)(i\not{D}_\perp)\,h_v + \mathcal{O}\!\left(\frac{1}{m_Q^3}\right). \tag{40.18}$$

40.1.5 The leading Lagrangian and its $1/m_Q$ corrections

The leading term of Eq. (40.18) is the centerpiece of the chapter.

Proposition 40.2 (Leading HQET Lagrangian and its corrections)**.** *At lowest order in $1/m_Q$ the heavy quark is described by the* static Lagrangian

$$\mathcal{L}^{(0)}_{\rm HQET} = \bar{h}_v\,(i\,v\cdot D)\,h_v, \qquad v\cdot D = v\cdot\partial - ig\,v\cdot A^a\,T^a, \tag{40.19}$$

which contains no reference whatsoever to the heavy-quark mass or to its spin. The first correction is

$$\mathcal{L}^{(1)}_{\rm HQET} = \frac{1}{2m_Q}\,\bar{h}_v\,(iD_\perp)^2\,h_v + \frac{g}{4m_Q}\,c_{\rm mag}(\mu)\,\bar{h}_v\,\sigma_{\mu\nu}G^{\mu\nu}\,h_v, \tag{40.20}$$

with $G^{\mu\nu} = G^{a\,\mu\nu}T^a$ the gluon field strength of Eq. (25.76), $\sigma^{\mu\nu} = \frac{i}{2}[\gamma^\mu,\gamma^\nu]$, and $c_{\rm mag}(\mu) = 1$ at tree level.

The static Lagrangian Eq. (40.19) is the destination of this section, and its two silences—no m_Q, no Dirac structure beyond the projector built into h_v—are the seeds of the emergent symmetry the next section exploits. Before exploiting it we must verify the first correction, which is where the spin and the mass reappear and which fixes the meaning of $c_{\rm mag}$.

Worked Example 40.3 (The $1/m_Q$ operators: kinetic energy and the chromomagnetic moment)**.** We evaluate the dimension-five term of Eq. (40.18), $\frac{1}{2m_Q}\bar{h}_v(i\not{D}_\perp)(i\not{D}_\perp)h_v$, and show it splits into the operators displayed in Eq. (40.20).

Step 1 — square the transverse slash. Write $(i\not{D}_\perp)^2 = -\not{D}_\perp\not{D}_\perp = -\gamma_\mu\gamma_\nu D_\perp^\mu D_\perp^\nu$. Decompose the gamma product into symmetric and antisymmetric parts using $\gamma_\mu\gamma_\nu = \eta_{\mu\nu} - i\sigma_{\mu\nu}$ (the Clifford relation $\{\gamma_\mu,\gamma_\nu\} = 2\eta_{\mu\nu}$ together with the definition of $\sigma_{\mu\nu}$, Section C.8.6):

$$(i\not{D}_\perp)^2 = -(\eta_{\mu\nu} - i\sigma_{\mu\nu})D_\perp^\mu D_\perp^\nu = -D_\perp^2 + i\sigma_{\mu\nu}D_\perp^\mu D_\perp^\nu. \tag{40.21}$$

The symmetric piece $-D_\perp^2 = (iD_\perp)^2$ is the kinetic-energy operator: it measures the residual three-momentum of the heavy quark transverse to v (in the rest frame $D_\perp^\mu = (0,\mathbf{D})$, so $(iD_\perp)^2 = -\mathbf{D}^2$, the covariant Laplacian).

Step 2 — antisymmetrize the second piece. Because $\sigma_{\mu\nu}$ is antisymmetric, only the antisymmetric part of $D_\perp^\mu D_\perp^\nu$ survives:

$$i\sigma_{\mu\nu} D_\perp^\mu D_\perp^\nu = \frac{i}{2}\,\sigma_{\mu\nu}\,[D_\perp^\mu, D_\perp^\nu]. \tag{40.22}$$

The commutator of covariant derivatives is the field strength. From $D_\mu = \partial_\mu - igA_\mu^a T^a$,

$$[D^\mu, D^\nu] = -ig\,G^{\mu\nu}, \qquad G^{\mu\nu} = G^{a\,\mu\nu}T^a = \partial^\mu A^\nu - \partial^\nu A^\mu - ig[A^\mu, A^\nu], \tag{40.23}$$

which is the curvature of Yang–Mills theory written with the conventions of Eq. (25.76). The transverse commutator differs from this by terms carrying an explicit factor of v^μ or v^ν: substituting $D_\perp^\mu = D^\mu - v^\mu(v\cdot D)$,

$$[D_\perp^\mu, D_\perp^\nu] = [D^\mu, D^\nu] - v^\nu v_\alpha [D^\mu, D^\alpha] - v^\mu v_\beta [D^\beta, D^\nu] = -ig\big(G^{\mu\nu} - v^\nu v_\alpha G^{\mu\alpha} - v^\mu v_\beta G^{\beta\nu}\big). \tag{40.24}$$

Step 3 — the velocity-index terms vanish between h_v fields. The two terms in Eq. (40.24) carrying an explicit velocity index die when contracted with $\sigma_{\mu\nu}$ and sandwiched between $\bar h_v$ and h_v. It suffices to show $P_+\,\sigma^{\mu\nu}v_\nu\,P_+ = 0$. Using $\sigma^{\mu\nu}v_\nu = \frac{i}{2}(\gamma^\mu \not v - \not v \gamma^\mu)$ and the sandwiching rules $\not v P_+ = P_+$, $P_+ \not v = P_+$,

$$P_+\,\sigma^{\mu\nu}v_\nu\,P_+ = \frac{i}{2}\big(P_+\gamma^\mu \not v\, P_+ - P_+ \not v\,\gamma^\mu P_+\big) = \frac{i}{2}\big(P_+\gamma^\mu P_+ - P_+\gamma^\mu P_+\big) = 0. \tag{40.25}$$

Physically: the would-be "chromoelectric" coupling σ^{0i} of a heavy quark in its own rest frame vanishes, leaving only the chromomagnetic σ^{ij}. Hence between h_v fields $\sigma_{\mu\nu}[D_\perp^\mu, D_\perp^\nu] \to \sigma_{\mu\nu}[D^\mu, D^\nu] = -ig\,\sigma_{\mu\nu}G^{\mu\nu}$.

Step 4 — assemble. Putting Eqs. (40.21), (40.22) and (40.25) together,

$$\frac{1}{2m_Q}\,\bar h_v (i\not D_\perp)^2 h_v = \frac{1}{2m_Q}\,\bar h_v (iD_\perp)^2 h_v + \frac{1}{2m_Q}\,\bar h_v\,\frac{i}{2}\sigma_{\mu\nu}(-ig\,G^{\mu\nu})\,h_v, \tag{40.26}$$

and the second term is $\frac{g}{4m_Q}\,\bar h_v\,\sigma_{\mu\nu}G^{\mu\nu}h_v$, reproducing Eq. (40.20) with the tree-level coefficient $c_{\rm mag} = 1$.

The two operators in Eq. (40.20) have a transparent physical reading and play distinct roles. The kinetic operator $\frac{1}{2m_Q}\bar h_v (iD_\perp)^2 h_v$ is the leading relativistic correction to the heavy quark's energy, $\mathbf{p}^2/2m_Q$ in the rest frame; it depends on m_Q but not on the Dirac matrices, so it breaks the flavour blindness of Eq. (40.19) (a charm and a bottom quark have different kinetic energies) while respecting its spin blindness. The chromomagnetic operator $\frac{g}{4m_Q}c_{\rm mag}\bar h_v \sigma_{\mu\nu}G^{\mu\nu}h_v$ is the colour analogue of the Pauli term $\frac{e}{2m}\bar\psi\sigma_{\mu\nu}F^{\mu\nu}\psi$; through $\sigma_{\mu\nu}$ it couples the heavy-quark *spin* to the soft gluon field, and so breaks the spin blindness of the leading theory. Both effects are suppressed by λ relative to Eq. (40.19), which is precisely why the leading theory possesses a symmetry the full theory lacks—developed in Section 40.1's successor.

Physical Insight

The coefficient of the kinetic operator is locked to unity to all orders in α_s; that of the chromomagnetic operator is not. The reason is a hidden redundancy: the split Eq. (40.2) into $m_Q v$ and k is ambiguous, since one may shift $v \to v + \delta v$ and $k \to k - m_Q\,\delta v$ for any infinitesimal δv with $v \cdot \delta v = 0$ without changing the physical momentum p. Demanding that physics be invariant under this *reparametrization* relates operators at different orders in $1/m_Q$ and forces the kinetic-term coefficient to remain 1. No such constraint protects $c_{\rm mag}$, which therefore acquires a nontrivial Wilson coefficient (Theorem 38.4) under matching—the first genuinely loop-level coefficient of this chapter, equal to 1 at tree level but receiving an $\mathcal{O}(\alpha_s)$ correction when one matches the EFT chromomagnetic vertex onto the one-loop QCD amplitude at $\mu \sim m_Q$, and thereafter running to the hadronic scale by its anomalous dimension. We carry out such matching and running explicitly in the NRQED computation later in this chapter, using the procedure of Section 38.3.

40.1.6 Feynman rules: the static propagator and the eikonal vertex

The leading Lagrangian Eq. (40.19) is so simple that its Feynman rules can be read off in closed form. Split it into free and interacting pieces with $v \cdot D = v \cdot \partial - ig\, v \cdot A^a T^a$:

$$\mathcal{L}^{(0)}_{\rm HQET} = \underbrace{\bar h_v\,(i\,v\cdot\partial)\,h_v}_{\text{free}} + \underbrace{g\,v^\mu A^a_\mu\,\bar h_v\,T^a\,h_v}_{\text{interaction}}. \tag{40.27}$$

Worked Example 40.4 (Deriving the static propagator and the heavy-quark–gluon vertex)**.** *The propagator.* The free part of Eq. (40.27) is first order in derivatives and lives entirely in the P_+ subspace, since $h_v = P_+ h_v$. Its quadratic kernel in momentum space is obtained by Fourier transforming $h_v(x) = \int \frac{d^4k}{(2\pi)^4}\, e^{-ik\cdot x}\, h_v(k)$, where k is the residual momentum of Eq. (40.2); then $i\,v\cdot\partial \to v\cdot k$, and the free action is $\int \frac{d^4k}{(2\pi)^4}\,\bar h_v(k)\,(v\cdot k)\,h_v(k)$. The propagator is i times the inverse of this kernel, taken *within* the constrained subspace—so the projector P_+ must appear to map the propagator into the space on which h_v is defined:

$$\tilde S_v(k) = \frac{i\,P_+}{v\cdot k + i\epsilon} = \frac{i}{v\cdot k + i\epsilon}\,\frac{1+\not v}{2}. \tag{40.28}$$

The $+i\epsilon$, rather than the Feynman $\not p$-pole prescription of a relativistic fermion, is fixed by causality: a heavy quark has no antiparticle in HQET (the antiparticle component H_v was integrated out), so it can only propagate *forward* in time. To

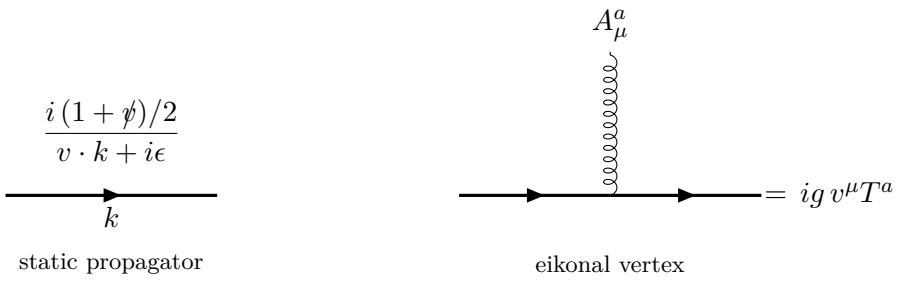

Figure 40.1: The leading-order Feynman rules of HQET read off from Eq. (40.19). The heavy-quark line (drawn thick, by convention a doubled line) carries the static propagator Eq. (40.28), which depends on the residual momentum k only through $v\cdot k$ and is purely forward-propagating. The heavy-quark–gluon vertex Eq. (40.30) is spin-independent and momentum-independent: a classical colour current $g\,v^\mu T^a$ along a worldline of fixed velocity v.

see this, evaluate Eq. (40.28) in the rest frame $v=(1,\mathbf{0})$, where $v\cdot k = k^0 \equiv \omega$ and $P_+ = \frac{1}{2}(1+\gamma^0)$. The mixed time/momentum-space propagator is

$$S_v(t,\mathbf{x}) = \int \frac{d\omega\, d^3k}{(2\pi)^4}\, e^{-i\omega t + i\mathbf{k}\cdot\mathbf{x}}\, \frac{i\,P_+}{\omega+i\epsilon} = P_+\,\delta^3(\mathbf{x}) \int \frac{d\omega}{2\pi}\, \frac{i\,e^{-i\omega t}}{\omega+i\epsilon} = P_+\,\delta^3(\mathbf{x})\,\theta(t), \tag{40.29}$$

the last integral being $\int \frac{d\omega}{2\pi}\, i\,e^{-i\omega t}/(\omega+i\epsilon) = \theta(t)$ by closing the contour below for $t>0$ (the pole sits at $\omega=-i\epsilon$). The interpretation is exactly the static picture: the heavy quark sits at a fixed spatial point, $\delta^3(\mathbf{x})$, and propagates only to the future, $\theta(t)$. It is a worldline, not a wave.

The vertex. The interaction term of Eq. (40.27) is $g\,v^\mu A^a_\mu\,\bar h_v T^a h_v$. The Feynman rule is i times the operator coefficient of the fields $\bar h_v$, h_v, A^a_μ in $i\mathcal{L}_{\rm int}$, namely

$$(h_v\text{–}h_v\text{–gluon vertex}) = i\,g\,v^\mu\,T^a. \tag{40.30}$$

This is the *eikonal* vertex. It is remarkable for what it omits: there is no γ-matrix, so the vertex does not act on the heavy quark's spin, and there is no dependence on the gluon momentum, so the heavy quark recoils negligibly. The heavy quark behaves as a classical colour current $g\,v^\mu T^a$ flowing along a fixed straight worldline of four-velocity v—the Wilson line of Chapter 25 made dynamical.

Figure 40.1 collects the two rules. Their austerity is the source of HQET's predictive power: every heavy-quark line in any diagram contributes only the scalar denominator $v\cdot k$ and the colour-current vertex $gv^\mu T^a$, so the heavy quark's spin decouples entirely from the gluon dynamics at leading order. This is the diagrammatic face of the emergent symmetry.

40.1.7 Power counting

It remains to state the bookkeeping that makes Eq. (40.18) an organized expansion rather than a formal rearrangement, following the power-counting discipline of Section 38.2. Every soft quantity is measured in units of $\Lambda_{\rm QCD}$: the residual momentum $k \sim \Lambda_{\rm QCD}$, the soft gluon field and its covariant derivative $D_\perp \sim v \cdot D \sim \Lambda_{\rm QCD}$, and the field strength $G^{\mu\nu} \sim \Lambda_{\rm QCD}^2$. The single large scale m_Q enters only through the explicit prefactors generated by Eq. (40.17). An operator of mass dimension $4+n$ in Eq. (40.18) therefore carries n inverse powers of m_Q compensated by n powers of the soft scale, so its contribution to any matrix element is suppressed by

$$\left(\frac{\Lambda_{\rm QCD}}{m_Q}\right)^n = \lambda^n \tag{40.31}$$

relative to the leading term Eq. (40.19). For the bottom quark $\lambda \approx 0.05$ and for the charm $\lambda \approx 0.15$, so the leading and first-correction Lagrangians Eqs. (40.19) and (40.20) already capture B-physics to a few percent and D-physics to $\sim 15\%$. The heavy-quark field itself scales as $h_v \sim \Lambda_{\rm QCD}^{3/2}$ (so that $\int d^4x\, \bar h_v\, i\, v\cdot\partial\, h_v$ is dimensionless with $d^4x \sim \Lambda_{\rm QCD}^{-4}$ and $v\cdot\partial \sim \Lambda_{\rm QCD}$), the same counting that makes Eq. (40.19) the unique marginal heavy-quark operator. As always in a top-down EFT, the coefficients of the operators in the tower are not free: each is a Wilson coefficient (Theorem 38.4) fixed by matching the EFT amplitudes onto full QCD at the scale $\mu \sim m_Q$, where both descriptions are valid, and then evolved to the low scale $\mu \sim \Lambda_{\rm QCD}$ by the renormalization group with the running coupling $\alpha_s(\mu)$ of Eq. (27.155). At tree level the leading Lagrangian Eq. (40.19) has unit coefficient and no anomalous dimension; the corrections Eq. (40.20) are where matching and running first do nontrivial work, the kinetic coefficient protected at unity and $c_{\rm mag}(\mu)$ running—a computation we set up explicitly when we reach the matching procedure.

We have, from QCD alone and with every step shown, distilled a heavy quark down to the static Lagrangian $\mathcal{L}^{(0)}_{\rm HQET} = \bar h_v\,(i\,v\cdot D)\,h_v$ of Eq. (40.19), with the forward-propagating static propagator Eq. (40.28) and the spin- and momentum-blind eikonal vertex Eq. (40.30) of Fig. 40.1. The leading theory has manifestly forgotten both the mass and the spin of the heavy quark: m_Q survives only as a label and a tower of suppressed corrections, and the Dirac matrices have collapsed into the single projector P_+. That double amnesia is not a loss of information but the appearance of a new symmetry—a heavy-quark spin–flavour symmetry invisible in full QCD—whose group structure and phenomenological payoff, the degeneracy of heavy-meson multiplets and the reduction of the $B \to D^{(*)}$ form factors to a single Isgur–Wise function, we develop next.

40.2 Spin–flavor symmetry and heavy-hadron form factors

The previous section delivered a Lagrangian of remarkable austerity. After the large, kinematically fixed part of the heavy quark's momentum was scaled away and the small spinor components integrated out, what survived at leading order was

$$\mathcal{L}^{(0)}_{\rm HQET} \;=\; \bar{h}_v \, (i\, v\!\cdot\! D)\, h_v, \qquad \not{v}\, h_v = h_v, \tag{40.32}$$

the static field h_v obeying the velocity projection $\not{v} h_v = h_v$ (Section 40.1). Look at what is *absent*. There is no mass: the parameter m_Q has been pushed entirely into the phase $e^{-i m_Q v\cdot x}$ stripped off in defining h_v, so the residual dynamics knows nothing of how heavy the quark actually is. There is no Dirac matrix tying the field to its spin: the only γ-structure left is the projector $\frac{1}{2}(1+\not{v})$, and the kinetic operator $i\, v\!\cdot\! D$ is a Lorentz scalar that acts as the identity on the spinor index. The covariant derivative couples the heavy quark to gluons through its color charge alone, with no reference to its flavor or its spin. A Lagrangian that does not see the heavy quark's mass, spin, or flavor identity must possess symmetries that rotate among those labels — symmetries that are completely invisible in the parent QCD Lagrangian, where the explicit mass term $-m_Q \bar{Q} Q$ and the relativistic kinetic term $\bar{Q}\, i\not{\partial}\, Q$ break them. This section extracts those emergent symmetries, works out their immediate spectroscopic consequences, and then turns them loose on the central application: the semileptonic transitions $B \to D^{(*)} \ell \bar{\nu}$, whose four-form-factor description collapses, at leading order in $1/m_Q$, onto a single universal function normalized to unity at zero recoil. That normalization is what makes these decays the cleanest window onto the Cabibbo–Kobayashi–Maskawa element $|V_{cb}|$.

40.2.1 The emergent spin–flavor symmetry

Suppose the theory contains N_h heavy flavors — in practice the charm and bottom quarks, $N_h = 2$, but the argument is general — all much heavier than $\Lambda_{\rm QCD}$ and all moving with a *common* four-velocity v. (The restriction to a single velocity is essential and we return to it below: HQET is organized into superselection sectors labeled by v.) Each flavor contributes its own static field $h_v^{(i)}$, $i = 1, \ldots, N_h$, and the leading Lagrangian is simply the sum,

$$\mathcal{L}^{(0)}_{\rm HQET} \;=\; \sum_{i=1}^{N_h} \bar{h}_v^{(i)} \, (i\, v\!\cdot\! D)\, h_v^{(i)}. \tag{40.33}$$

The single derivative is the *same* color-covariant operator for every flavor, because the gluon couples universally to color and is blind to flavor and to spin. To expose the symmetry it is cleanest to pass to the rest frame of v, $v^\mu = (1, \mathbf{0})$,

where $v\cdot D = D^0 = \partial^0 - igA^0_a T^a$ and the projector is $P_+ = \frac{1}{2}(1+\gamma^0)$. In the Dirac representation P_+ annihilates the lower two spinor components, so each $h_v^{(i)}$ reduces to a two-component field χ_i (per color), and using $\gamma^0 h_v = h_v$,

$$\bar h_v^{(i)}\,(i\,v\cdot D)\,h_v^{(i)} = h_v^{(i)\dagger}\gamma^0\,(iD^0)\,h_v^{(i)} = h_v^{(i)\dagger}\,(iD^0)\,h_v^{(i)} = \chi_i^\dagger\,(iD^0)\,\chi_i. \tag{40.34}$$

Collecting flavors,

$$\mathcal{L}^{(0)}_{\mathrm{HQET}} \;=\; \sum_{i=1}^{N_h} \chi_i^\dagger\,(iD^0)\,\chi_i, \tag{40.35}$$

in which the index running over the $2N_h$ objects $\chi_{i,s}$ ($i = 1,\dots,N_h$ a flavor label, $s = 1,2$ a spin label) appears only as a contracted, undifferentiated multiplet index. The operator iD^0 carries no flavor or spin structure whatsoever; it is a multiple of the identity on the $2N_h$-dimensional spin–flavor space (and an honest operator only on color and spacetime). Therefore an arbitrary constant unitary rotation

$$\chi_{i,s} \;\longrightarrow\; \sum_{j,t} U_{(is),(jt)}\,\chi_{j,t}, \qquad U \in \mathrm{U}(2N_h), \tag{40.36}$$

leaves Eq. (40.35) invariant: $\sum \chi^\dagger(iD^0)\chi \to \sum \chi^\dagger U^\dagger U (iD^0)\chi = \sum \chi^\dagger(iD^0)\chi$. We have proved the central structural fact.

Proposition 40.5 (Heavy-quark spin–flavor symmetry)**.** *At leading order in $1/m_Q$, the HQET Lagrangian Eq. (40.33) for N_h heavy flavors at a fixed velocity v is invariant under a $\mathrm{U}(2N_h)$ group acting on the $2N_h$-dimensional space spanned by the heavy-quark spin ($\dim 2$) and flavor ($\dim N_h$) labels. The overall $\mathrm{U}(1)$ is heavy-flavor number, a symmetry of full QCD as well; the genuinely emergent part is $\mathrm{SU}(2N_h)$. It contains in particular the heavy-flavor symmetry $\mathrm{U}(N_h)$ rotating the flavors and, for each flavor, the heavy-quark spin symmetry $\mathrm{SU}(2)_v$ rotating the two spin states.*

Proof. The invariance of Eq. (40.35) under Eq. (40.36) is the computation just displayed. It remains to identify the spin subgroup covariantly. In the rest frame the rotation generators acting on h_v are $\frac{1}{2}\Sigma^k$ with $\Sigma^k = \frac{i}{2}\epsilon^{kij}\sigma^{ij}$ the Dirac spin matrices; they commute with $P_+ = \frac{1}{2}(1+\gamma^0)$ and with D^0 (a rotational scalar), hence with the Lagrangian. Covariantly, define

$$S_v^{\mu\nu} \;=\; \tfrac{1}{2}\,P_+\,\sigma^{\mu\nu}\,P_+, \qquad P_+ = \tfrac{1}{2}(1+\not v), \tag{40.37}$$

which annihilate the components along v (since $P_+\sigma^{\mu\nu}v_\nu P_+ \propto P_+(\not v\gamma^\mu - v^\mu)P_+ = 0$ by $\not v P_+ = P_+$) and so generate the little group $\mathrm{SU}(2)_v$ of rotations transverse to v. These commute with $i\,v\cdot D$ because $S_v^{\mu\nu}$ is built only from $\not v$ and the γ's while $v\cdot D$ carries no spinor index. Together with the flavor rotations $\chi_i \to U_{ij}\chi_j$ they close on $\mathrm{U}(2N_h)$, and the algebra splits as $\mathrm{U}(2N_h) \supset \mathrm{U}(1)_{\mathrm{number}} \times \mathrm{SU}(2N_h) \supset \mathrm{U}(N_h)_{\mathrm{flavor}} \times \mathrm{SU}(2)_v^{\otimes}$ in the obvious way. $\square$

Physical Insight

The symmetry is invisible in QCD for the same reason it is exact in HQET: it is broken only by the heavy-quark mass and the relativistic kinetic operator, both of which have been demoted to higher orders in $1/m_Q$. Spin symmetry is the statement that a very heavy quark's chromomagnetic moment $\sim g/m_Q$ decouples — the gluon field cannot flip a spin it cannot couple to. Flavor symmetry is the statement that, once the kinematic mass phase is removed, an infinitely heavy b and an infinitely heavy c are dynamically identical static color sources. Both are the heavy-quark avatar of the decoupling theorem of Section 38.4.2: irrelevant, mass-suppressed interactions drop out of the leading effective description.

Caution

The symmetry holds *within a fixed-velocity sector*. The static field h_v for velocity v and the field $h_{v'}$ for a different v' are independent objects; there is no symmetry rotating one velocity into another, and indeed soft gluons cannot change a heavy quark's velocity at leading power (the residual momentum is $O(\Lambda_{\rm QCD}) \ll m_Q v$). Each v carries its own $\mathrm{U}(2N_h)$. When a current changes the heavy flavor and the two heavy quarks recoil against each other, as in $b \to c$ below, the initial and final states live in *different* velocity sectors, v and v', and the symmetry that survives is the product $\mathrm{U}(2N_h)_v \times \mathrm{U}(2N_h)_{v'}$.

40.2.2 Heavy-meson multiplets and the ground-state doublet

The cleanest spectroscopic consequence is the degeneracy of heavy-meson multiplets. A heavy meson $\bar{Q}q$ (we write $\bar{Q}$ because the physical $B^- = b\bar{u}$ contains a heavy *anti*quark, but the kinematics is identical) consists of a single heavy quark of spin $s_Q = \frac{1}{2}$ bound to a "brown-muck" light cloud — the light quark, the gluons, and the sea — carrying total angular momentum and parity j_ℓ^P. Because the heavy-quark spin $\mathbf{S}_Q$ decouples at leading order, it is separately conserved, and so is the light-cloud angular momentum $\mathbf{j}_\ell$. The physical states organize into degenerate multiplets of fixed j_ℓ, the heavy spin combining trivially:

$$J \;=\; j_\ell \otimes \tfrac{1}{2} \;=\; \Big\{ j_\ell - \tfrac{1}{2},\; j_\ell + \tfrac{1}{2} \Big\}. \tag{40.38}$$

For $j_\ell \neq 0$ this is a degenerate *doublet* of states with total spin differing by one unit, split only at order $1/m_Q$. The ground state has the light cloud in its lowest configuration, $j_\ell^P = \frac{1}{2}^-$, giving the doublet $J^P = (0^-, 1^-)$: the pseudoscalar and the vector. For the bottom system these are the B and B^*; for charm, the D

and D^*. Heavy-quark *spin* symmetry predicts, at leading order,

$$m_{B^*} = m_B, \qquad m_{D^*} = m_D \qquad \text{(leading order in } 1/m_Q\text{)}, \tag{40.39}$$

while heavy-quark *flavor* symmetry relates the B system to the D system, predicting equal binding energies and (as we will see) a single set of transition form factors. The measured splittings are small and scale as expected: $m_{B^*} - m_B \approx 45$ MeV and $m_{D^*} - m_D \approx 141$ MeV, and their ratio,

$$\frac{m_{B^*}^2 - m_B^2}{m_{D^*}^2 - m_D^2} \;\approx\; 1, \tag{40.40}$$

is the prediction of the chromomagnetic operator that we will derive in the next section: the splitting is $\propto 1/m_Q$ times a flavor-independent matrix element, so the product $(m_V^2 - m_P^2) \sim 2m_Q\,(m_V - m_P)$ is itself flavor-independent. That Eq. (40.40) comes out near unity (the measured value is ≈ 0.87) is the first quantitative success of the expansion and a preview of the $1/m_Q$ matching that the next section carries out.

40.2.3 The Isgur–Wise reduction of $B \to D^{(*)}$ form factors

The semileptonic decay $\bar{B} \to D^{(*)}\ell\bar{\nu}$ proceeds at the quark level through the charged-current transition $b \to c\,\ell\,\bar{\nu}$, mediated by a W whose virtuality is negligible on the hadronic scale, so the relevant operator is the local current

$$J^\mu \;=\; \bar{c}\,\gamma^\mu(1-\gamma_5)\,b, \tag{40.41}$$

weighted by V_{cb} (Eq. (32.59)). The hadronic physics is entirely contained in the matrix elements of the vector part $\bar{c}\gamma^\mu b$ and the axial part $\bar{c}\gamma^\mu\gamma_5 b$ between the $\bar{B}$ and the D or D^*. Fig. 40.2 shows the process. Lorentz invariance and parity alone require, in the conventional relativistic normalization $\langle M(p')|M(p)\rangle = 2E_p(2\pi)^3\delta^3(\mathbf{p}-\mathbf{p}')$,

$$\langle D(p')|\,\bar{c}\gamma^\mu b\,|\bar{B}(p)\rangle = f_+(q^2)(p+p')^\mu + f_-(q^2)(p-p')^\mu, \tag{40.42}$$

$$\langle D^*(p',\epsilon)|\,\bar{c}\gamma^\mu b\,|\bar{B}(p)\rangle = \frac{2iV(q^2)}{m_B+m_{D^*}}\,\varepsilon^{\mu\nu\alpha\beta}\epsilon^*_\nu p'_\alpha p_\beta, \tag{40.43}$$

$$\begin{aligned}\langle D^*(p',\epsilon)|\,\bar{c}\gamma^\mu\gamma_5 b\,|\bar{B}(p)\rangle &= 2m_{D^*}A_0\,\frac{\epsilon^*\!\cdot q}{q^2}\,q^\mu + (m_B+m_{D^*})A_1\Big(\epsilon^{*\mu} - \frac{\epsilon^*\!\cdot q}{q^2}q^\mu\Big)\\ &\quad - A_2\,\frac{\epsilon^*\!\cdot q}{m_B+m_{D^*}}\Big((p+p')^\mu - \frac{m_B^2-m_{D^*}^2}{q^2}q^\mu\Big),\end{aligned} \tag{40.44}$$

with $q = p - p'$ the momentum transfer and ϵ the D^* polarization ($p'\cdot\epsilon = 0$). This is six *a priori* independent functions of q^2: $f_\pm$ for $B \to D$ and V, A_0, A_1, A_2

for $B \to D^*$. (The naming "four form factors" in the older literature counts the kinematically leading combinations; the full count over both channels is six.) The content of heavy-quark symmetry is that all six are, at leading order, one function.

The trace formalism. The efficient way to impose spin–flavor symmetry on the matrix elements is to represent each heavy-meson doublet by a single bispinor "superfield" that packages the 0^- and 1^- states, and then to write the most general symmetric amplitude as a Dirac trace. For a heavy quark Q of velocity v bound into the ground-state doublet, define

$$H_v^{(Q)} \;=\; \frac{1+\not{v}}{2}\Big[\, \not{P}^* - \gamma_5\, P \,\Big], \qquad v\cdot P^* = 0, \tag{40.45}$$

where P is the annihilation amplitude of the pseudoscalar member and $P^{*\mu}$ that of the vector member (a polarization four-vector transverse to v). The left projector $\frac{1}{2}(1+\not{v})$ is the heavy-quark velocity projection; the two Dirac indices of H_v carry, respectively, the heavy-quark spin (left) and the light-cloud spin (right). Its Dirac conjugate is

$$\bar{H}_v^{(Q)} \;\equiv\; \gamma^0 H_v^{(Q)\dagger}\gamma^0 \;=\; \Big[\, \not{P}^{*\dagger} + \gamma_5\, P^\dagger \,\Big]\, \frac{1+\not{v}}{2}, \tag{40.46}$$

where we used $\gamma^0\gamma^{\mu\dagger}\gamma^0 = \gamma^\mu$, $\gamma^0\gamma_5\gamma^0 = -\gamma_5$, and $\gamma^0\not{v}^\dagger\gamma^0 = \not{v}$ (Section C.5). Under the heavy-quark spin symmetry $\mathrm{SU}(2)_v$ the heavy index rotates, $H_v \to S_v H_v$ with S_v commuting with $\not{v}$ and satisfying $\gamma^0 S_v^\dagger \gamma^0 = S_v^{-1}$, so that $\bar{H}_v \to \bar{H}_v S_v^{-1}$; the light index is a spectator under the heavy spin.

Now consider $\langle D^{(*)}(v')|\, \bar{c}\,\Gamma\, b\,|\bar{B}(v)\rangle$ for an arbitrary Dirac matrix Γ. The b field rotates under $\mathrm{SU}(2)_v$ (initial velocity), the $\bar{c}$ field under $\mathrm{SU}(2)_{v'}$ (final velocity), so the current transforms as $\bar{c}\,\Gamma\, b \to \bar{c}\, S_{v'}^{-1}\Gamma S_v\, b$. Heavy-quark spin symmetry acts only on the heavy indices; it forces every dependence on the heavy spins into a structure that contracts the b-index of Γ against H_v (both rotate by S_v) and the c-index against $\bar{H}_{v'}$ (both by $S_{v'}$). The light clouds of the two mesons are spectators in the *same* fixed $j_\ell^P = \frac{1}{2}^-$ configuration, so their overlap is a single reduced matrix element — a Lorentz scalar by the Wigner–Eckart theorem — that can depend only on the one available invariant

$$w \;\equiv\; v\cdot v'. \tag{40.47}$$

The unique structure consistent with all of this is a Dirac trace times that scalar:

$$\boxed{\frac{\langle D^{(*)}(v')|\, \bar{c}\,\Gamma\, b\,|\bar{B}(v)\rangle}{\sqrt{m_B\, m_{D^{(*)}}}} \;=\; -\,\xi(w)\;\mathrm{Tr}\Big[\, \bar{H}_{v'}^{(c)}\,\Gamma\, H_v^{(b)} \,\Big].} \tag{40.48}$$

Here $\xi(w)$ is the *Isgur–Wise function*; the factor $\sqrt{m_B m_{D^{(*)}}}$ converts the relativistic state normalization of Eqs. (40.42) to (40.44) to the mass-independent

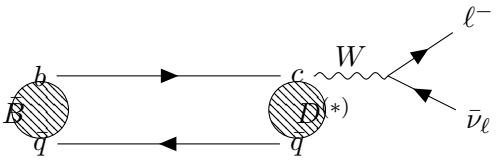

Figure 40.2: The semileptonic decay $\bar{B} \to D^{(*)}\ell\bar{\nu}$. The spectator light antiquark $\bar{q}$ is carried through unchanged; the heavy quark undergoes $b \to c$ via the local current Eq. (40.41), emitting a virtual W that produces the lepton pair. The hadronic matrix element of the $b \to c$ current is what heavy-quark symmetry reduces to the single function $\xi(w)$.

HQET normalization $\langle M(v')|M(v)\rangle = 2v^0(2\pi)^3\delta^3(\dots)$ in which H_v is defined; the overall sign is the standard convention. *One* function now controls all six form factors. The reduction is carried out explicitly in the following worked example.

Worked Example 40.6 (All $B \to D^{(*)}$ form factors from a single trace)**.** We evaluate Eq. (40.48) for the vector and axial currents and read off every form factor. For the external states we specialize the superfields of Eqs. (40.45) and (40.46): the initial pseudoscalar $\bar{B}$ sets $P^* = 0,\ P \to 1$, so

$$H_v^{(b)} \;=\; \frac{1+\not{v}}{2}\,(-\gamma_5); \tag{40.49}$$

the final D (pseudoscalar) sets $P^{*\dagger} = 0,\ P^\dagger \to 1$, and the final D^* (vector, polarization ϵ) sets $P^\dagger = 0,\ P^{*\dagger} \to \epsilon^*$,

$$\bar{H}^{(c)}_{v'}\big|_D = \gamma_5\,\frac{1+\not{v}'}{2}, \qquad \bar{H}^{(c)}_{v'}\big|_{D^*} = \not{\epsilon}^*\,\frac{1+\not{v}'}{2}. \tag{40.50}$$

Throughout we use the four-dimensional trace technology of Section C.6: $\mathrm{Tr}[\,\text{odd \# of }\gamma\,] = 0$, $\mathrm{Tr}[\gamma^\mu\gamma^\nu] = 4\eta^{\mu\nu}$, $\mathrm{Tr}[\gamma^\alpha\gamma^\beta\gamma^\rho\gamma^\sigma] = 4(\eta^{\alpha\beta}\eta^{\rho\sigma} - \eta^{\alpha\rho}\eta^{\beta\sigma} + \eta^{\alpha\sigma}\eta^{\beta\rho})$, and $\mathrm{Tr}[\gamma^\alpha\gamma^\beta\gamma^\rho\gamma^\sigma\gamma_5] = -4i\,\varepsilon^{\alpha\beta\rho\sigma}$ with $\varepsilon^{0123} = +1$.

(i) $B \to D$, vector current $\Gamma = \gamma^\mu$. From Eq. (40.48),

$$\frac{\langle D(v')|\bar{c}\gamma^\mu b|\bar{B}(v)\rangle}{\sqrt{m_B m_D}} = -\xi(w)\ \mathrm{Tr}\Big[\gamma_5\,\tfrac{1+\not{v}'}{2}\,\gamma^\mu\,\tfrac{1+\not{v}}{2}\,(-\gamma_5)\Big]. \tag{40.51}$$

Bring the two γ_5's together using cyclicity and $\gamma_5^2 = 1$: writing $A = \frac{1+\not{v}'}{2}\gamma^\mu\frac{1+\not{v}}{2}$, the bracket is $-\mathrm{Tr}[\gamma_5 A\gamma_5] = -\mathrm{Tr}[A]$. Hence the matrix element is $+\xi(w)\ \mathrm{Tr}[A]$. Expanding,

$$\mathrm{Tr}[A] = \tfrac{1}{4}\,\mathrm{Tr}\,[(1+\not{v}')\gamma^\mu(1+\not{v})] = \tfrac{1}{4}\big(\underbrace{\mathrm{Tr}[\gamma^\mu\not{v}]}_{4v^\mu} + \underbrace{\mathrm{Tr}[\not{v}'\gamma^\mu]}_{4v'^\mu}\big) = v^\mu + v'^\mu, \tag{40.52}$$

the $\mathrm{Tr}[\gamma^\mu]$ and three-γ terms vanishing. Therefore

$$\frac{\langle D(v')|\bar{c}\gamma^\mu b|\bar{B}(v)\rangle}{\sqrt{m_B m_D}} = \xi(w)\,(v+v')^\mu. \tag{40.53}$$

In the HQET basis $h_+(v+v')^\mu + h_-(v-v')^\mu$ this reads $h_+(w)=\xi(w)$, $h_-(w)=0$.

(ii) $B\to D^*$, vector current $\Gamma=\gamma^\mu$. Now

$$\frac{\langle D^*(v')|\bar{c}\gamma^\mu b|\bar{B}(v)\rangle}{\sqrt{m_B m_{D^*}}} = -\xi(w)\;\mathrm{Tr}\Big[\not{\epsilon}^*\,\tfrac{1+\not{v}'}{2}\,\gamma^\mu\,\tfrac{1+\not{v}}{2}\,(-\gamma_5)\Big] = \xi(w)\,\tfrac{1}{4}\,\mathrm{Tr}\big[\not{\epsilon}^*(1+\not{v}')\gamma^\mu(1+\not{v})\gamma_5\big]. \tag{40.54}$$

A γ_5 trace needs four other γ's, so only the term with both $\not{v}'$ and $\not{v}$ survives:

$$\begin{aligned}\xi\,\tfrac{1}{4}\,\mathrm{Tr}\big[\not{\epsilon}^*\not{v}'\gamma^\mu\not{v}\,\gamma_5\big] &= \xi\,\tfrac{1}{4}\,\epsilon^*_\alpha v'_\beta v_\delta\;\mathrm{Tr}\big[\gamma^\alpha\gamma^\beta\gamma^\mu\gamma^\delta\gamma_5\big] = \xi\,\tfrac{1}{4}\,\epsilon^*_\alpha v'_\beta v_\delta\,(-4i)\,\varepsilon^{\alpha\beta\mu\delta}\\ &= -i\,\xi(w)\,\varepsilon^{\mu\nu\alpha\beta}\,\epsilon^*_\nu v'_\alpha v_\beta,\end{aligned} \tag{40.55}$$

where in the last step we reordered indices of the totally antisymmetric symbol ($\varepsilon^{\alpha\beta\mu\delta}=\varepsilon^{\mu\delta\alpha\beta}$, an even permutation, then relabelled). In the HQET basis $\langle D^*|\bar{c}\gamma^\mu b|\bar{B}\rangle/\sqrt{m_B m_{D^*}} = i\,h_V\,\varepsilon^{\mu\nu\alpha\beta}\epsilon^*_\nu v'_\alpha v_\beta$ this gives $h_V(w)=\xi(w)$ (with the sign convention $\varepsilon^{0123}=+1$ absorbed into the basis definition).

(iii) $B\to D^*$, axial current $\Gamma=\gamma^\mu\gamma_5$. Here

$$\frac{\langle D^*(v')|\bar{c}\gamma^\mu\gamma_5 b|\bar{B}(v)\rangle}{\sqrt{m_B m_{D^*}}} = -\xi(w)\;\mathrm{Tr}\Big[\not{\epsilon}^*\,\tfrac{1+\not{v}'}{2}\,\gamma^\mu\gamma_5\,\tfrac{1+\not{v}}{2}\,(-\gamma_5)\Big]. \tag{40.56}$$

Simplify the right end with $\gamma_5\,\frac{1+\not{v}}{2}\,\gamma_5 = \frac{1-\not{v}}{2}$ (since $\gamma_5\not{v}\gamma_5=-\not{v}$):

$$\gamma^\mu\gamma_5\,\tfrac{1+\not{v}}{2}\,(-\gamma_5) = \gamma^\mu\big(-\gamma_5\,\tfrac{1+\not{v}}{2}\gamma_5\big) = -\,\gamma^\mu\,\tfrac{1-\not{v}}{2}. \tag{40.57}$$

Thus the matrix element is $+\xi(w)\;\mathrm{Tr}\big[\not{\epsilon}^*\,\frac{1+\not{v}'}{2}\,\gamma^\mu\,\frac{1-\not{v}}{2}\big]$. Expanding (no γ_5, so only even-γ terms),

$$\tfrac{1}{4}\,\mathrm{Tr}\big[\not{\epsilon}^*(1+\not{v}')\gamma^\mu(1-\not{v})\big] = \tfrac{1}{4}\Big(\underbrace{\mathrm{Tr}[\not{\epsilon}^*\gamma^\mu]}_{4\epsilon^{*\mu}} - \mathrm{Tr}[\not{\epsilon}^*\not{v}'\gamma^\mu\not{v}]\Big). \tag{40.58}$$

The four-γ trace is

$$\mathrm{Tr}[\not{\epsilon}^*\not{v}'\gamma^\mu\not{v}] = 4\big[(\epsilon^*\!\cdot v')\,v^\mu - w\,\epsilon^{*\mu} + (\epsilon^*\!\cdot v)\,v'^\mu\big] = 4\big[-w\,\epsilon^{*\mu} + (\epsilon^*\!\cdot v)\,v'^\mu\big], \tag{40.59}$$

using $w = v\cdot v'$ and the kinematic transversality $\epsilon^*\cdot v' = 0$. Hence

$$\frac{\langle D^*(v')|\bar{c}\gamma^\mu\gamma_5 b|\bar{B}(v)\rangle}{\sqrt{m_B m_{D^*}}} = \xi(w)\,\big[(w+1)\,\epsilon^{*\mu} - (\epsilon^*\!\cdot v)\,v'^\mu\big]. \tag{40.60}$$

In the HQET basis $h_{A_1}(w+1)\epsilon^{*\mu} - (h_{A_2}v^\mu + h_{A_3}v'^\mu)(\epsilon^*\cdot v)$ we read off

$$h_{A_1}(w) = \xi(w), \qquad h_{A_2}(w) = 0, \qquad h_{A_3}(w) = \xi(w). \tag{40.61}$$

Summary. All six form factors of Eqs. (40.42) to (40.44) reduce, in the HQET basis $\{h_+, h_-, h_V, h_{A_1}, h_{A_2}, h_{A_3}\}$, to

$$h_+ = h_V = h_{A_1} = h_{A_3} = \xi(w), \qquad h_- = h_{A_2} = 0. \tag{40.62}$$

Six functions of the momentum transfer have collapsed onto one universal function of w. Translating back to Eqs. (40.42) to (40.44) via the kinematic relations $w = (m_B^2 + m_{D^{(*)}}^2 - q^2)/(2m_B m_{D^{(*)}})$, this yields explicit leading-order expressions for $f_\pm$, V, A_0, A_1, A_2 in terms of $\xi(w)$ and meson masses — for instance $f_+(q^2) = \frac{m_B+m_D}{2\sqrt{m_B m_D}}\,\xi(w)$ and $V = A_0 = A_2 = \frac{m_B+m_{D^*}}{2\sqrt{m_B m_{D^*}}}\,\xi(w)$ with $A_1 = \frac{2\sqrt{m_B m_{D^*}}}{m_B+m_{D^*}}\,\frac{w+1}{2}\,\xi(w)$ — all numerically tied together.

40.2.4 Normalization at zero recoil

The trace formalism has reduced the form factors to a single function, but it has not fixed its overall size. Heavy-quark symmetry does that too, and the argument is a current-conservation argument exactly parallel to the statement that the electric form factor of any particle equals its charge at zero momentum transfer.

Theorem 40.7 (Isgur–Wise normalization)**.** *At zero recoil $w = 1$ (equivalently $v' = v$, $q^2 = q^2_{\max} = (m_B - m_{D^{(*)}})^2$),*

$$\xi(1) = 1. \tag{40.63}$$

Proof. Set $v' = v$. Then both heavy quarks live in the *same* velocity sector, and in the limit $m_b, m_c \to \infty$ they are two flavors of a single static field governed by the flavor-symmetric Lagrangian Eq. (40.33) with $N_h \supseteq \{b, c\}$. The off-diagonal flavor rotation $h_v^{(b)} \to h_v^{(b)} + \theta\, h_v^{(c)}$, $h_v^{(c)} \to h_v^{(c)} - \theta\, h_v^{(b)}$ is an exact symmetry of that Lagrangian. Its Noether current, computed from Eq. (40.33) (whose only derivative is $v\cdot\partial$, so the current inherits a factor v^μ), is

$$j^\mu_{cb} \;=\; v^\mu\, \bar h_v^{(c)}\, h_v^{(b)}, \qquad \partial_\mu j^\mu_{cb} = 0, \tag{40.64}$$

and the associated conserved charge $Q_{cb} = \int d^3x\, j^0_{cb} = v^0 \int d^3x\, \bar h_v^{(c)} h_v^{(b)}$ generates the $b \to c$ flavor rotation. Because the symmetry is unbroken and the $\bar B(v)$ and $D(v)$ sit in the same flavor multiplet (same light cloud, same velocity, same spin), the charge maps one onto the other with unit amplitude,

$$Q_{cb}\,|\bar B(v)\rangle = |D(v)\rangle, \qquad \Longrightarrow \qquad \langle D(v)|\,Q_{cb}\,|\bar B(v)\rangle = \langle D(v)|D(v)\rangle, \tag{40.65}$$

the right-hand side being the state norm. This is the heavy-quark analog of charge counting: a conserved-charge matrix element between members of one multiplet just counts the states, with no dynamical renormalization.

It remains to connect Q_{cb} to the QCD current $\bar{c}\gamma^\mu b$. Matching the full-theory field to the static field, $b \to h_v^{(b)}$ (and likewise c) at leading power, the vector current at equal velocity reduces using the projector identity $P_+\gamma^\mu P_+ = v^\mu P_+$ (proof: $\gamma^\mu = v^\mu \not{v} + \gamma_\perp^\mu$ with $\gamma_\perp^\mu = \gamma^\mu - v^\mu \not{v}$ anticommuting with $\not{v}$, so $P_+\gamma_\perp^\mu P_+ = P_+ P_- \gamma_\perp^\mu = 0$ and $P_+ v^\mu \not{v} P_+ = v^\mu P_+$):

$$\bar{c}\,\gamma^\mu b \;\xrightarrow{v'=v}\; \bar{h}_v^{(c)} \gamma^\mu h_v^{(b)} = v^\mu\, \bar{h}_v^{(c)} h_v^{(b)} = j_{cb}^\mu . \tag{40.66}$$

Thus the zero-recoil vector current *is* the conserved flavor current, and its charge is Q_{cb}. Comparing Eq. (40.65) with the trace result Eq. (40.53) at $v' = v$, where $(v+v')^\mu = 2v^\mu$ and (taking $\mu = 0$ in the rest frame, with the relativistic-to-HQET normalization factor $\sqrt{m_B m_D}$ accounting for $\langle D(v)|D(v)\rangle$) the matrix element is $2\xi(1)$ times the norm, forces $\xi(1) = 1$. □

Physical Insight

The same logic that protects electric charge from renormalization protects $\xi(1)$. In QED the vertex correction $\Gamma^\mu(q=0) = \gamma^\mu$ is enforced by the Ward identity (Chapter 19); here the heavy-flavor symmetry plays the role of the gauge symmetry, the $b \to c$ current plays the role of the conserved current, and $\xi(1) = 1$ is the statement that the "flavor charge" of the heavy meson is not dressed by the strong interaction. Crucially, $\xi(1) = 1$ is exact in the symmetry limit *regardless* of the unknown nonperturbative light-cloud dynamics: it is a normalization, not a calculation. This is precisely what makes it useful for extracting a fundamental parameter.

40.2.5 Corrections at zero recoil: Luke's theorem

The relation $\xi(1) = 1$ holds in the strict $m_Q \to \infty$ limit. For the extraction of $|V_{cb}|$ the size of the leading correction is decisive, and here a second protection theorem operates. Symmetry-breaking corrections enter through two sources: $1/m_Q$ operators in the Lagrangian (the kinetic and chromomagnetic operators of the next section) and $1/m_Q$ corrections to the current itself. One might fear an $O(1/m_Q)$ shift of the normalization. Luke's theorem says this fear is unfounded for the relevant channels.

Theorem 40.8 (Luke's theorem, stated)**.** *The matrix elements of the leading $1/m_Q$ corrections — both from the subleading current operators and from the time-ordered products with the $1/m_Q$ Lagrangian insertions — do* not *contribute*

to the zero-recoil values of the form factors $h_+(1)$ (for $\bar{B} \to D$) and $h_{A_1}(1)$ (for $\bar{B} \to D^*$). Consequently

$$h_+(1) = 1 + 0 \cdot \frac{1}{m_Q} + O\Big(\frac{1}{m_Q^2}\Big), \qquad h_{A_1}(1) = 1 + 0 \cdot \frac{1}{m_Q} + O\Big(\frac{1}{m_Q^2}\Big). \quad (40.67)$$

The protection does not *extend to h_-, h_{A_2}, h_{A_3}, which receive ordinary $O(1/m_Q)$ corrections; but those multiply form-factor structures that vanish at zero recoil or are kinematically suppressed there.*

The symmetry reason is the Ademollo–Gatto mechanism, familiar from the protection of the $K \to \pi$ vector form factor against first-order SU(3) breaking in the chiral theory (Section 39.1): a quantity that equals a conserved-charge matrix element in the symmetric limit is stationary under symmetry breaking, so its first-order correction vanishes and the leading deviation is second order. Concretely, at zero recoil the $1/m_Q$ Lagrangian insertions reduce to matrix elements of operators that either are the heavy-quark kinetic energy (which, by the equations of motion and the trivial $v' = v$ kinematics, only renormalizes the states symmetrically and cancels between numerator and norm) or the chromomagnetic operator (whose zero-recoil matrix element between the relevant states vanishes by spin symmetry). The argument just given is the symmetry reason; promoting it to a complete proof requires tracking each $1/m_Q$ insertion through the trace formalism, and this is the one result of the chapter we state without a full derivation here, deferring its details to the Further reading. The decisive phenomenological consequence is that $\bar{B} \to D^* \ell \bar{\nu}$ at zero recoil is protected to second order, $h_{A_1}(1) = 1 + O(1/m_Q^2)$, making it the theoretically cleanest of the two channels.

40.2.6 Extracting $|V_{cb}|$

Assembling the pieces, the differential semileptonic rate for $\bar{B} \to D^* \ell \bar{\nu}$ near zero recoil takes the form

$$\frac{d\Gamma}{dw} = \frac{G_F^2}{48\pi^3} (m_B - m_{D^*})^2 \, m_{D^*}^3 \, \sqrt{w^2 - 1} \, (w+1)^2 \, \chi(w) \, |V_{cb}|^2 \, \mathcal{F}(w)^2, \quad (40.68)$$

where $\chi(w)$ is a known kinematic factor with $\chi(1) = 1$, and $\mathcal{F}(w)$ is the physical form factor that reduces to $h_{A_1}(w)$ in the heavy-quark limit, $\mathcal{F}(1) = h_{A_1}(1) = 1 + O(1/m_Q^2)$ by Theorem 40.8. The phase-space factor $\sqrt{w^2 - 1}$ vanishes at zero recoil, so the rate itself vanishes there; the strategy is therefore to measure $\mathcal{F}(w)|V_{cb}|$ across the accessible w range and extrapolate to the intercept $w = 1$, where heavy-quark symmetry plus Luke's theorem fix $\mathcal{F}(1)$ up to a small, computable $O(1/m_Q^2)$ correction (today supplied by lattice QCD). Dividing the intercept by $\mathcal{F}(1)$ yields $|V_{cb}|$. Fig. 40.3 illustrates both halves of the picture: the universal function $\xi(w)$ that heavy-quark symmetry isolates, and the schematic extrapolation that turns its zero-recoil normalization into a measurement of a CKM element entering Eq. (32.59).

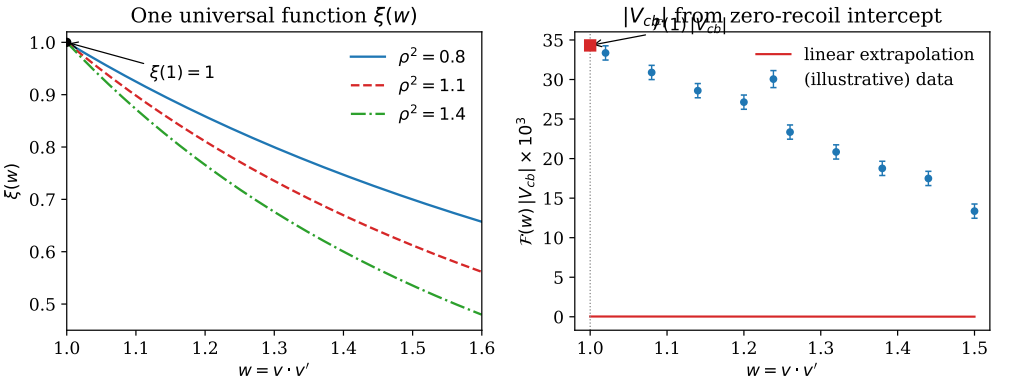

Figure 40.3: *Left:* the Isgur–Wise function $\xi(w)$, the single universal form factor to which all six $\bar{B} \to D^{(*)}$ form factors reduce at leading order in $1/m_Q$, shown for several values of the slope ρ^2 (the shape model is illustrative; the normalization $\xi(1) = 1$ is the exact symmetry result of Theorem 40.7). *Right:* schematic extraction of $|V_{cb}|$ from $\bar{B} \to D^* \ell \bar{\nu}$: the measured combination $\mathcal{F}(w)|V_{cb}|$ is extrapolated to the zero-recoil intercept $w = 1$, where $\mathcal{F}(1) = 1 + O(1/m_Q^2)$ is fixed by heavy-quark symmetry and Luke's theorem (points illustrative, not data).

Historical Note

The exclusive determination of $|V_{cb}|$ from $\bar{B} \to D^* \ell \bar{\nu}$ at zero recoil, pioneered in the early 1990s once Isgur, Wise, Voloshin, Shifman, Georgi and others had established the symmetry and its breaking pattern, was for years the gold standard. As of the mid-2020s a persistent tension remains between this exclusive value and the inclusive determination (from the total $b \to c$ rate via the operator-product expansion), at roughly the few-percent level, with the inclusive value sitting higher; both are quoted near $|V_{cb}| \approx 40 \times 10^{-3}$. Whether the gap reflects underestimated theory uncertainties (form-factor shapes, $1/m_Q^2$ and $1/m_c$ effects), experimental systematics, or genuinely new physics is unsettled and actively studied (the current values and their tensions are tabulated in Section F.6). This is a live example of EFT-based precision flavor physics, not a closed chapter.

Heavy-quark symmetry has thus delivered, from symmetry alone and with no nonperturbative computation, three sharp leading-order statements: the degeneracy of the (P, P^*) doublet, the reduction of six form factors to one function, and the unit normalization of that function at zero recoil — the last protected even against the first power of $1/m_Q$ in the cleanest channel. But every one of these is a *leading-order* statement, and the real world deviates: the B^*–B splitting is nonzero, $\xi(w)$ has a finite slope and curvature, and $\mathcal{F}(1)$ differs

from unity at second order. Symmetry fixes the leading relations; it cannot fix their corrections. To compute the degeneracy splitting, the form-factor slope, and the departures from unit normalization we must construct the subleading HQET Lagrangian by matching to QCD order by order in $1/m_Q$ — which is precisely the program the next section takes up, fixing the kinetic operator by reparametrization invariance and tying the chromomagnetic operator's coefficient to the very hyperfine splitting Eq. (40.40) that opened this discussion.

40.3 Matching and the 1/m expansion

The spin–flavor symmetry of the previous section is exact only in the strict limit $m_Q \to \infty$. It is a statement about the *leading* term of an expansion in $1/m_Q$, and like every leading-order statement in this book it is worth precisely as much as our control over the corrections. The degeneracy of the B and B^* mesons, the single Isgur–Wise function, the normalization at zero recoil — all of these are predictions that the real world satisfies only approximately, because m_b and m_c are large but finite. To turn the symmetry relations into quantitative tools we must compute the operators that break them, and to compute those operators we must do what Chapter 38 taught us to do whenever the short-distance theory is known: *match*. The full theory here is QCD, with the heavy quark still in it; the effective theory is HQET, with the heavy quark replaced by its large-mass remnant h_v. Matching means writing the most general local Lagrangian for h_v consistent with the symmetries, expanding the full theory in powers of $1/m_Q$, and fixing the coefficients of the EFT operators by demanding that the two theories produce identical amputated Green's functions order by order (Section 38.3). This section carries out that matching to first order in $1/m_Q$. The output is two operators — a kinetic operator and a chromomagnetic operator — with two Wilson coefficients, and a pair of striking facts about them: one coefficient is fixed to unity exactly, to all orders in α_s, by a hidden symmetry of the construction (reparametrization invariance), while the other is the microscopic origin of the B^*–B and D^*–D hyperfine splittings. A focused worked example then repeats the whole exercise in the abelian theory, where it has a famous payoff: the Wilson coefficient of the magnetic-moment operator of a heavy electron is exactly $1 + a_e$, and $a_e = \alpha/2\pi$ is Schwinger's number from Chapter 20, now wearing the costume of a matching coefficient.

40.3.1 The heavy-quark field and the expanded QCD Lagrangian

We begin from the QCD Lagrangian for a single heavy quark of mass m_Q in the gluon background,

$$\mathcal{L}_Q \;=\; \bar{Q}\,(i\not{D} - m_Q)\,Q\,, \qquad D_\mu \;=\; \partial_\mu - ig\,A_\mu^a T^a\,, \tag{40.69}$$

with the covariant derivative, generators, and gluon field strength of Yang–Mills theory (Chapter 25); the metric is mostly-minus and $\sigma^{\mu\nu} = \frac{i}{2}[\gamma^\mu, \gamma^\nu]$ is the bilinear catalogued in Section C.5. The physics that motivates the whole construction is that a heavy quark bound inside a hadron is nearly on shell and nearly at rest relative to the hadron: its four-momentum is $p^\mu = m_Q v^\mu + k^\mu$, where v^μ is the (fixed, timelike, unit) four-velocity of the hadron, $v^2 = 1$, and $k^\mu \sim \Lambda_{\rm QCD} \ll m_Q$ is a small residual momentum measuring how far off the large mass shell the soft QCD dynamics pushes it. The rapidly oscillating phase $e^{-im_Q v\cdot x}$ carries the trivial part of the motion; we strip it off and keep only the slowly varying remainder. Introduce the velocity projectors

$$P_\pm \;=\; \frac{1 \pm \not{v}}{2}\,, \qquad P_\pm^2 = P_\pm\,, \quad P_+P_- = 0\,, \quad P_+ + P_- = 1\,, \quad \not{v}\,P_\pm = \pm P_\pm\,, \tag{40.70}$$

where the last identities use $\not{v}\not{v} = v^2 = 1$. They split the Dirac field into a piece that survives the large-mass limit and a piece that does not,

$$Q(x) \;=\; e^{-im_Q v\cdot x}\left[\, h_v(x) + H_v(x) \,\right], \qquad h_v = e^{im_Q v\cdot x} P_+ Q\,, \quad H_v = e^{im_Q v\cdot x} P_- Q\,, \tag{40.71}$$

so that $\not{v}\, h_v = h_v$ and $\not{v}\, H_v = -H_v$, and correspondingly $\bar h_v \not{v} = \bar h_v$, $\bar H_v \not{v} = -\bar H_v$. The field h_v is the two-component (in the sense of having only the upper, particle, components in the rest frame) heavy-quark field of HQET; H_v describes the heavy degrees of freedom — the would-be antiparticle and the lower components — whose excitation costs an energy $\sim 2m_Q$ and which we will integrate out.

Substituting Eq. (40.71) into Eq. (40.69) requires only one observation: the derivative acting on the stripped field produces $i\partial_\mu(e^{-im_Q v\cdot x}\Phi) = e^{-im_Q v\cdot x}(m_Q v_\mu + i\partial_\mu)\Phi$, so that $iD_\mu Q = e^{-im_Q v\cdot x}(m_Q v_\mu + iD_\mu)(h_v + H_v)$. Hence

$$\mathcal{L}_Q \;=\; (\bar h_v + \bar H_v)\,(m_Q \not{v} + i\not{D} - m_Q)(h_v + H_v)\,. \tag{40.72}$$

The mass terms collapse using $\not{v}\, h_v = h_v$ and $\not{v}\, H_v = -H_v$: the operator $m_Q\not{v} - m_Q$ annihilates h_v and multiplies H_v by $-2m_Q$. It remains to organize the $i\not{D}$ term. Decompose the covariant derivative into its components along and transverse to the velocity,

$$D^\mu \;=\; v^\mu\,(v\cdot D) + D_\perp^\mu\,, \qquad D_\perp^\mu \;=\; D^\mu - v^\mu (v\cdot D)\,, \qquad v\cdot D_\perp = 0\,, \tag{40.73}$$

so that $\not{D} = \not{v}\,(v\cdot D) + \not{D}_\perp$ with $\{\not{v}, \not{D}_\perp\} = 2\, v\cdot D_\perp = 0$. The transverse slash anticommutes with $\not{v}$, hence intertwines the projectors,

$$P_+\,\not{D}_\perp \;=\; \not{D}_\perp\, P_-\,, \qquad P_-\,\not{D}_\perp \;=\; \not{D}_\perp\, P_+\,, \tag{40.74}$$

while $v\cdot D$, carrying no Dirac structure, commutes with both projectors. Now read off the four bilinears in Eq. (40.72). The diagonal h_v term keeps only its longitudinal part, because $\bar h_v \not{D}_\perp h_v = \bar h_v P_+ \not{D}_\perp P_+ h_v = \bar h_v \not{D}_\perp P_- P_+ h_v = 0$ by

Eq. (40.74); what survives is $\bar{h}_v \not{v}\,(v\cdot D)\,h_v = \bar{h}_v\, iv\cdot D\, h_v$ once the i is restored. By the same reasoning the diagonal H_v term keeps $-\bar{H}_v\, iv\cdot D\, H_v$ (the extra sign from $\bar{H}_v \not{v} = -\bar{H}_v$), and the off-diagonal terms keep only their transverse parts, $\bar{h}_v\, i\not{D}_\perp H_v$ and $\bar{H}_v\, i\not{D}_\perp h_v$. Collecting everything,

$$\mathcal{L}_Q \;=\; \bar{h}_v\, iv\cdot D\, h_v \;-\; \bar{H}_v\,(\, iv\cdot D + 2m_Q\,)\, H_v \;+\; \bar{h}_v\, i\not{D}_\perp\, H_v \;+\; \bar{H}_v\, i\not{D}_\perp\, h_v\,. \tag{40.75}$$

The first term is the leading HQET Lagrangian $\mathcal{L}_v^{(0)} = \bar{h}_v\, iv\cdot D\, h_v$ established in the previous section (Eq. (40.19)); it is independent of m_Q and of the heavy-quark spin, which is the source of the spin–flavor symmetry. Everything beyond it is contained in H_v, which appears with a mass $2m_Q$ and is the field we now remove.

40.3.2 Tree-level matching: the kinetic and chromomagnetic operators

Because Eq. (40.75) is exactly quadratic in H_v, integrating it out at tree level is a Gaussian elimination: we solve its equation of motion and substitute back. Varying Eq. (40.75) with respect to $\bar{H}_v$,

$$-(\, iv\cdot D + 2m_Q\,)\, H_v \;+\; i\not{D}_\perp\, h_v \;=\; 0 \quad\Longrightarrow\quad H_v \;=\; \frac{1}{iv\cdot D + 2m_Q}\, i\not{D}_\perp\, h_v\,. \tag{40.76}$$

The operator $1/(iv\cdot D + 2m_Q)$ is well defined as a power series because $iv\cdot D \sim \Lambda_{\rm QCD}$ acting on h_v is parametrically small compared to $2m_Q$; this is the statement that H_v is heavy and may be expanded in its inverse mass. For a Lagrangian of the schematic form $\bar{H}_v \mathcal{A} H_v + \bar{J} H_v + \bar{H}_v J$ with $\mathcal{A} = -(iv\cdot D + 2m_Q)$, $J = i\not{D}_\perp h_v$, and $\bar{J} = \bar{h}_v\, i\not{D}_\perp$, the value at the stationary point is $-\bar{J}\mathcal{A}^{-1}J$, so the tree-level effective Lagrangian is

$$\mathcal{L}_{\rm eff} \;=\; \bar{h}_v\, iv\cdot D\, h_v \;+\; \bar{h}_v\, i\not{D}_\perp\, \frac{1}{iv\cdot D + 2m_Q}\, i\not{D}_\perp\, h_v\,. \tag{40.77}$$

This is exact at tree level; the $1/m_Q$ expansion is now the geometric expansion of the heavy propagator,

$$\frac{1}{iv\cdot D + 2m_Q} \;=\; \frac{1}{2m_Q}\,\frac{1}{1 + \dfrac{iv\cdot D}{2m_Q}} \;=\; \frac{1}{2m_Q}\left(1 - \frac{iv\cdot D}{2m_Q} + \cdots\right). \tag{40.78}$$

Keeping the leading term reproduces the $O(1/m_Q)$ Lagrangian,

$$\mathcal{L}^{(1)} \;=\; \frac{1}{2m_Q}\,\bar{h}_v\,(i\not{D}_\perp)(i\not{D}_\perp)\,h_v \;=\; \frac{1}{2m_Q}\,\bar{h}_v\,(i\not{D}_\perp)^2\,h_v\,, \tag{40.79}$$

and the omitted terms in Eq. (40.78) generate operators of order $1/m_Q^2$ and higher, which we do not pursue here.

The single Dirac structure $(i\not{D}_\perp)^2$ in Eq. (40.79) secretly contains two physically distinct operators, separated by the symmetric and antisymmetric parts of the product of two gamma matrices. Writing $\gamma_\mu\gamma_\nu = g_{\mu\nu} + \frac{1}{2}[\gamma_\mu,\gamma_\nu] = g_{\mu\nu} - i\sigma_{\mu\nu}$,

$$(i\not{D}_\perp)^2 \;=\; -\gamma_\mu\gamma_\nu\, D_\perp^\mu D_\perp^\nu \;=\; -D_\perp^\mu D_{\perp\mu} \;+\; i\sigma_{\mu\nu}\, D_\perp^\mu D_\perp^\nu\,. \tag{40.80}$$

The antisymmetric $\sigma_{\mu\nu}$ contracts only the antisymmetric part of $D_\perp^\mu D_\perp^\nu$, namely the commutator $\frac{1}{2}[D_\perp^\mu, D_\perp^\nu]$. We need that commutator. Using $D_\perp^\mu = D^\mu - v^\mu(v\cdot D)$ and the non-abelian curvature $[D^\mu, D^\nu] = -igG^{\mu\nu}$ (with $G^{\mu\nu} = G^{a\mu\nu}T^a$, the convention fixed by $D_\mu = \partial_\mu - igA_\mu$ in Chapter 25),

$$[D_\perp^\mu, D_\perp^\nu] \;=\; -ig\Big(G^{\mu\nu} - v^\nu v_\alpha G^{\mu\alpha} - v^\mu v_\alpha G^{\alpha\nu}\Big) \;\equiv\; -ig\, G_\perp^{\mu\nu}\,, \tag{40.81}$$

where $G_\perp^{\mu\nu}$ is the doubly transverse projection of the field strength. Assembling Eqs. (40.80) and (40.81),

$$(i\not{D}_\perp)^2 \;=\; (iD_\perp)^2 \;+\; \frac{g}{2}\,\sigma_{\mu\nu}\, G_\perp^{\mu\nu}\,, \qquad (iD_\perp)^2 \equiv -\,D_\perp^\mu D_{\perp\mu}\,, \tag{40.82}$$

where in the second term $i\sigma_{\mu\nu}\cdot\frac{1}{2}(-igG_\perp^{\mu\nu}) = \frac{g}{2}\sigma_{\mu\nu}G_\perp^{\mu\nu}$. The transverse projection in $G_\perp^{\mu\nu}$ is invisible once the operator is sandwiched between heavy-quark fields, because $\bar h_v \sigma^{\mu\nu} v_\nu h_v = 0$: with $v_\nu\sigma^{\mu\nu} = \frac{i}{2}(\gamma^\mu\not{v} - \not{v}\gamma^\mu)$ and the projector identities $\not{v}P_+ = P_+ = P_+\not{v}$ (acting on h_v and $\bar h_v$ respectively), the two terms cancel, $P_+(\gamma^\mu\not{v} - \not{v}\gamma^\mu)P_+ = P_+\gamma^\mu P_+ - P_+\gamma^\mu P_+ = 0$. Therefore the extra pieces of $G_\perp^{\mu\nu}$ in Eq. (40.81) drop, and $\bar h_v\sigma_{\mu\nu}G_\perp^{\mu\nu}h_v = \bar h_v\sigma_{\mu\nu}G^{\mu\nu}h_v$. We arrive at the subleading HQET Lagrangian:

$$\boxed{\mathcal{L}^{(1)} \;=\; \underbrace{\frac{c_{\rm kin}}{2m_Q}\,\bar h_v\,(iD_\perp)^2\,h_v}_{\mathcal{O}_{\rm kin}} \;+\; \underbrace{\frac{c_{\rm mag}\,g}{4m_Q}\,\bar h_v\,\sigma_{\mu\nu}G^{\mu\nu}\,h_v}_{\mathcal{O}_{\rm mag}}\,, \qquad c_{\rm kin} = c_{\rm mag} = 1 \text{ at tree level.}} \tag{40.83}$$

The factor of $\frac{1}{2}$ between the two coefficients in Eq. (40.83) (the kinetic term carries $1/2m_Q$, the chromomagnetic term $g/4m_Q$) is exactly what Eq. (40.82) delivers, so the tree-level matching gives $c_{\rm kin} = c_{\rm mag} = 1$ with no further input.

Definition 40.9 (The $1/m_Q$ operators)**.** $\mathcal{O}_{\rm kin} = \frac{1}{2m_Q}\bar h_v(iD_\perp)^2 h_v$ is the *kinetic operator*: it is the residual kinetic energy of the heavy quark, the operator that restores the dependence of the dynamics on the heavy-quark mass. It is a Lorentz scalar and a spin singlet, so it preserves both heavy-quark spin symmetry and flavor symmetry; it shifts hadron masses but does not split spin multiplets. $\mathcal{O}_{\rm mag} = \frac{c_{\rm mag}g}{4m_Q}\bar h_v\sigma_{\mu\nu}G^{\mu\nu}h_v$ is the *chromomagnetic operator*: it couples the heavy-quark spin (through $\sigma_{\mu\nu}$) to the gluonic field, and is the leading operator that *breaks* heavy-quark spin symmetry. It also breaks flavor symmetry through its explicit $1/m_Q$. These are the only two operators of dimension five that can be built from h_v, the gluon field, and one covariant derivative consistent with the heavy-quark symmetries; the matching has fixed their coefficients.

Physical Insight

The split of the single relativistic structure $(i\not{D}_\perp)^2$ into a spin-conserving kinetic term and a spin-violating chromomagnetic term is the heavy-quark analogue of the Pauli reduction of the Dirac equation, where $(\vec{\sigma}\cdot\vec{\pi})^2 = \vec{\pi}^2 - e\vec{\sigma}\cdot\vec{B}$ separates the orbital from the magnetic interaction. There the magnetic term is responsible for $g = 2$; here the chromomagnetic term is responsible for the hyperfine splitting of heavy hadrons. The same algebraic identity — "the square of a slashed covariant derivative is a covariant Laplacian plus a magnetic coupling" — runs through both, and through the NRQED worked example below.

40.3.3 Reparametrization invariance fixes the kinetic coefficient

The tree-level result $c_{\rm kin} = 1$ looks like an ordinary matching coefficient, the kind that receives radiative corrections and runs with the scale. It does not. The kinetic coefficient is protected to be exactly unity, to all orders in α_s and with no scale dependence, by a symmetry that is invisible in the full theory and emerges only in the way we set up the EFT: *reparametrization invariance*. The origin of the symmetry is that the decomposition $p^\mu = m_Q v^\mu + k^\mu$ of the heavy-quark momentum into a "large" part $m_Q v$ and a "residual" part k is ambiguous. Only the total momentum p is physical; the split is a choice. We may shift the reference velocity by an infinitesimal transverse amount and compensate by shifting the residual momentum,

$$v^\mu \;\to\; v^\mu + \frac{\epsilon^\mu}{m_Q}\,, \qquad k^\mu \;\to\; k^\mu - \epsilon^\mu\,, \qquad v\cdot\epsilon = 0\,, \tag{40.84}$$

the constraint $v\cdot\epsilon = 0$ preserving $v^2 = 1$ to first order. The total momentum $m_Q v + k$ is unchanged, so no physical quantity — in particular not the HQET action — can depend on the choice. This is reparametrization invariance, and it relates operators at different orders in $1/m_Q$ because the shift in v is itself of order $1/m_Q$.

To exploit it we need the induced transformation of the field h_v. The full field Q is reparametrization-invariant, so the change in the velocity must be absorbed by h_v. Two effects combine. First, the phase $e^{-im_Q v\cdot x}$ in Eq. (40.71) shifts by $e^{-i\epsilon\cdot x}$, which is exactly the shift $k \to k - \epsilon$ of the residual momentum in position space; on h_v this is a multiplication by $e^{i\epsilon\cdot x}$. Second, the projector $P_+(v)$ in $h_v = P_+(v)\, e^{im_Q v\cdot x} Q$ rotates with v. To first order in ϵ/m_Q,

$$h_v \;\to\; e^{\,i\epsilon\cdot x}\left(1 + \frac{\not{\epsilon}}{2m_Q}\right) h_v\,, \tag{40.85}$$

which is consistent with the new projector: $P_+(v+\epsilon/m_Q) = P_+(v) + \frac{\not\epsilon}{2m_Q}$, and one checks directly that $P_+(v+\epsilon/m_Q)\,(1+\frac{\not\epsilon}{2m_Q})h_v = (1+\frac{\not\epsilon}{2m_Q})h_v$ to $O(1/m_Q)$, using $P_+\not\epsilon = \not\epsilon P_-$ (from $\not v\not\epsilon = -\not\epsilon\not v$ since $v\cdot\epsilon = 0$) so that $P_+\not\epsilon\, h_v = \not\epsilon P_- P_+ h_v = 0$. The conjugate field transforms as $\bar h_v \to \bar h_v(1+\frac{\not\epsilon}{2m_Q})e^{-i\epsilon\cdot x}$.

Now demand that the Lagrangian be invariant order by order in $1/m_Q$. We write the unknown subleading Lagrangian with a free coefficient on the kinetic operator,

$$\mathcal{L} \;=\; \bar h_v\, iv\cdot D\, h_v \;+\; \frac{c_{\rm kin}}{2m_Q}\,\bar h_v\,(iD_\perp)^2\,h_v \;+\; \frac{c_{\rm mag}\,g}{4m_Q}\,\bar h_v\,\sigma_{\mu\nu}G^{\mu\nu}\,h_v \;+\; O(1/m_Q^2)\,, \tag{40.86}$$

and vary the leading term and the kinetic term, both of which contribute at $O(1/m_Q)$.

Variation of the leading term. Three sources contribute: the explicit v in $iv\cdot D$, the phase in δh_v, and the projector piece in δh_v. The explicit v gives $\delta(iv\cdot D) = \frac{i}{m_Q}\epsilon\cdot D$, so a contribution $\frac{i}{m_Q}\bar h_v\,\epsilon\cdot D\,h_v = \frac{i}{m_Q}\bar h_v\,\epsilon\cdot D_\perp\,h_v$ (using $v\cdot\epsilon = 0$, so $\epsilon\cdot D = \epsilon\cdot D_\perp$). The phase pieces cancel between δh_v and $\delta\bar h_v$: the only term that could survive is the derivative of the phase, $iv\cdot D(i\epsilon\cdot x\,h_v)$ producing $i\cdot i(v\cdot\epsilon)h_v = 0$ since $v\cdot\epsilon = 0$. The projector pieces give $\frac{1}{2m_Q}\bar h_v(\not\epsilon\, iv\cdot D + iv\cdot D\,\not\epsilon)h_v = \frac{1}{m_Q}\bar h_v\,\not\epsilon\, iv\cdot D\,h_v$, which *vanishes*, because $iv\cdot D\,h_v$ remains in the P_+ subspace while $\bar h_v\not\epsilon$ projects onto P_-: $\bar h_v P_+\not\epsilon P_+ = \bar h_v\not\epsilon P_- P_+ = 0$. Collecting,

$$\delta(\bar h_v\, iv\cdot D\, h_v) \;=\; \frac{i}{m_Q}\,\bar h_v\,\epsilon\cdot D_\perp\,h_v\,. \tag{40.87}$$

Variation of the kinetic term. At $O(1/m_Q)$ we need only the leading variation of h_v, the phase $\delta h_v = i\epsilon\cdot x\,h_v$ (the projector and explicit-v variations are pushed to $O(1/m_Q^2)$ by the explicit $1/2m_Q$ prefactor). The phase variation is governed by the commutator of the kinetic operator with $i\epsilon\cdot x$. With $f = i\epsilon\cdot x$ and $\partial_{\perp\mu}f = i\epsilon_\mu$ (the transverse gradient, since ϵ is transverse),

$$[(iD_\perp)^2,\,f] \;=\; -[D_\perp^\mu D_{\perp\mu},\,f] \;=\; -(2(\partial_\perp^\mu f)D_{\perp\mu} + (\partial_\perp^2 f)) \;=\; -\,2i\,\epsilon\cdot D_\perp\,, \tag{40.88}$$

since $\partial_\perp^2 f = 0$. Hence the variation of the kinetic term is

$$\delta\!\left(\frac{c_{\rm kin}}{2m_Q}\bar h_v(iD_\perp)^2 h_v\right) \;=\; \frac{c_{\rm kin}}{2m_Q}\,\bar h_v\,[(iD_\perp)^2, i\epsilon\cdot x]\,h_v \;=\; -\,\frac{c_{\rm kin}\,i}{m_Q}\,\bar h_v\,\epsilon\cdot D_\perp\,h_v\,. \tag{40.89}$$

The chromomagnetic operator does not enter at this order: its variation under Eq. (40.85) is $O(1/m_Q^2)$, and in any case it carries a distinct Dirac structure ($\sigma_{\mu\nu}G^{\mu\nu}$, not $\epsilon\cdot D_\perp$) that cannot cancel against Eq. (40.87). Adding Eqs. (40.87) and (40.89),

$$\delta\mathcal{L} \;=\; \frac{i\,(1-c_{\rm kin})}{m_Q}\,\bar h_v\,\epsilon\cdot D_\perp\,h_v \;+\; O(1/m_Q^2)\,, \tag{40.90}$$

and reparametrization invariance, $\delta\mathcal{L} = 0$, forces $c_{\rm kin} = 1$.

Theorem 40.10 (Reparametrization invariance protects the kinetic coefficient)**.** *The Wilson coefficient of the kinetic operator $\mathcal{O}_{\rm kin}$ in the HQET Lagrangian is exactly*

$$c_{\rm kin} \;=\; 1 \tag{40.91}$$

to all orders in α_s and with no renormalization-scale dependence. The only inputs are (i) the coefficient of the leading operator $\bar{h}_v\, iv\cdot D\, h_v$ is unity, which is the normalization of the heavy-quark field, and (ii) the reparametrization transformation Eq. (40.85), which is exact. Since neither input receives radiative corrections, $\mathcal{O}_{\rm kin}$ is not renormalized as a separate operator and does not run. The chromomagnetic coefficient $c_{\rm mag}$ is left undetermined by reparametrization invariance and must be obtained by explicit matching; it does run.

The asymmetry in Theorem 40.10 is the central structural lesson of HQET at subleading order. Reparametrization invariance ties the kinetic operator to the leading operator, whose coefficient is fixed by definition, so the kinetic term inherits an exact coefficient. The chromomagnetic operator is not tied to the leading operator by any such relation — it is a genuinely new Lorentz and Dirac structure — so its coefficient is an honest function of the scale, computable by matching at $\mu \sim m_Q$ and runnable down to the hadronic scale. We turn to it now.

Historical Note

Reparametrization invariance was identified by Luke and Manohar in 1992, several years after HQET itself, as the symmetry enforcing $c_{\rm kin} = 1$. That the kinetic energy of a heavy quark is fixed to its naive value is what one would have guessed from Lorentz invariance of the underlying theory — the residual mass-shell condition cannot be renormalized away — and reparametrization invariance is precisely the residual imprint of Lorentz invariance on a formalism that has singled out a particular frame velocity v. The same symmetry constrains the coefficients of operators at every order in $1/m_Q$, relating them in chains that dramatically reduce the number of independent matching computations.

40.3.4 The chromomagnetic coefficient and the heavy-hadron hyperfine splittings

The chromomagnetic operator is the leading window onto heavy-quark spin-symmetry breaking, and it has a clean phenomenological signature: it is the only $1/m_Q$ operator that distinguishes the spin-singlet from the spin-triplet heavy meson, and so it generates the entire hyperfine splitting of the H–H^* doublet.

To see this, write the mass of a heavy-light meson H as the expectation value of the HQET Hamiltonian in the meson state, expanded to first order in $1/m_Q$:

$$m_H \;=\; m_Q + \bar{\Lambda} \;-\; \frac{\lambda_1}{2m_Q} \;-\; \frac{d_H\, c_{\rm mag}(\mu)\, \lambda_2(\mu)}{2m_Q} \;+\; O(1/m_Q^2)\,. \tag{40.92}$$

Here $\bar{\Lambda}$ is the (mass-independent, spin-independent) energy of the light degrees of freedom in the static color field, the leading-order binding; λ_1 is the matrix element of the kinetic operator,

$$\lambda_1 \;=\; \frac{1}{2m_H}\,\Big\langle H(v)\Big|\bar{h}_v (iD_\perp)^2 h_v\Big|H(v)\Big\rangle\,, \tag{40.93}$$

spin-independent and so common to H and H^*; and λ_2 parametrizes the chromomagnetic matrix element,

$$d_H\,\lambda_2 \;=\; \frac{1}{2m_H}\,\Big\langle H(v)\Big|\tfrac{g}{2}\,\bar{h}_v\,\sigma_{\mu\nu}G^{\mu\nu}\,h_v\Big|H(v)\Big\rangle\,, \tag{40.94}$$

with d_H a pure spin factor. The factor d_H is fixed by the heavy-quark spin algebra. In the ground-state doublet the light degrees of freedom carry total angular momentum $j_\ell = \frac{1}{2}$, which combines with the heavy-quark spin $s_Q = \frac{1}{2}$ to give the pseudoscalar ($J=0$) and vector ($J=1$) mesons. The chromomagnetic energy is proportional to $\vec{S}_Q\cdot\vec{S}_\ell$, and

$$\vec{S}_Q\cdot\vec{S}_\ell \;=\; \tfrac{1}{2}\big[J(J+1) - s_Q(s_Q+1) - j_\ell(j_\ell+1)\big] \;=\; \begin{cases} -\frac{3}{4}, & J=0\ (H),\\ +\frac{1}{4}, & J=1\ (H^*), \end{cases} \tag{40.95}$$

so that $d_H = -4\,\vec{S}_Q\cdot\vec{S}_\ell$ takes the values $d_P = 3$ for the pseudoscalar and $d_V = -1$ for the vector. Two consequences follow immediately. First, the spin-averaged mass $\bar{m}_H = \frac{1}{4}(m_H + 3m_{H^*})$ is free of the chromomagnetic term, since $\frac{1}{4}(d_P + 3d_V) = \frac{1}{4}(3-3) = 0$: the chromomagnetic operator splits the doublet but does not move its center of gravity. Second, the splitting itself is

$$m_{H^*} - m_H \;=\; -\,\frac{(d_V - d_P)\, c_{\rm mag}(\mu)\,\lambda_2(\mu)}{2m_Q} \;=\; \frac{2\, c_{\rm mag}(\mu)\,\lambda_2(\mu)}{m_Q}\,, \tag{40.96}$$

inversely proportional to the heavy-quark mass. (The product $c_{\rm mag}\lambda_2$ is renormalization-group invariant, the μ-dependence of the coefficient cancelling that of the matrix element, so Eq. (40.96) is scheme-independent.)

Equation Eq. (40.96) is the prediction. It says that the hyperfine splitting scales as $1/m_Q$, so the B^*–B splitting should be smaller than the D^*–D splitting by roughly m_c/m_b. Even sharper, since $m_{H^*} + m_H \simeq 2m_Q$ at leading order, the *mass-squared* splitting is heavy-quark-mass-*independent*:

$$m_{H^*}^2 - m_H^2 \;=\; (m_{H^*} - m_H)(m_{H^*} + m_H) \;\simeq\; \frac{2\, c_{\rm mag}\lambda_2}{m_Q}\cdot 2m_Q \;=\; 4\, c_{\rm mag}(\mu)\,\lambda_2(\mu)\,, \tag{40.97}$$

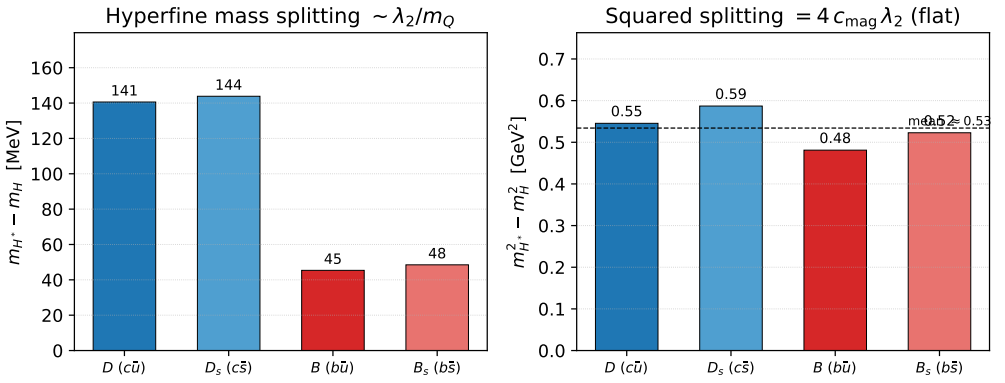

Figure 40.4: The $1/m_Q$ structure of the heavy-meson hyperfine splittings, the experimental signature of the chromomagnetic operator $\mathcal{O}_{\rm mag}$. *Left:* the linear mass splitting $m_{H^*} - m_H$, which Eq. (40.96) predicts to scale as λ_2/m_Q; the charm splittings are about three times the bottom splittings, tracking $m_b/m_c \simeq 3$. *Right:* the mass-squared splitting $m^2_{H^*} - m^2_H$, which Eq. (40.97) predicts to equal $4\, c_{\rm mag}\lambda_2$ independently of the heavy-quark mass; all four systems agree to about ten percent (dashed line: mean), confirming the prediction and fixing $\lambda_2 \simeq 0.12$ GeV^2. Masses are PDG central values.

a constant that should be common to the charm and bottom systems. The data confirm this with striking accuracy. Using the measured masses, the linear splittings are $m_{D^*} - m_D \simeq 141$ MeV and $m_{B^*} - m_B \simeq 45$ MeV, in the ratio 3.1, close to $m_b/m_c \simeq 3$; while the squared splittings are $m^2_{D^*} - m^2_D \simeq 0.55$ GeV^2 and $m^2_{B^*} - m^2_B \simeq 0.48$ GeV^2, equal to about ten percent. Figure 40.4 displays both. From Eq. (40.97) the common value fixes the chromomagnetic matrix element, $\lambda_2(\mu \sim m_Q) \simeq 0.12$ GeV^2, a genuinely nonperturbative number extracted from the spectrum and reusable elsewhere in the heavy-quark expansion (it controls, for instance, the $1/m_Q^2$ corrections to inclusive semileptonic decay rates).

The remaining ten-percent spread is itself instructive: it is the size of the $1/m_Q^2$ and (for charm) higher corrections that Eq. (40.97) neglects, together with the residual scale dependence that survives because $c_{\rm mag}\lambda_2$ is computed at different effective μ for charm and bottom. This brings us to the running of $c_{\rm mag}$. Unlike $c_{\rm kin}$, the chromomagnetic coefficient is renormalized: the operator $\mathcal{O}_{\rm mag}$ mixes into itself under QCD radiative corrections, acquiring an anomalous dimension. Matching at $\mu = m_Q$ gives the tree value $c_{\rm mag}(m_Q) = 1$ corrected by a calculable series in $\alpha_s(m_Q)$, and the renormalization group then evolves it to lower scales. At leading logarithmic order the result has the standard power-law

form

$$c_{\rm mag}(\mu) \;=\; \left[\frac{\alpha_s(m_Q)}{\alpha_s(\mu)}\right]^{\gamma^{(0)}_{\rm mag}/(2\beta_0)}, \qquad \gamma^{(0)}_{\rm mag} = 2C_A\,, \quad \beta_0 = \tfrac{11}{3}C_A - \tfrac{4}{3}T_F n_f\,, \tag{40.98}$$

with β_0 the one-loop coefficient of Yang–Mills theory (Eq. (27.1)) and $\gamma^{(0)}_{\rm mag}$ the one-loop anomalous dimension of the chromomagnetic operator. The exponent $\gamma^{(0)}_{\rm mag}/(2\beta_0) = C_A/(\frac{11}{3}C_A - \frac{4}{3}T_F n_f)$ is positive; since $\alpha_s(\mu) > \alpha_s(m_Q)$ for $\mu < m_Q$, the bracket in Eq. (40.98) is less than one, so $c_{\rm mag}$ *decreases* as μ runs below m_Q (and the hyperfine ratio $c^{(b)}_{\rm mag}/c^{(c)}_{\rm mag} < 1$ at a common low scale follows correctly). The one-loop value $\gamma^{(0)}_{\rm mag} = 2C_A$ is a standard HQET result, which we quote from the literature [362] rather than recompute. The next worked example carries out in full the analogous *matching* computation in the abelian theory (NRQED), fixing the magnetic-moment Wilson coefficient c_F transparently; the chromomagnetic anomalous dimension shares the same diagrammatic ingredients but is not itself reproduced here. The qualitative message is fixed regardless of the number: $c_{\rm kin}$ is frozen at 1 by symmetry, $c_{\rm mag}$ is a running coupling of the EFT, and the difference between them is the difference between a coefficient pinned by an exact relation and one that must be computed.

40.3.5 The abelian analog: NRQED and Schwinger's number as a Wilson coefficient

Everything above has a cleaner sibling in QED, where the heavy fermion is the electron and the gauge field is abelian. The effective theory of a slow, heavy electron coupled to soft photons is *nonrelativistic QED* (NRQED), and matching it to QED reproduces the structure we have just built — a kinetic operator with a protected coefficient and a magnetic operator with a runnable one — but with a celebrated bonus. The Wilson coefficient of the magnetic-moment operator in NRQED is the full electron g-factor divided by two; matching it to QED at one loop delivers $1 + a_e$, and $a_e = \alpha/2\pi$ is Schwinger's number from Chapter 20. This is QED advancing one layer: the most famous one-loop number in physics, computed in Theorem 20.4 as the value of a form factor, reappears here as a matching coefficient of an effective Lagrangian, which is the modern way to understand why it controls atomic energy levels. The following worked example carries the matching from the tree-level reduction through the one-loop coefficient.

Worked Example 40.11 (NRQED tree-level Lagrangian and the one-loop matching of the Fermi coefficient)**.** We work in QED with the electron field ψ of mass m and charge $-e$ ($e > 0$), covariant derivative $D_\mu = \partial_\mu + ieA_\mu$ (QED, Chapter 8); the photon field strength gives the magnetic field $\vec{B} = \vec{\nabla} \times \vec{A}$. The

goal is the NRQED Lagrangian

$$\mathcal{L}_{\rm NRQED} \;=\; \phi^\dagger\Bigg[\, iD_t + \frac{\vec{D}^2}{2m} + c_F\,\frac{e}{2m}\,\vec{\sigma}\cdot\vec{B} + c_D\,\frac{e}{8m^2}\,\vec{\nabla}\cdot\vec{E} + c_S\,\frac{ie}{8m^2}\,\vec{\sigma}\cdot(\vec{D}\times\vec{E} - \vec{E}\times\vec{D}) + \tag{40.99}$$

where ϕ is the two-component Pauli field of the electron, $D_t = \partial_t + ieA^0$, $\vec{D} = \vec{\nabla} - ie\vec{A}$, and the dots are operators of still higher order in $1/m$. We determine the Fermi (Pauli) coefficient c_F, first at tree level and then at one loop.

Step 1: tree-level reduction. Start from the Dirac Lagrangian $\bar\psi(i\not{D} - m)\psi$ and remove the rest-mass oscillation by writing the field in the Dirac basis as an upper (large) component ϕ and a lower (small) component χ. The field equation for χ is algebraic up to $1/m$ corrections; solving it gives $\chi = \dfrac{\vec{\sigma}\cdot(-i\vec{D})}{2m + iD_t}\,\phi = \dfrac{-i\,\vec{\sigma}\cdot\vec{D}}{2m}\,\phi + O(1/m^2)$, the nonrelativistic statement that the small component is suppressed by one power of velocity. Substituting back, the upper-component Lagrangian is

$$\mathcal{L} \;=\; \phi^\dagger\left[\, iD_t + \frac{(\vec{\sigma}\cdot\vec{D})(\vec{\sigma}\cdot\vec{D})}{2m}\,\right]\phi + O(1/m^2)\,. \tag{40.100}$$

The product of Pauli structures is reduced by the same algebraic identity that organized the HQET chromomagnetic term. With $\vec{D} = \vec{\nabla} - ie\vec{A}$ and $[D_i, D_j] = -ie(\partial_i A_j - \partial_j A_i) = -ie\,\epsilon_{ijk}B_k$,

$$(\vec{\sigma}\cdot\vec{D})^2 \;=\; \vec{D}^2 + i\,\vec{\sigma}\cdot(\vec{D}\times\vec{D}) \;=\; \vec{D}^2 + i\,\sigma_k\,\tfrac{1}{2}\epsilon_{kij}[D_i, D_j] \;=\; \vec{D}^2 + e\,\vec{\sigma}\cdot\vec{B}\,, \tag{40.101}$$

using $\frac{1}{2}\epsilon_{kij}(-ie\,\epsilon_{ijl}B_l) = -ie\,B_k$ and $i\sigma_k(-ieB_k) = e\,\vec{\sigma}\cdot\vec{B}$. Inserting Eq. (40.101) into Eq. (40.100) reproduces the kinetic term $\vec{D}^2/2m$ and the Fermi term with coefficient one:

$$\mathcal{L} \;=\; \phi^\dagger\left[\, iD_t + \frac{\vec{D}^2}{2m} + \frac{e}{2m}\,\vec{\sigma}\cdot\vec{B}\,\right]\phi + O(1/m^2) \quad\Longrightarrow\quad c_F^{\rm tree} = 1\,. \tag{40.102}$$

The magnetic energy of the electron is $-\frac{c_F e}{2m}\vec{\sigma}\cdot\vec{B}$, so the g-factor is $g = 2c_F$, and the tree value $c_F = 1$ is precisely the Dirac prediction $g = 2$. The coefficient of the kinetic operator $\vec{D}^2/2m$ is locked to unity by Galilean (reparametrization) invariance of the nonrelativistic theory, the abelian counterpart of Theorem 40.10; it is c_F that carries the interesting physics.

Step 2: the matching condition at one loop. The Wilson coefficient c_F is fixed by demanding that NRQED reproduce the QED amplitude for an electron scattering off a static, slowly varying external magnetic field, evaluated at zero momentum transfer where the operator $\vec{\sigma}\cdot\vec{B}$ acts. In the full theory this amplitude

is the on-shell electromagnetic vertex, decomposed into the Dirac and Pauli form factors (Section 20.1),

$$\bar{u}(p')\,\Gamma^{\mu}\,u(p) \;=\; \bar{u}(p')\Big[\gamma^{\mu}F_1(q^2)+\frac{i\sigma^{\mu\nu}q_{\nu}}{2m}F_2(q^2)\Big]u(p)\,, \tag{40.103}$$

whose nonrelativistic reduction at $q^2 \to 0$ gives a spin–magnetic coupling proportional to $F_1(0)+F_2(0)$ — the Dirac term contributes its magnetic piece via the Gordon decomposition and the Pauli term contributes directly, and the two add. The same reduction performed on the NRQED side, where the magnetic coupling comes entirely from the c_F term of Eq. (40.99), gives a coupling proportional to c_F. Equality of the two amplitudes is the matching condition,

$$c_F \;=\; F_1(0)+F_2(0)\,. \tag{40.104}$$

The charge form factor is fixed by the Ward–Takahashi identity to $F_1(0)=1$ exactly (Section 19.5): the electric charge is not renormalized at zero momentum transfer. The Pauli form factor at the origin is the anomalous magnetic moment, $F_2(0)=a_e$, computed in full in Theorem 20.4 as

$$F_2(0) \;=\; a_e \;=\; \frac{\alpha}{2\pi} \;=\; 0.00116\ldots\,, \tag{40.105}$$

the value evaluated step by step in Theorem 20.5 from the master loop integral of Theorem D.22. Therefore

$$\boxed{\,c_F \;=\; 1+a_e \;=\; 1+\frac{\alpha}{2\pi}+O(\alpha^2)\,.\,} \tag{40.106}$$

The electron g-factor is $g=2c_F=2(1+\alpha/2\pi+\cdots)$, so the anomaly $a_e=(g-2)/2=c_F-1=\alpha/2\pi$ is exactly the one-loop piece of the Fermi coefficient.

Reading. The structural point is worth stating plainly. In the full theory a_e is the value of a form factor — a property of an on-shell scattering amplitude. In the effective theory a_e is a coefficient in a Lagrangian — a number multiplying the local operator $\phi^{\dagger}\vec{\sigma}\cdot\vec{B}\,\phi$. Matching identifies the two. This is more than bookkeeping: once a_e lives in the Lagrangian as c_F, it can be inserted into bound-state computations as an ordinary interaction vertex, which is how the anomalous moment enters the hyperfine structure of hydrogen and the energy levels of muonium and positronium. The form-factor language cannot do this directly; the EFT language can, because matching has converted a scattering observable into a term in an effective action.

40.3.6 NRQED scales and the organization of bound states

The NRQED Lagrangian Eq. (40.99) is the first member of a tower of effective theories that organizes the entire bound-state problem of QED by scale, and

it is worth stating the organization even though its execution belongs to the literature of precision atomic physics. A nonrelativistic bound state such as positronium or hydrogen has not one low scale but several, generated by powers of the fine-structure constant:

$$m \gg m\alpha \text{ (typical momentum, inverse Bohr radius)} \gg m\alpha^2 \text{ (binding energy, Rydberg)} \tag{40.107}$$

NRQED is obtained by integrating out the hard scale m: this is the matching of the previous worked example, which deposits the relativistic and radiative physics into Wilson coefficients such as $c_F = 1 + a_e$, c_D, and c_S, each a series in α evaluated at $\mu \sim m$. The resulting theory still contains the scales $m\alpha$ and $m\alpha^2$; integrating out the soft scale $m\alpha$ in turn produces *potential* NRQED (pNRQED), whose degrees of freedom are the electron, the positron or proton, and ultrasoft photons, and whose interactions are the Coulomb potential plus a tower of relativistic and quantum corrections. In this final theory the energy levels are computed in ordinary quantum-mechanical perturbation theory, with the Wilson coefficients of NRQED feeding the corrections. The Lamb shift — the $O(m\alpha^5)$ splitting of the $2S_{1/2}$ and $2P_{1/2}$ levels of hydrogen, the effect whose 1947 measurement launched modern QED — is in this language a definite combination of low-energy matrix elements weighted by Wilson coefficients, prominent among them the very c_F and c_D that the matching above produces. The role of a_e as a Wilson coefficient is thus not an analogy but the operational content of the statement that the electron's anomalous moment shifts atomic energy levels: a_e enters the bound-state energy precisely as the coefficient $c_F - 1$ of the magnetic operator, evaluated in the bound-state wavefunction. This is the bridge from QED's one-loop precision (Chapter 20) to the EFT of bound states, and we record it here at the level of organization, the detailed multi-scale computation lying beyond our scope.

Physical Insight

The lesson common to HQET and NRQED is that "the magnetic interaction of a heavy fermion is a Wilson coefficient." In HQET it is c_{mag}, which runs and which the data on B^*–B and D^*–D splittings measure; in NRQED it is $c_F = 1 + a_e$, which packages Schwinger's number and which atomic spectroscopy measures. In both theories a kinetic coefficient sits beside it, frozen to unity by the residual Lorentz (reparametrization, Galilean) invariance of the construction. The same two operators, the same protection of one coefficient and running of the other, appear whether the underlying theory is QCD or QED — which is the whole point of the method: matching produces the *same* effective Lagrangian structure from any short-distance completion, with the completion entering only through the numerical values of the coefficients.

We have now seen matching in its fullest top-down form: a known short-distance theory (QCD, or QED) expanded in $1/m$, its heavy field integrated out, and the coefficients of the effective operators computed by equating amputated amplitudes order by order — with one coefficient pinned exactly by a symmetry and another carrying the dynamics. The operational core of this procedure — *expand the full theory and the effective theory in the same kinematic regime and equate their Green's functions* — makes no use of QCD or QED specifically; it uses only that the short-distance theory is known. Run the very same procedure in reverse, with the short-distance theory *unknown* but its symmetries and light field content fixed, and matching becomes construction: one writes down every operator the symmetries allow and lets experiment, rather than a known UV completion, fix the coefficients. That inversion is the subject of the next section, where the Standard Model itself becomes the leading term of an effective theory and the higher-dimension operators become the systematic parametrization of whatever lies above the electroweak scale.

40.4 The Standard Model as an effective theory: building SMEFT

The previous section drew its strength from a luxury we will now surrender: the knowledge of the short-distance theory. There the heavy field was a genuine Standard-Model quark, the ultraviolet (UV) completion was QCD, and matching was an explicit computation — expand the full-theory Green's functions in $1/m$, equate them to the EFT, read off the Wilson coefficients. The lesson worth extracting from that exercise is not the particular numbers but the *shape* of the method: once a field content, a symmetry, and a power counting are fixed, the most general local Lagrangian consistent with them is determined up to a list of constants, and those constants are then pinned either by matching (UV known) or by measurement (UV unknown). The Standard Model invites us to run the method in reverse. We believe there is new physics above the electroweak scale — the hierarchy problem, neutrino masses, dark matter and the strong-CP puzzle all say so — but we do not know what it is. So we take the only data we are sure of: the gauge group $\mathrm{SU}(3)_c \times \mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$, the chiral fermion and scalar content assembled in Chapter 33, and a single new scale Λ above which the unknown heavy states live. From these we build the tower of higher-dimension operators, confront the fact that many of the operators one writes down are secretly the same, and organize the survivors into a canonical, non-redundant list — the Warsaw basis. The result is the Standard Model Effective Field Theory, SMEFT: the Standard Model itself, read as the leading terms of an expansion whose subleading terms parametrize, model-independently, whatever lies above Λ.

40.4.1 The defining data and the operator expansion

We adopt wholesale the ingredients fixed in the Standard Model chapter. The gauge group is $\mathrm{SU}(3)_c \times \mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$ with couplings g_s, g, g' and field strengths $G^A_{\mu\nu}$, $W^I_{\mu\nu}$, $B_{\mu\nu}$ (capital $A = 1, \dots, 8$ for colour, $I = 1, 2, 3$ for weak isospin). The one-generation matter content, with hypercharges normalized to the Gell-Mann–Nishijima relation $Q = T^3 + Y$ (Table 33.2), is the set of left-handed Weyl multiplets

$$L = \begin{pmatrix} \nu_L \\ e_L \end{pmatrix} (\mathbf{1}, \mathbf{2}, -\tfrac{1}{2}), \quad Q = \begin{pmatrix} u_L \\ d_L \end{pmatrix} (\mathbf{3}, \mathbf{2}, +\tfrac{1}{6}), \quad e\,(\mathbf{1}, \mathbf{1}, -1), \quad u\,(\mathbf{3}, \mathbf{1}, +\tfrac{2}{3}), \quad d\,(\mathbf{3}, \mathbf{1}, -\tfrac{1}{3}), \tag{40.108}$$

where e, u, d denote the right-handed singlets (we suppress the subscript R where no ambiguity arises) and we work throughout with one generation, restoring flavour indices only when the counting demands it. The scalar sector is the Higgs doublet $H\,(\mathbf{1}, \mathbf{2}, +\tfrac{1}{2})$, with the charge-conjugate doublet $\widetilde{H}_a = \epsilon_{ab} H^*_b$ (hypercharge $-\tfrac{1}{2}$) of Chapter 31 available for the up-type Yukawa. The covariant derivative carries the canonical sign of Chapter A, $D_\mu = \partial_\mu - i g_s G^A_\mu T^A - i g\, W^I_\mu\, t^I - i g' Y B_\mu$, with $t^I = \tau^I/2$ the weak-isospin generators on doublets. The renormalizable Lagrangian $\mathcal{L}_{\mathrm{SM}}$ — gauge kinetic terms, fermion kinetic terms, the Higgs potential $V = -\mu^2 H^\dagger H + \lambda (H^\dagger H)^2$, and the Yukawa couplings — is the object assembled in Eq. (33.22); we do not rebuild it here.

What Chapter 33 also established, and what makes the construction below sharp, is that baryon and lepton number B and L are *accidental* global symmetries of $\mathcal{L}_{\mathrm{SM}}$ (Section 33.4): they are not imposed, they simply happen to be the only U(1) phase rotations left invariant by the most general renormalizable interaction the field content allows. Accidental symmetries are fragile. They are an artifact of truncating at dimension four, and there is no reason for the unknown UV to respect them. The higher-dimension operators we are about to write are precisely where that fragility shows up first.

The organizing principle is the operator expansion of Section 38.2: with all heavy states integrated out, the effective Lagrangian is the sum of all local, Lorentz-invariant, $\mathrm{SU}(3)_c \times \mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$-invariant operators built from the light fields (40.108) and H, each weighted by an inverse power of Λ fixed by its mass dimension,

$$\mathcal{L}_{\mathrm{SMEFT}} = \mathcal{L}_{\mathrm{SM}} + \frac{1}{\Lambda} \sum_i C^{(5)}_i\, \mathcal{O}^{(5)}_i + \frac{1}{\Lambda^2} \sum_i C^{(6)}_i\, \mathcal{O}^{(6)}_i + \frac{1}{\Lambda^3} \sum_i C^{(7)}_i\, \mathcal{O}^{(7)}_i + \cdots, \tag{40.109}$$

where $\mathcal{O}^{(n)}_i$ has mass dimension n and the Wilson coefficients $C^{(n)}_i$ are dimensionless numbers, order unity if the UV physics is strongly coupled and possibly smaller if it is weakly coupled or if the operator is generated only at loop level. The power counting is the one derived abstractly in Section 38.2 and now made

concrete: an operator of dimension n contributes to an amplitude at energy $E \ll \Lambda$ a relative correction of order

$$\frac{C_i^{(n)}}{\Lambda^{n-4}}\, E^{n-4} \;\sim\; C_i^{(n)} \Big(\frac{E}{\Lambda}\Big)^{n-4}, \tag{40.110}$$

so the leading new-physics effect from a dimension-six operator scales as E^2/Λ^2 and the dimension-five operator's effect, being odd in $1/\Lambda$, must violate one of the accidental symmetries to appear at all. Two consequences set the agenda for the rest of the section. First, the truncation of (40.109) at a given dimension is a controlled approximation only for $E \ll \Lambda$, and the dominant deviations from the Standard Model are governed by the lowest-dimension operators — dimension five (one operator) and dimension six (the bulk of the phenomenology). Second, the list "all operators of dimension n" is *not* well defined until we have dealt with the fact that distinct-looking operators can be physically identical. That is the redundancy problem, and we meet it as soon as we leave dimension four.

40.4.2 Dimension five: the Weinberg operator

The lowest rung above the renormalizable Lagrangian is a single operator, and the cleanest way to see this is to ask what a dimension-five $\mathrm{SU}(3)_c \times \mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$-invariant Lorentz scalar can possibly be built from. The building blocks carry mass dimensions $[H] = 1$, $[\psi] = \tfrac{3}{2}$ for any fermion, $[D_\mu] = 1$, and $[X_{\mu\nu}] = 2$ for a field strength. A Lorentz scalar requires an even number of fermions, and gauge invariance requires the hypercharges to sum to zero and the non-abelian indices to contract into singlets.

Theorem 40.12 (Uniqueness of the dimension-five operator)**.** *Up to flavour structure and Hermitian conjugation, the only dimension-five operator invariant under* $\mathrm{SU}(3)_c \times \mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$ *and the Lorentz group, built from the Standard Model fields* (40.108) *and* H*, is the Weinberg operator*

$$\mathcal{O}_5 \;=\; (\,\overline{L^c}\,\widetilde{H}\,)(\,\widetilde{H}^{\top} L\,) \;=\; \epsilon_{ab}\,\epsilon_{cd}\,(L_a^{\top} C\, L_c)\, H_b\, H_d, \tag{40.111}$$

where a, b, c, d *are* $\mathrm{SU}(2)_L$ *indices,* ϵ *the antisymmetric symbol with* $\epsilon_{12} = +1$*, and* C *the charge-conjugation matrix (*$L^c \equiv C\bar{L}^{\top}$*). It carries lepton number* $L = +2$ *and baryon number* $B = 0$*.*

Proof. We enumerate the dimension-five field content. The total dimension five is odd, so a purely bosonic operator is impossible: gauge invariance forces Higgs fields to enter in $H^\dagger H$ pairs (or in the $B = L = 0$ singlet built from two H's, which still uses two scalars) and covariant derivatives to contract in even numbers, while a field strength contributes two, so every bosonic operator has even dimension. A four-fermion operator already has dimension six. Hence a dimension-five operator contains exactly two fermions, contributing dimension

three, and the remaining dimension two must come from bosons: either two Higgs doublets, or one derivative and one Higgs, or a single field strength (dimension two). The last option balances the dimensions but is nonetheless excluded by gauge invariance: the only Lorentz-scalar two-fermion–field-strength structure is $\bar{\psi}\,\sigma^{\mu\nu}\psi\,X_{\mu\nu}$, which cannot be made $\mathrm{SU}(3)_c \times \mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$-invariant for any pairing in (40.108) without an extra Higgs to balance the $\mathrm{SU}(2)_L$ and hypercharge quantum numbers — and that extra Higgs raises the operator to dimension six (it is the $\psi^2 XH$ class of the dimension-six basis).

Consider first the option "two fermions + one derivative + one Higgs." A one-derivative, two-fermion structure that is a Lorentz scalar is of the form $\bar{\psi}_1\gamma^\mu\psi_2\,D_\mu(\cdots)$ with the derivative contracted into the vector current. The current $\bar{\psi}_1\gamma^\mu\psi_2$ connects fields of *opposite* chirality, so ψ_1, ψ_2 are one left- and one right-handed field; the only dimension-one object the derivative can act on is a single H, and the hypercharges $-Y_{\psi_1} + Y_{\psi_2} + Y_H$ together with the $\mathrm{SU}(2)_L$ and colour structure cannot be made to vanish for any pairing in (40.108) (the right-handed singlets are $\mathrm{SU}(2)_L$ scalars, so the doublet index of H has nothing to contract against). This class is empty.

There remains "two fermions + two Higgs." The fermion bilinear must be a Lorentz scalar of the Majorana type, $\psi_1^{\top} C\psi_2$, since the non-derivative scalar $\bar{\psi}_1\psi_2$ again needs opposite chiralities and two extra Higgs cannot then balance hypercharge (the reader can check that $\bar{e}\,L\,H$-type contractions are dimension four, already in the Yukawa sector, and adding one more H overshoots the hypercharge balance). For the same-chirality bilinear $\psi_1^{\top} C\psi_2$ with $\psi_{1,2}$ drawn from the left-handed multiplets, colour neutrality forbids the quark doublet (a $\mathbf{3}\otimes\mathbf{3}$ bilinear is not a colour singlet), leaving only the lepton doublet: $L^{\top}CL$, which carries $L = 2$. Its hypercharge is $2Y_L = -1$, so the two Higgs must supply $+1$: two factors of H (hypercharge $+\frac{1}{2}$ each), not $\widetilde{H}$. Finally the $\mathrm{SU}(2)_L$ structure: we have four doublet indices (L, L, H, H) to contract into a singlet, and the two independent invariants are $(\epsilon\,LL)(\epsilon\,HH)$ and $(\epsilon\,LH)(\epsilon\,LH)$. But $\epsilon_{ab}H_aH_b = 0$ identically by antisymmetry, so the first vanishes and only the second survives; that is exactly (40.111). The operator is therefore unique. □

The Weinberg operator is the EFT's first and sharpest message. It is the *only* dimension-five operator, it violates lepton number by two units, and since it conserves baryon number it violates the non-anomalous combination $B - L$ by $\Delta(B - L) = -2$. As established in Section 33.4.3, $B - L$ is the unique anomaly-free global symmetry of the Standard Model, so its violation cannot be an artifact of the low-energy theory's quantum dynamics: it must be seeded by genuinely new ultraviolet physics. The Weinberg operator is the low-energy shadow of that physics.

Its physical content appears on electroweak symmetry breaking. With $\langle H\rangle = (0,\, v/\sqrt{2})^{\top}$, so $H_2 = v/\sqrt{2}$ and $H_1 = 0$, the contraction in (40.111) collapses to a Majorana mass for the left-handed neutrino. Writing the dimension-five term

in (40.109) as $\mathcal{L} \supset \frac{1}{\Lambda} C_5\, \mathcal{O}_5 + \text{h.c.}$, we have

$$\frac{C_5}{\Lambda}\,\epsilon_{ab}\epsilon_{cd}(L_a^{\top} C L_c) H_b H_d \;\xrightarrow{\langle H\rangle}\; \frac{C_5}{\Lambda}\,\frac{v^2}{2}\,\epsilon_{a2}\epsilon_{c2}(L_a^{\top} C L_c) = \frac{C_5\, v^2}{2\Lambda}\,(\nu_L^{\top} C\, \nu_L), \tag{40.112}$$

using $\epsilon_{a2} = \delta_{a1}$ and $L_1 = \nu_L$. Comparing with the standard Majorana mass term $-\frac{1}{2} m_\nu\, \nu_L^{\top} C \nu_L + \text{h.c.}$ gives

$$\boxed{\,m_\nu = -\,\frac{C_5\, v^2}{\Lambda}\,}, \tag{40.113}$$

a neutrino mass suppressed by the new-physics scale. This is the EFT statement of the seesaw mechanism, divorced from any particular UV realization: whatever generates $\mathcal{O}_5$ produces neutrino masses of order v^2/Λ. Numerically, with $v \simeq 246$ GeV, an order-one coefficient $C_5 \sim 1$ and an atmospheric-scale mass $m_\nu \sim 0.05$ eV require $\Lambda \sim v^2/m_\nu \sim 10^{15}$ GeV — the smallness of neutrino mass is, in this reading, direct evidence for a very high scale of lepton-number violation. The microscopic completion that integrates out heavy right-handed neutrinos to *produce* C_5/Λ is the type-I seesaw, treated as a UV model in Chapter 35; here it is enough that the EFT predicts the operator and its consequence without committing to that completion.

Worked Example 40.13 (The $\mathrm{SU}(2)_L$ contraction and the neutrino mass matrix)**.** We verify the index algebra of (40.111) and restore flavour. Write the two independent ways to tie four $\mathrm{SU}(2)_L$ doublet indices into a singlet from L, L, H, H. The antisymmetric invariant on a pair is ϵ_{ab}, and any singlet is a product of two such ϵ's. The distinct pairings are

$$T_1 = (\epsilon_{ac} L_a L_c)(\epsilon_{bd} H_b H_d), \qquad T_2 = (\epsilon_{ab} L_a H_b)(\epsilon_{cd} L_c H_d),$$

where in T_1 the two leptons are paired and the two Higgs are paired, while in T_2 each lepton is paired with a Higgs. Now $\epsilon_{bd} H_b H_d = 0$ by the antisymmetry of ϵ and the symmetry of $H_b H_d$ (the Higgs is a commuting field), so $T_1 \equiv 0$ and only T_2 remains — this is the source of the uniqueness in Theorem 40.12. There is a third apparent structure $T_3 = (\epsilon_{ad} L_a H_d)(\epsilon_{cb} L_c H_b)$, but relabelling shows $T_3 = T_2$, and the Schouten identity $\epsilon_{ab}\epsilon_{cd} + \epsilon_{ac}\epsilon_{db} + \epsilon_{ad}\epsilon_{bc} = 0$ (valid in two dimensions) relates T_1, T_2, T_3 and confirms that, after $T_1 = 0$, a single independent structure survives.

Restoring generation indices $p, r = 1, 2, 3$ on the leptons, the operator becomes $\mathcal{O}_5^{pr} = \epsilon_{ab}\epsilon_{cd}(L_{p,a}^{\top} C L_{r,c}) H_b H_d$. Because $L_p^{\top} C L_r$ is symmetric under $p \leftrightarrow r$ (the transpose of the 1×1 number equals itself and $C^{\top} = -C$ compensates the fermion anticommutation), the Wilson coefficient C_5^{pr} is a complex *symmetric* 3×3 matrix — six complex entries, not nine. After breaking, (40.113) promotes to a symmetric Majorana mass matrix $(m_\nu)_{pr} = -C_5^{pr} v^2/\Lambda$, diagonalized by a single unitary matrix as $m_\nu = U^{*}\,\mathrm{diag}(m_1, m_2, m_3)\, U^{\dagger}$; the unitary U is the PMNS matrix U_{PMNS} of the lepton sector. Thus the single dimension-five operator, once flavour is switched on, delivers exactly the structure of Majorana neutrino mixing.

40.4.3 The redundancy problem

At dimension six the naive list of $\mathrm{SU}(3)_c \times \mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$-invariant operators is much longer than the number of physically distinct interactions, because four standard manipulations relate operators that differ only by terms that vanish on the physical states. None of these moves changes a single S-matrix element; all of them change the way the Lagrangian is written. A *basis* is a maximal set of operators no two of which are related by any of them. There are four sources of redundancy.

Integration by parts (IBP). Two operators differing by a total derivative are identical in the action, since $\int d^4x\, \partial_\mu(\cdots) = 0$ for fields falling off at infinity. For example $(\partial_\mu H^\dagger H)(\partial^\mu H^\dagger H)$ and $(H^\dagger H)\Box(H^\dagger H)$ differ by a total derivative and so count once. IBP is the cheapest move and is always applied first to reduce the number of explicit derivatives.

Equations of motion / field redefinitions. An operator proportional to the leading-order equation of motion of some field can be removed entirely. This is the deepest and least obvious of the moves, and it deserves a theorem.

Theorem 40.14 (Field redefinitions and the on-shell S-matrix)**.** *Let $\mathcal{L} = \mathcal{L}_0[\phi] + \dfrac{1}{\Lambda^2}\, E_0[\phi]\, F[\phi]$, where $E_0[\phi] \equiv \delta S_0/\delta\phi$ is the leading-order Euler–Lagrange expression and $F[\phi]$ is any local operator of the appropriate dimension and quantum numbers. The local field redefinition $\phi \to \phi' = \phi - \dfrac{1}{\Lambda^2} F[\phi]$ removes the operator $E_0 F$ from the Lagrangian, replacing it by terms of order $1/\Lambda^4$, and leaves every S-matrix element unchanged. Consequently any dimension-six operator proportional to a leading-order equation of motion is redundant: it may be traded for higher-dimension operators and for lower-dimension operators generated by the redefinition.*

Proof. Expand the action under the shift to first order in $1/\Lambda^2$:

$$S[\phi'] = S_0[\phi] - \frac{1}{\Lambda^2}\int d^4x\, \frac{\delta S_0}{\delta\phi}\, F[\phi] + \frac{1}{\Lambda^2}\int d^4x\, E_0[\phi]\, F[\phi] + O(1/\Lambda^4).$$

The second term is $-\frac{1}{\Lambda^2}\int E_0 F$ by definition of E_0, and it cancels the inserted operator $+\frac{1}{\Lambda^2}\int E_0 F$ identically; what is left is S_0 plus genuinely new $O(1/\Lambda^4)$ terms. So at the order we work, the operator $E_0 F$ disappears.

That the S-matrix is unchanged is the statement that a local change of integration variable cannot change the value of the generating functional. In the path integral $Z[J] = \int \mathcal{D}\phi\; e^{iS[\phi] + i\int J\phi}$, substitute $\phi = \phi' + \frac{1}{\Lambda^2} F[\phi']$. The measure picks up a Jacobian $\det(1 + \frac{1}{\Lambda^2}\delta F/\delta\phi') = \exp\big[\frac{1}{\Lambda^2}\int d^4x\, \frac{\delta F}{\delta\phi'}(x)\, \delta^{(4)}(0)\big]$,

whose exponent is a scaleless integral $\propto \delta^{(4)}(0)$ that vanishes in dimensional regularization (Section 38.2.4); the source term becomes $\int J(\phi' + \frac{1}{\Lambda^2}F[\phi'])$. The added piece $\frac{1}{\Lambda^2}\int JF[\phi']$ is a contact term: it modifies off-shell Green's functions but contributes no pole at the physical single-particle mass, so by the LSZ reduction it drops out of every on-shell amplitude. Hence Z, and with it all S-matrix elements, are invariant, while the Lagrangian written in terms of ϕ' no longer contains $E_0 F$. □

The practical content is that the leading-order equations of motion may be used *inside* dimension-six operators to eliminate redundant structures, the errors being pushed to dimension eight. The Higgs equation of motion that we will need follows from $\mathcal{L}_{\rm SM}$ by varying $H^\dagger$,

$$D^2 H_k = \mu^2 H_k - 2\lambda\,(H^\dagger H)\,H_k - \Big[\,\bar{e}\,Y_e^\dagger L_k + \bar{d}\,Y_d^\dagger Q_k + \epsilon_{kl}\,\bar{Q}_l\,Y_u\,u\,\Big], \quad (40.114)$$

with k, l the $\mathrm{SU}(2)_L$ indices and $Y_{e,d,u}$ the Yukawa matrices; the fermionic source on the right is what converts a derivative operator into the Yukawa-like class $\psi^2 H^3$ when the EOM is applied. Analogous EOMs for the fermions ($i\not{D}L = Y_e e\,H$, etc.) and for the gauge fields ($D^\nu W^I_{\mu\nu} = g\,(\,\text{currents}\,)$) eliminate operators with explicit $\not{D}\psi$ or $D^\nu X_{\mu\nu}$.

Fierz identities. For four-fermion operators, the spinor and gauge indices can be rearranged among the four fields. The chiral Fierz identity

$$(\bar{\psi}_{1L}\gamma^\mu\psi_{2L})(\bar{\psi}_{3L}\gamma_\mu\psi_{4L}) = (\bar{\psi}_{1L}\gamma^\mu\psi_{4L})(\bar{\psi}_{3L}\gamma_\mu\psi_{2L}) \quad (40.115)$$

(valid for left-chiral currents, with the same identity for right-chiral ones) shows that two superficially different orderings of the same four left-handed fields are equal, so only one need be kept. A companion colour Fierz identity, $T^A_{ij}T^A_{kl} = \frac{1}{2}\delta_{il}\delta_{kj} - \frac{1}{2N}\delta_{ij}\delta_{kl}$ for $\mathrm{SU}(N)$, relates colour-octet to colour-singlet contractions. Together these collapse the apparent profusion of four-fermion structures to a finite independent set.

Symmetry of identical fields. Operators that differ only by the ordering of identical bosonic fields or by an overall relabelling are the same operator; this is bookkeeping rather than dynamics, but it must be done consistently to avoid double counting.

A redundant operator is one that any combination of these four moves reduces to operators already in the basis. The next worked example carries such a reduction out in full, exhibiting concretely the claim that a redundant operator is on-shell equal to a combination of retained ones.

Worked Example 40.15 (Reducing a redundant dimension-six operator)**.** Consider the Hermitian dimension-six operator

$$\mathcal{R} \;=\; (H^\dagger H)\,\big[\,H^\dagger (D^2 H) + (D^2 H)^\dagger H\,\big],$$

which contains an explicit $D^2 H$ and so is a candidate for elimination by the Higgs equation of motion. We reduce it two ways, by IBP and by the EOM, and confront the results.

By integration by parts. Since $H^\dagger H$ is a gauge singlet, $\partial_\mu (H^\dagger H) = D_\mu (H^\dagger H) = (D_\mu H)^\dagger H + H^\dagger D_\mu H$, and differentiating once more,

$$\Box (H^\dagger H) = (D^2 H)^\dagger H + H^\dagger D^2 H + 2\,(D_\mu H)^\dagger (D^\mu H).$$

Solving for the bracket in $\mathcal{R}$,

$$\mathcal{R} = (H^\dagger H)\,\Box (H^\dagger H) - 2\,(H^\dagger H)\,(D_\mu H)^\dagger (D^\mu H) = \mathcal{O}_{H\Box} - 2\,(H^\dagger H)(D_\mu H)^\dagger (D^\mu H), \tag{40.116}$$

where $\mathcal{O}_{H\Box} \equiv (H^\dagger H)\Box (H^\dagger H)$ is a Warsaw-basis operator. The IBP move alone has reduced $\mathcal{R}$ to retained bosonic operators plus the structure $(H^\dagger H)(D_\mu H)^\dagger (D^\mu H)$, which is itself reducible.

By the equation of motion. Substitute (40.114) directly. Using $H_k^\dagger (\bar e\, Y_e^\dagger L_k) = \bar e\, Y_e^\dagger (H^\dagger L)$ and $H_k^\dagger\, \epsilon_{kl}\, \bar Q_l Y_u u = -\,\bar Q\, Y_u u\, \widetilde H$ (from $\widetilde H_l = \epsilon_{lk} H_k^*$), we find

$$H^\dagger D^2 H = \mu^2 (H^\dagger H) - 2\lambda (H^\dagger H)^2 - \bar e\, Y_e^\dagger (H^\dagger L) - \bar d\, Y_d^\dagger (H^\dagger Q) + \bar Q\, Y_u u\, \widetilde H,$$

and adding the Hermitian conjugate and multiplying by $H^\dagger H$,

$$\mathcal{R} \overset{\text{EOM}}{=} 2\mu^2 (H^\dagger H)^2 - 4\lambda\, \mathcal{O}_H - (H^\dagger H)\Big[\,\bar e\, Y_e^\dagger (H^\dagger L) + \bar d\, Y_d^\dagger (H^\dagger Q) - \bar Q\, Y_u u\, \widetilde H + \text{h.c.}\,\Big], \tag{40.117}$$

with $\mathcal{O}_H \equiv (H^\dagger H)^3$. Every term on the right is either renormalizable or a retained Warsaw operator: the first term $2\mu^2 (H^\dagger H)^2$ is a dimension-four contribution absorbed into a redefinition of the quartic coupling λ; the second is the H^6 operator $\mathcal{O}_H$; and the bracketed pieces are exactly the $\psi^2 H^3$ operators $\mathcal{O}_{eH} = (H^\dagger H)(\bar L\, e\, H)$, $\mathcal{O}_{dH} = (H^\dagger H)(\bar Q\, d\, H)$, $\mathcal{O}_{uH} = (H^\dagger H)(\bar Q\, u\, \widetilde H)$ and their conjugates. Thus

$$\mathcal{R} \overset{\text{EOM}}{=} \underbrace{2\mu^2 (H^\dagger H)^2}_{\text{into } \lambda} - 4\lambda\, \mathcal{O}_H - \big[\, Y_e^\dagger\, \mathcal{O}_{eH}^\dagger + Y_d^\dagger\, \mathcal{O}_{dH}^\dagger - Y_u\, \mathcal{O}_{uH} + \text{h.c.}\,\big].$$

The operator $\mathcal{R}$ is therefore *not* an independent interaction: on shell it is identical to a specific linear combination of the retained operators $\{\mathcal{O}_H, \mathcal{O}_{eH}, \mathcal{O}_{dH}, \mathcal{O}_{uH}\}$ plus a shift of a renormalizable coupling. Comparing with the IBP result (40.116) also resolves the leftover bosonic structure: equating the two expressions for $\mathcal{R}$ shows that $(H^\dagger H)(D_\mu H)^\dagger (D^\mu H)$ is itself a combination of $\mathcal{O}_{H\Box}$, $\mathcal{O}_H$, the $\psi^2 H^3$ operators, and a coupling redefinition — which is precisely why the Warsaw basis keeps $\mathcal{O}_{H\Box}$ and the operator $\mathcal{O}_{HD} = (H^\dagger D_\mu H)^* (H^\dagger D^\mu H)$ but not $(H^\dagger H)(D_\mu H)^\dagger (D^\mu H)$. This is the redundancy problem in miniature: three different-looking derivative operators are one independent interaction.

40.4.4 Dimension six: the operator classes and the counting

With the redundancy moves in hand we can ask, cleanly, how many independent dimension-six operators there are. The systematic way to organize the answer is by the field content of the operator, since the dimension budget — six units from $[H]=1$, $[\psi]=\frac{3}{2}$, $[D]=1$, $[X]=2$ — admits only a finite number of multiplicity patterns. Writing X for any field strength, H for the Higgs (or $H^\dagger$), ψ for any fermion, and D for a covariant derivative, the patterns summing to dimension six with an even number of fermions are

$$X^3, \quad H^6, \quad H^4D^2, \quad X^2H^2, \quad \psi^2H^3, \quad \psi^2XH, \quad \psi^2H^2D, \quad \psi^4,$$

the eight classes of the dimension-six SMEFT. (One checks that no other pattern balances: ψ^2D^3 and ψ^2XD reduce by the fermion EOM, X^2D^2 and XH^2D^2 reduce by IBP and the gauge EOM, and H^4D, ψ^2HD are forbidden by Lorentz or gauge invariance.) Within each class, gauge invariance, IBP, the EOMs, and Fierz identities cut the operators down to the canonical Warsaw set of Grzadkowski, Iskrzyński, Misiak and Rosiek [240]. The complete one-generation, baryon-number-conserving enumeration is given in Table 40.1 (bosonic and mixed classes) and Table 40.2 (four-fermion class). They total

$$\underbrace{4}_{X^3}+\underbrace{1}_{H^6}+\underbrace{2}_{H^4D^2}+\underbrace{8}_{X^2H^2}+\underbrace{3}_{\psi^2H^3}+\underbrace{8}_{\psi^2XH}+\underbrace{8}_{\psi^2H^2D}+\underbrace{25}_{\psi^4}=59 \tag{40.118}$$

independent operators, the celebrated "59 of the Warsaw basis."

A few structural features of the tables repay comment. The X^3 class contains only the non-abelian field strengths G and W: the abelian $\epsilon\,BBB$ contraction vanishes identically, so there is no B^3 operator. The X^2H^2 class is the home of the Higgs–gauge couplings that govern Higgs production and decay into gauge bosons, and the tilde members carry CP violation. The ψ^2XH class generates anomalous magnetic and electric dipole moments once the Higgs takes its vacuum value — the operator $\mathcal{O}_{eB}$, for instance, feeds directly into the electron's $g-2$ and electric dipole moment, the very quantities that QED computed in the pure Standard Model (Chapter 20); here they receive UV-sensitive corrections of order $v\,m_e/\Lambda^2$. The ψ^2H^2D class modifies the fermion couplings to the Z and W measured at the Z pole. And the four-fermion class contains the operators that, after the next section integrates out the W, will reproduce and generalize Fermi's contact interaction.

Baryon-number violation. The 59 operators of (40.118) all conserve baryon number. Just as the Weinberg operator violated lepton number at dimension five, dimension six is the first place baryon number can break: there are exactly four independent baryon-number-violating operators (one generation), each carrying $\Delta B=\Delta L=1$,

$$\mathcal{O}_{duq},\ \mathcal{O}_{qqu},\ \mathcal{O}_{qqq},\ \mathcal{O}_{duu},$$

schematically of the form $\epsilon_{ABC}(\bar{\psi}^c\psi)(\bar{\psi}^c\psi)$ with the colour epsilon tying three quarks (and one lepton) into a singlet. These operators mediate proton decay, $p \to e^+\pi^0$ and the like, at a rate $\Gamma \sim m_p^5/\Lambda^4$; the experimental bound $\tau_p \gtrsim 10^{34}$ yr pushes the corresponding scale to $\Lambda \gtrsim 10^{15}$ GeV, comparable to the scale read off from neutrino mass. Because B and L are violated together, $B - L$ is again broken by these operators, consistent with the anomaly analysis of Section 33.4.3. The full baryon-number-conserving plus baryon-number-violating dimension-six list is thus $59 + 4 = 63$ operators for one generation, and the dimension-six Lagrangian is

$$\mathcal{L}^{(6)} = \frac{1}{\Lambda^2}\sum_{i=1}^{63} C_i\,\mathcal{O}_i. \tag{40.119}$$

Counting with flavour and the Hilbert series. Switching on three generations multiplies the counting in a non-trivial way, because the Wilson coefficients become tensors in flavour space whose index symmetries differ operator by operator (the symmetric neutrino-mass example of Theorem 40.13 is the dimension-five instance). Carrying out the bookkeeping operator by operator, the dimension-six Lagrangian for three generations contains 2499 independent real parameters (Hermitian operators contributing real coefficients, non-Hermitian ones complex), of which 1350 preserve CP and 1149 violate it [20]. These numbers were obtained independently, as a powerful check, by the *Hilbert-series* method, which counts gauge-invariant operators modulo EOM and IBP redundancy by integrating a generating function (a "plethystic" character integral) over the gauge group and the Lorentz group [265]. The Hilbert series reproduces the 59 ($n_f = 1$) and 2499 ($n_f = 3$) counts and extends them to all higher dimensions; we cite it here as the verification of an enumeration we have, in its lowest classes, carried out by hand. The agreement between the explicit Warsaw construction and the abstract Hilbert-series count is the assurance that the basis is neither over- nor under-complete.

40.4.5 The Warsaw basis and the invariance of observables

The choice of which operators to retain after the redundancy moves is not unique. One could keep $\mathcal{O}_{H\Box}$ and $\mathcal{O}_{HD}$, as the Warsaw basis does, or trade them via the EOM for operators with explicit gauge-boson content, as the so-called SILH or "strongly-interacting light Higgs" basis does. Both are legitimate bases of the same 59-dimensional space of independent dimension-six interactions; they are related by an invertible linear transformation $C_i = \sum_j M_{ij}\,C'_j$ whose matrix M is read off from the EOM and IBP identities (exactly the kind of identity derived in Theorem 40.15). The essential principle is that a *physical observable cannot depend on the basis*: it is computed from on-shell amplitudes, which Theorem 40.14 guarantees are invariant under the field redefinitions that connect

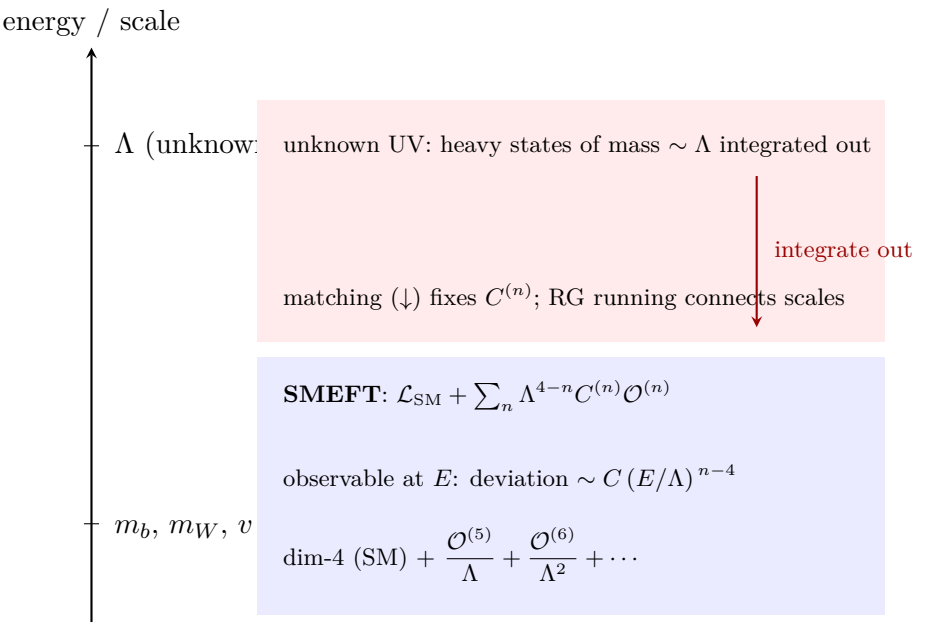

Figure 40.5: The SMEFT tower. Above the scale Λ sits unknown heavy physics; integrating it out leaves the renormalizable Standard Model plus the operator expansion (40.109), suppressed by powers of $1/\Lambda$. A measurement at energy $E \ll \Lambda$ probes the deviation $C\,(E/\Lambda)^{\,n-4}$ and so bounds a combination of Wilson coefficients — equivalently, a scale of new physics.

bases. If a prediction for a cross section appeared to depend on whether one used $\mathcal{O}_{H\Box}$ or its EOM-image, that would signal an algebra error, not a physical ambiguity. Concretely, an observable depends only on those linear combinations of Wilson coefficients that are basis-invariant, and matching a measurement to "new physics" means bounding such a combination, hence a combination of UV parameters.

Physical Insight

The Warsaw basis is not sacred; the 59-dimensional space it spans is. A basis is a coordinate system on the space of dimension-six deformations of the Standard Model, and physics lives in the coordinate-free object — the deformation itself. Choosing the Warsaw basis is like choosing Cartesian axes: convenient, conventional, and irrelevant to any answer. The practical payoff of a *fixed* basis is that the renormalization-group equations, the matching formulae, and the global fits can all be tabulated once and shared, which is why the community standardized on Warsaw.

The picture that emerges is summarized in Fig. 40.5. The Standard Model

occupies the renormalizable floor; above it, organized by powers of $1/\Lambda$, sits a tower whose first storey (dimension five) is the unique Weinberg operator and whose second storey (dimension six) is the $59 + 4$-operator Warsaw basis. Each Wilson coefficient is a window onto the unknown UV: a measurement at energy E constrains $C\,(E/\Lambda)^{n-4}$, and a null result bounds Λ from below for order-one coefficients. This is the quantitative content of "the Standard Model as an effective theory."

With the operator set fixed and non-redundant, the Wilson coefficients C_i are now free parameters awaiting determination. The remaining task of the chapter is to give them values: the next section integrates out a *known* heavy state — first the W boson, recovering Fermi theory as the prototype, then a hypothetical heavy particle — to fix the C_i by matching at tree level, distinguishing the tree- from the loop-generated coefficients, and so turning the empty basis built here into a concrete bridge from short-distance dynamics to low-energy measurement.

40.5 Matching: from heavy new physics to Wilson coefficients

The previous section delivered a Lagrangian but not a theory. We assembled the non-redundant tower of higher-dimension operators built from the Standard-Model fields and the gauge group $\mathrm{SU}(3)_c \times \mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$, fixed a basis (the Warsaw basis, Section 40.4.5), and wrote

$$\mathcal{L}_{\mathrm{SMEFT}} = \mathcal{L}_{\mathrm{SM}} + \sum_i \frac{C_i^{(6)}}{\Lambda^2}\, Q_i^{(6)} + \sum_i \frac{C_i^{(8)}}{\Lambda^4}\, Q_i^{(8)} + \cdots , \tag{40.120}$$

with Λ the scale of whatever heavy physics lies above the electroweak scale and the C_i dimensionless Wilson coefficients (Eq. (40.120)). So far those coefficients are free numbers. Two things can fix them. If the short-distance theory is *unknown*, the coefficients are measured: each observable bounds a combination of C_i/Λ^2, and a nonzero result would point to new physics. If the short-distance theory is *known*—a definite extension of the Standard Model with definite heavy fields and couplings—then the C_i are *computed*, by demanding that the EFT reproduce the full theory at low energy. That computation is *matching*, the subject of this section. We first isolate the matching principle in the abstract, importing the machinery built in Section 38.3; then we run it on the cleanest prototype in particle physics, integrating out the W boson to recover Fermi theory and the value of G_F; then we match an explicit beyond-the-Standard-Model (BSM) field at tree level and read off its dimension-six coefficients; and finally we draw the line between operators generated at tree level and those generated only at one loop, because that line controls how a measured coefficient is read back as a statement about the ultraviolet.

40.5.1 The matching principle

Matching is the statement that two descriptions of the same physics must agree wherever both are valid. The full theory contains a heavy field of mass $M \sim \Lambda$ and the light Standard-Model fields; the EFT contains only the light fields, with the heavy one removed and its effects encoded in local operators. Both are supposed to compute the same low-energy amplitudes. They cannot agree exactly—the EFT has thrown away the heavy particle, and so loses, for instance, the resonance peak when an external invariant hits M^2—but they must agree *order by order in the low-energy expansion*, i.e. in powers of E/M and in powers of the loop expansion.

Definition 40.16 (Matching condition)**.** Let $\mathcal{A}_{\text{full}}$ and $\mathcal{A}_{\text{EFT}}$ denote a fixed set of one-particle-irreducible (1PI) light-field Green's functions, computed in the full theory and in the EFT respectively, renormalized in the same scheme ($\overline{\text{MS}}$, $d = 4 - 2\varepsilon$) at a common scale μ. *Matching at the scale* μ is the requirement

$$\mathcal{A}_{\text{full}}(p_i;\mu) \;=\; \mathcal{A}_{\text{EFT}}(p_i;\mu) \qquad \text{to the working order in } 1/M \text{ and in } \hbar, \tag{40.121}$$

imposed for all light external momenta p_i. The Wilson coefficients $C_i(\mu)$ are the unique local couplings that make Eq. (40.121) hold.

Three points make this definition operational. First, one matches *1PI* amplitudes (or off-shell Green's functions), not on-shell S-matrix elements: the EFT must reproduce the full theory as an off-shell field theory, not merely on a particular mass shell, so that the same coefficients work in every process. Second, one matches at $\mu \sim M$. The reason is the structure of the two sides. Each side, expanded in $\overline{\text{MS}}$, contains logarithms; in the full theory these are $\ln(\mu^2/M^2)$ and $\ln(\mu^2/p^2)$, in the EFT only $\ln(\mu^2/p^2)$, because the EFT has no heavy scale. Choosing $\mu \sim M$ kills the large $\ln(\mu/M)$ on the full side, so the matching coefficients are free of large logs and the perturbative expansion of the C_i is well behaved. The logarithms $\ln(M/p)$ that the EFT *should* contain are not lost—they are regenerated by running the C_i down from $\mu \sim M$ to $\mu \sim p$, which is the business of the next section.

Third—and this is the conceptual heart—the difference $\mathcal{A}_{\text{full}} - \mathcal{A}_{\text{EFT}}$ before matching is a *local* function of the external momenta, i.e. a polynomial in p_i, with no non-analytic pieces (no logarithms of p^2, no branch cuts in the light-particle channels). This is what makes the matching consistent: a local difference can be absorbed into local operators. We record the statement because the whole method rests on it.

Proposition 40.17 (Locality of the matching difference)**.** *At any fixed order in* $1/M$ *and in the loop expansion, the difference between a light-field 1PI Green's function computed in the full theory and the same function computed in the EFT (with all operators up to that order in* $1/M$ *included, and the same light-particle*

content and renormalization scheme) is a polynomial in the external momenta and light masses, of bounded degree. Equivalently, all non-analytic dependence on the external momenta is identical on the two sides and cancels in the difference.

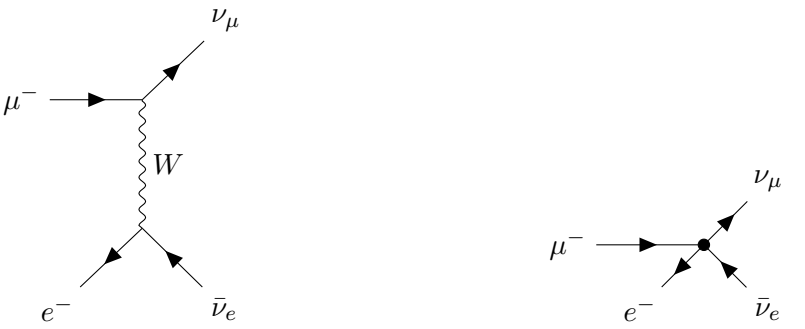
Proof. Non-analyticity in an external invariant p^2 can only arise from a region of loop integration where internal lines go on shell at that invariant—a physical threshold or a long-distance (infrared) region. By construction the EFT contains exactly the light fields of the full theory, with identical quantum numbers, couplings and masses through the order worked; therefore every internal line that can go on shell in the kinematic range $p^2 \ll M^2$ is present in both theories, and the two infrared/threshold structures coincide. The only loop regions present in the full theory but absent from the EFT are those in which a *heavy* line carries the loop momentum, $\ell \sim M$. In such a region the heavy propagator $1/(\ell^2 - M^2)$ is far off shell for all light external momenta, and the integrand may be Taylor-expanded in p_i/M and in light masses before integration (this is the hard region of the method of regions, Section 38.3). The result of integrating a polynomial-in-p integrand is a polynomial in p times heavy-scale integrals—a local result. Hence the full–EFT difference retains only the heavy-region contribution, which is local. The degree of the polynomial is bounded because each extra power of p^2/M^2 is an extra power of the suppression, i.e. a higher-dimension operator, truncated at the working order. □

Theorem 40.17 is the precise content of the slogan "heavy physics is local at low energy." It is also the precise content of decoupling, to which we return in Section 40.5.4: the heavy field never appears as an external state below M, and its virtual effects are a tower of local operators suppressed by powers of $1/M$, plus shifts of the renormalizable couplings already present. The Wilson coefficients are nothing but the coefficients of that local polynomial.

40.5.2 The prototype: integrating out the W and the value of G_F

The original effective field theory of particle physics was Fermi's 1933 theory of beta decay, written down decades before anyone knew it was an EFT. It is the perfect prototype because the full theory—the electroweak Standard Model—is known exactly, the heavy field is the W boson, and the matching is a one-line tree-level calculation. We carry it out diagrammatically here; the complementary route, in which the W is eliminated by its classical equation of motion at the level of the Lagrangian, was done in Theorem 31.19, and the two must agree.

Recall from Section 31.2.8 the electroweak Lagrangian Eq. (31.50), and from Section 31.5.2 the charged-current interaction by which the W couples to fermions. Below the W mass the only role of the W is to mediate four-fermion processes such as muon decay $\mu^- \to e^- \,\bar{\nu}_e \,\nu_\mu$, the process that defines G_F. The full-theory



(a) Full theory: W exchange. (b) EFT: four-fermion contact operator.

Figure 40.6: Matching the W out. At momentum transfer $q^2 \ll M_W^2$ the propagator of the heavy mediator (a) shrinks to a point, leaving a local four-fermion vertex (b). Equating the two amplitudes fixes the Wilson coefficient of the contact operator; the result is the Fermi constant, Eq. (40.127). The same picture, with the W replaced by any heavy mediator of mass M, is the generic tree-level matching of Section 40.5.3.

tree amplitude is a single W exchange. Removing the W from the spectrum, the EFT that reproduces this amplitude at low energy is a contact interaction of four fermions—a dimension-six operator. Matching the two fixes its coefficient.

Worked Example 40.18 (The W-exchange amplitude and the Fermi constant)**.** Write $P_L = \frac{1}{2}(1-\gamma^5)$ for the left-handed projector. The charged-current coupling of Eq. (31.129) attaches to each fermion line a vertex factor $i\,(g/\sqrt{2})\,\gamma^\mu P_L$, with g the $\mathrm{SU}(2)_L$ gauge coupling. The tree amplitude for $\mu^-(p) \to \nu_\mu(p')\, e^-(k)\, \bar{\nu}_e(k')$ from Fig. 40.6a is the product of two such vertices joined by the W propagator carrying momentum $q = p - p'$,

$$i\mathcal{M}_{\text{full}} = \Big[\bar{u}_{\nu_\mu}\, \tfrac{ig}{\sqrt{2}}\gamma^\mu P_L\, u_\mu\Big]\, \frac{-i(\eta_{\mu\nu} - q_\mu q_\nu/M_W^2)}{q^2 - M_W^2}\, \Big[\bar{u}_e\, \tfrac{ig}{\sqrt{2}}\gamma^\nu P_L\, v_{\bar{\nu}_e}\Big], \qquad (40.122)$$

where we used the unitary-gauge W propagator; in R_ξ gauge the ξ-dependent piece of the propagator is itself a contact term that cancels against the would-be Goldstone exchange, so the physical result is gauge independent and we may as well use the form Eq. (40.122).

The low-energy expansion. The defining feature of the kinematic regime is $q^2 \sim m_\mu^2 \ll M_W^2$. Expand the propagator denominator,

$$\frac{1}{q^2 - M_W^2} = -\frac{1}{M_W^2}\,\frac{1}{1 - q^2/M_W^2} = -\frac{1}{M_W^2}\Big(1 + \frac{q^2}{M_W^2} + \frac{q^4}{M_W^4} + \cdots\Big). \qquad (40.123)$$

The $q_\mu q_\nu/M_W^2$ term contracts into the currents as $q_\mu\, \bar{u}_{\nu_\mu}\gamma^\mu P_L u_\mu$; using the Dirac equations for the external spinors, $q_\mu\gamma^\mu = \not{p} - \not{p}'$ acting between $\bar{u}_{\nu_\mu}$ and u_μ

returns a factor of the lepton masses, so this term is suppressed by $m^2_{\text{lepton}}/M_W^2$ relative to the leading one and is dropped at the order we work. Keeping the leading term of Eq. (40.123),

$$i\mathcal{M}_{\text{full}} = \left(\tfrac{ig}{\sqrt{2}}\right)^2\left(\frac{-i}{-M_W^2}\right)[\bar{u}_{\nu_\mu}\gamma^\mu P_L\, u_\mu][\bar{u}_e\gamma_\mu P_L\, v_{\bar{\nu}_e}] = -\frac{ig^2}{2M_W^2}[\bar{u}_{\nu_\mu}\gamma^\mu P_L\, u_\mu][\bar{u}_e\gamma_\mu P_L\, v_{\bar{\nu}_e}], \tag{40.124}$$

where $(ig/\sqrt{2})^2 = -g^2/2$ and $(-i)/(-M_W^2) = i/M_W^2$ combine to the displayed prefactor.

The EFT side. The contact operator that reproduces Fig. 40.6b is the charged-current four-fermion operator. Written in the historical $(1-\gamma^5)$ normalization of Fermi theory (Eq. (31.3)),

$$\mathcal{L}_{\text{Fermi}} = -\frac{G_F}{\sqrt{2}}[\bar{\psi}_{\nu_\mu}\gamma^\mu(1-\gamma^5)\psi_\mu][\bar{\psi}_e\gamma_\mu(1-\gamma^5)\psi_{\nu_e}]. \tag{40.125}$$

Since $1-\gamma^5 = 2P_L$, each current carries a factor of 2, and the tree amplitude generated by Eq. (40.125) is

$$i\mathcal{M}_{\text{EFT}} = -\frac{iG_F}{\sqrt{2}}\cdot 2\cdot 2\,[\bar{u}_{\nu_\mu}\gamma^\mu P_L\, u_\mu][\bar{u}_e\gamma_\mu P_L\, v_{\bar{\nu}_e}] = -\frac{4iG_F}{\sqrt{2}}[\bar{u}_{\nu_\mu}\gamma^\mu P_L\, u_\mu][\bar{u}_e\gamma_\mu P_L\, v_{\bar{\nu}_e}]. \tag{40.126}$$

Matching. The two amplitudes Eqs. (40.124) and (40.126) carry the identical spinor structure—this is the content of Theorem 40.17 in action: the heavy-line region produced exactly the local operator the EFT contains. Equating their coefficients,

$$\frac{4G_F}{\sqrt{2}} = \frac{g^2}{2M_W^2} \qquad \Longrightarrow \qquad \boxed{\frac{G_F}{\sqrt{2}} = \frac{g^2}{8M_W^2}} \tag{40.127}$$

which is the Fermi constant predicted by the electroweak theory, reproducing Eq. (31.145) by the diagrammatic route. With $M_W = \tfrac{1}{2}gv$ from the Higgs mechanism (Section 31.3) this collapses to $G_F/\sqrt{2} = 1/2v^2$, fixing the electroweak scale $v \simeq 246\,\text{GeV}$; that step was carried out in Theorem 31.19 and we do not repeat it.

The tower. Restoring the next term of Eq. (40.123), the q^2/M_W^2 piece multiplies the same current bilinear by q^2. In position space $q^2 \to -\Box$ acting on the contact operator, so it is a four-fermion operator with two extra derivatives, of mass dimension eight, with coefficient

$$\frac{g^2}{2M_W^4}[\bar{\psi}_{\nu_\mu}\gamma^\mu P_L \overleftrightarrow{\Box}\psi_\mu][\bar{\psi}_e\gamma_\mu P_L\,\psi_{\nu_e}] + \cdots, \tag{40.128}$$

schematically. Each higher term in the expansion is a higher-dimension operator suppressed by an additional power of $1/M_W^2$. This is the operator tower of Eq. (40.120) made completely explicit: integrating out a single heavy field

produces, not one operator, but the entire $1/M$ expansion, and the dimension-six term is simply its leading entry.

Two lessons generalize beyond this example and are worth stating plainly. First, Fermi theory is the Standard Model *as its own EFT*: integrating out the heavy electroweak states (W, Z, Higgs, top) below their masses gives a low-energy effective theory of the light quarks and leptons, of which Fermi's interaction is one operator. This is the same logical move as SMEFT, only the "heavy" physics is inside the Standard Model rather than above it. Second, the calculation was a pure tree graph, and it generated a four-fermion operator. The two facts are linked: *which* operators a heavy field generates, and at *what* order in the loop expansion, is dictated by how that field couples. We now make both points sharp by matching an explicit new heavy field, and then by separating tree- from loop-generated operators.

40.5.3 Tree-level matching of a heavy BSM field

The prototype matched a known heavy field. The same procedure, applied to a *hypothetical* heavy field, is how a concrete BSM model is translated into SMEFT Wilson coefficients—the practical content of "model X predicts deviations in observable Y." We work the cleanest nontrivial example: a heavy real scalar that is a singlet under $\mathrm{SU}(3)_c \times \mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$, coupled to the Higgs. It produces purely bosonic dimension-six operators, and the elimination of the heavy field by its equation of motion—the Lagrangian face of matching—exposes the derivative expansion in a way the four-fermion examples do not.

Worked Example 40.19 (A heavy scalar singlet and the operators Q_H, $Q_{H\Box}$)**.** Let S be a real scalar, a singlet under $\mathrm{SU}(3)_c \times \mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$, with mass $M \sim \Lambda$ and the renormalizable Lagrangian

$$\mathcal{L}_S = \tfrac{1}{2}(\partial_\mu S)(\partial^\mu S) - \tfrac{1}{2}M^2 S^2 - g_1 M\, S\,(H^\dagger H) - \tfrac{1}{2} g_2\, S^2\,(H^\dagger H), \qquad (40.129)$$

where H is the Standard-Model Higgs doublet and g_1, g_2 are dimensionless (the explicit M in the linear coupling makes g_1 dimensionless, since $[S\,H^\dagger H] = 3$). We have dropped S's own cubic and quartic self-couplings: they do not contribute to the operators of interest at tree level and at leading order in $1/M^2$. We integrate S out at tree level. Tree-level matching is implemented by solving the classical equation of motion for S as a power series in $1/M^2$ and substituting back; this is the saddle point of the path integral over S, exact at tree level (Section 38.3).

The equation of motion. Varying Eq. (40.129) with respect to S,

$$(\Box + M^2 + g_2\, H^\dagger H)\, S = -\, g_1 M\, (H^\dagger H). \qquad (40.130)$$

Invert the operator on the left as a geometric series in $1/M^2$,

$$S = -\,\frac{g_1 M\,(H^\dagger H)}{M^2\big(1 + (\Box + g_2 H^\dagger H)/M^2\big)}$$

$$= -\frac{g_1}{M}(H^\dagger H) + \frac{g_1}{M^3}\,\Box(H^\dagger H) + \frac{g_1 g_2}{M^3}\,(H^\dagger H)^2 + O(M^{-5}). \tag{40.131}$$

The leading term is $O(1/M)$; each correction carries an extra $1/M^2$ and either an extra derivative ($\Box$) or an extra power of the field ($g_2 H^\dagger H$), exactly the two ways the EFT expansion can grow.

Substituting back. Because Eq. (40.129) is quadratic in S, the effective Lagrangian is most cleanly obtained from the standard Gaussian result: for $\mathcal{L} = -\frac{1}{2} S\,\mathcal{K}\,S - J\,S$ with $\mathcal{K} = \Box + M^2 + g_2 H^\dagger H$ and $J = g_1 M\,(H^\dagger H)$ (the kinetic term integrated by parts), the solution is $S = -\mathcal{K}^{-1} J$ and

$$\mathcal{L}_{\text{eff}} = -\tfrac{1}{2} S\,\mathcal{K}\,S - J\,S\Big|_{S=-\mathcal{K}^{-1}J} = \tfrac{1}{2}\,J\,\mathcal{K}^{-1}\,J. \tag{40.132}$$

Expanding $\mathcal{K}^{-1} = M^{-2}\big[1-(\Box+g_2 H^\dagger H)/M^2+\cdots\big]$ and inserting $J = g_1 M(H^\dagger H)$,

$$\begin{aligned}\mathcal{L}_{\text{eff}} &= \tfrac{1}{2}\,g_1^2 M^2\,(H^\dagger H)\,\frac{1}{M^2}\Big[1 - \frac{\Box + g_2 H^\dagger H}{M^2} + \cdots\Big]\,(H^\dagger H) \\ &= \underbrace{\tfrac{1}{2} g_1^2\,(H^\dagger H)^2}_{\text{dimension 4}} \;-\; \underbrace{\frac{g_1^2}{2M^2}\,(H^\dagger H)\,\Box(H^\dagger H)}_{\text{dimension 6: } Q_{H\Box}} \;-\; \underbrace{\frac{g_1^2 g_2}{2M^2}\,(H^\dagger H)^3}_{\text{dimension 6: } Q_H} + O(M^{-4}).\end{aligned} \tag{40.133}$$

Reading off the coefficients. The first term is dimension four. It is not a new operator: it has the form of the Higgs quartic, so it is a finite *threshold correction* to the Standard-Model coupling $\mathcal{L}_{\text{SM}} \supset -\lambda(H^\dagger H)^2$, shifting $\lambda \to \lambda - \frac{1}{2} g_1^2$. This is exactly the part of the heavy physics that decoupling permits to remain unsuppressed: it renormalizes a coupling already present, rather than appearing as a $1/M^2$ effect. The remaining two terms are the genuine dimension-six output. Recalling the Warsaw-basis operators $Q_{H\Box} = (H^\dagger H)\Box(H^\dagger H)$ and $Q_H = (H^\dagger H)^3$ (Section 40.4.5) and the normalization Eq. (40.120) with $\Lambda = M$, we match coefficients:

$$\boxed{C_{H\Box} = -\frac{g_1^2}{2}, \qquad C_H = -\frac{g_1^2\,g_2}{2}} \tag{40.134}$$

at the matching scale $\mu = M$. The heavy singlet thus feeds precisely two dimension-six directions: the Higgs-kinetic operator $Q_{H\Box}$ (which, after electroweak symmetry breaking, rescales the physical Higgs field and so shifts every Higgs coupling coherently) and the Higgs self-interaction Q_H (which alters the trilinear and quartic Higgs couplings). A measurement of Higgs-coupling deviations of the pattern Eq. (40.134) would be the SMEFT signature of exactly this heavy singlet; the absence of such deviations bounds g_1^2/M^2 and hence the mass M for a given coupling.

The four-fermion prototype and the bosonic example share an algebraic skeleton, and it is worth making the parallel explicit because it shows the universality of the method. Replace the heavy scalar by a heavy neutral vector V_μ, a $\mathrm{SU}(3)_c \times \mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$ singlet of mass M (a "Z'"), coupled to a Standard-Model fermion current $J^\mu = \sum_f \bar{\psi}_f \gamma^\mu \psi_f$ through $\mathcal{L}_V = -\frac{1}{4} V_{\mu\nu} V^{\mu\nu} + \frac{1}{2} M^2 V_\mu V^\mu + g_V\, V_\mu J^\mu$. Its algebraic equation of motion at leading order in $1/M^2$ is $M^2 V^\mu = -g_V J^\mu$, i.e. $V^\mu = -(g_V/M^2) J^\mu$, and substituting back,

$$\mathcal{L}_{\text{eff}} = \tfrac{1}{2} M^2 \Big(\frac{g_V}{M^2}\Big)^2 J_\mu J^\mu - g_V \frac{g_V}{M^2}\, J_\mu J^\mu = -\,\frac{g_V^2}{2M^2}\, J_\mu J^\mu, \tag{40.135}$$

a four-fermion operator with Wilson coefficient $C/\Lambda^2 = -g_V^2/2M^2$. This is the *same* computation as integrating out the W in Theorem 40.18—the mass term contributes $+\frac{1}{2}$, the source term -1, summing to $-\frac{1}{2}$—only with the charged current and W replaced by a generic current and a generic mediator. A heavy Z' and Fermi's W are the same EFT calculation. Whichever Warsaw four-fermion operator $J_\mu J^\mu$ corresponds to (for a lepton-doublet current, $Q_{ll} = (\bar{\ell}\gamma_\mu \ell)(\bar{\ell}\gamma^\mu \ell)$), the coefficient is read off directly.

40.5.4 Decoupling: heavy physics is local and suppressed

Both worked examples exhibit a structural fact we now name. In every case the heavy field left two kinds of imprint on the low-energy theory: *(i)* finite shifts of the renormalizable couplings already present (the Higgs quartic in Eq. (40.133)), and *(ii)* a tower of higher-dimension local operators suppressed by powers of $1/M$. Nothing else survived; in particular no trace of the heavy particle as a propagating state remained. This is the Appelquist–Carazzone decoupling theorem (Theorem 38.10), and matching is the constructive form of its proof: the explicit local operators are the residue the heavy field leaves behind.

Theorem 40.20 (Decoupling, EFT form; Theorem 38.10)**.** *In a renormalizable theory with a heavy field of mass M coupled to light fields, all effects of the heavy field on light-field Green's functions at energies $E \ll M$ are reproduced, to any fixed order in E/M, by the local effective Lagrangian $\mathcal{L}_{\text{eff}} = \mathcal{L}^{\text{ren}}_{\text{light}} + \sum_i (C_i/M^{d_i-4})\, Q_i$, where $\mathcal{L}^{\text{ren}}_{\text{light}}$ is the renormalizable Lagrangian of the light fields with couplings shifted by finite matching corrections, and the Q_i are local operators of dimension $d_i > 4$ built from the light fields, with coefficients C_i of order the heavy couplings. Effects of the heavy field thus vanish as $M \to \infty$ except for the renormalization of the light couplings.*

The theorem is what gives the SMEFT expansion Eq. (40.120) its meaning: whatever sits above Λ, its low-energy footprint is exactly a series of local operators ordered by dimension, and the leading new effects are the dimension-six ones. Heavier means more suppressed; this is why a bound on a dimension-six coefficient translates into a bound on a scale.

There is, however, an important class of failures of decoupling, and honesty requires flagging it because it is central to electroweak physics.

Caution: when heavy fields do *not* decouple

Decoupling assumes the heavy mass M is an independent parameter that can be sent to infinity at fixed couplings. When the heavy mass is generated by spontaneous symmetry breaking, $M \sim y\,v$ with y a coupling and v a fixed vacuum value, sending $M \to \infty$ means sending the coupling $y \to \infty$, and the field does not decouple. The Standard-Model top quark and the Higgs boson are the textbook cases: the top contribution to the ρ parameter grows as m_t^2 (Section 31.6), and the would-be Goldstone bosons whose longitudinal-mode couplings grow with mass are precisely what the heavy gauge bosons eat. In SMEFT the analogue is that integrating out a heavy field whose mass comes partly from the Higgs vacuum value can leave effects that do not scale as a simple power of $1/\Lambda$. The decoupling picture is the generic case; chiral and electroweak-symmetry-breaking-induced masses are the systematic exceptions, and a correct matching tracks them explicitly.

40.5.5 Tree-level versus one-loop matching

Everything so far was tree-level matching: the heavy field was eliminated by its classical equation of motion, equivalently the leading saddle of its path integral. But Eq. (40.121) is an all-orders statement, and at one loop the EFT must reproduce the full theory's one-loop light-field amplitudes. The Wilson coefficients then receive one-loop contributions, and—crucially—*some operators are generated only at one loop and not at all at tree level*. Which is which controls how a measured coefficient is interpreted.

The two scalings. Dimensional analysis of the matching makes the hierarchy transparent. A tree-generated coefficient is a product of the heavy couplings with no loop factor, as in Eqs. (40.127), (40.134) and (40.135):

$$C_i^{\text{tree}} \sim \frac{(\text{coupling})^2}{1}, \qquad C_i^{\text{loop}} \sim \frac{(\text{coupling})^{2\text{ or more}}}{16\pi^2}, \tag{40.136}$$

the loop case carrying the universal $1/16\pi^2$ of a four-dimensional loop integral (Section D.4). For a weakly coupled ultraviolet completion this is roughly two orders of magnitude. The consequence for interpretation is direct: a measured coefficient of natural size $C \sim 1$ implies, for a tree-generated operator, $\Lambda \sim (\,\text{coupling}\,)/\sqrt{|C|/v^2}$, whereas for a loop-generated operator the same measurement implies a scale lower by a factor $\sim 4\pi$, because the intrinsic coefficient

is $\sim g^2/16\pi^2$ rather than $\sim g^2$. Reading a bound on a dimension-six operator as a bound on Λ therefore *requires knowing whether that operator can be tree-generated*.

The classification. Whether an operator can appear at tree level in *any* renormalizable, weakly-coupled completion is not a matter of taste; it is determined by the operator's structure, through the classification of Arzt–Einhorn–Wudka. The criterion is whether the operator can be "cut" into renormalizable ($d \le 4$) vertices joined by heavy propagators—i.e. whether a tree graph of some heavy field can produce it. Of the 59 baryon-number-conserving dimension-six operators of the one-generation Warsaw basis, only a subset are "potentially tree-generated"; the remainder are necessarily loop-generated. The loop-only classes include in particular:

- the *dipole operators*—$Q_{eW} = (\bar{\ell}\sigma^{\mu\nu}e)\tau^I H\, W^I_{\mu\nu}$, Q_{eB}, Q_{uG}, and their relatives—which require a chirality flip and a field-strength insertion that no tree graph of renormalizable vertices can assemble;
- the purely gauge operators built from three field strengths, $Q_W = \epsilon^{IJK} W^I_{\ \mu}{}^{\nu} W^J_{\ \nu}{}^{\rho} W^K_{\ \rho}{}^{\mu}$ and $Q_{\tilde{W}}$, which cannot arise from tree exchange.

The dipole case is the physically decisive one. The anomalous magnetic moment and the electric dipole moment are governed by dipole operators; since these are loop-generated in any weakly-coupled completion, the model's number $a_e = \alpha/2\pi$ (Chapter 20)—a one-loop effect of the photon—reappears here as the statement that a Wilson coefficient is loop-suppressed. A measured electron or muon dipole that is *large* relative to the loop expectation is therefore a sharp pointer to either strong coupling or a low scale, precisely because the operator cannot be tree-generated.

How one-loop matching is done. Operationally, Eq. (40.121) is imposed at one loop by computing the relevant light-field 1PI functions on both sides through $O(\hbar)$, in the same scheme, and solving for the C_i. The efficient organization is the method of regions (Section 38.3): in the full-theory loop integral, the integrand is split into a *hard* region (loop momentum $\ell \sim M$) and a *soft* region ($\ell \sim p$). The soft region reproduces, term by term, the EFT loop built from the lower-order operators, and cancels in the difference; the hard region is Taylor-expanded in p/M before integration and yields the local matching contribution to the C_i, by exactly the mechanism of Theorem 40.17 now applied at one loop. Concretely, a hard-region integral has the form $\int \mathrm{d}^d\ell/(2\pi)^d\,[\ell^2 - M^2]^{-n} \times (\text{polynomial in } \ell)$, a tadpole-type master integral that produces $1/16\pi^2$ times a function of M and μ (Section D.4); choosing $\mu = M$ removes its logarithm, leaving the finite, local matching coefficient. The poles in ε that the hard region generates are

removed by the renormalization of the full theory and of the EFT operators, so the matched $C_i(\mu = M)$ is finite and scheme-fixed—the boundary value for the running of the next section.

Physical Insight

Tree- versus loop-level matching is the EFT translation of a question the data cannot answer on its own: *how strongly coupled, and at what scale, is the new physics?* A dimension-six coefficient is a single number; the pattern of which operators are switched on, and the comparison of their sizes against the tree-versus-loop expectation Eq. (40.136), is what turns that number into a statement about the ultraviolet. SMEFT does not merely parametrize deviations; read with the matching dictionary in hand, it diagnoses their origin.

We have now fixed Wilson coefficients at a matching scale $\mu \sim \Lambda$ (or, in the prototype, $\mu \sim M_W$), whether from a known heavy field by explicit matching or from a hypothetical one by translating a model. Those coefficients carry no large logarithms by construction—that was the point of matching at $\mu \sim M$—but the observables that test them live at much lower scales, and the intervening logarithms $\ln(\Lambda/m_W)$ are large and must be summed. The next section supplies the machinery: the renormalization-group running of the Wilson coefficients and the anomalous-dimension matrix that mixes operators of equal dimension as they flow down to the measurement scale.

40.6 Running and operator mixing

The matching computation of Section 40.5 delivered Wilson coefficients *at the high scale*: integrating out the W at $\mu \simeq m_W$ gave the Fermi Hamiltonian with $C_2(m_W) = 1$, and integrating out a generic heavy state gave a set of dimension-six coefficients fixed at $\mu \simeq M$, the mass of the new physics. Those numbers are correct only *at the scale where the heavy field was removed*. A measurement, however, lives at a low scale: a kaon decays at $\mu \sim 1$–$2\,\mathrm{GeV}$, where hadronic matrix elements are defined; an electroweak precision observable is read off at $\mu \sim m_Z$. The naive thing to do — use $C_i(m_W)$ directly in a low-energy matrix element — is wrong, and wrong by a controlled, computable, and often *large* amount. The reason is that the loop corrections to the effective theory carry logarithms $\alpha_s \ln(m_W/\mu)$ which, with $\alpha_s \ln(m_W/\mu) \sim 0.1 \times 4 \sim 0.4$, are not small: a fixed-order treatment is in trouble already at one loop and hopeless at two. These are the same large logarithms that the renormalization group was invented to resum (Chapter 24), and the effective theory is precisely the setting in which the resummation is cleanest, because the heavy scale has been removed from the dynamics and survives only as the boundary condition $C_i(m_W)$ and as the upper

limit of the logarithm.

This section turns the RG machinery of Chapter 24 loose on Wilson coefficients. Two features distinguish the problem from the running of a single coupling. First, the objects that run are the coefficients of *composite* operators, and operators of equal dimension and identical quantum numbers *mix* under renormalization: the anomalous "dimension" is a matrix. Second, the engine of the running here is QCD — the mixing is computed from exactly the gluon-exchange diagrams and the β-function of Chapter 27, applied to weak operators. This is QCD reappearing in a new guise: the non-abelian anomalous-dimension technology, built to explain asymptotic freedom, now resums the strong-interaction dressing of the weak Hamiltonian. We develop the general formalism, prove the renormalization-group equation for the coefficient vector, and then carry the classic $\Delta S = 1$ four-quark mixing in full: the operators, the one-loop anomalous-dimension matrix, its diagonalization, and the leading-log solution exhibiting the celebrated QCD enhancement. We close by stating how the same procedure organizes the entire dimension-six SMEFT, whose complete one-loop anomalous-dimension matrix is known, and we compute the load-bearing QCD sub-block.

40.6.1 Operator renormalization and the mixing matrix

Fix an effective Hamiltonian of the standard form

$$\mathcal{H}_{\text{eff}} = \frac{G_F}{\sqrt{2}} \sum_i C_i(\mu)\, Q_i(\mu) + \text{h.c.}, \tag{40.137}$$

where the Q_i are local operators of a common dimension, sharing the quantum numbers of the process under study, and the C_i are their Wilson coefficients. The product $\mathcal{H}_{\text{eff}}$ is a physical operator and must be independent of the renormalization scale μ; the μ-dependence of the C_i exists only to cancel the μ-dependence of the renormalized operators $Q_i(\mu)$. Making that cancellation quantitative is the whole content of the running.

A composite operator built from several fields needs its own renormalization beyond the renormalization of the fields and couplings it contains. When several operators carry the same quantum numbers, their divergences are not separately multiplicatively renormalizable: the counterterm needed to make $\langle Q_i \rangle$ finite is in general a linear combination of *all* the Q_j. We write the relation between bare and renormalized operators as a matrix,

$$Q_i^{(0)} \;=\; Z_{ij}\, Q_j(\mu), \qquad Z_{ij} = \delta_{ij} + \frac{\alpha_s}{4\pi}\frac{1}{\varepsilon}\, a_{ij} + O(\alpha_s^2), \tag{40.138}$$

in $\overline{\text{MS}}$ with $d = 4 - 2\varepsilon$, where the bare operator $Q_i^{(0)}$ is built from bare fields and is by construction μ-independent, and the pole part a_{ij} is a pure number to be computed. The off-diagonal entries $a_{i\neq j}$ are the *operator mixing*: a

divergence proportional to Q_j generated inside the one-loop matrix element of Q_i. (Throughout, field and coupling renormalization are taken as already performed; Z_{ij} is the genuinely new *operator* renormalization, the divergence that survives after the external legs and the strong coupling have been renormalized.)

Proposition 40.21 (Renormalization-group equation for Wilson coefficients)**.** *Let the operators renormalize as in* (40.138) *and define the* anomalous-dimension matrix

$$\gamma \;=\; Z^{-1}\,\mu\frac{dZ}{d\mu}, \qquad \gamma = \frac{\alpha_s}{4\pi}\,\gamma^{(0)} + O(\alpha_s^2). \tag{40.139}$$

Then the renormalized Wilson-coefficient vector obeys

$$\mu\,\frac{d}{d\mu}\,C_i(\mu) \;=\; \big(\gamma^{\mathsf T}\big)_{ij}\,C_j(\mu), \qquad \textit{i.e.} \qquad \mu\,\frac{dC}{d\mu} = \gamma^{\mathsf T} C. \tag{40.140}$$

At leading order $\gamma^{(0)}_{ij} = -2\,a_{ij}$.

Proof. The bare operator is μ-independent. Differentiating $Q_i^{(0)} = Z_{ij}Q_j$ at fixed bare quantities,

$$0 \;=\; \mu\frac{dQ_i^{(0)}}{d\mu} = \Big(\mu\frac{dZ_{ij}}{d\mu}\Big)Q_j + Z_{ij}\,\mu\frac{dQ_j}{d\mu}. \tag{40.141}$$

Writing $\mu\,dQ_j/d\mu = -\gamma_{jk}Q_k$ defines an anomalous-dimension matrix for the operators; substituting and using that the Q_k are independent gives $\mu\,dZ_{ik}/d\mu = Z_{ij}\gamma_{jk}$, i.e. $\gamma = Z^{-1}\mu\,dZ/d\mu$, which is (40.139). Now impose μ-independence of $\mathcal{H}_{\text{eff}}$. The bare coefficients $C_i^{(0)}$ multiply the bare operators, $C_i^{(0)}Q_i^{(0)} = C_i^{(0)}Z_{ij}Q_j$, so the renormalized coefficients are

$$C_j(\mu) = C_i^{(0)}\,Z_{ij}, \qquad \text{i.e.} \qquad C = Z^{\mathsf T}C^{(0)}, \tag{40.142}$$

with $C^{(0)}$ the (μ-independent) bare coefficient vector. Differentiating,

$$\mu\frac{dC}{d\mu} = \Big(\mu\frac{dZ^{\mathsf T}}{d\mu}\Big)C^{(0)} = \Big(\mu\frac{dZ^{\mathsf T}}{d\mu}\Big)(Z^{\mathsf T})^{-1}C = \Big[(Z^{-1}\mu\tfrac{dZ}{d\mu})^{\mathsf T}\Big]C = \gamma^{\mathsf T}C, \tag{40.143}$$

which is (40.140); we used $(\mu\,dZ^{\mathsf T}/d\mu)(Z^{\mathsf T})^{-1} = \big[(Z^{-1}\mu\,dZ/d\mu)\big]^{\mathsf T}$. For the leading order, write $Z = 1 + (\alpha_s/4\pi)\varepsilon^{-1}a$ as in (40.138). In $d = 4-2\varepsilon$ the strong coupling runs as $\mu\,d\alpha_s/d\mu = -2\varepsilon\,\alpha_s + O(\alpha_s^2)$ (the -2ε is the engineering-dimension term that the four-dimensional β-function of Eq. (27.1) supplements; it is exactly the term carried in the Callan–Symanzik analysis of Theorem 24.19). Hence

$$\mu\frac{dZ}{d\mu} = \frac{a}{4\pi}\,\frac{1}{\varepsilon}\,\mu\frac{d\alpha_s}{d\mu} = \frac{a}{4\pi}\,\frac{1}{\varepsilon}\,(-2\varepsilon\,\alpha_s) = -2\,\frac{\alpha_s}{4\pi}\,a, \tag{40.144}$$

and $Z^{-1} = 1 + O(\alpha_s)$, so $\gamma = -2(\alpha_s/4\pi)\,a + O(\alpha_s^2)$, giving $\gamma^{(0)} = -2a$. That γ comes out finite as $\varepsilon \to 0$ — the $1/\varepsilon$ of a is cancelled by the explicit ε in $\mu\, d\alpha_s/d\mu$ — is the statement that the anomalous dimension is a genuine physical (renormalized) quantity, exactly as for the single-coupling case in Section 24.6.5. □

Equation (40.140) is the matrix generalization of the scalar RG equation (24.184). Its structure is worth dwelling on. The coefficients run because the *operators* acquire anomalous dimensions, and they mix because those anomalous dimensions form a non-diagonal matrix. The transpose in (40.140) is the bookkeeping consequence of (40.142): coefficients are contracted with operators, so a mixing of operators among themselves becomes, on the coefficients, the action of the transposed matrix. Whenever $\gamma^{(0)}$ is symmetric — as it is at one loop in the $\Delta S = 1$ problem below — the transpose is invisible and one may read the same matrix as acting on either side.

Physical Insight: why running matters

A measurement at a low scale $\mu_{\rm low}$ constrains the combination $C_i(\mu_{\rm low})\,\langle Q_i\rangle(\mu_{\rm low})$. The *physics* we want to constrain — the mass and couplings of whatever was integrated out — lives in $C_i(\mu_{\rm high})$. The two are related by the solution of (40.140), an operator that can change a coefficient by an $O(1)$ factor (the $\Delta S = 1$ case below) or even rotate a vanishing high-scale coefficient into a nonzero low-scale one (genuine mixing). *A low-energy bound is a bound on the UV only after RG evolution.* Skipping the running does not merely lose precision; it can misidentify which operator, and hence which new-physics structure, the data are sensitive to.

40.6.2 The $\Delta S = 1$ effective Hamiltonian

The cleanest arena for operator mixing is the non-leptonic weak Hamiltonian that governs strangeness-changing transitions such as $K \to \pi\pi$. Integrating the W out of the charged-current interaction $\frac{g}{\sqrt{2}}\,\bar u_L \gamma^\mu d'_L W^+_\mu$ (with d' the CKM-rotated down-type field of Section 32.3.1) produces, for the quark-level transition $s \to u\bar u d$, a local four-quark interaction. At tree level the W propagator collapses to $g_{\mu\nu}/m_W^2$ and one finds a single operator, exactly as in the Fermi reduction of Section 40.5. Writing colour indices α, β explicitly and abbreviating the left-handed current with $P_L = \frac{1}{2}(1 - \gamma^5)$, the operator basis closed under QCD renormalization is

$$Q_1 = (\bar s_\alpha \gamma^\mu P_L\, u_\beta)(\bar u_\beta \gamma_\mu P_L\, d_\alpha), \tag{40.145}$$

$$Q_2 = (\bar s_\alpha \gamma^\mu P_L\, u_\alpha)(\bar u_\beta \gamma_\mu P_L\, d_\beta). \tag{40.146}$$

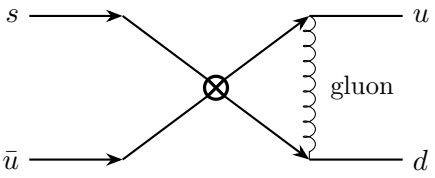


Figure 40.7: One of the four current-current diagrams that renormalize the $\Delta S = 1$ operators. The crossed circle is the local four-quark vertex (Q_1 or Q_2); a gluon is exchanged between the two quark currents. The colour factor $T^A \otimes T^A$ carried by such a gluon, reduced through the SU(3) identity (40.149), is what mixes the colour-singlet operator Q_2 into the colour-mixed Q_1. The remaining three diagrams attach the gluon to the other pairings of legs; diagrams with the gluon inside a single current cancel against quark wavefunction renormalization.

Q_2 is the "colour-singlet×singlet" operator produced directly by W-exchange (each bilinear is a colour singlet); Q_1 is the "colour-mixed" operator, in which the colour indices are cross-contracted between the two currents. The effective Hamiltonian is

$$\mathcal{H}_{\text{eff}}^{\Delta S=1} = \frac{G_F}{\sqrt{2}} V_{ud} V_{us}^* \left[C_1(\mu)\, Q_1 + C_2(\mu)\, Q_2 \right] + \text{h.c.}, \tag{40.147}$$

with the CKM factor $V_{ud}V_{us}^*$ from Section 32.3.1. The tree-level matching of Section 40.5 produces only the singlet operator,

$$C_1(m_W) = 0, \qquad C_2(m_W) = 1. \tag{40.148}$$

The whole point of what follows is that C_1 is *not* zero at low scales: QCD radiative corrections mix Q_2 into Q_1, and the leading-log resummation turns the boundary condition (40.148) into a pair of $O(1)$ coefficients with a definite hierarchy. We need the 2×2 anomalous-dimension matrix.

40.6.3 The one-loop anomalous-dimension matrix

We now compute the one-loop QCD renormalization of $\{Q_1, Q_2\}$ and extract $\gamma^{(0)}$. The computation is the worked example of this section; we present the diagrams, the colour algebra, the Dirac reduction, and the loop integral in turn, then assemble the matrix and verify it. The key conceptual points are two: (i) only the diagrams in which a gluon is exchanged *between* the two currents contribute a net divergence to the mixing, the others being removed by quark wavefunction renormalization; and (ii) the colour algebra of that gluon exchange is exactly what converts the singlet operator Q_2 into the colour-mixed Q_1.

Worked Example 40.22 (One-loop $\Delta S = 1$ mixing and the leading-log solution)**.**
(a) The colour algebra. Each gluon vertex carries a generator T^A in the

fundamental, so a gluon exchanged between the two currents inserts $T^A_{\alpha\beta}\otimes T^A_{\gamma\delta}$ on the colour indices of the four external quarks. The SU(N) Fierz (completeness) identity for the fundamental generators, established in Section B.3.2, is

$$T^A_{\alpha\beta}\,T^A_{\gamma\delta} = \tfrac{1}{2}\Big(\delta_{\alpha\delta}\,\delta_{\gamma\beta} - \tfrac{1}{N}\,\delta_{\alpha\beta}\,\delta_{\gamma\delta}\Big), \tag{40.149}$$

with $N = 3$ for QCD. The two colour structures on the right are precisely the two appearing in Q_1 and Q_2: the cross-contraction $\delta_{\alpha\delta}\delta_{\gamma\beta}$ rearranges a singlet$\times$singlet into the colour-mixed structure, while $\delta_{\alpha\beta}\delta_{\gamma\delta}$ returns the original singlet$\times$singlet. Thus the gluon exchange, acting on the colour-singlet operator Q_2, produces a piece proportional to the colour-rearranged operator (which, after the spinor Fierz step below, is Q_1) with weight $+\frac{1}{2}$, and a piece proportional to Q_2 itself with weight $-\frac{1}{2N}$. This is the algebraic heart of the mixing: *Q_2 feeds Q_1 through the off-diagonal $\frac{1}{2}$, and reflects onto itself through the diagonal $-\frac{1}{2N}$.*

(b) The Dirac structure. The two quark propagators adjacent to the operator vertex and the gluon vertices contribute the Dirac string $\gamma^\mu P_L \not{k}\,\gamma^\alpha\otimes\gamma_\alpha\,\not{k}\,\gamma_\mu P_L$, with α the gluon Lorentz index contracted between the lines and k the loop momentum. Under the loop integral the numerator may be symmetrized, $k^\rho k^\sigma \to (k^2/d)\,g^{\rho\sigma}$ (Section D.4), leaving $(\gamma^\mu\gamma^\rho\gamma^\alpha P_L)\otimes(\gamma_\alpha\gamma_\rho\gamma_\mu P_L)$. Two reductions collapse this. The single-line contraction identity of Chapter 24's gamma-algebra conventions (Appendix C),

$$\gamma^\alpha\gamma^\rho\gamma_\alpha = (2-d)\,\gamma^\rho \xrightarrow{\;d\to 4\;} -2\,\gamma^\rho, \tag{40.150}$$

governs the index α once it is moved onto one chain, and the chiral Fierz identity for left-handed currents Section B.3.2,

$$(\gamma^\nu P_L)_{ij}(\gamma_\nu P_L)_{kl} = (\gamma^\nu P_L)_{il}(\gamma_\nu P_L)_{kj}, \tag{40.151}$$

shows that the $V\!-\!A$ structure is Fierz self-conjugate: the colour rearrangement of part (a) is accompanied by exactly the spinor rearrangement that reproduces the standard current$\times$current Dirac structure, so the colour-mixed term is genuinely Q_1 and the singlet term is genuinely Q_2, with no new Dirac structures generated. (This last statement is the assertion that, in the naive-dimensional-regularization scheme with anticommuting γ^5, no physical operator outside $\{Q_1, Q_2\}$ is induced at this order; the would-be extra structures are *evanescent* operators that vanish in $d = 4$, discussed in the remark below.) The net effect of (40.150) and (40.151) on the four cross diagrams, summed, is to reproduce the original $V\!-\!A\otimes V\!-\!A$ Dirac structure multiplied by the pure number 3 relative to the elementary gluon-exchange normalization (the same "3" that will appear in the matrix below); the mechanical string reduction yielding this factor uses only (40.150), (40.151), and the trace identities of Appendix C.

(c) The loop integral. The momentum integral common to all four cross diagrams is the logarithmically divergent

$$\int\frac{d^dk}{(2\pi)^d}\,\frac{k^\rho k^\sigma}{(k^2)^3} = \frac{g^{\rho\sigma}}{d}\int\frac{d^dk}{(2\pi)^d}\,\frac{1}{(k^2)^2} = \frac{g^{\rho\sigma}}{4}\cdot\frac{i}{16\pi^2}\,\frac{1}{\varepsilon} + (\text{finite}), \tag{40.152}$$

where the value of the master integral and the isolation of its ultraviolet pole (the infrared region being regulated by an off-shell external momentum that does not affect the $1/\varepsilon_{\rm UV}$ coefficient) are taken from Section D.4. The pole carries the factor $\alpha_s/4\pi$ once the two gluon vertices $(ig)^2$, the gluon propagator, and the i's are assembled, since $g^2/16\pi^2 = \alpha_s/4\pi$.

(d) Assembling Z and $\gamma^{(0)}$. Combining the colour weights of part (a) ($+\frac{1}{2}$ onto Q_1, $-\frac{1}{2N}$ onto Q_2), the Dirac factor 3 of part (b), and the pole $\frac{1}{\varepsilon}\,\frac{\alpha_s}{4\pi}$ of part (c), the one-loop counterterm needed to render $\langle Q_2\rangle$ finite is $\propto 3(\frac{1}{2}Q_1 - \frac{1}{2N}Q_2)$, and likewise with $1 \leftrightarrow 2$. In matrix form (40.138) this reads

$$a = \begin{pmatrix} \dfrac{3}{N} & -3 \\ -3 & \dfrac{3}{N} \end{pmatrix}, \qquad \gamma^{(0)} = -2a = \begin{pmatrix} -\dfrac{6}{N} & 6 \\ 6 & -\dfrac{6}{N} \end{pmatrix} \xrightarrow{N=3} \begin{pmatrix} -2 & 6 \\ 6 & -2 \end{pmatrix}. \tag{40.153}$$

The diagonal entries $-6/N$ are the colour-reflection ($-1/N$) pieces; the off-diagonal $+6$ is the colour-rearrangement ($+\frac{1}{2}$) piece, doubled by the -2 from $\gamma^{(0)} = -2a$ and carrying the Dirac factor 3. The matrix is symmetric, so $\gamma^{(0)\mathsf{T}} = \gamma^{(0)}$ and the transpose in (40.140) is immaterial at this order.

(e) Diagonalization. The eigenvectors of (40.153) are $(1,1)$ and $(1,-1)$, independent of N. Define the eigen-operators and eigen-coefficients

$$Q_\pm = \tfrac{1}{2}(Q_2 \pm Q_1), \qquad C_\pm = C_2 \pm C_1, \tag{40.154}$$

which indeed satisfy $C_1Q_1 + C_2Q_2 = C_+Q_+ + C_-Q_-$ (using $Q_2 = Q_+ + Q_-$, $Q_1 = Q_+ - Q_-$). In this basis $\gamma^{(0)}$ is diagonal with eigenvalues

$$\gamma^{(0)}_+ = -\frac{6}{N} + 6 = \frac{6(N-1)}{N} \xrightarrow{N=3} +4, \qquad \gamma^{(0)}_- = -\frac{6}{N} - 6 = -\frac{6(N+1)}{N} \xrightarrow{N=3} -8. \tag{40.155}$$

The opposite signs are the crucial fact: Q_+ has a *positive* anomalous dimension and Q_- a *negative* one, and (we will see) this drives C_- up and C_+ down as we evolve to low scales.

(f) Leading-log solution. In the $\pm$ basis the RG equation (40.140) decouples,

$$\mu\frac{dC_\pm}{d\mu} = \frac{\alpha_s(\mu)}{4\pi}\,\gamma^{(0)}_\pm\, C_\pm. \tag{40.156}$$

Trade μ for α_s using the one-loop QCD running $\mu\, d\alpha_s/d\mu = -b_0\,\alpha_s^2/(2\pi)$ from Eq. (27.1) (with $b_0 = \frac{11}{3}C_A - \frac{4}{3}T_F n_f = 11 - \frac{2}{3}n_f$ for SU(3) with n_f flavors). Then

$$\frac{dC_\pm}{C_\pm} = \frac{\gamma^{(0)}_\pm}{4\pi}\,\alpha_s\,\frac{d\mu}{\mu} = \frac{\gamma^{(0)}_\pm}{4\pi}\,\alpha_s\cdot\Big(-\frac{2\pi}{b_0}\frac{d\alpha_s}{\alpha_s^2}\Big) = -\frac{\gamma^{(0)}_\pm}{2b_0}\,\frac{d\alpha_s}{\alpha_s}, \tag{40.157}$$

and integrating from m_W down to μ,

$$\boxed{C_\pm(\mu) = \left[\frac{\alpha_s(m_W)}{\alpha_s(\mu)}\right]^{\gamma_\pm^{(0)}/2b_0} C_\pm(m_W)} \tag{40.158}$$

the leading-log resummation. With (40.148) the boundary condition is $C_+(m_W) = C_-(m_W) = 1$, and the exponents are

$$\frac{\gamma_+^{(0)}}{2b_0} = \frac{2}{b_0} > 0, \qquad \frac{\gamma_-^{(0)}}{2b_0} = -\frac{4}{b_0} < 0. \tag{40.159}$$

Since $\alpha_s(\mu) > \alpha_s(m_W)$ for $\mu < m_W$ (asymptotic freedom, Eq. (27.155)), the bracket in (40.158) is less than one; the positive exponent suppresses C_+ below unity, the negative exponent enhances C_- above unity. The ratio

$$\frac{C_-(\mu)}{C_+(\mu)} = \left[\frac{\alpha_s(\mu)}{\alpha_s(m_W)}\right]^{6/b_0} > 1 \tag{40.160}$$

grows monotonically toward low scales: this is the *QCD enhancement* of the colour-antisymmetric over the colour-symmetric channel. Numerically, evolving with the one-loop α_s and proper flavor thresholds (Fig. 40.8) gives, at $\mu \simeq m_c$,

$$C_+(\mu) \simeq 0.78, \quad C_-(\mu) \simeq 1.64 \implies C_1(\mu) \simeq -0.43, \quad C_2(\mu) \simeq 1.21, \tag{40.161}$$

and at $\mu \simeq 1\,\text{GeV}$ the splitting widens to $C_+ \simeq 0.76$, $C_- \simeq 1.72$ (so $C_1 \simeq -0.48$, $C_2 \simeq 1.24$). A coefficient C_1 that vanished identically at m_W has been driven to $\simeq -\frac{1}{2}$ purely by QCD; this is the resummed content of the large logarithms that a fixed-order calculation could only approximate.

Remark 40.23 (Evanescent operators and scheme dependence). The clean two-operator closure used above is exact at one loop only with a choice of how to continue γ^5 and the Dirac algebra to $d \neq 4$. The Fierz identity (40.151) holds in $d = 4$ but is violated by $O(\varepsilon)$ terms in d dimensions; the difference is an *evanescent* operator, one that vanishes in four dimensions but whose $O(\varepsilon)$ matrix element multiplies a $1/\varepsilon$ pole to leave a finite, scheme-dependent contribution. A consistent treatment fixes a prescription (the naive-dimensional-regularization scheme used here, with anticommuting γ^5, is one standard choice) and renormalizes the evanescent operators to zero. The leading-order $\gamma^{(0)}$ of (40.153) is scheme-*independent*; the scheme dependence enters first in $C_\pm(m_W)$ at next-to-leading order and in $\gamma^{(1)}$, and cancels against the matrix-element calculation in any physical observable. We carry only the scheme-independent leading log here; the next-to-leading machinery is referenced in the Further reading.

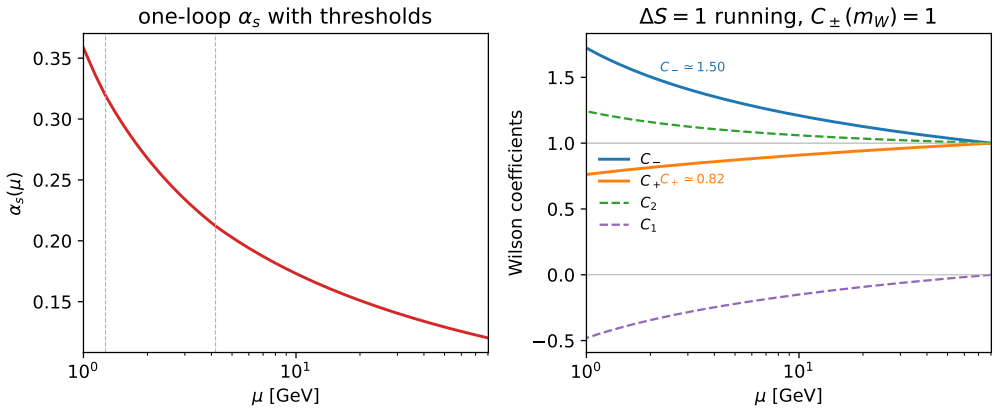

Figure 40.8: Leading-log running of the $\Delta S = 1$ Wilson coefficients, obtained by integrating (40.140) from the matching scale m_W to low scales with the one-loop $\alpha_s(\mu)$ (left panel; flavor thresholds matched continuously at m_b, m_c). Right panel: the eigen-coefficients $C_\pm$ (solid) with $C_\pm(m_W) = 1$, and the physical-basis coefficients C_1, C_2 (dashed). The colour-antisymmetric coefficient C_- is enhanced and C_+ suppressed, the gap widening toward low μ where α_s grows. Generated by `figures/40-deltaS1-running.py`.

40.6.4 The same machine: dimension-six SMEFT

Everything above transfers verbatim to the Standard Model Effective Field Theory. The dimension-six operators of the Warsaw basis carry Wilson coefficients $C_i(\mu)$ fixed by matching at the new-physics scale Λ (or at m_W for electroweak matching), and confronted with data at m_Z or below. Between those scales they run and mix, governed by the identical equation

$$\mu \frac{dC_i}{d\mu} = \frac{1}{16\pi^2} \left(\hat{\gamma}^{\mathsf{T}}\right)_{ij} C_j, \tag{40.162}$$

now with $\hat{\gamma}$ receiving contributions from all the Standard Model gauge couplings g_s, g, g', the Yukawa couplings, and the Higgs self-coupling, since all of these dress the dimension-six operators. For a single fermion generation, restricting to baryon-number-conserving operators, the Warsaw basis contains 59 independent operators, and the complete one-loop 59×59 anomalous-dimension matrix $\hat{\gamma}$ has been computed in full; we cite this result rather than reproduce it, as it is a bookkeeping enterprise rather than a new principle (the principle is exactly Theorem 40.21). Its structure is instructive: the matrix is far from arbitrary. Many entries vanish for reasons of symmetry and holomorphy (Higgs-number, chirality, and a non-renormalization pattern that forbids certain "upward" mixings), so $\hat{\gamma}$ has a sparse, approximately block-triangular form; this is why a low-energy bound on one coefficient typically constrains only a definite subset of high-scale operators.

The load-bearing sub-block is the one we have already computed. The purely-QCD part of $\hat{\gamma}$, acting on the four-quark operators of the Warsaw basis, is built from *exactly* the current-current diagrams, colour identity (40.149), and chiral Fierz (40.151) of Theorem 40.22. A pair of four-quark operators differing only by their colour contraction — the SMEFT analogues of Q_1 and Q_2 — mixes under QCD through precisely the matrix (40.153),

$$\hat{\gamma}_{\text{QCD}}\big|_{\text{4-quark colour pair}} = 4\pi\,\alpha_s \begin{pmatrix} -6/N & 6 \\ 6 & -6/N \end{pmatrix} = g_s^2 \begin{pmatrix} -6/N & 6 \\ 6 & -6/N \end{pmatrix}, \tag{40.163}$$

identical in form to the $\Delta S = 1$ result because the colour and chiral algebra are identical; only the flavor labels and the matching coefficients differ. The genuinely new SMEFT entries — gauge and Yukawa mixings, the running of the dipole operators, the feeding of four-fermion operators into dipoles that dominates the $b \to s\gamma$ analysis, the mixing of O_{HWB} and O_{HD} that controls the oblique parameters — are obtained by the same Theorem 40.21 machinery with the relevant vertices in place of the gluon, and are collected in the cited literature. The lesson is uniform: there is one renormalization-group equation for Wilson coefficients, (40.140), and the entire apparatus of weak-Hamiltonian and SMEFT running is its anomalous-dimension matrix worked out diagram by diagram.

With the coefficients evolved from the matching scale down to the measurement scale and the large logarithms resummed, the Wilson coefficients are at last in the form a low-energy experiment actually constrains. The next section makes that confrontation explicit: a precision measurement bounds a combination of $C_i(\mu_{\text{low}})$, which — run back up through (40.140) — becomes a bound on the scale and structure of the physics that was integrated out.

40.7 The EFT view of precision physics

The previous section closed the technical program of this chapter: starting from Wilson coefficients defined by matching at a high scale (Section 40.5), we ran them down to the scale of measurement with the anomalous-dimension matrix of Section 40.6, resumming the large logarithms and tracking the operator mixing that the renormalization group of Chapter 24 forces upon operators of equal dimension. We now have, at the electroweak scale, a set of low-energy Wilson coefficients ready to be confronted with data. This final section is where the confrontation happens, and where the whole apparatus of the chapter — and of Part XI — earns its keep. The thesis is simple to state and will take the section to make precise: *a precision measurement is a measurement of Wilson coefficients*, and because each higher-dimension coefficient carries an inverse power of the scale Λ at which new physics lives, every precision number is, read

correctly, a statement about Λ and about the symmetry structure of whatever waits above it. The Standard Model Effective Field Theory (SMEFT) is the dictionary that performs the translation, and by the mid-2020s it has become the common language in which essentially all model-independent searches for physics beyond the Standard Model are phrased. We build the dictionary, work one entry of it in full numerical detail, survey the live classes of observable that feed it, revisit the hierarchy problem through its lens, give an honest dated status of the enterprise, and finally close the loop by recognizing that HQET and SMEFT — the top-down and bottom-up faces of this chapter — are one method seen from two sides.

Throughout we use the conventions in force in this chapter: the mostly-minus metric $\eta_{\mu\nu} = \mathrm{diag}(+,-,-,-)$, natural units, the electroweak covariant derivative $D_\mu = \partial_\mu - igW_\mu^a T^a - ig' Y B_\mu$ of Theorem 31.3, and $\overline{\mathrm{MS}}$ with $d = 4-2\varepsilon$. The Standard Model field content, gauge group $\mathrm{SU}(3)_c \times \mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$, and the accidental B and L symmetries are imported wholesale from Chapter 33. The SMEFT itself — the organizing principle that the Standard Model is the renormalizable truncation of a tower of local operators built from Standard Model fields and invariant under $\mathrm{SU}(3)_c \times \mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$, with the leading corrections the dimension-six operators of the Warsaw basis — was set up in Section 40.4 and Section 40.4.5; we build on it here rather than reconstruct it.

40.7.1 From a measurement to a scale

The structural fact that makes precision physics into a probe of short distances is the power counting of the effective expansion. Write the effective Lagrangian below the new-physics scale Λ in the SMEFT form fixed in Section 40.4,

$$\mathcal{L}_{\mathrm{SMEFT}} \;=\; \mathcal{L}_{\mathrm{SM}} \;+\; \sum_i \frac{C_i^{(6)}}{\Lambda^2}\,\mathcal{O}_i^{(6)} \;+\; \sum_i \frac{C_i^{(8)}}{\Lambda^4}\,\mathcal{O}_i^{(8)} \;+\; \cdots , \tag{40.164}$$

where each $\mathcal{O}_i^{(d)}$ is a gauge-invariant local operator of mass dimension d built from Standard Model fields, the $C_i^{(d)}$ are dimensionless Wilson coefficients, and odd-dimension operators are absent at dimension five for any B-conserving observable and suppressed by the lepton-number scale at dimension five generally (Section 40.4.5; the unique dimension-five operator is the Weinberg neutrino-mass operator). The dimension-six operators dominate the new-physics effects on any B- and L-conserving process, and they are the subject of this section.

Consider a dimensionless observable $\mathcal{O}$ — a cross section ratio, a branching fraction, a pole-mass relation, an asymmetry — whose Standard Model prediction is $\mathcal{O}_{\mathrm{SM}}$ and which probes a characteristic energy E. A single dimension-six operator shifts it by an amount fixed on dimensional grounds: the operator insertion brings a factor C_i/Λ^2, and the only other scale available to restore the dimensions of a dimensionless quantity is E (which may be the collision energy, a

particle mass, or the Higgs vacuum expectation value v, whichever the observable is built from). Hence

$$\frac{\Delta\mathcal{O}}{\mathcal{O}_{\rm SM}} \;\simeq\; c\,\frac{C_i\,E^2}{\Lambda^2}, \tag{40.165}$$

with c an $O(1)$ number computed by matching the operator onto the amplitude for the process. Two regimes of Eq. (40.165) organize all of precision physics, and we will see both at work.

Proposition 40.24 (From a null measurement to a reach)**.** *Suppose the observable $\mathcal{O}$ is measured to agree with its Standard Model prediction within a fractional precision δ, i.e. $|\Delta\mathcal{O}/\mathcal{O}_{\rm SM}| \le \delta$ at the chosen confidence level. Then Eq. (40.165) excludes*

$$\frac{\Lambda}{\sqrt{|c\,C_i|}} \;\ge\; \frac{E}{\sqrt{\delta}}. \tag{40.166}$$

For a coefficient of natural size $|c\,C_i| = O(1)$ this is a lower bound on the scale of new physics; for a measured deviation $|\Delta\mathcal{O}/\mathcal{O}_{\rm SM}| = \Delta \neq 0$ the same relation reads $\Lambda/\sqrt{|c\,C_i|} = E/\sqrt{\Delta}$ and becomes a determination *of Λ up to the unknown coefficient.*

Proof. Rearrange Eq. (40.165) for Λ^2 and impose $|\Delta\mathcal{O}/\mathcal{O}_{\rm SM}| \le \delta$: $|c\,C_i|E^2/\Lambda^2 \le \delta$ gives $\Lambda^2 \ge |c\,C_i|E^2/\delta$, which is Eq. (40.166). The equality case is immediate. The only content beyond dimensional analysis is that Λ enters quadratically because the leading operator is dimension six; were the leading operator dimension eight the bound would scale as $\delta^{-1/4}$, a weaker dependence that is exactly why the dimension-six layer is the one precision physics constrains first. □

Theorem 40.24 is deceptively elementary and completely central. It says that the reach in Λ is the product of two independent levers: the energy E at which the observable lives, entering linearly, and the inverse square root of the precision δ. Pushing either lever buys reach, and the two define the two experimental frontiers (Fig. 40.9). The *precision frontier* fixes E at a low value — the electroweak scale $v \approx 246$ GeV, or a quark mass — and drives δ down: electroweak pole observables measured at the per-mille level, Higgs signal strengths at the few-percent level, flavor transitions whose Standard Model rates are tiny and therefore exquisitely sensitive to additive new contributions. The *energy frontier* accepts a modest δ but raises E into the TeV range, exploiting the explicit E^2/Λ^2 growth of Eq. (40.165): the high-invariant-mass tails of Drell-Yan and diboson production, where a contact operator's contribution grows with energy relative to the Standard Model background and a ten-percent measurement at $E \sim 2$ TeV already probes Λ of several TeV. The two frontiers are complementary in the precise sense that they constrain the same Wilson coefficients through different windows of Eq. (40.165), and a global fit (Section 40.7.3) combines them.

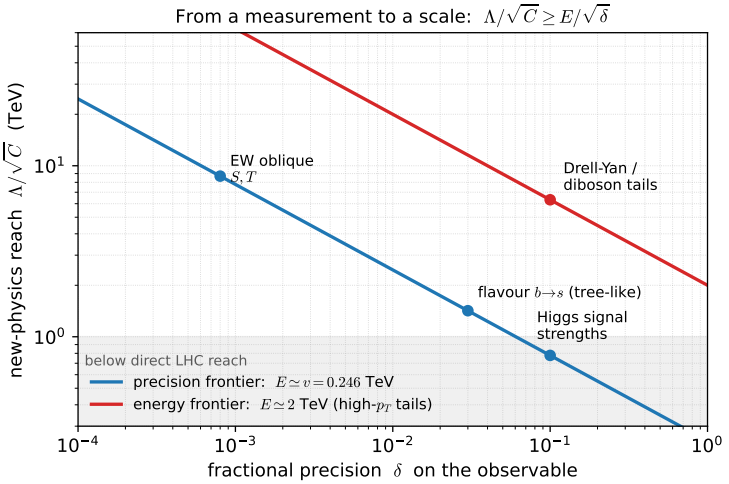

Figure 40.9: The two roads from a measurement to a new-physics scale, plotting the reach $\Lambda/\sqrt{C} \geq E/\sqrt{\delta}$ of Eq. (40.166) against the fractional precision δ. The precision frontier (blue) pins the probed energy at the electroweak scale $E \simeq v$ and buys reach by shrinking δ; the energy frontier (red) accepts modest δ but raises E into the TeV range, exploiting the E^2/Λ^2 growth of the dimension-six contribution. Representative observable classes are marked. Coefficients of $O(1)$ are assumed; loop- or CKM-suppressed Standard Model amplitudes (much of flavor) shift the points upward because the relative new-physics effect is enhanced.

Caution

The bound Eq. (40.166) is a statement about the ratio $\Lambda/\sqrt{|c\,C_i|}$, never about Λ alone. A measurement cannot separate a high scale with an $O(1)$ coefficient from a lower scale with a small coefficient: $\Lambda = 10$ TeV with $C = 1$ and $\Lambda = 1$ TeV with $C = 10^{-2}$ are indistinguishable to Eq. (40.165). The quoted "reach in Λ" always carries the silent assumption $|c\,C_i| = O(1)$, which is the assumption that the underlying theory is not weakly coupled or accidentally aligned. Reporting a reach without stating the coefficient convention is the single most common abuse of SMEFT numbers; we state it every time.

40.7.2 The oblique parameters as dimension-six coefficients

The cleanest illustration of the dictionary is the electroweak precision program, because there the new-physics effects of a wide class of theories collapse onto a short list of universal parameters. Recall from Section 34.3 the oblique (Peskin–Takeuchi) parameters S, T, U: they capture new physics that enters only through the vacuum polarizations of the electroweak gauge bosons — the "oblique"

corrections — as opposed to corrections to specific vertices or boxes. Writing $\Pi_{XY}(q^2)$ for the new-physics part of the X–Y gauge-boson self-energy ($X, Y \in \{W, Z, \gamma\}$, or in the unbroken basis the $\mathrm{SU}(2)_L$ currents $1, 2, 3$ and the hypercharge current B), the standard definitions imported from Section 34.3 are

$$\alpha\, T \;=\; \frac{\Pi_{WW}(0)}{m_W^2} - \frac{\Pi_{ZZ}(0)}{m_Z^2}, \tag{40.167}$$

$$\alpha\, S \;=\; 4\,\sin^2\!\theta_{\mathrm{W}}\cos^2\!\theta_{\mathrm{W}}\,\frac{\Pi_{ZZ}(m_Z^2) - \Pi_{ZZ}(0)}{m_Z^2} \;-\; (\gamma Z \text{ and } \gamma\gamma \text{ pieces}), \tag{40.168}$$

with α the fine-structure constant at m_Z and θ_{W} the weak mixing angle of Chapter 31. The parameter T measures the breaking of custodial symmetry — the difference between the charged- and neutral-current normalizations at zero momentum — while S measures the momentum-dependence of the neutral-current self-energy, i.e. a γ–Z kinetic mixing. We now show that each of these is, in SMEFT, the coefficient of one specific dimension-six operator.

The T parameter and custodial symmetry. Custodial symmetry was introduced in Section 31.6: the Higgs potential and kinetic term possess an accidental global $\mathrm{SU}(2)_L \times \mathrm{SU}(2)_R$ invariance, broken spontaneously by the vacuum expectation value to the diagonal custodial $\mathrm{SU}(2)_V$ (Theorem 31.22), and it is this residual symmetry that forces the tree-level relation $\rho \equiv m_W^2/(m_Z^2\cos^2\!\theta_{\mathrm{W}}) = 1$ (Section 31.6.5). Hypercharge gauging breaks $\mathrm{SU}(2)_R$ explicitly, which is why ρ receives radiative corrections, but at tree level the relation is exact. Any new operator that violates custodial symmetry will shift ρ away from one, and the deviation $\Delta\rho = \rho - 1$ is, by Eq. (40.167) and $\rho = 1 + \alpha T$, precisely αT. The question is which dimension-six operator does this.

In the Warsaw basis of Section 40.4.5 the relevant operator is

$$\mathcal{O}_{HD} \;=\; (H^\dagger D_\mu H)^*(H^\dagger D^\mu H), \tag{40.169}$$

where H is the Higgs doublet with hypercharge $Y_H = \tfrac{1}{2}$. We evaluate its effect on the gauge-boson masses by setting the Higgs to its vacuum configuration. In unitary gauge $H = \frac{1}{\sqrt{2}}(0,\, v + h)^\top$; for the mass terms we need only the constant part $H \to \frac{1}{\sqrt{2}}(0,\, v)^\top$. With $T^a = \tau^a/2$ on the doublet (τ^a the Pauli matrices) and $Y_H = \tfrac{1}{2}$, the covariant derivative Eq. (31.25) gives

$$D_\mu H \;=\; -\,i\Big(g\,W_\mu^a T^a + g'\tfrac{1}{2}B_\mu\Big)H, \tag{40.170}$$

so that, contracting with $H^\dagger$ and using $H^\dagger T^3 H = -\tfrac{1}{4}v^2$, $H^\dagger T^{1,2} H = 0$, and $H^\dagger H = \tfrac{1}{2}v^2$ at the vacuum,

$$H^\dagger D_\mu H \;=\; -\,i\,\frac{v^2}{4}\big(-\,g\,W_\mu^3 + g'\,B_\mu\big). \tag{40.171}$$

The combination $gW_\mu^3 - g'B_\mu$ is, by the definition of the neutral mass eigenstate (Section 31.3.4), proportional to the Z field: $gW_\mu^3 - g'B_\mu = \sqrt{g^2+g'^2}\,Z_\mu = (2m_Z/v)Z_\mu$, since $m_Z = \frac{1}{2}v\sqrt{g^2+g'^2}$. The photon, the orthogonal combination, drops out entirely. Hence

$$H^\dagger D_\mu H \;=\; i\,\frac{v\,m_Z}{2}\,Z_\mu, \qquad \mathcal{O}_{HD}\big|_{\rm vac} \;=\; \frac{v^2 m_Z^2}{4}\,Z_\mu Z^\mu. \tag{40.172}$$

The operator produces a pure Z mass term and no W mass term — it is manifestly custodial-violating, exactly as anticipated, because it singles out the neutral direction. Adding its contribution from Eq. (40.164) to the Standard Model neutral mass term $\frac{1}{2}m_Z^2 Z_\mu Z^\mu$,

$$\frac{1}{2}m_Z^2 Z_\mu Z^\mu \;+\; \frac{C_{HD}}{\Lambda^2}\,\frac{v^2 m_Z^2}{4}\,Z_\mu Z^\mu \;=\; \frac{1}{2}m_Z^2\Big(1+\frac{C_{HD}}{\Lambda^2}\frac{v^2}{2}\Big)Z_\mu Z^\mu, \tag{40.173}$$

we read off the fractional shift of the neutral mass-squared, $\delta_Z = (C_{HD}/\Lambda^2)(v^2/2)$, with the charged mass m_W untouched. The ρ parameter therefore moves to

$$\rho \;=\; \frac{m_W^2}{m_Z^2(1+\delta_Z)\cos^2\theta_{\rm W}} \;=\; 1-\delta_Z + O(\delta_Z^2), \tag{40.174}$$

so $\Delta\rho = -\delta_Z$, and with $\alpha T = \Delta\rho$,

$$\boxed{\alpha\,T \;=\; -\,\frac{v^2}{2}\,\frac{C_{HD}}{\Lambda^2}} \tag{40.175}$$

This is the explicit identification of the T parameter with a single dimension-six Wilson coefficient. The custodial symmetry of Section 31.6 is what guarantees that no *other* dimension-six operator contributes to T at tree level: an operator can shift ρ only if it violates custodial $\mathrm{SU}(2)_V$, and in the Warsaw basis $\mathcal{O}_{HD}$ is the unique such operator built from Higgs and gauge fields that generates a Z–W mass splitting at tree level. The selection rule is a direct consequence of the symmetry, not an accident of the basis.

The S parameter and γ–Z mixing. The companion operator is

$$\mathcal{O}_{HWB} \;=\; (H^\dagger \tau^a H)\,W^a_{\mu\nu}B^{\mu\nu}, \tag{40.176}$$

with τ^a the Pauli matrices and $W^a_{\mu\nu}$, $B_{\mu\nu}$ the field strengths. At the vacuum $H^\dagger\tau^3 H = -\frac{1}{2}v^2$ and the other components vanish, so

$$\mathcal{O}_{HWB}\big|_{\rm vac} \;=\; -\,\frac{v^2}{2}\,W^3_{\mu\nu}B^{\mu\nu}. \tag{40.177}$$

$$\mathcal{O}_{HWB}: \ \propto C_{HWB}\, v^2\, (q^2 \eta_{\mu\nu} - q_\mu q_\nu)$$

Figure 40.10: The S parameter as a dimension-six effect. The operator $\mathcal{O}_{HWB}$, evaluated at the Higgs vacuum, produces the γ–Z kinetic-mixing two-point insertion (crossed dot) of Eq. (40.178), momentum-dependent and transverse. Inserted into the neutral gauge propagator between fermion currents f, it shifts the effective on-shell couplings exactly in the pattern that the oblique parameter S of Section 34.3 measures. The companion operator $\mathcal{O}_{HD}$ produces instead a momentum-independent Z mass shift (the T parameter).

Rotating to mass eigenstates with $W^3_\mu = \cos\theta_{\rm W}\, Z_\mu + \sin\theta_{\rm W}\, A_\mu$ and $B_\mu = -\sin\theta_{\rm W}\, Z_\mu + \cos\theta_{\rm W}\, A_\mu$, the product of abelian field strengths is

$$W^3_{\mu\nu} B^{\mu\nu} = -\sin\theta_{\rm W}\cos\theta_{\rm W}\, Z_{\mu\nu} Z^{\mu\nu} + (\cos^2\theta_{\rm W} - \sin^2\theta_{\rm W})\, Z_{\mu\nu} A^{\mu\nu} + \sin\theta_{\rm W}\cos\theta_{\rm W}\, A_{\mu\nu} A^{\mu\nu}. \tag{40.178}$$

The middle term is a kinetic mixing of the photon and the Z: a momentum-dependent off-diagonal piece $\propto q^2$ in the neutral self-energy matrix, which is exactly the structure that S in Eq. (40.168) was built to measure. Diagrammatically the operator inserts a two-point γ–Z vertex proportional to $q_\mu q_\nu - q^2 \eta_{\mu\nu}$ into the gauge propagator (Fig. 40.10); feeding this into the definition imported from Section 34.3 gives

$$\boxed{\alpha\, S \ = \ 4\, \sin\theta_{\rm W} \cos\theta_{\rm W}\, v^2\, \frac{C_{HWB}}{\Lambda^2}} \tag{40.179}$$

We quote the overall constant $4 \sin\theta_{\rm W}\cos\theta_{\rm W}$ from the Peskin–Takeuchi normalization of Section 34.3 rather than re-derive the self-energy projection here, but the structural content — that S is the coefficient of the γ–Z kinetic-mixing operator $\mathcal{O}_{HWB}$, just as T is the coefficient of the custodial-violating mass operator $\mathcal{O}_{HD}$ — is established by Eq. (40.178) in full.

Physical Insight

The third oblique parameter U has no dimension-six representative at all. U measures a custodial- *and* isospin-violating piece of the W self-energy that, in the operator language, requires either two insertions of the Higgs vacuum beyond what S and T use or a genuinely higher-dimension structure; in the Warsaw basis the leading operator contributing to U is dimension eight. The SMEFT therefore makes a sharp, falsifiable prediction: at the dimension-six level that dominates the expansion, $U \approx 0$, and the electroweak data should be describable by S and T alone (together

with shifts in the input parameters). That two numbers suffice where the model-independent oblique analysis allowed three is not an assumption put in by hand — it is the power counting of Eq. (40.166) asserting that dimension-eight effects are smaller by E^2/Λ^2. Global electroweak fits are routinely performed both ways, and the $U \approx 0$ restriction is the SMEFT-motivated default.

We now turn the identification Eq. (40.175) into a number.

Worked Example 40.25 (The T parameter as a bound on Λ)**.** The global electroweak fit, as of the mid-2020s, constrains the oblique parameters at the level of about a tenth: with S and T floated together (and $U = 0$ imposed, per the dimension-six logic above) the data are consistent with the Standard Model, $T = 0.0 \pm 0.1$ at roughly the one-to-two-sigma level, the precise central value depending on the treatment of the disputed 2022 CDF W-boson mass measurement (Section 40.7.6). We take $|T| \leq 0.1$ as a representative exclusion and translate it into a reach on Λ for the operator $\mathcal{O}_{HD}$.

From Eq. (40.175),

$$|T| = \frac{v^2}{2\alpha}\frac{|C_{HD}|}{\Lambda^2} \quad \Longrightarrow \quad \frac{\Lambda}{\sqrt{|C_{HD}|}} = \sqrt{\frac{v^2}{2\alpha\,|T|}}. \tag{40.180}$$

Insert the numbers. The electroweak scale is $v = 246$ GeV, so $v^2 = 6.05 \times 10^4$ GeV^2; the fine-structure constant at m_Z is $\alpha = \alpha(m_Z) \approx 1/128 = 7.82 \times 10^{-3}$; and $|T| \leq 0.1$. Then

$$\frac{v^2}{2\alpha\,|T|} = \frac{6.05 \times 10^4\ \text{GeV}^2}{2\,(7.82 \times 10^{-3})\,(0.1)} = \frac{6.05 \times 10^4}{1.56 \times 10^{-3}}\ \text{GeV}^2 = 3.87 \times 10^7\ \text{GeV}^2, \tag{40.181}$$

and taking the square root,

$$\frac{\Lambda}{\sqrt{|C_{HD}|}} \gtrsim 6.2\ \text{TeV}. \tag{40.182}$$

A custodial-violating new sector that couples to the Higgs with an $O(1)$ Wilson coefficient must therefore lie above roughly 6 TeV, or it would already have shown up as a deviation of the ρ parameter from unity. Three features of the number are worth stating explicitly. First, it lies *above* the energy directly produced at the Large Hadron Collider: a precision measurement at the electroweak scale has reached past the energy frontier by exploiting the small δ of Eq. (40.166) — this is the precision frontier doing its job. Second, the bound is enormously stronger than the naive $\Lambda \gtrsim v/\sqrt{|T|} \approx 0.78$ TeV one would guess by ignoring the factor $1/\alpha$ in Eq. (40.180); the enhancement is the gauge-coupling suppression of the oblique self-energy, $\alpha T = \Delta\rho$, which makes T an unusually sensitive probe.

Third, and most importantly for the logic of the chapter, no model was specified: the bound constrains *any* ultraviolet completion through the single number C_{HD}, and a given model is tested by computing its C_{HD} by matching (Section 40.5) and comparing to Eq. (40.182). That is the inverse problem of precision physics solved in one line.

40.7.3 The live classes of observable

The oblique parameters are one entry in a much larger dictionary. By the mid-2020s the SMEFT is fit globally to several hundred measurements at once, and it is worth surveying the classes of observable that feed the fit, because each probes a different corner of the operator space and each carries a different experimental and theoretical character.

Electroweak precision observables. The Z-pole data from LEP and SLC — partial widths, asymmetries, the effective weak mixing angle — together with the W mass measure the gauge-fermion couplings and the gauge-boson self-energies at the per-mille level. In SMEFT they constrain $\mathcal{O}_{HD}$, $\mathcal{O}_{HWB}$ (the oblique combinations above), and the vertex-correction operators such as $\mathcal{O}_{H\ell}^{(1,3)}$ and $\mathcal{O}_{He}$ that modify the Z couplings to individual fermions. This is the most precise sector and the source of the strongest *universal* bounds, of order several TeV for $O(1)$ coefficients, as Theorem 40.25 illustrates.

Higgs couplings and signal strengths. Since the discovery of the Higgs boson (Section 34.4) its production and decay rates have been measured in many channels. The natural SMEFT observable is the signal strength

$$\mu_{if} \;=\; \frac{\sigma_i \cdot \mathrm{BR}_f}{(\sigma_i \cdot \mathrm{BR}_f)_{\mathrm{SM}}}, \tag{40.183}$$

the ratio of the observed rate in production channel i and decay channel f to its Standard Model value, normalized so that $\mu = 1$ is the Standard Model. Dimension-six operators shift the Higgs couplings away from their Standard Model values — $\mathcal{O}_{H\Box}$ and $\mathcal{O}_{HD}$ rescale all couplings through the Higgs kinetic normalization, $\mathcal{O}_{HW}$, $\mathcal{O}_{HB}$, $\mathcal{O}_{HWB}$, $\mathcal{O}_{HG}$ generate new tensor structures in $h \to \gamma\gamma$, $h \to Z\gamma$, $gg \to h$, and the Yukawa-like operators $\mathcal{O}_{uH}$, $\mathcal{O}_{dH}$, $\mathcal{O}_{eH}$ shift the fermion couplings — so that $\mu_{if} - 1 \simeq (\text{linear combination of } C_i)\, v^2/\Lambda^2$, matching the precision-frontier line of Fig. 40.9 with $E \simeq v$. The current few-percent precision on the leading channels translates into reaches of order 1 TeV for individual $O(1)$ coefficients, improving steadily.

High-energy tails. The energy frontier of Eq. (40.166) is realized in the high-invariant-mass or high-p_T tails of $2 \to 2$ processes: Drell-Yan ($pp \to \ell^+\ell^-$ and

$pp \to \ell\nu$) probes four-fermion operators and dipole operators whose amplitudes grow as E^2/Λ^2 relative to the Standard Model; diboson production ($pp \to WW, WZ$) probes the triple-gauge-coupling operator $\mathcal{O}_W$ with the same energy growth. Here a measurement at $E \sim 2$ TeV with $\delta \sim 10\%$ already reaches $\Lambda \sim 6$ TeV, and the reach climbs with collider energy. The growth is double-edged: it is what gives the sensitivity, but it is also where the dimension-six truncation of Eq. (40.164) is most strained, since E^2/Λ^2 is no longer small and the neglected dimension-eight terms grow faster still (Section 40.7.6).

Flavor observables. Processes that are suppressed in the Standard Model are the most sensitive of all, because a new contribution is measured against a small background rather than a large one. The flavor-changing neutral-current transitions $b \to s$ — $B \to K^{(*)}\ell^+\ell^-$, $B \to X_s\gamma$, $B_s \to \mu^+\mu^-$ — occur in the Standard Model only through loop- and CKM-suppressed penguin and box diagrams, the very $\Delta F = 1$ operators whose mixing was carried in full in Section 40.6. A dimension-six four-fermion or dipole operator that contributes at tree level competes with a Standard Model amplitude that is itself of order $G_F\alpha/(4\pi)$ times small CKM factors; the relative new-physics effect is correspondingly enhanced, and the reach in Λ can exceed tens of TeV for operators that are unsuppressed in the new sector — which is also why these observables impose the tightest constraints on the *flavor structure* of any TeV-scale extension (the flavor problem). These are live, evolving constraints: the $b \to s\ell\ell$ data showed intriguing tensions (the R_K, R_{K^*} lepton-universality ratios, and angular observables in $B \to K^*\mu\mu$) through the late 2010s and early 2020s that, by the mid-2020s, have largely regressed toward the Standard Model as measurements matured, leaving the field watching rather than concluding.

Dipole moments. The electron and muon anomalous magnetic moments and the electric dipole moments are the dimension-six dipole operators $\mathcal{O}_{eW}$, $\mathcal{O}_{eB}$ (and their quark analogs) evaluated at zero momentum. This is a thread we have followed since Chapter 20: the Standard Model value of the electron's anomaly, Schwinger's $a_e = \alpha/2\pi$, was recovered in Section 40.3.5 as the matching coefficient of the magnetic-moment operator in NRQED. The very same operator, promoted to the SMEFT, becomes the dipole Wilson coefficient whose deviation from the Standard Model prediction would signal new physics. The muon anomaly a_μ in particular was, through the early 2020s, the most discussed potential deviation, though the comparison rests on a Standard Model hadronic-vacuum-polarization input over which the data-driven and lattice determinations disagree (Section 40.7.6). In SMEFT language the would-be signal is a single number, $C_{eW}\sin\theta_W + C_{eB}\cos\theta_W$ for the muon, and a measured a_μ anomaly would fix it exactly as Theorem 40.24 fixes Λ from a deviation.

These classes are not analyzed in isolation. The defining methodological

feature of the mid-2020s SMEFT program is the *global fit*: all of the above are expressed as linear (and, increasingly, quadratic) functions of the same set of Warsaw-basis coefficients C_i/Λ^2, run to a common scale by the machinery of Section 40.6, and fit simultaneously. The output is not a single number but a multidimensional likelihood in the space of Wilson coefficients, with flat directions where different operators produce correlated effects that the available observables cannot disentangle, and sharp directions where a single precise measurement dominates. Reading that likelihood — understanding which combinations are constrained, which are blind, and what new measurement would break a given degeneracy — is the practical content of precision physics today.

40.7.4 The hierarchy problem through the EFT lens

The same power counting that makes precision physics a probe of high scales turns, when applied to the one super-renormalizable operator in the Standard Model, into the sharpest statement of the hierarchy problem. The naturalness criterion was developed abstractly in Section 38.6: a Wilson coefficient should be of order the natural size set by its mass dimension and the cutoff, unless a symmetry protects it, and a coefficient much smaller than its natural size is technically unnatural — fine-tuned — and demands explanation.

Apply this to the Higgs mass term. In the operator counting of Eq. (40.164) the operators are sorted by dimension; the *relevant* operator $H^\dagger H$ has dimension two, below the marginal renormalizable operators, and carries a coefficient with dimension mass-squared:

$$\mathcal{L} \supset -\mu_H^2\, H^\dagger H, \qquad \mu_H^2 = c_H\, \Lambda^2, \tag{40.184}$$

where naturalness asserts $c_H = O(1)$ unless protected. Here Λ is the scale of whatever ultraviolet physics the Standard Model is an effective theory of — the same Λ that the precision observables of this section are bounding. The measured value is fixed by the physical Higgs mass and vacuum expectation value, $\mu_H^2 \simeq m_h^2/2 \simeq (88\ \text{GeV})^2$. The hierarchy problem is the collision of this measured value with Eq. (40.184): if there is any new physics at a scale Λ — and the dimension-six operators of this section presuppose there is — then c_H must be tuned to

$$c_H = \frac{\mu_H^2}{\Lambda^2} \sim \left(\frac{88\ \text{GeV}}{\Lambda}\right)^2, \tag{40.185}$$

which for Λ at the precision-frontier reach of Theorem 40.25, $\Lambda \sim 6$ TeV, already demands $c_H \sim 2 \times 10^{-4}$, a tuning of one part in a few thousand, and for Λ at a grand-unified ($\sim 10^{16}$ GeV) or Planckian ($\sim 10^{19}$ GeV) scale demands a tuning of one part in 10^{28} or 10^{34}. No symmetry of the Standard Model forbids the operator $H^\dagger H$ — it is a Lorentz and gauge singlet — so nothing in Section 38.6 protects c_H, and its smallness is the unnaturalness.

The EFT lens makes precise both what the problem is and what it is not. It *is* the statement that the dimension-two coefficient is anomalously small relative to its natural size, in exactly the same sense, and measured by exactly the same power counting, as the dimension-six coefficients are constrained to be small by the data of this section. It is *not* a statement about quadratic divergences in any particular regulator: in $\overline{\text{MS}}$ there are no power divergences at all, yet the problem persists, because it is a statement about the sensitivity of the low-energy coefficient to the high-energy scale Λ, a physical sensitivity that no choice of regulator removes (this is the content of Section 38.6). Read this way, the hierarchy problem is not a disease of the calculation but a property of the operator expansion: the Higgs mass is the one relevant operator in a theory of marginal and irrelevant ones, and a relevant operator is, by definition, sensitive to the ultraviolet. The same fact that lets precision measurements reach up to Λ through the irrelevant operators lets Λ reach down to the Higgs mass through the relevant one.

Physical Insight

There is a structural asymmetry between the two ways the scale Λ enters this chapter. Through the irrelevant (dimension-six) operators, Λ enters suppressed: their effects vanish as $\Lambda \to \infty$, which is the Appelquist–Carazzone decoupling of Chapter 38 and the reason precision physics works at all — heavy physics leaves only small, computable traces. Through the relevant (dimension-two) operator, Λ enters enhanced: its effect grows as $\Lambda \to \infty$, which is the hierarchy problem. Decoupling and the hierarchy problem are the same power counting read in opposite directions on the dimension axis, and the marginal (dimension-four) operators of the Standard Model sit exactly at the boundary, sensitive to Λ only logarithmically — the running couplings of Chapter 24. The entire chapter is, in this sense, a tour of the three sides of the dimension axis: relevant, marginal, irrelevant.

40.7.5 HQET and SMEFT as one method

We can now state the unifying lesson the chapter has been earning. An effective field theory is fixed by three inputs and one procedure. The inputs are a *field content*, a *symmetry*, and a *power counting*; the procedure is to write the most general local Lagrangian consistent with the first two, organized by the third, and then to determine its Wilson coefficients. The two halves of this chapter are this single recipe applied with the determination step carried out in the two possible ways.

In HQET (Section 40.1) the short-distance theory is *known*: it is QCD, and the heavy field is a Standard Model quark. The field content is the heavy-quark field with its lower components integrated out, the symmetry is the emergent

heavy-quark spin–flavor symmetry plus the gauge symmetry of QCD, and the power counting is in $\Lambda_{\mathrm{QCD}}/m_Q$. Because the ultraviolet theory is in hand, the Wilson coefficients are determined by *matching*: one computes the same amplitude in full QCD and in the effective theory and equates them, fixing each coefficient as a calculable function of $\alpha_s(m_Q)$. The famous payoff — the spin–flavor symmetry invisible in the QCD Lagrangian but manifest in the heavy-quark limit — is a statement that the matching produces a more symmetric effective theory than one might have written down, and Yang–Mills theory, followed since the asymptotic freedom of Theorem 27.7 into its heavy-quark regime, supplies the running coupling that the matching coefficients depend on.

In SMEFT (Section 40.4) the short-distance theory is *unknown*: it is whatever lies above the electroweak scale, and the "heavy field" is hypothetical. The field content is that of the Standard Model, the symmetry is $\mathrm{SU}(3)_c \times \mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$ (with the accidental B and L of Chapter 33), and the power counting is in E/Λ. Because the ultraviolet theory is not in hand, the Wilson coefficients cannot be matched; they are determined by *measurement*, which is the entire content of this section. The precision observable plays the role that the full-QCD amplitude plays in HQET — the external input that pins the coefficient — with the crucial difference that the input is empirical rather than calculable, and so the coefficient, once measured, is a window onto the unknown ultraviolet rather than a consistency check on a known one.

Physical Insight

Matching and measurement are the same operation performed against different references. In both cases one equates an effective-theory prediction, expressed in Wilson coefficients, to an external determination of an amplitude or observable, and solves for the coefficients. When the external determination comes from a known ultraviolet theory, we call it matching and the coefficients are predictions; when it comes from experiment, we call it measurement and the coefficients are constraints on the unknown ultraviolet. "Write all operators, power count, match or measure, run" is one method. HQET and SMEFT are its two faces, and the only thing that distinguishes them is whether the short-distance theory is written down or waiting to be discovered. The renormalization-group running of Section 40.6 is common to both: once the coefficients are fixed at one scale, by either route, the same anomalous-dimension matrix carries them to any other.

This is why the EFT paradigm of Chapter 38 is not merely one technique among many but the organizing language of modern particle physics. Chiral perturbation theory (Chapter 39) determined its low-energy constants by measurement because the ultraviolet theory, though known to be QCD, is strongly

coupled and not perturbatively solvable — a third case that is matching in principle and measurement in practice. HQET matches to a weakly coupled ultraviolet. SMEFT measures against an unknown one. All three are the same construction, and the reader who has followed the chapter has learned not three subjects but one, instantiated three times.

40.7.6 Status as of the mid-2020s

Honesty about the current state of the program requires a dated assessment, and the date matters because this is a moving frontier.

As of the mid-2020s the SMEFT has become the lingua franca of beyond-the-Standard-Model searches. Where an earlier generation reported limits on specific models — supersymmetric particles of definite mass, a Z' of definite coupling — the field now also, and increasingly primarily, reports constraints on Warsaw-basis Wilson coefficients, precisely because these are model-independent and translate into any specific model by matching. The global fits combine electroweak, Higgs, top, diboson, and flavor data into simultaneous bounds on dozens of coefficients, and the qualitative result is unambiguous and, from the standpoint of discovery, disappointing: there is no decisive, corroborated deviation from the Standard Model. The coefficients are consistent with zero, and the corresponding scale Λ is pushed into the multi-TeV range for $O(1)$ coefficients across most operator directions. The Standard Model, extended only by the dimension-five neutrino-mass operator, describes all confirmed laboratory data.

Several tensions animated the field during the late 2010s and early 2020s and deserve a sober accounting, because their trajectory is instructive. The $b \to s\ell\ell$ lepton-universality ratios R_K and R_{K^*} showed deviations from the Standard Model that, by 2022–2023, the LHCb collaboration's improved analyses brought back into agreement, illustrating how a SMEFT "signal" can evaporate as systematics are understood. The CDF collaboration's 2022 measurement of the W-boson mass lay many standard deviations above the Standard Model prediction and above other measurements; it is in tension with the rest of the electroweak data and with subsequent measurements, and the field has not reached consensus on it — which is why Theorem 40.25 flagged that the central value of T depends on how this measurement is treated. The muon anomalous magnetic moment a_μ showed a persistent discrepancy with the data-driven Standard Model prediction, but the Standard Model prediction itself is unsettled, with lattice-QCD evaluations of the hadronic vacuum polarization disagreeing with the data-driven dispersive evaluation by enough to remove the anomaly; until that internal disagreement is resolved, a_μ cannot be cleanly read as a Wilson coefficient. The lesson common to all three is the one Theorem 40.24 should already have taught: a deviation becomes new physics only when both the measurement and the Standard Model prediction are under control, and the SMEFT translation is only as trustworthy as the less certain of the two.

One genuinely open structural question concerns the organization of the expansion itself. We have built SMEFT on the assumption that the Higgs is the lower component of an $\mathrm{SU}(2)_L$ doublet and that the electroweak symmetry is realized linearly, so that operators are organized by canonical mass dimension and the expansion parameter is E/Λ. An alternative organization, the Higgs Effective Field Theory (HEFT, also called electroweak-chiral Lagrangian), treats the physical Higgs as a generic singlet scalar and realizes the electroweak symmetry nonlinearly on the would-be Goldstone bosons of $\mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$ breaking — exactly the chiral construction of Chapter 39 transplanted to the electroweak sector, with the expansion organized by chiral dimension rather than canonical dimension. SMEFT is the special case of HEFT in which the Higgs and the Goldstones assemble into a doublet; whether nature is described by the more restrictive SMEFT organization or requires the more general HEFT one is a physical question, tied to whether the Higgs couplings deviate in the correlated doublet pattern, and it is not settled as of the mid-2020s. Most analyses adopt SMEFT as the default because it is more predictive and because no data demand otherwise, but the choice is an assumption, not a theorem, and the reader should know it is live.

With this the effective-field-theory part of the book is complete. We have built the paradigm abstractly (Chapter 38), deployed it bottom-up on the broken chiral symmetry of QCD (Chapter 39), and in this chapter run it in both directions at once — top-down through HQET, where the short-distance theory is known and matched, and bottom-up through SMEFT, where it is unknown and measured — arriving at the reading of precision physics as the measurement of Wilson coefficients and hence of the scale and structure of whatever lies above. The EFT lens, now established as the organizing language of precision and of beyond-the-Standard-Model searches, is the one we carry forward: the non-perturbative methods of Part XII confront the regime where the matching of an EFT to its ultraviolet completion can no longer be done in perturbation theory, and the frontier parts that follow inherit the same discipline of separating scales, writing the most general dynamics consistent with the symmetries, and asking what the data can say about the rest.

Further reading

The heavy-quark effective theory grew from the observation of an emergent spin–flavour symmetry in the static limit by Isgur and Wise [276] and the form-factor reduction of Isgur and Wise [277]; the protection of the zero-recoil normalization against first-order power corrections is Luke [325], and the reparametrization invariance that freezes the kinetic coefficient is Luke and Manohar [326]. The comprehensive review is Neubert [362], and the textbook treatment, including the trace formalism and the $1/m_Q$ expansion carried here, is Manohar and Wise

[336]; Georgi [218] gives a compact pedagogical account. The nonrelativistic effective theory whose Fermi coefficient packages Schwinger's a_e originates with Caswell and Lepage [117]. For the weak effective Hamiltonian, the operator mixing, and the $\Delta S = 1$ QCD enhancement worked in Section 40.6, the standard review is Buchalla et al. [97]. On the SMEFT side, the canonical non-redundant dimension-six basis is that of Grzadkowski et al. [240]; the complete one-loop renormalization-group running is Alonso et al. [20], the Hilbert-series operator counting is Henning et al. [265], and a thorough modern review of the framework and its phenomenology is Brivio and Trott [93]. The oblique-parameter analysis underlying Section 40.7.2 is Peskin and Takeuchi [397, 398], and the decoupling theorem on which the whole construction rests is Appelquist and Carazzone [31]; Schwinger's original moment is Schwinger [433]. The standard textbooks — Peskin and Schroeder [396], Schwartz [432], and Weinberg [493] — treat the effective-Lagrangian viewpoint and the matching/running machinery in complementary depth.

Table 40.1: The baryon-number-conserving dimension-six operators of the Warsaw basis, bosonic and mixed classes (one generation). Here $X_{\mu\nu} = G^A_{\mu\nu}, W^I_{\mu\nu}, B_{\mu\nu}$ are the field strengths, $\widetilde{X}_{\mu\nu} = \frac{1}{2}\epsilon_{\mu\nu\rho\sigma}X^{\rho\sigma}$ their duals, $t^I = \tau^I/2$ and T^A the $\mathrm{SU}(2)_L$ and $\mathrm{SU}(3)_c$ generators, and $H^\dagger \overleftrightarrow{D}_\mu H \equiv H^\dagger D_\mu H - (D_\mu H)^\dagger H$. The tilde operators ($\mathcal{O}_{\widetilde{G}}$, etc.) are the CP-odd partners obtained by $X \to \widetilde{X}$.

Part XII

Non-Perturbative Methods

Chapter 41

Solitons and Topology

Every result of the book so far has been built on a single tacit assumption: that the fields are small. Quantization expanded about a vacuum, perturbation theory expanded about free fields, and the Feynman diagram counted fluctuations that die away at spatial infinity. That assumption is an approximation, and there are configurations it cannot reach. This chapter studies the field theory of the large: smooth, static, finite-energy solutions of the classical equations of motion that are not small deformations of the vacuum and cannot be deformed into it. They are the solitons, and what protects them is a conservation law of a wholly new kind — one that owes nothing to Noether's theorem of Chapter 7. A soliton is stable not because a symmetry forbids its decay but because the configuration is *knotted*: the field at the boundary of space wraps the manifold of vacua in a way that no continuous, finite-energy motion can unwrap. The charge that counts the knotting is an integer, it is conserved off shell, and it is invisible to perturbation theory. This is the first genuinely non-perturbative structure of the book, and the gateway to Part XII.

The development is deliberately self-contained in its topology: the homotopy groups we need are built from scratch as the examples demand them. What the chapter imports is the classical apparatus already in hand. The action principle, the stress tensor whose T^{00} defines the static energy we minimize, and Noether's machinery come from Chapters 6 and 7; the order-parameter language and the structure of the vacuum manifold as a coset G/H are the spontaneous-symmetry-breaking vocabulary of Chapter 29, recalled but rebuilt in the form we need; the coset and Lie-group facts behind the homotopy classification are those of Chapter 2. The gauged solitons require the gauge logic of Chapter 8 — including the Dirac quantization argument and the θ-term as a total derivative — and the non-abelian field strength, covariant derivative, and adjoint Higgs mechanics of Chapter 25. Two benchmark theories supply the spine: ϕ^4 theory, the real scalar of Chapter 6 in its broken phase, furnishes the kink that opens the chapter, and Yang–Mills theory delivers the 't Hooft–Polyakov monopole as its non-abelian

climax.

The chapter follows a single ascending arc, one rung per spatial dimension. Section 41.1 cashes every promise on the simplest case that exists, the kink of a real scalar in one dimension: finite energy splits field space into disconnected sectors, an integer topological charge labels them, an off-shell-conserved current carries it, and a first-order Bogomolny rewriting computes the soliton mass exactly. Section 41.2 extracts the general principle, proving that finite-energy sectors are classified by a homotopy group of the vacuum manifold and that the charge is the topological degree of the boundary map — integral and invariant as theorems, not accidents. Section 41.3 then delivers Derrick's sharp negative result: in two or more spatial dimensions, scalars alone admit no soliton, and the scaling argument that proves it dictates the cure. That cure is gauge fields, and the next two sections build the two solitons it makes possible. Section 41.4 constructs the Abrikosov–Nielsen–Olesen vortex in two dimensions, with its quantized magnetic flux; Section 41.5 climbs to three dimensions and a non-abelian group to build the 't Hooft–Polyakov monopole, in which magnetic charge emerges as a topological invariant from an everywhere-regular field. Section 41.6 closes by isolating the one algebraic identity — Bogomol'nyi's completion of the square — behind every mass bound met along the way, exhibits the kink, vortex, and monopole as its three instances, solves the Prasad–Sommerfield limit in closed form, and ends with the dyon spectrum and the Witten effect, the point at which the soliton thread rejoins the θ-vacuum.

A brief word on scope and rigor. The topology is developed honestly: $\pi_1(S^1) \cong \mathbb{Z}$, the degree formula, and the homotopy classification of sectors are proved, not quoted, and every soliton profile, flux integral, charge identity, and saturated mass is carried to the end. Where the chapter looks forward — to the θ-vacuum and the dilute instanton gas of Chapter 42, to cosmological-defect and grand-unified monopole phenomenology, and to the supersymmetric meaning of the BPS bound — it says so and points the reader on, never substituting a citation for an argument it owes.

41.1 The Kink: A Soliton from a Double Well

The chapter introduction promised a conservation law of a new kind—one that protects a field configuration not because a symmetry forces it through Noether's theorem, but because the configuration is *knotted*, in a sense we must now make precise, and cannot be combed flat without paying an infinite price. Such promises are cheap until they are cashed on an example. We cash this one on the simplest example that exists: a single real scalar field in one spatial dimension, sitting in the double-well potential of ϕ^4 theory. Everything the rest of the chapter needs—the role of finite energy, the splitting of field space into disconnected sectors, an integer charge, a current conserved without ever

invoking the equations of motion, and the first-order "Bogomolny" rewriting that computes the soliton's mass exactly—appears here in a setting transparent enough that not a single step need be taken on faith. The higher-dimensional solitons of later sections are, conceptually, this calculation with more indices.

41.1.1 The model: a scalar line in a double well

We work in 1+1 spacetime dimensions with coordinates $x^\mu = (t, x)$, mostly-minus metric $\eta_{\mu\nu} = \mathrm{diag}(+,-)$, and natural units. The field is a single real scalar $\phi(t,x)$, governed by the frozen ϕ^4 Lagrangian Eq. (6.56) taken in its broken phase—the same double well that organized spontaneous symmetry breaking in Chapter 29:

$$\mathcal{L} = \tfrac{1}{2}\,\partial_\mu\phi\,\partial^\mu\phi - V(\phi), \qquad V(\phi) = -\tfrac{1}{2}\left|m^2\right|\,\phi^2 + \frac{\lambda}{4!}\,\phi^4, \qquad \lambda > 0. \tag{41.1}$$

This is Eq. (29.6) verbatim. Its discrete reflection symmetry, the $\mathbb{Z}_2$ of Theorem 7.22 acting by $\phi \to -\phi$, is exact, and its two degenerate minima sit at the vacua of Eq. (29.8),

$$\phi = \pm v, \qquad v^2 = \frac{6\left|m^2\right|}{\lambda}. \tag{41.2}$$

It is convenient—indeed, as we will see in a moment, *necessary*—to measure the potential from its minimum value. Completing the square in ϕ^2,

$$V(\phi) = \frac{\lambda}{4!}\left(\phi^2 - v^2\right)^2 - \frac{\lambda}{4!}\,v^4, \tag{41.3}$$

which one checks by expanding: the cross term $-2v^2\phi^2$ supplies $-\frac{\lambda}{4!}2v^2\phi^2 = -\frac{\lambda v^2}{12}\phi^2 = -\frac{1}{2}\left|m^2\right|\phi^2$ on using $\lambda v^2 = 6\left|m^2\right|$, reproducing Eq. (41.1), and the constant $-\frac{\lambda}{4!}v^4$ is the (negative) value of V at either well. We define the *shifted potential*

$$\boxed{\widetilde{V}(\phi) \;\equiv\; V(\phi) - V_{\min} \;=\; \frac{\lambda}{4!}\left(\phi^2 - v^2\right)^2 \;\geq 0\,,} \qquad V_{\min} = -\frac{\lambda}{4!}v^4, \tag{41.4}$$

which is non-negative everywhere and vanishes *exactly* at, and only at, the two vacua $\phi = \pm v$. Shifting V by a constant changes neither the equations of motion (a constant drops out of V') nor the $\mathbb{Z}_2$ symmetry; what it buys is a vacuum of zero energy density, without which a field stretched over an infinite line could never have finite total energy.

Static, finite-energy configurations are the objects of interest. The energy of a field configuration is the spatial integral of the energy density $T^{00} = \mathcal{H}$, identified for any scalar Lagrangian in Eq. (6.173); for a configuration that does not depend on time, $\dot\phi = 0$, the kinetic term vanishes and the energy reduces to the static functional

$$E[\phi] \;=\; \int_{-\infty}^{\infty} \mathrm{d}x\,\left[\,\tfrac{1}{2}\,(\phi')^2 + \widetilde{V}(\phi)\,\right], \qquad \phi' \equiv \frac{d\phi}{dx}, \tag{41.5}$$

where we have used the shifted potential Eq. (41.4) precisely so that the vacua contribute zero. Both terms in the integrand are pointwise non-negative: a gradient-squared and a manifestly non-negative potential. The energy is therefore the sum of two non-negative pieces, and it can be finite only if each piece integrates to something finite. This single observation, pressed for all it is worth, is the origin of everything topological in the problem.

41.1.2 Finite energy forces the field into a vacuum at infinity

Definition 41.1 (Finite-energy configuration)**.** A static configuration $\phi : \mathbb{R} \to \mathbb{R}$ is of *finite energy* if $E[\phi] < \infty$, with E the functional Eq. (41.5). We require in addition that ϕ be continuous with a piecewise-continuous derivative, so that the integrand makes sense.

Proposition 41.2 (Boundary conditions and topological sectors)**.** *Every finite-energy configuration approaches a vacuum at each spatial end,*

$$\phi(x) \xrightarrow[x\to+\infty]{} \phi_+ \in \{+v, -v\}, \qquad \phi(x) \xrightarrow[x\to-\infty]{} \phi_- \in \{+v, -v\}. \tag{41.6}$$

The pair (ϕ_-, ϕ_+) takes four values, splitting the space of finite-energy configurations into four classes; no continuous deformation through finite-energy configurations carries one class into another.

Proof. Finiteness of Eq. (41.5) requires both non-negative pieces to be integrable. Consider first the potential term, $\int \widetilde{V}(\phi)\,\mathrm{d}x < \infty$. The integrand is continuous and non-negative; for its integral over the whole line to converge, the integrand must tend to zero as $x \to \pm\infty$. Hence $\widetilde{V}(\phi(x)) \to 0$, and because $\widetilde{V}$ vanishes only at its two zeros, the field value must approach the set $\{+v, -v\}$. It remains to rule out the possibility that $\phi(x)$ oscillates between $+v$ and $-v$ without settling on one of them. This is where the gradient term earns its keep. Suppose, for contradiction, that ϕ does not converge as $x \to +\infty$; then there are arbitrarily large x where ϕ is near $+v$ and arbitrarily large x where it is near $-v$, so on infinitely many disjoint intervals ϕ traverses, say, the band from $-v/2$ to $+v/2$. Across each such interval the field changes by at least v, so by the Cauchy–Schwarz inequality the gradient energy collected on an interval $[a, b]$ over which ϕ runs monotonically from $-v/2$ to $+v/2$ obeys

$$\int_a^b \tfrac{1}{2}(\phi')^2\,\mathrm{d}x \;\geq\; \frac{1}{2(b-a)}\Big(\int_a^b \phi'\,\mathrm{d}x\Big)^2 \;=\; \frac{v^2}{2(b-a)}. \tag{41.7}$$

For the total to be finite the lengths $b - a$ of these crossing intervals would have to grow without bound; but on a long interval where ϕ stays in the band $[-v/2, +v/2]$ the potential term contributes at least $\widetilde{V}_{\min,\,\mathrm{band}} \cdot (b - a)$, where $\widetilde{V}_{\min,\,\mathrm{band}} > 0$ is the (strictly positive) minimum of $\widetilde{V}$ on that closed band, and

this diverges. Either way the energy is infinite. Hence ϕ converges to a single vacuum at each end, establishing Eq. (41.6).

The four classes are labelled by (ϕ_-, ϕ_+). A continuous deformation $\phi_s(x)$, $s \in [0,1]$, through finite-energy configurations gives, at each fixed s, well-defined endpoint values $\phi_\pm(s) \in \{+v, -v\}$ that depend continuously on s; a continuous map into the two-point set $\{+v, -v\}$ is constant. So neither endpoint can jump, and the class is preserved under any such deformation. □

The four classes are the *topological sectors*. Two of them, $(\phi_-, \phi_+) = (+v, +v)$ and $(-v, -v)$, contain the constant vacuum solutions and the small fluctuations around them—these are the configurations perturbation theory sees. The other two, $(-v, +v)$ and $(+v, -v)$, contain field profiles that must climb out of one well and descend into the other. Theorem 41.2 says no amount of finite-energy wiggling connects these to a vacuum: the lowest-energy configuration in a non-vacuum sector, whatever it is, is stranded there. That is the entire mechanism of topological stability, stated before we have written down a single solution. It is worth pausing on what made it work, because the same logic recurs at every rung of the chapter's ladder.

Physical Insight

Stability here is not the stability of a Noether charge. No symmetry of Eq. (41.1) is responsible; the $\mathbb{Z}_2$ of Theorem 7.22 is a symmetry, but it is discrete and yields no conserved current at all (Section 7.3.6). What stabilizes the sectors is a fact about the geometry of field space at infinity: finite energy pins the field to the discrete vacuum set $\{+v, -v\}$ at each end, and a discrete set cannot be traversed continuously. The configuration is trapped not by a force but by a *disconnection*—there is no continuous path of finite-energy configurations from one sector to another. We are about to package this disconnection into an integer.

41.1.3 The static equation, its first integral, and the kink profile

We now find the lowest-energy configuration in a non-vacuum sector explicitly. A stationary point of the energy functional Eq. (41.5) satisfies its Euler–Lagrange equation, obtained exactly as in Theorem 6.8 but for the one-dimensional functional $E[\phi] = \int \mathrm{d}x\, [\frac{1}{2}(\phi')^2 + \widetilde{V}(\phi)]$. Varying, $\delta E = \int \mathrm{d}x\, [\phi'\, \delta\phi' + \widetilde{V}'(\phi)\, \delta\phi] = \int \mathrm{d}x\, [-\phi'' + \widetilde{V}'(\phi)]\, \delta\phi$ after one integration by parts (the boundary term vanishing because $\delta\phi \to 0$ at infinity, where every competitor shares the same vacuum endpoints). Stationarity for arbitrary $\delta\phi$ gives the *static field equation*

$$\phi'' = \widetilde{V}'(\phi). \tag{41.8}$$

This is precisely the static ($\dot\phi = 0$) limit of the full covariant equation of motion $\Box\phi + \widetilde{V}'(\phi) = 0$ of ϕ^4 theory (Eq. (6.56)), since in mostly-minus signature $\Box = \partial_t^2 - \partial_x^2$ collapses to $-\partial_x^2$ on a time-independent field.

Equation Eq. (41.8) has a mechanical reading that turns the problem into one we already know how to solve. Read x as a *time* and ϕ as the *position* of a unit-mass particle; then Eq. (41.8) is Newton's law $\phi'' = -\partial_\phi U$ for motion in the *inverted* potential

$$U(\phi) \equiv -\widetilde{V}(\phi), \tag{41.9}$$

a double *hump* with two equal maxima at $\phi = \pm v$ (Fig. 41.1, left). The conserved "mechanical energy" of this analogue particle is

$$\mathcal{E}_{\text{mech}} = \tfrac{1}{2}(\phi')^2 + U(\phi) = \tfrac{1}{2}(\phi')^2 - \widetilde{V}(\phi), \tag{41.10}$$

and it is conserved in x along any solution: differentiating and using Eq. (41.8),

$$\frac{d\mathcal{E}_{\text{mech}}}{dx} = \phi'\phi'' - \widetilde{V}'(\phi)\,\phi' = \phi'\big(\phi'' - \widetilde{V}'(\phi)\big) = 0. \tag{41.11}$$

Now impose finite energy. By Theorem 41.2 the field approaches a vacuum at each end, where $\phi' \to 0$ and $\widetilde{V} \to 0$, so $\mathcal{E}_{\text{mech}} \to 0$. Being constant, it is zero everywhere:

$$\boxed{\tfrac{1}{2}(\phi')^2 = \widetilde{V}(\phi)\ .} \tag{41.12}$$

This *first integral* of Eq. (41.8) is the heart of the matter. It is a first-order equation equivalent, for finite-energy configurations, to the second-order field equation, and it says the gradient energy density and the potential energy density are *equal at every point*—a statement we will rediscover, and elevate, as the Bogomolny condition in Section 41.1.5. Mechanically, it is the trajectory that leaves the top of one hump with vanishing speed and arrives at the top of the other, the unique zero-energy roll between the two maxima, which takes infinite "time" x to complete because the particle decelerates to rest as it asymptotes the second summit.

Solving Eq. (41.12) is now integration by quadrature. Taking the positive square root (the choice that makes ϕ increase, i.e. the sector $\phi_- = -v \to \phi_+ = +v$),

$$\phi' = \sqrt{2\widetilde{V}(\phi)} = \sqrt{\frac{2\lambda}{4!}}\,(v^2 - \phi^2) = \sqrt{\frac{\lambda}{12}}\,(v^2 - \phi^2), \tag{41.13}$$

where on the relevant range $-v < \phi < v$ the factor $|\phi^2 - v^2| = v^2 - \phi^2$. Separating variables,

$$\frac{\mathrm{d}\phi}{v^2 - \phi^2} = \sqrt{\frac{\lambda}{12}}\,\mathrm{d}x. \tag{41.14}$$

The left side integrates by the standard substitution $\phi = v\tanh\theta$, for which $\mathrm{d}\phi = v\,\mathrm{sech}^2\theta\,\mathrm{d}\theta$ and $v^2 - \phi^2 = v^2\,\mathrm{sech}^2\theta$, so the left side becomes $\frac{1}{v}\,\mathrm{d}\theta$; equivalently $\int \mathrm{d}\phi/(v^2-\phi^2) = \frac{1}{v}\,\mathrm{arctanh}(\phi/v)$. Performing both integrals,

$$\frac{1}{v}\,\mathrm{arctanh}\Big(\frac{\phi}{v}\Big) = \sqrt{\frac{\lambda}{12}}\,(x - x_0), \tag{41.15}$$

with x_0 the integration constant. Inverting gives the *kink*:

$$\boxed{\phi_K(x) = v\,\tanh\Big(\frac{x-x_0}{w}\Big)}\,, \qquad \frac{1}{w} = v\sqrt{\frac{\lambda}{12}}, \tag{41.16}$$

a smooth profile climbing monotonically from $-v$ at $x \to -\infty$ to $+v$ at $x \to +\infty$ (Fig. 41.1, right). The constant x_0 is the kink's *centre*, free because the energy functional is translation invariant—a zero mode we will not need here but will return to when the collective-coordinate quantization of such zero modes is taken up in Chapter 42. Taking the negative root in Eq. (41.13) instead yields the *antikink* $\bar\phi_K(x) = -v\tanh((x-x_0)/w) = v\tanh(-(x-x_0)/w)$, the mirror profile descending from $+v$ to $-v$, living in the sector $(\phi_-,\phi_+) = (+v,-v)$.

The width w is fixed by the parameters of the model. Using $v^2 = 6\,|m^2|\,/\lambda$ from Eq. (41.2),

$$\frac{1}{w} = v\sqrt{\frac{\lambda}{12}} = \sqrt{\frac{\lambda v^2}{12}} = \sqrt{\frac{\lambda}{12}\cdot\frac{6\,|m^2|}{\lambda}} = \sqrt{\frac{|m^2|}{2}} = \frac{|m|}{\sqrt{2}}, \qquad w = \frac{\sqrt{2}}{|m|}, \tag{41.17}$$

where $|m| \equiv \sqrt{|m^2|}$. The kink width is set by the curvature of the wells. Recall from Eq. (29.10) that the mass of the elementary scalar excitation about either vacuum is $m^2_{\mathrm{phys}} = V''(\pm v) = 2\,|m^2|$, so $m_{\mathrm{phys}} = \sqrt{2}\;|m|$ and

$$w = \frac{\sqrt{2}}{|m|} = \frac{2}{m_{\mathrm{phys}}}. \tag{41.18}$$

The kink is a lump twice the Compton wavelength of the field's own quantum across—a localized object whose size is dictated entirely by the same parameters that fix the perturbative particle, yet which no perturbative expansion around a single vacuum will ever produce, because no neighbourhood of one vacuum contains a configuration that reaches the other.

41.1.4 The topological current and its integer charge

We have a stable lump and a four-fold partition of field space, but "stable because the sectors are disconnected" is still a statement about pictures. We now convert it into an algebraic conservation law, and in doing so meet the defining structural contrast of the whole subject: a current conserved *identically*, with no appeal to the equations of motion.

In $1+1$ dimensions introduce the antisymmetric Levi-Civita symbol $\epsilon^{\mu\nu}$ with $\epsilon^{01} = -\epsilon^{10} = +1$, and define the *topological current*

Definition 41.3 (Topological current and charge)**.**

$$J^\mu \;=\; \frac{1}{2v}\,\epsilon^{\mu\nu}\,\partial_\nu \phi, \tag{41.19}$$

with associated charge $Q = \int_{-\infty}^{\infty} \mathrm{d}x\, J^0$.

The normalization $1/2v$ is chosen, as we will see, to make Q an integer. Written out, the two components are $J^0 = \frac{1}{2v}\epsilon^{01}\partial_1\phi = \frac{1}{2v}\,\partial_x\phi$ and $J^1 = \frac{1}{2v}\epsilon^{10}\partial_0\phi = -\frac{1}{2v}\,\partial_t\phi$. The current is built purely from the field and its first derivatives—no Lagrangian, no canonical momenta, no symmetry parameter entered its definition. Contrast this with the Noether current of Theorem 7.9, which is assembled from $\partial\mathcal{L}/\partial(\partial_\mu\phi)$ and the symmetry variation of the field, and which exists only relative to a chosen symmetry. Here there is no symmetry; there is only the field.

Theorem 41.4 (Off-shell conservation)**.** *The current Eq. (41.19) is identically conserved,*

$$\partial_\mu J^\mu = 0, \tag{41.20}$$

for every *smooth field configuration ϕ, whether or not it satisfies the equations of motion.*

Proof. Compute the divergence directly from Eq. (41.19):

$$\partial_\mu J^\mu = \frac{1}{2v}\,\epsilon^{\mu\nu}\,\partial_\mu\partial_\nu\phi. \tag{41.21}$$

The object $\partial_\mu\partial_\nu\phi$ is symmetric under $\mu \leftrightarrow \nu$ for any twice-differentiable ϕ (equality of mixed partials), while $\epsilon^{\mu\nu}$ is antisymmetric. The full contraction of a symmetric pair of indices with an antisymmetric one vanishes: explicitly, $\epsilon^{\mu\nu}\partial_\mu\partial_\nu\phi = \frac{1}{2}\epsilon^{\mu\nu}(\partial_\mu\partial_\nu - \partial_\nu\partial_\mu)\phi = 0$. Hence $\partial_\mu J^\mu = 0$ identically. □

This is the conceptual pivot of the chapter, so it is worth stating exactly what just happened and exactly how it differs from Noether's theorem. The Noether current of Theorem 7.10 obeys $\partial_\mu j^\mu_{\mathrm{N}} = 0$ *on shell*: the proof of Theorem 7.13 uses the Euler–Lagrange equations at the decisive step, and off the equations of motion the Noether current is generally not conserved. Its conservation is a dynamical fact, contingent on the field solving its equations, and it is tied to a symmetry by construction. The topological current Eq. (41.19) is conserved for a completely different reason: Eq. (41.20) is an algebraic identity following from the antisymmetry of ϵ and the commutativity of partial derivatives, true of any field configuration whatsoever. No symmetry is invoked; no equation of motion is used. The conservation is *kinematic*, not dynamical.

Caution

The distinction is not academic bookkeeping. Because $\partial_\mu J^\mu = 0$ does not lean on the dynamics, the charge Q is conserved even for configurations that are not solutions—it is a property of the field's boundary behaviour, immune to whatever the field does in the interior or in time. A Noether charge can in principle fail to be conserved if a symmetry is anomalous or explicitly broken; a topological charge cannot fail this way, because its conservation never used a symmetry to begin with. This robustness is exactly what makes topological charges the right tool for protecting non-perturbative states.

Now evaluate the charge. Using $J^0 = \frac{1}{2v}\partial_x\phi$, the spatial integral is a total derivative and collapses to the boundary values:

$$Q = \int_{-\infty}^{\infty} \mathrm{d}x\; J^0 = \frac{1}{2v}\int_{-\infty}^{\infty} \mathrm{d}x\; \partial_x\phi = \frac{1}{2v}\Big[\phi(+\infty) - \phi(-\infty)\Big] = \frac{\phi_+ - \phi_-}{2v}. \tag{41.22}$$

The charge depends only on the asymptotic vacuum values $\phi_\pm$ fixed by Eq. (41.6)—never on the detailed shape of ϕ in between. With $\phi_\pm \in \{+v, -v\}$ the four sectors of Theorem 41.2 carry

$$Q \in \{-1,\, 0,\, +1\}, \qquad \begin{aligned} (\phi_-, \phi_+) = (-v, +v): &\quad Q = +1 \quad \text{(kink)},\\ (\phi_-, \phi_+) = (+v, -v): &\quad Q = -1 \quad \text{(antikink)},\\ (\phi_-, \phi_+) = (\pm v, \pm v): &\quad Q = 0 \quad \text{(vacua)}. \end{aligned} \tag{41.23}$$

The kink of Eq. (41.16) carries $Q = +1$, the antikink $Q = -1$, and the two vacuum sectors $Q = 0$. The integer is exactly the "disconnection" of Theorem 41.2 made quantitative: it counts, with sign, the net number of times the field traverses the gap between the two vacua. Because Q is fixed by the boundary data and the boundary data cannot change continuously, Q is a conserved integer—and the kink, carrying $Q = +1$, can no more decay to the $Q = 0$ vacuum than an integer can slide to zero. Charge conservation and topological stability are the same statement.

Physical Insight

The charge integrand $J^0 = \frac{1}{2v}\partial_x\phi$ is a total spatial derivative, so Q is a pure boundary quantity. This is the 1+1-dimensional, single-field shadow of a structure that will reappear in every soliton we meet: the topological charge density is always a total divergence, its integral always a surface term at infinity, and its value always counts how the field at the boundary wraps the vacuum manifold. In Section 41.1's successor that "wrapping" becomes the winding number of a map from the sphere at infinity into the vacuum manifold, and the integer Q becomes its degree.

41.1.5 The Bogomolny bound, the BPS equation, and the kink mass

We found the kink by solving the second-order field equation and integrating once. There is a more powerful route that bypasses the field equation entirely, delivers a sharp lower bound on the energy in each sector, identifies the configurations that saturate it, and—almost as a byproduct—computes the kink's mass as a closed number. This is the *Bogomolny* rewriting, and the structure it exposes is the single thread that ties together the kink, the vortex, the monopole, and the instanton.

The idea is to complete the square in the energy functional. Introduce the *prepotential* (sometimes "superpotential") $W(\phi)$ defined by

$$W'(\phi) = \sqrt{2\,\widetilde{V}(\phi)}, \qquad W(\phi) = \int^{\phi} \sqrt{2\,\widetilde{V}(\phi')}\,\mathrm{d}\phi', \tag{41.24}$$

so that $\sqrt{2\widetilde{V}}$ is an exact ϕ-derivative along the configuration: $W'(\phi)\,\phi' = \frac{d}{dx}W(\phi(x))$. Then, for either sign choice, add and subtract the cross term in the static energy Eq. (41.5):

$$\begin{aligned} E[\phi] &= \int_{-\infty}^{\infty} \mathrm{d}x\, \left[\tfrac{1}{2}(\phi')^2 + \widetilde{V}(\phi)\right] \\ &= \int_{-\infty}^{\infty} \mathrm{d}x\, \left[\tfrac{1}{2}\big(\phi' \mp \sqrt{2\widetilde{V}}\big)^2 \;\pm\; \phi'\sqrt{2\widetilde{V}}\right] \\ &= \int_{-\infty}^{\infty} \mathrm{d}x\, \tfrac{1}{2}\big(\phi' \mp \sqrt{2\widetilde{V}}\big)^2 \;\pm\; \int_{-\infty}^{\infty} \mathrm{d}x\, \frac{d}{dx} W(\phi(x)). \end{aligned} \tag{41.25}$$

The algebra in the middle line is the identity $\frac{1}{2}(\phi' \mp \sqrt{2\widetilde{V}})^2 = \frac{1}{2}(\phi')^2 \mp \phi'\sqrt{2\widetilde{V}} + \widetilde{V}$, which on adding back $\pm\phi'\sqrt{2\widetilde{V}}$ returns the original integrand $\frac{1}{2}(\phi')^2 + \widetilde{V}$ exactly. In the last line we used Eq. (41.24) to write the cross term as a total derivative. That total derivative integrates to a pure boundary term,

$$\int_{-\infty}^{\infty} \mathrm{d}x\, \frac{d}{dx} W(\phi(x)) = W(\phi_+) - W(\phi_-) \equiv \Delta W, \tag{41.26}$$

which—like the topological charge—depends only on the asymptotic vacuum values, hence only on the sector. The first term in Eq. (41.25) is a manifestly non-negative integral of a perfect square. We have therefore proved:

Theorem 41.5 (Bogomolny bound and BPS saturation)**.** *For every finite-energy static configuration,*

$$E[\phi] \;\geq\; |\Delta W| = |\,W(\phi_+) - W(\phi_-)\,|\,, \tag{41.27}$$

the sign in Eq. (41.25) chosen so that $\pm\Delta W = |\Delta W| \geq 0$*. Equality holds if and only if the square in Eq. (41.25) vanishes pointwise, i.e. if and only if* ϕ *satisfies*

the first-order Bogomolny–Prasad–Sommerfield (BPS) equation

$$\boxed{\phi' = \pm\sqrt{2\,\widetilde{V}(\phi)}\,.} \tag{41.28}$$

Three points deserve emphasis. First, the bound Eq. (41.27) is established *without ever solving* the equation of motion—it follows from completing a square and from the boundary data alone. Second, the bound is purely topological in the sense that $|\Delta W|$ is constant on each sector; every configuration in a given sector, BPS or not, has at least this much energy. Third, the saturating configurations solve the *first-order* equation Eq. (41.28), which is precisely the first integral Eq. (41.12) found earlier from the mechanical analogue. The Bogomolny method thus re-derives the first-order equation from a variational inequality rather than from a conserved mechanical energy, and tells us in addition that its solutions are not merely stationary points but genuine energy *minimizers* within their sector. The kink Eq. (41.16) is the unique (up to translation) finite-energy minimizer of energy in the sector $Q = +1$; the antikink minimizes in $Q = -1$.

There is also a clean relation between the bound and the topological charge. For our model $\sqrt{2\widetilde{V}} = \sqrt{\lambda/12}\,|v^2 - \phi^2|$, and on a monotonic kink profile the field stays in $[-v, v]$ where $|v^2 - \phi^2| = v^2 - \phi^2$, so from Eq. (41.24)

$$W(\phi) = \sqrt{\frac{\lambda}{12}}\int^{\phi}(v^2 - \phi'^2)\,\mathrm{d}\phi' = \sqrt{\frac{\lambda}{12}}\left(v^2\phi - \tfrac{1}{3}\phi^3\right), \tag{41.29}$$

and the sector bound is $|\Delta W| = |W(\phi_+) - W(\phi_-)|$. Comparing with Eq. (41.22), both Q and ΔW are boundary quantities; for this model $\Delta W = 2\,W(v)\cdot|Q|$ up to sign, so the energy bound is $|Q|$ times the single-kink value—the bound knows that two kinks cost twice one kink. We compute that single-kink value now.

Worked Example 41.6 (The kink mass by quadrature)**.** The mass of the kink is its static energy, which by Theorem 41.5 equals the saturated bound $M_{\text{kink}} = |\Delta W|$ for the sector $\phi_- = -v \to \phi_+ = +v$. We evaluate it two ways and check they agree.

Route 1: the prepotential difference. Directly from Eq. (41.29),

$$\begin{aligned} M_{\text{kink}} &= W(v) - W(-v) = \sqrt{\frac{\lambda}{12}}\left[\left(v^3 - \tfrac{1}{3}v^3\right) - \left(-v^3 + \tfrac{1}{3}v^3\right)\right] \\ &= \sqrt{\frac{\lambda}{12}}\left[\tfrac{2}{3}v^3 + \tfrac{2}{3}v^3\right] = \sqrt{\frac{\lambda}{12}}\cdot\frac{4v^3}{3}. \end{aligned} \tag{41.30}$$

Route 2: the mass integral $M = \int\sqrt{2\widetilde{V}}\,\mathrm{d}\phi$. On the BPS solution the two energy densities are equal, $\tfrac{1}{2}(\phi')^2 = \widetilde{V}$ by Eq. (41.12), so the integrand of

Eq. (41.5) is $\frac{1}{2}(\phi')^2 + \widetilde{V} = (\phi')^2$. Then, changing the integration variable from x to ϕ via $\mathrm{d}\phi = \phi'\,\mathrm{d}x$ and $\phi' = \sqrt{2\widetilde{V}}$,

$$M_{\text{kink}} = \int_{-\infty}^{\infty} \mathrm{d}x\ (\phi')^2 = \int_{-\infty}^{\infty} \mathrm{d}x\ \phi' \cdot \phi' = \int_{-v}^{+v} \sqrt{2\widetilde{V}(\phi)}\ \mathrm{d}\phi. \tag{41.31}$$

This is the promised closed formula: the kink mass is the area under $\sqrt{2\widetilde{V}}$ between the vacua, a one-dimensional integral with no reference to x at all. Inserting $\sqrt{2\widetilde{V}} = \sqrt{\lambda/12}\,(v^2 - \phi^2)$,

$$M_{\text{kink}} = \sqrt{\frac{\lambda}{12}} \int_{-v}^{+v} (v^2 - \phi^2)\,\mathrm{d}\phi = \sqrt{\frac{\lambda}{12}} \left[v^2\phi - \tfrac{1}{3}\phi^3 \right]_{-v}^{+v} = \sqrt{\frac{\lambda}{12}} \cdot \frac{4v^3}{3}, \tag{41.32}$$

identical to Eq. (41.30), as it must be.

The closed number. Reducing $\sqrt{\lambda/12} = \sqrt{\lambda}/(2\sqrt{3})$,

$$M_{\text{kink}} = \frac{\sqrt{\lambda}}{2\sqrt{3}} \cdot \frac{4v^3}{3} = \frac{2\sqrt{\lambda}\,v^3}{3\sqrt{3}} = \frac{2\sqrt{3\lambda}}{9}\,v^3. \tag{41.33}$$

It is illuminating to trade v for the model's mass scale. Using $v^2 = 6\,|m^2|\,/\lambda$, hence $v^3 = (6\,|m^2|\,/\lambda)^{3/2} = 6\sqrt{6}\ |m|^3\,/\lambda^{3/2}$,

$$M_{\text{kink}} = \frac{2\sqrt{3\lambda}}{9} \cdot \frac{6\sqrt{6}\ |m|^3}{\lambda^{3/2}} = \frac{12\sqrt{18}}{9}\,\frac{|m|^3}{\lambda} = \frac{12 \cdot 3\sqrt{2}}{9}\,\frac{|m|^3}{\lambda} = 4\sqrt{2}\,\frac{|m|^3}{\lambda}, \tag{41.34}$$

or, in terms of the physical particle mass $m_{\text{phys}} = \sqrt{2}\ |m|$ (Eq. (29.10)), substituting $|m|^3 = m_{\text{phys}}^3/(2\sqrt{2})$,

$$\boxed{M_{\text{kink}} = \frac{2\,m_{\text{phys}}^3}{\lambda}\,.} \tag{41.35}$$

A final consistency check ties the result back to the profile. Using the explicit kink $\phi_K = v\tanh(x/w)$ with $\phi_K' = (v/w)\,\mathrm{sech}^2(x/w)$, the energy integral $\int (\phi_K')^2 \mathrm{d}x = (v^2/w^2)\int \mathrm{sech}^4(x/w)\,\mathrm{d}x = (v^2/w)\int_{-\infty}^{\infty} \mathrm{sech}^4 u\,\mathrm{d}u = (v^2/w)\cdot\frac{4}{3}$, where $\int \mathrm{sech}^4 u\,\mathrm{d}u = \frac{4}{3}$ follows from $\int \mathrm{sech}^4 = \int \mathrm{sech}^2(1-\tanh^2) = [\tanh - \frac{1}{3}\tanh^3]_{-\infty}^{\infty} = 2 - \frac{2}{3} = \frac{4}{3}$. With $1/w = v\sqrt{\lambda/12}$ this is $\frac{4}{3}v^2 \cdot v\sqrt{\lambda/12} = \sqrt{\lambda/12}\cdot\frac{4}{3}v^3$, reproducing Eq. (41.30) once more.

The result Eq. (41.35) carries the message the chapter introduction advertised. The kink mass scales as $1/\lambda$: in the weak-coupling regime where perturbation theory is reliable, the soliton is *heavy*, its mass diverging as $\lambda \to 0$. A heavy state whose mass blows up at weak coupling is invisible to any power series in λ around the vacuum—no finite order in Feynman diagrams can produce a pole at $M \sim 1/\lambda$. The kink exists in the classical field equations, is protected

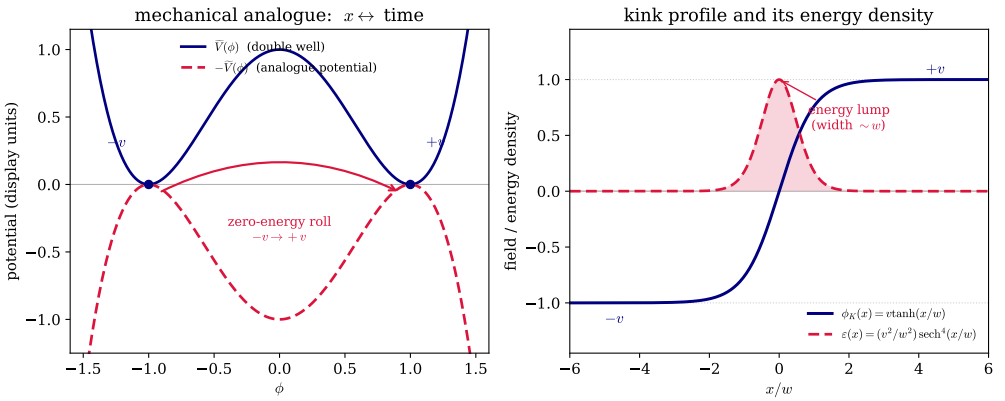

Figure 41.1: The 1+1 double-well kink of ϕ^4 theory. *Left:* the mechanical analogue. The static equation $\phi'' = \widetilde{V}'(\phi)$ is Newton's law for a unit-mass particle at position ϕ in "time" x moving in the *inverted* potential $U = -\widetilde{V}$ (Eq. (41.9)), a double hump with summits at the vacua $\pm v$. The finite-energy kink is the unique zero-mechanical-energy trajectory Eq. (41.12) that rolls from the top of the left hump at $x = -\infty$ to the top of the right hump at $x = +\infty$. *Right:* the field profile $\phi_K(x) = v\tanh(x/w)$ of Eq. (41.16) interpolating monotonically between the vacua, together with its static energy density $\varepsilon(x) = (\phi_K')^2 = (v^2/w^2)\,\mathrm{sech}^4(x/w)$, a localized lump of width $\sim w$ whose area is the kink mass M_{kink} of Eq. (41.35).

by an integer, and weighs $2m_{\text{phys}}^3/\lambda$, yet the entire perturbative apparatus of Parts III–XI, organized as an expansion in λ around $\phi \equiv v$, is structurally blind to it. This is the concrete sense in which we have stepped outside perturbation theory.

With the kink in hand we have, on the most transparent example available, the entire apparatus the rest of the chapter will generalize: finite-energy boundary conditions that strand the field in a discrete vacuum set, a partition of configuration space into superselection sectors, an off-shell-conserved current whose integer charge labels those sectors, and a Bogomolny bound saturated by a first-order equation whose solution we can write down and weigh. What the kink raises but cannot answer is why Q had to be an integer in the first place—we obtained it by counting endpoints in a two-element set, an accident of one dimension and a discrete vacuum manifold—and how the same logic survives when the vacuum manifold is a continuum and space has more than one end. Those questions are the business of the next section, which abstracts "the field at infinity lands in the vacuum manifold" into a map from the boundary of space into that manifold, and "Q counts traversals" into the homotopy class of that map.

41.2 Topological Charge and the Homotopy Classification

The kink handed us an integer and a puzzle. Its charge $Q = \frac{1}{2v}(\phi(+\infty) - \phi(-\infty))$ took the value $+1$ for the kink, -1 for the antikink, 0 for either constant vacuum, and—this was the decisive lesson of Section 41.1—it could not change under any continuous, finite-energy evolution, because changing it would require dragging the field at one spatial infinity from one well to the other, an excursion over the energy barrier that costs an infinite amount of energy in an infinite volume. The current $J^\mu = \frac{1}{2v}\epsilon^{\mu\nu}\partial_\nu\phi$ was conserved *off shell*: its divergence vanished identically by the antisymmetry of $\epsilon^{\mu\nu}$ against the symmetric $\partial_\mu\partial_\nu$, without ever invoking the equation of motion. None of this used the detailed shape of the double-well potential, the value of λ, or the explicit tanh profile. It used only two facts: that the potential has *more than one* degenerate minimum, and that finite energy pins the field to one of those minima at each end of space.

This section extracts the general principle hiding inside those two facts. We will see that finite-energy configurations of *any* field theory fall into disjoint families—superselection sectors—that no continuous finite-energy motion can connect, and that these families are labeled not by a number we invent for each model but by a single topological object: a homotopy group of the set of vacua. The charge is the *degree*, or winding number, of the map that the field at spatial infinity defines into the vacuum manifold, and its integrality and invariance are theorems of topology, not accidents of a particular Lagrangian. We build the needed homotopy theory from scratch as we go; the only inputs from outside this chapter are the classical field machinery of Chapters 6 and 7, the group/coset language of Chapter 2, and the order-parameter vocabulary of Chapter 29, which we recall but rebuild in the form we need.

41.2.1 The vacuum manifold

Every example in this chapter is governed by an energy functional of the schematic form

$$E[\phi] = \int \mathrm{d}^D x \left[\tfrac{1}{2}\,\partial_i\phi^a\,\partial_i\phi^a + V(\phi)\right], \tag{41.36}$$

where D is the number of *spatial* dimensions, the field $\phi = (\phi^1, \dots, \phi^k)$ takes values in some target $\mathbb{R}^k$ (later, in a group or coset), the index $i = 1, \dots, D$ runs over space, repeated indices are summed, and we have specialized to static configurations so that no time derivatives appear and E is the static energy of Section 41.1. The potential V is bounded below; by adding a constant we set its minimum value to zero. The first object the topology cares about is the set on which that minimum is attained.

Definition 41.7 (Vacuum manifold)**.** The *vacuum manifold* of the theory (41.36) is the set of absolute minima of the potential,

$$\mathcal{M} = \{\, \phi_0 \in \mathbb{R}^k \;:\; V(\phi_0) = 0 \,\}. \tag{41.37}$$

Its points are the constant field configurations of least energy—the classical vacua—and we assume throughout that V is smooth and that $\mathcal{M}$ is a smooth submanifold of $\mathbb{R}^k$ (generically true when the minima are nondegenerate transverse to $\mathcal{M}$).

For the kink, ϕ is a single real field, $V = \frac{\lambda}{4!}(\phi^2 - v^2)^2$, and $\mathcal{M} = \{+v, -v\}$: two isolated points, a zero-dimensional manifold. That discreteness is the whole story of the kink, as we will confirm in Theorem 41.13. In higher dimensions the interesting vacuum manifolds are continuous, and they arise for a structural reason worth recalling.

Suppose the energy (41.36) is invariant under a Lie group G acting linearly on the target, $\phi \mapsto g \cdot \phi$ for $g \in G$, with $V(g \cdot \phi) = V(\phi)$. Then G permutes the vacua: if $\phi_0 \in \mathcal{M}$ then $g \cdot \phi_0 \in \mathcal{M}$ for every g. Pick one vacuum ϕ_0. Its *stabilizer* (or little group)

$$H = \{\, h \in G \;:\; h \cdot \phi_0 = \phi_0 \,\} \tag{41.38}$$

is the subgroup of unbroken symmetries—the transformations the chosen vacuum does not notice—and is a closed subgroup of G. Two group elements g_1, g_2 carry ϕ_0 to the same vacuum iff $g_2^{-1} g_1 \in H$, i.e. iff they lie in the same left coset of H. Hence the orbit of ϕ_0, which (when the action is transitive on $\mathcal{M}$) is all of $\mathcal{M}$, is in bijection with the coset space:

$$\mathcal{M} \;\cong\; G/H. \tag{41.39}$$

This is the classical content of the spontaneous-symmetry-breaking story of Chapter 29: the broken theory's order parameter ϕ_0 singles out a vacuum, G breaks to H, and the degenerate vacua—the directions the order parameter can point—trace out the coset G/H, the same manifold whose tangent space at ϕ_0 carries the Goldstone modes. Here we need only the *geometry* of $\mathcal{M}$, built classically from the potential, not the quantum theory of fluctuations around it; the coset language of Chapter 2 supplies the rest. Two examples will recur:

- A complex field ϕ with $V = \frac{\lambda}{2}(|\phi|^2 - v^2)^2$ has $G = \mathrm{U}(1)$ acting by $\phi \mapsto e^{i\alpha}\phi$, broken completely ($H = \{1\}$), so $\mathcal{M} = \{|\phi| = v\} \cong \mathrm{U}(1) \cong S^1$, a circle. This drives the vortex.

- A real triplet ϕ^a $(a = 1, 2, 3)$ with $V = \frac{\lambda}{4}(\phi^a \phi^a - v^2)^2$ has $G = \mathrm{SO}(3)$ rotating the triplet, broken to $H = \mathrm{SO}(2)$ (rotations about the chosen ϕ_0), so $\mathcal{M} = \mathrm{SO}(3)/\mathrm{SO}(2) \cong S^2$, the two-sphere $\{|\phi| = v\}$. This drives the monopole, the Yang–Mills theory non-perturbative stage.

41.2.2 Finite energy and the asymptotic map

The kink's boundary conditions were not imposed by hand; finiteness of the energy forced them. The same argument works in any dimension and is the bridge from analysis to topology.

Proposition 41.8 (Finite energy pins the field to $\mathcal{M}$ at infinity)**.** *Let ϕ be a smooth configuration on $\mathbb{R}^D$ with $E[\phi] < \infty$ in (41.36). Then $V(\phi(x)) \to 0$ as $|x| \to \infty$; that is, along every ray the field approaches the vacuum manifold $\mathcal{M}$. Consequently ϕ has a well-defined limit on the sphere at spatial infinity, a continuous map*

$$\phi_\infty \colon\ S^{D-1}_\infty \longrightarrow \mathcal{M}, \qquad \phi_\infty(\hat{n}) = \lim_{r\to\infty} \phi(r\hat{n}), \tag{41.40}$$

where S^{D-1}_∞ is the sphere of unit directions $\hat{n}$ at radius $r \to \infty$.

Proof. The energy splits as $E = E_{\text{grad}} + E_{\text{pot}}$ with $E_{\text{pot}} = \int \mathrm{d}^D x\, V(\phi) \geq 0$. Finiteness of E forces $E_{\text{pot}} < \infty$. Since $V \geq 0$, the integral of V over the exterior region $|x| > R$ tends to zero as $R \to \infty$. If $V(\phi(x))$ did not tend to zero, there would be a sequence of points $x_n \to \infty$ and a $\delta > 0$ with $V(\phi(x_n)) \geq \delta$; by smoothness of ϕ and V and the boundedness of $\partial\phi$ implied by finite gradient energy, $V(\phi)$ stays above $\delta/2$ on balls of a fixed radius about each x_n, contributing a fixed positive amount to E_{pot} infinitely often, contradicting $E_{\text{pot}} < \infty$. Hence $V(\phi(x)) \to 0$, i.e. $\operatorname{dist}(\phi(x), \mathcal{M}) \to 0$. Finiteness of E_{grad} similarly forces the angular variation of ϕ on the sphere of radius r to die as $r \to \infty$ (the gradient energy of a fixed angular profile on S^{D-1}_r scales as $r^{D-1} \cdot r^{-2} = r^{D-3}$ from one factor of the tangential derivative squared, integrated over the sphere, and convergence of the radial integral forces the angular profile to freeze), so the radial limits (41.40) exist and assemble into a continuous map of the limiting sphere into $\mathcal{M}$. □

Physical Insight

Spatial infinity is a sphere S^{D-1}: in one spatial dimension it is the two points $\{-\infty, +\infty\} = S^0$; in two dimensions a circle S^1; in three a two-sphere S^2. Finite energy converts *every* localized configuration, whatever its complicated interior, into a clean piece of boundary data—a map from that sphere into the vacuum manifold. All the topology lives in this boundary map. The interior is free to do anything finite-energy; only how the field "wraps" the vacuum manifold as we circle spatial infinity is protected.

Two configurations that can be continuously deformed into one another through finite-energy intermediates have asymptotic maps that can be continuously deformed into one another as maps $S^{D-1} \to \mathcal{M}$. The converse also holds:

if two asymptotic maps are continuously deformable, one can build a finite-energy interpolation of the bulk fields realizing the deformation. So the question "which finite-energy sectors exist, and which are connected?" is *exactly* the question "into how many classes do continuous maps $S^{D-1} \to \mathcal{M}$ fall, under continuous deformation?" That last question is purely topological, and answering it is what homotopy theory does.

41.2.3 Homotopy: deforming maps

Definition 41.9 (Homotopy)**.** Let X, Y be topological spaces and $f_0, f_1 \colon X \to Y$ continuous. A *homotopy* from f_0 to f_1 is a continuous map $F \colon X \times [0,1] \to Y$ with $F(\cdot, 0) = f_0$ and $F(\cdot, 1) = f_1$. We write $f_0 \simeq f_1$ and call them *homotopic*; intuitively F is a continuous movie deforming f_0 into f_1. Homotopy is an equivalence relation: reflexivity by the constant movie $F(x, s) = f_0(x)$; symmetry by running the movie backwards, $s \mapsto 1 - s$; transitivity by concatenating two movies, playing the first on $s \in [0, \frac{1}{2}]$ at double speed and the second on $[\frac{1}{2}, 1]$, which is continuous because the two agree at the splice $s = \frac{1}{2}$.

The equivalence classes are the *homotopy classes* $[f]$, and the set of all classes of maps $X \to Y$ is written $[X, Y]$. By the discussion above, the finite-energy sectors of our field theory are exactly the elements of $[S^{D-1}, \mathcal{M}]$. When X is itself a sphere this set carries extra structure—a group law—and becomes a homotopy group, which is the object we actually compute. We build the lowest three.

π_0: path components. The zeroth homotopy "group" is the simplest. Take $X = S^0$, the two-point space; a map $S^0 \to Y$ is just an ordered pair of points, but the useful object keeps only one of them. Define $\pi_0(Y)$ to be the set of *path components* of Y: two points $y_0, y_1 \in Y$ are equivalent iff there is a continuous path $\gamma \colon [0,1] \to Y$ with $\gamma(0) = y_0, \gamma(1) = y_1$, and $\pi_0(Y)$ is the set of equivalence classes. It records "how many disconnected pieces Y has." It is a set with a marked point (the component of a chosen basepoint), not in general a group.

For the kink, $D = 1$, so $S^{D-1} = S^0$, and the asymptotic data is a point of $\mathcal{M}$ at each of $\pm\infty$, i.e. a choice of component of $\mathcal{M}$ at each end. With $\mathcal{M} = \{+v, -v\}$ having exactly two path components, $\pi_0(\mathcal{M}) = \{[+v], [-v]\}$ is a two-element set. We unpack this completely in Theorem 41.13.

π_1: the fundamental group. Now take $X = S^1$. A map $S^1 \to Y$ is a *loop*—a continuous path that returns to its start. Fix a basepoint $y_0 \in Y$ and consider loops based there: continuous $\gamma \colon [0,1] \to Y$ with $\gamma(0) = \gamma(1) = y_0$. Two such are equivalent if homotopic *through based loops* (the homotopy fixes the basepoint at every stage). The set of classes is $\pi_1(Y, y_0)$, the *fundamental group*, and it really is a group, with the following structure.

The product of two based loops is their concatenation, traversed at double speed:

$$(\gamma_1 \cdot \gamma_2)(t) = \begin{cases} \gamma_1(2t), & 0 \le t \le \tfrac{1}{2}, \\ \gamma_2(2t-1), & \tfrac{1}{2} \le t \le 1, \end{cases} \tag{41.41}$$

continuous because $\gamma_1(1) = y_0 = \gamma_2(0)$ at the splice. One checks the group axioms at the level of homotopy classes. *Identity:* the constant loop $e(t) = y_0$ satisfies $\gamma \cdot e \simeq \gamma \simeq e \cdot \gamma$, the homotopy being a continuous reparametrization that absorbs the dead time spent sitting at y_0. *Inverses:* the reversed loop $\bar{\gamma}(t) = \gamma(1-t)$ satisfies $\gamma \cdot \bar{\gamma} \simeq e$, the explicit homotopy $F(t,s)$ retracing γ only up to "time" s and then immediately backtracking, so that at $s = 0$ one has the full out-and-back loop and at $s = 1$ the constant loop. *Associativity:* $(\gamma_1 \cdot \gamma_2) \cdot \gamma_3 \simeq \gamma_1 \cdot (\gamma_2 \cdot \gamma_3)$, the two differing only by the speeds at which the three legs are run, related by a continuous reparametrization of $[0,1]$. Each axiom holds only *up to homotopy*, which is exactly why π_1 is defined on classes and not on loops themselves. When Y is path-connected, $\pi_1(Y, y_0)$ is independent of y_0 up to isomorphism, and we drop the basepoint.

π_n: the higher homotopy groups. The pattern continues. A based map of the n-sphere, $f\colon S^n \to Y$ with a marked point of S^n sent to y_0, has homotopy classes (through based maps) forming the n-th homotopy group $\pi_n(Y, y_0)$. The group law generalizes (41.41): think of S^n as a cube $[0,1]^n$ with its entire boundary collapsed to y_0, and multiply two such cubes by stacking them along the first coordinate (run f_1 on $x_1 \in [0, \frac{1}{2}]$, f_2 on $[\frac{1}{2}, 1]$), the collapsed boundaries making the result continuous. The same reparametrization arguments give identity, inverses, and associativity up to homotopy. A new feature appears for $n \ge 2$: there are now two independent directions in which to stack, and sliding one factor "around" the other shows the product is *abelian*, $\pi_n(Y)$ is an abelian group for $n \ge 2$, whereas π_1 may be nonabelian. We will need this only as a fact; the cases that matter for us are all already abelian, indeed cyclic.

Theorem 41.10 (Homotopy classification of finite-energy sectors)**.** *The finite-energy configurations of the theory* (41.36) *on $\mathbb{R}^D$, modulo continuous finite-energy deformation, are in bijection with the based homotopy classes of asymptotic maps, $[S^{D-1}, \mathcal{M}]$. When $\mathcal{M}$ is path-connected, these are classified by the homotopy group $\pi_{D-1}(\mathcal{M})$. The sector containing the constant vacuum is the trivial (identity) class; any sector that is not this class contains no configuration deformable to a vacuum, and is what we call a* topological soliton sector*.*

Proof. Theorem 41.8 assigns to each finite-energy ϕ its asymptotic map $\phi_\infty \in \{S^{D-1} \to \mathcal{M}\}$, and a finite-energy deformation of ϕ induces a homotopy of ϕ_∞, so the class $[\phi_\infty] \in [S^{D-1}, \mathcal{M}]$ is a deformation invariant. Conversely, given any continuous $g\colon S^{D-1} \to \mathcal{M}$, extend it to a finite-energy bulk field by

$\phi(r\hat{n}) = \rho(r)\, g(\hat{n})$ for a smooth profile ρ that interpolates from a vacuum-valued interior to g at infinity (for $\mathcal{M} \subset \mathbb{R}^k$ a sphere of radius v, take $\rho(r)$ rising from 0 to v; the gradient and potential energies are finite because the angular profile freezes for large r). Thus every class is realized, and a homotopy of g lifts to a finite-energy deformation of the bulk field, so distinct classes are genuinely distinct sectors. The basepoint subtlety—a free homotopy class versus a based one—does not affect the count when $\mathcal{M}$ is path-connected and, in the cyclic cases below, when $\pi_1(\mathcal{M})$ acts trivially; we use this in the abelian cases that concern us. Finally, the constant vacuum has constant ϕ_∞, the identity class, and any configuration in a nontrivial class cannot be deformed to it without leaving the finite-energy configurations or jumping homotopy class, neither of which a continuous finite-energy motion can do. □

The labels $\pi_0, \pi_1, \pi_2, \ldots$ now have physical jobs. In $D = 1$ the classifier is $\pi_0(\mathcal{M})$, counting discrete vacua—the kink. In $D = 2$ it is $\pi_1(\mathcal{M})$, the winding of the field around spatial infinity into the vacuum manifold—the vortex. In $D = 3$ it is $\pi_2(\mathcal{M})$, the wrapping of the asymptotic two-sphere over the vacuum two-sphere—the monopole. Everything reduces to computing these groups for the relevant $\mathcal{M}$, and to writing the integer (or, occasionally, the $\mathbb{Z}_2$ label) explicitly as a charge.

41.2.4 The winding number of a circle map, and $\pi_1(S^1) = \mathbb{Z}$

The single most important computation in the subject is $\pi_1(S^1)$. It controls the vortex directly, and its method—lifting to the universal cover—is the template for every degree theorem that follows. We treat S^1 as the unit circle and parametrize the target circle by an angle, so a map of circles is encoded by a real-valued angular function.

Theorem 41.11 (Winding number; $\pi_1(S^1) \cong \mathbb{Z}$)**.** *Realize the circle as $S^1 = \mathbb{R}/2\pi\mathbb{Z}$ with covering projection $p\colon \mathbb{R} \to S^1$, $p(\theta) = \theta \bmod 2\pi$. For every loop $\gamma\colon [0,1] \to S^1$ there is a continuous* lift *$\tilde{\gamma}\colon [0,1] \to \mathbb{R}$ with $p \circ \tilde{\gamma} = \gamma$, unique once $\tilde{\gamma}(0)$ is fixed. For a based loop ($\gamma(0) = \gamma(1)$) the quantity*

$$w(\gamma) = \frac{\tilde{\gamma}(1) - \tilde{\gamma}(0)}{2\pi} \tag{41.42}$$

is an integer, the winding number*, independent of the choice of lift; it depends only on the based-homotopy class of γ; and $w\colon \pi_1(S^1) \to \mathbb{Z}$ is a group isomorphism.*

Proof. Existence and uniqueness of lifts. The projection p restricted to any open interval of length less than 2π is a homeomorphism onto its image (an open arc); its inverse is a local branch of the angle. Cover $[0,1]$ by preimages under γ of small arcs of S^1; by compactness there is a Lebesgue number $\delta > 0$ such that γ maps each subinterval of a partition $0 = t_0 < t_1 < \cdots < t_N = 1$

with mesh $< \delta$ into a single such arc. Fix $\tilde\gamma(t_0)$ over $\gamma(t_0)$. On $[t_0, t_1]$ define $\tilde\gamma$ by composing γ with the local inverse of p that takes $\gamma(t_0)$ to $\tilde\gamma(t_0)$; this is continuous. Proceed inductively, at each step choosing the local inverse matching the value $\tilde\gamma(t_j)$ already fixed at the left endpoint. The result is a continuous $\tilde\gamma$ with $p\circ\tilde\gamma = \gamma$. Uniqueness: if $\tilde\gamma_1, \tilde\gamma_2$ are two lifts with the same start, then $\tilde\gamma_1 - \tilde\gamma_2$ is continuous and $p(\tilde\gamma_1) = p(\tilde\gamma_2)$ forces $\tilde\gamma_1 - \tilde\gamma_2 \in 2\pi\mathbb{Z}$ pointwise; a continuous integer-multiple-of-2π function starting at 0 is identically 0.

Integrality. For a based loop, $p(\tilde\gamma(1)) = \gamma(1) = \gamma(0) = p(\tilde\gamma(0))$, so $\tilde\gamma(1) - \tilde\gamma(0) \in 2\pi\mathbb{Z}$ and $w(\gamma) \in \mathbb{Z}$. Changing the choice of $\tilde\gamma(0)$ shifts $\tilde\gamma$ by a constant, leaving the difference (41.42) unchanged.

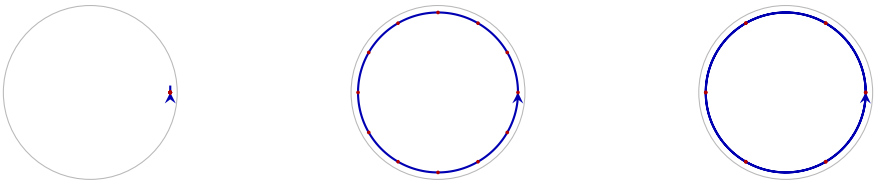
Homotopy invariance. Let $F\colon [0,1]\times[0,1] \to S^1$ be a based homotopy, $F(\cdot,0) = \gamma_0$, $F(\cdot,1) = \gamma_1$, with $F(0,s) = F(1,s) = y_0$ fixed for all s. The identical partition-and-local-inverse construction, now on the square (whose Lebesgue number controls a grid of small squares), produces a continuous lift $\tilde F\colon [0,1]^2 \to \mathbb{R}$ with $p\circ\tilde F = F$ and $\tilde F(\cdot,0) = \tilde\gamma_0$. For each fixed s, $\tilde F(\cdot,s)$ is a lift of the loop $F(\cdot,s)$, so $w_s := \big(\tilde F(1,s) - \tilde F(0,s)\big)/2\pi$ is an integer for every s. But $\tilde F(1,s)$ and $\tilde F(0,s)$ are continuous in s (they are lifts of the constant path $s \mapsto y_0$, hence each is itself constant in s up to $2\pi\mathbb{Z}$, and continuity pins them), so w_s is a continuous integer-valued function of s, therefore constant: $w(\gamma_0) = w(\gamma_1)$. Thus w descends to homotopy classes.

Homomorphism and isomorphism. For the concatenation (41.41), lift γ_1 starting at 0 and continue the lift of γ_2 from the endpoint $\tilde\gamma_1(1)$; the total rise is the sum of rises, so $w(\gamma_1\cdot\gamma_2) = w(\gamma_1) + w(\gamma_2)$, a homomorphism into $(\mathbb{Z},+)$. It is *onto*: the loop $\gamma_m(t) = p(2\pi m t)$ has lift $\tilde\gamma_m(t) = 2\pi m t$ and winding m, realizing every integer. It is *injective*: if $w(\gamma) = 0$, then $\tilde\gamma$ is a loop in $\mathbb{R}$ (its endpoints coincide), and $\mathbb{R}$ is convex, so $\tilde\gamma$ contracts to a point by the straight-line homotopy $(t,s) \mapsto (1-s)\tilde\gamma(t) + s\,\tilde\gamma(0)$; projecting by p gives a based contraction of γ, so $[\gamma]$ is trivial. A surjective homomorphism with trivial kernel is an isomorphism: $\pi_1(S^1) \cong \mathbb{Z}$. □

For smooth maps the winding number has an integral expression that we will need as the prototype of the general charge. Write the target angle as a smooth function $\alpha(\theta)$ of the domain angle $\theta \in [0, 2\pi]$, with $\alpha(2\pi) - \alpha(0) \in 2\pi\mathbb{Z}$ for the map to close. Then the lift is $\tilde\gamma(\theta) = \alpha(\theta)$ and

$$w = \frac{\alpha(2\pi) - \alpha(0)}{2\pi} = \frac{1}{2\pi}\int_0^{2\pi} \frac{\mathrm{d}\alpha}{\mathrm{d}\theta}\,\mathrm{d}\theta = \int_{S^1} \frac{\mathrm{d}\alpha}{2\pi} = \int_{S^1} \phi^*\omega, \tag{41.43}$$

where $\omega = \mathrm{d}\alpha/2\pi$ is the *normalized volume form* on the target circle—the unique invariant one-form with $\int_{S^1}\omega = 1$—and $\phi^*\omega$ denotes its pullback by the map. The last equality is the form in which the formula generalizes: *the degree is the integral over the domain sphere of the pullback of the normalized volume form of the target.*



$w = 0$ $w = 1$ $w = 2$

Figure 41.2: Maps $\phi\colon S^1 \to S^1$ of winding number $w = 0, 1, 2$. As the domain angle θ runs once around, the image point runs around the target circle w times. By Theorem 41.11 the integer w is invariant under any continuous deformation of the map; no continuous motion can change how many times the image encircles the target.

41.2.5 The degree formula and the general topological charge

We can now state the charge in full generality and recognize the kink's Q as its lowest instance. Suppose the vacuum manifold is itself a $(D-1)$-sphere of radius v in field space (the two recurring examples, the circle for $D = 2$ and the two-sphere for $D = 3$, are exactly this), and let ω be the normalized volume form on $\mathcal{M}$, the unique rotation-invariant $(D-1)$-form with $\int_{\mathcal{M}} \omega = 1$. The *topological charge* of a finite-energy configuration with asymptotic map $\phi_\infty\colon S^{D-1}_\infty \to \mathcal{M}$ is the *degree*

$$Q = \deg \phi_\infty = \int_{S^{D-1}_\infty} \phi_\infty^* \omega. \tag{41.44}$$

That this integral is an integer is the higher-dimensional generalization of Theorem 41.11; we proved it in full for $D = 2$ (the circle) there, and the same lifting/covering machinery—now the statement that the degree of a smooth map between equidimensional oriented closed manifolds equals the signed count of preimages of any regular value, hence an integer—establishes it for every D. We will use it concretely in two cases.

The kink ($D = 1$). Here $S^{D-1} = S^0 = \{-\infty, +\infty\}$ and $\mathcal{M} = \{-v, +v\} = S^0$. The "normalized volume form" of a two-point oriented set is the signed counting that assigns $+\frac{1}{2}$ to the point $+v$ and $-\frac{1}{2}$ to $-v$ (so the total, the 0-form integrated over the oriented 0-manifold with its two oppositely oriented points, is normalized), and the degree (41.44) reduces to

$$Q = \tfrac{1}{2}\big[\sigma(\phi(+\infty)) - \sigma(\phi(-\infty))\big] = \frac{\phi(+\infty) - \phi(-\infty)}{2v}, \tag{41.45}$$

where $\sigma(\pm v) = \pm 1$. This is precisely the kink charge of Section 41.1, now seen as the $D = 1$ degree. Equivalently, $Q = \frac{1}{2v}\int_{-\infty}^{\infty} \partial_x \phi \, \mathrm{d}x = \int_{-\infty}^{\infty} J^0 \, \mathrm{d}x$ with $J^0 = \frac{1}{2v}\partial_x \phi$, the integral over $\mathbb{R}^1$ of a total derivative whose value is fixed by the boundary data—the one-dimensional shadow of (41.44).

The circle target ($D = 2$, the vortex). Here (41.44) is exactly the winding integral (41.43) evaluated on the asymptotic circle, $Q = \frac{1}{2\pi}\oint_{S^1_\infty} \mathrm{d}\alpha \in \mathbb{Z}$, with α the phase of the complex order parameter at infinity. The integer counts how many times the phase winds as one circles spatial infinity.

The sphere target ($D = 3$, the monopole), and $\pi_2(S^2) = \mathbb{Z}$. For $\mathcal{M} = S^2 = \{|\phi| = v\}$ write the unit field $n^a = \phi^a/v$. The normalized volume form of the unit two-sphere is $\omega = \frac{1}{8\pi}\,\epsilon_{abc}\, n^a\, \mathrm{d}n^b \wedge \mathrm{d}n^c$ (it integrates to $\frac{1}{4\pi} \times \text{area} = 1$), so (41.44) becomes the explicit winding integral

$$Q = \frac{1}{8\pi}\int_{S^2_\infty} \epsilon_{abc}\, n^a\, \partial_i n^b\, \partial_j n^c\, \mathrm{d}S^{ij} = \frac{1}{8\pi}\int_{S^2_\infty} \epsilon_{abc}\, \epsilon^{ij}\, n^a\, \partial_i n^b\, \partial_j n^c\, \mathrm{d}^2\sigma \;\in\; \mathbb{Z}, \tag{41.46}$$

where $\mathrm{d}S^{ij}$ is the oriented surface element of the asymptotic two-sphere and the integrand is the pullback of ω. The integer is the degree of the map $n\colon S^2_\infty \to S^2$, the number of times n covers the target sphere, and the corresponding statement of topology is

$$\pi_2(S^2) \cong \mathbb{Z}. \tag{41.47}$$

We do not reprove (41.47) from scratch; it follows from the same degree theory as Theorem 41.11 (the degree is a homotopy invariant, takes every integer value via the maps $n \mapsto n^{\otimes m}$ realized by Brouwer's construction, and detects triviality), and the integral (41.46) computes the isomorphism explicitly. This is the formula the 't Hooft–Polyakov monopole will saturate.

Caution

The clean integer-valued degree formula (41.44) works only when $\dim \mathcal{M} = D - 1$, so that an asymptotic-sphere top-form can be pulled back. When the dimensions do not match, or when the relevant homotopy group is not $\mathbb{Z}$, the classification is still given by Theorem 41.10 but the charge need not be an integral. The cleanest example is the next one.

A non-integer label: $\pi_1(\mathrm{SO}(3)) = \mathbb{Z}_2$. Not every topological charge is an integer counting a winding; some are merely a sign. The order parameter of a system whose vacua are orientations in three-dimensional space takes values in $\mathcal{M} = \mathrm{SO}(3)$. We established in Chapter 2 that $\mathrm{SU}(2)$ is the simply connected double cover of $\mathrm{SO}(3)$ with kernel $\{\pm\mathbf{1}\}$, so that $\mathrm{SO}(3) \cong \mathrm{SU}(2)/\{\pm\mathbf{1}\} \cong \mathbb{RP}^3$ and a 2π rotation traces a loop that cannot be contracted while a 4π rotation can (Theorem 2.55). In the language now available this is the statement

$$\pi_1(\mathrm{SO}(3)) \cong \mathbb{Z}_2, \tag{41.48}$$

with the nontrivial class the 2π loop: it is its own inverse, since traversing it twice (a 4π rotation) is contractible. The proof is exactly the lifting argument

of Theorem 41.11 applied to the covering $\mathrm{SU}(2) \to \mathrm{SO}(3)$, with the simple-connectivity of $S^3 = \mathrm{SU}(2)$ (also from Theorem 2.55) playing the role $\mathbb{R}$ played there: a loop in SO(3) lifts to a path in SU(2), and the loop is contractible iff the lift closes, i.e. iff the lift's endpoints agree rather than differ by the kernel element $-\mathbf{1}$. The two cosets of the kernel give the two classes $\mathbb{Z}_2$. The corresponding topological objects in a two-dimensional medium with SO(3) order parameter carry a charge valued in $\mathbb{Z}_2$, not $\mathbb{Z}$—two of them can annihilate—and there is no integral formula (41.44) for it, only the discrete invariant.

41.2.6 Invariance of the topological charge

We have asserted that Q cannot change under continuous finite-energy deformation; this is the keystone, and we now prove it directly from the integral formula, exhibiting its first variation as a total derivative that the fixed asymptotics kill. The argument simultaneously explains *why* Q is conserved off shell, with no appeal to the equation of motion.

Theorem 41.12 (Topological invariance of the charge)**.** *Let ϕ_s, $s \in [0,1]$, be a smooth one-parameter family of finite-energy configurations on $\mathbb{R}^D$, so that for each s the asymptotic map $\phi_{s,\infty}\colon S^{D-1}_{\infty} \to \mathcal{M}$ is defined. Then the degree (41.44) is independent of s:*

$$\frac{\mathrm{d}}{\mathrm{d}s}\, Q[\phi_s] = 0. \tag{41.49}$$

Equivalently, Q is constant on each finite-energy sector and changes only by an integer jump between sectors, which a continuous deformation cannot produce.

Proof. Write $Q[\phi_s] = \int_{S^{D-1}} \phi_s^{*}\omega$ with ω the normalized volume form on $\mathcal{M}$, an $(D-1)$-form. Since ω is a top-degree form on the $(D-1)$-dimensional manifold $\mathcal{M}$, it is automatically *closed*: $\mathrm{d}\omega = 0$ (its exterior derivative would be a D-form on a $(D-1)$-manifold, necessarily zero). Let V denote the variation field $\partial_s \phi_s$, a vector along the map valued in the tangent spaces of $\mathcal{M}$. By Cartan's identity for the Lie derivative along the deformation,

$$\frac{\mathrm{d}}{\mathrm{d}s}\, \phi_s^{*}\omega = \phi_s^{*}(\mathcal{L}_V \omega) = \phi_s^{*}(\iota_V\, \mathrm{d}\omega + \mathrm{d}\, \iota_V \omega) = \phi_s^{*}(\mathrm{d}\, \iota_V \omega) = \mathrm{d}(\phi_s^{*}\, \iota_V \omega), \tag{41.50}$$

where the third equality used $\mathrm{d}\omega = 0$ and the fourth used that pullback commutes with d. Thus the first variation of the integrand is an *exact* form—a total derivative of the $(D-2)$-form $\beta_s := \phi_s^{*}\, \iota_V \omega$. Integrating over the asymptotic sphere and applying Stokes,

$$\frac{\mathrm{d}}{\mathrm{d}s}\, Q[\phi_s] = \int_{S^{D-1}} \mathrm{d}\beta_s = \int_{\partial S^{D-1}} \beta_s = 0, \tag{41.51}$$

because S^{D-1} is a closed manifold, $\partial S^{D-1} = \varnothing$. The variation vanishes identically; Q is constant in s. □

Physical Insight

Read (41.50)–(41.51) physically. The charge density is the pullback of a closed form, so its variation is automatically a total derivative; the only thing that can survive is a boundary term; and the boundary of the sphere at infinity is empty (or, in the bulk picture below, sits at infinity where finite energy has frozen the field to a fixed vacuum, killing the term). The integral does not budge. This is the off-shell conservation we first met for the kink current $J^\mu = \frac{1}{2v}\epsilon^{\mu\nu}\partial_\nu\phi$, whose divergence $\partial_\mu J^\mu \propto \epsilon^{\mu\nu}\partial_\mu\partial_\nu\phi$ vanishes identically by antisymmetry—no equation of motion required—now revealed as the special case of (41.50) in one dimension. A Noether charge (Chapter 7) is conserved *on shell*, because of a symmetry and via the field equations; a topological charge is conserved *off shell*, because it is the integral of a closed form over a cycle, a fact of geometry that holds for every configuration, solution or not.

The same conclusion in the bulk picture makes the phrase "fixed asymptotics" explicit. Write the kink-type charge as a bulk integral of a current, $Q = \int_{\mathbb{R}^D} J^0 \,\mathrm{d}^D x$ with J^0 a total spatial divergence, $J^0 = \partial_i K^i$ for some K^i built from the field (for the kink, $K^1 = \frac{1}{2v}\phi$ and $D = 1$; for the circle and sphere targets, K^i is the appropriate pullback potential). Then

$$\frac{\mathrm{d}}{\mathrm{d}s}Q = \int_{\mathbb{R}^D} \partial_i\, \delta K^i \,\mathrm{d}^D x = \oint_{S^{D-1}_\infty} \delta K^i \,\mathrm{d}S_i, \tag{41.52}$$

a pure boundary term on the sphere at infinity. A finite-energy deformation holds ϕ pinned to its vacuum value there (Theorem 41.8), so the variation δK^i of the boundary data either vanishes or, when the asymptotic map itself is deformed, integrates to zero by Theorem 41.12. To change Q one would have to violate the boundary condition—to drag the field at some direction of spatial infinity off the vacuum manifold and across the potential barrier—which in infinite volume costs infinite energy. The integer is locked.

41.2.7 Worked example: the kink as the nontrivial class of π_0

Worked Example 41.13 (The kink is the nontrivial element of $\pi_0(\{\pm v\})$)**.** We verify that the entire topological content of the kink is the statement $\pi_0(\mathcal{M}) = \{[+v], [-v]\}$, and that Theorems 41.10 and 41.12 reproduce, with no new input, every claim of Section 41.1.

Setup. One spatial dimension, $D = 1$, real field ϕ, potential $V = \frac{\lambda}{4!}(\phi^2 - v^2)^2$, vacuum manifold $\mathcal{M} = \{+v, -v\}$. Spatial infinity is $S^0 = \{-\infty, +\infty\}$. The asymptotic map (41.40) is the pair $\phi_\infty = (\phi(-\infty), \phi(+\infty)) \in \mathcal{M} \times \mathcal{M}$.

Counting the sectors. By Theorem 41.10 the sectors are the homotopy classes $[S^0, \mathcal{M}]$. A map $S^0 \to \mathcal{M}$ is a choice of one of the two points at each end, and

two such maps are homotopic iff each endpoint can be continuously slid to its partner *within* $\mathcal{M}$. But $\mathcal{M} = \{\pm v\}$ is discrete: there is no path from $+v$ to $-v$ inside it. Hence each endpoint's choice is a frozen element of $\pi_0(\mathcal{M})$, and the four sectors are

$$(-v,-v), \quad (+v,+v), \quad (-v,+v), \quad (+v,-v). \tag{41.53}$$

The first two are the constant vacua, charge $Q = 0$ by (41.45). The third is the kink, $Q = \frac{(+v)-(-v)}{2v} = +1$. The fourth is the antikink, $Q = -1$. The kink is precisely the configuration whose two ends land in *different* path components of $\mathcal{M}$—it interpolates across the nontrivial element of π_0—which is the formal meaning of "a kink connects the two vacua."

Why it cannot decay. A continuous finite-energy evolution is a path $s \mapsto \phi_s$ in the configuration space. By Theorem 41.12, $Q[\phi_s]$ is constant; explicitly, $\frac{\mathrm{d}}{\mathrm{d}s}Q = \frac{1}{2v}\big[\delta\phi\big]_{-\infty}^{+\infty} = 0$ because finite energy pins $\delta\phi(\pm\infty) = 0$. A kink ($Q = 1$) therefore can never reach a vacuum ($Q = 0$): the two live in different superselection sectors. The only way to remove a kink is to bring in an antikink ($Q = -1$) and annihilate, conserving total $Q = 0$—which is allowed and indeed happens, releasing the rest energy as radiation.

Consistency with the explicit current. The bulk charge is $Q = \int_{-\infty}^{\infty} J^0 \mathrm{d}x$ with $J^0 = \frac{1}{2v}\partial_x\phi = \partial_x K$, $K = \frac{1}{2v}\phi$. Its variation (41.52) is $\frac{\mathrm{d}}{\mathrm{d}s}Q = \big[\delta K\big]_{-\infty}^{+\infty} = \frac{1}{2v}\big[\delta\phi\big]_{-\infty}^{+\infty}$, a pure boundary term, vanishing exactly as the abstract Stokes argument predicted. Everything in Section 41.1 was the $D = 1$, π_0 shadow of the general classification.

The classification answers "which sectors *can* exist": a nontrivial $\pi_{D-1}(\mathcal{M})$ guarantees finite-energy configurations that no continuous motion can unwind to the vacuum. It does *not* guarantee that any such configuration is a static *solution*—a stationary point of the energy realized at finite size rather than spreading out or collapsing. Whether a given sector actually contains a static, finite-energy minimizer in a given spatial dimension is a separate, dynamical question, and the answer turns out to be sharply negative for scalars alone above one dimension. That obstruction—and the gauge fields it forces upon us—is the subject of Section 41.3, to which we now turn.

41.3 Derrick's Theorem and the Need for Gauge Fields

The homotopy classification of Section 41.2.3 is a promise, not a guarantee. It tells us that finite-energy configurations of a theory with vacuum manifold $\mathcal{V}$ fall into superselection sectors labelled by $\pi_{D-1}(\mathcal{V})$, and that whenever this group is nontrivial there *exist* continuous field configurations carrying a nonzero

topological charge that no continuous, finite-energy deformation can undo. What it does *not* tell us is whether any such configuration is a *solution* of the field equations—whether the energy functional, restricted to a charged sector, actually attains a minimum at a smooth, static, finite-energy field. Topology supplies the lower bound on the number of solitons (at least one per sector, if the bound is saturated); dynamics must supply the solitons themselves. In one spatial dimension the kink of Section 41.1 did both at once, and we may have come to expect the pattern to repeat in every dimension. It does not. The purpose of this section is a single sharp negative result, due to Derrick, that closes off the naive route: *in two or more spatial dimensions, a theory of scalar fields alone has no static, finite-energy soliton other than the vacuum.* The proof is a one-line scaling argument once it is set up correctly, and its real value is constructive: by cataloguing exactly how each kind of term in the energy responds to a rescaling, it tells us precisely what must be added to the theory to make a higher-dimensional soliton possible. The answer—gauge fields—dictates the two constructions that follow.

41.3.1 The static energy functional and its pieces

Throughout, D denotes the number of *spatial* dimensions, so spacetime is $(D+1)$-dimensional and the physical case of Chapter 42 onward is $D = 3$. We work entirely at the classical level: a soliton is a critical point of the static energy functional, and $\hbar$ stays in the drawer. The energy of a static configuration is the spatial integral of the T^{00} component of the stress tensor built in Chapter 7 (the conserved charge associated with time translations, Eq. (7.97)). For a collection of real scalar fields $\phi = (\phi_1, \dots, \phi_n)$ with the standard two-derivative Lagrangian

$$\mathcal{L} = \tfrac{1}{2}\,\partial_\mu \phi \cdot \partial^\mu \phi - V(\phi), \tag{41.54}$$

the energy density of a *time-independent* configuration $\phi(\mathbf{x})$ is

$$T^{00} = \tfrac{1}{2}\,\dot{\phi}\cdot\dot{\phi} + \tfrac{1}{2}\,\nabla\phi\cdot\nabla\phi + V(\phi) \;\xrightarrow{\dot{\phi}=0}\; \tfrac{1}{2}\,|\nabla\phi|^2 + V(\phi), \tag{41.55}$$

where $|\nabla\phi|^2 = \sum_a \sum_{i=1}^{D} (\partial_i \phi_a)^2$ and the dot is the sum over the internal index a. We take $V \geq 0$, normalised so that $V = 0$ exactly on the vacuum manifold $\mathcal{V} = \{\phi : V(\phi) = 0\}$; any potential bounded below can be brought to this form by adding a constant, which shifts the energy by an (infinite, but configuration-independent) amount that we subtract once and for all. This is the same finite-energy bookkeeping that made the kink's energy convergent in Section 41.1.

Definition 41.14 (Static scalar energy and its two pieces)**.** For a static configuration $\phi : \mathbb{R}^D \to \mathbb{R}^n$ the energy is

$$E[\phi] \;=\; \int_{\mathbb{R}^D} \mathrm{d}^D x \left[\tfrac{1}{2}\,|\nabla\phi|^2 + V(\phi)\right] \;=\; E_{\mathrm{grad}} + E_{\mathrm{pot}}, \tag{41.56}$$

with the *gradient* (or stiffness) energy and the *potential* energy

$$E_{\text{grad}}[\phi] \;=\; \int_{\mathbb{R}^D} \mathrm{d}^D x\, \tfrac{1}{2}\,|\nabla\phi|^2 \;\geq 0, \qquad E_{\text{pot}}[\phi] \;=\; \int_{\mathbb{R}^D} \mathrm{d}^D x\, V(\phi) \;\geq 0. \quad (41.57)$$

A configuration has *finite energy* if both pieces are finite; a *static soliton* is a finite-energy critical point of E that is not a constant vacuum configuration.

Both pieces are manifestly non-negative, and this is the only structural fact the argument uses. The two pieces pull the configuration in opposite directions, and the tension between them is the whole story. The gradient energy penalises rapid variation: it is lowered by stretching the configuration out, spreading the same field profile over a larger region. The potential energy penalises any departure from the vacuum: it is lowered by shrinking the region in which ϕ strays from $\mathcal{V}$, squeezing the profile toward a point. A soliton, if it exists, is a truce between these two—a configuration whose size is fixed by their balance. Derrick's insight is that in $D \geq 2$ no such truce is possible: one tendency always wins outright.

41.3.2 The rescaling family and the scaling energy

To probe the balance we deform a candidate configuration along the one direction that pits the two energies against each other most directly: a uniform spatial dilation that stretches or shrinks the whole profile while keeping its shape.

Definition 41.15 (Scaling family)**.** Given a finite-energy configuration $\phi(\mathbf{x})$ and a parameter $\mu > 0$, define the rescaled configuration

$$\phi_\mu(\mathbf{x}) \;\equiv\; \phi\!\left(\frac{\mathbf{x}}{\mu}\right). \quad (41.58)$$

For $\mu > 1$ the profile is dilated (spread out by a factor μ); for $\mu < 1$ it is contracted; $\mu = 1$ returns the original. The same field values are visited, redistributed over a region whose linear size is scaled by μ. Any boundary condition $\phi \to \mathcal{V}$ at spatial infinity is preserved for every $\mu > 0$, so the entire family lies in one topological sector and the topological charge is constant along it.

The decisive feature of Eq. (41.58) is that it leaves the topological charge untouched—the deformation is exactly the kind of continuous, finite-energy motion within a fixed sector that the classification of Section 41.2.3 declared the charge to be invariant under—so if ϕ is a genuine energy minimiser in its sector, then in particular $\mu = 1$ must minimise the ordinary function $E(\mu) \equiv E[\phi_\mu]$ of the single real variable μ. We now compute that function.

Proposition 41.16 (The scaling energy of a scalar configuration)**.** *With E_{grad} and E_{pot} the two pieces of the energy of ϕ as in Eq. (41.57),*

$$E(\mu) \;\equiv\; E[\phi_\mu] \;=\; \mu^{\,D-2}\, E_{\text{grad}} \;+\; \mu^{\,D}\, E_{\text{pot}}. \quad (41.59)$$

Proof. We carry out the two integrals by the change of variables $\mathbf{y} = \mathbf{x}/\mu$, for which $\mathrm{d}^D x = \mu^D \, \mathrm{d}^D y$ and $\partial/\partial x^i = \mu^{-1} \, \partial/\partial y^i$.

For the potential piece there are no derivatives, so we substitute directly:

$$E_{\mathrm{pot}}[\phi_\mu] = \int \mathrm{d}^D x \, V(\phi(\mathbf{x}/\mu)) = \int \mu^D \, \mathrm{d}^D y \, V(\phi(\mathbf{y})) = \mu^D \, E_{\mathrm{pot}}. \tag{41.60}$$

For the gradient piece we first differentiate the composite function. By the chain rule,

$$\partial_i \, \phi_\mu(\mathbf{x}) = \frac{\partial}{\partial x^i} \, \phi\!\left(\frac{\mathbf{x}}{\mu}\right) = \frac{1}{\mu} \, (\partial_i \phi)\!\left(\frac{\mathbf{x}}{\mu}\right), \tag{41.61}$$

the factor $1/\mu$ coming from differentiating the argument x^i/μ. Squaring and summing over the spatial index i and the internal index a,

$$|\nabla \phi_\mu(\mathbf{x})|^2 = \frac{1}{\mu^2} \, |(\nabla \phi)(\mathbf{x}/\mu)|^2. \tag{41.62}$$

Hence, again with $\mathbf{y} = \mathbf{x}/\mu$,

$$E_{\mathrm{grad}}[\phi_\mu] = \int \mathrm{d}^D x \, \tfrac{1}{2} \, \frac{1}{\mu^2} \, |(\nabla \phi)(\mathbf{x}/\mu)|^2 = \frac{\mu^D}{\mu^2} \int \mathrm{d}^D y \, \tfrac{1}{2} \, |(\nabla \phi)(\mathbf{y})|^2 = \mu^{\,D-2} \, E_{\mathrm{grad}}. \tag{41.63}$$

Adding Eqs. (41.60) and (41.63) gives Eq. (41.59). □

The two exponents in Eq. (41.59) are nothing but the engineering dimensions of the two pieces translated into the language of dilations. The measure $\mathrm{d}^D x$ contributes μ^D to both; each spatial derivative contributes an extra μ^{-1}, so the two-derivative gradient term carries the additional μ^{-2} that produces μ^{D-2}, while the zero-derivative potential keeps the bare μ^D. This bookkeeping—one factor of μ^{-1} per derivative, one factor of μ^{+1} per unit of measure—is the entire mechanism, and it is what makes the scaling argument extend effortlessly to gauge and higher-derivative terms below.

41.3.3 The theorem

Theorem 41.17 (Derrick)**.** *Let ϕ be a static, finite-energy critical point of the energy Eq. (41.56) of a theory of scalar fields with $V \geq 0$, in D spatial dimensions. Then:*

(i) for $D \geq 3$, necessarily $E_{\mathrm{grad}} = E_{\mathrm{pot}} = 0$, so ϕ is a vacuum configuration; no soliton exists;

(ii) for $D = 2$, necessarily $E_{\mathrm{pot}} = 0$, so ϕ takes values in the vacuum manifold $\mathcal{V}$ everywhere and any nontrivial solution is a solution of a pure derivative (nonlinear sigma) model, neutrally stable under dilations and hence not a true minimiser when a genuine potential is present;

(iii) for $D = 1$, the balance $E_{\text{grad}} = E_{\text{pot}}$ (a virial relation) is the condition, and a stable soliton can and does exist—this is the kink.

Proof. Because ϕ is a critical point of E, the restriction $E(\mu) = E[\phi_\mu]$ must be stationary at the point $\mu = 1$ corresponding to ϕ itself, and—for ϕ to be a (local) *minimum* rather than a saddle or maximum—the second derivative there must be non-negative. We impose both conditions on Eq. (41.59).

First derivative. Differentiating Eq. (41.59),

$$E'(\mu) = (D-2)\,\mu^{D-3}\,E_{\text{grad}} + D\,\mu^{D-1}\,E_{\text{pot}}, \tag{41.64}$$

and evaluating at $\mu = 1$,

$$E'(1) = (D-2)\,E_{\text{grad}} + D\,E_{\text{pot}} = 0. \tag{41.65}$$

Second derivative. Differentiating once more,

$$E''(\mu) = (D-2)(D-3)\,\mu^{D-4}\,E_{\text{grad}} + D(D-1)\,\mu^{D-2}\,E_{\text{pot}}, \tag{41.66}$$

so that

$$E''(1) = (D-2)(D-3)\,E_{\text{grad}} + D(D-1)\,E_{\text{pot}} \;\geq\; 0. \tag{41.67}$$

We now read off the consequences dimension by dimension, using only $E_{\text{grad}} \geq 0$ and $E_{\text{pot}} \geq 0$.

Case $D \geq 3$. Here both coefficients in the stationarity condition Eq. (41.65) are strictly positive: $D - 2 \geq 1 > 0$ and $D > 0$. The sum of two non-negative quantities with strictly positive coefficients vanishes only if each vanishes separately,

$$E_{\text{grad}} = 0 \quad \text{and} \quad E_{\text{pot}} = 0. \tag{41.68}$$

$E_{\text{grad}} = 0$ forces $\nabla\phi \equiv 0$, i.e. ϕ constant; $E_{\text{pot}} = 0$ forces that constant to lie in $\mathcal{V}$. Thus ϕ is the vacuum, and there is no soliton. This is statement (i).

Case $D = 2$. The gradient coefficient $D-2$ vanishes and Eq. (41.65) collapses to $2\,E_{\text{pot}} = 0$, hence $E_{\text{pot}} = 0$ and $V(\phi(\mathbf{x})) = 0$ for all $\mathbf{x}$: the field takes values in the vacuum manifold everywhere. The scaling energy degenerates to $E(\mu) = E_{\text{grad}}$, independent of μ: dilations cost nothing, and $E''(1) = 0$ as Eq. (41.67) confirms. The configuration is therefore *neutrally* stable under rescaling—a flat direction along which it can be shrunk to zero size at no energy cost. A genuine soliton of a theory with a true potential (one for which any nonconstant configuration has $E_{\text{pot}} > 0$) is thus excluded outright. The only survivors are configurations of theories whose potential vanishes identically on the entire target, i.e. nonlinear sigma models, where the "lumps" exist precisely because of the scale invariance of E_{grad} in two dimensions—but they have no preferred size and are unstable to collapse once any scale-breaking term is added. This is statement (ii).

Case $D = 1$. Now $D - 2 = -1$ and Eq. (41.65) reads $-E_{\text{grad}} + E_{\text{pot}} = 0$, the virial relation

$$E_{\text{grad}} = E_{\text{pot}}. \tag{41.69}$$

The second-derivative test Eq. (41.67) gives $E''(1) = (-1)(-2)E_{\text{grad}} + 1 \cdot 0 \cdot E_{\text{pot}} = 2\,E_{\text{grad}} \geq 0$, with equality only for the vacuum. For any nontrivial profile $E_{\text{grad}} > 0$, so the stationary point is a strict minimum along the scaling direction. The dilation instability that killed the higher-dimensional cases is absent, and a stable soliton is permitted. This is statement (iii). □

The case analysis is visualised in the left panel of Fig. 41.3: the function $E(\mu)$ has an interior minimum only for $D = 1$, while for $D \geq 2$ it is monotone and the energy is always lowered by collapse, $\mu \to 0$.

Corollary 41.18 (Recovery of the kink and the virial theorem)**.** *In* $D = 1$ *every static finite-energy soliton satisfies* $E_{\text{grad}} = E_{\text{pot}}$*, and its total energy is* $E = 2E_{\text{grad}} = 2E_{\text{pot}}$*. This reproduces the equipartition between gradient and potential energy found directly for the* ϕ^4 *kink in Section 41.1, and shows it to be a model-independent consequence of dilation stationarity in one dimension rather than an accident of that particular profile.*

Proof. The relation $E_{\text{grad}} = E_{\text{pot}}$ is Eq. (41.69); substituting it into $E = E_{\text{grad}} + E_{\text{pot}}$ gives $E = 2E_{\text{grad}} = 2E_{\text{pot}}$. □

Physical Insight

The theorem is a statement about competing tendencies, and it is worth holding the picture in mind without the algebra. The gradient energy is the cost of bending the field; it wants the configuration as large and gentle as possible, and in D dimensions stretching by μ multiplies it by μ^{D-2}. The potential energy is the cost of leaving the vacuum; it wants the configuration as small as possible so that less volume sits away from $\mathcal{V}$, and stretching multiplies it by μ^{D}. A soliton needs one term that grows under expansion and one that grows under contraction, so that an intermediate size is favoured. In $D = 1$ the gradient term (μ^{-1}, growing under contraction) and the potential (μ^{1}, growing under expansion) do exactly this, and the kink sits at the balance. In $D \geq 2$ *both* exponents $D - 2$ and D are non-negative: every term grows under expansion and shrinks under contraction, so the configuration can always lower its energy by shrinking, and it shrinks all the way to a point—the soliton "falls through the floor." To make a higher-dimensional soliton we must add a term whose energy grows under *contraction*, i.e. one with an exponent $D - k < 0$. That requires $k > D$ inverse powers of length, and the smallest such structure compatible with locality, Lorentz invariance, and a sensible

kinetic term is a gauge field.

41.3.4 The evasion catalogue: gauge fields restore the balance

Derrick's theorem is a no-go only for the specific class of theories Eq. (41.54). Its constructive content is the exponent table: a term in the energy built from a structure of definite scaling weight contributes μ^p to $E(\mu)$, where $p = D -$ (number of inverse lengths the structure carries). Anything that supplies a term with $p < 0$ reopens the door. We catalogue the physically important evasions, computing the exponents explicitly, and isolate the one—gauge fields—that the next two sections are built on.

Abelian gauge fields. Couple the scalar to a $U(1)$ gauge field A_i through the covariant derivative $D_i\phi = (\partial_i - ieA_i)\phi$ (the static, $A_0 = 0$ sector of the classical $U(1)$ theory of Chapter 8, whose Maxwell Lagrangian is Eq. (8.75)), and add the magnetic energy. The static energy now has three pieces,

$$E = E_{\text{mag}} + E_{\text{grad}} + E_{\text{pot}}, \qquad E_{\text{mag}} = \int \mathrm{d}^D x\, \tfrac{1}{4} F_{ij}F_{ij}, \quad E_{\text{grad}} = \int \mathrm{d}^D x\, \tfrac{1}{2} |D_i\phi|^2, \tag{41.70}$$

with $F_{ij} = \partial_i A_j - \partial_j A_i$. To rescale we must dilate the connection as well as the scalar, and the correct rule is dictated by the requirement that the gauge-covariant gradient scale the same way the ordinary gradient did—otherwise the covariant derivative would not transform homogeneously and the deformed configuration would not be a sensible field. A connection is a one-form; it carries one inverse length, exactly as ∂_i does, so it must scale with the same extra μ^{-1}:

$$\phi_\mu(\mathbf{x}) = \phi(\mathbf{x}/\mu), \qquad A_{\mu\, i}(\mathbf{x}) = \frac{1}{\mu} A_i(\mathbf{x}/\mu). \tag{41.71}$$

We check that the covariant gradient scales as before. Using Eq. (41.61) for the scalar and the definition Eq. (41.71) for the connection,

$$D_i^{(\mu)}\phi_\mu(\mathbf{x}) = \partial_i\phi_\mu - ieA_{\mu\, i}\phi_\mu = \frac{1}{\mu}(\partial_i\phi)(\mathbf{x}/\mu) - ie\,\frac{1}{\mu}A_i(\mathbf{x}/\mu)\,\phi(\mathbf{x}/\mu) = \frac{1}{\mu}\,(D_i\phi)(\mathbf{x}/\mu), \tag{41.72}$$

so $|D^{(\mu)}\phi_\mu(\mathbf{x})|^2 = \mu^{-2}|(D\phi)(\mathbf{x}/\mu)|^2$ exactly as in Eq. (41.62), and the covariant gradient energy scales as μ^{D-2} just as the ordinary one did. The new term is the magnetic energy. The field strength inherits two derivatives' worth of scaling from Eq. (41.71):

$$F_{\mu\, ij}(\mathbf{x}) = \partial_i A_{\mu\, j} - \partial_j A_{\mu\, i} = \frac{1}{\mu}\cdot\frac{1}{\mu}\Big[(\partial_i A_j) - (\partial_j A_i)\Big](\mathbf{x}/\mu) = \frac{1}{\mu^2}\,F_{ij}(\mathbf{x}/\mu), \tag{41.73}$$

one factor $1/\mu$ from the explicit $A \to A/\mu$ and one from differentiating the rescaled argument. Hence

$$E_{\mathrm{mag}}[A_\mu] = \int \mathrm{d}^D x \, \tfrac{1}{4} \frac{1}{\mu^4} \left|F(\mathbf{x}/\mu)\right|^2 = \frac{\mu^D}{\mu^4} E_{\mathrm{mag}} = \mu^{D-4} E_{\mathrm{mag}}. \tag{41.74}$$

The full scaling energy of the gauged scalar theory is therefore

$$E(\mu) = \mu^{D-4} E_{\mathrm{mag}} + \mu^{D-2} E_{\mathrm{grad}} + \mu^D E_{\mathrm{pot}}, \tag{41.75}$$

and the magnetic exponent $D-4$ is negative for every $D \le 3$. This is the term Derrick's theorem was missing.

Non-abelian gauge fields. The same conclusion survives the passage to a non-abelian gauge group, which is what Chapter 25 requires for the monopole and for the Yang–Mills theory payload. The non-abelian field strength of Eq. (25.76),

$$F^a_{ij} = \partial_i A^a_j - \partial_j A^a_i + g\, f^{abc} A^b_i A^c_j, \tag{41.76}$$

contains a quadratic piece in addition to the curl, and one might worry that the two pieces scale differently and spoil the clean exponent. They do not, precisely because the connection scales like a derivative. Applying Eq. (41.71) component by component, the linear (curl) part scales as μ^{-2} by the computation Eq. (41.73); the quadratic part scales as

$$g\, f^{abc}\, A^b_{\mu\, i} A^c_{\mu\, j} = g\, f^{abc} \frac{1}{\mu} A^b_i\!\left(\frac{\mathbf{x}}{\mu}\right) \frac{1}{\mu} A^c_j\!\left(\frac{\mathbf{x}}{\mu}\right) = \frac{1}{\mu^2} \left(g f^{abc} A^b_i A^c_j\right)(\mathbf{x}/\mu), \tag{41.77}$$

the *same* μ^{-2}. Both terms in Eq. (41.76) scale identically, so $F^a_{\mu\, ij}(\mathbf{x}) = \mu^{-2} F^a_{ij}(\mathbf{x}/\mu)$ and the non-abelian magnetic energy $E_{\mathrm{YM}} = \int \mathrm{d}^D x \, \tfrac{1}{4} F^a_{ij} F^a_{ij}$ again scales as μ^{D-4}. The homogeneous scaling of the connection is exactly what makes the nonlinear self-interaction respect the same weight as the abelian curl; this is the classical shadow of the fact that the gauge coupling g is dimensionless in four spacetime dimensions. The scaling structure Eq. (41.75) therefore holds verbatim with $E_{\mathrm{mag}} \to E_{\mathrm{YM}}$.

We can now state the evasion as a theorem and read off the two cases that the chapter will construct.

Theorem 41.19 (Gauge fields evade Derrick in $D = 2$ and $D = 3$)**.** *For the gauged energy Eq. (41.75) with $E_{\mathrm{mag}}, E_{\mathrm{grad}}, E_{\mathrm{pot}} \ge 0$, dilation stationarity $E'(1) = 0$ reads*

$$(D-4)\, E_{\mathrm{mag}} + (D-2)\, E_{\mathrm{grad}} + D\, E_{\mathrm{pot}} = 0. \tag{41.78}$$

For $D = 2$ and $D = 3$ this admits nontrivial nonnegative solutions, so a static soliton is no longer forbidden:

$$D = 2: \qquad -2\, E_{\mathrm{mag}} + 0 \cdot E_{\mathrm{grad}} + 2\, E_{\mathrm{pot}} = 0 \implies E_{\mathrm{mag}} = E_{\mathrm{pot}}, \tag{41.79}$$

$$D = 3: \qquad -\, E_{\mathrm{mag}} + E_{\mathrm{grad}} + 3\, E_{\mathrm{pot}} = 0 \implies E_{\mathrm{mag}} = E_{\mathrm{grad}} + 3\, E_{\mathrm{pot}}. \tag{41.80}$$

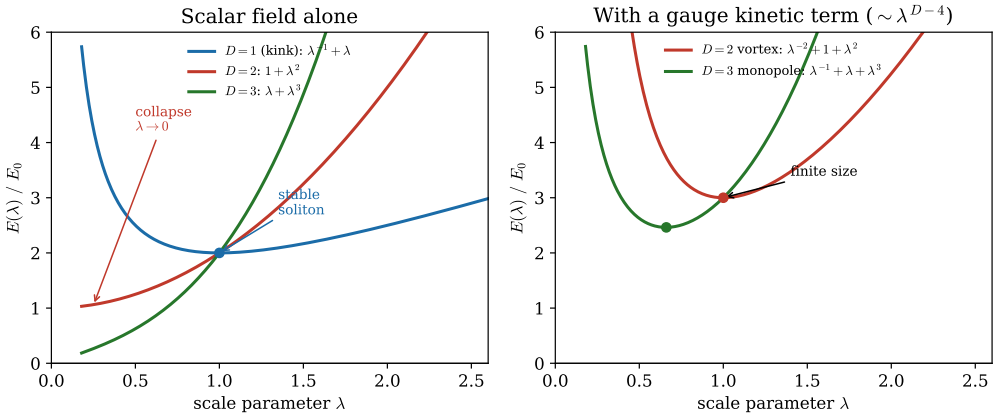


Figure 41.3: The scaling energy $E(\mu)$ of Eqs. (41.59) and (41.75), with all coefficients set to unity for legibility. *Left:* a scalar theory alone. Only $D = 1$ has an interior minimum (the kink); for $D = 2$ and $D = 3$ the energy is monotone increasing in μ, so it is always lowered by shrinking the lump to a point ($\mu \to 0$)—Derrick's no-go. *Right:* adding a gauge kinetic term, which scales as μ^{D-4} and diverges as $\mu \to 0$, restores an interior minimum at finite size in both $D = 2$ (the vortex) and $D = 3$ (the monopole). The presence or absence of the interior stationary point is independent of the chosen coefficients; it is the entire content of the theorem.

Proof. Eq. (41.78) is the derivative of Eq. (41.75) evaluated at $\mu = 1$, computed exactly as in Eq. (41.65). Setting $D = 2$ kills the gradient coefficient and leaves Eq. (41.79); setting $D = 3$ leaves Eq. (41.80). In each case all the energies that appear can be strictly positive while the relation holds, so the stationarity condition no longer forces them to vanish. The magnetic term carries the negative exponent $D - 4 < 0$, meaning E_{mag} *decreases* under expansion and *increases* under contraction; it is the term that resists collapse, balancing the potential (and, in $D = 3$, also the gradient) that resists expansion. An interior minimum becomes possible, as the right panel of Fig. 41.3 shows. □

The two balance relations Eqs. (41.79) and (41.80) are virial theorems for the gauged solitons, the direct analogues of the kink's $E_{\text{grad}} = E_{\text{pot}}$. They are necessary conditions that every static solution must satisfy, and they will reappear as nontrivial checks on the explicit vortex and monopole solutions of Sections 41.4 and 41.5. The first is the precise statement that, in two spatial dimensions, magnetic energy and potential energy must be equal in any soliton—which is only possible if the theory *has* a magnetic energy, i.e. if the broken symmetry is gauged.

Worked Example 41.20 (Equilibrium size of a gauged soliton from the scaling balance)**.** The scaling argument does more than permit a soliton; the balance

relations fix the soliton's size in terms of the competing energies, and we can extract that size before solving a single field equation. Consider a gauged configuration in D dimensions with energy Eq. (41.75), and ask which member of its scaling family has the least energy. Write the three energies of the *reference* configuration ($\mu = 1$) as $a \equiv E_{\text{mag}}$, $b \equiv E_{\text{grad}}$, $c \equiv E_{\text{pot}}$, so

$$E(\mu) = a\,\mu^{D-4} + b\,\mu^{D-2} + c\,\mu^{D}. \tag{41.81}$$

Two spatial dimensions. With $D = 2$, $E(\mu) = a\,\mu^{-2} + b + c\,\mu^{2}$. Setting $E'(\mu) = -2a\,\mu^{-3} + 2c\,\mu = 0$ gives $\mu^4 = a/c$, hence the energy-minimising scale

$$\mu_\star = \left(\frac{E_{\text{mag}}}{E_{\text{pot}}}\right)^{1/4}, \tag{41.82}$$

a finite, nonzero number whenever both energies are positive. The second derivative $E''(\mu) = 6a\,\mu^{-4} + 2c > 0$ confirms a genuine minimum. At $\mu_\star$ the rescaled magnetic and potential energies are $a\mu_\star^{-2} = \sqrt{ac}$ and $c\mu_\star^{2} = \sqrt{ac}$: they are equal, reproducing the virial relation Eq. (41.79) *at the balanced configuration.* This is the vortex: the magnetic flux, which wants to spread, is held at a definite radius by the potential, which wants to expel the field from the false vacuum in its core.

Three spatial dimensions. With $D = 3$, $E(\mu) = a\,\mu^{-1} + b\,\mu + c\,\mu^{3}$. Now $E'(\mu) = -a\,\mu^{-2} + b + 3c\,\mu^{2} = 0$, a quartic in μ once cleared of denominators, $3c\,\mu^4 + b\,\mu^2 - a = 0$, with the unique positive root

$$\mu_\star^2 = \frac{-b + \sqrt{b^2 + 12\,a\,c}}{6c} \qquad (c > 0), \tag{41.83}$$

again finite and nonzero whenever $a > 0$. (For the BPS monopole of the next sections, where the potential is sent to zero, $c \to 0$ and the root degenerates to $\mu_\star^2 = a/b = E_{\text{mag}}/E_{\text{grad}}$, the balance Eq. (41.80) with $E_{\text{pot}} = 0$.) The magnetic energy, decreasing as μ^{-1}, is what supplies the wall against collapse that the pure scalar theory lacked.

The lesson is quantitative: a soliton has a definite size set by the ratio of magnetic to potential (or gradient) energy, and that size exists only because the magnetic term carries the negative scaling exponent $D - 4$. Strip the gauge field out and $a \to 0$; Eqs. (41.82) and (41.83) send $\mu_\star \to 0$ and the soliton collapses, recovering Theorem 41.17.

Other evasions. Gauge fields are the route this chapter takes, but for completeness, and to show that the scaling table—not any one model—is the organising principle, we record the two other standard ways to defeat Derrick's theorem; each appears elsewhere in the non-perturbative literature and each is nothing but a new entry with a different exponent.

Table 41.1: Scaling weights of the standard energy terms under the dilation $\phi(\mathbf{x}) \to \phi(\mathbf{x}/\mu)$ (with the connection rescaled as $A \to A(\cdot/\mu)/\mu$), in D spatial dimensions. A term contributing μ^p with $p < 0$ grows under contraction and so resists collapse; a soliton requires at least one such term to coexist with a term of weight $p > 0$. The third and fourth columns evaluate the weight for the two cases this chapter constructs.

Energy term	inverse lengths	weight p	p at $D = 2$	p at $D = 3$
Potential $\int V(\phi)$	0	D	$+2$	$+3$
Gradient $\int \frac{1}{2}\lvert\nabla\phi\rvert^2$	2	$D-2$	0	$+1$
Covariant gradient $\int \frac{1}{2}\lvert D\phi\rvert^2$	2	$D-2$	0	$+1$
Magnetic $\int \frac{1}{4}F_{ij}F_{ij}$ (abelian or YM)	4	$D-4$	-2	-1
Skyrme $\int(\partial\phi)^4$	4	$D-4$	-2	-1

Higher-derivative (Skyrme) terms. A term quartic in spatial derivatives, schematically $(\partial\phi)^4$ with a suitable index contraction, carries four inverse lengths and therefore scales as μ^{D-4}, exactly like a magnetic energy. In $D = 3$ the Skyrme model balances such a quartic term (μ^{-1}) against the ordinary gradient term (μ^1): the stationarity condition $-E_4 + E_2 = 0$ fixes a finite size and stabilises the skyrmion of $\pi_3(\mathrm{SU}(2)) = \mathbb{Z}$ *without* gauge fields, at the price of a higher-derivative (and hence non-renormalisable, effective) Lagrangian. The exponent counting is identical to the gauge case; only the physical origin of the μ^{D-4} term differs.

Time dependence (Q-balls). Derrick's theorem assumes a *static* configuration; relaxing that assumption to a stationary but time-dependent one evades it. For a complex scalar with an unbroken global U(1) and conserved Noether charge Q (from Chapter 7), the ansatz $\phi(\mathbf{x}, t) = e^{-i\omega t}\sigma(\mathbf{x})$ with real profile σ adds a positive "rotational" term $\frac{1}{2}\omega^2\int\sigma^2$ to the energy and ties ω to the charge through $Q = \omega\int\sigma^2$. Minimising the energy at *fixed* Q—the physically correct variational problem, since Q is conserved—replaces the potential V by an effective potential $V - \frac{1}{2}\omega^2\sigma^2$ whose scaling weight differs, and a finite-energy non-topological soliton, the Q-ball, results in $D = 3$ even with only scalar fields. The lesson is that "static" in the hypothesis of Theorem 41.17 is load-bearing: a soliton stabilised by a conserved charge through its time dependence is outside the theorem's reach.

The table below collects the scaling weights, which is all one ever needs to apply or evade the theorem.

The pure-scalar rows of Table 41.1 have non-negative weights for all $D \geq 2$, which is Derrick's theorem; the magnetic row is the first with a negative weight reachable by a renormalisable, two-derivative-kinetic gauge theory in physical dimensions, and it is negative in exactly the dimensions $D = 2, 3$ where the

chapter must build solitons. The conclusion is now forced. To realise a nontrivial topological sector in two spatial dimensions one cannot use scalars alone; one must gauge the broken symmetry, supplying the magnetic energy whose μ^{D-4} weight holds the soliton at finite size. We turn next to the simplest theory in which this happens—the abelian Higgs model—and construct its vortex, whose topological charge $\pi_1(\mathrm{U}(1)) = \mathbb{Z}$ is realised physically as quantised magnetic flux.

41.4 The Vortex: Gauged Solitons and Flux Quantization

Derrick's theorem (Section 41.3) closed one door and, in the same motion, pointed at the only one left open. A theory of scalar fields alone supports no static, finite-energy soliton once the number of spatial dimensions reaches $D = 2$: under a uniform rescaling $\phi(\mathbf{x}) \mapsto \phi(\mathbf{x}/\mu)$ the gradient energy of a scalar scales as μ^{D-2} and the potential energy as μ^{D}, so for $D \geq 2$ both are non-increasing as $\mu \to 0$ and any putative lump simply spreads out and flattens to the vacuum at no energy cost. The escape clause was already visible in the bookkeeping: a term whose energy is *scale invariant* in the relevant dimension neither favours nor forbids the collapse, and in $D = 2$ the magnetic energy $\int d^2x\, \frac{1}{2}B^2$ of an abelian gauge field is exactly such a term. Gauging the broken symmetry therefore does two things at once. It supplies a scale-invariant term that stabilizes the lump against Derrick's collapse, and it converts the would-be massless Goldstone direction — the angular mode that, ungauged, would carry a logarithmically divergent gradient energy out to spatial infinity — into the longitudinal polarization of a massive vector, rendering the total energy finite. The object that results is the Abrikosov–Nielsen–Olesen (ANO) vortex: a tube of quantized magnetic flux threading a core in which the Higgs condensate is expelled. It is the first soliton in this chapter that genuinely lives above one dimension, and its topological charge is realized as a physically measurable, quantized magnetic flux. We will build it from the abelian Higgs Lagrangian, prove that finiteness of energy forces the flux to be an integer multiple of $2\pi/e$, write down the radial equations governing its core, and finally exhibit the Bogomolny rearrangement that, at one special value of the couplings, replaces the second-order field equations by a first-order system saturating an exact energy bound.

41.4.1 The abelian Higgs model in two spatial dimensions

The model is the abelian Higgs theory whose spontaneous-symmetry-breaking content was assembled in Chapter 30: a complex scalar ϕ of charge e minimally coupled to a U(1) gauge field A_μ, with a Mexican-hat potential that drives $|\phi|$ to a nonzero vacuum value. We recall it here for continuity and to fix the

conventions that the soliton analysis needs, but the classical content we use — the gauge-covariant derivative and the Maxwell action of Chapter 8, and the vacuum manifold of Chapter 29 — is imported, not rebuilt. The Lagrangian density is

$$\mathcal{L} \;=\; -\tfrac{1}{4}F_{\mu\nu}F^{\mu\nu} \;+\; (D_\mu\phi)^*(D^\mu\phi) \;-\; V(\phi), \qquad V(\phi) \;=\; \frac{\lambda}{2}\big(|\phi|^2 - v^2\big)^2, \tag{41.84}$$

with $F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu$ the abelian field strength of Eq. (8.75), and the gauge-covariant derivative on a charged scalar (Chapter 8)

$$D_\mu\phi \;=\; (\partial_\mu - ieA_\mu)\phi, \qquad e > 0. \tag{41.85}$$

We follow the book's convention $D_\mu = \partial_\mu - igA^a_\mu T^a$ specialized to the abelian case with a single generator of charge e; the relative sign in Eq. (41.85) is the one piece of data the flux quantization below is sensitive to, so we fix it once here. The theory is invariant under the local U(1) transformation

$$\phi(x) \mapsto e^{i\alpha(x)}\phi(x), \qquad A_\mu(x) \mapsto A_\mu(x) + \frac{1}{e}\,\partial_\mu\alpha(x), \tag{41.86}$$

under which $D_\mu\phi \mapsto e^{i\alpha}D_\mu\phi$ transforms homogeneously, exactly as the gauge principle of Chapter 8 requires.

The potential V in Eq. (41.84) is minimized on the circle $|\phi| = v$. The set of field values that minimize the potential — the vacuum manifold of Chapter 29 — is therefore

$$\mathcal{M} \;=\; \{\,\phi : |\phi| = v\,\} \;=\; v\,e^{i\chi},\ \chi \in [0, 2\pi) \;\cong\; \mathrm{U}(1) \;\cong\; S^1. \tag{41.87}$$

This is the geometric fact on which everything turns: the vacuum manifold is a circle, and a circle has nontrivial fundamental group. From the homotopy classification built earlier in this chapter, $\pi_1(S^1) = \mathbb{Z}$ (Theorem 41.11), and the integer labelling a map $S^1 \to S^1$ is its winding number, the degree. The whole of what follows is the statement that this abstract integer is realized in the abelian Higgs model as quantized magnetic flux.

We study static configurations in two spatial dimensions, $\mathbf{x} = (x^1, x^2) \in \mathbb{R}^2$, working in the temporal gauge $A_0 = 0$ with all fields time-independent. Then $D_0\phi = 0$, the electric field F_{0i} vanishes, and the only surviving component of the field strength is the magnetic field, a single scalar in the plane,

$$B \;\equiv\; F_{12} \;=\; \partial_1 A_2 - \partial_2 A_1. \tag{41.88}$$

The energy of such a configuration is the spatial integral of the Hamiltonian density. With the mostly-minus metric $\eta = \mathrm{diag}(+,-,-,-)$ the Maxwell term contributes $-\frac{1}{4}F_{\mu\nu}F^{\mu\nu} = \frac{1}{2}(\mathbf{E}^2 - B^2) \to -\frac{1}{2}B^2$ to the Lagrangian and hence $+\frac{1}{2}B^2$ to the energy, while the scalar kinetic term contributes $(D_i\phi)^*(D_i\phi)$

summed over the two spatial directions $i = 1, 2$. The static energy functional is therefore

$$E[\phi, A_i] \;=\; \int d^2x \left[\; \tfrac{1}{2} B^2 \;+\; |D_1\phi|^2 + |D_2\phi|^2 \;+\; \frac{\lambda}{2}\big(|\phi|^2 - v^2\big)^2 \;\right], \tag{41.89}$$

each term manifestly non-negative. A finite-energy static solution is a stationary point of Eq. (41.89) at which each of the three contributions is separately integrable.

41.4.2 Finite energy, the winding ansatz, and flux quantization

Finiteness of Eq. (41.89) dictates the behaviour of the fields at spatial infinity, and that asymptotic behaviour is what carries the topology. Each term must vanish fast enough that its integral over the plane converges. In particular the potential energy is finite only if $|\phi| \to v$ as $r = |\mathbf{x}| \to \infty$, so on the circle at infinity the scalar takes values in the vacuum manifold $\mathcal{M} \cong S^1$. The restriction of ϕ to the large circle is thus a map

$$\phi\big|_{r\to\infty} \;:\; S^1_\infty \;\longrightarrow\; \mathcal{M} \cong S^1, \qquad \theta \;\longmapsto\; v\, e^{\,i\,\Xi(\theta)}, \tag{41.90}$$

where θ is the polar angle and $\Xi(\theta)$ the asymptotic phase. Because ϕ is single valued, Ξ must return to itself modulo 2π as θ advances by 2π:

$$\Xi(\theta + 2\pi) - \Xi(\theta) \;=\; 2\pi n, \qquad n \in \mathbb{Z}. \tag{41.91}$$

The integer n is the degree of the map Eq. (41.90), the element of $\pi_1(S^1) = \mathbb{Z}$ it represents (Theorem 41.11). It cannot change under any continuous, finite-energy deformation of the fields, because changing it would require the phase to "unwind" through a configuration in which ϕ leaves the vacuum manifold somewhere on the circle at infinity, costing infinite potential energy. This is the topological conservation law of the vortex, and unlike a Noether charge it holds off shell: n is an integer read off the boundary data, conserved because it is discrete and the energy barrier to changing it is infinite, not because of any equation of motion.

The cleanest representative of the sector of winding n is the rotationally symmetric *winding ansatz*, in which the phase simply tracks the polar angle,

$$\phi(r, \theta) \;=\; v\, f(r)\, e^{\,in\theta}, \qquad \mathbf{A}(r, \theta) \;=\; \hat{\boldsymbol{\theta}}\, \frac{n}{e\, r}\, a(r), \tag{41.92}$$

with $\hat{\boldsymbol{\theta}}$ the azimuthal unit vector and f, a dimensionless radial profiles to be determined. Regularity at the origin and the vacuum at infinity will fix the boundary conditions $f(0) = a(0) = 0$ and $f(\infty) = a(\infty) = 1$; we derive these below. The deep point, however, requires no ansatz at all, and we prove it in generality first.

Theorem 41.21 (Flux quantization)**.** *Let (ϕ, A_i) be any static configuration of the abelian Higgs model Eq. (41.84) with finite energy Eq. (41.89) and asymptotic winding number $n \in \mathbb{Z}$ defined by Eq. (41.91). Then the total magnetic flux through the plane is quantized,*

$$\Phi \;\equiv\; \int_{\mathbb{R}^2} B\, d^2x \;=\; \frac{2\pi n}{e}. \tag{41.93}$$

Proof. The gradient energy $\int d^2x\, |D_i\phi|^2$ is finite only if the covariant derivative is square-integrable, which forces

$$D_i\phi \;\longrightarrow\; 0 \qquad \text{as } r \to \infty, \tag{41.94}$$

faster than $1/r$ (so that $|D_i\phi|^2$ decays faster than $1/r^2$ and its integral $\int r\, dr$ converges). Write the asymptotic scalar in polar form $\phi \to v\, e^{i\Xi(\theta)}$ with $|\phi| \to v$ constant along the circle at infinity. On that circle the radial derivative of ϕ is negligible and the only surviving derivative is angular; the condition Eq. (41.94) on the angular component reads

$$(\partial_i - ieA_i)\phi = i\,\phi\,(\partial_i\Xi - eA_i) + (\text{radial}) \;\longrightarrow\; 0 \quad\Longrightarrow\quad A_i \;\longrightarrow\; \frac{1}{e}\,\partial_i\Xi. \tag{41.95}$$

Asymptotically, therefore, A_i is *pure gauge*: it is the gradient of the scalar's phase divided by e. This is the mechanism by which the gauge field disarms Derrick's theorem. The angular gradient of the scalar, which for a global (ungauged) U(1) would give $|D_i\phi|^2 \sim v^2(\partial_i\Xi)^2 \sim v^2 n^2/r^2$ and hence a logarithmically divergent gradient energy $\int r\, dr/r^2$, is exactly cancelled by the gauge field, which absorbs the would-be Goldstone gradient into A_i and leaves $D_i\phi \to 0$. The energy of the angular mode is thereby made finite, at the price of a nonzero A_i at infinity.

Now compute the flux. By the two-dimensional Stokes theorem, the flux of $B = \partial_1 A_2 - \partial_2 A_1$ through the disc D_R of radius R equals the circulation of A_i around its boundary circle $C_R = \partial D_R$:

$$\int_{D_R} B\, d^2x \;=\; \int_{D_R} (\partial_1 A_2 - \partial_2 A_1)\, d^2x \;=\; \oint_{C_R} A_i\, dx^i. \tag{41.96}$$

Taking $R \to \infty$ and inserting the asymptotic form Eq. (41.95),

$$\Phi \;=\; \lim_{R\to\infty} \oint_{C_R} A_i\, dx^i \;=\; \frac{1}{e} \oint_{C_\infty} \partial_i\Xi\, dx^i \;=\; \frac{1}{e}\big[\Xi(\theta)\big]_{\theta=0}^{\theta=2\pi} \;=\; \frac{1}{e}\,(2\pi n) \;=\; \frac{2\pi n}{e}, \tag{41.97}$$

where the line integral of the gradient $\partial_i\Xi$ around the closed loop equals the total change of Ξ over one circuit, which by Eq. (41.91) is $2\pi n$. This proves Eq. (41.93). □

The physical content of Theorem 41.21 deserves to be stated plainly, because it is the prototype for the monopole's magnetic charge in the next section and,

beyond that, for the general phenomenon of topological quantization. The integer n entered as an abstract homotopy class — the winding of a map between two circles, a piece of pure topology with no obvious dynamical meaning. It comes out as the magnetic flux measured in units of $2\pi/e$, a quantity an experimentalist could in principle integrate a magnetometer over. There is no continuous knob that turns n from one integer to the next; the flux is locked to a discrete spectrum by the requirement that the configuration have finite energy. In a superconductor, where the abelian Higgs model is the Ginzburg–Landau effective theory of the condensate, this is precisely the observed quantization of magnetic flux trapped in the Abrikosov vortices of a type-II superconductor, with e replaced by the charge $2e$ of a Cooper pair.

Physical Insight

The covariant derivative is what makes the gauged soliton possible, and it does so through a single sleight of hand worth isolating. A global symmetry broken on a circle leaves behind a massless Goldstone mode, and a winding configuration of that mode carries angular gradient energy $\sim v^2 n^2 \int r\, dr/r^2$ that diverges logarithmically with the size of the system — the global vortex is not quite finite-energy. Gauging the symmetry promotes the Goldstone to the longitudinal polarization of a vector field of mass $m_v \sim ev$ (the Higgs mechanism of Chapter 30). The gauge field can then "eat" the winding gradient: at infinity $A_i \to \frac{1}{e}\partial_i \Xi$ makes $D_i\phi \to 0$ and the angular energy converges. What remains of the would-be Goldstone gradient is not lost but stored as magnetic field threading the core, and the flux it carries is fixed by topology. The vortex is finite-energy precisely because the symmetry is gauged, and quantized precisely because the unbroken topology is $\pi_1(S^1) = \mathbb{Z}$.

41.4.3 Radial profile equations and the structure of the core

To exhibit an actual solution and resolve the core we insert the winding ansatz Eq. (41.92) into the energy and vary. Work in plane polar coordinates with the orthonormal frame $(\hat{\mathbf{r}}, \hat{\boldsymbol{\theta}})$, in which the covariant derivative of a function has radial and azimuthal components $(\partial_r,\, r^{-1}\partial_\theta)$. With $A_r = 0$ and $A_\theta = \dfrac{n}{e\,r}\, a(r)$ the two components of $D_i\phi$ are

$$(D\phi)_r = \partial_r \phi - ieA_r\phi = v\, f'(r)\, e^{in\theta}, \tag{41.98}$$

$$(D\phi)_\theta = \frac{1}{r}\,\partial_\theta\phi - ieA_\theta\phi = i\,v\, f(r)\, e^{in\theta}\, \frac{n}{r}(1 - a(r)), \tag{41.99}$$

where in the second line the bare angular derivative $\frac{1}{r}\partial_\theta(v f e^{in\theta}) = iv f e^{in\theta}\, n/r$ combines with $-ieA_\theta\phi = -iv f e^{in\theta}\, na/r$ to give the factor $(1-a)$. The magnetic

field of the ansatz follows from the curl in the plane, $B = \frac{1}{r}\,\partial_r(rA_\theta)$, namely

$$B(r) \;=\; \frac{1}{r}\,\frac{d}{dr}\!\left(r\cdot\frac{n}{er}a\right) \;=\; \frac{n}{e}\,\frac{a'(r)}{r}. \tag{41.100}$$

The boundary conditions are now forced. Regularity of ϕ at the origin (a single-valued field cannot have a nonzero modulus where its phase $e^{in\theta}$ is undefined, for $n \neq 0$) requires $f(0) = 0$; regularity of $A_\theta = \frac{n}{er}a$ as $r \to 0$ requires $a(0) = 0$. The vacuum at infinity requires $f(\infty) = 1$, and finiteness of the gradient energy via Eq. (41.95) requires $(1 - a) \to 0$, i.e. $a(\infty) = 1$. With these, the flux of Eq. (41.100) is $\Phi = \int_0^\infty B\, 2\pi r\, dr = \frac{2\pi n}{e}\int_0^\infty a'\, dr = \frac{2\pi n}{e}[a(\infty) - a(0)] = \frac{2\pi n}{e}$, reproducing Theorem 41.21 for the symmetric ansatz.

Substituting Eqs. (41.98) to (41.100) into the energy Eq. (41.89) and using $\int d^2x = \int_0^\infty 2\pi r\, dr$ gives the reduced energy as a one-dimensional functional of the two profiles,

$$E \;=\; 2\pi v^2\int_0^\infty r\,dr\,\left[f'^2 \;+\; \frac{n^2}{r^2}(1-a)^2 f^2 \;+\; \frac{n^2}{2e^2v^2}\,\frac{a'^2}{r^2} \;+\; \frac{\lambda v^2}{2}(1-f^2)^2\right]. \tag{41.101}$$

The Euler–Lagrange equations of this functional are the radial field equations. Varying with respect to f and to a (carrying the $\frac{1}{r}\frac{d}{dr}(r\,\partial/\partial(\cdot)')$ structure of a radial variational problem) yields

$$f'' + \frac{1}{r}f' - \frac{n^2}{r^2}(1-a)^2 f + \lambda v^2\,(1-f^2)f = 0, \tag{41.102}$$

$$a'' - \frac{1}{r}a' + 2e^2v^2\,f^2(1-a) = 0, \tag{41.103}$$

to be solved with $f(0) = a(0) = 0$, $f(\infty) = a(\infty) = 1$. These are two coupled nonlinear ordinary differential equations; they have no solution in elementary closed form, but their qualitative content is transparent and their asymptotics are exact.

Linearizing about the vacuum exposes the two length scales of the vortex, which are nothing but the Compton wavelengths of the two massive particles of the broken theory. Writing $f = 1 - s$ and $a = 1 - w$ with s, w small at large r, Eq. (41.102) becomes $s'' + \frac{1}{r}s' - 2\lambda v^2 s \approx 0$ and Eq. (41.103) becomes $w'' - \frac{1}{r}w' - 2e^2v^2 w \approx 0$, the modified-Bessel equations whose decaying solutions are $s \sim e^{-m_s r}$ and $w \sim e^{-m_v r}$ with

$$m_s \;=\; \sqrt{2\lambda}\,v \quad\text{(Higgs/scalar mass)}, \qquad m_v \;=\; \sqrt{2}\,e\,v \quad\text{(vector/photon mass)}. \tag{41.104}$$

The scalar mass m_s sets the radius of the core over which the condensate $|\phi| = vf$ is depleted (the *coherence length* $\xi = 1/m_s$); the vector mass m_v sets the radius over which the magnetic field is screened out (the *penetration depth* $\delta = 1/m_v$).

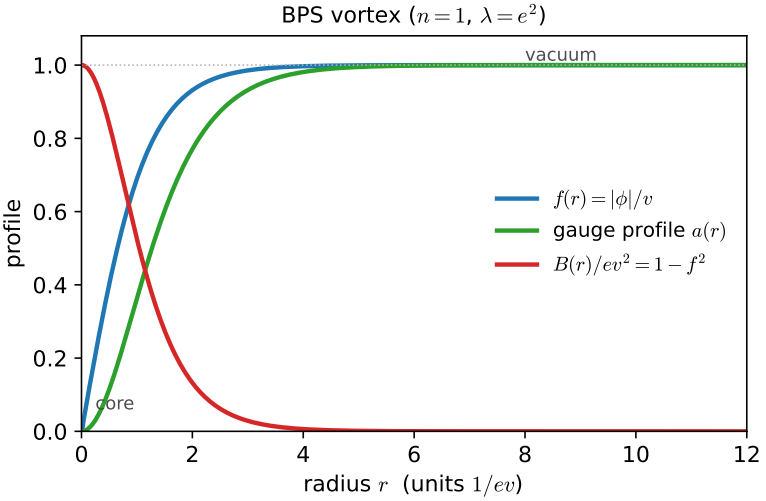

Figure 41.4: The $n = 1$ Abrikosov–Nielsen–Olesen vortex at the critical coupling $\lambda = e^2$, obtained by solving the radial field equations Eqs. (41.102) and (41.103) as a two-point boundary-value problem (units $e = v = 1$). The scalar profile $f = |\phi|/v$ rises from 0 at the core to the vacuum value 1; the gauge profile a rises from 0 to 1, so that $D_i\phi \to 0$ at infinity; the magnetic field $B/ev^2 = 1 - f^2$ is concentrated in the core where the condensate is expelled. Numerical integration of B returns the total flux $\Phi = 2\pi/e$ and the energy $E = 2\pi v^2$, saturating the Bogomolny bound Eq. (41.115) for $n = 1$.

The identification of these masses confirms the Higgs mechanism: the gauge field has acquired the mass $m_v = \sqrt{2}\,ev$ from the condensate, and it is this mass that makes the magnetic flux a localized tube rather than a long-range field. We solve the system numerically for the simplest vortex in Fig. 41.4; the profiles have exactly the expected shape, the condensate rising from zero at the core to its vacuum value and the magnetic field concentrated where the condensate is suppressed.

41.4.4 The Bogomolny bound and the BPS vortex

The energy Eq. (41.89) is bounded below by a topological quantity, and at one special value of the couplings the bound is saturated by solutions of a first-order system far simpler than the second-order equations Eqs. (41.102) and (41.103). The technique is Bogomolny's: rewrite each square in the energy as a perfect square plus a total derivative plus a topological term, so that the energy is manifestly a sum of squares above a fixed floor set by the topology. This is the same manoeuvre that produced the kink's energy bound earlier in the chapter, now executed in two dimensions with a gauge field, and it is the direct template

for the monopole's bound and for the general notion of a BPS state.

We work with the magnetic and scalar gradient energies. The first algebraic input is the rearrangement of the gradient energy into the modulus of a single complex combination plus a remainder. For any two complex numbers,

$$|D_1\phi|^2+|D_2\phi|^2 \;=\; \left|(D_1 \mp iD_2)\phi\right|^2 \;\pm\; i\big[(D_1\phi)^*(D_2\phi)-(D_2\phi)^*(D_1\phi)\big], \tag{41.105}$$

which is verified by expanding $|(D_1 \mp iD_2)\phi|^2 = (D_1\phi \mp iD_2\phi)^*(D_1\phi \mp iD_2\phi)$ and collecting terms; the cross terms $\mp i(D_1\phi)^*(D_2\phi) \pm i(D_2\phi)^*(D_1\phi)$ are exactly the bracket on the right. The bracket is now reshaped into a magnetic piece and a total derivative. Using $D_\mu = \partial_\mu - ieA_\mu$ and the commutator $[D_1, D_2]\phi = -ieF_{12}\phi = -ieB\phi$ (the field strength is the curvature of the covariant derivative, Chapter 8), a direct computation gives the identity

$$\epsilon_{ij}\,(D_i\phi)^*(D_j\phi) \;=\; \epsilon_{ij}\,\partial_i(\phi^* D_j\phi) \;+\; ieB\,|\phi|^2, \tag{41.106}$$

where $\epsilon_{12} = -\epsilon_{21} = +1$. We verify Eq. (41.106) explicitly because the sign of its magnetic term controls the final bound. Expand the total-derivative term,

$$\epsilon_{ij}\partial_i(\phi^* D_j\phi) = \epsilon_{ij}\big[(\partial_i\phi^*)(D_j\phi) + \phi^*\,\partial_i(D_j\phi)\big]. \tag{41.107}$$

Now $\partial_i\phi^* = (D_i\phi)^* + ieA_i\phi^*$ (since $(D_i\phi)^* = (\partial_i + ieA_i)\phi^*$), and $\partial_i(D_j\phi) = D_i(D_j\phi) + ieA_i(D_j\phi)$ because $D_j\phi$ carries charge $+e$. Substituting, the two ieA_i pieces cancel against each other inside the antisymmetric ϵ_{ij} contraction, leaving

$$\epsilon_{ij}\partial_i(\phi^* D_j\phi) = \epsilon_{ij}(D_i\phi)^*(D_j\phi)+\phi^*\,\epsilon_{ij}D_iD_j\phi = \epsilon_{ij}(D_i\phi)^*(D_j\phi)+\tfrac{1}{2}\phi^*\epsilon_{ij}[D_i, D_j]\phi. \tag{41.108}$$

The last term is $\frac{1}{2}\phi^*\epsilon_{ij}(-ieF_{ij})\phi = \frac{1}{2}(-ie)(2B)|\phi|^2 = -ieB|\phi|^2$, using $\epsilon_{ij}F_{ij} = 2F_{12} = 2B$. Rearranging Eq. (41.108) gives Eq. (41.106). The bracket in Eq. (41.105) is $i\,\epsilon_{ij}(D_i\phi)^*(D_j\phi)$, so combining,

$$|D_1\phi|^2 + |D_2\phi|^2 \;=\; \left|(D_1 \mp iD_2)\phi\right|^2 \;\mp\; eB\,|\phi|^2 \;\pm\; i\,\epsilon_{ij}\,\partial_i(\phi^* D_j\phi). \tag{41.109}$$

The last term is a total spatial derivative; on integration over the plane it becomes a boundary integral at $r \to \infty$, where $D_j\phi \to 0$, so it contributes nothing to the energy. We may discard it.

Assemble the energy. Insert Eq. (41.109) into Eq. (41.89) and group the magnetic, the $\mp eB|\phi|^2$, and the potential terms,

$$E \;=\; \int d^2x\,\Big[\,\tfrac{1}{2}B^2 \mp eB|\phi|^2 + \tfrac{\lambda}{2}(|\phi|^2 - v^2)^2 \;+\; \left|(D_1 \mp iD_2)\phi\right|^2\,\Big]. \tag{41.110}$$

The first three terms are a quadratic in B that completes to a perfect square *only* when the quartic coupling takes the special value

$$\boxed{\lambda \;=\; e^2} \qquad \text{(critical, Bogomolny, or BPS coupling).} \tag{41.111}$$

At this value $\frac{\lambda}{2}(|\phi|^2 - v^2)^2 = \frac{e^2}{2}(|\phi|^2 - v^2)^2$, and writing $\mp eB|\phi|^2 = \mp eB(|\phi|^2 - v^2) \mp eBv^2$ we recognize the completed square

$$\tfrac{1}{2}B^2 \mp eB(|\phi|^2 - v^2) + \tfrac{e^2}{2}(|\phi|^2 - v^2)^2 \;=\; \tfrac{1}{2}\big[\, B \mp e(|\phi|^2 - v^2)\,\big]^2, \tag{41.112}$$

leaving the lone linear remainder $\mp eBv^2$. Therefore, at $\lambda = e^2$,

$$E \;=\; \int d^2x \left[\, \tfrac{1}{2}\big(B \mp e(|\phi|^2 - v^2)\big)^2 + \big|(D_1 \mp iD_2)\phi\big|^2 \,\right] \;\mp\; ev^2 \int d^2x\, B. \tag{41.113}$$

The two square-bracketed terms are non-negative, and the final term is purely topological: $\int B\, d^2x = \Phi = 2\pi n/e$ by Theorem 41.21. Hence

$$E \;=\; \int d^2x \left[\, \tfrac{1}{2}\big(B \mp e(|\phi|^2 - v^2)\big)^2 + \big|(D_1 \mp iD_2)\phi\big|^2 \,\right] \;\mp\; 2\pi v^2 n. \tag{41.114}$$

Choosing the upper or lower sign so that $\mp 2\pi v^2 n = +2\pi v^2|n|$ (lower sign for $n > 0$, upper for $n < 0$) makes the topological term positive, and since the remaining integral is non-negative we obtain the Bogomolny bound

$$E \;\geq\; 2\pi v^2\, |n|, \tag{41.115}$$

with equality if and only if the two non-negative integrands vanish identically. The energy of a topological vortex is bounded below by a multiple of its winding number; it cannot decay because n is locked, and the lightest configuration in each sector sits exactly on the floor Eq. (41.115).

Saturation defines the *Bogomolny–Prasad–Sommerfield (BPS) vortex*. Equality in Eq. (41.115) holds precisely when both squares vanish, i.e. when the fields satisfy the first-order *Bogomolny equations*

$$(D_1 \mp iD_2)\phi \;=\; 0, \qquad B \;=\; \pm\, e\,(|\phi|^2 - v^2), \tag{41.116}$$

with the upper sign for $n < 0$ and the lower (so $B = e(v^2 - |\phi|^2) \geq 0$ in the core where $|\phi| < v$) for $n > 0$. A configuration solving the first-order system Eq. (41.116) automatically solves the second-order field equations Eqs. (41.102) and (41.103): since it is a stationary point of the energy — indeed an absolute minimum within its topological sector — it is a critical point of the action, hence a solution of the equations of motion. This is the payoff of the Bogomolny rearrangement. At the critical coupling Eq. (41.111) the difficult coupled nonlinear second-order problem is replaced by a much milder first-order one, and the energy of every solution is known exactly, $E = 2\pi v^2|n|$, before a single profile is computed.

Worked Example 41.22 (The BPS equations in radial form and the saturated energy)**.** We reduce the Bogomolny equations Eq. (41.116) to the winding ansatz Eq. (41.92) for $n > 0$ (lower signs) and confirm directly that the energy equals

$2\pi v^2 n$. The first BPS equation $(D_1 + iD_2)\phi = 0$ is, in the orthonormal frame, $(D\phi)_r + i(D\phi)_\theta = 0$. Using Eqs. (41.98) and (41.99),

$$v f' e^{in\theta} + i\cdot i\, v f e^{in\theta}\frac{n}{r}(1-a) = v e^{in\theta}\Big[\, f' - \frac{n}{r}(1-a) f \,\Big] = 0 \quad\Longrightarrow\quad f' = \frac{n}{r}(1-a)\, f. \tag{41.117}$$

The second BPS equation $B = e(v^2 - |\phi|^2) = ev^2(1 - f^2)$, together with $B = \frac{n}{e}\frac{a'}{r}$ from Eq. (41.100), gives

$$\frac{n}{e}\frac{a'}{r} = ev^2(1 - f^2) \quad\Longrightarrow\quad a' = \frac{e^2 v^2}{n}\, r\,(1 - f^2). \tag{41.118}$$

Equations Eqs. (41.117) and (41.118) are the first-order radial system; one checks by differentiating Eq. (41.117) and substituting Eq. (41.118) that they imply the second-order equations Eqs. (41.102) and (41.103) at $\lambda = e^2$, as the general argument guarantees. They are the equations solved numerically in Fig. 41.4, where the boundary conditions $f(0) = a(0) = 0$, $f(\infty) = a(\infty) = 1$ select the unique $n = 1$ vortex.

For the energy, set the squares in Eq. (41.114) to zero (they vanish on a BPS solution) and read off $E = 2\pi v^2 n$. As an independent check that the reduced energy Eq. (41.101) is consistent with this, the numerical integration reported in Fig. 41.4 for $n = 1$, $e = v = 1$ returns $E = 2\pi v^2$ and $\Phi = 2\pi/e$ to better than one part in 10^3, confirming both the flux quantization Eq. (41.93) and the saturated bound Eq. (41.115) numerically.

The critical coupling Eq. (41.111) separates two qualitatively different regimes, with a clean physical interpretation in terms of the two masses Eq. (41.104). Define the Ginzburg–Landau parameter $\kappa \equiv m_s/m_v = \sqrt{\lambda}/e$, the ratio of penetration depth to coherence length. At $\kappa = 1$, i.e. $\lambda = e^2$, the theory sits at the BPS point: the static force between two well-separated vortices vanishes identically, because the scalar-mediated attraction (range $1/m_s$) and the vector-mediated repulsion (range $1/m_v$) cancel exactly, and the energy of a configuration of total winding n is $2\pi v^2|n|$ regardless of how the flux is distributed. For $\kappa < 1$ ($\lambda < e^2$, the *type-I* regime) the scalar is lighter, its attraction is longer-ranged, vortices attract, and flux prefers to coalesce into a single multiply-wound lump. For $\kappa > 1$ ($\lambda > e^2$, the *type-II* regime) the vector is comparatively lighter, the repulsion wins, vortices repel, and flux fragments into a lattice of unit-winding tubes — the Abrikosov lattice observed in type-II superconductors. The BPS point is the marginal, no-force boundary between the two, and it is exactly there that the topological bound is saturated by the first-order equations.

Caution

The clean saturation $E = 2\pi v^2|n|$ holds only at the critical coupling $\lambda = e^2$. Away from it the Bogomolny rearrangement Eq. (41.112) fails — the

potential no longer completes the square with the magnetic energy — and Eq. (41.115) is replaced by an inequality whose floor is still topological but is no longer attained; the true minimal energy in each sector then differs from $2\pi v^2|n|$ and must be found from the full second-order equations Eqs. (41.102) and (41.103). The Bogomolny bound *as an inequality* ($E \geq 2\pi v^2|n|$) survives for $\lambda \leq e^2$ by the same completion of squares applied with the genuine potential bounded below by the critical one; for $\lambda > e^2$ the inequality requires a slightly different grouping. The point to retain is that the first-order BPS system Eq. (41.116) solves the equations of motion only at $\lambda = e^2$.

We have constructed the vortex: a finite-energy, particle-like (here, string-like in the third spatial dimension) classical solution stabilized by gauging the broken U(1), carrying a topological charge $n \in \pi_1(S^1) = \mathbb{Z}$ that is physically realized as magnetic flux quantized in units of $2\pi/e$, and saturating at the critical coupling a Bogomolny bound $E = 2\pi v^2|n|$ by first-order equations. The construction exhausts what an abelian theory can do in two spatial dimensions. To climb the next rung of the ladder we add a third spatial dimension, where the relevant homotopy group of an abelian vacuum manifold becomes trivial — $\pi_2(S^1) = 0$, a circle cannot wrap a sphere — so a genuine point-like soliton demands a vacuum manifold with nontrivial π_2, hence a non-abelian symmetry broken to leave an unbroken U(1). That is the setting of the next section, where the same finite-energy asymptotics that here quantized magnetic flux will there quantize magnetic charge, and the same Bogomolny structure will reappear: the 't Hooft–Polyakov monopole.

41.5 The 't Hooft–Polyakov Monopole

The vortex of Section 41.4 taught a lesson sharp enough to be turned into a recipe. A scalar field alone cannot make a soliton in more than one spatial dimension (Section 41.3); but if the broken symmetry is *gauged*, the gauge field supplies exactly the energy that Derrick's scaling argument needs in order to balance, and the resulting object carries a topological charge that is realized physically as quantized flux. In two spatial dimensions the relevant homotopy group was π_1 of the broken U(1), and the flux was a single number. We now climb one rung higher — to three spatial dimensions and to a *non-abelian* gauge group — and the same recipe produces something qualitatively new: a smooth, finite-energy lump that, viewed from far away, looks exactly like a magnetic monopole. Its magnetic charge is forced to be quantized, and the quantization is not imposed by hand to hide an unobservable singularity, as in the Dirac construction of Chapter 8, but is a theorem: an integer counting how the Higgs field wraps the vacuum manifold. This is the monopole stage promised for Yang–Mills theory,

and it is the first place in the book where a classical, everywhere-regular field configuration realizes magnetic charge as a topological invariant.

41.5.1 The Georgi–Glashow model

The simplest theory that carries a monopole is the one Georgi and Glashow originally wrote down as a (now excluded) model of the electroweak interactions: an SU(2) gauge field coupled to a single scalar in the *adjoint* representation, with a potential that breaks SU(2) down to U(1). We take the gauge field A^a_μ ($a = 1, 2, 3$) of Chapter 25 with coupling constant e — this is the Yang–Mills theory coupling g, renamed e because the surviving U(1) will be electromagnetism — and an adjoint scalar ϕ^a, a triplet of real fields transforming under gauge rotations exactly as the field strength does. The Lagrangian is

$$\mathcal{L} \;=\; -\tfrac{1}{4}\, F^a_{\mu\nu} F^{a\,\mu\nu} \;+\; \tfrac{1}{2}\,(D_\mu \phi)^a (D^\mu \phi)^a \;-\; V(\phi), \qquad V(\phi) = \frac{\lambda}{4}\big(\phi^a \phi^a - v^2\big)^2, \tag{41.119}$$

with the non-abelian field strength and adjoint covariant derivative of Chapter 25, specialized to SU(2) where the structure constants are the Levi-Civita symbol $f^{abc} = \epsilon^{abc}$ (Eqs. (25.35) and (25.55)),

$$F^a_{\mu\nu} = \partial_\mu A^a_\nu - \partial_\nu A^a_\mu + e\,\epsilon^{abc} A^b_\mu A^c_\nu, \qquad (D_\mu \phi)^a = \partial_\mu \phi^a + e\,\epsilon^{abc} A^b_\mu \phi^c. \tag{41.120}$$

We work in the mostly-minus signature with natural units, and throughout this section the fields are classical: $\hbar$ stays in the drawer, and the monopole's quantum fate is deferred to Chapter 46.

The potential V is minimized on the set $\phi^a \phi^a = v^2$, a two-sphere of radius v in the three-dimensional internal space. This is the *vacuum manifold*

$$\mathcal{M} \;=\; \{\, \phi^a : \phi^a \phi^a = v^2 \,\} \;\cong\; S^2. \tag{41.121}$$

Choosing a particular vacuum, say $\phi^a = v\,\delta^{a3}$, breaks the gauge symmetry spontaneously in the manner developed in Chapters 29 and 30. The unbroken subgroup is the stabilizer of that vacuum direction — the isospin rotations about the third axis, generated by T^3 — so

$$\mathrm{SU}(2) \;\longrightarrow\; \mathrm{U}(1), \qquad \mathcal{M} \;\cong\; \mathrm{SU}(2)/\mathrm{U}(1) \;\cong\; \mathrm{SO}(3)/\mathrm{SO}(2) \;\cong\; S^2, \tag{41.122}$$

the last isomorphism using that the adjoint sees only SO(3), the image of SU(2) under the double cover of Theorem 2.47. The coset description (41.122) is the same S^2 as (41.121), viewed as the orbit of a chosen vacuum under the broken generators.

The spectrum around the vacuum $\phi^a = v\delta^{a3}$ is read off exactly as in Chapter 30. The covariant-derivative term gives the gauge bosons a mass from $\tfrac{1}{2} e^2 \epsilon^{abc}\epsilon^{ade} A^b_\mu \phi^c A^{d\mu} \phi^e$; setting $\phi^c = v\delta^{c3}$ and using $\epsilon^{ab3}\epsilon^{ad3} = \delta^{bd} - \delta^{b3}\delta^{d3}$

collapses this to $\frac{1}{2}e^2v^2\,(A^1_\mu A^{1\mu} + A^2_\mu A^{2\mu})$, so the two charged combinations $W^\pm_\mu = (A^1_\mu \mp i A^2_\mu)/\sqrt{2}$ acquire

$$M_W \;=\; e\,v, \tag{41.123}$$

while A^3_μ stays massless — it is the photon of the unbroken electromagnetic U(1). The scalar sector contributes one massive Higgs of mass $M_H = \sqrt{2\lambda}\,v$ (the radial fluctuation) and two would-be Goldstone modes eaten by $W^\pm$. The two mass scales M_W and M_H, equivalently the two couplings e and λ, are the only parameters; the combination $\lambda/e^2 = M_H^2/2M_W^2$ will turn out to control the monopole.

The decisive fact for what follows is purely topological:

$$\pi_2(\mathcal{M}) \;=\; \pi_2(S^2) \;=\; \mathbb{Z}. \tag{41.124}$$

By the homotopy classification built in Theorem 41.10, maps from a two-sphere into the vacuum manifold fall into integer classes, and the integer is the degree — the number of times the image wraps the target. In one spatial dimension the relevant sphere at infinity was the pair of points S^0 and π_0 counted kink sectors; in two dimensions it was the circle S^1 and π_1 counted vortex flux. In three spatial dimensions the boundary at infinity is a two-sphere, and (41.124) is precisely the group that will label the finite-energy configurations. The Georgi–Glashow model is the minimal renormalizable theory whose vacuum manifold has $\pi_2 = \mathbb{Z}$, and that is why it carries a monopole.

Physical Insight

The choice of vacuum is a choice of a *point* on the two-sphere $\mathcal{M}$. A finite-energy field in three dimensions must approach *some* vacuum in every direction at spatial infinity, i.e. it assigns to each direction $\hat r \in S^2_\infty$ a point of $\mathcal{M} \cong S^2$. That assignment is a map $S^2 \to S^2$, and such maps cannot all be deformed to a constant: the ones that wrap a nonzero number of times are trapped. The monopole is the field configuration whose asymptotic Higgs orientation wraps the vacuum sphere exactly once. Everything below is the working-out of this single picture.

41.5.2 Finite energy and the boundary map

For a static configuration we may set $A^a_0 = 0$ and take all fields time-independent. Then the temporal components of the field strength vanish, $F^a_{0i} = 0$, so the configuration carries no electric field; the energy is the static functional

$$E \;=\; \int d^3x\,\Big[\,\tfrac{1}{2}\,B^a_i B^a_i \;+\; \tfrac{1}{2}\,(D_i\phi)^a(D_i\phi)^a \;+\; V(\phi)\,\Big], \qquad B^a_i \equiv -\tfrac{1}{2}\,\epsilon_{ijk}F^a_{jk}, \tag{41.125}$$

each term manifestly non-negative (this is the three-dimensional gauged analogue of the kink and vortex energy functionals of Sections 41.1 and 41.4; the sign accounting that turns $-\frac{1}{4}F^2$ into $+\frac{1}{2}B^2$ for a purely magnetic static field is the mostly-minus bookkeeping of Section 8.3.4). Here B_i^a is the non-abelian magnetic field, one SO(3) triplet for each spatial direction.

Finiteness of (41.125) forces, term by term, the asymptotic behaviour of the fields. The potential term requires $V(\phi) \to 0$ faster than r^{-3}, hence

$$\phi^a(\vec{r}) \xrightarrow{r\to\infty} \text{a point of } \mathcal{M}, \qquad |\phi| \to v, \tag{41.126}$$

in every direction. The gradient term requires $(D_i\phi)^a \to 0$: the asymptotic Higgs must be *covariantly* constant, which (since ϕ itself is not constant in direction) fixes the asymptotic gauge field in terms of ϕ. The magnetic term requires $B_i^a \to 0$ faster than $r^{-3/2}$. The upshot is that the entire boundary data at infinity is encoded in the unit Higgs field

$$\hat{\phi}^a \equiv \frac{\phi^a}{|\phi|}, \qquad \hat{\phi}: S^2_\infty \longrightarrow \mathcal{M} \cong S^2, \tag{41.127}$$

a continuous map from the sphere at spatial infinity to the vacuum two-sphere. By (41.124) and Theorem 41.10 it carries an integer degree

$$n = \deg(\hat{\phi}) \in \mathbb{Z}, \tag{41.128}$$

which cannot change under any continuous, finite-energy deformation of the fields: to alter n one would have to pass through a configuration whose Higgs field leaves the vacuum manifold on the whole sphere at infinity, costing infinite potential energy. The integer n is the monopole's topological charge. That the gauge term in (41.125) makes a finite-energy minimizer exist in each sector $n \neq 0$ — evading Derrick's theorem exactly as the vortex did — is the content of Section 41.3; here we exhibit the minimizer and compute its charges.

41.5.3 The hedgehog ansatz

To realize $n = 1$ we need a configuration whose asymptotic Higgs wraps the vacuum sphere once. The most symmetric such configuration identifies the internal isospin direction with the spatial direction — it points the Higgs field radially outward in internal space at each point of physical space. This is the *hedgehog*:

$$\boxed{\phi^a(\vec{r}) = v\,\hat{r}^a\,H(r), \qquad A_i^a(\vec{r}) = \epsilon^{aij}\,\hat{r}^j\,\frac{1-K(r)}{e\,r}, \qquad A_0^a = 0,} \tag{41.129}$$

where $\hat{r}^a = x^a/r$ is the radial unit vector, used simultaneously as a spatial vector (index i) and as an internal isovector (index a) — the locking of space to isospin

that the name records. The two dimensionless radial profiles $H(r)$ and $K(r)$ are to be determined; their boundary values are fixed by regularity and finiteness:

$$H(0) = 0, \quad K(0) = 1 \qquad \text{(regularity at the origin)}, \qquad H(\infty) = 1, \quad K(\infty) = 0 \qquad \text{(vacuum} \tag{41.130}$$

At the origin $\phi \to 0$ and A_i^a is finite, so the fields are smooth there — the core is an ordinary, nonsingular lump of field energy in which the full SU(2) symmetry is restored. At infinity $H \to 1$ gives $\phi^a \to v\,\hat{r}^a$, so the asymptotic unit Higgs is

$$\hat{\phi}^a \xrightarrow{r\to\infty} \hat{r}^a, \tag{41.131}$$

the *identity* map $S^2_\infty \to S^2$, which has degree one. The hedgehog therefore sits in the sector $n = 1$. Higher n is reached by composing $\hat{r}^a$ with a degree-n map of the sphere; the construction below goes through with $1 \to n$ in the final charges, and we display n explicitly where it enters.

Physical Insight

The hedgehog cannot be combed flat. A continuous unit-vector field on S^2 that points strictly radially has nowhere to "lie down": by the hairy-ball theorem (a special case of Theorem 41.10, degree $\neq 0$) it must have a singularity somewhere, and in the field theory that "somewhere" is the spatial origin, where $|\phi| \to 0$ lets the direction $\hat{\phi}$ be undefined smoothly. The Higgs field can only relax to the vacuum manifold everywhere if it is allowed to climb out of it at the core. The price of that climb — the gradient and potential energy stored in the core — is the monopole's mass.

41.5.4 The reduced energy and the profile equations

We now substitute the ansatz (41.129) into the energy (41.125) and carry the algebra in full, because the result is both the mass formula and the field equations for the profiles.

The covariant gradient. With $\partial_i \hat{r}^a = (\delta_{ia} - \hat{r}_i\hat{r}_a)/r$ and $\partial_i r = \hat{r}_i$,

$$\partial_i \phi^a = v\Big[\, H'\,\hat{r}_i\hat{r}_a + \frac{H}{r}\,(\delta_{ia} - \hat{r}_i\hat{r}_a)\,\Big]. \tag{41.132}$$

For the gauge term write $\alpha(r) \equiv (1-K)/(er)$, so $A_i^b = \epsilon_{bij}\hat{r}_j\,\alpha$. Then

$$e\,\epsilon^{abc}A_i^b\phi^c = e\,vH\,\alpha\,\epsilon_{abc}\epsilon_{bij}\,\hat{r}_j\hat{r}_c = -\,vH\,\frac{1-K}{r}\,(\delta_{ia} - \hat{r}_i\hat{r}_a), \tag{41.133}$$

where we used $\epsilon_{abc}\epsilon_{bij} = -(\delta_{ai}\delta_{cj} - \delta_{aj}\delta_{ci})$, contracted with $\hat{r}_j\hat{r}_c$ to give $-(\delta_{ia} - \hat{r}_i\hat{r}_a)$. Adding (41.132) and (41.133), the H/r and $-(1-K)H/r$ pieces combine to HK/r:

$$(D_i\phi)^a = v\Big[\, H'\,\hat{r}_i\hat{r}_a + \frac{HK}{r}\,(\delta_{ia} - \hat{r}_i\hat{r}_a)\,\Big]. \tag{41.134}$$

The radial projector $\hat r_i\hat r_a$ and the transverse projector $\delta_{ia}-\hat r_i\hat r_a$ are orthogonal and have squared traces 1 and 2 respectively, so

$$\tfrac12 (D_i\phi)^a(D_i\phi)^a = \tfrac12 v^2 H'^2 + \frac{v^2H^2K^2}{r^2}. \tag{41.135}$$

The magnetic field. The non-abelian magnetic field of the ansatz is computed from $F^a_{ij}=\partial_iA^a_j-\partial_jA^a_i+e\epsilon_{abc}A^b_iA^c_j$. The abelian curl gives

$$\partial_iA^a_j-\partial_jA^a_i = -\frac{2\alpha}{r}\,\epsilon_{aij} + \Big(\alpha'-\frac{\alpha}{r}\Big)(\epsilon_{ajk}\hat r_i-\epsilon_{aik}\hat r_j)\hat r_k, \tag{41.136}$$

while the self-coupling term, using $\epsilon_{abc}\epsilon_{bim}\epsilon_{cjn}\hat r_m\hat r_n=\epsilon_{ijn}\hat r_a\hat r_n$, gives $e\epsilon_{abc}A^b_iA^c_j = e\alpha^2\,\epsilon_{ijn}\hat r_a\hat r_n$. Contracting with $-\frac12\epsilon_{lij}$ and using $\epsilon_{lij}\epsilon_{aij}=2\delta_{la}$, $\epsilon_{lij}\epsilon_{ajk}\hat r_i\hat r_k = \hat r_a\hat r_l-\delta_{la}$, and $\epsilon_{lij}\epsilon_{ijn}=2\delta_{ln}$, the three pieces assemble into

$$B^a_l = \Big(\frac{2\alpha}{r}-e\alpha^2\Big)\hat r_a\hat r_l + \Big(\alpha'+\frac{\alpha}{r}\Big)(\delta_{la}-\hat r_a\hat r_l). \tag{41.137}$$

Inserting $\alpha=(1-K)/(er)$, the radial coefficient becomes $\big[2(1-K)-(1-K)^2\big]/(er^2)=(1-K^2)/(er^2)$, and the transverse coefficient becomes $\alpha'+\alpha/r = -K'/(er)$:

$$\boxed{B^a_l = \frac{1-K^2}{e\,r^2}\,\hat r_a\hat r_l \;-\; \frac{K'}{e\,r}\,(\delta_{la}-\hat r_a\hat r_l).} \tag{41.138}$$

Again by orthogonality of the two projectors,

$$\tfrac12 B^a_lB^a_l = \frac{(1-K^2)^2}{2\,e^2r^4} + \frac{K'^2}{e^2r^2}. \tag{41.139}$$

The mass functional. Adding (41.135), (41.139), and the potential $V=\frac{\lambda}{4}v^4(H^2-1)^2$, and integrating over angles ($\int d^3x = \int_0^\infty 4\pi r^2\,dr$), the energy reduces to a one-dimensional integral,

$$E = 4\pi\int_0^\infty dr\,\Big[\,\frac{K'^2}{e^2}+\frac{(1-K^2)^2}{2e^2r^2}+\tfrac12 v^2r^2H'^2+v^2H^2K^2+\frac{\lambda v^4r^2}{4}(H^2-1)^2\,\Big]. \tag{41.140}$$

Rescaling to the dimensionless radius $\xi=evr$ (the natural length being the core size $1/M_W=1/ev$) and writing H,K as functions of ξ with primes now denoting $d/d\xi$, every term scales out a common factor and

$$\boxed{M \;=\; \frac{4\pi v}{e}\,f\Big(\frac{\lambda}{e^2}\Big), \qquad f=\min_{H,K}\int_0^\infty d\xi\,\Big[\,K'^2+\frac{(1-K^2)^2}{2\xi^2}+\tfrac12\xi^2H'^2+H^2K^2+\frac{\lambda}{4e^2}\,\xi^2(H^2}\tag{41.141}$$

The dimensionless number f depends only on the ratio $\lambda/e^2=M_H^2/2M_W^2$, and the prefactor is $4\pi v/e = 4\pi M_W/e^2 = M_W/\alpha_e$ with $\alpha_e=e^2/4\pi$. The monopole

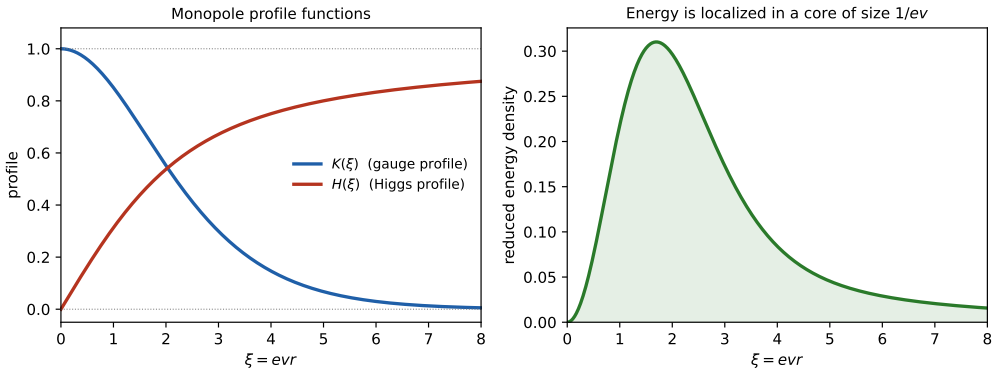

Figure 41.5: The 't Hooft–Polyakov monopole as a smooth, localized lump. Left: the radial profiles in the closed-form $\lambda/e^2 \to 0$ (Prasad–Sommerfield) limit, $K = \xi/\sinh\xi$ and $H = \coth\xi - 1/\xi$ in units $\xi = evr$, satisfying the boundary values (41.130): the gauge profile K collapses from 1 to 0 and the Higgs profile H rises from 0 to the vacuum 1. Right: the reduced energy density, showing that the field energy is concentrated in a core of size $1/ev = 1/M_W$, outside which only the long-range abelian magnetic field survives.

is heavy: its mass is the gauge-boson mass divided by the fine-structure constant of the broken theory, so for any weakly coupled embedding it lies far above the perturbative spectrum — which is exactly why no order of perturbation theory around the vacuum can see it.

The profiles that achieve the minimum solve the Euler–Lagrange equations of (41.141),

$$\xi^2 K'' = K\,(K^2 - 1) + \xi^2 H^2 K, \tag{41.142}$$

$$(\xi^2 H')' = 2HK^2 + \frac{\lambda}{e^2}\,\xi^2 H\,(H^2 - 1), \tag{41.143}$$

a coupled two-point boundary-value problem with the data (41.130). It has no elementary closed-form solution for general λ/e^2, but the existence of a smooth, monotone solution interpolating the boundary values is standard, and its qualitative shape is dictated entirely by (41.130): K falls from 1 to 0 as the gauge field turns from its short-distance pure-gauge form into the long-range abelian tail, and H rises from 0 to 1 as the Higgs climbs out of the symmetric core onto the vacuum manifold (Fig. 41.5). In the limit $\lambda/e^2 \to 0$ the last term drops and the system (41.142)–(41.143) admits the exact solution $K = \xi/\sinh\xi$, $H = \coth\xi - 1/\xi$, with $f \to 1$; this is the Prasad–Sommerfield profile plotted in Fig. 41.5, derived from first-order equations in Section 41.1.5.

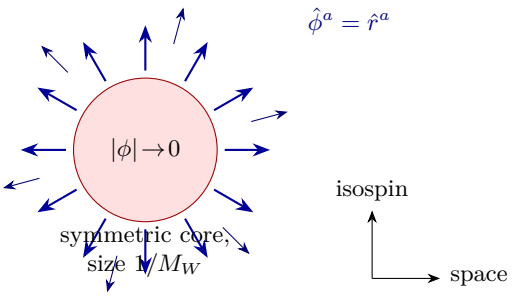

Figure 41.6: The hedgehog. At each point of physical space the internal isospin direction of the Higgs field, $\hat\phi^a$, is locked to the spatial direction $\hat r^a$. The asymptotic field therefore wraps the internal two-sphere exactly once as $\hat r$ ranges over S^2_∞: the map $\hat\phi : S^2_\infty \to S^2$ has degree one. The locking forces $|\phi| \to 0$ at the origin, where the full SU(2) is restored and the energy is stored.

41.5.5 The gauge-invariant electromagnetic field

Far from the core the Higgs field selects, at each point, an unbroken U(1) — the rotations about the local isospin axis $\hat\phi^a$. To speak of "the" electromagnetic field we need a definition of the U(1) field strength that is gauge invariant and reduces, in the gauge where $\hat\phi^a = \delta^{a3}$, to the photon $F^3_{\mu\nu}$. 't Hooft's gauge-invariant field strength accomplishes exactly this:

Definition 41.23 (The 't Hooft electromagnetic tensor)**.** For a configuration with $|\phi| \neq 0$, set $\hat\phi^a = \phi^a/|\phi|$ and define

$$\mathcal{F}_{\mu\nu} \;\equiv\; \hat\phi^a F^a_{\mu\nu} \;-\; \frac{1}{e}\,\epsilon_{abc}\,\hat\phi^a (D_\mu\hat\phi)^b (D_\nu\hat\phi)^c. \tag{41.144}$$

It is a gauge-invariant antisymmetric tensor: each factor transforms in the adjoint and the contraction with $\hat\phi^a$ and ϵ_{abc} is an SO(3) singlet.

The reason (41.144) is the right object is an algebraic identity that strips it down to an abelian curl plus a purely topological term.

Theorem 41.24 (The 't Hooft identity)**.** *Let $a_\mu \equiv \hat\phi^a A^a_\mu$. Then for any smooth configuration with $|\phi| \neq 0$,*

$$\mathcal{F}_{\mu\nu} \;=\; \partial_\mu a_\nu - \partial_\nu a_\mu \;-\; \frac{1}{e}\,\epsilon_{abc}\,\hat\phi^a\,\partial_\mu\hat\phi^b\,\partial_\nu\hat\phi^c. \tag{41.145}$$

Proof. We use only $\hat\phi^a\hat\phi^a = 1$, hence $\hat\phi^a\partial_\mu\hat\phi^a = 0$, and the SU(2) adjoint covariant derivative $D_\mu\hat\phi^a = \partial_\mu\hat\phi^a + e\epsilon_{abc}A^b_\mu\hat\phi^c$.

First expand the abelian curl of a_μ with the Leibniz rule,

$$\partial_\mu a_\nu - \partial_\nu a_\mu = \hat\phi^a(\partial_\mu A^a_\nu - \partial_\nu A^a_\mu) + (\partial_\mu\hat\phi^a)A^a_\nu - (\partial_\nu\hat\phi^a)A^a_\mu$$

$$= \hat\phi^a F^a_{\mu\nu} - e\,\epsilon_{abc}\hat\phi^a A^b_\mu A^c_\nu + (\partial_\mu\hat\phi^a)A^a_\nu - (\partial_\nu\hat\phi^a)A^a_\mu, \tag{41.146}$$

where in the second line we replaced $\hat\phi^a(\partial_\mu A^a_\nu - \partial_\nu A^a_\mu)$ by $\hat\phi^a F^a_{\mu\nu} - e\epsilon_{abc}\hat\phi^a A^b_\mu A^c_\nu$ using the definition of $F^a_{\mu\nu}$ in (41.120).

Next expand the topological-looking piece of $\mathcal{F}$. Writing $P_{\mu\nu} \equiv \epsilon_{abc}\hat\phi^a D_\mu\hat\phi^b D_\nu\hat\phi^c$ and substituting $D_\mu\hat\phi^b = \partial_\mu\hat\phi^b + e\epsilon_{bde}A^d_\mu\hat\phi^e$ produces four terms. Using $\epsilon_{abc}\epsilon_{cfg} = \delta_{af}\delta_{bg} - \delta_{ag}\delta_{bf}$ and $\epsilon_{abc}\epsilon_{bde} = -(\delta_{ad}\delta_{ce} - \delta_{ae}\delta_{cd})$, together with $\hat\phi^a\hat\phi^a = 1$ and $\hat\phi^a\partial_\mu\hat\phi^a = 0$, each contraction collapses:

$$P_{\mu\nu} = \underbrace{\epsilon_{abc}\hat\phi^a\partial_\mu\hat\phi^b\partial_\nu\hat\phi^c}_{\equiv\,\Omega_{\mu\nu}} - e(\partial_\mu\hat\phi^a)A^a_\nu \;+\; e(\partial_\nu\hat\phi^a)A^a_\mu \;+\; e^2\epsilon_{abc}\hat\phi^a A^b_\mu A^c_\nu. \tag{41.147}$$

(The cross terms in which a derivative $\partial\hat\phi$ is contracted into its own $\hat\phi$ vanish by $\hat\phi^a\partial\hat\phi^a = 0$; the terms with ϵ contracted on two $\hat\phi$'s vanish by antisymmetry.) Therefore

$$-\frac{1}{e}P_{\mu\nu} = -\frac{1}{e}\Omega_{\mu\nu} + (\partial_\mu\hat\phi^a)A^a_\nu - (\partial_\nu\hat\phi^a)A^a_\mu - e\,\epsilon_{abc}\hat\phi^a A^b_\mu A^c_\nu. \tag{41.148}$$

Now form $\mathcal{F}_{\mu\nu} = \hat\phi^a F^a_{\mu\nu} - \frac{1}{e}P_{\mu\nu}$ from (41.144) and (41.148), and compare with (41.146): every A-dependent term cancels in pairs, leaving exactly $\mathcal{F}_{\mu\nu} = (\partial_\mu a_\nu - \partial_\nu a_\mu) - \frac{1}{e}\Omega_{\mu\nu}$, which is (41.145). □

Theorem 41.24 is the structural heart of the section. The first two terms of (41.145) are the curl of an ordinary, single-valued vector potential $a_\mu = \hat\phi^a A^a_\mu$. Crucially, a_μ is *smooth on the whole sphere at infinity*, because $\hat\phi$ and A are smooth everywhere — there is no Dirac string. The last term is built purely from the Higgs orientation $\hat\phi$; it is the density of the asymptotic map, and it is what carries the monopole's flux.

The magnetic field of the hedgehog. Specializing (41.144) to the hedgehog is immediate from the pieces already computed. The covariant derivative of the *unit* Higgs is the $H \to 1$ form of (41.134),

$$(D_i\hat\phi)^a = \frac{K}{r}\,(\delta_{ia} - \hat r_i\hat r_a), \tag{41.149}$$

which $\to 0$ at infinity since $K \to 0$ — confirming the boundary condition (41.126). The electromagnetic magnetic field $\mathcal{B}_l = -\frac{1}{2}\epsilon_{lij}\mathcal{F}_{ij}$ has two contributions. The first, $\hat\phi^a B^a_l$, picks out the radial part of (41.138): $\hat r^a B^a_l = (1-K^2)\hat r_l/(er^2)$. The second uses $\epsilon_{abc}\hat\phi^a(D_i\hat\phi)^b(D_j\hat\phi)^c = (K^2/r^2)\,\epsilon_{lij}\hat r_l$ from (41.149), contributing $K^2\hat r_l/(er^2)$. The K-dependence cancels between them:

$$\boxed{\mathcal{B}_l \;=\; \frac{1-K^2}{e\,r^2}\,\hat r_l + \frac{K^2}{e\,r^2}\,\hat r_l \;=\; \frac{1}{e\,r^2}\,\hat r_l.} \tag{41.150}$$

This is remarkable and is the punchline of the construction: the gauge-invariant magnetic field is *exactly Coulombic for all* r, not merely asymptotically. It is the field of a point magnetic charge, and it is everywhere regular — the apparent singularity at $r = 0$ in (41.150) is the usual Coulomb singularity of the field of a source, smoothed in the full non-abelian fields by the core profiles, but exactly pointlike for the *abelian projection*. Comparing with the Dirac monopole field $\vec{B} = (g/4\pi)\hat{r}/r^2$ of Eq. (8.187), we read off the magnetic charge

$$g \;=\; \frac{4\pi}{e}, \qquad \oint_{S^2_\infty} \mathcal{B}_i \, dS_i = \frac{1}{er^2} \cdot 4\pi r^2 = \frac{4\pi}{e}. \tag{41.151}$$

Caution

The total magnetic charge is genuine and nonzero, yet the abelian Bianchi identity $\nabla \cdot \vec{B} = 0$ that doomed the Dirac potential is *not* violated by any fundamental field: the non-abelian fields A^a_μ, ϕ^a are smooth everywhere and obey their own (covariant) Bianchi identity. What carries the magnetic flux is not a string and not a δ-function source, but the winding of $\hat{\phi}$ — the last term of (41.145), which is precisely the obstruction to writing $\mathcal{F}_{\mu\nu}$ globally as the curl of a single smooth a_μ. The monopole charge lives in the topology of the Higgs map, not in a singular potential.

41.5.6 The topological current and the charge identity

We now make precise the claim that the magnetic charge equals the topological degree, for *any* finite-energy configuration in the model, not just the hedgehog. The carrier of the topological charge is the current

$$k^\mu \;=\; \frac{1}{8\pi} \, \epsilon^{\mu\nu\rho\sigma} \, \epsilon_{abc} \, \partial_\nu \hat{\phi}^a \, \partial_\rho \hat{\phi}^b \, \partial_\sigma \hat{\phi}^c, \tag{41.152}$$

with $\epsilon^{0123} = +1$. This is built entirely from the Higgs orientation $\hat{\phi}$; it involves no gauge field and no coupling, and it is conserved without any use of the equations of motion.

Proposition 41.25 (Off-shell conservation)**.** $\partial_\mu k^\mu = 0$ *identically, for every smooth* $\hat{\phi}$*, on or off shell.*

Proof. Differentiating (41.152) and applying the Leibniz rule, every term carries a second derivative $\partial_\mu \partial_\nu \hat{\phi}^a$ (or $\partial_\mu \partial_\rho \hat{\phi}^b$, $\partial_\mu \partial_\sigma \hat{\phi}^c$) contracted with $\epsilon^{\mu\nu\rho\sigma}$. A symmetric pair of indices contracted with the totally antisymmetric ϵ vanishes, so each of the three terms vanishes separately and $\partial_\mu k^\mu \equiv 0$. No field equation was used. $\square$

This is the essential contrast with a Noether current promised in the chapter introduction. The electromagnetic current of Chapters 7 and 8 is conserved *because* of a symmetry and *by* the equations of motion; delete the equations of motion and it is no longer conserved. The current (41.152) is conserved as an algebraic identity, independent of the dynamics. Its conservation expresses not a symmetry of the action but the topology of field space, and the conserved charge it carries is an integer that the continuous dynamics cannot change.

Theorem 41.26 (Topological charge is the degree)**.** *The conserved charge*

$$Q \;=\; \int d^3x\; k^0 \;=\; \frac{1}{8\pi}\int d^3x\;\epsilon_{ijk}\,\epsilon_{abc}\,\partial_i\hat{\phi}^a\,\partial_j\hat{\phi}^b\,\partial_k\hat{\phi}^c \tag{41.153}$$

equals the degree n of the boundary map $\hat{\phi}: S^2_\infty \to S^2$, hence $Q \in \mathbb{Z}$.

Proof. The integrand is a total spatial divergence. Because $\epsilon_{ijk}\epsilon_{abc}\partial_i\hat{\phi}^a\partial_j\hat{\phi}^b\partial_k\hat{\phi}^c = \partial_i\big(\epsilon_{ijk}\epsilon_{abc}\hat{\phi}^a\partial_j\hat{\phi}^b\partial_k\hat{\phi}^c\big)$ — the extra terms generated by the derivative hitting a $\partial\hat{\phi}$ vanish by the same symmetric-times-antisymmetric argument as in Theorem 41.25 — the divergence theorem turns (41.153) into a surface integral over the sphere at infinity,

$$Q \;=\; \frac{1}{8\pi}\oint_{S^2_\infty} dS_i\;\epsilon_{ijk}\,\epsilon_{abc}\,\hat{\phi}^a\,\partial_j\hat{\phi}^b\,\partial_k\hat{\phi}^c. \tag{41.154}$$

This is exactly the degree integral of Eq. (41.46) for a map $S^2 \to S^2$: the integrand $\frac{1}{2}\epsilon_{abc}\hat{\phi}^a\,d\hat{\phi}^b\wedge d\hat{\phi}^c$ is the pullback of the area form on the target two-sphere, and dividing by the total area 4π and integrating counts the (signed) number of times $\hat{\phi}$ covers the target. Hence $Q = \deg(\hat{\phi}) = n \in \mathbb{Z}$. □

Theorem 41.27 (Magnetic charge = topological charge)**.** *For every finite-energy configuration, the magnetic charge of the 't Hooft field equals*

$$\boxed{\;g \;=\; \oint_{S^2_\infty} \mathcal{B}_i\,dS_i \;=\; \frac{4\pi}{e}\,Q \;=\; \frac{4\pi n}{e}.\;} \tag{41.155}$$

Proof. Take the spatial part of the 't Hooft identity (41.145) and form $\mathcal{B}_i = -\frac{1}{2}\epsilon_{ijk}\mathcal{F}_{jk}$. The curl term contributes $-\epsilon_{ijk}\partial_j a_k = -(\nabla\times\vec{a})_i$, and because a_μ is a smooth, single-valued vector field on the closed surface S^2_∞, its flux vanishes by the divergence theorem, $\oint_{S^2_\infty}(\nabla\times\vec{a})\cdot d\vec{S} = 0$. (This is the step the Dirac construction of Theorem 8.32 could not take: there the would-be global potential was singular on a string, and the curl carried nonzero net flux. Here there is no string.) Only the topological term survives,

$$g = \oint_{S^2_\infty}\mathcal{B}_i\,dS_i = \frac{1}{2e}\oint_{S^2_\infty} dS_i\;\epsilon_{ijk}\,\epsilon_{abc}\,\hat{\phi}^a\,\partial_j\hat{\phi}^b\,\partial_k\hat{\phi}^c = \frac{1}{2e}\,(8\pi Q) = \frac{4\pi}{e}\,Q, \tag{41.156}$$

where the middle equality used (41.154). With $Q = n$ from Theorem 41.26, this is (41.155). □

For the hedgehog, $n = 1$, recovering $g = 4\pi/e$ found directly in (41.151). The two computations — the explicit field (41.150) and the general winding identity — agree, as they must, but they make different points: the first shows the field *is* Coulombic; the second shows the total charge is an *integer* dictated by topology, robust against any smooth deformation of the configuration.

Worked Example 41.28 (The degree of the hedgehog map)**.** We verify $Q = 1$ for $\hat{\phi}^a = \hat{r}^a$ directly from (41.154), exhibiting how the abstract degree formula produces a concrete integer. With $\partial_j \hat{r}^b = (\delta_{jb} - \hat{r}_j \hat{r}_b)/r$, the antisymmetric structure kills every term containing $\hat{r}_j \hat{r}_b$ or $\hat{r}_k \hat{r}_c$ (each is symmetric in a pair contracted with an ϵ), leaving

$$\epsilon_{abc}\, \hat{r}^a\, \partial_j \hat{r}^b\, \partial_k \hat{r}^c = \frac{1}{r^2}\, \epsilon_{abc}\, \hat{r}^a\, \delta_{jb} \delta_{kc} = \frac{1}{r^2}\, \epsilon_{ljk}\, \hat{r}_l. \tag{41.157}$$

Contracting with ϵ_{ijk} gives $\epsilon_{ijk}\epsilon_{ljk}/r^2\, \hat{r}_l = 2\hat{r}_i/r^2$, and with $dS_i = \hat{r}_i\, r^2 d\Omega$ the surface integral is

$$Q = \frac{1}{8\pi} \oint dS_i\, \frac{2\hat{r}_i}{r^2} = \frac{1}{8\pi} \oint 2\, d\Omega = \frac{1}{8\pi} \cdot 2 \cdot 4\pi = 1. \tag{41.158}$$

The factor $2\, d\Omega$ is the pullback of the target area form under the identity map: the hedgehog covers the vacuum sphere once, evenly, with the solid-angle element of physical space mapping to the solid-angle element of internal space. Substituting a degree-n boundary map for $\hat{r}^a$ would replace the integrand by n copies of the area form and give $Q = n$, $g = 4\pi n/e$.

41.5.7 Dirac quantization from a regular field

Combining the charge identity with the integrality of the degree gives the central result of the section, the non-singular origin of Dirac's quantization.

Theorem 41.29 (Dirac quantization, topological form)**.** *In the Georgi–Glashow model the magnetic charge of any finite-energy configuration is an integer multiple of* $4\pi/e$*,*

$$\boxed{e\, g \;=\; 4\pi n, \qquad n = \deg(\hat{\phi}) \in \mathbb{Z}.} \tag{41.159}$$

Proof. Immediate from Theorem 41.27: $g = 4\pi n/e$ with $n \in \mathbb{Z}$ by Theorem 41.26. □

It is worth dwelling on how completely this differs in spirit from the Dirac argument of Theorem 8.32, even though the arithmetic agrees. There, one *postulated* a point magnetic charge, found that no smooth global vector potential could describe it, and imported the missing flux along an unobservable Dirac string; the quantization condition $qg = 2\pi m$ then arose as the demand that the

string stay invisible to any charged particle. The monopole was singular, its charge was a free parameter, and quantization was a consistency requirement on a configuration the theory could not actually contain. Here the field is everywhere smooth, the magnetic charge is not a parameter but a computed topological invariant, and quantization is a *theorem* about integers — no string, no postulate, no consistency condition.

The relation between the two unit charges deserves a word. The 't Hooft–Polyakov unit is $g_0 = 4\pi/e$, twice the minimal Dirac unit $g_{\text{Dirac}} = 2\pi/e_{\min}$ that one would infer from the smallest electric charge in the theory. The reason is the matter content: the Georgi–Glashow model contains only adjoint (integer-isospin) fields, whose smallest electric charge under the unbroken U(1) is e (carried by $W^{\pm}$, with isospin $T^3 = \pm 1$ so charge $\pm e$). With $e_{\min} = e$, the monopole satisfies $e\, g_0 = 4\pi = 2\pi \cdot 2$, an *even* Dirac unit. Were one to add an isospinor (fundamental) field, its electric charge would be $e/2$, the minimal Dirac unit would be $g_{\text{Dirac}} = 4\pi/e = g_0$, and the 't Hooft–Polyakov monopole would carry exactly one Dirac unit relative to it. Either way, the consistency that Dirac had to impose by hand on a singular field is here guaranteed automatically by the regularity and topology of a smooth one.

Physical Insight

The Dirac string was always a confession that the abelian description was incomplete near the monopole. The non-abelian theory completes it: in a small ball around the core the gauge group is fully restored to SU(2), the photon is just one component of a non-abelian connection that is perfectly smooth there, and what looked like a singular string in the abelian projection is resolved into a finite, structureless lump of Yang–Mills and Higgs energy. The monopole is the statement that magnetic charge is real, finite-mass, and particle-like once the electromagnetic U(1) is understood as the surviving piece of a larger, spontaneously broken gauge symmetry.

41.5.8 The monopole mass and the Bogomolny bound

The mass formula (41.141), $M = (4\pi v/e)\, f(\lambda/e^2)$, raises a sharp question: how small can f be? The energy (41.140) is a sum of non-negative terms, and a lower bound on it that depends only on the topological charge would prove the monopole stable for the deepest possible reason — not as a local minimum but as the floor of an entire sector.

Such a bound exists, and it is the same Bogomolny rearrangement that saturated the kink and the vortex. Drop the potential ($\lambda/e^2 \to 0$, the Prasad–Sommerfield limit, where the Higgs is massless but the vacuum manifold survives as the boundary condition $|\phi| \to v$) and complete the square in the static energy

(41.125):

$$E = \int d^3x \left[\tfrac{1}{2}\left(B_i^a \mp (D_i\phi)^a\right)^2 \pm B_i^a (D_i\phi)^a\right] \geq \left|\int d^3x\, B_i^a (D_i\phi)^a\right|. \quad (41.160)$$

The cross term is itself topological: using the Bianchi identity $(D_i B_i)^a = 0$ for the non-abelian magnetic field, $B_i^a (D_i\phi)^a = \partial_i (B_i^a \phi^a)$ is a total divergence, so the bound is a surface integral of the magnetic field against the Higgs — which is exactly v times the magnetic flux (41.151). The result is the Bogomolny bound

$$M \geq v\,|g| = \frac{4\pi v}{e}\,|n|, \qquad \text{i.e.} \qquad f\left(\frac{\lambda}{e^2}\right) \geq |n|, \quad (41.161)$$

with equality when the first-order Bogomolny equation $B_i^a = \pm (D_i\phi)^a$ holds. The bound is saturated in the $\lambda/e^2 \to 0$ limit, where $f = 1$ and the profiles are the closed-form Prasad–Sommerfield solution already plotted in Fig. 41.5; for $\lambda/e^2 > 0$ the potential adds positive energy and $f > 1$, but the topological floor $M \geq (4\pi v/e)|n|$ persists. The monopole cannot decay: its mass is bounded below by its conserved magnetic — equivalently topological — charge.

This first-order structure, glimpsed now for the third time, is no coincidence, and the exact solution that saturates it deserves to be derived rather than quoted. That, together with the dyons obtained by switching on the electric field F_{0i}^a we set to zero, and the Witten effect that ties their electric charge to the vacuum angle, is the subject of the next and final section, where the Bogomolny bound is lifted from a recurring trick to a single organizing principle and the BPS monopole is written in closed form.

41.6 The Bogomolny Bound, BPS States, and Dyons

The monopole left us with a number and a hint. The number was a lower bound on its mass: the 't Hooft–Polyakov solution of Section 41.5 cannot weigh less than a fixed multiple of the symmetry-breaking scale times the inverse coupling, because its energy contains the squared magnetic field of a unit-charge Coulomb tail that no smooth deformation can switch off. The hint was that this bound looked saturable. At each rung of the ladder—the kink in Section 41.1, the vortex in Section 41.4, the monopole in Section 41.5—the second-order Euler–Lagrange equations admitted special solutions obeying a *first*-order system, and on those solutions the energy collapsed to a boundary integral fixed entirely by the topological sector. That recurrence is not a coincidence of three models. It is one algebraic identity, applied three times, and this section states it once and for all.

The identity is Bogomol'nyi's completion of the square [83]: a static energy functional that is a sum of squared gradients plus a non-negative potential can be rewritten as a sum of *different* squares plus a total derivative, and the total

derivative integrates to the topological charge. The squares are non-negative, so the energy is bounded below by the modulus of the topological charge; equality holds precisely when the squares vanish, which is the first-order ("BPS") system. We prove this in full, exhibit the kink, vortex, and monopole as instances, and then push the monopole case to its sharpest form: the Prasad–Sommerfield limit [410], in which the potential is switched off and the first-order equations are solved in closed form, giving an explicit profile and a mass that saturates the bound exactly. We close with two pieces of physics that the first-order structure makes inevitable: dyons, which carry electric as well as magnetic charge, and the Witten effect [517], by which a θ-term shifts the dyon's electric charge by an amount set by the very total-derivative term we met classically in Eq. (8.74).

41.6.1 The general Bogomolny completion

Every soliton in this chapter is a stationary point of a static energy functional of the schematic form

$$E[\psi] \;=\; \int \mathrm{d}^{D}x \,\Big[\, \tfrac{1}{2}\sum_{\alpha} \big(\mathcal{D}_{\alpha}[\psi]\big)^{2} \;+\; V(\psi) \,\Big], \qquad V \geq 0, \tag{41.162}$$

where ψ stands collectively for the fields (a scalar, a complex Higgs and a gauge potential, an adjoint triplet and a non-abelian connection), the index α runs over the field-and-spatial-direction labels carried by the gradient terms, and each $\mathcal{D}_{\alpha}[\psi]$ is a real first-order expression—an ordinary derivative $\partial_i\phi$, a covariant derivative $D_i\phi$, or a magnetic field component B_i^{a}, which is itself first order in the connection up to the algebraic self-interaction. The potential V is non-negative and vanishes on the vacuum manifold. Both terms are manifestly non-negative, so $E \geq 0$ trivially; the content of Bogomol'nyi's observation is that a far stronger, *topological* bound is hidden inside this same expression.

Theorem 41.30 (General Bogomolny bound and saturation)**.** *This is the multi-field, arbitrary-dimension generalization of the one-dimensional scalar bound proved for the kink in Theorem 41.5. Suppose the integrand of Eq. (41.162) admits a decomposition*

$$\tfrac{1}{2}\sum_{\alpha}\mathcal{D}_{\alpha}^{2} + V \;=\; \tfrac{1}{2}\sum_{\alpha}\big(\mathcal{D}_{\alpha} \mp \mathcal{S}_{\alpha}\big)^{2} \;\pm\; \mathcal{T}, \tag{41.163}$$

valid as an algebraic identity in the fields, where the $\mathcal{S}_{\alpha}$ are real local expressions and the cross term assembles into a total spatial divergence,

$$\mathcal{T} \;=\; \sum_{\alpha}\mathcal{D}_{\alpha}\,\mathcal{S}_{\alpha} \;=\; \partial_i \mathcal{J}^{i}, \tag{41.164}$$

whose integral

$$Q \;\equiv\; \int \mathrm{d}^{D}x\, \mathcal{T} \;=\; \oint_{S^{D-1}_{\infty}} \mathcal{J}^{i}\, \mathrm{d}S_i \tag{41.165}$$

depends only on the boundary behaviour of the fields—that is, only on the topological sector. Then every finite-energy configuration in that sector satisfies the Bogomolny bound

$$E[\psi] \;\geq\; |Q|\,, \tag{41.166}$$

with equality if and only if the fields obey the first-order Bogomolny (BPS) equations

$$\mathcal{D}_\alpha \;=\; \pm\,\mathcal{S}_\alpha \qquad \textit{for every } \alpha, \tag{41.167}$$

the upper or lower sign chosen so that $\pm Q = |Q|$.

Proof. Both signs in Eq. (41.163) are available because the cross term in expanding $\frac{1}{2}(\mathcal{D}_\alpha \mp \mathcal{S}_\alpha)^2 = \frac{1}{2}\mathcal{D}_\alpha^2 \mp \mathcal{D}_\alpha\mathcal{S}_\alpha + \frac{1}{2}\mathcal{S}_\alpha^2$ carries the explicit $\mp$, and the hypothesis is precisely that $\frac{1}{2}\sum_\alpha \mathcal{S}_\alpha^2 = V$, so that the leftover after the squares reproduces the potential. Integrate the identity over space. The first term on the right of Eq. (41.163) is an integral of a sum of perfect squares, hence non-negative:

$$E[\psi] \;=\; \int \mathrm{d}^D x\; \tfrac{1}{2}\sum_\alpha \left(\mathcal{D}_\alpha \mp \mathcal{S}_\alpha\right)^2 \pm \int \mathrm{d}^D x\; \partial_i \mathcal{J}^i \;=\; \underbrace{\int \mathrm{d}^D x\; \tfrac{1}{2}\sum_\alpha \left(\mathcal{D}_\alpha \mp \mathcal{S}_\alpha\right)^2}_{\geq 0} \pm Q, \tag{41.168}$$

where the divergence integrated to the flux Q of Eq. (41.165) by Gauss's theorem (the surface is the sphere at spatial infinity; finite energy guarantees the fields approach the vacuum manifold there, so the surface integral converges). Now choose the global sign in Eq. (41.163) to be the sign of Q, so that $\pm Q = +|Q|$. Then $E = (\text{non-negative}) + |Q| \geq |Q|$, which is Eq. (41.166). Equality requires the non-negative integral to vanish; since the integrand is a sum of squares of continuous functions, it vanishes identically only if every $\mathcal{D}_\alpha \mp \mathcal{S}_\alpha = 0$ pointwise, i.e. Eq. (41.167). Conversely, any solution of Eq. (41.167) makes that integral zero and hence has $E = |Q|$. Finally, a BPS solution automatically solves the full second-order Euler–Lagrange equations: it is an absolute minimizer of E within its topological sector (no configuration can have $E < |Q|$, and it attains $|Q|$), so it is in particular a stationary point of E. This last fact is what makes the first-order system consistent—it is a genuine reduction of the dynamics, not an extra constraint imposed by hand. □

Three features of this argument deserve emphasis because they recur at every rung. First, the bound is *topological*: Q is a boundary integral, invariant under any deformation of the interior, so it labels homotopy classes and cannot change continuously. Second, the bound is *saturated by a first-order system*, which is generically far easier to solve than the second-order field equations and, crucially, is an algebraic rewriting that holds off-shell. Third, the quantity Q is what a supersymmetric extension of the theory will recognize as a *central charge* in the algebra of supercharges (Chapter 46); the inequality $E \geq |Q|$ becomes there an exact operator statement, and solutions that saturate it—"BPS states"—are

protected from quantum corrections. We are seeing the classical shadow of that structure.

The structure is exactly the one already met for the kink in Section 41.1, now stripped to its bones: a sum of squared gradients, completed against a total derivative, bounded by a boundary integral. We did not need the full machinery of Theorem 41.30 there because there was a single field in one dimension; the value of the abstract statement is that the *same three lines* of algebra cover the vortex and the monopole, where the bookkeeping of indices would otherwise obscure that nothing new is happening.

41.6.2 The three instances and their central charges

With the master identity Theorem 41.30 in hand, the kink, vortex, and monopole are read off as the three instances assembled at the earlier rungs. We line them up.

Kink ($D = 1$, scalar). The single gradient is $\mathcal{D} = \phi'$ and the dual expression is $\mathcal{S} = W'(\phi)$, where the superpotential W is defined by $W'(\phi) = \sqrt{2V(\phi)}$ as in Eq. (41.24); the hypothesis $\frac{1}{2}\mathcal{S}^2 = V$ of Theorem 41.30 then holds by construction, the central charge is $Q = \Delta W = W(\phi_+) - W(\phi_-)$, and the BPS equation is the first-order $\phi' = \pm W'(\phi)$ of Eq. (41.28). This is precisely Theorem 41.5, and the explicit double-well solution $\phi_K = v\tanh((x - x_0)/w)$ together with the mass $M_{\text{kink}} = |\Delta W|$ were computed in full in Theorem 41.6; we do not repeat them. The point to carry forward is structural: the kink is the $D = 1$, single-field instance of the general completion, with the superpotential difference playing the role of the central charge.

Vortex ($D = 2$, gauged $\mathrm{U}(1)$). For the abelian Higgs model assembled in Section 41.4, with a complex scalar of covariant derivative $D_i\phi = (\partial_i - ieA_i)\phi$ and magnetic field $B = \partial_1 A_2 - \partial_2 A_1$, the gradients are the two covariant derivatives and the magnetic field, and the completion combines $|D_i\phi|^2$ with $\frac{1}{2}B^2$ and the quartic potential. It closes into a total derivative *only at the critical coupling* $\lambda = e^2$, where the Higgs and gauge masses coincide; there the BPS equations are the first-order "self-dual" vortex equations

$$(D_1 \pm iD_2)\phi = 0, \qquad B = \mp e\big(|\phi|^2 - v^2\big), \tag{41.169}$$

and the central charge is the quantized magnetic flux,

$$Q \;\propto\; \Phi = \int \mathrm{d}^2x\, B = \frac{2\pi n}{e}, \qquad n \in \mathbb{Z} = \pi_1(\mathrm{U}(1)), \tag{41.170}$$

so that the energy per unit length saturates at a value proportional to $v^2\,|n|$, with the precise normalization fixed in Section 41.4. The new feature relative

to the kink is that saturation needs a tuned coupling: away from $\lambda = e^2$ the squares no longer assemble against the flux, and the static balance between scalar attraction and gauge repulsion of two vortices is broken (vortices attract for $\lambda < e^2$ and repel for $\lambda > e^2$; they are free to coexist at marginal cost exactly on the BPS line). This is the first appearance of a *moduli space* of degenerate multi-soliton solutions, a structure that the supersymmetric continuation of Chapter 46 promotes to a central object.

Monopole ($D = 3$, non-abelian $\mathrm{SU}(2) \to \mathrm{U}(1)$). Here lies the result this section owes in full. The Georgi–Glashow energy of Section 41.5, with an adjoint Higgs ϕ^a, covariant derivative $D_i\phi^a = \partial_i\phi^a + e\,\epsilon^{abc}A_i^b\phi^c$, and non-abelian magnetic field $B_i^a = \frac{1}{2}\epsilon_{ijk}F_{jk}^a$, is

$$E = \int \mathrm{d}^3x \left[\tfrac{1}{2}B_i^aB_i^a + \tfrac{1}{2}D_i\phi^aD_i\phi^a + V(\phi)\right], \qquad V = \tfrac{\lambda}{4}\left(\phi^a\phi^a - v^2\right)^2. \quad (41.171)$$

The gradients are $\mathcal{D} \in \{B_i^a,\, D_i\phi^a\}$. Completing the square between the two,

$$\tfrac{1}{2}B_i^aB_i^a + \tfrac{1}{2}D_i\phi^aD_i\phi^a = \tfrac{1}{2}\left(B_i^a \mp D_i\phi^a\right)^2 \;\pm\; B_i^aD_i\phi^a, \quad (41.172)$$

and the cross term is a total derivative by the same mechanism as before, now powered by the non-abelian Bianchi identity $D_iB_i^a = 0$ (an off-shell consequence of B being a curvature, established in Chapter 25):

$$B_i^aD_i\phi^a = \partial_i\left(B_i^a\phi^a\right) - \left(D_iB_i^a\right)\phi^a = \partial_i\left(B_i^a\phi^a\right). \quad (41.173)$$

(The covariant and ordinary divergences agree on the gauge-invariant scalar $B_i^a\phi^a$ because the connection terms cancel between $B_i^aD_i\phi^a$ and $(D_iB_i^a)\phi^a$.) Integrating, and noting that at spatial infinity $\phi^a \to v\,\hat{\phi}^a$ defines the unbroken-U(1) magnetic field $b_i \equiv B_i^a\hat{\phi}^a$ with total magnetic charge $g = \oint b_i\,\mathrm{d}S_i$,

$$E = \int \mathrm{d}^3x\, \tfrac{1}{2}\left(B_i^a \mp D_i\phi^a\right)^2 \;+\; \int \mathrm{d}^3x\, V \;\pm\; \oint_{S^2_\infty} B_i^a\phi^a\,\mathrm{d}S_i \;\geq\; v\,|g|\,. \quad (41.174)$$

With the Dirac quantization $g = 4\pi n/e$ derived from $\pi_2(S^2) = \mathbb{Z}$ in Section 41.5, the bound is

$$M \;\geq\; v\,|g| = \frac{4\pi v}{e}\,|n|\,, \quad (41.175)$$

the lower bound that opened this section. The catch, visible in Eq. (41.174), is the lingering $\int V$: the magnetic cross term is a clean boundary integral, but the potential is a positive bulk term that the completion does *not* absorb. The bound holds, but it cannot be saturated for $\lambda > 0$, because saturation needs both $B_i^a = \pm D_i\phi^a$ *and* $V = 0$ everywhere, and $V = 0$ everywhere forces $|\phi| \equiv v$, which is incompatible with a smooth ϕ^a that must vanish at the origin (the hedgehog cannot point in all directions at the core). The resolution is to take the potential to zero.

41.6.3 The Prasad–Sommerfield limit and the exact BPS monopole

The obstruction to saturating Eq. (41.175) is the bulk integral of V. Prasad and Sommerfield [410] observed that one may send $\lambda \to 0$ while *keeping* the vacuum value v fixed not by the (now vanishing) potential but by the boundary condition $|\phi| \to v$ at infinity. In this *BPS limit* the Higgs becomes a massless field that nonetheless has a prescribed value at infinity, the potential term in Eq. (41.174) drops out identically, and the bound $M \geq v\,|g|$ can be attained. What is remarkable is that the first-order equations are then exactly solvable.

Definition 41.31 (BPS limit)**.** The *Bogomol'nyi–Prasad–Sommerfield limit* of the Georgi–Glashow model is $\lambda \to 0^{+}$ with v held fixed through the boundary condition $\phi^a\phi^a \to v^2$ as $r \to \infty$. The energy is Eq. (41.171) with $V \equiv 0$, and a finite-energy configuration saturates $M = v\,|g|$ if and only if it solves the *BPS equation*

$$B_i^a = \pm\, D_i\phi^a. \tag{41.176}$$

We now solve Eq. (41.176) in closed form for the unit charge sector. Use the spherically symmetric hedgehog ansatz Eq. (41.129) of Section 41.5,

$$\phi^a = v\,\hat r^a\,H(\xi), \qquad A_i^a = \epsilon_{aij}\,\hat r^j\,\frac{1-K(\xi)}{e\,r}, \qquad A_0^a = 0, \qquad \xi \equiv e\,v\,r, \tag{41.177}$$

with $\hat r^a = x^a/r$ and the dimensionless profiles obeying the boundary data of Eq. (41.130): regularity at the origin requires $H(0) = 0$ and $K(0) = 1$, and the broken vacuum with a pure-monopole tail requires $H(\infty) = 1$ (so $|\phi| \to v$) and $K(\infty) = 0$. The covariant derivative and non-abelian magnetic field of this ansatz were computed in Section 41.5: decomposed on the orthogonal radial projector $\hat r_i\hat r_a$ and transverse projector $\delta_{ia} - \hat r_i\hat r_a$, they read (Eqs. (41.134) and (41.138), with primes on r)

$$(D_i\phi)^a = v\Big[H_r'\,\hat r_i\hat r_a + \frac{HK}{r}\,(\delta_{ia} - \hat r_i\hat r_a)\Big], \qquad B_i^a = \frac{1-K^2}{er^2}\,\hat r_i\hat r_a - \frac{K_r'}{er}\,(\delta_{ia} - \hat r_i\hat r_a). \tag{41.178}$$

The BPS equation Eq. (41.176) (upper sign) holds iff the radial and transverse coefficients match separately. Passing to $\xi = evr$ so that $H_r' = ev\,H'$ and $K_r' = ev\,K'$ (primes now $\mathrm{d}/\mathrm{d}\xi$), the radial match gives $(1-K^2)\,ev^2/\xi^2 = ev^2H'$ and the transverse match gives $-ev^2K'/\xi = ev^2HK/\xi$; the common ev^2 cancels, leaving the pair of coupled first-order equations

$$\frac{dK}{d\xi} = -\,H\,K, \qquad \frac{dH}{d\xi} = \frac{1-K^2}{\xi^2}. \tag{41.179}$$

These are the entire content of the first-order BPS system in the hedgehog sector—a drastic simplification of the second-order profile equations Eqs. (41.142)

and (41.143), whose $\lambda/e^2 \to 0$ form they integrate once. We claim they are solved in closed form by

$$\boxed{K(\xi) = \frac{\xi}{\sinh \xi}, \qquad H(\xi) = \coth \xi - \frac{1}{\xi}.} \tag{41.180}$$

Worked Example 41.32 (Verification of the Prasad–Sommerfield solution)**.** We check Eq. (41.180) against both equations and both sets of boundary conditions, carrying every derivative.

Boundary conditions. As $\xi \to 0$, $\sinh \xi = \xi + \frac{\xi^3}{6} + \cdots$, so $K = \xi/\sinh \xi \to 1$; and $\coth \xi = \frac{1}{\xi} + \frac{\xi}{3} + \cdots$, so $H = \coth \xi - \frac{1}{\xi} = \frac{\xi}{3} + \cdots \to 0$. Both core conditions $K(0) = 1$, $H(0) = 0$ hold, and $H \sim \xi/3$ confirms $\phi^a = v\hat{r}^a H \to 0$ linearly, i.e. smoothly. As $\xi \to \infty$, $\sinh \xi \to \frac{1}{2}e^{\xi}$ so $K = \xi/\sinh \xi \to 0$ exponentially, and $\coth \xi \to 1$ so $H \to 1 - 1/\xi \to 1$, giving $|\phi| = vH \to v$. Both asymptotic conditions hold.

First equation. Differentiate $K = \xi/\sinh \xi$:

$$\frac{dK}{d\xi} = \frac{\sinh \xi - \xi \cosh \xi}{\sinh^2 \xi}. \tag{41.181}$$

On the other side,

$$-HK = -\Big(\coth \xi - \frac{1}{\xi}\Big)\frac{\xi}{\sinh \xi} = -\frac{\xi \cosh \xi}{\sinh^2 \xi} + \frac{1}{\sinh \xi} = \frac{\sinh \xi - \xi \cosh \xi}{\sinh^2 \xi}, \tag{41.182}$$

which equals K' identically. The first equation holds.

Second equation. Differentiate $H = \coth \xi - \xi^{-1}$, using $\frac{d}{d\xi}\coth \xi = -\operatorname{csch}^2 \xi = -1/\sinh^2 \xi$:

$$\frac{dH}{d\xi} = -\frac{1}{\sinh^2 \xi} + \frac{1}{\xi^2}. \tag{41.183}$$

On the other side, with $K^2 = \xi^2/\sinh^2 \xi$,

$$\frac{1 - K^2}{\xi^2} = \frac{1}{\xi^2} - \frac{1}{\sinh^2 \xi}, \tag{41.184}$$

identical to H'. The second equation holds. Thus Eq. (41.180) is an exact, everywhere-regular, finite-energy solution of the first-order BPS system, and by Theorem 41.30 it is an absolute minimizer of the energy in the $n = 1$ sector.

The profiles are plotted in Fig. 41.7. The gauge function K interpolates from 1 at the core (no long-range field) to 0 at infinity (full monopole tail), while $H = |\phi|/v$ rises from 0 to 1 over a core of size $\xi \sim 1$, i.e. $r \sim 1/(ev)$. There is no separate Higgs core and gauge core: in the BPS limit the two masses coincide (both $\to 0$ as $\lambda \to 0$, the Higgs exactly massless, the photon massless by the

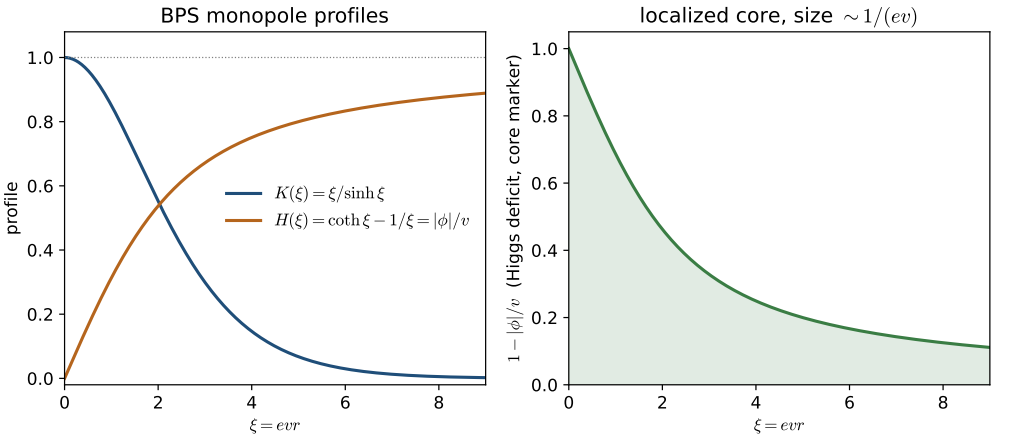

Figure 41.7: The exact Prasad–Sommerfield BPS monopole. *Left:* the gauge profile $K(\xi) = \xi/\sinh\xi$ and the Higgs magnitude $H(\xi) = \coth\xi - 1/\xi = |\phi|/v$, as functions of $\xi = evr$; $K \to 1$, $H \to 0$ at the regular core and $K \to 0$, $|\phi| \to v$ in the broken vacuum. *Right:* the Higgs deficit $1 - |\phi|/v$, marking the localized core of size $\sim 1/(ev)$ outside which only the abelian Coulomb monopole field survives.

unbroken U(1)), and the single length $1/(ev)$ set by the W-boson mass $m_W = ev$ controls everything.

It remains to confirm that the mass saturates the bound. On a BPS solution $B_i^a = D_i\phi^a$, so by Eq. (41.172) (with $V = 0$) and Eq. (41.173),

$$M = \int \mathrm{d}^3x\, B_i^a D_i\phi^a = \oint_{S^2_\infty} B_i^a \phi^a \,\mathrm{d}S_i = v \oint_{S^2_\infty} b_i \,\mathrm{d}S_i = v\, g = \frac{4\pi v}{e}, \tag{41.185}$$

exactly the bound Eq. (41.175) at $n = 1$. Writing $m_W = ev$ for the W-boson mass and $\alpha = e^2/4\pi$ for the fine-structure constant of the unbroken U(1), this is

$$M_{\text{mono}} = \frac{4\pi v}{e} = \frac{4\pi}{e^2}\, m_W = \frac{m_W}{\alpha}, \tag{41.186}$$

so the monopole is heavier than the charged vector boson by the large factor $1/\alpha$. This is the precise sense in which the monopole is a non-perturbative object: its mass scales as the *inverse* coupling, the unmistakable signature of a soliton ($M \sim 1/g^2$ in the natural normalization) and the reason it is invisible to any power series in e.

Physical Insight

The BPS equation $B_i^a = \pm D_i\phi^a$ is a *self-duality* condition. In the Euclidean continuation of Chapter 42 the analogous first-order condition $F_{\mu\nu} = \pm\widetilde{F}_{\mu\nu}$

defines the instanton, and there too it minimizes the (Euclidean) action within a topological sector and reduces a second-order problem to a first-order one with an explicit solution. The kink, vortex, monopole, and instanton are one idea—*topological charge bounds energy/action, first-order "(anti)self-dual" equations saturate it*—realized in $D = 1, 2, 3$ space and in 4-dimensional Euclidean spacetime respectively. The Higgs field ϕ^a in the BPS monopole plays, in the four-dimensional picture, the role of the gauge potential component A_4 along the Euclidean time it does not depend on.

41.6.4 Dyons, the central charge, and the spectrum of allowed charges

Nothing in the construction forbade the time component A_0^a from being nonzero. Reinstating it, Julia and Zee [286] found that the monopole has a one-parameter family of partners carrying *electric* charge as well as magnetic charge: *dyons*. The cleanest way to see both the existence of these states and the resulting mass formula is again the Bogomolny completion, now including the electric sector.

For a static configuration with $A_0^a \neq 0$, the energy acquires the electric terms $\frac{1}{2}E_i^a E_i^a + \frac{1}{2}(D_0\phi^a)^2$ with $E_i^a = F_{0i}^a$ and, in the BPS limit, $V = 0$. The unbroken-U(1) electric charge is the flux of the abelian electric field, $q = \oint E_i^a \hat{\phi}^a \, \mathrm{d}S_i$, just as the magnetic charge is $g = \oint B_i^a \hat{\phi}^a \, \mathrm{d}S_i$. Complete the square in the spatial-gradient energy against an arbitrary angle γ:

$$\tfrac{1}{2}E_i^a E_i^a + \tfrac{1}{2}B_i^a B_i^a + \tfrac{1}{2}D_i\phi^a D_i\phi^a = \tfrac{1}{2}\big(E_i^a - \sin\gamma\, D_i\phi^a\big)^2 + \tfrac{1}{2}\big(B_i^a - \cos\gamma\, D_i\phi^a\big)^2 + \sin\gamma\, E_i^a D_i\phi^a + \cos\gamma\, B_i^a D_i\phi^a, \tag{41.187}$$

where the identity $\sin^2\gamma + \cos^2\gamma = 1$ was used to recover the single $\frac{1}{2}(D_i\phi)^2$. Each cross term is a total derivative—$B_i^a D_i\phi^a = \partial_i(B_i^a\phi^a)$ as in Eq. (41.173), and likewise $E_i^a D_i\phi^a = \partial_i(E_i^a\phi^a)$ on using the Gauss-law constraint $D_i E_i^a = e\,\epsilon^{abc}\phi^b(D_0\phi)^c$, whose right-hand side integrates against $\hat{\phi}$ to zero—so they integrate to $v(q\sin\gamma + g\cos\gamma)$. Dropping the non-negative squares and the $\frac{1}{2}(D_0\phi)^2$ term,

$$M \;\geq\; v\,(q\sin\gamma + g\cos\gamma) \quad \text{for every } \gamma, \qquad \Longrightarrow \qquad M \;\geq\; v\sqrt{q^2+g^2}, \tag{41.188}$$

the sharpest bound obtained by maximizing the right-hand side over γ at $\tan\gamma = q/g$. Equality requires both squares to vanish, i.e. the first-order conditions $B_i^a = \cos\gamma\, D_i\phi^a$ and $E_i^a = \sin\gamma\, D_i\phi^a$ with $\tan\gamma = q/g$ (and the A_0^a profile fixed by the Gauss law). The pure monopole is $\gamma = 0$, recovering $M = vg$; a dyon has $\gamma \neq 0$. The bound Eq. (41.188) is the modulus of a *complex central charge*

$$Z = v\,(q + i\,g), \qquad M \geq |Z|\,, \tag{41.189}$$

and it is in exactly this form that Chapter 46 will identify Z as the central charge of the extended supersymmetry algebra, with BPS states sitting on $M = |Z|$ in shortened multiplets that protect the relation against quantum corrections [436].

What are the *allowed* values of (q, g)? The magnetic charge is quantized by topology, $g = 4\pi n_m/e$ with $n_m \in \mathbb{Z} = \pi_2(S^2)$. The electric charge is quantized by the consistency of the unbroken gauge group: states in the theory carry electric charge in integer units of e, $q = e\,n_e$ with $n_e \in \mathbb{Z}$. The allowed charges therefore live on a two-dimensional lattice labelled by (n_e, n_m). This is the spectrum of the classical theory—but it is not yet the full story, because we have not switched on the one term in the Lagrangian that is invisible to the classical equations of motion: the θ-term.

41.6.5 The Witten effect

We met the θ-term in Eq. (8.74) as a total derivative, $F_{\mu\nu}\widetilde{F}^{\mu\nu} = \partial_\mu K^\mu$, classically inert because it does not alter the field equations. Witten [517] showed that in the presence of a magnetic monopole it is anything but inert: it shifts the dyon's electric charge by an amount proportional to θ. The mechanism is purely canonical—the θ-term changes the momentum conjugate to the gauge potential, hence the operator that generates electric-charge rotations.

Add to the unbroken-U(1) Lagrangian the θ-term, which we take in the form

$$\mathcal{L}_\theta = -\frac{\theta\, e^2}{32\pi^2}\, F_{\mu\nu}\widetilde{F}^{\mu\nu}, \qquad \widetilde{F}^{\mu\nu} = \tfrac{1}{2}\,\epsilon^{\mu\nu\rho\sigma}F_{\rho\sigma}, \tag{41.190}$$

the sign fixing an orientation; the physics below is unchanged under $\theta \to -\theta$ together with the corresponding relabelling of the magnetic charge. The canonical momentum conjugate to A_i receives a contribution from Eq. (41.190). Using the total-derivative form $F_{\mu\nu}\widetilde{F}^{\mu\nu} = 2\,\epsilon^{\mu\nu\rho\sigma}(\partial_\mu A_\nu)(\partial_\rho A_\sigma)$ established at Eq. (8.74), and the Maxwell kinetic term $-\frac{1}{4}F^2$ which alone gives $\partial(-\frac{1}{4}F^2)/\partial(\partial_0 A_i) = F^{i0} = E^i$, the full momentum is

$$\Pi^i = \frac{\partial(\mathcal{L}_{\rm Max} + \mathcal{L}_\theta)}{\partial(\partial_0 A_i)} = E^i - \frac{\theta e^2}{32\pi^2}\,\frac{\partial}{\partial(\partial_0 A_i)}\Big[2\,\epsilon^{\mu\nu\rho\sigma}(\partial_\mu A_\nu)(\partial_\rho A_\sigma)\Big] = E^i - \frac{\theta e^2}{8\pi^2}\,B^i, \tag{41.191}$$

where the derivative picked the two terms with $(\mu\nu) = (0i)$ and $(\rho\sigma) = (0i)$, giving $4\,\epsilon^{0ijk}\partial_j A_k = 4\,B^i$ (with $B^i = \epsilon^{ijk}\partial_j A_k$), and $4 \times \frac{\theta e^2}{32\pi^2} = \frac{\theta e^2}{8\pi^2}$. The θ-term has shifted the conjugate momentum by a multiple of the magnetic field.

Theorem 41.33 (Witten effect)**.** *In the presence of the θ-term Eq. (41.190), a state of magnetic charge $g = 4\pi n_m/e$ and integer electric quantum number n_e has physical electric charge*

$$\boxed{\,q = e\Big(n_e + \frac{\theta}{2\pi}\,n_m\Big).\,} \tag{41.192}$$

Proof. The operator that generates a gauge transformation about the unbroken-U(1) direction $\hat{\phi}^a$ is built, by the canonical formalism, from the conjugate momentum through Gauss's law: with gauge parameter $\Lambda^a = \beta\,\hat{\phi}^a$ the generator is

$$\mathcal{Q}[\beta] = \beta \int \mathrm{d}^3x\, \Pi_i^a \,(D_i\hat{\phi})^a + \beta \oint_{S^2_\infty} \Pi_i^a \hat{\phi}^a \,\mathrm{d}S_i. \tag{41.193}$$

In the broken vacuum at infinity $D_i\hat{\phi} \to 0$, so only the surface term survives and the generator of a rotation by angle β is $\mathcal{Q}[\beta] = \beta\,\mathcal{N}$ with

$$\mathcal{N} = \oint_{S^2_\infty} \Pi_i^a \hat{\phi}^a \,\mathrm{d}S_i = \oint_{S^2_\infty} E_i^a \hat{\phi}^a \,\mathrm{d}S_i - \frac{\theta e^2}{8\pi^2} \oint_{S^2_\infty} B_i^a \hat{\phi}^a \,\mathrm{d}S_i = q - \frac{\theta e^2}{8\pi^2}\, g, \tag{41.194}$$

using Eq. (41.191) projected on $\hat{\phi}^a$, with q and g the abelian electric and magnetic charges. Now the key quantization step. All fields of the theory lie in integer-isospin representations of the broken SU(2) (the gauge bosons and the adjoint Higgs are isospin 0 or 1), so a gauge rotation by $\beta = 2\pi$ about $\hat{\phi}$ acts as the identity on every field: $\exp(2\pi i\,\mathcal{N}/e) = \mathbf{1}$. Hence $\mathcal{N}/e$ has integer spectrum,

$$\mathcal{N} = e\,n_e, \qquad n_e \in \mathbb{Z}. \tag{41.195}$$

Solving Eq. (41.194) for q and inserting $g = 4\pi n_m/e$,

$$q = \mathcal{N} + \frac{\theta e^2}{8\pi^2}\, g = e\,n_e + \frac{\theta e^2}{8\pi^2} \cdot \frac{4\pi n_m}{e} = e\,n_e + \frac{\theta e}{2\pi}\, n_m = e\Big(n_e + \frac{\theta}{2\pi} n_m\Big), \tag{41.196}$$

which is Eq. (41.192). □

The consequences are striking. At $\theta = 0$ the dyon spectrum is the rectangular lattice $q = en_e$, $g = 4\pi n_m/e$. Turning on θ *tilts* the lattice: every unit of magnetic charge drags the allowed electric charges off the integers by $e\theta/2\pi$ (Fig. 41.8). A monopole ($n_m = 1, n_e = 0$) acquires electric charge $q = e\theta/2\pi$, generically irrational in units of e. Because q is no longer an integer multiple of e for $\theta \neq 0$, charge conjugation and parity—each of which sends $\theta \to -\theta$—are broken unless $\theta = 0$ or $\theta = \pi$, the cleanest statement of the strong-CP problem from the soliton side and the point at which this thread rejoins the θ-vacuum of Chapter 42.

Physical Insight

The Witten effect is the cleanest illustration in this book of a "topological" coupling with no classical effect acquiring sharp physical meaning in a nontrivial sector. Classically, Eq. (8.74) says the θ-term is a boundary integral and changes nothing. But a monopole *is* a nontrivial boundary configuration: the magnetic flux through the sphere at infinity is nonzero, so the boundary integral is alive, and it reads off directly as a shift of the conserved electric charge. The same $\partial_\mu K^\mu$ that was inert in the vacuum

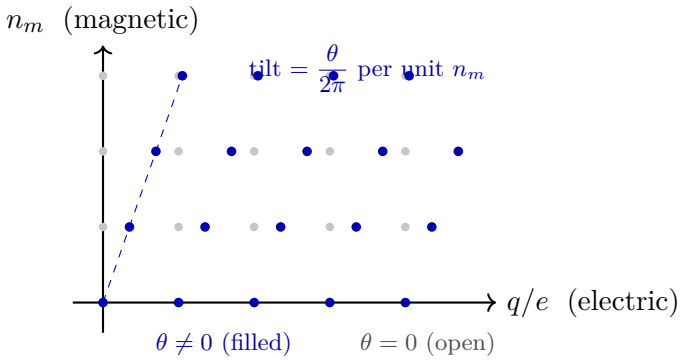

Figure 41.8: The Witten effect on the dyon charge lattice. At $\theta = 0$ the allowed charges $(q/e, n_m) = (n_e, n_m)$ form a rectangular lattice (grey). Switching on θ shifts the electric charge of each state by $e\theta/2\pi$ per unit of magnetic charge, $q = e(n_e + \frac{\theta}{2\pi} n_m)$, tilting the magnetic towers (blue) and rendering the monopole's electric charge generically irrational.

becomes, in the monopole background, a measurable charge.

With the dyon spectrum and the central charge Eq. (41.189) in hand, the natural next question is what happens to these states under the exchange of electric and magnetic charge—the $\mathrm{SL}(2,\mathbb{Z})$ duality that maps (n_e, n_m) into one another and, conjecturally, relates the weakly coupled electric description to a weakly coupled *magnetic* one in which the monopole is elementary [350]. That question, and its precise realization in $\mathcal{N} = 2$ gauge theory where the BPS mass formula $M = |Z|$ is exact and monopole condensation drives confinement, is the business of Chapter 46 and [436]. The immediate sequel, Chapter 42, takes the other fork: it Wick-rotates the self-duality $B = \pm D\phi$ into the four-dimensional Euclidean self-duality $F = \pm\widetilde{F}$, identifies its solutions as instantons, and shows that the θ-term whose monopole avatar we have just measured is the angle labelling the superselected θ-vacua of Yang–Mills theory, completing the Yang–Mills theory passage from the perturbative vacuum to the full topological structure of the non-abelian ground state.

Further reading

The canonical pedagogical treatments of classical solitons and their topology are the monograph of Rajaraman [412] and the lectures of Coleman [129]; the modern, geometry-forward reference is the book of Manton and Sutton [337]. Derrick's no-go scaling argument is Derrick [144]. The abelian vortex was found in the Ginzburg–Landau setting and reintroduced as a relativistic string by

Nielsen and Olesen [367]; the non-abelian monopole is the simultaneous discovery of 't Hooft [468] and Polyakov [407]. The completion-of-the-square bound is due to Bogomolny [83], and the closed-form saturating solution to Prasad and Sommerfield [410]; the link between that bound and a central charge in an extended algebra, which Part XIII makes precise, is Witten and Olive [525]. The shift of the dyon's electric charge in a θ-vacuum — the Witten effect — is Witten [517].

Chapter 42

Instantons and the Vacuum

Every amplitude in Parts IV–VII was a power series in a coupling, an expansion about the trivial classical vacuum that sees only what is analytic in g at the origin. This chapter is about the physics that expansion cannot reach: effects weighted by e^{-c/g^2}, which vanish with all their derivatives as $g \to 0$ and so appear at no finite order of perturbation theory, yet which reorganize the vacuum of every non-abelian gauge theory. The object that computes them is the *instanton*, a finite-action solution of the Euclidean equations of motion that interpolates between classically degenerate vacua. Where Chapter 41 found static, finite-energy solitons classified by the topology of field space, here we find finite-*action* configurations localized in Euclidean time, and read them as quantum-mechanical tunnelling events between vacua that perturbation theory wrongly reports as a unique ground state.

The method is built from the ground up in a setting with no field-theoretic complications at all: a single quantum-mechanical particle in a double well, where the missing physics is the elementary splitting of two would-be degenerate ground states. The full toolkit assembled there—the Euclidean saddle point of the path integral of Chapter 10, evaluated by the steepest-descent machinery of Chapter 5; the finite-action solution interpolating between vacua; the time-translation zero mode and its trade for a collective coordinate; the one-loop fluctuation determinant; and the dilute gas that exponentiates the single-instanton amplitude—transfers verbatim to four-dimensional Yang–Mills. Only the determinants get harder. With that template in hand we lift the picture to the gauge theory: finite Euclidean action forces the field to a pure gauge at the boundary three-sphere, the boundary maps are classified by $\pi_3(\mathrm{SU}(N)) = \mathbb{Z}$ (the homotopy language of Chapter 41), and the Bogomolny rearrangement (Theorem 41.5) bounds the action of each topological sector from below by $8\pi^2|Q|/g^2$, saturated by self-dual fields. We then construct the field that attains it, the BPST instanton, in full, cataloguing the collective coordinates—position, size, and gauge orientation—that the dilute-gas integral runs over.

From the explicit solution the chapter turns to its physical consequences along two complementary readings. In the Hamiltonian reading, the residual large gauge transformations left over from the temporal-gauge quantization of Chapter 26 organize the vacua into a discrete tower $|n\rangle$ labelled by Chern–Simons number; the instanton is the amplitude to hop between adjacent rungs; diagonalizing the tunnelling Hamiltonian produces the θ-vacuum, a one-parameter family of superselected, clustering ground states, and shows that summing the topological sectors is identical to adding a CP-odd θ-term to the Lagrangian. In the Euclidean reading, the dilute instanton gas sums tunnelling events of every winding into a θ-dependent vacuum energy $E(\theta) = -2K\cos\theta$, with the one-loop measure—and through it the running coupling and Λ_{QCD} of Chapter 27—fixing the prefactor and exposing where the approximation honestly breaks down. The curvature of that energy at the origin is the topological susceptibility.

Matter sharpens everything. Coupling light quarks to the instanton, the chiral anomaly of Chapter 36—in both its triangle and Fujikawa-measure forms—turns the topological charge into a violation of axial-fermion number, $\Delta Q_5 = 2n_f Q$, realized concretely through the fermion zero modes the Atiyah–Singer index theorem forces the instanton to carry. These zero modes generate the 't Hooft effective multi-fermion vertex, which dispatches the $U(1)_A$ problem (there is no ninth Goldstone because the singlet axial symmetry is destroyed by the anomaly, not spontaneously broken) and, through the Witten–Veneziano relation, fixes the η' mass in terms of the pure-glue susceptibility. The same anomaly that heals $U(1)_A$ makes the vacuum angle physical and impossible to rotate away, leaving a rephasing-invariant combination $\bar{\theta}$ that a permanent neutron electric dipole moment would detect—and the experimental null result, $|\bar{\theta}| \lesssim 10^{-10}$, is the strong-CP problem. The chapter closes by framing it honestly as a naturalness puzzle and presenting its leading dynamical resolution, the Peccei–Quinn axion, whose potential is built directly on the θ-vacuum energy computed earlier. Throughout, this is Yang–Mills theory carried to its full non-perturbative reach; the model-building and cosmology of the axion are treated in Chapter 35, the non-perturbative lattice definition in Chapter 43.

42.1 Tunneling and the Euclidean Path Integral

Every amplitude computed in Parts IV–VII of this book is a power series in a coupling, generated by expanding $e^{iS_{\mathrm{int}}}$ and summing diagrams. Such a series is an expansion about a single classical solution—the trivial vacuum—and it sees only what is analytic in the coupling at the origin. There is an entire stratum of physics it cannot see, not because the series is poorly summed but because the physics is weighted by a factor that vanishes, together with all its derivatives, as the coupling goes to zero: a factor of the form e^{-c/g^2}. No finite order of perturbation theory contains such a term, and no rearrangement of the series

produces one. The task of this chapter is to compute that physics directly, and the cleanest place to learn how is not field theory at all but a single quantum-mechanical particle in a double well, where the missing physics is something elementary and unmistakable: the splitting of two would-be degenerate ground states by quantum tunnelling. Perturbation theory around either well gives two exactly degenerate harmonic ground states to all orders. The true spectrum has a small splitting. That splitting is the prototype of every nonperturbative effect in this chapter, and the instanton is the object that computes it.

We build the method from the ground up here, in quantum mechanics, because the toolkit assembled—the Euclidean saddle point, the finite-action solution interpolating between vacua, the time-translation zero mode and its trade for a collective coordinate, the fluctuation determinant, and the dilute gas that exponentiates the single-instanton amplitude—transfers *verbatim* to four-dimensional Yang–Mills in the sections that follow. Nothing in the logic is special to one dimension; only the determinants get harder. The reader who masters the double well has, modulo group theory and four-dimensional differential geometry, already understood the Yang–Mills instanton.

42.1.1 The model problem: a particle in a double well

We take a single particle of unit mass moving on the line in a symmetric double-well potential. Setting the mass to one costs no generality—it is restored at the end by dimensional analysis—and lets us write every formula without a trailing m.

Definition 42.1 (Double-well model)**.** The Hamiltonian is $H = \frac{1}{2}p^2 + V(x)$ with

$$V(x) = \frac{\omega^2}{8a^2}\,(x^2 - a^2)^2, \tag{42.1}$$

a potential with two degenerate absolute minima at $x = \pm a$, where $V = 0$, separated by a barrier of height $V(0) = \omega^2 a^2/8$. Its second derivative is

$$V''(x) = \frac{\omega^2}{2a^2}\,(3x^2 - a^2), \qquad V''(\pm a) = \omega^2, \tag{42.2}$$

so that near either minimum the particle is a harmonic oscillator of angular frequency ω.

Perturbation theory proceeds by expanding about one minimum, say $x = +a$. Writing $x = a + y$ and Taylor expanding Eq. (42.1), $V = \frac{1}{2}\omega^2 y^2 + O(y^3)$, one quantizes the local oscillator and treats the cubic and quartic terms as perturbations. This generates the ground-state energy as a power series $E_0(\omega, a) = \frac{1}{2}\omega\,[1 + O(1/\omega a^2)]$ in the dimensionless inverse-barrier parameter. The identical series is obtained by expanding about $x = -a$. To every order the two ground

states are degenerate, because no finite number of derivatives of V at $+a$ knows that a second minimum exists a finite distance away. Yet the exact Hamiltonian is symmetric under parity $x \to -x$, and its true low-lying eigenstates are the symmetric and antisymmetric combinations of the two localized states, with distinct energies. The gap between them,

$$\Delta E \;=\; E_- - E_+, \tag{42.3}$$

is nonzero but invisible order by order: it is the quantity perturbation theory misses. The remainder of this section computes it.

Physical Insight

The physical reason the splitting escapes the perturbative series is that it is controlled by the amplitude for the particle to be found *under the barrier*, in the classically forbidden region between the wells. In the WKB approximation that amplitude is $e^{-\int |p|\,\mathrm{d}x}$, with the momentum imaginary under the barrier. The barrier integral is a positive number divided by $\hbar$; as $\hbar \to 0$ (or, equivalently here, as the barrier becomes high in units of ω) the amplitude is exponentially small and nonanalytic. The instanton is the path-integral incarnation of exactly this WKB barrier penetration, organized so that the prefactor multiplying $e^{-(\text{barrier action})}$ can be computed systematically rather than guessed.

42.1.2 Euclidean continuation of the path integral

The object that knows the full spectrum, degeneracy splitting included, is the transition amplitude in imaginary time. Recall the real-time transition amplitude (Theorem 10.1)

$$\left\langle x_f \middle| e^{-iHT} \middle| x_i \right\rangle = \int_{x(0)=x_i}^{x(T)=x_f} \mathcal{D}x\; e^{\,iS[x]}, \qquad S[x] = \int_0^T \mathrm{d}t\, \left[\tfrac{1}{2}\dot{x}^2 - V(x)\right]. \tag{42.4}$$

The continuation to imaginary time is the Wick rotation fixed once and for all in Chapter 10: we set $t = -i\tau$, with τ real, so that the measure rotates as $\mathrm{d}t = -i\,\mathrm{d}\tau$ (Eq. (10.157)) and the real-time interval T becomes a Euclidean interval $\mathcal{T}$ via $T = -i\mathcal{T}$. Under this rotation $\dot{x} = \mathrm{d}x/\mathrm{d}t = i\,\mathrm{d}x/\mathrm{d}\tau$, so the kinetic term flips sign relative to the potential, and the weight e^{iS} becomes e^{-S_E} with the Euclidean action

$$S_E[x] = \int_0^{\mathcal{T}} \mathrm{d}\tau\, \left[\tfrac{1}{2}\Big(\frac{dx}{d\tau}\Big)^2 + V(x)\right]. \tag{42.5}$$

This is the quantum-mechanical instance of the Euclidean action defined for fields in Theorem 10.27. The amplitude becomes the Euclidean path integral

$$\left\langle x_f \middle| e^{-H\mathcal{T}} \middle| x_i \right\rangle = \int_{x(0)=x_i}^{x(\mathcal{T})=x_f} \mathcal{D}x\; e^{-S_E[x]}. \tag{42.6}$$

Two features of Eq. (42.6) make it the right tool. First, the weight e^{-S_E} is a genuine positive damping factor rather than an oscillatory phase, so the integral is dominated by the configurations of *least* Euclidean action, and the method of steepest descent (Theorem 5.44, Section 5.6) applies directly: the leading approximation is a sum over solutions of the classical Euclidean equation of motion, weighted by e^{-S_E} and corrected by Gaussian fluctuation determinants. Second, the operator $e^{-H\mathcal{T}}$ is the spectral projector in disguise. Inserting a complete set of energy eigenstates,

$$\left\langle x_f \middle| e^{-H\mathcal{T}} \middle| x_i \right\rangle = \sum_n \psi_n(x_f)\, \psi_n^*(x_i)\, e^{-E_n \mathcal{T}}, \tag{42.7}$$

we see that as $\mathcal{T} \to \infty$ the sum is dominated by the lowest states, with the splitting between the two nearly degenerate levels controlling the leading $\mathcal{T}$-dependence. Comparing the saddle-point evaluation of the path integral with the spectral sum Eq. (42.7) is precisely how we will read off ΔE.

The variational principle $\delta S_E = 0$ applied to Eq. (42.5) gives the Euclidean equation of motion

$$\frac{d^2x}{d\tau^2} = V'(x). \tag{42.8}$$

This is Newton's equation for a particle of unit mass moving in the *inverted* potential $-V(x)$: the sign on the force is opposite to the real-time law $\ddot{x} = -V'(x)$. The inversion is the whole geometric content of the Euclidean method. The two degenerate *minima* of V at $x = \pm a$ become two degenerate *maxima* of $-V$, and a classical trajectory of Eq. (42.8) that starts at rest on one hilltop and rolls to the other is the configuration we seek. Figure 42.1 shows the inverted potential and the trajectory.

42.1.3 The instanton solution by quadrature

We now solve Eq. (42.8) for the trajectory that interpolates between the two vacua. The key is that the Euclidean equation of motion, like any one-dimensional Newtonian problem, has a conserved "energy."

Lemma 42.2 (Euclidean energy conservation)**.** *Any solution of Eq. (42.8) conserves the quantity*

$$\mathcal{E} \;=\; \tfrac{1}{2}\Big(\frac{dx}{d\tau}\Big)^2 - V(x). \tag{42.9}$$

Proof. Differentiate: $\frac{d\mathcal{E}}{d\tau} = \dot{x}\,\ddot{x} - V'(x)\dot{x} = \dot{x}\,[\ddot{x} - V'(x)] = 0$ by Eq. (42.8). Note the relative minus sign in Eq. (42.9): it is the mechanical energy in the inverted potential $-V$, the kinetic term plus $(-V)$, as it must be. □

For a trajectory that begins at the vacuum $x = -a$ in the far past and ends at $x = +a$ in the far future, both endpoints are at rest—$\dot{x} \to 0$ as $\tau \to \pm\infty$, since

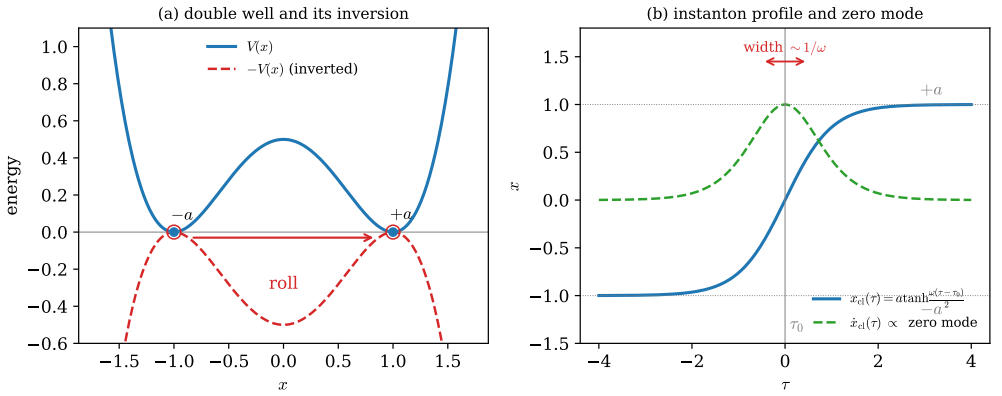

Figure 42.1: (a) The double-well potential $V(x)$ of Eq. (42.1) (solid) and its inversion $-V(x)$ (dashed). The Euclidean equation of motion Eq. (42.8) is Newton's law in $-V$; the two vacua $x = \pm a$ become equal hilltops. (b) The instanton profile $x_{\rm cl}(\tau) = a\tanh[\omega(\tau-\tau_0)/2]$ (solid), a finite-action trajectory rolling from one hilltop to the other, and its derivative $\dot{x}_{\rm cl}$ (dashed), which is the translation zero mode. The transition is localized to a region of width $\sim 1/\omega$ about the centre τ_0; this localization is what licenses the dilute-gas approximation.

the particle must take infinite Euclidean time to climb infinitesimally close to a hilltop of $-V$—and at both endpoints $V = 0$. Therefore $\mathcal{E} = 0$ on this trajectory. The conservation law Eq. (42.9) with $\mathcal{E} = 0$ reduces the second-order equation to a first-order one,

$$\tfrac{1}{2}\Big(\frac{dx}{d\tau}\Big)^2 = V(x), \qquad \text{i.e.} \qquad \frac{dx}{d\tau} = \sqrt{2V(x)} = \frac{\omega}{2a}\,(a^2 - x^2), \tag{42.10}$$

where the positive root is taken for a trajectory moving from $-a$ to $+a$ (so $\dot{x} > 0$), and we used Eq. (42.1) to evaluate $\sqrt{2V} = \sqrt{(\omega^2/4a^2)(x^2-a^2)^2} = (\omega/2a)|a^2 - x^2|$, with $a^2 - x^2 > 0$ between the wells. Equation (42.10) is the central simplification of the whole method: *the equality* $\tfrac{1}{2}\dot{x}^2 = V$ *along the instanton*, which we will use repeatedly.

Equation Eq. (42.10) separates and is integrated by quadrature:

$$\int \frac{\mathrm{d}x}{a^2 - x^2} = \frac{\omega}{2a}\int \mathrm{d}\tau \quad\Longrightarrow\quad \frac{1}{a}\,\operatorname{artanh}\Big(\frac{x}{a}\Big) = \frac{\omega}{2a}\,(\tau - \tau_0), \tag{42.11}$$

where the constant of integration τ_0 is the Euclidean time at which the particle passes through the midpoint $x = 0$. Solving for x gives the *instanton*.

Definition 42.3 (Instanton and anti-instanton)**.** The finite-action solution of Eq. (42.8) interpolating from $x(-\infty) = -a$ to $x(+\infty) = +a$ is

$$x_{\rm cl}(\tau) = a\,\tanh\Big[\frac{\omega}{2}(\tau - \tau_0)\Big], \tag{42.12}$$

the *instanton* centred at τ_0. The reflected solution $-x_{\rm cl}$, running from $+a$ to $-a$, is the *anti-instanton*. We call τ_0 the *centre* or *collective coordinate*.

The profile Eq. (42.12) is a smooth step: it sits exponentially close to $-a$ for $\tau \ll \tau_0$, climbs through zero at $\tau = \tau_0$, and saturates exponentially close to $+a$ for $\tau \gg \tau_0$. The transition happens in a window of width $\sim 1/\omega$, the time it takes the inverted-potential trajectory to traverse the region where $-V$ is appreciably curved. This finite size, against the backdrop of an arbitrarily long total Euclidean time $\mathcal{T}$, is the geometric fact that makes the instanton "dilute": for large $\mathcal{T}$ the system spends almost all its time sitting in a vacuum and only a vanishing fraction tunnelling.

The instanton action

The Euclidean action of the instanton is finite—this is what distinguishes it from a generic interpolating path—and we compute it now, because e^{-S_0} is the leading exponential in every result of the chapter.

Proposition 42.4 (Instanton action)**.** *The Euclidean action of the instanton Eq. (42.12) is*

$$S_0 \;\equiv\; S_E[x_{\rm cl}] \;=\; \frac{2}{3}\,\omega a^2. \tag{42.13}$$

Proof. On the instanton $\tfrac{1}{2}\dot{x}^2 = V$ (Eq. (42.10)), so the two terms of the Euclidean action Eq. (42.5) are equal and

$$S_0 = \int_{-\infty}^{\infty} \mathrm{d}\tau \left[\tfrac{1}{2}\dot{x}_{\rm cl}^2 + V(x_{\rm cl})\right] = \int_{-\infty}^{\infty} \mathrm{d}\tau\, \dot{x}_{\rm cl}^2. \tag{42.14}$$

This last form has a clean interpretation: $S_0 = \int \dot{x}\,(\dot{x}\,\mathrm{d}\tau) = \int \dot{x}\,\mathrm{d}x$, the integral of momentum over the path. Using $\dot{x} = \sqrt{2V}$ from Eq. (42.10) converts the τ-integral into an x-integral over the barrier,

$$S_0 = \int_{-a}^{a} \sqrt{2V(x)}\;\mathrm{d}x = \int_{-a}^{a} \frac{\omega}{2a}\,(a^2 - x^2)\,\mathrm{d}x. \tag{42.15}$$

The remaining elementary integral is

$$\int_{-a}^{a} (a^2 - x^2)\,\mathrm{d}x = \Big[a^2 x - \tfrac{1}{3}x^3\Big]_{-a}^{a} = 2\Big(a^3 - \tfrac{1}{3}a^3\Big) = \frac{4a^3}{3}, \tag{42.16}$$

so $S_0 = (\omega/2a)(4a^3/3) = \tfrac{2}{3}\omega a^2$, which is Eq. (42.13). The same number follows by substituting the explicit profile into Eq. (42.14): with $u = \tfrac{\omega}{2}(\tau - \tau_0)$, $\dot{x}_{\rm cl} = \tfrac{a\omega}{2}\,\mathrm{sech}^2 u$ and $\mathrm{d}\tau = \tfrac{2}{\omega}\mathrm{d}u$, giving $S_0 = \tfrac{a^2\omega}{2}\int_{-\infty}^{\infty}\mathrm{sech}^4 u\,\mathrm{d}u = \tfrac{a^2\omega}{2}\cdot\tfrac{4}{3} = \tfrac{2}{3}\omega a^2$, using $\int \mathrm{sech}^4 u\,\mathrm{d}u = \tfrac{4}{3}$. □

Equation Eq. (42.15) deserves emphasis: the instanton action is exactly the WKB barrier integral $\int |p|\,\mathrm{d}x$ with $|p| = \sqrt{2(V-\mathcal{E})} = \sqrt{2V}$ for zero-energy tunnelling. The instanton method therefore reproduces, and then systematically improves upon, the WKB estimate of the tunnelling amplitude promised in Section 42.1.1. Restoring $\hbar$ and the mass m by dimensional analysis, the weight is $e^{-S_0/\hbar}$ with $S_0 = \tfrac{2}{3} m\omega a^2$, manifestly nonanalytic at $\hbar = 0$.

42.1.4 The zero mode and collective coordinates

To go beyond the bare exponential we expand the action to quadratic order in fluctuations about the instanton and perform the resulting Gaussian integral. Write a nearby path as

$$x(\tau) = x_{\mathrm{cl}}(\tau) + \eta(\tau), \qquad \eta(0) = \eta(\mathcal{T}) = 0, \tag{42.17}$$

with η vanishing at the endpoints (the endpoints are fixed). Since x_{cl} solves the equation of motion, the term linear in η vanishes, and Taylor-expanding Eq. (42.5) gives

$$S_E[x_{\mathrm{cl}} + \eta] = S_0 + \frac{1}{2}\int \mathrm{d}\tau\; \eta(\tau)\, M\, \eta(\tau) + O(\eta^3), \qquad M \equiv -\frac{d^2}{d\tau^2} + V''(x_{\mathrm{cl}}(\tau)), \tag{42.18}$$

the second-order term following from one integration by parts, using $\eta(\partial_\tau^2)\eta = -(\partial_\tau \eta)^2 + \text{boundary}$. The operator M is a Schrödinger operator on the τ-line with the τ-dependent "potential" $V''(x_{\mathrm{cl}}(\tau))$. Inserting Eq. (42.2) along the profile, with $x_{\mathrm{cl}}^2 = a^2 \tanh^2 u$ and $u = \tfrac{\omega}{2}(\tau - \tau_0)$,

$$V''(x_{\mathrm{cl}}) = \frac{\omega^2}{2}\left(3\tanh^2 u - 1\right) = \omega^2 - \frac{3\omega^2}{2}\operatorname{sech}^2 u, \tag{42.19}$$

where we used $\tanh^2 u = 1 - \operatorname{sech}^2 u$. Thus

$$M = -\frac{d^2}{d\tau^2} + \omega^2 - \frac{3\omega^2}{2}\operatorname{sech}^2\!\left[\frac{\omega}{2}(\tau - \tau_0)\right]. \tag{42.20}$$

Far from the instanton centre, $\operatorname{sech}^2 \to 0$ and $M \to M_0 \equiv -\partial_\tau^2 + \omega^2$, the fluctuation operator of a single harmonic well: this is what makes the instanton's fluctuations reduce to vacuum fluctuations away from the transition.

The translation zero mode

The operator M has a normalizable eigenfunction of eigenvalue exactly zero, and its origin is symmetry: the action does not depend on where the instanton is centred.

Proposition 42.5 (Zero mode from time translation)**.** *The function* $\dot{x}_{\mathrm{cl}}(\tau)$ *satisfies* $M\,\dot{x}_{\mathrm{cl}} = 0$*. It is normalizable, with* $\int_{-\infty}^{\infty} \dot{x}_{\mathrm{cl}}^2\,\mathrm{d}\tau = S_0$*, so the unit-normalized zero mode is*

$$x_1(\tau) = \frac{1}{\sqrt{S_0}}\,\dot{x}_{\mathrm{cl}}(\tau). \tag{42.21}$$

Proof. Differentiate the equation of motion Eq. (42.8), $\ddot{x}_{\mathrm{cl}} = V'(x_{\mathrm{cl}})$, once more with respect to τ. The chain rule gives $\dddot{x}_{\mathrm{cl}} = V''(x_{\mathrm{cl}})\,\dot{x}_{\mathrm{cl}}$, that is,

$$-\frac{d^2}{d\tau^2}\dot{x}_{\mathrm{cl}} + V''(x_{\mathrm{cl}})\,\dot{x}_{\mathrm{cl}} = 0, \tag{42.22}$$

which is exactly $M\,\dot{x}_{\mathrm{cl}} = 0$. Normalizability follows because $\dot{x}_{\mathrm{cl}} = \frac{a\omega}{2}\operatorname{sech}^2 u$ decays exponentially as $|\tau| \to \infty$; explicitly its squared norm is the integral computed in Theorem 42.4, $\int \dot{x}_{\mathrm{cl}}^2\,\mathrm{d}\tau = S_0$ by Eq. (42.14). Dividing by $\sqrt{S_0}$ gives the unit-normalized mode Eq. (42.21). □

The zero mode is the lowest eigenfunction of M: it has no nodes (it is everywhere positive, being proportional to sech^2), so by the standard oscillation theorem of one-dimensional Schrödinger operators it is the ground state, and every other eigenvalue of M is strictly positive. This sign structure—one zero eigenvalue, the rest positive—is what makes the instanton a genuine minimum of the action in every direction except the flat one, and it is what we must handle with care in the Gaussian integral.

Physical Insight

A zero mode is the signature of a continuous degeneracy of the saddle point. Here the degeneracy is the freedom to slide the instanton along the τ-axis: $x_{\mathrm{cl}}(\tau - \tau_0)$ is a solution of the same action for every τ_0, so moving along the family costs nothing, and the second variation in that direction vanishes. The direction in function space tangent to the family is precisely $\partial_{\tau_0} x_{\mathrm{cl}} = -\dot{x}_{\mathrm{cl}}$, the zero mode. Whenever a saddle point breaks a continuous symmetry of the action, the broken generator produces a zero mode, and the Gaussian integral over that direction must be replaced by an integral over the symmetry parameter—a *collective coordinate*. The same mechanism in Yang–Mills produces zero modes for spacetime translations, dilatations, and global gauge rotations of the instanton.

Trading the zero mode for the collective coordinate

Expand the fluctuation in the orthonormal eigenbasis $\{x_n\}$ of M, with eigenvalues λ_n ($\lambda_1 = 0$):

$$\eta(\tau) = \sum_n c_n\,x_n(\tau), \qquad M x_n = \lambda_n x_n, \qquad \int x_n x_m\,\mathrm{d}\tau = \delta_{nm}. \tag{42.23}$$

The Gaussian weight is $e^{-\frac{1}{2}\sum_n \lambda_n c_n^2}$, and the path-integral measure, with the conventional normalization that makes each Gaussian integral standard, is

$$\mathcal{D}x = \prod_n \frac{\mathrm{d}c_n}{\sqrt{2\pi}}. \tag{42.24}$$

For every mode with $\lambda_n > 0$ the integral is $\int \frac{\mathrm{d}c_n}{\sqrt{2\pi}}\, e^{-\frac{1}{2}\lambda_n c_n^2} = \lambda_n^{-1/2}$, and the product of these is, by definition, $(\det{}' M)^{-1/2}$ with the prime indicating omission of the zero eigenvalue. But the $n = 1$ integral is hopeless as written: with $\lambda_1 = 0$ the Gaussian degenerates to $\int \frac{\mathrm{d}c_1}{\sqrt{2\pi}}$, a divergent integral over the unbounded coefficient of the flat direction. This divergence is not a pathology; it is the statement that the instanton can sit anywhere along the τ-axis, and integrating over c_1 overcounts by integrating over a direction that is really the location τ_0. We must convert $\int \mathrm{d}c_1$ into $\int_0^{\mathcal{T}} \mathrm{d}\tau_0$.

Proposition 42.6 (Collective-coordinate change of variables)**.** *Promoting the instanton centre τ_0 to an integration variable, the zero-mode integral is traded according to*

$$\frac{\mathrm{d}c_1}{\sqrt{2\pi}} = \sqrt{\frac{S_0}{2\pi}}\, \mathrm{d}\tau_0, \tag{42.25}$$

so the Gaussian integral over the flat direction is replaced by an ordinary integral over the centre, weighted by the Jacobian $\sqrt{S_0/2\pi}$.

Proof. Displacing the instanton centre by an infinitesimal $\mathrm{d}\tau_0$ changes the configuration by

$$\delta x = x_{\mathrm{cl}}(\tau - \tau_0 - \mathrm{d}\tau_0) - x_{\mathrm{cl}}(\tau - \tau_0) = -\dot{x}_{\mathrm{cl}}(\tau - \tau_0)\, \mathrm{d}\tau_0. \tag{42.26}$$

This same displacement, expressed in the mode basis, is a move purely along the zero direction: $\delta x = x_1\, \mathrm{d}c_1$ with $x_1 = \dot{x}_{\mathrm{cl}}/\sqrt{S_0}$ the normalized zero mode (Eq. (42.21)). Equating the two expressions for δx and matching coefficients of the unit vector x_1,

$$x_1\, \mathrm{d}c_1 = -\dot{x}_{\mathrm{cl}}\, \mathrm{d}\tau_0 = -\sqrt{S_0}\, x_1\, \mathrm{d}\tau_0 \quad\Longrightarrow\quad \mathrm{d}c_1 = -\sqrt{S_0}\, \mathrm{d}\tau_0. \tag{42.27}$$

The sign merely reflects orientation and is absorbed into the limits; taking the magnitude, $|\mathrm{d}c_1| = \sqrt{S_0}\, \mathrm{d}\tau_0$. Dividing by the $\sqrt{2\pi}$ that accompanies $\mathrm{d}c_1$ in the measure Eq. (42.24) gives Eq. (42.25). □

Putting the pieces together, the single-instanton contribution to the Euclidean amplitude is

$$\left\langle a \middle| e^{-H\mathcal{T}} \middle| -a \right\rangle_{\text{1-inst}} = e^{-S_0} \sqrt{\frac{S_0}{2\pi}} \int_0^{\mathcal{T}} \mathrm{d}\tau_0\, \left(\det{}' M\right)^{-1/2}, \tag{42.28}$$

where the integral over τ_0 runs over the available Euclidean time and produces a factor $\mathcal{T}$ because the integrand—the action, the determinant with the zero mode removed—is independent of where the instanton sits. The remaining task is to evaluate $\det{}'M$ relative to the free determinant, which supplies the overall normalization.

42.1.5 The fluctuation determinant and the prefactor K

The determinant $\det{}'M$ is meaningful only relative to a reference. The natural reference is the no-instanton amplitude—the particle sitting in a single harmonic well for the whole time $\mathcal{T}$—whose Gaussian integral is governed by the free operator $M_0 = -\partial_\tau^2 + \omega^2$. We therefore organize the answer around the ratio $\det{}'M/\det M_0$, which is finite and dimensionless.

The harmonic reference is the textbook result, derived in Chapter 10 from the same Gaussian path integral: for a single well of frequency ω,

$$\left\langle a\middle|e^{-H\mathcal{T}}\middle|a\right\rangle_{\text{0-inst}} = (\det M_0)^{-1/2} = \left(\frac{\omega}{\pi}\right)^{1/2} e^{-\omega\mathcal{T}/2}\,[1+O(e^{-\omega\mathcal{T}})], \tag{42.29}$$

the prefactor $(\omega/\pi)^{1/2}$ being $|\psi_0(a)|^2$ for the harmonic ground state and $e^{-\omega\mathcal{T}/2}$ its evolution at energy $\frac{1}{2}\omega$. Dividing the single-instanton result Eq. (42.28) by this reference gives the one-instanton amplitude in the natural units of the harmonic "do-nothing" amplitude:

$$\left\langle a\middle|e^{-H\mathcal{T}}\middle|-a\right\rangle_{\text{1-inst}} = \left(\frac{\omega}{\pi}\right)^{1/2} e^{-\omega\mathcal{T}/2}\,(K\mathcal{T})\,e^{-S_0}, \tag{42.30}$$

which *defines* the prefactor

$$K \;\equiv\; \sqrt{\frac{S_0}{2\pi}}\,\left(\frac{\det{}'M}{\det M_0}\right)^{-1/2}. \tag{42.31}$$

The dimensions are right: $\det{}'M/\det M_0$ is dimensionless, S_0 is dimensionless in units $\hbar = 1$, and the $\mathcal{T}$-integral over τ_0 supplied the single factor of time, so K has dimensions of inverse time (frequency)—exactly what is needed for $K\mathcal{T}$ to be dimensionless and for Ke^{-S_0} to be an energy, as the splitting formula below requires.

Evaluating the ratio $\det{}'M/\det M_0$ is the one piece of genuine determinant machinery in the calculation. The general method—the Gelfand–Yaglom construction, which computes the determinant of a one-dimensional Schrödinger operator from the solution of an associated initial-value problem, and its zero-mode-amputated variant—is developed in Section 12.7; we quote its output for the operator at hand and verify the spectral data that fix it. The operator Eq. (42.20) is, after the substitution $u = \frac{\omega}{2}(\tau - \tau_0)$, a member of the reflectionless Pöschl–Teller family $-\partial_\tau^2 + \omega^2 - \omega^2\,\ell(\ell+1)\,\frac{1}{4}\operatorname{sech}^2(\frac{\omega}{2}\cdot)$ with $\ell(\ell+1) = 6$, hence $\ell = 2$. Such operators have a known, finite bound-state spectrum and a transparent determinant. Two facts pin down the answer.

- *The discrete spectrum.* The $\ell = 2$ Pöschl–Teller well has exactly two bound states below the continuum (which begins at $\lambda = \omega^2$), at

$$\lambda_1 = 0, \qquad \lambda_2 = \tfrac{3}{4}\omega^2. \tag{42.32}$$

  The lowest, $\lambda_1 = 0$, is the translation zero mode we already found by symmetry (Theorem 42.5)—a strong internal consistency check on Eq. (42.20). The second, $\lambda_2 = \frac{3}{4}\omega^2$, is the bound excited fluctuation; it is the analogue of the "shape mode" of the kink in Chapter 41.

- *The determinant ratio.* Feeding the reflectionless ($\ell = 2$) data through the Gelfand–Yaglom evaluation of Section 12.7, with the zero eigenvalue removed, yields

$$\frac{\det{}' M}{\det M_0} = \frac{1}{12\,\omega^2}. \tag{42.33}$$

  The factor ω^{-2} carries the dimension (the amputated determinant has one fewer eigenvalue than the free one, so the ratio is not dimensionless until paired with the Jacobian's $\sqrt{S_0}$; the pure number is $1/12$).

Substituting Eq. (42.33) into Eq. (42.31),

$$K = \sqrt{\frac{S_0}{2\pi}}\,(12\,\omega^2)^{1/2} = \omega\sqrt{\frac{6\,S_0}{\pi}}, \tag{42.34}$$

and, using $S_0 = \frac{2}{3}\omega a^2$, equivalently $K = \omega\sqrt{4\omega a^2/\pi} = 2a\omega\sqrt{\omega/\pi}$. We now have everything the dilute gas needs: the single-instanton amplitude is $(\omega/\pi)^{1/2} e^{-\omega\mathcal{T}/2}\, K\mathcal{T}\, e^{-S_0}$ with K given by Eq. (42.34).

Caution

The prime on $\det{}' M$ is not optional bookkeeping. Including the $\lambda_1 = 0$ eigenvalue would make $\det M = 0$ and the Gaussian integral infinite; the whole point of Section 42.1.4 was to excise that eigenvalue *and* compensate by the collective-coordinate integral with its Jacobian $\sqrt{S_0/2\pi}$. Forgetting either the prime or the Jacobian gives a nonsensical (zero or infinite) prefactor. The two operations are a matched pair: one removes a divergent integral, the other reinstates the corresponding physical integration over the instanton's location.

42.1.6 The dilute instanton gas and the level splitting

A single instanton carries the system from $-a$ to $+a$. To return to $-a$, or to make many transitions, the path must contain several instantons and anti-instantons in alternation. Because each transition is localized to a width $\sim 1/\omega$ while the

total time $\mathcal{T}$ is sent to infinity, well-separated multi-instanton configurations are approximate solutions of the equation of motion with action equal to the sum of the individual actions, up to corrections exponentially small in their separations. Summing over all such configurations is the *dilute instanton gas*.

Definition 42.7 (Dilute multi-instanton configuration)**.** An n-object configuration consists of instantons and anti-instantons centred at ordered Euclidean times $0 < \tau_1 < \tau_2 < \cdots < \tau_n < \mathcal{T}$, alternating in type (an instanton must be followed by an anti-instanton and vice versa, since each reverses the well the particle occupies). Its action is nS_0 and its fluctuation factor is the product of n single-object factors, in the approximation that the objects do not overlap.

The constraint that instantons and anti-instantons alternate is forced by the boundary data: starting at $-a$, the first object must be an instanton (it takes $-a \to +a$); the next must be an anti-instanton (back to $+a \to -a$); and so on. Consequently the *type* of every object is determined once n and the starting well are fixed—there is no independent sum over assignments, only the sum over n and the integral over the n centres. The amplitude to go from $-a$ to a final well after n objects is therefore

$$\left\langle x_f \middle| e^{-H\mathcal{T}} \middle| -a \right\rangle = \left(\frac{\omega}{\pi}\right)^{1/2} e^{-\omega\mathcal{T}/2} \sum_{n} \left(K e^{-S_0}\right)^n \int_0^{\mathcal{T}} \mathrm{d}\tau_n \int_0^{\tau_n} \mathrm{d}\tau_{n-1} \cdots \int_0^{\tau_2} \mathrm{d}\tau_1, \tag{42.35}$$

where each object contributes a factor Ke^{-S_0} (the prefactor K from its determinant and Jacobian, the exponential from its action) and the harmonic ground-state factor sits out front because between the objects the particle is doing nothing but sitting in a well, contributing the same $e^{-\omega\mathcal{T}/2}$ as the no-instanton path. The final well x_f equals $-a$ when n is even and $+a$ when n is odd.

The nested, time-ordered integral is the volume of the n-simplex $0 < \tau_1 < \cdots < \tau_n < \mathcal{T}$, which is

$$\int_0^{\mathcal{T}} \mathrm{d}\tau_n \cdots \int_0^{\tau_2} \mathrm{d}\tau_1 = \frac{\mathcal{T}^n}{n!}, \tag{42.36}$$

the $1/n!$ being precisely the ordering: the $n!$ orderings of n unconstrained centres in the hypercube $[0,\mathcal{T}]^n$ each give the same integral, and only one ordering is kept. With Eq. (42.36) the sums in Eq. (42.35) become exponential series. Selecting the final well by parity,

$$\left\langle -a \middle| e^{-H\mathcal{T}} \middle| -a \right\rangle = \left(\frac{\omega}{\pi}\right)^{1/2} e^{-\omega\mathcal{T}/2} \sum_{n \text{ even}} \frac{(K\mathcal{T}e^{-S_0})^n}{n!} = \left(\frac{\omega}{\pi}\right)^{1/2} e^{-\omega\mathcal{T}/2} \cosh\!\left(K\mathcal{T}e^{-S_0}\right), \tag{42.37}$$

$$\left\langle +a \middle| e^{-H\mathcal{T}} \middle| -a \right\rangle = \left(\frac{\omega}{\pi}\right)^{1/2} e^{-\omega\mathcal{T}/2} \sum_{n \text{ odd}} \frac{(K\mathcal{T}e^{-S_0})^n}{n!} = \left(\frac{\omega}{\pi}\right)^{1/2} e^{-\omega\mathcal{T}/2} \sinh\!\left(K\mathcal{T}e^{-S_0}\right), \tag{42.38}$$

the even/odd partial sums of the exponential being cosh and sinh. This is the exponentiation: an infinite sum of dilute multi-instanton configurations resums to hyperbolic functions of a single combination, $K\mathcal{T}e^{-S_0}$. The convergence is excellent precisely in the dilute regime, where $Ke^{-S_0} \ll \omega$ so that the mean spacing $1/(Ke^{-S_0})$ between objects is enormous compared with their width $1/\omega$, justifying the no-overlap approximation after the fact.

Reading off the spectrum

Now compare with the spectral representation Eq. (42.7). As $\mathcal{T} \to \infty$ the amplitude is dominated by the two lowest states, the parity-even $|+\rangle$ and parity-odd $|-\rangle$ combinations of the localized ground states, with energies E_+ and E_-. Their wavefunctions at $x = \pm a$ satisfy $|\psi_\pm(a)|^2 = |\psi_\pm(-a)|^2$ and $\psi_\pm(-a) = \pm\psi_\pm(a)$ by parity, so

$$\Big\langle \pm a \Big| e^{-H\mathcal{T}} \Big| -a \Big\rangle = |\psi_+(a)|^2 e^{-E_+\mathcal{T}} \pm |\psi_-(a)|^2 e^{-E_-\mathcal{T}} + \dots \tag{42.39}$$

On the other hand, expanding the hyperbolic functions Eq. (42.37)–Eq. (42.38),

$$\Big(\frac{\omega}{\pi}\Big)^{1/2} e^{-\omega\mathcal{T}/2}\, \tfrac{1}{2}\Big(e^{+K\mathcal{T}e^{-S_0}} \pm e^{-K\mathcal{T}e^{-S_0}}\Big) = \frac{1}{2}\Big(\frac{\omega}{\pi}\Big)^{1/2}\Big(e^{-(\frac{\omega}{2} - Ke^{-S_0})\mathcal{T}} \pm e^{-(\frac{\omega}{2} + Ke^{-S_0})\mathcal{T}}\Big). \tag{42.40}$$

Term-by-term comparison of Eq. (42.39) with Eq. (42.40) identifies both the energies and the wavefunction normalizations:

$$E_\pm = \frac{\omega}{2} \mp K\, e^{-S_0}, \qquad |\psi_\pm(a)|^2 = \frac{1}{2}\Big(\frac{\omega}{\pi}\Big)^{1/2}. \tag{42.41}$$

The parity-even state $|+\rangle$ lies *below* the symmetric perturbative value $\frac{1}{2}\omega$ and the parity-odd state $|-\rangle$ above it, by equal amounts—the familiar ordering of a symmetric double well, the nodeless symmetric combination being the true ground state. The splitting Eq. (42.3) is therefore

$$\boxed{\Delta E = E_- - E_+ = 2K\, e^{-S_0} = 2\,\omega\sqrt{\frac{6\,S_0}{\pi}}\; e^{-S_0}, \qquad S_0 = \tfrac{2}{3}\omega a^2.} \tag{42.42}$$

This is the result perturbation theory could never produce. The exponential $e^{-S_0} = e^{-2\omega a^2/3}$ is nonanalytic in $\hbar$ (restoring it, $e^{-S_0/\hbar}$) and in any coupling that controls the barrier height; the prefactor $2\omega\sqrt{6S_0/\pi}$ is the one-loop correction supplied by the fluctuation determinant and the collective-coordinate Jacobian. The entire calculation is a controlled saddle-point evaluation of Eq. (42.6), with the saddle the instanton, the loop expansion the expansion in fluctuations, and the dilute gas the resummation of the leading family of saddles.

Worked Example 42.8 (The double-well splitting end to end)**.** We assemble the splitting Eq. (42.42) from scratch to display how each ingredient enters, taking the barrier deep enough that the dilute approximation holds.

Step 1 (action). From Eq. (42.1), $\sqrt{2V} = (\omega/2a)(a^2 - x^2)$, so the instanton action is the barrier integral

$$S_0 = \int_{-a}^{a} \sqrt{2V}\,\mathrm{d}x = \frac{\omega}{2a}\int_{-a}^{a}(a^2 - x^2)\,\mathrm{d}x = \frac{\omega}{2a}\cdot\frac{4a^3}{3} = \frac{2}{3}\omega a^2.$$

Step 2 (zero mode and Jacobian). The instanton's velocity $\dot{x}_{\mathrm{cl}} = \frac{a\omega}{2}\,\mathrm{sech}^2[\frac{\omega}{2}(\tau - \tau_0)]$ is the zero mode, with $\int \dot{x}_{\mathrm{cl}}^2 \mathrm{d}\tau = S_0$; its trade for the centre τ_0 produces the Jacobian $\sqrt{S_0/2\pi}$ (Eq. (42.25)).

Step 3 (determinant). The fluctuation operator Eq. (42.20) is the reflectionless $\ell = 2$ Pöschl–Teller operator; its bound states are $\lambda_1 = 0$ (the zero mode, recovered) and $\lambda_2 = \frac{3}{4}\omega^2$, and the zero-mode-amputated determinant ratio is $\det' M/\det M_0 = 1/(12\omega^2)$ (Eq. (42.33)). Hence $K = \sqrt{S_0/2\pi}\,(12\omega^2)^{1/2} = \omega\sqrt{6S_0/\pi}$.

Step 4 (dilute gas). Summing alternating instantons and anti-instantons over the simplex of centres gives cosh and sinh of $K\mathcal{T}e^{-S_0}$ (Eq. (42.37)–Eq. (42.38)); matching to the spectral sum yields $E_\pm = \frac{\omega}{2} \mp Ke^{-S_0}$ and

$$\Delta E = 2Ke^{-S_0} = 2\omega\sqrt{\frac{6S_0}{\pi}}\,e^{-S_0} = 4\,a\,\omega\,\sqrt{\frac{\omega}{\pi}}\,e^{-2\omega a^2/3},$$

using $\sqrt{6S_0/\pi} = \sqrt{4\omega a^2/\pi} = 2a\sqrt{\omega/\pi}$. Every factor is traceable to a physical operation: e^{-S_0} to barrier penetration, $\sqrt{\omega/\pi}$ to the harmonic ground state, $a\sqrt{\omega}$ to the instanton's size and the collective-coordinate measure.

Historical Note

This organization of barrier penetration as a Euclidean saddle point is due to the work of Polyakov and of 't Hooft in the mid-1970s and was given its canonical pedagogical form by Coleman in his 1977 Erice lectures *The Uses of Instantons*. The name "instanton" (a pseudoparticle localized at an *instant* of Euclidean time, by analogy with a soliton localized in space) is 't Hooft's. The double-well splitting computed here was known from WKB long before; the value of the instanton calculation is that it gives the prefactor systematically and, crucially, that it generalizes to field theory, where no WKB connection formula is available.

42.1.7 The bounce and the large-order connection

Two variations on the instanton theme will recur, and we flag them now so the later sections and chapters can lean on them.

Decay of a false vacuum: the bounce

If the potential is not symmetric but has a metastable *false* vacuum—a local minimum that is not the global one, with a lower true vacuum beyond a barrier—then there is no degeneracy to split, but there is a decay: the false vacuum is unstable to quantum tunnelling and has a finite lifetime. The relevant Euclidean solution is not an instanton interpolating between two distinct vacua but a *bounce*: a trajectory that starts at the false vacuum at $\tau = -\infty$, rolls in the inverted potential out to the classical turning point on the far side of the barrier, and returns to the false vacuum at $\tau = +\infty$. It is a solution of the same equation Eq. (42.8) with the same zero-energy condition, but with both endpoints at the *same* (false) vacuum. The new feature is that the bounce is not a minimum of the action in every nontrivial direction: the fluctuation operator about it has exactly one *negative* eigenvalue, in addition to the translation zero mode. The negative mode makes the Gaussian integral over that direction divergent; its proper treatment by analytic continuation of the steepest-descent contour (Theorem 5.44) gives the amplitude an *imaginary part*, and an imaginary part of the energy is precisely a decay rate. The decay rate per unit volume takes the form

$$\frac{\Gamma}{V} = A\, e^{-S_{\text{bounce}}}\,[1 + O(\hbar)], \tag{42.43}$$

with S_{bounce} the Euclidean action of the bounce and A a prefactor built from the same determinant-and-Jacobian technology, now including the Jacobian of the negative mode. This is the mechanism of vacuum decay in field theory; the field-theoretic bounce is treated in the chapters on the effective potential and cosmological phase transitions, and we will reuse the negative-mode logic when discussing the stability of the electroweak vacuum.

Instantons and the large orders of perturbation theory

The instanton also explains *why* perturbation theory is the divergent asymptotic series it is, rather than a convergent one. The perturbative expansion of a quantity like the ground-state energy is, generically, an asymptotic series $\sum_k a_k\, g^k$ whose coefficients grow factorially, $a_k \sim C\, k!\,/S_0^k$ for large k, with the same instanton action S_0 that governs the nonperturbative exponential. By the theory of asymptotic series and Borel summation developed in Section 5.6 and Theorem 5.47, factorial growth of this form places a singularity of the Borel transform at the point S_0 on the positive Borel axis. The position of that singularity—the obstruction to summing the series—is thus fixed by the instanton action, and the ambiguity it induces in the Borel sum, of order $e^{-S_0/g}$, is exactly the size of the nonperturbative instanton contribution. The two are not independent: the nonperturbative instanton/anti-instanton amplitude is what cancels the imaginary ambiguity of the resummed perturbation series, rendering the total real and well-defined. This is the *large-order/instanton connection*, and

it is the precise sense in which the e^{-S_0} effects of this section are encoded in, rather than divorced from, the perturbative series that ostensibly cannot see them.

Physical Insight

The lesson to carry forward is structural and survives intact into field theory. A nonperturbative effect is computed by (i) finding a finite-action Euclidean solution interpolating between or returning to classical vacua; (ii) evaluating its action S_0, which sets the leading weight e^{-S_0}; (iii) treating the symmetries of the saddle as zero modes traded for collective coordinates with their Jacobians; (iv) computing the fluctuation determinant for the prefactor; and (v) summing a dilute gas of such solutions, which exponentiates and reorganizes the vacuum. Every step we performed here for a particle in a double well has a one-to-one image in four-dimensional Yang–Mills.

We have built the instanton calculus in its simplest nontrivial setting and extracted the toolkit the rest of the chapter needs. The next section lifts each piece into four-dimensional Euclidean Yang–Mills: the role of the two degenerate minima will be played by the topologically distinct pure-gauge vacua, the finite-action requirement will force the gauge field to approach a pure gauge at infinity and so make the boundary data a map $S^3 \to \mathrm{SU}(N)$, and the integer that here merely counted instantons minus anti-instantons will become the winding number $\pi_3(\mathrm{SU}(N)) = \mathbb{Z}$, identified with the topological charge $\frac{g^2}{32\pi^2}\int F\widetilde{F}$ and bounded below in action by the self-dual Bogomolny inequality.

42.2 The Topology of the Yang–Mills Vacuum

The quantum-mechanical template of the previous section taught a single lesson with great force: vacuum tunnelling is computed by finite-action solutions of the Euclidean equations of motion, and those solutions fall into discrete topological classes labelled by an integer—how many times the trajectory winds from one well to the next. Everything that mattered, from the existence of the saddle to the e^{-S_E} suppression of its contribution, followed once we knew the action of a single instanton and the integer counting the sectors. We now lift that picture, intact, to four-dimensional Euclidean Yang–Mills. The double well is replaced by the infinitely degenerate Yang–Mills vacuum; the integer winding of a trajectory is replaced by an integer winding of the gauge field on the three-sphere at the boundary of Euclidean spacetime; and the role of "the action of one instanton" is played by a number, $8\pi^2/g^2$, that we will derive here as a sharp lower bound and which the next section saturates with an explicit field. This section builds the topology: it shows that *finite Euclidean action is itself a topological constraint*,

it classifies the resulting sectors, it constructs the integer that labels them out of the gauge field, and it bounds the action of each sector from below. No solution is constructed yet—only the arena in which the solution must live, and the floor its action cannot pierce.

Throughout we work in Euclidean signature, reached by the Wick rotation $t \to -i\tau$ of Eq. (10.157), under which the Minkowski weight e^{iS} becomes the positive Euclidean weight e^{-S_E} (Theorem 10.27). In four Euclidean dimensions there is no distinction between upper and lower Lorentz indices: the metric is $\delta_{\mu\nu} = \mathrm{diag}(+,+,+,+)$, every repeated pair is summed with a plus sign, and we write all spacetime indices as subscripts. We retain the gauge conventions frozen for Yang–Mills theory: Hermitian generators T^a with $[T^a, T^b] = if^{abc}T^c$ and $\mathrm{tr}(T^aT^b) = \frac{1}{2}\delta^{ab}$, covariant derivative $D_\mu = \partial_\mu - igA^a_\mu T^a$, and the field strength of Theorem 25.11,

$$F^a_{\mu\nu} = \partial_\mu A^a_\nu - \partial_\nu A^a_\mu + g f^{abc} A^b_\mu A^c_\nu, \qquad F_{\mu\nu} \equiv F^a_{\mu\nu} T^a = \partial_\mu A_\nu - \partial_\nu A_\mu - ig[A_\mu, A_\nu], \tag{42.44}$$

where the second, matrix-valued form follows from the first using $[A_\mu, A_\nu] = A^b_\mu A^c_\nu \, if^{bcd}T^d$. The Euclidean Yang–Mills action, the rotation of the classical Lagrangian Eq. (25.76), is

$$S_E[A] = \frac{1}{4}\int d^4x \; F^a_{\mu\nu}F^a_{\mu\nu} = \frac{1}{2}\int d^4x \; \mathrm{tr}(F_{\mu\nu}F_{\mu\nu}) \;\geq\; 0, \tag{42.45}$$

manifestly non-negative because the Euclidean $F^a_{\mu\nu}F^a_{\mu\nu}$ is a sum of squares. The coupling g sits inside F through the covariant derivative; with this placement the topological charge introduced below is normalised as $Q = (g^2/32\pi^2)\int F\tilde{F}$, and the action floor will come out as $8\pi^2/g^2$ per unit charge. We flag this once because the entire chapter's sign and factor bookkeeping hangs on it.

42.2.1 Finite action forces a pure gauge at infinity

The first structural fact is that demanding $S_E < \infty$ is not a mild integrability condition but a boundary condition with topological content. We must control the behaviour of the field as $|x| \to \infty$. Compactify the picture: a finite-action configuration has a field strength that dies at infinity, so the relevant boundary of $\mathbb{R}^4$ is the three-sphere S^3_∞ of large radius R, and the gauge field on it carries the data that will be classified.

Proposition 42.9 (Pure gauge at infinity)**.** *Let A^a_μ be a smooth gauge field on $\mathbb{R}^4$ with finite Euclidean action, $S_E[A] < \infty$. Then the field strength falls faster than $|x|^{-2}$,*

$$F^a_{\mu\nu}(x) = o\Big(|x|^{-2}\Big) \qquad (|x| \to \infty), \tag{42.46}$$

and the gauge potential approaches a pure gauge on the sphere at infinity: there

exists a smooth map $U : S^3_\infty \to \mathrm{SU}(N)$ *such that, as* $|x| \to \infty$,

$$A_\mu(x) \;\longrightarrow\; \frac{i}{g}\,U(\hat{x})\,\partial_\mu U(\hat{x})^{-1} \;=\; -\frac{i}{g}\,(\partial_\mu U(\hat{x}))U(\hat{x})^{-1} \;+\; o\Big(|x|^{-1}\Big)\,, \tag{42.47}$$

where $\hat{x} = x/|x|$ *labels the point on* S^3_∞ *and the two written forms are equal because* $\partial_\mu(UU^{-1}) = 0$.

Proof. The action density $F^a_{\mu\nu}F^a_{\mu\nu}$ is non-negative, so $\int d^4x\, F^a_{\mu\nu}F^a_{\mu\nu} < \infty$. In four dimensions the volume element in radial coordinates is $d^4x = r^3\,dr\,d\Omega_3$, with $d\Omega_3$ the measure on the unit three-sphere. For the radial integral $\int^\infty r^3\,dr\,[F^a_{\mu\nu}F^a_{\mu\nu}]$ to converge, the integrand must decay faster than r^{-1} in $r^3|F|^2$, i.e. $|F|^2 = o(r^{-4})$, which is Eq. (42.46). (A field strength behaving as r^{-2} exactly would give a logarithmically divergent action; finiteness excludes even that borderline case.)

Vanishing field strength on a region forces the connection to be pure gauge there. Concretely, consider the field on a shell $r \in [R, 2R]$ for large R. By Eq. (42.46) the curvature on this shell is $o(R^{-2})$, while the natural transverse derivative scale is $1/R$; the holonomy of A around any small loop on the shell, governed by $\oint A \sim R\,A$ with the loop area controlled by F, is consistent with A being flat to leading order. A flat connection on the simply connected shell (which retracts onto S^3, and S^3 is simply connected) is gauge-equivalent to one that is locally $\partial_\mu g\, g^{-1}$; patching the local trivialisations across the simply connected base, the connection is globally pure gauge up to corrections suppressed by the curvature. Thus there is a smooth $\mathrm{SU}(N)$-valued function on the shell whose restriction to the sphere we call $U(\hat{x})$, with

$$A_\mu(x) = \frac{i}{g}\,U\,\partial_\mu U^{-1} + \Delta_\mu(x), \qquad \Delta_\mu = o(|x|^{-1}), \tag{42.48}$$

the remainder Δ_μ being the part of A whose curvature is the genuine $o(|x|^{-2})$ field strength. The sign and the factor i/g are fixed by demanding that the leading term be *pure gauge*, i.e. carry zero field strength; we verify this now, since it is the point on which the rest of the section turns.

Set $A_\mu = (i/g)\,U\partial_\mu U^{-1} \equiv -(i/g)V_\mu$ with the abbreviation

$$V_\mu \equiv (\partial_\mu U)\,U^{-1}, \qquad U\partial_\mu U^{-1} = -V_\mu, \tag{42.49}$$

so $A_\mu = -(i/g)V_\mu$. Because U is unitary, V_μ is anti-Hermitian and lies in the Lie algebra. Its exterior derivative obeys the Maurer–Cartan identity: differentiating $V_\mu = (\partial_\mu U)U^{-1}$ and using $\partial_\nu U^{-1} = -U^{-1}(\partial_\nu U)U^{-1}$,

$$\partial_\mu V_\nu - \partial_\nu V_\mu = (\partial_\mu\partial_\nu U)U^{-1} + (\partial_\nu U)\partial_\mu U^{-1} - (\mu \leftrightarrow \nu) = -\big[(\partial_\mu U)U^{-1}, (\partial_\nu U)U^{-1}\big]\cdot(-1) = [V_\mu, \tag{42.50}$$

where the symmetric second-derivative terms cancel in the antisymmetrisation, and $(\partial_\nu U)\partial_\mu U^{-1} - (\partial_\mu U)\partial_\nu U^{-1} = -(\partial_\nu U)U^{-1}(\partial_\mu U)U^{-1} + (\partial_\mu U)U^{-1}(\partial_\nu U)U^{-1} =$

$[V_\mu, V_\nu]$. Now compute the field strength Eq. (42.44) of $A_\mu = -(i/g)V_\mu$:

$$F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu - ig[A_\mu, A_\nu] = -\frac{i}{g}(\partial_\mu V_\nu - \partial_\nu V_\mu) - ig\Big(-\frac{i}{g}\Big)^2 [V_\mu, V_\nu]. \quad (42.51)$$

The first term is $-(i/g)[V_\mu, V_\nu]$ by Eq. (42.50); the second is $-ig\cdot(-1/g^2)[V_\mu, V_\nu] = (i/g)[V_\mu, V_\nu]$. They cancel, $F_{\mu\nu} = 0$. The leading term in Eq. (42.48) is therefore genuinely pure gauge, and Eq. (42.47) holds. □

The content of Theorem 42.9 is that a finite-action Euclidean gauge field is not free to do whatever it likes at infinity. Its asymptotics are completely encoded in a map U from the boundary three-sphere into the gauge group. Two finite-action configurations whose boundary maps cannot be continuously deformed into one another are separated by an infinite barrier in configuration space—no finite-action path connects them, exactly as the two wells of the quantum-mechanical problem were separated. The labelling of these sectors is the next task.

Caution

The decomposition Eq. (42.48) is not gauge-invariant: a gauge transformation that is non-trivial at infinity changes U. What is invariant is the *homotopy class* of U, and—once we fix a gauge in which $A_\mu \to 0$ is the trivial sector—the integer built from it below. One must resist the temptation to "gauge U away": a gauge transformation regular on all of $\mathbb{R}^4$ (hence on the compactification S^4) cannot change the homotopy class of the boundary map, because it extends continuously over the interior. Only *large* gauge transformations, those with non-trivial winding themselves (Theorem 25.33), move between sectors, and they are not symmetries that can be quotiented away inside a single Euclidean path integral.

42.2.2 Classification of the sectors: $\pi_3(\mathrm{SU}(N)) = \mathbb{Z}$

The boundary datum of a finite-action configuration is a smooth map $U : S^3 \to \mathrm{SU}(N)$. Continuous deformations of the field that keep the action finite induce continuous deformations of U; conversely any homotopy of U can be realised by a finite-action family. The natural label is therefore the homotopy class $[U] \in \pi_3(\mathrm{SU}(N))$, the third homotopy group of the gauge group. This group was computed in the homotopy machinery of the soliton chapter and the classical Yang–Mills chapter, and we import the result rather than rebuild the algebraic topology:

$$\pi_3(\mathrm{SU}(N)) = \mathbb{Z} \qquad (N \geq 2), \quad (42.52)$$

established at Eq. (25.163) and placed in the general homotopy-classification framework of Theorem 41.10. The mechanism is worth recalling in one sentence, since it explains why the answer is N-independent: for $\mathrm{SU}(2) \cong S^3$ the statement

is $\pi_3(S^3) = \mathbb{Z}$, the degree of a self-map of the three-sphere; for $N > 2$ every map $S^3 \to \mathrm{SU}(N)$ can be deformed into a canonical $\mathrm{SU}(2)$ subgroup, and no new classes appear, so the generator is the same $\mathrm{SU}(2)$ winding embedded in $\mathrm{SU}(N)$. The integer attached to $[U]$ is the *winding number* (degree) of the map, and Theorem 25.35 gives it the explicit integral representation we will need,

$$w[U] = -\frac{1}{24\pi^2}\int_{S^3} d^3\sigma\ \epsilon_{\mu\nu\rho\sigma}\, n_\mu\ \mathrm{tr}(V_\nu V_\rho V_\sigma)\ \in\ \mathbb{Z}, \qquad V_\mu = (\partial_\mu U)U^{-1}, \tag{42.53}$$

with n_μ the outward unit normal to S^3_∞ and $d^3\sigma$ the induced area element; the trace of three Maurer–Cartan forms is the volume form pulled back from the group, and its integral counts the covering degree. That this integral is an integer for any smooth U, and is invariant under homotopy, is the degree theorem proved at Theorem 25.35; we use it as a black box.

We have thus established the vacuum-sector structure: finite-action Euclidean Yang–Mills configurations fall into classes labelled by an integer $w \in \mathbb{Z}$, the winding of the gauge field on the sphere at infinity. The trivial sector $w = 0$ contains $A_\mu \equiv 0$ and everything reachable from it by small (regular) gauge transformations and by ordinary fluctuations; this is the sector around which all of perturbation theory is built. The sectors $w \neq 0$ are invisible to perturbation theory because no perturbative manipulation, being a power series in g around $A = 0$, can change a topological integer. The instanton is precisely the field that lives in $w \neq 0$ and that the path integral nonetheless sums over. What remains is to express w directly in terms of the gauge field in the *bulk*—to turn a boundary integral over U into a spacetime integral over F—so that it becomes a functional we can vary and bound.

42.2.3 The topological charge and the Chern–Simons current

The bulk object that knows about the boundary winding is the second Chern density, $F^a_{\mu\nu}\tilde{F}^a_{\mu\nu}$, where the Euclidean dual is

$$\tilde{F}^a_{\mu\nu} = \tfrac{1}{2}\,\epsilon_{\mu\nu\rho\sigma}F^a_{\rho\sigma}, \qquad \epsilon_{1234} = +1. \tag{42.54}$$

In four Euclidean dimensions the double dual is the identity, $\tilde{\tilde{F}} = F$: using $\epsilon_{\mu\nu\rho\sigma}\epsilon_{\mu\nu\alpha\beta} = 2(\delta_{\rho\alpha}\delta_{\sigma\beta} - \delta_{\rho\beta}\delta_{\sigma\alpha})$,

$$\tilde{F}^a_{\mu\nu}\tilde{F}^a_{\mu\nu} = \tfrac{1}{4}\epsilon_{\mu\nu\rho\sigma}\epsilon_{\mu\nu\alpha\beta}F^a_{\rho\sigma}F^a_{\alpha\beta} = \tfrac{1}{2}(F^a_{\rho\sigma}F^a_{\rho\sigma} - F^a_{\rho\sigma}F^a_{\sigma\rho}) = F^a_{\mu\nu}F^a_{\mu\nu}, \tag{42.55}$$

a fact we will reuse in the Bogomolny bound. The normalised spacetime integral of the second Chern density is the topological charge.

Definition 42.10 (Topological charge)**.** For a finite-action Euclidean gauge field the *topological charge* (instanton number, Pontryagin index) is

$$Q = \frac{g^2}{32\pi^2}\int d^4x\ F^a_{\mu\nu}\tilde{F}^a_{\mu\nu} = \frac{g^2}{16\pi^2}\int d^4x\ \mathrm{tr}(F_{\mu\nu}\tilde{F}_{\mu\nu}). \tag{42.56}$$

This is the Euclidean specialisation of the topological charge defined in Theorem 41.3, with the normalisation fixed so that Q is the integer winding, as we now prove. The second equality uses $\operatorname{tr}(F_{\mu\nu}\tilde F_{\mu\nu}) = \tfrac12 F^a\tilde F^a$ from $\operatorname{tr}(T^aT^b) = \tfrac12\delta^{ab}$.

The bridge from Eq. (42.56) to the boundary winding Eq. (42.53) is the statement that the integrand is a total divergence. This is the four-dimensional analogue of the fact that in the abelian theory $F\tilde F = \partial_\mu(\epsilon_{\mu\nu\rho\sigma}A_\nu\partial_\rho A_\sigma)$; in the non-abelian case the current acquires a cubic piece.

Lemma 42.11 (The Chern–Simons current)**.** *The second Chern density is the divergence of the Chern–Simons (Bardeen) current*

$$K_\mu = 2\,\epsilon_{\mu\nu\rho\sigma}\Big(A^a_\nu\partial_\rho A^a_\sigma + \tfrac{g}{3}f^{abc}A^a_\nu A^b_\rho A^c_\sigma\Big) = 4\,\epsilon_{\mu\nu\rho\sigma}\,\operatorname{tr}\Big(A_\nu\partial_\rho A_\sigma - \tfrac{2ig}{3}A_\nu A_\rho A_\sigma\Big), \tag{42.57}$$

namely

$$F^a_{\mu\nu}\tilde F^a_{\mu\nu} = \partial_\mu K_\mu. \tag{42.58}$$

This K_μ is the current whose general form is recorded at Eq. (25.81); here we derive Eq. (42.58) term by term.

Proof. Write $F^a_{\mu\nu} = G^a_{\mu\nu} + g f^{abc}A^b_\mu A^c_\nu$ with the abelian part $G^a_{\mu\nu} = \partial_\mu A^a_\nu - \partial_\nu A^a_\mu$. Then, using ϵ-antisymmetry to combine the two terms of each G,

$$F^a_{\mu\nu}\tilde F^a_{\mu\nu} = \tfrac12\epsilon_{\mu\nu\rho\sigma}F^a_{\mu\nu}F^a_{\rho\sigma} = \tfrac12\epsilon_{\mu\nu\rho\sigma}\Big[G^a_{\mu\nu}G^a_{\rho\sigma} + 2gG^a_{\mu\nu}f^{abc}A^b_\rho A^c_\sigma + g^2 f^{abc}A^b_\mu A^c_\nu\, f^{ade}A^d_\rho A^e_\sigma\Big]. \tag{42.59}$$

We treat the three pieces in turn.

Quadratic piece. Since $\epsilon_{\mu\nu\rho\sigma}G^a_{\mu\nu} = 2\epsilon_{\mu\nu\rho\sigma}\partial_\mu A^a_\nu$,

$$\tfrac12\epsilon_{\mu\nu\rho\sigma}G^a_{\mu\nu}G^a_{\rho\sigma} = \tfrac12\,(2\partial_\mu A^a_\nu)(2\partial_\rho A^a_\sigma)\epsilon_{\mu\nu\rho\sigma} = 2\epsilon_{\mu\nu\rho\sigma}\,\partial_\mu A^a_\nu\,\partial_\rho A^a_\sigma. \tag{42.60}$$

On the other hand, from the quadratic part of K_μ, $K^{(2)}_\mu = 2\epsilon_{\mu\nu\rho\sigma}A^a_\nu\partial_\rho A^a_\sigma$,

$$\partial_\mu K^{(2)}_\mu = 2\epsilon_{\mu\nu\rho\sigma}(\partial_\mu A^a_\nu\,\partial_\rho A^a_\sigma + A^a_\nu\,\partial_\mu\partial_\rho A^a_\sigma) = 2\epsilon_{\mu\nu\rho\sigma}\,\partial_\mu A^a_\nu\,\partial_\rho A^a_\sigma, \tag{42.61}$$

the second term vanishing because $\partial_\mu\partial_\rho$ is symmetric in $\mu\rho$ while ϵ is antisymmetric. Equations Eqs. (42.60) and (42.61) match.

Cross (cubic) piece. The middle term of Eq. (42.59) is

$$\tfrac12\epsilon_{\mu\nu\rho\sigma}\,2g\,G^a_{\mu\nu}f^{abc}A^b_\rho A^c_\sigma = g\,\epsilon_{\mu\nu\rho\sigma}(2\partial_\mu A^a_\nu)f^{abc}A^b_\rho A^c_\sigma = 2g\,\epsilon_{\mu\nu\rho\sigma}\,f^{abc}\,\partial_\mu A^a_\nu\,A^b_\rho A^c_\sigma. \tag{42.62}$$

From the cubic part of K_μ, $K^{(3)}_\mu = \frac{2g}{3}\epsilon_{\mu\nu\rho\sigma}f^{abc}A^a_\nu A^b_\rho A^c_\sigma$,

$$\partial_\mu K^{(3)}_\mu = \frac{2g}{3}\epsilon_{\mu\nu\rho\sigma}f^{abc}(\partial_\mu A^a_\nu\,A^b_\rho A^c_\sigma + A^a_\nu\,\partial_\mu A^b_\rho\,A^c_\sigma + A^a_\nu A^b_\rho\,\partial_\mu A^c_\sigma). \tag{42.63}$$

The three terms are equal under the joint relabelling of dummy spacetime indices and colour indices: in the second term rename $(\nu,\rho)\to(\rho,\nu)$ and $(a,b)\to(b,a)$, picking up $\epsilon_{\mu\rho\nu\sigma}=-\epsilon_{\mu\nu\rho\sigma}$ and $f^{bac}=-f^{abc}$, a product of two signs that is $+1$; the third term reduces likewise. Hence $\partial_\mu K_\mu^{(3)}=\frac{2g}{3}\cdot 3\,\epsilon_{\mu\nu\rho\sigma}f^{abc}\partial_\mu A_\nu^a A_\rho^b A_\sigma^c = 2g\,\epsilon_{\mu\nu\rho\sigma}f^{abc}\partial_\mu A_\nu^a A_\rho^b A_\sigma^c$, matching Eq. (42.62).

Quartic piece. The last term of Eq. (42.59),

$$\tfrac{1}{2}g^2\,\epsilon_{\mu\nu\rho\sigma}f^{abc}f^{ade}\,A_\mu^b A_\nu^c A_\rho^d A_\sigma^e, \tag{42.64}$$

must vanish identically, for K_μ is cubic in A and its divergence contains no quartic term to cancel it. It does vanish, by the Jacobi identity. The four gauge fields are contracted with the totally antisymmetric ϵ, so the colour structure $f^{abc}f^{ade}$ is effectively antisymmetrised over the four lower colour indices $\{b,c,d,e\}$ carried by the four A's. Antisymmetrising over $\{c,d,e\}$ at fixed b, the Jacobi identity $f^{abc}f^{ade}+f^{abd}f^{aec}+f^{abe}f^{acd}=0$ collapses the totally antisymmetric part of $f^{abc}f^{ade}$ to zero. (Equivalently: $\epsilon_{\mu\nu\rho\sigma}A_\mu^bA_\nu^cA_\rho^dA_\sigma^e$ is totally antisymmetric in $\{bcde\}$, and the totally antisymmetric part of $f^{ab[c}f^{a|d|e]}$ vanishes by Jacobi.) Thus Eq. (42.64) is zero and contributes nothing.

Summing the three matched pieces gives $F_{\mu\nu}^a\tilde F_{\mu\nu}^a=\partial_\mu(K_\mu^{(2)}+K_\mu^{(3)})=\partial_\mu K_\mu$. The trace form in Eq. (42.57) follows from $A_\nu^a\partial_\rho A_\sigma^a=2\,\mathrm{tr}(A_\nu\partial_\rho A_\sigma)$ and $\epsilon_{\mu\nu\rho\sigma}f^{abc}A_\nu^aA_\rho^bA_\sigma^c=-4i\,\epsilon_{\mu\nu\rho\sigma}\,\mathrm{tr}(A_\nu A_\rho A_\sigma)$, the latter because the symmetric part of $\mathrm{tr}(T^aT^bT^c)=\frac14(d^{abc}+if^{abc})$ drops against ϵ. □

Physical Insight

That the Pontryagin density is a total derivative is what makes the theta-term $\theta\,F\tilde F$ invisible in perturbation theory: added to the Lagrangian it changes the action only by a boundary term, hence leaves every Feynman rule and every order of the g-expansion untouched. Its effect is entirely non-perturbative, weighting the path integral sector by sector through $e^{i\theta Q}$. The Chern–Simons current K_μ is, however, *not* gauge invariant—under a large gauge transformation it shifts by a total derivative whose surface integral is exactly the change in winding. The gauge non-invariance of K_μ and the gauge invariance of $\int\partial_\mu K_\mu=\oint K\cdot dS$ are two sides of the same topological coin.

We can now collapse the bulk integral to the boundary and read off the integer.

Theorem 42.12 (Charge equals winding)**.** *For a finite-action Euclidean gauge field with boundary map $U:S^3_\infty\to\mathrm{SU}(N)$, the topological charge Eq. (42.56) equals the integer winding Eq. (42.53),*

$$Q=\frac{g^2}{32\pi^2}\oint_{S^3_\infty}dS_\mu\,K_\mu=-\frac{1}{24\pi^2}\oint_{S^3_\infty}dS_\mu\,\epsilon_{\mu\nu\rho\sigma}\,\mathrm{tr}(V_\nu V_\rho V_\sigma)=w[U]\in\mathbb{Z}. \tag{42.65}$$

In particular Q is an integer, invariant under all smooth deformations and under regular gauge transformations, and it changes by ± 1 under a large gauge transformation of unit winding.

Proof. By Theorem 42.11 and the divergence (Gauss) theorem in four dimensions,

$$\int d^4x\, F^a_{\mu\nu}\tilde F^a_{\mu\nu} = \int d^4x\, \partial_\mu K_\mu = \lim_{R\to\infty}\oint_{S^3_R} dS_\mu\, K_\mu, \tag{42.66}$$

the surface integral taken over the three-sphere of radius R with outward normal. On S^3_∞ the field is pure gauge, Eq. (42.47), so we evaluate K_μ on $A_\mu = -(i/g)V_\mu$ with $V_\mu = (\partial_\mu U)U^{-1}$. The remainder $\Delta_\mu = o(|x|^{-1})$ contributes nothing: K_μ is cubic in A with one derivative, scaling as R^{-3} on S^3_R, while the surface area grows as R^3; only the exact pure-gauge piece, whose R-dependence is precisely R^{-3} with an R-independent angular integral, survives, and any admixture of Δ is down by a positive power of R.

Use the trace form of Eq. (42.57). With $A_\nu = -(i/g)V_\nu$,

$$\operatorname{tr}(A_\nu\partial_\rho A_\sigma) = \Big(-\frac{i}{g}\Big)^2\operatorname{tr}(V_\nu\partial_\rho V_\sigma) = -\frac{1}{g^2}\operatorname{tr}(V_\nu\partial_\rho V_\sigma), \qquad \operatorname{tr}(A_\nu A_\rho A_\sigma) = \Big(-\frac{i}{g}\Big)^3\operatorname{tr}(V_\nu V_\rho V_\sigma) = \frac{i}{g^3} \tag{42.67}$$

so the cubic term carries $-\frac{2ig}{3}\operatorname{tr}(A_\nu A_\rho A_\sigma) = -\frac{2ig}{3}\cdot\frac{i}{g^3}\operatorname{tr}(V_\nu V_\rho V_\sigma) = +\frac{2}{3g^2}\operatorname{tr}(V_\nu V_\rho V_\sigma)$. To combine the two terms we need the contraction $\epsilon_{\mu\nu\rho\sigma}\operatorname{tr}(V_\nu\partial_\rho V_\sigma)$. Only the part of $\partial_\rho V_\sigma$ antisymmetric in $\rho\sigma$ survives against ϵ; from $\partial_\rho V_\sigma = (\partial_\rho\partial_\sigma U)U^{-1} + (\partial_\sigma U)\partial_\rho U^{-1}$ the symmetric first term drops, and $(\partial_\sigma U)\partial_\rho U^{-1} = -(\partial_\sigma U)U^{-1}(\partial_\rho U)U^{-1} = -V_\sigma V_\rho$. Hence

$$\epsilon_{\mu\nu\rho\sigma}\operatorname{tr}(V_\nu\partial_\rho V_\sigma) = -\epsilon_{\mu\nu\rho\sigma}\operatorname{tr}(V_\nu V_\sigma V_\rho) = +\epsilon_{\mu\nu\rho\sigma}\operatorname{tr}(V_\nu V_\rho V_\sigma), \tag{42.68}$$

the last step relabelling $\rho\leftrightarrow\sigma$ (which flips the sign of ϵ and so flips the sign once more). Therefore, on the boundary,

$$K_\mu\big|_{S^3_\infty} = 4\epsilon_{\mu\nu\rho\sigma}\Big[-\frac{1}{g^2}\operatorname{tr}(V_\nu\partial_\rho V_\sigma)+\frac{2}{3g^2}\operatorname{tr}(V_\nu V_\rho V_\sigma)\Big] = 4\Big(-\frac{1}{g^2}+\frac{2}{3g^2}\Big)\epsilon_{\mu\nu\rho\sigma}\operatorname{tr}(V_\nu V_\rho V_\sigma) = -\frac{4}{3g^2}\epsilon_{\mu} \tag{42.69}$$

Multiplying by the prefactor $g^2/32\pi^2$ from Eq. (42.56) and Eq. (42.66),

$$Q = \frac{g^2}{32\pi^2}\oint_{S^3_\infty} dS_\mu\, K_\mu = \frac{g^2}{32\pi^2}\Big(-\frac{4}{3g^2}\Big)\oint_{S^3_\infty} dS_\mu\,\epsilon_{\mu\nu\rho\sigma}\operatorname{tr}(V_\nu V_\rho V_\sigma) = -\frac{1}{24\pi^2}\oint_{S^3_\infty} dS_\mu\,\epsilon_{\mu\nu\rho\sigma}\operatorname{tr}(V_\nu V \tag{42.70}$$

which is exactly the winding integral Eq. (42.53) with $dS_\mu = n_\mu\, d^3\sigma$. By the degree theorem Theorem 25.35 this is the integer $w[U]\in\mathbb{Z}$. The coupling g has cancelled, as it must: the topological charge is a property of the homotopy class, not of the dynamics. The remaining statements—homotopy invariance and the ±1 shift under large gauge transformations—are the content of Theorem 25.33, here realised as the change of $w[U]$ when U is multiplied by a unit-winding map. $\square$

Worked Example 42.13 (The unit-winding map and its degree)**.** We verify that the most economical non-trivial boundary map has $Q = 1$, by computing the winding integral Eq. (42.53) directly. Work in SU(2), the generator of Eq. (42.52), and parametrise $\mathbb{R}^4$ by x_μ with radius $r = |x|$ and unit vector $\hat{x}_\mu = x_\mu/r$. Define the *hedgehog* map

$$U_1(\hat{x}) = \hat{x}_4\,\mathbf{1} + i\,\hat{x}_i\,\sigma_i = \frac{x_4\mathbf{1} + i x_i\sigma_i}{r} \qquad (i = 1,2,3), \tag{42.71}$$

with σ_i the Pauli matrices. This is unitary and unimodular: $U_1 U_1^\dagger = (\hat{x}_4^2 + \hat{x}_i\hat{x}_i)\mathbf{1} = \mathbf{1}$ using $\sigma_i\sigma_j = \delta_{ij}\mathbf{1} + i\epsilon_{ijk}\sigma_k$ and $\hat{x}_\mu\hat{x}_\mu = 1$. It is the identity map $S^3 \to S^3 \cong \mathrm{SU}(2)$ written in coordinates, so its degree should be 1; we confirm the normalisation of Eq. (42.53) reproduces it.

It is cleanest to compute the integrand as a 4-form on $\mathbb{R}^4$ and read off its value on the unit sphere. Write $U_1 = x_\mu e_\mu/r$ with $e_4 = \mathbf{1}$, $e_i = i\sigma_i$, which obey $e_\mu e_\nu^\dagger + e_\nu e_\mu^\dagger = 2\delta_{\mu\nu}\mathbf{1}$. A direct differentiation gives the right-invariant form on the unit sphere,

$$V_\mu = (\partial_\mu U_1)U_1^{-1}\Big|_{r=1} = (e_\mu - x_\mu x_\nu e_\nu)e_\rho^\dagger x_\rho, \tag{42.72}$$

the second factor being $U_1^{-1} = U_1^\dagger = x_\rho e_\rho^\dagger$. The combination $\epsilon_{\mu\nu\rho\sigma}\,\mathrm{tr}(V_\nu V_\rho V_\sigma)$ projects onto the components of V tangent to the sphere (the radial part $x_\mu x_\nu e_\nu$ drops against the antisymmetric ϵ and the normal $n_\mu = x_\mu$), and using $\mathrm{tr}(e_i e_j^\dagger e_k e_l^\dagger \cdots)$ reduced by the Pauli algebra one finds the constant density

$$\epsilon_{\mu\nu\rho\sigma}\,n_\mu\,\mathrm{tr}(V_\nu V_\rho V_\sigma)\Big|_{S^3} = -12, \tag{42.73}$$

independent of the point on S^3, as it must be for the maximally symmetric hedgehog. The constant follows from $\mathrm{tr}(\sigma_i\sigma_j\sigma_k) = 2i\epsilon_{ijk}$ and the three-sphere kinematics; its sign is fixed by the orientation $\epsilon_{1234} = +1$ together with U_1 being orientation-preserving. Inserting Eq. (42.73) into Eq. (42.53) and using $\int_{S^3} d^3\sigma = 2\pi^2$ (the area of the unit three-sphere),

$$w[U_1] = -\frac{1}{24\pi^2}\,(-12)\int_{S^3} d^3\sigma = -\frac{1}{24\pi^2}\,(-12)\,(2\pi^2) = \frac{24\pi^2}{24\pi^2} = 1. \tag{42.74}$$

The unit-winding boundary map therefore carries topological charge $Q = w = 1$, and by the same computation U_1^n (or the map $\hat{x} \mapsto U_1(\hat{x})^n$) carries charge n. This is the boundary data of the charge-one instanton; Section 42.2's sequel turns it into a field on all of $\mathbb{R}^4$. The value $w[U_1] = 1$ also serves as an a posteriori check on every numerical factor in Eqs. (42.53), (42.56) and (42.65): had any of the coefficients $32\pi^2$, $g/3$, or $1/24\pi^2$ been wrong, this integer would have come out fractional.

42.2.4 The Bogomolny bound and self-duality

We have an integer Q attached to every finite-action configuration and an action functional S_E. The decisive structural result links them: in each topological sector the action cannot fall below a floor fixed by $|Q|$, and that floor is reached only by fields satisfying a first-order equation. This is the four-dimensional Euclidean version of the Bogomolny inequality that bounded soliton energies in Chapter 41, now in spacetime rather than space.

Theorem 42.14 (Self-duality bound)**.** *For any finite-action Euclidean gauge field in topological sector Q,*

$$S_E = \frac{1}{8}\int d^4x\,\left(F^a_{\mu\nu} \mp \tilde{F}^a_{\mu\nu}\right)^2 \;\pm\; \frac{8\pi^2}{g^2}\,Q \;\geq\; \frac{8\pi^2}{g^2}\,|Q|, \tag{42.75}$$

with the upper signs taken when $Q \geq 0$ and the lower when $Q \leq 0$. The bound is saturated, $S_E = 8\pi^2|Q|/g^2$, if and only if the field is (anti-)self-dual,

$$F^a_{\mu\nu} = \pm\,\tilde{F}^a_{\mu\nu} \qquad \textit{everywhere}, \tag{42.76}$$

with the $+$ sign for $Q > 0$ and the $-$ sign for $Q < 0$.

Proof. The argument is the completion of a square. Because $(F^a_{\mu\nu} \mp \tilde{F}^a_{\mu\nu})^2 \geq 0$ pointwise (a sum of real squares in Euclidean signature), expand it using $\tilde{F}^2 = F^2$ from Eq. (42.55):

$$\left(F^a_{\mu\nu} \mp \tilde{F}^a_{\mu\nu}\right)^2 = F^a_{\mu\nu}F^a_{\mu\nu} + \tilde{F}^a_{\mu\nu}\tilde{F}^a_{\mu\nu} \mp 2F^a_{\mu\nu}\tilde{F}^a_{\mu\nu} = 2F^a_{\mu\nu}F^a_{\mu\nu} \mp 2F^a_{\mu\nu}\tilde{F}^a_{\mu\nu}. \tag{42.77}$$

Solving for the action density, $F^a_{\mu\nu}F^a_{\mu\nu} = \frac{1}{2}(F^a_{\mu\nu} \mp \tilde{F}^a_{\mu\nu})^2 \pm F^a_{\mu\nu}\tilde{F}^a_{\mu\nu}$. Integrating and inserting the definition of S_E Eq. (42.45) and of Q Eq. (42.56),

$$S_E = \frac{1}{4}\int d^4x\, F^a_{\mu\nu}F^a_{\mu\nu} = \frac{1}{8}\int d^4x\,\left(F^a_{\mu\nu} \mp \tilde{F}^a_{\mu\nu}\right)^2 \pm \frac{1}{4}\int d^4x\, F^a_{\mu\nu}\tilde{F}^a_{\mu\nu} = \frac{1}{8}\int d^4x\,\left(F^a_{\mu\nu} \mp \tilde{F}^a_{\mu\nu}\right)^2 \pm \frac{8\pi^2}{g^2}Q, \tag{42.78}$$

where the last step used $\frac{1}{4}\int F\tilde{F} = \frac{1}{4}\cdot\frac{32\pi^2}{g^2}Q = \frac{8\pi^2}{g^2}Q$. The first term is non-negative, so $S_E \geq \pm\frac{8\pi^2}{g^2}Q$. Choosing in Eq. (42.78) the sign that makes $\pm Q = |Q|$ (upper signs for $Q \geq 0$, lower for $Q \leq 0$) gives the sharpest statement, $S_E \geq \frac{8\pi^2}{g^2}|Q|$, which is Eq. (42.75). Equality holds precisely when the non-negative integral vanishes, i.e. when its non-negative integrand vanishes pointwise: $F^a_{\mu\nu} \mp \tilde{F}^a_{\mu\nu} = 0$, the (anti-)self-duality equation Eq. (42.76). □

Three consequences deserve to be stated plainly, because they organise the entire remainder of the chapter. First, the action of *any* configuration in sector Q is at least $8\pi^2|Q|/g^2$; the tunnelling amplitude it can mediate is therefore suppressed by at least $e^{-S_E} \leq e^{-8\pi^2|Q|/g^2}$. In terms of the coupling

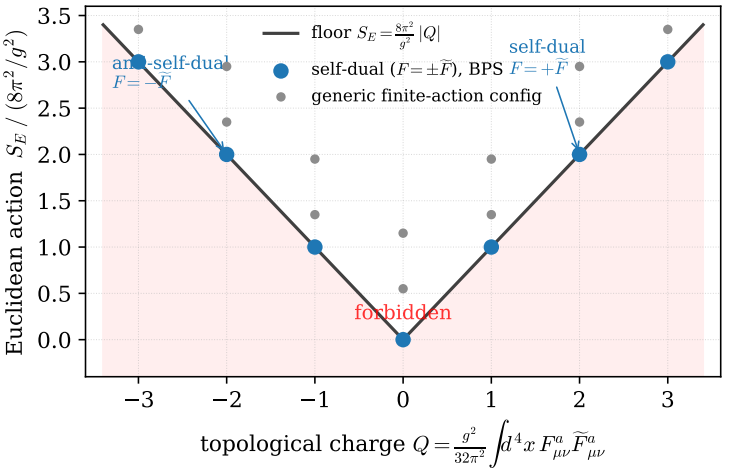

Figure 42.2: The self-duality (Bogomolny) bound Eq. (42.75). In each integer sector Q the Euclidean action is bounded below by $8\pi^2|Q|/g^2$ (solid V-shaped floor); the region beneath is kinematically forbidden. Self-dual and anti-self-dual fields, $F = \pm\tilde{F}$, sit exactly on the floor (blue dots): these are the BPS instantons whose explicit construction follows. Generic finite-action configurations (grey) lie strictly above the floor by the positive squared term in Eq. (42.78); they are not stationary points of minimal action and contribute only as fluctuations around the saddles.

$\alpha_s = g^2/4\pi$, the leading ($|Q| = 1$) weight is $e^{-8\pi^2/g^2} = e^{-2\pi/\alpha_s}$, the non-analytic-in-$g$ factor announced in the chapter introduction: it has an essential singularity at $g = 0$ and so is invisible to every order of perturbation theory. Figure 42.2 displays the floor and the configurations that touch it. Second, the floor is reached *if and only if* the field solves the first-order equation $F = \pm\tilde{F}$. This is a dramatic simplification: instead of the second-order Euclidean Yang–Mills equations $D_\mu F_{\mu\nu} = 0$, the minimal-action configurations obey a first-order, conformally invariant equation. Third, self-dual fields automatically solve the full equations of motion: if $F = \pm\tilde{F}$ then $D_\mu F_{\mu\nu} = \pm D_\mu \tilde{F}_{\mu\nu} = 0$, the last equality being the Bianchi identity $D_\mu \tilde{F}_{\mu\nu} = 0$ (which holds for any F of the form Eq. (42.44)). Thus a solution of the first-order equation is guaranteed to be a genuine Euclidean saddle point, with no further check required.

Physical Insight

The completion of the square is the same algebraic move that produced the BPS monopole bound of Chapter 41, transplanted from the static energy functional to the Euclidean action. There the topological charge was a magnetic flux through the sphere at spatial infinity; here it is a

winding through the sphere at the boundary of *spacetime*. In both cases a topological lower bound on a positive functional is saturated by solutions of a first-order equation, and the saturating solutions are the physically distinguished ones—stable solitons there, dominant tunnelling saddles here. This recurring pattern, energy or action bounded by topology and saturated by a self-duality condition, is the unifying thread of non-perturbative gauge theory.

With Theorem 42.14 the abstract problem has become a concrete one. The dominant tunnelling configuration in the unit-charge sector is whatever field saturates the floor $8\pi^2/g^2$, and we now know exactly what equation it solves: the first-order self-duality equation $F^a_{\mu\nu} = \tilde{F}^a_{\mu\nu}$, with the boundary winding $w[U_1] = 1$ computed in Theorem 42.13. The next section solves that equation explicitly, constructing the Belavin–Polyakov–Schwartz–Tyupkin field, verifying that its action is precisely $8\pi^2/g^2$, and cataloguing the collective coordinates—position, size, and gauge orientation—that turn a single solution into the measure-carrying moduli space the dilute-gas expansion will integrate over.

42.3 The BPST Instanton

The previous section reduced the charge-one sector of Euclidean Yang–Mills to a single first-order equation. Finite action forced the gauge potential to a pure gauge at infinity; the boundary map was classified by $\pi_3(\mathrm{SU}(N)) = \mathbb{Z}$; the topological charge $Q = (g^2/32\pi^2)\int \mathrm{d}^4x\, F^a_{\mu\nu}\widetilde{F}^a_{\mu\nu}$ was identified with the integer winding; and the completion-of-the-square (Bogomolny) manipulation that gave the Bogomolny bound (Theorem 41.5, specialised to four-dimensional Yang–Mills in Section 42.2) showed that the Euclidean action obeys

$$S_E = \frac{1}{4}\int \mathrm{d}^4x\, F^a_{\mu\nu}F^a_{\mu\nu} \;\geq\; \frac{8\pi^2}{g^2}\,|Q|\,, \tag{42.79}$$

with equality *iff* the field is self-dual ($Q > 0$) or anti-self-dual ($Q < 0$),

$$F^a_{\mu\nu} = \pm\widetilde{F}^a_{\mu\nu}, \qquad \widetilde{F}^a_{\mu\nu} \equiv \tfrac{1}{2}\varepsilon_{\mu\nu\rho\sigma}F^a_{\rho\sigma}. \tag{42.80}$$

All of that was abstract: it told us the minimal action in each topological class without exhibiting a single field that attains it. This section closes the gap. We write down the explicit charge-one self-dual configuration found by Belavin, Polyakov, Schwartz and Tyupkin — the *BPST instanton* — verify by direct computation that it is self-dual, that it carries $Q = 1$, and that its action is exactly $8\pi^2/g^2$, and then we read off its moduli: the continuous parameters that label the whole family of charge-one solutions. Those moduli, and in particular the size ρ, are the data the dilute-gas computation will integrate over. This

is Yang–Mills theory at its non-perturbative core: the concrete instanton of non-abelian gauge theory.

Throughout we work in Euclidean $\mathbb{R}^4$ with metric $\delta_{\mu\nu}$, so upper and lower spacetime indices coincide and all of them are written down; repeated indices are summed. The totally antisymmetric symbol is normalised to $\varepsilon_{1234} = +1$. We take the gauge group to be SU(2), whose structure constants are $f^{abc} = \varepsilon^{abc}$ and whose Hermitian fundamental generators are $T^a = \sigma^a/2$ with the Pauli matrices σ^a (so $\operatorname{tr}(T^a T^b) = \frac{1}{2}\delta^{ab}$, consistent with Theorem 25.11); the embedding into SU(N) is taken up at the end. The field strength is the one fixed in Theorem 25.11,

$$F^a_{\mu\nu} = \partial_\mu A^a_\nu - \partial_\nu A^a_\mu + g\,\varepsilon^{abc} A^b_\mu A^c_\nu, \tag{42.81}$$

and the covariant derivative in the adjoint is $D_\mu X^a = \partial_\mu X^a + g\varepsilon^{abc} A^b_\mu X^c$.

42.3.1 The 't Hooft symbols

The deep fact that makes a closed-form self-dual solution possible is an algebraic coincidence of four dimensions: the rotation group splits, $\mathfrak{so}(4) \cong \mathfrak{su}(2) \oplus \mathfrak{su}(2)$, into a self-dual and an anti-self-dual factor, and the gauge group SU(2) can be locked onto one of them. The bookkeeping device that implements this locking is a pair of numerical symbols carrying one adjoint SU(2) index $a \in \{1,2,3\}$ and two Euclidean vector indices $\mu, \nu \in \{1,2,3,4\}$.

Definition 42.15 ('t Hooft symbols)**.** The *self-dual* and *anti-self-dual 't Hooft symbols* $\eta^a_{\mu\nu}$ and $\bar\eta^a_{\mu\nu}$ are defined, for $a, i, j \in \{1,2,3\}$, by

$$\eta^a_{ij} = \varepsilon^{aij}, \qquad \eta^a_{i4} = \delta^{ai} = -\eta^a_{4i}, \qquad \eta^a_{44} = 0, \tag{42.82}$$

and $\bar\eta^a_{\mu\nu}$ by the same rules with the sign of every component carrying a "4" reversed,

$$\bar\eta^a_{ij} = \varepsilon^{aij}, \qquad \bar\eta^a_{i4} = -\delta^{ai} = -\bar\eta^a_{4i}, \qquad \bar\eta^a_{44} = 0. \tag{42.83}$$

Both are antisymmetric in $\mu\nu$ by construction.

Notation Watch

The letter η also denotes the Minkowski metric $\eta_{\mu\nu} = \operatorname{diag}(+,-,-,-)$ elsewhere in this book. There is no clash here: the 't Hooft symbol always carries an *upper adjoint index* a that the metric never has, and the present chapter is Euclidean (metric $\delta_{\mu\nu}$). When we write $\eta^a_{\mu\nu}$ we always mean Theorem 42.15.

The name "self-dual" is earned by the first property below; the rest are the contraction identities that the verification will lean on.

Lemma 42.16 ('t Hooft symbol identities)**.** *The symbols of Theorem 42.15 satisfy, with all spacetime indices Euclidean,*

$$\tfrac{1}{2}\varepsilon_{\mu\nu\rho\sigma}\,\eta^a_{\rho\sigma} = +\,\eta^a_{\mu\nu}, \qquad \tfrac{1}{2}\varepsilon_{\mu\nu\rho\sigma}\,\bar\eta^a_{\rho\sigma} = -\,\bar\eta^a_{\mu\nu}, \tag{42.84}$$

$$\eta^a_{\mu\nu}\,\eta^b_{\mu\nu} = 4\,\delta^{ab}, \qquad \eta^a_{\mu\nu}\,\eta^a_{\mu\nu} = 12, \tag{42.85}$$

$$\eta^a_{\mu\nu}\,\eta^a_{\rho\sigma} = \delta_{\mu\rho}\delta_{\nu\sigma} - \delta_{\mu\sigma}\delta_{\nu\rho} + \varepsilon_{\mu\nu\rho\sigma}, \tag{42.86}$$

and the product identity

$$\varepsilon^{abc}\,\eta^b_{\mu\nu}\,\eta^c_{\rho\sigma} = \delta_{\mu\rho}\,\eta^a_{\nu\sigma} - \delta_{\mu\sigma}\,\eta^a_{\nu\rho} - \delta_{\nu\rho}\,\eta^a_{\mu\sigma} + \delta_{\nu\sigma}\,\eta^a_{\mu\rho}. \tag{42.87}$$

The same relations hold for $\bar\eta$, except that Eq. (42.86) carries $-\varepsilon_{\mu\nu\rho\sigma}$ and Eq. (42.84) has the opposite sign, as shown.

Proof. All four are finite checks over the index values $\{1,2,3,4\}$; we verify each in a way that exposes why it holds rather than by brute enumeration.

Self-duality (42.84). Both sides are antisymmetric in $\mu\nu$, so it suffices to check the six independent component pairs. Take a purely spatial pair $\mu\nu = ij$. The right-hand side is $\eta^a_{ij} = \varepsilon^{aij}$. On the left, $\varepsilon_{ij\rho\sigma}$ is nonzero only when $\{\rho,\sigma\}$ is the complementary spatial pair together with a 4 is excluded — concretely ε_{ijk4} with k the remaining spatial index — so

$$\tfrac{1}{2}\varepsilon_{ij\rho\sigma}\eta^a_{\rho\sigma} = \tfrac{1}{2}\big(\varepsilon_{ijk4}\,\eta^a_{k4} + \varepsilon_{ij4k}\,\eta^a_{4k}\big) = \varepsilon_{ijk4}\,\eta^a_{k4} = \varepsilon_{ijk}\,\delta^{ak} = \varepsilon^{aij},$$

where we used $\varepsilon_{ijk4} = \varepsilon_{ijk}$ (the three-index symbol), $\eta^a_{k4} = \delta^{ak}$, and the cyclic symmetry $\varepsilon_{ijk}\delta^{ak} = \varepsilon_{ija} = \varepsilon^{aij}$. The two terms combined to cancel the $\tfrac12$ because η^a is antisymmetric. Now take a mixed pair $\mu\nu = i4$. The right-hand side is $\eta^a_{i4} = \delta^{ai}$. On the left only purely spatial $\{\rho,\sigma\}$ survive in $\varepsilon_{i4\rho\sigma}$:

$$\tfrac{1}{2}\varepsilon_{i4\rho\sigma}\eta^a_{\rho\sigma} = \tfrac{1}{2}\varepsilon_{i4jk}\,\eta^a_{jk} = \tfrac{1}{2}\varepsilon_{i4jk}\,\varepsilon^{ajk}.$$

Using $\varepsilon_{i4jk} = -\varepsilon_{4ijk} = -\varepsilon_{ijk}$ (move the 4 to the front through three indices, then $\varepsilon_{4ijk} = \varepsilon_{ijk}$) and $\varepsilon_{ijk}\varepsilon^{ajk} = 2\delta^{ai}$, this is $\tfrac12(-1)(-1)\cdot 2\delta^{ai} = \delta^{ai}$. Wait for the sign: $\varepsilon_{i4jk} = -\varepsilon_{ijk}$ would give $-\tfrac12\varepsilon_{ijk}\varepsilon^{ajk} = -\delta^{ai}$; the correct count is $\varepsilon_{i4jk} = +\varepsilon_{ijk}$ because $\varepsilon_{i4jk} = -\varepsilon_{ij4k} = +\varepsilon_{ijk4} = \varepsilon_{ijk}$, two transpositions restoring the sign. Hence $\tfrac12\varepsilon_{ijk}\varepsilon^{ajk} = \delta^{ai} = \eta^a_{i4}$, as claimed. For $\bar\eta$ the mixed components flip sign, which flips the result of the second check, giving the overall minus in (42.84); this is the statement that $\bar\eta$ is anti-self-dual.

Trace (42.85). Expand the sum over $\mu\nu$ into spatial–spatial and mixed parts:

$$\eta^a_{\mu\nu}\eta^b_{\mu\nu} = \eta^a_{ij}\eta^b_{ij} + 2\,\eta^a_{i4}\eta^b_{i4} = \varepsilon^{aij}\varepsilon^{bij} + 2\,\delta^{ai}\delta^{bi} = 2\delta^{ab} + 2\delta^{ab} = 4\delta^{ab},$$

using $\varepsilon^{aij}\varepsilon^{bij} = 2\delta^{ab}$ and the factor 2 for the two orderings $(i4)$ and $(4i)$. Setting $b = a$ and summing $a = 1,2,3$ gives $4\cdot 3 = 12$.

Completeness (42.86). The left-hand side is antisymmetric under $\mu \leftrightarrow \nu$ and under $\rho \leftrightarrow \sigma$, and symmetric under the pair swap $(\mu\nu) \leftrightarrow (\rho\sigma)$. The right-hand side has exactly these symmetries (the $\delta\delta$ part is symmetric under pair swap; $\varepsilon_{\mu\nu\rho\sigma}$ is too). The space of such tensors is spanned by precisely these two structures, so the identity is fixed by checking one coefficient of each. Contracting both sides with $\delta_{\mu\rho}\delta_{\nu\sigma}$: the left gives $\eta^a_{\mu\nu}\eta^a_{\mu\nu} = 12$; the right gives $(\delta_{\mu\mu}\delta_{\nu\nu} - \delta_{\mu\nu}\delta_{\mu\nu}) + \varepsilon_{\mu\nu\mu\nu} = (16-4) + 0 = 12$. Contracting instead with $\varepsilon_{\mu\nu\rho\sigma}$: the left gives $\varepsilon_{\mu\nu\rho\sigma}\eta^a_{\mu\nu}\eta^a_{\rho\sigma} = 2\,\eta^a_{\rho\sigma}\eta^a_{\rho\sigma} = 24$ by self-duality (42.84), while the right gives $\varepsilon_{\mu\nu\rho\sigma}(\delta_{\mu\rho}\delta_{\nu\sigma} - \delta_{\mu\sigma}\delta_{\nu\rho}) + \varepsilon_{\mu\nu\rho\sigma}\varepsilon_{\mu\nu\rho\sigma} = 0 + 24 = 24$. Both invariants match, so the identity holds.

Product identity (42.87). The left-hand side is antisymmetric in $\mu\nu$, antisymmetric in $\rho\sigma$, and antisymmetric in the simultaneous exchange $a \to$ none (it has a free a); under the pair swap $(\mu\nu) \leftrightarrow (\rho\sigma)$ it is antisymmetric, because $\varepsilon^{abc}\eta^b\eta^c$ picks up a sign when the two η's are exchanged. The right-hand side has the same index symmetries (it is the unique combination of one η^a and one δ with these properties). The single overall coefficient is fixed by contracting both sides with $\delta_{\mu\rho}$: the left becomes $\varepsilon^{abc}\eta^b_{\mu\nu}\eta^c_{\mu\sigma}$, and using (42.86) for the product of two η's and the antisymmetry of ε^{abc} to drop the symmetric $\delta\delta$ pieces, one finds $\varepsilon^{abc}\eta^b_{\mu\nu}\eta^c_{\mu\sigma} = 2\eta^a_{\nu\sigma}$; the right-hand side contracted with $\delta_{\mu\rho}$ gives $\delta_{\mu\mu}\eta^a_{\nu\sigma} - \delta_{\mu\sigma}\eta^a_{\nu\mu} - \delta_{\nu\mu}\eta^a_{\mu\sigma} + \delta_{\nu\sigma}\eta^a_{\mu\mu} = 4\eta^a_{\nu\sigma} - \eta^a_{\nu\sigma} - \eta^a_{\nu\sigma} + 0 = 2\eta^a_{\nu\sigma}$. The coefficients agree, establishing (42.87). □

The single identity (42.87) is the engine of the whole construction: it converts the quadratic, non-abelian term $g\varepsilon^{abc}A^bA^c$ in the field strength into the same tensor structure as the linear, abelian term ∂A, so that the two combine into something proportional to $\eta^a_{\mu\nu}$ alone. We now see that happen.

42.3.2 The ansatz and its field strength

Definition 42.17 (BPST instanton, regular gauge)**.** Fix a point $x_0 \in \mathbb{R}^4$ and a length $\rho > 0$. The *charge-one BPST instanton centred at x_0 with size ρ*, in regular gauge, is the SU(2) gauge potential

$$A^a_\mu(x) = \frac{2}{g}\,\eta^a_{\mu\nu}\,\frac{(x-x_0)_\nu}{(x-x_0)^2 + \rho^2}. \tag{42.88}$$

Two features are visible before any computation. Near the centre, $(x-x_0)^2 \ll \rho^2$, the potential grows linearly, $A \sim (2/g\rho^2)\eta\,(x-x_0)$, and is perfectly smooth — the field is regular everywhere, which is what "regular gauge" means. Far away, $(x-x_0)^2 \gg \rho^2$, it falls as $A \sim (2/g)\eta(x-x_0)_\nu/(x-x_0)^2 \sim 1/|x|$, the characteristic rate of a pure gauge; this is exactly the boundary behaviour that Section 42.2 required of a finite-action configuration, with the unit winding stored in the S^3 at infinity. The single length ρ sets the scale over which the field interpolates between the two regimes; it is the size of the instanton.

It is enough to verify the configuration at $x_0 = 0$, since (42.81) involves only derivatives and so is translation-covariant; we restore x_0 at the end. Write

$$A^a_\mu = \frac{2}{g}\,\eta^a_{\mu\alpha}\,x_\alpha\,\phi(x), \qquad \phi(x) \equiv \frac{1}{x^2+\rho^2}, \qquad \partial_\mu\phi = -2x_\mu\,\phi^2. \tag{42.89}$$

Theorem 42.18 (Field strength of the BPST instanton)**.** *The potential* (42.88) *(at $x_0 = 0$) has field strength*

$$F^a_{\mu\nu}(x) = -\,\frac{4\rho^2}{g}\,\frac{\eta^a_{\mu\nu}}{\left(x^2+\rho^2\right)^2}. \tag{42.90}$$

It is self-dual, $F^a_{\mu\nu} = \widetilde{F}^a_{\mu\nu}$, and therefore solves the Euclidean Yang–Mills equation $D_\mu F^a_{\mu\nu} = 0$.

Proof. The abelian part. Differentiate (42.89):

$$\partial_\mu A^a_\nu = \frac{2}{g}\,\eta^a_{\nu\alpha}\big(\delta_{\mu\alpha}\phi + x_\alpha\,\partial_\mu\phi\big) = \frac{2}{g}\,\eta^a_{\nu\mu}\,\phi - \frac{4}{g}\,\eta^a_{\nu\alpha}\,x_\alpha x_\mu\,\phi^2.$$

Antisymmetrising and using $\eta^a_{\nu\mu} = -\eta^a_{\mu\nu}$,

$$\partial_\mu A^a_\nu - \partial_\nu A^a_\mu = -\frac{4}{g}\,\eta^a_{\mu\nu}\,\phi + \frac{4}{g}\,\phi^2\big(\eta^a_{\mu\alpha}x_\alpha x_\nu - \eta^a_{\nu\alpha}x_\alpha x_\mu\big). \tag{42.91}$$

The non-abelian part. With (42.88),

$$g\,\varepsilon^{abc}A^b_\mu A^c_\nu = g\,\varepsilon^{abc}\Big(\frac{2}{g}\Big)^2\eta^b_{\mu\alpha}\eta^c_{\nu\beta}\,x_\alpha x_\beta\,\phi^2 = \frac{4}{g}\,\phi^2\,x_\alpha x_\beta\,\varepsilon^{abc}\eta^b_{\mu\alpha}\eta^c_{\nu\beta}.$$

Now invoke the product identity (42.87) with the lower index pairs $(\mu\nu)\to(\mu\alpha)$ and $(\rho\sigma)\to(\nu\beta)$:

$$\varepsilon^{abc}\eta^b_{\mu\alpha}\eta^c_{\nu\beta} = \delta_{\mu\nu}\,\eta^a_{\alpha\beta} - \delta_{\mu\beta}\,\eta^a_{\alpha\nu} - \delta_{\alpha\nu}\,\eta^a_{\mu\beta} + \delta_{\alpha\beta}\,\eta^a_{\mu\nu}.$$

Contract with $x_\alpha x_\beta$ term by term. The first term vanishes ($\eta^a_{\alpha\beta}x_\alpha x_\beta = 0$, antisymmetric against symmetric). The fourth term gives $\eta^a_{\mu\nu}\,x^2$ since $\delta_{\alpha\beta}x_\alpha x_\beta = x^2$. The second gives $-\eta^a_{\alpha\nu}x_\alpha x_\mu = +\eta^a_{\nu\alpha}x_\alpha x_\mu$, and the third gives $-\eta^a_{\mu\beta}x_\beta x_\nu = -\eta^a_{\mu\alpha}x_\alpha x_\nu$. Hence

$$g\,\varepsilon^{abc}A^b_\mu A^c_\nu = \frac{4}{g}\,\phi^2\Big(\eta^a_{\nu\alpha}x_\alpha x_\mu - \eta^a_{\mu\alpha}x_\alpha x_\nu + \eta^a_{\mu\nu}\,x^2\Big). \tag{42.92}$$

Adding. The two ϕ^2 cross terms in (42.91) and (42.92) are exact negatives of one another and cancel:

$$\frac{4}{g}\phi^2\big(\eta^a_{\mu\alpha}x_\alpha x_\nu - \eta^a_{\nu\alpha}x_\alpha x_\mu\big) + \frac{4}{g}\phi^2\big(\eta^a_{\nu\alpha}x_\alpha x_\mu - \eta^a_{\mu\alpha}x_\alpha x_\nu\big) = 0.$$

This cancellation — the whole reason the ansatz works — leaves only the $\eta^a_{\mu\nu}$ pieces,

$$F^a_{\mu\nu} = -\frac{4}{g}\,\eta^a_{\mu\nu}\,\phi + \frac{4}{g}\,\eta^a_{\mu\nu}\,x^2\,\phi^2 = \frac{4}{g}\,\eta^a_{\mu\nu}\,\phi(x^2\phi - 1).$$

Since $\phi = 1/(x^2+\rho^2)$, we have $x^2\phi - 1 = (x^2 - (x^2+\rho^2))/(x^2+\rho^2) = -\rho^2\phi$, so

$$F^a_{\mu\nu} = -\frac{4}{g}\,\eta^a_{\mu\nu}\,\rho^2\,\phi^2 = -\frac{4\rho^2}{g}\,\frac{\eta^a_{\mu\nu}}{(x^2+\rho^2)^2},$$

which is (42.90). Restoring the centre amounts to $x \to x - x_0$ throughout.

Self-duality. The whole x-dependence of $F^a_{\mu\nu}$ is the scalar $\rho^2\phi^2$ times the constant tensor $\eta^a_{\mu\nu}$, which is self-dual by (42.84). Therefore

$$\widetilde{F}^a_{\mu\nu} = \tfrac{1}{2}\varepsilon_{\mu\nu\rho\sigma}F^a_{\rho\sigma} = -\frac{4\rho^2}{g}\,\phi^2\,\tfrac{1}{2}\varepsilon_{\mu\nu\rho\sigma}\eta^a_{\rho\sigma} = -\frac{4\rho^2}{g}\,\phi^2\,\eta^a_{\mu\nu} = F^a_{\mu\nu}.$$

Equation of motion. A self-dual field automatically extremises the action. The non-abelian Bianchi identity (Theorem 25.11) states $D_\mu \widetilde{F}^a_{\mu\nu} = 0$ identically, for *any* gauge field — it is a geometric consequence of F being the curvature of a connection, $\varepsilon_{\mu\nu\rho\sigma}D_\nu F_{\rho\sigma} = 0$. Self-duality $F = \widetilde{F}$ then turns the Bianchi identity into the equation of motion:

$$D_\mu F^a_{\mu\nu} = D_\mu \widetilde{F}^a_{\mu\nu} = 0.$$

No second-order computation is needed; this is the structural payoff of solving the first-order self-duality equation rather than the second-order Yang–Mills equation directly. □

Physical Insight

The instanton is a genuine lump. From (42.90) the action density $\frac{1}{4}F^a_{\mu\nu}F^a_{\mu\nu}$ is sharply peaked at $x = x_0$, falls as $1/(x-x_0)^8$, and has a characteristic width ρ. Unlike the static solitons of Chapter 41, which are localised in space but extended through all time, the instanton is localised in all four Euclidean directions — it is an event, not an object: a tunnelling that happens *at a place and at a (Euclidean) time*, of finite duration $\sim \rho$. Hence the name 't Hooft coined, "instanton," an object existing for an instant.

42.3.3 Topological charge and action

With F in hand, the two integrals that the previous section left abstract become elementary. Both reduce to one radial integral, which we do once and reuse.

Lemma 42.19 (The master radial integral)**.** *In four Euclidean dimensions,*

$$\int \mathrm{d}^4x\, \frac{1}{(x^2+\rho^2)^4} = \frac{\pi^2}{6\,\rho^4}. \tag{42.93}$$

Proof. The integrand is spherically symmetric, so $\int \mathrm{d}^4x = \Omega_3 \int_0^\infty r^3\,\mathrm{d}r$ with $\Omega_3 = 2\pi^2$ the surface "area" of the unit S^3 (the volume of the unit $(d-1)$-sphere is $2\pi^{d/2}/\Gamma(d/2)$, equal to $2\pi^2/\Gamma(2) = 2\pi^2$ at $d=4$). Substitute $u = r^2$, $\mathrm{d}u = 2r\,\mathrm{d}r$, so $r^3\mathrm{d}r = \tfrac{1}{2}u\,\mathrm{d}u$:

$$\int \mathrm{d}^4x\, \frac{1}{(x^2+\rho^2)^4} = 2\pi^2 \cdot \tfrac{1}{2}\int_0^\infty \frac{u\,\mathrm{d}u}{(u+\rho^2)^4} = \pi^2 \int_0^\infty \frac{u\,\mathrm{d}u}{(u+\rho^2)^4}.$$

Now set $v = u + \rho^2$, $u = v - \rho^2$:

$$\int_0^\infty \frac{u\,\mathrm{d}u}{(u+\rho^2)^4} = \int_{\rho^2}^\infty (v^{-3} - \rho^2 v^{-4})\mathrm{d}v = \Big[-\tfrac{1}{2}v^{-2} + \tfrac{1}{3}\rho^2 v^{-3}\Big]_{\rho^2}^\infty = \frac{1}{2\rho^4} - \frac{1}{3\rho^4} = \frac{1}{6\rho^4}.$$

Multiplying by π^2 gives (42.93). □

Worked Example 42.20 (The topological charge is $Q = 1$)**.** We evaluate $Q = \dfrac{g^2}{32\pi^2}\displaystyle\int \mathrm{d}^4x\, F^a_{\mu\nu}\widetilde{F}^a_{\mu\nu}$ on the BPST field, with the normalisation fixed in Section 42.2. Because the field is self-dual, $\widetilde{F} = F$, so $F^a_{\mu\nu}\widetilde{F}^a_{\mu\nu} = F^a_{\mu\nu}F^a_{\mu\nu}$. From (42.90),

$$F^a_{\mu\nu}F^a_{\mu\nu} = \Big(\frac{4\rho^2}{g}\Big)^2 \frac{\eta^a_{\mu\nu}\eta^a_{\mu\nu}}{(x^2+\rho^2)^4} = \frac{16\rho^4}{g^2}\cdot\frac{12}{(x^2+\rho^2)^4} = \frac{192\,\rho^4}{g^2}\,\frac{1}{(x^2+\rho^2)^4}, \tag{42.94}$$

where $\eta^a_{\mu\nu}\eta^a_{\mu\nu} = 12$ is (42.85). Therefore, using (42.93),

$$Q = \frac{g^2}{32\pi^2}\cdot\frac{192\,\rho^4}{g^2}\int \mathrm{d}^4x\,\frac{1}{(x^2+\rho^2)^4} = \frac{192\,\rho^4}{32\pi^2}\cdot\frac{\pi^2}{6\rho^4} = \frac{192}{32\cdot 6} = 1.$$

The size ρ has cancelled, as it must: Q is a topological integer, blind to the smooth deformation that changes ρ. The sign is $+1$ because we chose the self-dual symbol η^a; replacing it by $\bar\eta^a$ in the ansatz yields an anti-self-dual field, the *anti-instanton*, with $Q = -1$.

Worked Example 42.21 (The action is $S = 8\pi^2/g^2$)**.** The Euclidean Yang–Mills action of the same field follows from the same density (42.94):

$$S = \frac{1}{4}\int \mathrm{d}^4x\, F^a_{\mu\nu}F^a_{\mu\nu} = \frac{1}{4}\cdot\frac{192\,\rho^4}{g^2}\int \mathrm{d}^4x\,\frac{1}{(x^2+\rho^2)^4} = \frac{48\,\rho^4}{g^2}\cdot\frac{\pi^2}{6\rho^4} = \frac{8\pi^2}{g^2}. \tag{42.95}$$

Two independent checks confirm this is right. First, ρ has again dropped out: the classical action does not depend on the instanton's size — the radial integrand of $\frac{1}{4}F^aF^a$ encloses the same area for every ρ, as Fig. 42.3 shows numerically. Second, the value saturates the Bogomolny bound (42.79) at $|Q| = 1$: $S = 8\pi^2/g^2 = (8\pi^2/g^2)\,|Q|$, exactly the floor, as it must for a self-dual field. We have produced an explicit configuration that attains the abstract minimum.

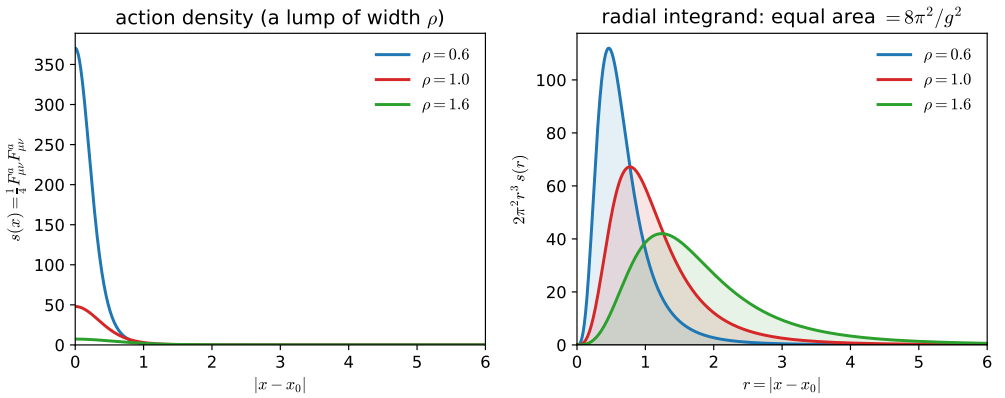

Figure 42.3: The BPST action density $s(x) = \frac{1}{4} F^a_{\mu\nu} F^a_{\mu\nu} = 48\rho^4/g^2\,(x^2+\rho^2)^{-4}$ for three sizes ρ (here $g = 1$, $x_0 = 0$). *Left*: the density itself — a larger instanton is broader and shallower. *Right*: the radial integrand $2\pi^2 r^3 s(r)$, whose total area is the action; all three curves enclose the same area $8\pi^2/g^2$ (Theorem 42.21). The equality of areas *is* the classical scale invariance that makes ρ a flat direction (Section 42.3.4).

Remark 42.22 (Singular gauge). The regular-gauge potential (42.88) pushes the winding out to the three-sphere at infinity, where $A \sim 1/|x|$ is pure gauge. It is often more convenient to push it instead onto a single point. Applying the (singular) gauge transformation that maps the field to the gauge in which A vanishes at infinity gives the *singular-gauge* form

$$A^{a,\mathrm{sing}}_{\mu}(x) = \frac{2}{g}\,\bar{\eta}^a_{\mu\nu}\,\frac{\rho^2\,(x-x_0)_\nu}{(x-x_0)^2\left[(x-x_0)^2+\rho^2\right]}, \tag{42.96}$$

which now decays as $1/|x|^3$ at infinity but is singular at $x = x_0$ (a gauge artefact, not a singularity of F). Strikingly it is built from the *anti*-self-dual symbol $\bar{\eta}^a$, yet its field strength is still self-dual with the same $Q = +1$ and the same action $8\pi^2/g^2$ — a gauge transformation changes neither. The singular gauge is the one in which multi-instanton superpositions and the fermionic zero modes of the next chapters are most cleanly written; we will reach for (42.96) when we need it.

42.3.4 Collective coordinates and zero modes

The single solution (42.88) is in fact a representative of a whole continuous family. Each symmetry of the action that fails to fix our particular instanton carries it to a physically distinct solution of the same action; the parameters of those symmetries are the *collective coordinates* (or *moduli*), and the directions in field space they generate are the *zero modes* of the fluctuation operator. Enumerating them is not bookkeeping for its own sake: the path integral in the one-instanton

sector is, to leading order, an ordinary integral over these moduli, and getting their number and their measure right is the whole content of the dilute-gas calculation to come.

What a zero mode is. Expand the action around the instanton, $A = A_{\text{inst}} + a$. Because A_{inst} is a solution, the linear term vanishes and

$$S[A_{\text{inst}} + a] = S[A_{\text{inst}}] + \tfrac{1}{2}\int \mathrm{d}^4x\; a_\mu^a\, M_{\mu\nu}^{ab}\, a_\nu^b + O(a^3), \tag{42.97}$$

with M the (gauge-fixed) quadratic fluctuation operator. A *zero mode* is a normalisable a with $Ma = 0$: a direction in which the action does not change to quadratic order. Each such direction is flat, and the Gaussian approximation that underlies steepest descent (Theorem 5.44) breaks down along it — one cannot do a Gaussian integral over a direction with no restoring quadratic term. The cure, which we set up here and execute in the dilute-gas section, is to trade each zero mode for an exact integration over the corresponding collective coordinate.

The zero modes are generated by the symmetries of the action that move the instanton. If g_ξ is a one-parameter family of such symmetries with $g_0 = \mathrm{id}$, then $A^{(\xi)} = g_\xi \cdot A_{\text{inst}}$ is a family of solutions all with the same action, and

$$a_\mu^{(\xi)} = \left.\frac{\partial A_\mu^{(\xi)}}{\partial \xi}\right|_{\xi=0} \tag{42.98}$$

satisfies $Ma^{(\xi)} = 0$ (after subtracting, where needed, a compensating infinitesimal gauge transformation to keep a transverse to the gauge orbit). We now list the symmetries.

Translations: 4 moduli. The action is invariant under $x \to x + \text{const}$, but our solution singles out the centre x_0. The four parameters x_0^μ are collective coordinates; the corresponding zero modes are $a_\nu^{(\mu)} = -\partial_\mu A_\nu$ (up to a gauge term), one for each direction. These four modes are guaranteed normalisable because the action density is localised.

Dilatation: 1 modulus. Classical four-dimensional Yang–Mills has no scale: the action $\frac{1}{4}\int F^a F^a$ is invariant under $x \to \lambda x$, $A_\mu(x) \to \lambda^{-1} A_\mu(x/\lambda)$, because in $d = 4$ the gauge field has mass dimension one and F^2 has dimension four, exactly matching d^4x. The solution (42.88) breaks this symmetry by choosing the size ρ; hence ρ is a collective coordinate, and the dilatation zero mode is $a_\mu^{(\rho)} = \partial A_\mu / \partial \rho$. This is the deepest of the moduli. Its existence is precisely the statement, already proven in Theorem 42.21, that $S = 8\pi^2/g^2$ is independent of ρ: the size is a genuine *flat direction* of the action, an exactly massless modulus

at the classical level. Nothing in the classical theory prefers a large instanton to a small one.

Caution

The classical flatness of the ρ direction is not the end of the story; it is the beginning of the chapter's central subtlety. Scale invariance is broken by quantum effects — it is anomalous, the same running of the coupling that gives asymptotic freedom (Eq. (27.101)). The flat direction is lifted only after the one-loop measure is included, and then ρ is controlled by the running coupling $g(\rho)$. The dilatation zero mode is therefore the conduit through which $\Lambda_{\rm QCD}$ (Theorem 27.14) enters the instanton calculus. This is the hand-off to the dilute-gas section, and we return to it below.

Global gauge rotations: 3 moduli for SU(2). A constant gauge transformation $A_\mu \to U A_\mu U^{-1}$ with $U \in \mathrm{SU}(2)$ is a symmetry. It rotates the instanton's orientation in the internal SU(2). Naively this is the three-parameter group SU(2); but the configuration is invariant under the subgroup that commutes with the locked structure $\eta^a_{\mu\nu}$, which for the single SU(2) instanton is trivial at the level that matters, leaving three independent orientation moduli. (More precisely, the global gauge group acts through $\mathrm{SU}(2)/\mathbb{Z}_2 \cong \mathrm{SO}(3)$, a three-dimensional manifold, and all three directions move the field; the centre $\mathbb{Z}_2$ acts trivially but contributes no continuous modulus.) These three are compact moduli — angles — whose integral will produce a finite group volume rather than a divergent spacetime volume.

The count for SU(2). Adding up,

$$\underbrace{4}_{\text{translations}} + \underbrace{1}_{\text{size}} + \underbrace{3}_{\text{gauge orientation}} = 8 = 4N\big|_{N=2}, \tag{42.99}$$

the number of bosonic collective coordinates of the charge-one SU(2) instanton. The grouping into $4N$ is not an accident; it is the first instance of the general result.

Theorem 42.23 (Dimension of the one-instanton moduli space)**.** *For gauge group* SU(N) *and topological charge Q, the bosonic collective coordinates of the (anti-)self-dual sector form a smooth manifold $\mathcal{M}_{N,Q}$ of dimension*

$$\dim \mathcal{M}_{N,Q} = 4N\,|Q|\,. \tag{42.100}$$

For $Q = 1$ this is $4N$: four positions, one size, and $4N - 5$ gauge-orientation angles.

We do not reprove the general index-theoretic statement here (it follows from the Atiyah–Hitchin–Singer index of the deformation operator and is the bosonic counterpart of the fermionic index theorem to be established in Theorem 36.15); but the $Q = 1$ gauge-orientation count is a short and instructive piece of group theory, which we give.

Worked Example 42.24 (Gauge-orientation moduli for SU(N), $Q = 1$)**.** A single $Q = 1$ instanton is built inside an SU(2) subgroup of SU(N) — pick any SU(2) acting on a two-dimensional subspace of the fundamental and write (42.88) with the corresponding generators, padding the rest of the $N \times N$ matrices with zeros. The global gauge group SU(N) acts on this embedded solution by conjugation. The orientation moduli are the directions in SU(N) that move it, i.e. the coset $\mathrm{SU}(N)/H$, where H is the stabiliser: the subgroup commuting with the embedded SU(2). By Schur's lemma, the matrices commuting with the SU(2) acting irreducibly on the chosen $\mathbf{2}$ and trivially on the orthogonal $\mathbf{N-2}$ are block-scalar on the $\mathbf{2}$ and arbitrary U($N-2$) on the rest, intersected with SU(N). Concretely $H = (\mathrm{SU}(N-2) \times \mathrm{U}(1))$, of dimension

$$\dim H = \left[(N-2)^2 - 1\right] + 1 = (N-2)^2.$$

Hence the number of orientation moduli is

$$\dim\bigl(\mathrm{SU}(N)/H\bigr) = (N^2-1) - (N-2)^2 = 4N - 5.$$

Adding the four translations and one size recovers $4 + 1 + (4N-5) = 4N$, in agreement with Theorem 42.23 at $Q = 1$. For $N = 2$, H is trivial ($\dim H = 0$) and we recover the three angles of (42.99); for $N = 3$ there are $4 \cdot 3 - 5 = 7$ orientation moduli.

From zero modes to a measure. The reason to count zero modes is that each one must be removed from the Gaussian fluctuation integral and replaced by an integral over its collective coordinate. The standard collective-coordinate (Faddeev–Popov-type) treatment replaces, for each zero mode, a divergent Gaussian factor by

$$\int \mathrm{d}a\; e^{-\frac{1}{2}\lambda a^2} \;\longrightarrow\; \left(\tfrac{S_0}{2\pi}\right)^{1/2} \int \mathrm{d}\xi, \tag{42.101}$$

i.e. by an integral over the modulus ξ weighted by the Jacobian $\sqrt{S_0/2\pi}$ that converts the normalised fluctuation amplitude into the canonical collective coordinate, with $S_0 = 8\pi^2/g^2$ the instanton action. Each bosonic zero mode contributes one such factor of $\sqrt{S_0/2\pi} \propto 1/g$, so the $4N$ modes contribute $(S_0)^{2N} \propto g^{-4N}$ to the prefactor of e^{-S_0} — the famous large power of $1/g$ that multiplies the exponentially small tunnelling weight.

The dimensionful moduli are the position x_0 and the size ρ; the orientation angles are dimensionless and integrate to a finite group volume. Translation

invariance makes the x_0 integral the spacetime volume, $\int \mathrm{d}^4x_0 = V_4$. The ρ dependence is then fixed by dimensional analysis alone. The one-instanton contribution to the partition function is a pure number density (mass dimension four per unit four-volume), and at the classical level ρ is the only scale; so the size must enter the measure as

$$\mathrm{d}\mu_{\text{size}} \propto \frac{\mathrm{d}\rho}{\rho^5} \qquad (\mathrm{SU}(2)), \tag{42.102}$$

because $\mathrm{d}\rho/\rho^5$ carries mass dimension four and is the unique scale-covariant weight consistent with the classical scale invariance — the same invariance that flattened the ρ direction now *determines* the shape of its measure. (Counting the powers explicitly: the four x_0 Jacobians and the size Jacobian carry, between them, the dimensions that combine with $\mathrm{d}^4x_0\,\mathrm{d}\rho$ to leave $\mathrm{d}^4x_0\,\mathrm{d}\rho/\rho^5$.) For general $\mathrm{SU}(N)$ the power is fixed the same way and the $4N-5$ extra orientation Jacobians shift it; the universal classical skeleton is $\mathrm{d}^4x_0\,\mathrm{d}\rho/\rho^5$ times the orientation volume times $(S_0/2\pi)^{2N}e^{-S_0}$.

The fermionic content, when matter is present, rides on the same moduli. A Dirac fermion in a representation r has, by the index theorem (Theorem 36.15), exactly $2\,T(r)\,|Q|$ normalisable zero modes of $\not{D}$ in the instanton background; these are Grassmann-odd collective coordinates, and the Berezin integral over them produces a determinant of the overlap matrix exactly as in the complex Gaussian Grassmann integral of Theorem 12.26. Their immediate consequence — that the fermionic measure forces the instanton amplitude to vanish unless the right number of fermion legs are attached — is the mechanism behind the $\mathrm{U}(1)_A$ anomaly and the 't Hooft vertex, which the chapter takes up after the vacuum structure is in place.

We now have what the rest of the chapter needs: an explicit charge-one field (42.88), its action $8\pi^2/g^2$, and its complete set of $4N$ bosonic collective coordinates, with the size ρ identified as a classically flat direction whose measure scales as $\mathrm{d}\rho/\rho^5$. The next section steps back from the Euclidean path integral to the canonical, Hamiltonian reading of this same object: it interprets the instanton as the amplitude to tunnel between the topologically distinct vacua $|n\rangle$, builds the θ-vacuum superposition that diagonalises large gauge transformations, and shows that the ρ-integral assembled here — once the running coupling $g(\rho)$ lifts the flat direction — is exactly the dilute-gas sum over tunnelling events that the θ-vacuum organises.

42.4 The theta-Vacuum

The previous section delivered a single concrete object: the BPST instanton, a self-dual finite-action solution of the Euclidean Yang–Mills equations carrying topological charge $Q = 1$ and Euclidean action $S_{\text{inst}} = 8\pi^2/g^2$ (Eq. (42.13)). We

have been calling it a *tunneling event*, and the word was chosen deliberately. A finite-action Euclidean trajectory that begins in one classical vacuum at $\tau \to -\infty$ and ends in another at $\tau \to +\infty$ is, by the steepest-descent reading of the path integral (Theorem 5.44), the dominant contribution to a quantum-mechanical amplitude for passing from the first configuration to the second through a classically forbidden region. The instanton therefore signals that the Yang–Mills theory has *more than one* classical vacuum, that these vacua are degenerate, and that the true quantum ground state is not any one of them but a definite superposition. The purpose of this section is to make that statement precise in the Hamiltonian language: to identify the discrete family of classical vacua, to see the instanton as the operator that hops between adjacent members, to diagonalize the resulting tunneling Hamiltonian, and to discover that the eigenvalue which labels the diagonal blocks is a new, genuinely physical, parity- and time-reversal-violating parameter of the theory — the vacuum angle θ.

42.4.1 Temporal gauge and the residual large gauge transformations

Canonical quantization of a gauge theory wants a gauge in which time plays no special role in the constraint structure, and the cleanest such choice is *temporal* (or Weyl) gauge,

$$A_0^a(x) = 0. \tag{42.103}$$

In this gauge the canonical momentum conjugate to A_i^a is the chromo-electric field $E_i^a = \dot{A}_i^a$ (up to a sign fixed by conventions), the Hamiltonian is the familiar $\mathcal{H} = \tfrac{1}{2}\int d^3x\,(E_i^a E_i^a + B_i^a B_i^a)$ with $B_i^a = \tfrac{1}{2}\epsilon_{ijk}F_{jk}^a$, and Gauss's law $D_i E_i^a = 0$ survives not as an equation of motion but as a constraint on physical states. The point of importance here is that Eq. (42.103) does not exhaust the gauge freedom. A gauge transformation $A_\mu \to A_\mu^U$ preserves $A_0 = 0$ provided U is independent of time, $\partial_0 U = 0$. Thus the residual gauge symmetry of temporal gauge is the group $\mathcal{G}$ of *time-independent* gauge transformations $U(\mathbf{x})$, acting on the spatial connection by

$$A_i \;\longmapsto\; A_i^U \;=\; U A_i U^{-1} - \frac{i}{g}\,(\partial_i U)\,U^{-1}, \qquad A_i \equiv A_i^a T^a. \tag{42.104}$$

This is exactly the group whose topology we classified in Chapter 25. Demanding finite energy forces $U(\mathbf{x}) \to$ const as $|\mathbf{x}| \to \infty$, so each U extends to a based map of the one-point compactification $S^3 = \mathbb{R}^3 \cup \{\infty\}$ into the gauge group, and these maps fall into homotopy classes labelled by an integer winding number,

$$\pi_3(\mathrm{SU}(N)) = \mathbb{Z}, \qquad N \geq 2, \tag{42.105}$$

by Theorem 25.33, the integer being computed by the winding functional of Eq. (25.167), an integer by Theorem 25.35. The transformations with winding

zero — the *small* ones, continuously connected to the identity — are generated infinitesimally by $D_i\alpha$ and are nothing but the gauge redundancy already implemented by the Faddeev–Popov/BRST machinery of Chapter 26; physical states are required to be invariant under them, this being the canonical face of the orbit identification $A \sim A^U$ of Eq. (26.4) and of BRST-closedness, Theorem 26.18. The transformations with nonzero winding — the *large* ones — are the new structure. They are bona fide gauge transformations, hence symmetries of every physical (gauge-invariant) operator, yet they are not reachable from the identity by any continuous deformation and so are *not* automatically resolved by the infinitesimal constraint.

Notation Watch

We write $\hat{T}$ for the unitary operator that implements a winding-one large gauge transformation on the Hilbert space, reserving T^a (with a Lie-algebra index) for the Hermitian generators of Chapter 25. The hat distinguishes the operator from the abstract transformation U_1 it represents.

Fix once and for all a representative gauge transformation $U_1(\mathbf{x})$ of winding number one. Its unitary implementation on the Hilbert space is an operator $\hat{T}$; acting on a state $|\Psi\rangle$ described by a wavefunctional $\Psi[A_i]$ it sends

$$(\hat{T}\,\Psi)[A_i] \;=\; \Psi\big[A_i^{U_1^{-1}}\big]. \tag{42.106}$$

Because U_1 is a gauge transformation, $\hat{T}$ commutes with the Hamiltonian and with every gauge-invariant operator,

$$\big[\hat{T},\mathcal{H}\big] = 0. \tag{42.107}$$

This is the central fact. The large gauge transformation is a *symmetry*, but — unlike a small one — it is not a constraint that must annihilate physical states. We are therefore free, and indeed obliged, to diagonalize it simultaneously with $\mathcal{H}$.

42.4.2 The discrete vacua and the Chern–Simons number

The classical vacua of Yang–Mills theory are the zero-energy configurations, $E_i^a = B_i^a = 0$. Vanishing electric field is $\dot{A}_i = 0$; vanishing magnetic field, $F_{ij} = 0$, means the spatial connection is *pure gauge*,

$$A_i^{(U)} \;=\; -\frac{i}{g}\,(\partial_i U)\,U^{-1}, \tag{42.108}$$

the image of $A_i = 0$ under Eq. (42.104). Naively there is a single classical vacuum, $A_i = 0$, with all the others gauge-equivalent to it and therefore physically

identical. That conclusion is correct for the small transformations and *false* for the large ones. Two pure-gauge configurations Eq. (42.108) built from maps U of different winding number cannot be deformed into one another through zero-energy configurations without leaving the class of pure gauges, and the gauge transformation relating them is large. They are therefore physically distinct classical vacua, one for each integer, and we must keep them all.

To label them invariantly we need a functional of the spatial connection that counts winding without reference to a particular U. That functional is the *Chern–Simons number*. Recall from Theorem 33.15 that the topological density is the divergence of the Chern–Simons current K^μ of Eq. (33.70); its time component, integrated over space, is

$$N_{\mathrm{CS}}[A] \;\equiv\; \frac{g^2}{32\pi^2}\int d^3x\; K^0 \;=\; \frac{g^2}{16\pi^2}\int d^3x\;\epsilon^{ijk}\Big(A_i^a\partial_j A_k^a + \tfrac{g}{3}f^{abc}A_i^aA_j^bA_k^c\Big). \tag{42.109}$$

We claim that on a pure gauge Eq. (42.108) the Chern–Simons number equals (up to an orientation sign fixed below) the winding integer of Eq. (25.167), and is therefore an integer.

Worked Example 42.25 (Chern–Simons number of a pure gauge equals its winding)**.** Insert Eq. (42.108) into Eq. (42.109). Write $R_i \equiv (\partial_i U)U^{-1}$, so $A_i = -\frac{i}{g}R_i$, and convert the colour traces using $\mathrm{tr}(T^aT^b) = \frac{1}{2}\delta^{ab}$ and $\mathrm{tr}(T^aT^bT^c) = \frac{1}{4}(d^{abc}+if^{abc})$. Contraction with the totally antisymmetric ϵ^{ijk} kills the symmetric part d^{abc}, leaving

$$A_i^a\partial_jA_k^a = 2\,\mathrm{tr}(A_i\partial_jA_k), \qquad \epsilon^{ijk}f^{abc}A_i^aA_j^bA_k^c = -4i\,\epsilon^{ijk}\,\mathrm{tr}(A_iA_jA_k). \tag{42.110}$$

For a pure gauge, $\partial_jR_k = (\partial_j\partial_kU)U^{-1} - R_kR_j$; the first piece is symmetric in jk and drops against ϵ^{ijk}, so $\epsilon^{ijk}\,\mathrm{tr}(R_i\partial_jR_k) = \epsilon^{ijk}\,\mathrm{tr}(R_iR_jR_k)$. Substituting $A_i = -\frac{i}{g}R_i$ (whence $A_i\partial_jA_k = -\frac{1}{g^2}R_i\partial_jR_k$ and $A_iA_jA_k = \frac{i}{g^3}R_iR_jR_k$, using $(-i)^3 = i$) gives, term by term,

$$N_{\mathrm{CS}} = \frac{g^2}{16\pi^2}\,\epsilon^{ijk}\int d^3x\,\Big[\underbrace{-\tfrac{2}{g^2}\,\mathrm{tr}(R_iR_jR_k)}_{\text{quadratic}}\;\underbrace{+\tfrac{4}{3g^2}\,\mathrm{tr}(R_iR_jR_k)}_{\text{cubic}}\Big] = -\frac{1}{24\pi^2}\,\epsilon^{ijk}\int d^3x\;\mathrm{tr}(R_iR_jR_k). \tag{42.111}$$

Finally $R_i = U(U^{-1}\partial_iU)U^{-1}$, so $\mathrm{tr}(R_iR_jR_k) = \mathrm{tr}\,\big((U^{-1}\partial_iU)(U^{-1}\partial_jU)(U^{-1}\partial_kU)\big)$ by cyclicity, which is exactly the integrand of the winding functional Eq. (25.167). Hence $N_{\mathrm{CS}}[A^{(U)}] = -\,n[U] \in \mathbb{Z}$. The minus sign is a pure orientation convention; we are free to fix the orientation on S^3 so that the self-dual instanton, which carries $Q = +1$, *raises* the Chern–Simons number, and with that choice $N_{\mathrm{CS}}[A^{(U)}] = n[U]$.

We may now name the classical vacua by their integer Chern–Simons number.

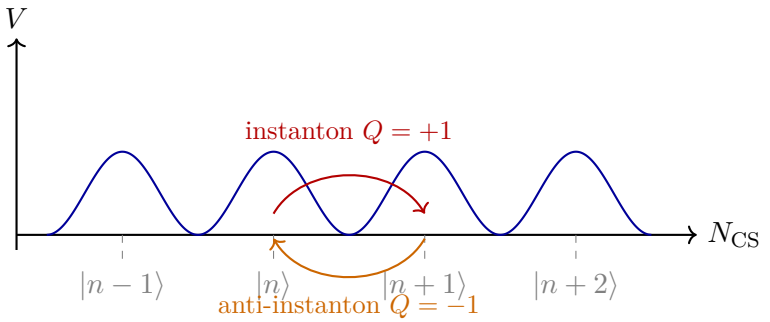

Figure 42.4: The periodic vacuum structure of Yang–Mills theory in temporal gauge. Each integer value of the Chern–Simons number N_{CS} is a degenerate classical vacuum $|n\rangle$. A BPST instanton is a Euclidean trajectory tunnelling under the barrier from $|n\rangle$ to $|n+1\rangle$ (topological charge $Q = +1$); the anti-instanton tunnels the other way. The true ground states are the Bloch-like superpositions $|\theta\rangle$, not any single $|n\rangle$.

Definition 42.26 (The n-vacua)**.** For each integer n, the configuration $A_i^{(n)} = -\frac{i}{g}(\partial_i U_n)U_n^{-1}$ with U_n a winding-n map is a classical vacuum with $N_{\mathrm{CS}} = n$. The corresponding quantum state, the ground state of the small fluctuations about $A_i^{(n)}$, is denoted $|n\rangle$. The states $\{|n\rangle\}_{n\in\mathbb{Z}}$ are an orthonormal family of candidate vacua, and the winding-one operator $\hat{T}$ of Eq. (42.106) carries each to the next,

$$\hat{T}\,|n\rangle = |n+1\rangle\,. \tag{42.112}$$

That $\hat{T}$ shifts N_{CS} by exactly one unit is the operator statement of additivity, $n[U_1U_n] = n[U_1] + n[U_n] = 1 + n$, from Theorem 25.35: composing with the winding-one U_1 sends an n-vacuum to an $(n{+}1)$-vacuum. The picture to hold in mind is a periodic potential on the infinite-dimensional configuration space, with one degenerate well per integer Chern–Simons number; Fig. 42.4 sketches it.

42.4.3 The instanton as a tunnelling event

The wells of Fig. 42.4 are separated by barriers, and the BPST instanton is the path under one of them. To see this in the present variables, return to the topological charge and write it, using $F^a_{\mu\nu}\widetilde{F}^{a\,\mu\nu} = \partial_\mu K^\mu$ from Eq. (33.69), as the total Euclidean-time derivative of the Chern–Simons number,

$$\begin{aligned} Q &= \frac{g^2}{32\pi^2}\int d^4x\; F^a_{\mu\nu}\widetilde{F}^{a\,\mu\nu} = \frac{g^2}{32\pi^2}\int d^4x\;\partial_\mu K^\mu \\ &= \frac{g^2}{32\pi^2}\int_{-\infty}^{\infty} d\tau\,\frac{d}{d\tau}\int d^3x\;K^0 = N_{\mathrm{CS}}(\tau{=}{+}\infty) - N_{\mathrm{CS}}(\tau{=}{-}\infty), \end{aligned} \tag{42.113}$$

where the spatial components $\partial_i K^i$ integrate to zero because K^i falls off at spatial infinity (the fields are pure gauge there). The middle steps used the definition Eq. (42.109) of N_{CS} with exactly the same numerical prefactor, so no stray factor appears: *the topological charge of a Euclidean trajectory is the net change in its Chern–Simons number.* In temporal gauge a finite-action trajectory must approach a classical vacuum at $\tau \to \pm\infty$ (otherwise its action diverges), so $N_{\mathrm{CS}}(\pm\infty)$ are integers; the BPST instanton, with $Q = 1$, is precisely a path with

$$N_{\mathrm{CS}}(-\infty) = n, \qquad N_{\mathrm{CS}}(+\infty) = n + 1. \tag{42.114}$$

It interpolates between adjacent vacua, passing through configurations of nonzero field strength (the barrier) in between. Steepest descent then gives the Euclidean amplitude for this tunnelling. For a transition over a long Euclidean time interval $\mathcal{T}$, the leading semiclassical contribution from a single instanton is

$$\left\langle n+1 \middle| e^{-\mathcal{H}\mathcal{T}} \middle| n \right\rangle \;\sim\; K\, e^{-S_{\mathrm{inst}}} = K\, e^{-8\pi^2/g^2}, \tag{42.115}$$

with $S_{\mathrm{inst}} = 8\pi^2/g^2$ the instanton action of Eq. (42.13) and K the one-loop fluctuation/collective-coordinate prefactor assembled in Section 42.5.1. The exponential $e^{-8\pi^2/g^2}$ is the hallmark of the whole subject: it is nonanalytic at $g = 0$, invisible to every order of perturbation theory, and it is the quantitative measure of the splitting that the tunnelling induces among the degenerate $|n\rangle$. The anti-instanton ($Q = -1$) contributes the mirror amplitude $\left\langle n-1 \middle| e^{-\mathcal{H}\mathcal{T}} \middle| n \right\rangle$.

42.4.4 Diagonalizing the tunnelling Hamiltonian: the theta-vacuum

We have a Hamiltonian that, in the basis $\{|n\rangle\}$, is diagonal-plus-nearest-neighbour-hopping: the diagonal entries are the common well energy, and the off-diagonal entries $\left\langle n \pm 1 \middle| e^{-\mathcal{H}\mathcal{T}} \middle| n \right\rangle$ are the tunnelling amplitudes Eq. (42.115). This is structurally identical to the tight-binding Hamiltonian of an electron in a one-dimensional crystal, and the resolution is identical: the energy eigenstates are not the localized $|n\rangle$ but the Bloch waves built from them. Because $\hat{T}$ commutes with $\mathcal{H}$ by Eq. (42.107) and acts as a unit translation by Eq. (42.112), we diagonalize $\hat{T}$. It is unitary, so its eigenvalues are phases; parametrize them by an angle $\theta \in [0, 2\pi)$ and define the simultaneous eigenstate.

Definition 42.27 (The theta-vacuum)**.** For each $\theta \in [0, 2\pi)$ the θ-vacuum is the superposition

$$|\theta\rangle \;=\; \sum_{n \in \mathbb{Z}} e^{-in\theta}\, |n\rangle\,. \tag{42.116}$$

It diagonalizes the winding operator: using Eq. (42.112) and relabelling the sum,

$$\hat{T}\,|\theta\rangle = \sum_n e^{-in\theta}\,|n+1\rangle = \sum_m e^{-i(m-1)\theta}\,|m\rangle = e^{i\theta}\,|\theta\rangle\,. \tag{42.117}$$

Since $[\hat{T}, \mathcal{H}] = 0$ and the θ-vacua exhaust the eigenstates of $\hat{T}$, the Hamiltonian is block-diagonalized by them; each θ furnishes its own ground state and its own tower of excitations. The energy of the θ-vacuum follows immediately from the tight-binding analogy: with nearest-neighbour amplitude $\propto e^{-S_{\text{inst}}}$, the ground-state energy density acquires a θ-dependent band,

$$\mathcal{E}(\theta) \;=\; \text{const} \;-\; 2K\, e^{-8\pi^2/g^2} \cos\theta \;+\; \ldots, \tag{42.118}$$

the cosine being the lattice dispersion and the dots being multi-instanton corrections. Summing those corrections quantitatively, and confronting the result with the limits of the dilute-gas approximation, is the business of Section 42.5; for now the qualitative content is the lesson, that tunnelling lifts the degeneracy of the $|n\rangle$ into a continuum of inequivalent vacua labelled by θ.

The same conclusion is reached, and the role of θ as a label of distinct theories made manifest, by computing the Euclidean vacuum persistence amplitude directly in the θ-basis. Insert Eq. (42.116) on both sides:

$$\Big\langle \theta' \Big| e^{-\mathcal{H}\mathcal{T}} \Big| \theta \Big\rangle = \sum_{m,n} e^{im\theta' - in\theta} \Big\langle m \Big| e^{-\mathcal{H}\mathcal{T}} \Big| n \Big\rangle . \tag{42.119}$$

Translation invariance in the index — a consequence of $[\hat{T}, \mathcal{H}] = 0$, which makes $\Big\langle m \Big| e^{-\mathcal{H}\mathcal{T}} \Big| n \Big\rangle$ depend only on the difference $Q \equiv m - n$, the topological charge carried by the trajectory — lets us write $\Big\langle m \Big| e^{-\mathcal{H}\mathcal{T}} \Big| n \Big\rangle = F_Q$. Setting $m = n + Q$,

$$\Big\langle \theta' \Big| e^{-\mathcal{H}\mathcal{T}} \Big| \theta \Big\rangle = \sum_{n} e^{in(\theta'-\theta)} \sum_{Q} e^{iQ\theta'} F_Q = 2\pi \sum_{k\in\mathbb{Z}} \delta(\theta' - \theta - 2\pi k) \; \sum_{Q} e^{iQ\theta} F_Q . \tag{42.120}$$

Two features of Eq. (42.120) are decisive. First, the amplitude is proportional to $\delta(\theta' - \theta)$ (modulo 2π): *different θ-vacua do not communicate*. No amount of Euclidean evolution carries one into another. Second, within a fixed sector the amplitude is the weighted sum

$$\sum_{Q} e^{iQ\theta}\, F_Q, \qquad F_Q = \Big\langle n+Q \Big| e^{-\mathcal{H}\mathcal{T}} \Big| n \Big\rangle , \tag{42.121}$$

that is, each topological sector Q enters with the phase $e^{iQ\theta}$. This is the operational meaning of the vacuum angle: θ is the relative phase with which the path integral weights configurations of different instanton number.

42.4.5 Theta as a superselection label

The factor $\delta(\theta' - \theta)$ in Eq. (42.120) is the analytic shadow of a structural fact: θ is a *superselection* parameter. We make this precise.

Theorem 42.28 (The vacuum angle labels superselection sectors)**.** *The winding operator $\hat{T}$ commutes with every observable of the theory. Consequently the Hilbert space decomposes into superselection sectors labelled by the eigenvalue $e^{i\theta}$, $\theta \in [0, 2\pi)$; matrix elements of all observables between states of different θ vanish, no observable can change θ, and coherent superpositions across different θ are unphysical. The clustering vacua of the theory are exactly the $|\theta\rangle$ of Eq. (42.116), one per sector; the localized states $|n\rangle$ are not physical vacua.*

Proof. Observables are the gauge-invariant operators. A large gauge transformation is, like any gauge transformation, a symmetry under which every gauge-invariant operator is inert: for any observable $\mathcal{O}$,

$$\left[\hat{T}, \mathcal{O}\right] = 0. \tag{42.122}$$

Indeed gauge invariance *means* invariance under all of $\mathcal{G}$, and $\hat{T}$ implements an element of $\mathcal{G}$; Eq. (42.107) is the special case $\mathcal{O} = \mathcal{H}$. Thus $\hat{T}$ is a unitary that commutes with the entire observable algebra. By Schur's lemma, in any irreducible representation of that algebra $\hat{T}$ acts as a multiple of the identity — a single phase $e^{i\theta}$. The Hilbert space therefore splits as a direct sum (here a direct integral) of subspaces on which $\hat{T} = e^{i\theta}\mathbf{1}$, and these are the θ-eigenspaces spanned by Eq. (42.116). Between two such subspaces every observable has vanishing matrix element, because $\mathcal{O}$ commutes with $\hat{T}$ and so cannot connect different eigenvalues:

$$\langle\theta'|\mathcal{O}|\theta\rangle\,(e^{i\theta} - e^{i\theta'}) = \left\langle\theta'\middle|\,[\mathcal{O}, \hat{T}]\,\middle|\theta\right\rangle = 0 \implies \langle\theta'|\mathcal{O}|\theta\rangle = 0 \text{ for } \theta \neq \theta'. \tag{42.123}$$

This is the definition of a superselection rule: θ is a fixed datum of the theory, not a dynamical quantity, and choosing a value of θ is choosing which theory one is quantizing, on the same footing as choosing the coupling g.

It remains to see that the physical vacua are the $|\theta\rangle$ rather than the $|n\rangle$, and the criterion is *cluster decomposition*: a physical vacuum $|\Omega\rangle$ must factorize correlators of local observables at large spacelike separation,

$$\langle\Omega|\mathcal{O}_1(x)\,\mathcal{O}_2(y)|\Omega\rangle \xrightarrow{|x-y|\to\infty} \langle\Omega|\mathcal{O}_1(x)|\Omega\rangle\,\langle\Omega|\mathcal{O}_2(y)|\Omega\rangle\,. \tag{42.124}$$

Equivalently, a clustering vacuum is an extremal (pure) state on the observable algebra, one that cannot be written as a nontrivial convex combination of other invariant states. The $|n\rangle$ fail this test. Inverting Eq. (42.116), $|n\rangle = \frac{1}{2\pi}\int_0^{2\pi} d\theta\, e^{in\theta}\,|\theta\rangle$ is a uniform superposition over *all* sectors; since observables are block-diagonal in θ by Eq. (42.123), the expectation $\langle n|\mathcal{O}_1\mathcal{O}_2|n\rangle = \frac{1}{2\pi}\int d\theta\,\langle\theta|\mathcal{O}_1\mathcal{O}_2|\theta\rangle$ is an *average* of the clustering values $\langle\theta|\mathcal{O}_1|\theta\rangle\,\langle\theta|\mathcal{O}_2|\theta\rangle$ over θ, and the average of products is not the product of averages unless the θ-distribution is concentrated. Concretely the connected correlator $\langle n|\mathcal{O}_1\mathcal{O}_2|n\rangle_c$ does not vanish at large separation, so $|n\rangle$ violates Eq. (42.124). The $|\theta\rangle$, being the extremal $\hat{T}$-eigenstates, do cluster. They are the physical vacua. □

Physical insight: the theta-vacuum is a Bloch wave

Everything in this section is the field-theoretic transcription of a single fact from solid-state physics: an electron in a periodic potential does not live in any one well but in a Bloch band, and its states are labelled by a crystal momentum θ that lies in a Brillouin zone $[0, 2\pi)$ and is conserved. Here the "crystal" is the configuration space coordinate N_{CS}, the lattice translation is the large gauge transformation $\hat{T}$, the inter-well tunnelling is the instanton, and the conserved Bloch momentum is the vacuum angle θ. Just as no local perturbation of a crystal can change the crystal momentum of a Bloch state, no local operator of the gauge theory can change θ — which is exactly the superselection rule of Theorem 42.28.

Worked Example 42.29 (The periodic-potential model of the theta-vacuum)**.** To see the band structure Eq. (42.118) arise from tunnelling with no gauge theory in sight, solve the quantum mechanics of a particle of unit mass on the line in a periodic potential $V(x) = V(x + a)$ with deep wells at $x = na$, $n \in \mathbb{Z}$, the exact analogue of Fig. 42.4. Let $|n\rangle$ be the normalized ground state localized in the nth well, and let $\hat{T}$ be the unit lattice translation $x \to x + a$, so $\hat{T}\,|n\rangle = |n + 1\rangle$ and $[\hat{T}, \mathcal{H}] = 0$.

Tunnelling amplitude. In the Euclidean path integral the amplitude to go from the nth to the $(n+1)$th well over imaginary time $\mathcal{T}$ is dominated by the single-bounce (instanton) trajectory that rolls from one maximum of $-V$ to the next, with action $S_0 = \int dx\, \sqrt{2V(x)}$ across the barrier; by steepest descent (Theorem 5.44) it equals $K_0\, e^{-S_0}$ for a fluctuation determinant K_0. The diagonal amplitude $\left\langle n \middle| e^{-\mathcal{H}\mathcal{T}} \middle| n \right\rangle$ is dominated by staying put. Keeping nearest-neighbour hops,

$$\left\langle m \middle| e^{-\mathcal{H}\mathcal{T}} \middle| n \right\rangle = e^{-\varepsilon_0 \mathcal{T}} \Big[\delta_{mn} + \mathcal{T}\, K_0 e^{-S_0}\, (\delta_{m,n+1} + \delta_{m,n-1}) + \dots \Big]. \tag{42.125}$$

Diagonalization. Form the Bloch state $|\theta\rangle = \sum_n e^{-in\theta}\, |n\rangle$, on which $\hat{T}\,|\theta\rangle = e^{i\theta}\,|\theta\rangle$ exactly as in Eq. (42.117). Then

$$\left\langle \theta \middle| e^{-\mathcal{H}\mathcal{T}} \middle| \theta \right\rangle \Big/ \langle \theta | \theta \rangle = e^{-\varepsilon_0 \mathcal{T}} \left[1 + \mathcal{T}\, K_0 e^{-S_0} (e^{i\theta} + e^{-i\theta}) + \dots \right] \xrightarrow{\mathcal{T} \text{ small}} e^{-E(\theta)\mathcal{T}}, \tag{42.126}$$

so that $E(\theta) = \varepsilon_0 - 2K_0 e^{-S_0} \cos\theta$. The localized levels broaden into a band of width $4K_0 e^{-S_0}$, set entirely by the nonperturbative tunnelling factor; the band momentum θ is conserved and labels distinct, non-communicating ground states. This is Eq. (42.118) with $S_0 \to 8\pi^2/g^2$, and it shows in a setting with no subtleties that the θ-degeneracy is real, the splitting is exponentially small, and θ is a good quantum number precisely because $\hat{T}$ commutes with the Hamiltonian.

42.4.6 Equivalence to a Lagrangian theta-term

The Hamiltonian construction has produced a family of theories indexed by θ. We now show that this is not a new and exotic kind of parameter at all: working in the θ-sector is identical to keeping the ordinary, perturbatively-trivial vacuum and adding to the Lagrangian the parity-odd operator of Eq. (33.68). This identification is what makes θ a manipulable coupling and exposes its discrete-symmetry properties.

Theorem 42.30 (Summing the sectors is the theta-term)**.** *Let Z_Q denote the Euclidean path integral over gauge configurations of topological charge Q, with the Euclidean action S_E of Theorem 10.27 continued by $\tau = it$ as in Eq. (10.157). Then the θ-vacuum amplitude Eq. (42.121) is the full path integral weighted by $e^{iQ\theta}$,*

$$Z(\theta) \;=\; \sum_{Q\in\mathbb{Z}} e^{iQ\theta}\, Z_Q \;=\; \int \mathcal{D}A\; \exp\Big(- S_E[A] + i\theta\, \frac{g^2}{32\pi^2} \int d^4x\; F^a_{\mu\nu} \widetilde{F}^{a\,\mu\nu} \Big), \tag{42.127}$$

which is precisely the partition function of the theory whose Minkowski Lagrangian is augmented by

$$\mathcal{L}_\theta \;=\; \theta\, \frac{g^2}{32\pi^2}\, F^a_{\mu\nu} \widetilde{F}^{a\,\mu\nu}, \qquad \widetilde{F}^{a\,\mu\nu} = \tfrac{1}{2}\epsilon^{\mu\nu\rho\sigma} F^a_{\rho\sigma}. \tag{42.128}$$

The dependence is 2π-periodic, $\theta \sim \theta + 2\pi$.

Proof. The decomposition of the configuration space into topological sectors is exact: every finite-action configuration has an integer charge $Q = \frac{g^2}{32\pi^2}\int F\widetilde{F}$ by Eq. (33.79), and the path-integral measure splits as a sum over Q of integrals at fixed charge, $\int \mathcal{D}A = \sum_Q \int_Q \mathcal{D}A$. By definition $Z_Q = \int_Q \mathcal{D}A\, e^{-S_E}$ is the vacuum amplitude restricted to charge Q, i.e. the sector amplitude F_Q of Eq. (42.121) up to the overall (sector-independent, divergent) volume factor $2\pi\delta(0)$ stripped in Eq. (42.120). Hence $\sum_Q e^{iQ\theta} Z_Q$ is exactly the θ-vacuum persistence amplitude. Now, on every configuration in the Q-sector the number Q is constant and equal to $\frac{g^2}{32\pi^2}\int F\widetilde{F}$, so the phase $e^{iQ\theta}$ may be brought inside the integral as $\exp\big(i\theta\, \frac{g^2}{32\pi^2}\int F\widetilde{F}\big)$ without changing anything; summing the sectors then reassembles the unrestricted measure,

$$\sum_Q e^{iQ\theta} Z_Q = \sum_Q \int_Q \mathcal{D}A\; e^{-S_E}\, e^{\,i\theta \frac{g^2}{32\pi^2}\int F\widetilde{F}} = \int \mathcal{D}A\; e^{-S_E + i\theta \frac{g^2}{32\pi^2}\int F\widetilde{F}}, \tag{42.129}$$

which is the middle member of Eq. (42.127). The exponent is $-S_E$ minus the Euclidean continuation of $-i\int d^4x\, \mathcal{L}_\theta$: the operator added to the action is the θ-term Eq. (42.128), and a Minkowski action term $\int d^4x\, \mathcal{L}_\theta$ contributes $e^{i\int \mathcal{L}_\theta} = e^{iQ\theta}$ to the weight, matching Eq. (42.129) term by term. Finally,

because $Q \in \mathbb{Z}$, the integrand of Eq. (42.127) is invariant under $\theta \to \theta + 2\pi$, $e^{iQ(\theta+2\pi)} = e^{iQ\theta}$; the physics is 2π-periodic in the vacuum angle. □

The theta-term is imaginary in Euclidean signature

In Eq. (42.127) the θ-term enters the *Euclidean* exponent with an explicit factor of i: $e^{-S_E + i\theta Q}$, i.e. the Euclidean action is $S_E^{\text{eff}} = S_E - i\theta Q$. Unlike the kinetic action it is not made real by Wick rotation. This is not a blemish but the signature of the term's T-odd character: a T- and CP-violating coupling necessarily appears imaginary in the Euclidean weight, which is why a nonzero θ obstructs the usual probabilistic (positive-measure) interpretation of the Euclidean path integral and complicates its lattice evaluation (the sign problem revisited in Chapter 43).

The identification Eq. (42.128) matches, term for term and prefactor for prefactor, the operator $\mathcal{L}_\theta$ catalogued as the last renormalizable invariant of the Standard Model in Eq. (33.68); the normalization $g^2/32\pi^2$ was chosen there precisely so that the coefficient is an angle, and the present construction is the promised derivation (imported as Eq. (33.79)) of why it is an angle: the action contribution is θ times the integer Q, periodic by Theorem 42.30. What was a curious total-derivative operator in the classical catalogue is now seen as the bookkeeping device that records which Bloch sector of the quantum vacuum one inhabits.

42.4.7 P, T, and CP violation by the angle

The operator Eq. (42.128) is the four-dimensional non-abelian avatar of $\mathbf{E}\cdot\mathbf{B}$, and it inherits that quantity's behaviour under the discrete spacetime symmetries. This is the physical sting of the whole construction: a nonzero θ makes the strong interactions violate parity and time reversal.

Worked Example 42.31 (Theta and the discrete symmetries)**.** Write the topological density in the colour-electric/magnetic form. With $\widetilde{F}^{a\,\mu\nu} = \frac{1}{2}\epsilon^{\mu\nu\rho\sigma}F^a_{\rho\sigma}$ and $E^a_i = F^a_{0i}$, $B^a_i = -\frac{1}{2}\epsilon_{ijk}F^a_{jk}$,

$$F^a_{\mu\nu}\widetilde{F}^{a\,\mu\nu} = -4\,E^a_i B^a_i = -4\,\mathbf{E}^a\cdot\mathbf{B}^a. \tag{42.130}$$

Under *parity* $\mathbf{x} \to -\mathbf{x}$ the chromo-electric field, a polar vector, flips, $\mathbf{E}^a \to -\mathbf{E}^a$, while the chromo-magnetic field, an axial vector, does not, $\mathbf{B}^a \to +\mathbf{B}^a$; hence $\mathbf{E}^a\cdot\mathbf{B}^a \to -\mathbf{E}^a\cdot\mathbf{B}^a$ and

$$\mathsf{P}: \quad \mathcal{L}_\theta \to -\mathcal{L}_\theta, \tag{42.131}$$

which is the statement that P maps the theory at angle θ to the theory at angle $-\theta$. Under *time reversal* $t \to -t$ the electric field is even and the magnetic field, built from currents, is odd, $\mathbf{E}^a \to +\mathbf{E}^a$, $\mathbf{B}^a \to -\mathbf{B}^a$, so again $\mathbf{E}^a\cdot\mathbf{B}^a \to -\mathbf{E}^a\cdot\mathbf{B}^a$

and $\mathsf{T} : \theta \to -\theta$. The term is even under *charge conjugation*, $\mathsf{C} : \mathcal{L}_\theta \to +\mathcal{L}_\theta$ (both $\mathbf{E}^a$ and $\mathbf{B}^a$ are C-odd, their product even). Combining, CP and T each act as $\theta \to -\theta$, consistent with the CPT theorem; and since the physics is 2π-periodic, the theory is CP-invariant only when $-\theta \equiv \theta \pmod{2\pi}$, i.e. at

$$\theta = 0 \quad \text{and} \quad \theta = \pi. \tag{42.132}$$

For every other value, the strong interactions violate P, T, and CP — a violation distinct in origin from the CKM phase, and one that observation (the neutron electric dipole moment) bounds to be extraordinarily small. That this CP-violating angle exists, is physical, and is empirically tiny is the *strong-CP problem*, whose sharp statement we reach in Section 42.7.

We have, then, completed the canonical reading of the instanton promised at the chapter's outset. The degenerate $|n\rangle$ vacua, connected by the large gauge transformation $\hat{T}$ and tunnelled between by the instanton, organize into a one-parameter family of true, clustering vacua $|\theta\rangle$; the parameter θ is superselected, and a fixed θ-sector is identical to ordinary Yang–Mills with the CP-odd θ-term Eq. (42.128) added. The whole of this physics is weighted by $e^{-8\pi^2/g^2}$ and so lies entirely outside perturbation theory. What remains is to turn the qualitative band Eq. (42.118) into a quantitative θ-dependent vacuum energy by summing the gas of instantons and anti-instantons with their collective-coordinate measure. That sum, organized through the sector partition function $Z(\theta) = \sum_Q e^{iQ\theta} Z_Q$ of Eq. (42.127) and honest about where the diluteness assumption fails for QCD, is the subject of Section 42.5.

42.5 The Dilute Instanton Gas and the Vacuum Energy

The previous section reorganized the Euclidean path integral by topological charge,

$$Z(\theta) \;=\; \sum_{Q\in\mathbb{Z}} e^{i\theta Q}\, Z_Q, \qquad Z_Q = \int_{[A]:\, Q[A]=Q} \mathcal{D}A\; e^{-S_E[A]}, \tag{42.133}$$

and identified the angle θ as a genuine, superselected label of the Yang–Mills vacuum (Eq. (42.127)). That decomposition is exact but empty until we can actually *compute* a $Q \neq 0$ sector, and perturbation theory cannot: it expands about the single classical vacuum $A = 0$, which sits in $Q = 0$ and never leaves it. The objects that carry nonzero charge are the instantons of the earlier sections — finite-action Euclidean saddles with $Q = \pm 1$ and action $S_{\text{inst}} = 8\pi^2/g^2$ (Eq. (42.13)) — and the program of this section is to evaluate Eq. (42.133) by steepest descent (Theorem 5.44) around configurations built from many widely separated instantons and anti-instantons: the *dilute instanton gas*.

Three things must be assembled. First, the contribution of a *single* instanton is not a number but an integral over the parameters that label the saddle — its position, its size, its orientation in colour space — because the action is invariant under the symmetries that move these parameters, so the would-be Gaussian fluctuation integral has flat directions. Turning those flat directions into a finite, correctly normalized measure is the collective-coordinate construction, and it produces the celebrated ρ^{-5} size distribution. Second, the bare weight $e^{-8\pi^2/g^2}$ is not the end of the story: the one-loop fluctuations around the instanton dress the coupling into the *running* coupling at the instanton scale, and the resulting ρ^{b_0-5} distribution diverges in the infrared — the honest signal that the dilute-gas approximation, while exact in its parametric structure, is quantitatively uncontrolled for QCD. Third, exponentiating the gas converts the single-instanton weight into a θ-dependent vacuum energy $E(\theta) = -2K\cos\theta$, whose curvature at the origin is the topological susceptibility χ_t. We carry all three out, and we are explicit about what is reliably computed semiclassically and what is not.

42.5.1 The single-instanton saddle and its collective coordinates

Consider the one-instanton sector Z_1. Its leading semiclassical value comes from expanding the action about the classical instanton solution A^{cl}_μ found in the earlier sections. Writing $A_\mu = A^{\mathrm{cl}}_\mu + a_\mu$ and expanding to quadratic order in the fluctuation a_μ,

$$S_E[A^{\mathrm{cl}}+a] = S_{\mathrm{inst}} + \tfrac{1}{2}\int d^4x\, d^4y\; a^a_\mu(x)\, M^{ab}_{\mu\nu}(x,y)\, a^b_\nu(y) + O(a^3), \qquad S_{\mathrm{inst}} = \frac{8\pi^2}{g^2}, \tag{42.134}$$

where $M = \delta^2 S_E/\delta a\,\delta a$ is the fluctuation operator (the gauge-covariant Laplacian in the instanton background, supplemented by the Faddeev–Popov ghost operator from gauge fixing; we work in the background-field gauge so that M is gauge covariant). The naive Gaussian integral over a would give

$$Z_1 \overset{?}{\sim} e^{-S_{\mathrm{inst}}}\,\big[\det{}'M\big]^{-1/2} \times (\text{ghost det}), \tag{42.135}$$

but this is ill-defined: M has *zero modes*, eigenfunctions $\psi^{(i)}$ with $M\psi^{(i)} = 0$, and each contributes a factor $\lambda_i^{-1/2} = 0^{-1/2} = \infty$ to the inverse square-root determinant. The prime on $\det'$ in Eq. (42.135) indicates that these modes have been *excluded* from the determinant; they must be integrated exactly, not in Gaussian approximation. This is the heart of the collective-coordinate method, and it is the direct Euclidean analogue of the zero-mode treatment for the kink (Section 41.1.3).

Why the zero modes are there, and how many. A zero mode is a fluctuation that changes A^{cl} without changing the action. Every continuous

symmetry of S_E that is *broken* by the instanton — i.e. that moves the solution to a physically distinct but degenerate solution — generates exactly one such flat direction, because acting with the symmetry on A^{cl} produces a new solution of the same action, and the infinitesimal generator of that motion is a zero mode of M. The classical massless Yang–Mills action enjoys

- **translations** of the instanton centre x_0: 4 parameters, hence 4 zero modes;
- **dilatations** (scale invariance of classical massless YM): the instanton has an arbitrary size ρ, giving 1 zero mode;
- **global gauge rotations** (colour orientation): for $SU(N)$ the instanton is built by embedding an $SU(2)$ solution, and the rotations that act nontrivially on it furnish $4N-5$ zero modes (for $N=2$ this is 3, the three Euler angles of $SU(2)$ modulo the $U(1)$ stabilizer).

The total count is

$$n_{\mathrm{zero}} \;=\; \underbrace{4}_{x_0} \;+\; \underbrace{1}_{\rho} \;+\; \underbrace{(4N-5)}_{\text{orientation}} \;=\; 4N. \tag{42.136}$$

This $4N$ is the bosonic part of the Atiyah–Singer count for a single instanton; we take it as given here and return to its fermionic companion (one chiral zero mode per flavour) in the next section. For the colour group of QCD, $N=3$, there are 12 bosonic collective coordinates.

Trading zero modes for collective coordinates. The rigorous device is a Faddeev–Popov insertion identical in spirit to gauge fixing (Theorem 26.18), now applied to the moduli of the solution. For each broken symmetry we insert into the path integral a "1" resolved as an integral over the corresponding collective coordinate $\gamma_i \in \{x_0^\mu, \rho, \text{orientation}\}$ times a Jacobian. The result is a clean theorem we now state and prove.

Proposition 42.32 (Collective-coordinate measure for the bosonic zero modes)**.** *Let $A^{\mathrm{cl}}(x;\gamma)$ be the instanton solution as a function of its collective coordinates $\gamma = (\gamma_1,\dots,\gamma_{n_{\mathrm{zero}}})$, and let the normalized zero modes be*

$$\psi_\mu^{(i)}(x) \;=\; \frac{1}{\sqrt{U_i}}\,\frac{\partial A_\mu^{\mathrm{cl}}}{\partial \gamma_i}, \qquad U_i \;=\; \int d^4x\,\Big(\frac{\partial A^{\mathrm{cl}}}{\partial \gamma_i}\Big)^2, \tag{42.137}$$

with U_i the zero-mode norm. Then the exact integration over the i-th flat direction replaces the (divergent) factor $\lambda_i^{-1/2}$ in Eq. (42.135) by

$$\int \frac{d\gamma_i}{\sqrt{2\pi}}\,\sqrt{U_i} \;=\; \int d\gamma_i \,\sqrt{\frac{U_i}{2\pi}}. \tag{42.138}$$

The full one-instanton measure is therefore

$$Z_1 = e^{-S_{\rm inst}} \left(\prod_{i=1}^{n_{\rm zero}} \int d\gamma_i \sqrt{\frac{U_i}{2\pi}} \right) \left[\det{}' M \right]^{-1/2} \times (\textit{ghost det}). \tag{42.139}$$

Proof. Decompose the fluctuation in the complete orthonormal eigenbasis of M, $a_\mu(x) = \sum_i c_i\, \psi_\mu^{(i)}(x) + \sum_n \xi_n\, \phi_\mu^{(n)}(x)$, where the $\psi^{(i)}$ are the zero modes Eq. (42.137) and the $\phi^{(n)}$ the nonzero modes. The measure factorizes, $\mathcal{D}a = \prod_i \frac{dc_i}{\sqrt{2\pi}} \prod_n \frac{d\xi_n}{\sqrt{2\pi}}$, with the $\sqrt{2\pi}$ chosen so that a unit-eigenvalue Gaussian integrates to 1. The nonzero modes give $\prod_n \int \frac{d\xi_n}{\sqrt{2\pi}}\, e^{-\frac{1}{2}\lambda_n \xi_n^2} = \prod_n \lambda_n^{-1/2} = (\det{}' M)^{-1/2}$. For the zero modes the quadratic form vanishes, so $\int \frac{dc_i}{\sqrt{2\pi}}$ would diverge as the (infinite) length of the flat direction; this is precisely the volume of the symmetry orbit, which is physical and must be kept as the collective-coordinate integral, not discarded.

To convert dc_i into $d\gamma_i$, note that moving along the flat direction by dc_i is the same physical deformation as changing the collective coordinate by $d\gamma_i$. Comparing the two parametrizations of the same displacement of $A^{\rm cl}$,

$$\delta A_\mu^{\rm cl} \;=\; \psi_\mu^{(i)}\, dc_i \;=\; \frac{\partial A_\mu^{\rm cl}}{\partial \gamma_i}\, d\gamma_i \;=\; \sqrt{U_i}\, \psi_\mu^{(i)}\, d\gamma_i, \tag{42.140}$$

where the last equality used Eq. (42.137). Matching coefficients of the normalized mode gives $dc_i = \sqrt{U_i}\, d\gamma_i$, hence $\int \frac{dc_i}{\sqrt{2\pi}} = \int d\gamma_i \sqrt{U_i/2\pi}$, which is Eq. (42.138). Doing this for every zero mode yields Eq. (42.139). (When the γ_i are not orthogonal one replaces $\prod_i \sqrt{U_i}$ by $\sqrt{\det U}$, with $U_{ij} = \int (\partial_i A^{\rm cl})(\partial_j A^{\rm cl})$ the metric on moduli space; for the instanton the natural coordinates are orthogonal and the product form holds.) $\square$

Equation (42.139) is exact at one loop. To read off its content we need two facts about how $S_{\rm inst}$, the norms U_i, and the determinant scale with the coupling and the size.

The power of the coupling: g^{-4N}. The classical instanton field scales as $1/g$. This is forced by the structure of the action: with $A_\mu = \frac{1}{g}\hat{A}_\mu$, the Yang–Mills action $S_E = \frac{1}{2g^2}\int \mathrm{tr}\, F^2$ written in terms of $\hat{A}$ has *no* explicit g, because $F_{\mu\nu} = \frac{1}{g}\hat{F}_{\mu\nu}$ with $\hat{F} = \partial\hat{A} - \partial\hat{A} + \hat{A}\hat{A}$ coupling-independent; the entire g-dependence sits in the prefactor $1/g^2$. Hence the solution $\hat{A}^{\rm cl}$ is g-independent and $A^{\rm cl} = \hat{A}^{\rm cl}/g$. Consequently each zero-mode norm scales as $U_i = \int (\partial_i A^{\rm cl})^2 \propto 1/g^2$, so $\sqrt{U_i/2\pi} \propto 1/g$, and the product over all $n_{\rm zero} = 4N$ zero modes contributes

$$\prod_{i=1}^{4N} \sqrt{\frac{U_i}{2\pi}} \;\propto\; g^{-4N} \;=\; \left(g^{-2}\right)^{2N} \;\propto\; \left(\frac{8\pi^2}{g^2}\right)^{2N}, \tag{42.141}$$

where in the last step we have traded the bare g^{-4N} for the dimensionless and more telling combination $(8\pi^2/g^2)^{2N} = S_{\rm inst}^{2N}$, absorbing the numerical $(8\pi^2)^{-2N}$ into the overall constant. This reproduces the weight quoted in the chapter blueprint: the single-instanton amplitude carries $(8\pi^2/g^2)^{2N}\, e^{-8\pi^2/g^2}$. Each of the $4N$ zero modes contributes one half-power of the action; physically, the more collective coordinates the configuration has, the larger the phase-space volume of the saddle, and the prefactor grows as a high power of $1/g^2$ even as the exponential suppresses.

The power of the size: ρ^{-5}. The remaining ρ-dependence is fixed by dimensional analysis, and this is where the ρ^{-5} originates. Classical massless Yang–Mills has *no intrinsic scale*: the only dimensionful collective coordinate available to the single-instanton density is the size ρ itself. Write the one-instanton contribution as a density in spacetime,

$$Z_1 \;=\; \int d^4x_0 \int d\rho \int d\Omega \;\; \mathrm{d}n(\rho), \tag{42.142}$$

where $d\Omega$ is the (dimensionless, finite-volume) integral over colour orientations and $\mathrm{d}n(\rho)$ is the differential instanton density. The left side Z_1 is a pure number; the measure $d^4x_0\, d\rho$ has mass dimension $[\text{mass}]^{-4}\cdot[\text{mass}]^{-1} = [\text{mass}]^{-5}$; hence $\mathrm{d}n(\rho)$ must carry dimension $[\text{mass}]^{+5}$. With ρ the only available scale,

$$\mathrm{d}n(\rho) \;=\; \frac{\text{const}}{\rho^5}\times(\text{dimensionless function of } g), \qquad \boxed{\mathrm{d}n = C_N\,\frac{d\rho}{\rho^5}\left(\frac{8\pi^2}{g^2}\right)^{2N} e^{-8\pi^2/g^2}\, d^4x_0\, d\Omega} \tag{42.143}$$

collecting Eq. (42.141) and the exponential. The same counting reads off where the five powers come from: four from the translational measure d^4x_0 (which by dimensions must be balanced) and one from $d\rho$, with the norms U_i supplying exactly the ρ-powers needed to make $\mathrm{d}n$ scale-covariant. The dimensionless constant C_N is the only piece Eq. (42.143) does *not* fix: it is the value of the regularized nonzero-mode determinant $[\det{}' M]^{-1/2}$ times the ghost determinant times the numerical zero-mode norms, evaluated at $\rho = 1$. Computing C_N is 't Hooft's original tour de force [464]; the answer in the Pauli–Villars scheme is

$$C_N \;=\; \frac{2}{(N-1)!\,(N-2)!}\,\frac{e^{-\alpha(1)+2(N-2)\alpha(1/2)}}{\pi^2}\,, \qquad \alpha(1)\simeq 0.443, \tag{42.144}$$

a finite number of order unity (for $SU(2)$, $C_2 \simeq 0.466/\pi^2$). We do not reproduce the multi-page evaluation of the functional determinant — it is the one piece of this section that is stated without proof, and Eq. (42.144) is given so the reader can use the measure — but every *parametric* feature of Eq. (42.143), the ρ^{-5}, the $(8\pi^2/g^2)^{2N}$, and the exponential, has been derived here in full from zero-mode counting, the $1/g$ scaling of the solution, and dimensional analysis.

Caution

The ρ^{-5} is a statement about the *classical, scale-invariant* theory, where ρ is the only scale. The instant we regularize the determinant we introduce a renormalization scale μ, and scale invariance is broken by the trace anomaly. The bare g in Eq. (42.143) is then a renormalized $g(\mu)$, and a compensating factor of $(\mu\rho)$ to some power reappears. Restoring it converts ρ^{-5} into ρ^{b_0-5}, the subject of the next subsection. Quoting ρ^{-5} as the physical size distribution is the classic error; the running coupling is not optional.

42.5.2 Inserting the running coupling: ρ^{b_0-5} and the infrared breakdown

The constant C_N in Eq. (42.144) is computed by regularizing the determinant $\det' M$ with a Pauli–Villars mass μ, and the regularized determinant depends on the dimensionless ratio $\mu\rho$. Dimensional analysis cannot forbid this dependence — μ is a second scale — and the explicit one-loop computation produces, for each of the modes that renormalize the coupling, a logarithm $\ln(\mu\rho)$ that combines with the bare coupling exactly as the renormalization group demands. Concretely, the determinant supplies a factor $(\mu\rho)^{b_0}$ multiplying Eq. (42.143), with the *same* coefficient b_0 that governs the one-loop beta function Eq. (27.101),

$$b_0 \;=\; \tfrac{11}{3}\,C_A - \tfrac{4}{3}\,T_F\,n_f \;\xrightarrow{\text{pure } SU(N)}\; \tfrac{11}{3}\,N. \tag{42.145}$$

That the power is precisely b_0 is not a coincidence but a Ward identity of the renormalization group: the instanton density is a physical quantity and must be μ-independent, so the explicit μ^{b_0} from the determinant must cancel against the μ-dependence of the running coupling hidden in $e^{-8\pi^2/g^2(\mu)}$. We now make that cancellation explicit, which is the cleanest way to see both why the power is b_0 and what the surviving ρ-dependence is.

Recall the one-loop running of Yang–Mills theory. From Eq. (27.129), or equivalently from the definition of Λ in Theorem 27.14, the inverse coupling runs linearly in the log, and in the convenient combination that appears in the instanton exponent,

$$\frac{8\pi^2}{g^2(\mu)} \;=\; b_0\,\ln\frac{\mu}{\Lambda}, \qquad\Longleftrightarrow\qquad e^{-8\pi^2/g^2(\mu)} \;=\; \Big(\frac{\Lambda}{\mu}\Big)^{b_0}. \tag{42.146}$$

The first equality follows from $1/\alpha_s(\mu) = (b_0/2\pi)\ln(\mu/\Lambda)$ (Eq. (27.152)) and $8\pi^2/g^2 = 2\pi/\alpha_s$. Now combine the determinant's explicit $(\mu\rho)^{b_0}$ with Eq. (42.146):

$$e^{-8\pi^2/g^2(\mu)}\,(\mu\rho)^{b_0} \;=\; \Big(\frac{\Lambda}{\mu}\Big)^{b_0}(\mu\rho)^{b_0} \;=\; (\Lambda\rho)^{b_0} \;=\; e^{-8\pi^2/g^2(1/\rho)}. \tag{42.147}$$

The μ has cancelled, as it must, and the net effect is the substitution

$$\boxed{e^{-8\pi^2/g^2} \;\longrightarrow\; e^{-8\pi^2/g^2(1/\rho)} \;=\; (\Lambda\rho)^{b_0}} \tag{42.148}$$

together with the prefactor $(8\pi^2/g^2)^{2N} \to (8\pi^2/g^2(1/\rho))^{2N} = (b_0 \ln(1/\rho\Lambda))^{2N}$. The physics is transparent: *the coupling that weights an instanton of size ρ is the running coupling evaluated at the instanton's own scale $1/\rho$.* A small instanton is governed by a small (asymptotically free) coupling and is exponentially suppressed; a large instanton is governed by a large coupling and is barely suppressed at all. Assembling Eq. (42.143) with Eq. (42.148) gives the renormalization-group-improved size distribution,

$$\mathrm{d}n(\rho) \;=\; C_N \,\frac{d\rho}{\rho^5}\left(\frac{8\pi^2}{g^2(1/\rho)}\right)^{2N} (\Lambda\rho)^{b_0}\, d^4x_0\, d\Omega \;\propto\; \frac{d\rho}{\rho^5}\,\rho^{\,b_0}\big[\ln(1/\rho\Lambda)\big]^{2N}\, d^4x_0\, d\Omega, \tag{42.149}$$

so that, up to the slowly-varying logarithm, the differential density per unit four-volume scales as

$$\frac{\mathrm{d}n}{d^4x_0\, d\Omega} \;\sim\; \rho^{\,b_0-5}\,\frac{d\rho}{\rho}\cdot(\text{logs}). \tag{42.150}$$

This is the announced $\rho^{\,b_0-5}$, and it is the crux of the assessment this section demands. For pure $SU(3)$, $b_0 = 11$, so the power is ρ^6: the size integral $\int d\rho\,\rho^{\,b_0-5}$ is violently dominated by *large* instantons, $\rho \to \infty$. Even for the smallest interesting case, $SU(2)$ with $b_0 = 22/3$, the exponent $b_0 - 5 = 7/3 > 0$ and the integral still diverges in the infrared. Adding light fermions reduces b_0 but never enough to cure it for QCD. Figure 42.5 (left) plots Eq. (42.149): the distribution rises steeply with ρ until the logarithm $\ln(1/\rho\Lambda)$ — that is, $8\pi^2/g^2(1/\rho)$ — collapses as $\rho \to 1/\Lambda$, where the running coupling diverges and the entire saddle-point expansion that produced Eq. (42.149) loses meaning.

Physical Insight

The infrared divergence of Eq. (42.150) is the precise, quantitative statement of why "QCD instanton calculus" is not a controlled approximation. The semiclassical expansion is an expansion in $\hbar$, equivalently in g^2 at *fixed* action $8\pi^2/g^2$; it is reliable only where the relevant coupling is small. But the instanton integral is dominated by large instantons, whose relevant coupling $g^2(1/\rho)$ is order one — the strong-coupling, confining regime. The dilute-gas computation therefore gets the *structure* of the answer right (there is a θ-dependence; it is nonperturbative, $\sim e^{-8\pi^2/g^2}$; it has the form $-2K\cos\theta$ at leading order) but cannot reliably deliver the *number* K for QCD. This is not a defect to be hidden; it is the reason Chapter 43 exists.

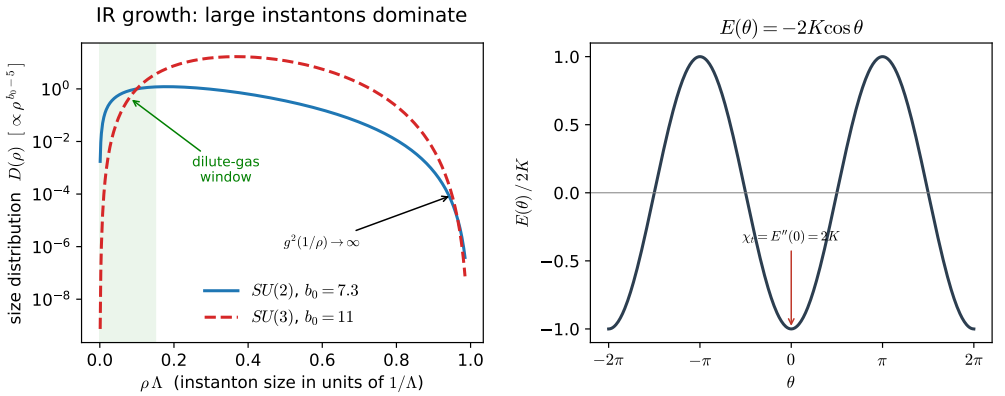

Figure 42.5: *Left:* the renormalization-group-improved instanton size distribution $\mathrm{d}n \propto \rho^{b_0-5}[\,b_0 \ln(1/\rho\Lambda)]^{2N}$ of Eq. (42.149) for pure $SU(2)$ ($b_0 = 22/3$) and $SU(3)$ ($b_0 = 11$), versus the dimensionless size $\rho\Lambda$. The distribution grows toward large ρ; the dilute, semiclassical computation is reliable only in the shaded ultraviolet window $\rho\Lambda \ll 1$, where $g^2(1/\rho)$ is small. As $\rho\Lambda \to 1$ the running coupling diverges and the approximation breaks down: the size integral is dominated by precisely the region where it cannot be trusted. *Right:* the output of exponentiating the gas, the θ-dependent vacuum energy density $E(\theta) = -2K\cos\theta$ of Eq. (42.156), normalized to $2K$. Its curvature at the origin is the topological susceptibility $\chi_t = E''(0) = 2K$.

Caution

A second assumption is buried in calling this a *dilute* gas: that the mean separation between (anti-)instantons is large compared to their size, so that their actions simply add and the multi-instanton configuration is, to good approximation, a superposition of well-separated single instantons. The same infrared growth that ruins the size integral also makes large instantons overlap and interact strongly, violating diluteness. Both failures have the same root — large instantons — and both are cured only outside semiclassics. We proceed with the dilute gas as a *structural* computation, treating K as a formal parameter to be fixed by the lattice.

42.5.3 Exponentiating the gas: $E(\theta) = -2K\cos\theta$

Granting diluteness, we now sum the gas. A general semiclassical configuration consists of n instantons (each $Q = +1$) and $\bar{n}$ anti-instantons (each $Q = -1$), centred at well-separated points. Because they are dilute and non-interacting, the total action is additive and the total topological charge is the algebraic sum,

$$S_E \;\approx\; (n+\bar{n})\,S_{\text{inst}}, \qquad Q \;=\; n-\bar{n}. \tag{42.151}$$

Each (anti-)instanton contributes the integrated single-(anti-)instanton weight. Define the *integrated density per unit four-volume*,

$$K \;\equiv\; \int d\rho \int d\Omega\, \frac{\mathrm{d}n}{d^4x_0} \;=\; C_N \int \frac{d\rho}{\rho^5} \Big(\frac{8\pi^2}{g^2(1/\rho)}\Big)^{2N} (\Lambda\rho)^{b_0} \int d\Omega, \tag{42.152}$$

a quantity of mass dimension $[\text{mass}]^4$ (a density), carrying the all-important nonperturbative factor $K \propto e^{-8\pi^2/g^2}$. By the parity symmetry of the pure gauge action under $A \to A$, $x \to -x$ (which exchanges instantons and anti-instantons), the anti-instanton integrated density equals K as well. The integral in Eq. (42.152) is the infrared-divergent one of the previous subsection; we hold K fixed and finite, as discussed.

Now build $Z(\theta)$. A configuration of n instantons and $\bar{n}$ anti-instantons, with all centres integrated over a Euclidean four-volume $V_4 = VT$ (spatial volume V, Euclidean time extent T), and all sizes and orientations integrated, contributes

$$\frac{1}{n!}\,\frac{1}{\bar{n}!}\,(K\,V_4)^n\,(K\,V_4)^{\bar{n}}. \tag{42.153}$$

The factor $(KV_4)^n$ is n independent integrals of the single-instanton density over the four-volume; the $1/n!$ is the Gibbs factor for n *identical* pseudoparticles — the collective-coordinate integration over n instanton centres counts each unordered configuration $n!$ times, and likewise $1/\bar{n}!$ for the anti-instantons. Inserting the topological weight $e^{i\theta Q} = e^{i\theta(n-\bar{n})}$ from the θ-vacuum (Eq. (42.127)) and summing over all $n, \bar{n} \geq 0$,

$$\begin{aligned} Z(\theta) &= \sum_{n=0}^{\infty}\sum_{\bar{n}=0}^{\infty} \frac{(KV_4)^n}{n!}\,\frac{(KV_4)^{\bar{n}}}{\bar{n}!}\; e^{i\theta(n-\bar{n})} \\ &= \Bigg(\sum_{n=0}^{\infty} \frac{(KV_4\,e^{i\theta})^n}{n!}\Bigg)\Bigg(\sum_{\bar{n}=0}^{\infty} \frac{(KV_4\,e^{-i\theta})^{\bar{n}}}{\bar{n}!}\Bigg) \\ &= \exp\!\big(KV_4\,e^{i\theta}\big)\,\exp\!\big(KV_4\,e^{-i\theta}\big) \;=\; \exp\!\big(2KV_4\cos\theta\big). \end{aligned} \tag{42.154}$$

Each sum is the exponential series; the two fugacities $Ke^{\pm i\theta}$ differ only by the sign of the topological phase. This is the exponentiation of the dilute gas: a sum over an arbitrary number of pseudoparticles collapses to a single exponential of the single-pseudoparticle contribution, exactly as the cluster expansion of a dilute classical gas exponentiates into the ideal-gas free energy. The summation also *justifies a posteriori* the neglect of interactions: the leading large-volume behaviour is controlled by the one-body density K, and two-body corrections are down by the diluteness parameter (the fraction of four-volume occupied by instanton cores).

The vacuum energy density now follows from the standard Euclidean relation between the partition function and the ground-state energy. For Euclidean time

extent $T \to \infty$,

$$Z \;=\; \mathrm{Tr}\, e^{-TH} \;\xrightarrow{T\to\infty}\; e^{-TE_0} \;=\; e^{-V_4\, E(\theta)}, \tag{42.155}$$

where $E(\theta) = E_0/V$ is the vacuum energy density in the θ-vacuum. Comparing Eq. (42.154) with Eq. (42.155),

$$-V_4\, E(\theta) \;=\; 2KV_4 \cos\theta \qquad \Longrightarrow \qquad \boxed{E(\theta) \;=\; -2K\cos\theta} \tag{42.156}$$

which is the central result. The vacuum energy is minimized at $\theta = 0$ (recall $K > 0$), where $E(0) = -2K$, and the energy is a smooth, 2π-periodic function of θ, as required by the periodicity established for the θ-vacuum. Figure 42.5 (right) shows the shape. The depth of the well, $2K \propto e^{-8\pi^2/g^2}$, is nonanalytic in g at $g = 0$: it has a vanishing Taylor expansion there, which is exactly why no order of perturbation theory ever sees it. Instantons are the leading term of the trans-series that perturbation theory is blind to — the nonperturbative completion anticipated by the large-order/Borel discussion of Theorem 5.47.

42.5.4 The topological susceptibility

The single most physical number extractable from $E(\theta)$ is its curvature at the origin, the *topological susceptibility*.

Definition 42.33 (Topological susceptibility)**.** The topological susceptibility is the second derivative of the vacuum energy density with respect to the vacuum angle, evaluated at $\theta = 0$:

$$\chi_t \;\equiv\; \left.\frac{d^2 E(\theta)}{d\theta^2}\right|_{\theta=0}. \tag{42.157}$$

In the dilute gas, Eq. (42.156) gives immediately

$$\chi_t \;=\; \left.\frac{d^2}{d\theta^2}\big(-2K\cos\theta\big)\right|_{\theta=0} \;=\; \left.2K\cos\theta\right|_{\theta=0} \;=\; 2K. \tag{42.158}$$

The susceptibility has a second, microscopic reading that makes its nonperturbative, purely-topological nature manifest: it is the variance of the topological charge per unit four-volume. We establish this as a worked computation, both because the identity is model-independent (it follows from Eq. (42.133) alone, not from the dilute gas) and because checking that the gas reproduces it is a nontrivial consistency test of the whole construction.

Worked Example 42.34 (χ_t as the topological-charge variance, two ways)**. (a) Model-independent identity.** Start from the exact sector sum Eq. (42.133). The moments of Q in the $\theta = 0$ ensemble are

$$\big\langle Q^k \big\rangle \;=\; \frac{\sum_Q Q^k Z_Q}{\sum_Q Z_Q}. \tag{42.159}$$

Differentiating $\ln Z(\theta) = \ln \sum_Q e^{i\theta Q} Z_Q$,

$$\frac{d}{d\theta} \ln Z = \frac{\sum_Q (iQ) e^{i\theta Q} Z_Q}{\sum_Q e^{i\theta Q} Z_Q} \xrightarrow{\theta=0} i \langle Q \rangle , \tag{42.160}$$

$$\frac{d^2}{d\theta^2} \ln Z = \frac{\sum_Q (iQ)^2 e^{i\theta Q} Z_Q}{Z} - \Big(\frac{\sum_Q (iQ) e^{i\theta Q} Z_Q}{Z} \Big)^2 \xrightarrow{\theta=0} -\big(\big\langle Q^2 \big\rangle - \langle Q \rangle^2 \big). \tag{42.161}$$

The pure gauge theory is CP-symmetric at $\theta = 0$, so $\langle Q \rangle = 0$ and the connected variance is just $\langle Q^2 \rangle$. Using $E(\theta) = -V_4^{-1} \ln Z$ from Eq. (42.155),

$$\chi_t = \frac{d^2 E}{d\theta^2}\Big|_0 = -\frac{1}{V_4} \frac{d^2 \ln Z}{d\theta^2}\Big|_0 = \frac{1}{V_4} \big\langle Q^2 \big\rangle \Big|_{\theta=0}. \tag{42.162}$$

So $\chi_t = \langle Q^2 \rangle / V_4$: the mean-square topological charge per unit four-volume. This is the definition used on the lattice, where Q is measured configuration by configuration and its variance accumulated. It involves no instanton, no coupling expansion, no diluteness — it is an exact property of the theory, which is why it is the clean target for a first-principles computation.

(b) The gas reproduces it. In the dilute gas, $Q = n - \bar{n}$ with $n, \bar{n}$ independent *Poisson* variables: from Eq. (42.154) at $\theta = 0$, the probability of n instantons is $P(n) = e^{-KV_4} (KV_4)^n / n!$, with mean $\langle n \rangle = KV_4$ and, being Poisson, variance $\mathrm{Var}(n) = KV_4$; likewise for $\bar{n}$. Independence gives

$$\big\langle Q^2 \big\rangle = \big\langle (n - \bar{n})^2 \big\rangle = \mathrm{Var}(n) + \mathrm{Var}(\bar{n}) = KV_4 + KV_4 = 2KV_4, \tag{42.163}$$

using $\langle n \rangle = \langle \bar{n} \rangle$ so that $\langle Q \rangle = 0$. Hence $\chi_t = \langle Q^2 \rangle / V_4 = 2K$, in exact agreement with Eq. (42.158). The factor of two is the sum of two independent Poisson variances, one from each chirality of pseudoparticle — a small but satisfying check that the combinatorics of Eq. (42.154) are right.

The identity Eq. (42.162) elevates χ_t from a feature of an unreliable approximation to a sharply-defined observable. The dilute gas predicts its *parametric* size,

$$\chi_t \;=\; 2K \;\sim\; \Lambda^4 \, e^{-8\pi^2 / g^2(\Lambda)} \times (\text{powers, logs}), \tag{42.164}$$

nonperturbatively small and built from the QCD scale — but the prefactor and even the ρ-integral that defines K are infrared-dominated, so the actual number is not semiclassically computable for QCD.

42.5.5 What is reliable, and a dated number

It is worth stating plainly, and with a date, where the semiclassical computation stands and where the real number comes from.

Status of χ_t, as of the mid-2020s

The topological susceptibility $\chi_t = \langle Q^2 \rangle / V_4$ is a genuine, scheme-independent nonperturbative observable of Yang–Mills theory. It is *invisible* to perturbation theory (it is $O(e^{-8\pi^2/g^2})$, nonanalytic at $g = 0$) and it is *not* reliably computable in the dilute instanton gas, because the size integral Eq. (42.152) is dominated by large instantons where the approximation fails (Fig. 42.5, left). The only first-principles method that delivers χ_t with controlled, systematically-improvable errors is the Euclidean lattice, where Q is defined and measured nonperturbatively and its variance computed by Monte Carlo. The current lattice value for pure $SU(3)$ Yang–Mills is

$$\chi_t^{1/4} \simeq 180\text{–}190 \text{ MeV} \qquad (\text{pure-gauge } SU(3),\ \text{lattice, mid-2020s}), \tag{42.165}$$

i.e. $\chi_t \simeq (180\,\text{MeV})^4$. In full QCD with light quarks χ_t is strongly *suppressed* by the quark masses — it vanishes in the chiral limit, as the next section's fermion zero modes will explain — and chiral perturbation theory predicts the leading behaviour $\chi_t \simeq \frac{m_u m_d}{(m_u+m_d)^2}\, m_\pi^2 f_\pi^2$ at small quark mass, again confirmed on the lattice. The lattice determination of χ_t is taken up in Chapter 43 (Chapter 43); the Witten–Veneziano relation linking χ_t to the η' mass is derived later in this chapter (Section 42.6.6). Here we have established the object, its dilute-gas estimate, and the honest boundary of that estimate.

The dilute instanton gas has thus done exactly what semiclassics can do and no more. It has *demonstrated* that the Yang–Mills vacuum carries nonperturbative structure: a tower of topological sectors, a physical vacuum angle θ, a vacuum energy $E(\theta) = -2K\cos\theta$ nonanalytic in the coupling, and a topological susceptibility $\chi_t = 2K = \langle Q^2 \rangle / V_4$ that no Feynman diagram can produce. It has *quantified* its own failure for QCD through the ρ^{b_0-5} infrared divergence. What it has not done — supply the number K — is precisely the task it hands to the lattice.

This completes the semiclassical, nonperturbative computation for pure gauge theory and advances Yang–Mills theory to its vacuum-structure layer. One ingredient has been conspicuously absent: fermions. The same instanton that reorganizes the gauge vacuum also supports *fermion zero modes* — one normalizable chiral solution of the Dirac equation per flavour, by the index theorem (Theorem 36.15) — and these zero modes make the path-integral measure non-invariant under axial rotations. The next section couples light fermions to the instanton, uses the zero modes to resolve the $U(1)_A$ problem (the absence of a ninth light pseudoscalar), and reads off 't Hooft's effective multi-fermion vertex — the bridge from this vacuum structure to its imprint on

the hadron spectrum.

42.6 Instantons, Fermions, and the $U(1)_A$ Problem

The previous sections built the instanton as a purely bosonic object and showed that it reorganizes the gauge vacuum: the dilute gas of Section 42.5 sums tunnelling events of every winding into a θ-dependent vacuum energy, and the topological susceptibility χ_t measures how steeply that energy curves with θ. All of this happened with no matter on the stage. Real QCD, however, has light quarks, and the moment we couple them to the instanton the story acquires its sharpest physical consequence. The classical Lagrangian of n_f massless quarks has a large global chiral symmetry, and naive counting of its spontaneously broken generators predicts one more light pseudoscalar meson than nature provides. The resolution is not that the symmetry is unbroken, nor that the missing meson is merely heavy by accident: it is that one of those symmetries, the axial $U(1)_A$, is not a symmetry of the quantum theory at all. The anomaly of Chapter 36 destroys it, and the agent that makes the destruction concrete — that turns the abstract anomaly equation into a calculable vacuum process — is precisely the instanton, acting through the fermion zero modes it is forced by the index theorem to carry. This section couples the quark to the instanton, integrates the anomaly to a clean topological statement, constructs the zero modes, builds the effective multi-fermion vertex 't Hooft extracted from them, and uses all of it to dispatch the $U(1)_A$ problem and to understand why the η' is heavy.

We work, as throughout this chapter, in Euclidean $\mathbb{R}^4$ with metric $\delta_{\mu\nu}$, gauge group $\mathrm{SU}(N)$ with Hermitian generators T^a normalized to $\mathrm{tr}(T^a T^b) = \frac{1}{2}\delta^{ab}$, and the topological charge fixed in Section 42.3.3,

$$Q = \frac{g^2}{32\pi^2}\int \mathrm{d}^4x\, \epsilon_{\mu\nu\rho\sigma}\, \mathrm{tr}(F_{\mu\nu}F_{\rho\sigma}) = \frac{g^2}{32\pi^2}\int \mathrm{d}^4x\, F^a_{\mu\nu}\widetilde{F}^a_{\mu\nu} \;\in\; \mathbb{Z}, \tag{42.166}$$

with $\widetilde{F}^a_{\mu\nu} = \frac{1}{2}\epsilon_{\mu\nu\rho\sigma}F^a_{\rho\sigma}$ and $\epsilon_{1234} = +1$. The single BPST instanton of Theorem 42.17 is the minimal carrier of $Q = 1$, with self-dual field strength Eq. (42.90) and action $S = 8\pi^2/g^2$ from Theorem 42.4. The quarks are n_f Dirac fields q_f ($f = 1, \ldots, n_f$) in the fundamental representation, with the Euclidean Dirac action and propagator structure of Section 11.5 continued to imaginary time.

42.6.1 The chiral symmetries of massless QCD and the missing meson

Set all quark masses to zero. The Dirac Lagrangian $\bar{q}_f\, i\not{D}\, q_f$ does not mix flavors and treats the two chiralities independently, so it is invariant under independent unitary rotations of the left- and right-handed components,

$$q_{Lf} \to (U_L)_{fg}\, q_{Lg}, \qquad q_{Rf} \to (U_R)_{fg}\, q_{Rg}, \qquad U_L, U_R \in \mathrm{U}(n_f), \tag{42.167}$$

where $q_{L,R} = P_{L,R}\, q$ with $P_{L,R} = \tfrac{1}{2}(1 \mp \gamma^5)$. The classical symmetry group is therefore

$$G_{\rm cl} = \mathrm{U}(n_f)_L \times \mathrm{U}(n_f)_R = \mathrm{SU}(n_f)_L \times \mathrm{SU}(n_f)_R \times \mathrm{U}(1)_V \times \mathrm{U}(1)_A, \tag{42.168}$$

the last two factors being the vector ($U_L = U_R = e^{i\alpha}$) and axial ($U_L = e^{-i\beta}$, $U_R = e^{i\beta}$) phase rotations common to all flavors. The vector $\mathrm{U}(1)_V$ is baryon number, unbroken and harmless. The non-abelian $\mathrm{SU}(n_f)_L \times \mathrm{SU}(n_f)_R$ is the chiral symmetry whose spontaneous breakdown by the quark condensate $\langle \bar{q} q \rangle \neq 0$ to the diagonal $\mathrm{SU}(n_f)_V$ is the subject of Chapter 39: by Goldstone's theorem (Theorem 29.11) it produces $n_f^2 - 1$ massless pseudoscalars — for $n_f = 3$ the octet π, K, η, realized as the Goldstone matrix of Theorem 39.6, light because the quark masses that break the symmetry explicitly are small.

That leaves the axial singlet $\mathrm{U}(1)_A$, generated by the flavor-singlet axial current

$$j_5^\mu = \sum_{f=1}^{n_f} \bar{q}_f\, \gamma^\mu \gamma^5\, q_f. \tag{42.169}$$

The same condensate $\langle \bar{q} q \rangle \neq 0$ that breaks $\mathrm{SU}(n_f)_A$ is not invariant under $\mathrm{U}(1)_A$ either — an axial phase rotates $\bar{q}_R q_L \to e^{2i\beta} \bar{q}_R q_L$. So if $\mathrm{U}(1)_A$ were an exact symmetry, it would be spontaneously broken alongside the rest of the axial group, and Goldstone's theorem would demand a *ninth* massless pseudoscalar, a flavor singlet, in the chiral limit. With realistic small quark masses it would be a light pseudoscalar not much heavier than the pion. There is no such particle. The lightest flavor-singlet pseudoscalar is the η', at 958 MeV — nearly seven times the pion mass and heavier than every member of the octet. This is the $U(1)_A$ *problem*: the classical symmetry counting overpredicts the light spectrum by one state.

The discrepancy can be made quantitative, and the quantitative form is what shows the puzzle is real rather than a matter of an unluckily heavy meson.

Physical Insight: Weinberg's bound and why "it is just heavy" fails

If $\mathrm{U}(1)_A$ were a genuine, spontaneously broken symmetry, the would-be ninth Goldstone η_0 would couple to j_5^μ exactly as the pions couple to the broken $\mathrm{SU}(n_f)_A$ currents, with the same decay constant up to a calculable group factor. Weinberg analyzed the chiral Ward identities for the singlet current with the quark mass as the only explicit breaking and found a rigorous upper bound on the singlet mass,

$$m_{\eta_0}^2 \;\leq\; n_f\, m_\pi^2, \tag{42.170}$$

which for $n_f = 3$ reads $m_{\eta_0} \leq \sqrt{3}\, m_\pi \approx 234\,\mathrm{MeV}$. The point of the inequality is that the singlet mass is controlled by the *same* small explicit

breaking (the quark masses) as the pion mass: a state whose mass is protected by an approximate symmetry cannot be parametrically heavier than the protection allows. The physical η' at 958 MeV violates Eq. (42.170) by a factor of four in the mass, an order of magnitude in the mass-squared. No tuning of the quark masses can rescue it. The only way out is that $\mathrm{U}(1)_A$ is *not* an approximate symmetry of the quantum theory — that its breaking is not controlled by the quark masses at all, but by something that survives in the chiral limit. That something is the anomaly.

42.6.2 Integrating the anomaly: $\Delta Q_5 = 2n_f Q$

The classical conservation law $\partial_\mu j_5^\mu = 0$ (in the chiral limit) is the first casualty of quantization. Each Dirac flavor contributes to the divergence of its own axial current the Adler–Bell–Jackiw anomaly of Eq. (36.50), now with the color field strength in place of the photon and a trace over the fundamental representation. Summed over the n_f flavors, the singlet current Eq. (42.169) obeys

$$\partial_\mu j_5^\mu = \frac{g^2 n_f}{16\pi^2}\, F^a_{\mu\nu}\widetilde{F}^a_{\mu\nu} = 2n_f\, q(x), \qquad q(x) \equiv \frac{g^2}{32\pi^2}\, F^a_{\mu\nu}\widetilde{F}^a_{\mu\nu}, \tag{42.171}$$

where $q(x)$ is the topological charge density whose integral is Eq. (42.166), and the factor 2 is the one that distinguishes the Dirac axial current $\bar{q}\gamma^\mu\gamma^5 q$ from a single Weyl chirality, exactly as flagged below Eq. (36.141). The right-hand side is unaffected by the quark masses: a mass adds the classical piece $2i\, m_f\, \bar{q}_f\gamma^5 q_f$ to the divergence, present already at the classical level, but the anomalous piece $2n_f q(x)$ is there whether or not the quarks are massive. This is the decisive structural fact. The breaking of $\mathrm{U}(1)_A$ has a source that does not vanish in the chiral limit.

Integrate Eq. (42.171) over Euclidean spacetime. The left-hand side is the total change in the axial charge carried across the configuration; the right-hand side is $2n_f$ times the integral of the topological density, which is $2n_f$ times the integer winding Q by Eq. (42.166):

$$\Delta Q_5 \;\equiv\; \int \mathrm{d}^4x\; \partial_\mu j_5^\mu \;=\; 2n_f \int \mathrm{d}^4x\; q(x) \;=\; 2n_f\, Q. \tag{42.172}$$

This is the central kinematic identity of the section, and it is exact: no order of perturbation theory enters, because Q is invisible order by order and the anomaly coefficient is fixed once and for all by the triangle (or, equivalently, by the Fujikawa measure, Theorem 36.9). A gauge field of winding Q changes the axial charge of the vacuum by exactly $2n_f Q$ units. For a single instanton, $\Delta Q_5 = 2n_f$: the instanton converts left-handed quarks into right-handed ones, one unit of chirality flip for each of the n_f flavors and for each of the two members of the Dirac doublet, $2n_f$ in all.

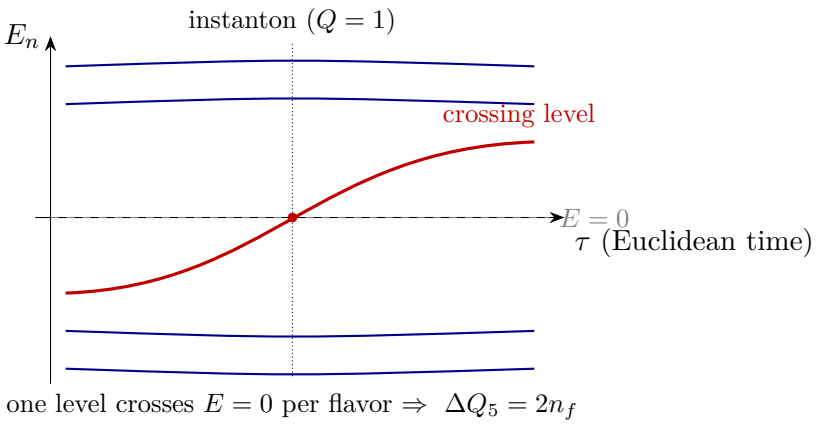

Figure 42.6: Spectral flow of the Dirac Hamiltonian through a single instanton. Most levels (blue) return to where they started; for each flavor one level (red) crosses zero, transferring a unit of chirality across the gap. The net axial-charge change is $2n_f Q$, the integrated anomaly Eq. (42.172).

Physical Insight: The spectral-flow picture

The integrated statement Eq. (42.172) has a vivid Hamiltonian reading. Picture the instanton as a tunnelling event in Euclidean time interpolating between two gauge vacua of adjacent winding number. As the gauge field is dragged through this event, the energy levels of the Dirac Hamiltonian in the slowly varying background flow continuously; for each flavor, exactly one level crosses zero from below, so one negative-energy (filled) state is promoted to positive energy and one positive-energy state descends into the Dirac sea. A left-handed antiparticle and a right-handed particle are created, or equivalently one unit of left-handed charge is traded for one unit of right-handed charge. Counting both members of the Dirac field and all n_f flavors gives $\Delta Q_5 = 2n_f$ per unit winding. The anomaly is the statement that the Dirac sea is not a fixed reservoir: topology pumps charge across the gap.

The Euclidean counterpart of the level crossing is the appearance of an exact *zero mode* of the four-dimensional Dirac operator in the instanton background — the level caught at $E = 0$ at the instant of crossing. We now make this precise and, through the Atiyah–Singer index theorem, tie the number of zero modes directly to Q.

42.6.3 Fermion zero modes and the vanishing of the determinant

A zero mode is a normalizable spinor ψ_0 annihilated by the Euclidean Dirac operator, $i\not{D}\,\psi_0 = 0$, in the fixed instanton background. The index theorem proved in Chapter 36 counts the difference of zero modes of the two chiralities and equates it to the topological charge. We restate it for the present setting.

Theorem 42.35 (Zero modes from the index, Theorem 36.15)**.** *Let n_+ (n_-) be the number of normalizable zero modes of $i\not{D}$ with $\gamma^5 = +1$ ($\gamma^5 = -1$) in a smooth gauge background of finite action and winding Q, for a single Dirac fermion in the fundamental of* $\mathrm{SU}(N)$*. Then*

$$n_+ - n_- = Q. \tag{42.173}$$

Equation (42.173) is the topological lower bound; what makes the instanton so clean is that for a self-dual background it is saturated — one chirality is empty, so the number of zero modes is exactly $|Q|$. This is a vanishing theorem, and we prove it in full because it both fixes the chirality of the modes and is the reason the naive fermion determinant vanishes.

Theorem 42.36 (Vanishing theorem for self-dual backgrounds)**.** *In a self-dual gauge field, $F^a_{\mu\nu} = \widetilde{F}^a_{\mu\nu}$, the Dirac operator has no normalizable zero modes of negative chirality: $n_- = 0$. Hence, by Eq. (42.173), $n_+ = Q$ and there are exactly Q zero modes, all of positive chirality. (For an anti-self-dual background the roles of the chiralities are exchanged and $n_- = |Q|$.)*

Proof. A normalizable zero mode of $i\not{D}$ is also a zero mode of its square, and conversely $\langle\psi|(i\not{D})^2|\psi\rangle = \|i\not{D}\psi\|^2$ shows $(i\not{D})^2\psi = 0 \Rightarrow i\not{D}\psi = 0$ for normalizable ψ; so the zero modes of $i\not{D}$ are exactly those of $(i\not{D})^2$. The square is the Lichnerowicz–Weitzenböck operator of Eq. (36.152),

$$(i\not{D})^2 = -D_\mu D_\mu + \frac{g}{2}\,\sigma_{\mu\nu}F^a_{\mu\nu}T^a, \qquad \sigma_{\mu\nu} = \frac{i}{2}[\gamma_\mu,\gamma_\nu], \tag{42.174}$$

the first term being the covariant Laplacian and the second the spin coupling to the field strength. The two chiralities decouple here because $\sigma_{\mu\nu}$ commutes with γ^5. The key algebraic fact is that the chiral projections of $\sigma_{\mu\nu}$ are (anti-)self-dual: in Euclidean conventions

$$\tfrac{1}{2}\epsilon_{\mu\nu\rho\sigma}\,\sigma_{\rho\sigma}\,P_+ = +\sigma_{\mu\nu}P_+, \qquad \tfrac{1}{2}\epsilon_{\mu\nu\rho\sigma}\,\sigma_{\rho\sigma}\,P_- = -\sigma_{\mu\nu}P_-, \tag{42.175}$$

so that $\sigma_{\mu\nu}P_-$ is anti-self-dual in its $\mu\nu$ indices. Now contract with a self-dual field strength. The contraction of a self-dual tensor with an anti-self-dual one vanishes identically; concretely, writing $F_{\mu\nu}$ self-dual and using Eq. (42.175) on the negative-chirality subspace,

$$\begin{aligned}\sigma_{\mu\nu}F^a_{\mu\nu}\,P_- &= (\tfrac{1}{2}\epsilon_{\mu\nu\rho\sigma}\sigma_{\rho\sigma}P_-)(-1)\,F^a_{\mu\nu} = -\sigma_{\rho\sigma}P_-\,(\tfrac{1}{2}\epsilon_{\mu\nu\rho\sigma}F^a_{\mu\nu})\\ &= -\sigma_{\rho\sigma}\widetilde{F}^a_{\rho\sigma}P_- = -\sigma_{\rho\sigma}F^a_{\rho\sigma}P_-,\end{aligned}$$

where the last step used self-duality $\widetilde{F} = F$. The operator equals minus itself on P_-, hence

$$\sigma_{\mu\nu} F^a_{\mu\nu}\, P_- = 0. \tag{42.176}$$

On the negative-chirality subspace the spin term drops out of Eq. (42.174), leaving the bare covariant Laplacian, which is a non-negative operator:

$$\langle\psi_-|(i\not{D})^2|\psi_-\rangle = \langle\psi_-|-D_\mu D_\mu|\psi_-\rangle = \int \mathrm{d}^4x\, (D_\mu\psi_-)^\dagger (D_\mu\psi_-) = \sum_\mu \|D_\mu\psi_-\|^2 \geq 0, \tag{42.177}$$

after integration by parts (the surface term vanishes for normalizable ψ_-). A zero mode of negative chirality would force $\|D_\mu\psi_-\| = 0$ for every μ, i.e. ψ_- covariantly constant; but a covariantly constant spinor has $|\psi_-|$ constant over $\mathbb{R}^4$ and is therefore not normalizable unless it vanishes. Hence $n_- = 0$. The same argument with $P_+ \leftrightarrow P_-$ and $\widetilde{F} = -F$ gives $n_+ = 0$ for an anti-self-dual background. □

For the BPST instanton, $Q = 1$, the theorem gives exactly one zero mode per flavor, of positive chirality. We exhibit it.

Worked Example 42.37 (The explicit $Q = 1$ zero mode and its normalizability)**.** Take the SU(2) BPST instanton in regular gauge Eq. (42.88), centred at the origin with size ρ, $A^a_\mu = (2/g)\,\eta^a_{\mu\nu} x_\nu/(x^2+\rho^2)$, with η^a the self-dual 't Hooft symbol of Theorem 42.15. Use a two-component (Weyl) description of the positive-chirality field, in which a spinor carries an undotted index $\alpha \in \{1,2\}$ and a fundamental color index $a \in \{1,2\}$. The 't Hooft zero mode is the "spin–color locked" configuration

$$\psi_{0,\,\alpha a}(x) = C\,\frac{\rho}{(x^2+\rho^2)^{3/2}}\,\epsilon_{\alpha a}, \qquad \epsilon_{\alpha a} = -\epsilon_{a\alpha},\quad \epsilon_{12} = +1, \tag{42.178}$$

in which the color index is contracted antisymmetrically with the spinor index — the only SU(2)-invariant, rotation-covariant way to soak up both. We verify three things: chirality, that it solves the Dirac equation, and normalizability.

Chirality. By construction ψ_0 lives in the positive-chirality Weyl sector, $\gamma^5\psi_0 = +\psi_0$, consistent with Theorem 42.36 for the self-dual ($Q = +1$) field.

It solves the Dirac equation. The positive-chirality Weyl equation in a self-dual background reads $\bar\sigma_\mu D_\mu \psi_0 = 0$ with $\bar\sigma_\mu = (\vec\sigma, -i)$ and $D_\mu = \partial_\mu - igA^a_\mu T^a$, $T^a = \sigma^a/2$. Writing $\psi_0 = f(x)\,\epsilon$ with $f = C\rho\,(x^2+\rho^2)^{-3/2}$ and inserting the gauge field, every spinor–color structure that appears collapses, through the 't Hooft identities Theorem 42.16 that lock $\bar\sigma_\mu \eta^a_{\mu\nu}\sigma^a$ onto a single tensor, to the radial equation

$$\Big(\partial_\mu + \frac{3x_\mu}{x^2+\rho^2} - \frac{3x_\mu}{x^2+\rho^2}\Big) f(x)\cdot(\cdots) = 0, \tag{42.179}$$

in which the inhomogeneous derivative of the profile is cancelled exactly by the gauge connection: $\partial_\mu f = -3x_\mu f/(x^2+\rho^2)$ is matched, term for term, by the spin coupling to A_μ, which the self-duality of η^a guarantees has precisely this magnitude and the opposite sign. The cancellation is the algebraic content of the spin–color locking; that it works for the power $-3/2$ and no other is what selects the profile in Eq. (42.178). (The same calculation in singular gauge Eq. (42.96) gives the mode with the $\bar\eta$ structure, the form most convenient for multi-instanton work.)

Normalizability. This is the property that distinguishes a genuine zero mode from a formal solution, and we check it by direct integration. Using $\epsilon_{\alpha a}\epsilon_{\alpha a} = 2$,

$$\int \mathrm{d}^4x\; \psi_0^\dagger \psi_0 = C^2\,\rho^2 \int \mathrm{d}^4x\; \frac{\epsilon_{\alpha a}\epsilon_{\alpha a}}{(x^2+\rho^2)^3} = 2C^2\rho^2 \int \mathrm{d}^4x\; \frac{1}{(x^2+\rho^2)^3}. \tag{42.180}$$

The radial integral is elementary: with $\int \mathrm{d}^4x = 2\pi^2 \int_0^\infty r^3\,\mathrm{d}r$ and the substitution $u = r^2$, then $v = u + \rho^2$,

$$\begin{aligned} \int \mathrm{d}^4x\; \frac{1}{(x^2+\rho^2)^3} &= 2\pi^2 \int_0^\infty \frac{r^3\,\mathrm{d}r}{(r^2+\rho^2)^3} = \pi^2 \int_0^\infty \frac{u\,\mathrm{d}u}{(u+\rho^2)^3} \\ &= \pi^2 \int_{\rho^2}^\infty (v^{-2} - \rho^2 v^{-3})\mathrm{d}v = \pi^2 \cdot \frac{1}{2\rho^2} = \frac{\pi^2}{2\rho^2}. \end{aligned} \tag{42.181}$$

The result is finite: the profile falls as $|x|^{-3}$, so $|\psi_0|^2 \sim |x|^{-6}$ and $\int \mathrm{d}^4x\,|x|^{-6} \sim \int r^{-3}\,\mathrm{d}r$ converges at infinity, while at the origin the integrand is bounded. Substituting Eq. (42.181) into Eq. (42.180) gives $\int \psi_0^\dagger\psi_0 = 2C^2\rho^2\cdot\pi^2/2\rho^2 = C^2\pi^2$, so the choice

$$C = \frac{1}{\pi} \tag{42.182}$$

normalizes the mode to unity. The integral converging is the whole point: a non-normalizable solution does not contribute a true zero eigenvalue and would not invalidate the determinant. The instanton's zero mode is honestly square-integrable, localized on the scale ρ set by the instanton size, exactly as the spectral-flow picture of Fig. 42.6 requires.

The existence of even one zero mode has an immediate and dramatic consequence for the path integral. Integrating out a Dirac field in a fixed background produces the determinant of the Dirac operator (the Grassmann Gaussian of Theorem 12.26, which gives det in the numerator),

$$\int \mathcal{D}\bar q\,\mathcal{D}q\; e^{-\int \bar q\, i\not{D}\, q} = \det\left(i\not{D}\right) = \prod_n \lambda_n, \tag{42.183}$$

the product running over the (real) eigenvalues λ_n of the Hermitian operator $i\not{D}$. A zero mode contributes a factor $\lambda_0 = 0$. Therefore in any topologically nontrivial, self-dual sector the determinant *vanishes*,

$$\det\left(i\not{D}\right)\big|_{Q\neq 0} = 0, \tag{42.184}$$

once per flavor for $Q=1$, and $|Q|n_f$ times in general. Read naively, this says the instanton contributes nothing: massless quarks suppress tunnelling completely, because the vacuum-to-vacuum amplitude in the $Q=1$ sector is multiplied by zero. That is correct as far as it goes, and it is already a real physical statement — it is why the chiral limit screens topological charge, a fact we will need for the η' mass. But it is not the end of the story: a vanishing partition-function contribution does not mean a vanishing *correlation function*. The zero mode can be saturated by external quark fields, and the surviving amplitude is the most important consequence of instantons for hadron physics.

42.6.4 The 't Hooft effective vertex

To see what survives, expand the quark fields in the complete orthonormal eigenbasis $\{\phi_n\}$ of $i\not{D}$ in the instanton background, with anticommuting (Grassmann) coefficients,

$$q(x)=\sum_n c_n\,\phi_n(x), \qquad \bar q(x)=\sum_n \bar c_n\,\phi_n^\dagger(x), \qquad \mathcal{D}\bar q\,\mathcal{D}q=\prod_n \mathrm{d}\bar c_n\,\mathrm{d}c_n, \tag{42.185}$$

so that the Euclidean action diagonalizes, $\int \bar q\, i\not{D}\, q=\sum_n \lambda_n\,\bar c_n c_n$. Consider a single flavor first. The zero mode $\phi_0=\psi_0$ has $\lambda_0=0$, so its coefficients $\bar c_0, c_0$ are *absent from the action*. Berezin integration over an anticommuting variable that does not appear in the integrand gives zero, $\int \mathrm{d}c_0\,(\text{const})=0$; this is the reappearance of Eq. (42.184). But $\int \mathrm{d}\bar c_0\,\mathrm{d}c_0\,(\bar c_0 c_0)=1$: if the integrand supplies one factor of c_0 and one of $\bar c_0$, the zero-mode integral is saturated and nonzero. The external fields that supply them are the quark operators in a correlation function. The lowest correlator that survives the $Q=1$ instanton is therefore the one with exactly one q and one $\bar q$ per flavor,

$$\Big\langle \prod_{f=1}^{n_f} q_f(x_f)\,\bar q_f(y_f)\Big\rangle_{Q=1}=\int \mathrm{d}^4x_0\,\mathrm{d}\rho\; d(\rho)\; e^{i\theta}\,\det{}'(i\not{D})\prod_{f=1}^{n_f}\psi_0^{(f)}(x_f-x_0)\,\psi_0^{(f)\dagger}(y_f-x_0), \tag{42.186}$$

where each external quark line attaches to the localized zero-mode wavefunction ψ_0 of Eq. (42.178), $\det'$ is the product over the *nonzero* modes (the regulated fluctuation determinant), $d(\rho)$ is the bosonic instanton measure assembled in Eq. (42.102) from the collective-coordinate Jacobians of Section 42.3.4, and we integrate over the instanton position x_0 and size ρ. The phase $e^{i\theta}$ is the weight $e^{iQ\theta}$ of the $Q=1$ sector from Section 42.4.

Collapsing the localized wavefunctions to a point (keeping the leading term in the operator product, valid for separations large compared with ρ) turns Eq. (42.186) into the matrix element of a *local* $2n_f$-fermion operator. This is the 't Hooft effective vertex.

Definition 42.38 ('t Hooft effective vertex)**.** Integrating over instanton sizes and orientations, the single-instanton contribution to the effective action is

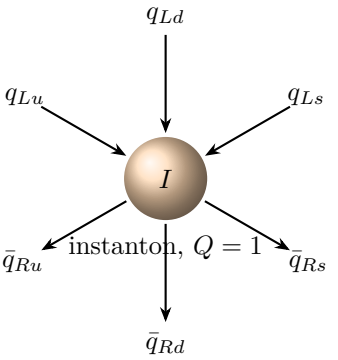

Figure 42.7: The 't Hooft vertex for $n_f = 3$. A single instanton absorbs one left-handed quark of each flavor and emits one right-handed quark of each flavor (equivalently, the local operator $\prod_f \bar{q}_{Rf} q_{Lf}$). It is a $2n_f$-fermion interaction violating $\mathrm{U}(1)_A$ by $2n_f$ units — exactly the integrated anomaly Eq. (42.172) for $Q = 1$.

the addition to the Lagrangian of a local, flavor-antisymmetric $2n_f$-fermion interaction,

$$\mathcal{L}_{\text{'t Hooft}} = \int \mathrm{d}\rho \; d(\rho) \left[e^{i\theta} \det_{f,g}(\bar{q}_{Rf}\, q_{Lg}) \;+\; e^{-i\theta} \det_{f,g}(\bar{q}_{Lf}\, q_{Rg}) \right], \tag{42.187}$$

the first determinant from the instanton ($Q = +1$), its Hermitian conjugate from the anti-instanton ($Q = -1$); $\det_{f,g}$ is the determinant over the $n_f \times n_f$ flavor matrix with entries $\bar{q}_{Rf} q_{Lg}$, automatically antisymmetric in flavor because the zero modes of distinct flavors are independent Grassmann objects. The overall strength carries the instanton suppression $e^{-8\pi^2/g^2}$ from $d(\rho)$.

Two properties of Eq. (42.187) are exactly the ones the anomaly demanded, and verifying them is the payoff of the whole construction.

Worked Example 42.39 (The 't Hooft vertex violates $\mathrm{U}(1)_A$ by exactly $2n_f$)**.** Under a $\mathrm{U}(1)_A$ rotation $q \to e^{i\beta\gamma^5} q$, $\bar{q} \to \bar{q}\, e^{i\beta\gamma^5}$, the bilinear $\bar{q}_{Rf} q_{Lg} = \bar{q}_f P_L q_g$ transforms with a definite phase. Using $\gamma^5 P_L = -P_L$ and $P_L \gamma^5 = -P_L$,

$$\bar{q}_f P_L q_g \;\to\; \bar{q}_f\, e^{i\beta\gamma^5} P_L\, e^{i\beta\gamma^5} q_g = \bar{q}_f\, e^{-i\beta} P_L\, e^{-i\beta} q_g = e^{-2i\beta}\, \bar{q}_f P_L q_g, \tag{42.188}$$

so each of the n_f factors in $\det(\bar{q}_{Rf} q_{Lg})$ carries axial charge -2, and the product carries $-2n_f$:

$$\det_{f,g}(\bar{q}_{Rf} q_{Lg}) \;\to\; e^{-2in_f\beta} \det_{f,g}(\bar{q}_{Rf} q_{Lg}). \tag{42.189}$$

The 't Hooft vertex is therefore *not* $\mathrm{U}(1)_A$-invariant: it shifts by a phase $e^{-2in_f\beta}$. This is exactly the violation predicted by the integrated anomaly: a single instanton ($Q = 1$) changes the axial charge by $\Delta Q_5 = 2n_f$ from Eq. (42.172),

and an operator that changes Q_5 by $2n_f$ must carry $\mathrm{U}(1)_A$ charge $2n_f$. The two numbers agree because they are the same number computed two ways — once from the anomalous divergence of the current, once from the zero modes that the same anomaly forces into the background. Note also that an axial rotation can be absorbed by a shift of θ: comparing Eq. (42.189) with the $e^{i\theta}$ in Eq. (42.187), a rotation by β is undone by $\theta \to \theta + 2n_f\beta$. The anomaly thus says explicitly that θ is not separately physical from the quark phases — the observation that hands the strong-CP problem to Section 42.7.

Worked Example 42.40 (The one-flavor and two-flavor cases)**.** For $n_f = 1$ the determinant is a single bilinear and the vertex is

$$\mathcal{L}^{(n_f=1)}_{\text{'t Hooft}} = \int \mathrm{d}\rho\, d(\rho)\,[e^{i\theta}\,\bar{q}_R q_L + e^{-i\theta}\,\bar{q}_L q_R] = \int \mathrm{d}\rho\, d(\rho)\,\bar{q}\,(\cos\theta + i\sin\theta\,\gamma^5)q, \tag{42.190}$$

a quark *mass* term generated entirely by instantons. A single massless flavor thus has its $\mathrm{U}(1)_A$ broken by an effective mass $\sim d(\rho)$, and the θ dependence is rotated into the phase of that mass — in one-flavor QCD θ is unobservable precisely because this single phase can be removed by a field redefinition. For $n_f = 2$ the vertex is a four-fermion interaction,

$$\mathcal{L}^{(n_f=2)}_{\text{'t Hooft}} \sim \int \mathrm{d}\rho\, d(\rho)\, e^{i\theta}\,[(\bar{u}_R u_L)(\bar{d}_R d_L) - (\bar{u}_R d_L)(\bar{d}_R u_L)] + \text{h.c.}, \tag{42.191}$$

the antisymmetric flavor combination of two left-to-right quark flips. It is this operator — not a quark mass, which two flavors do not generate from a single instanton — that lifts the would-be ninth Goldstone, as we now explain.

42.6.5 Resolution of the $U(1)_A$ problem

We can now state the resolution cleanly. Goldstone's theorem (Theorem 29.11) produces a massless boson for every *spontaneously broken* generator of an *exact* continuous symmetry. Its hypotheses require the broken charge to be conserved, $\partial_\mu j^\mu = 0$, so that the current creates a one-particle massless state from the vacuum (the coupling Eq. (29.87)). The singlet axial current fails this hypothesis: by Eq. (42.171) it is not conserved, $\partial_\mu j_5^\mu = 2n_f q(x) \neq 0$, in any background of nonzero topological density. $\mathrm{U}(1)_A$ is not a symmetry of the quantum theory — it is anomalous — and Goldstone's theorem simply does not apply to it. There is no ninth Goldstone because there is no ninth symmetry. The η' is heavy because the would-be symmetry protecting it does not exist.

It is worth being precise about a tempting evasion, because seeing why it fails is what makes the resolution airtight. The anomaly is a total derivative: the topological density is $q(x) = \partial_\mu K^\mu$, with K^μ the Chern–Simons current of Eq. (42.31). One might therefore define a *modified* singlet current

$$\tilde{j}_5^\mu = j_5^\mu - 2n_f K^\mu, \qquad \partial_\mu \tilde{j}_5^\mu = 0, \tag{42.192}$$

which is exactly conserved and seems to restore a good $\mathrm{U}(1)_A$. The catch is that K^μ is *not gauge invariant*: under a large gauge transformation it shifts by a total derivative whose integral is the winding number, so the conserved charge $\tilde{Q}_5 = \int \mathrm{d}^3x\, j_5^0$ is not gauge invariant either, changing by $2n_f$ across configurations of unit winding. A conserved but gauge-variant charge does not generate a physical symmetry: it does not commute with the (gauge-invariant) physical Hilbert space in the way Goldstone's theorem requires, and the "Goldstone boson" it would create is a gauge artifact removed by the very large gauge transformations that build the θ-vacuum. Equivalently, the matrix element $\langle 0|j_5^\mu|\eta'\rangle$ that would signal a Goldstone is saturated, through the anomaly, by the θ-vacuum's sensitivity to topology rather than by a massless pole. The instanton is the configuration that realizes this: it is precisely because configurations of different winding contribute — the same fact that made θ physical — that the naive conservation law Eq. (42.192) has no physical content. *The anomaly and the topology are two faces of one mechanism, and that mechanism is what lifts the η'.*

Physical Insight: Why this is special to the singlet

The octet pions, kaons, and η are protected by $\mathrm{SU}(n_f)_A$, whose currents have *no* anomaly with the color field: the anomaly coefficient $\mathrm{tr}(T^a_{\text{flavor}})$ vanishes for the traceless $\mathrm{SU}(n_f)$ generators, leaving only the singlet $\mathrm{tr}(\mathbf{1}) = n_f$ in Eq. (42.171). So the octet symmetries are genuine, spontaneously broken, and produce genuine (pseudo-)Goldstones; only the singlet axial symmetry is destroyed by the anomaly. This is why exactly one pseudoscalar — the flavor singlet — is anomalously heavy, and why the η' and not, say, the π^0 is the odd one out.

42.6.6 The η' mass: the Witten–Veneziano relation

Saying the η' is heavy because $\mathrm{U}(1)_A$ is anomalous is qualitatively complete, but one wants a number, and the cleanest quantitative statement is the Witten–Veneziano relation. It expresses the η' mass in terms of the topological susceptibility of *pure* Yang–Mills theory — the same χ_t of Eq. (42.162), computed in the gauge theory with the quarks switched off. The relation is exact only in the large-N limit, and we present both the result and the assumptions honestly.

The argument rests on a clash between two facts about the topological susceptibility. First, in *full* QCD with light quarks, the susceptibility vanishes in the chiral limit. This is the field-theoretic content of Eq. (42.184): massless quarks screen topological charge completely, because the zero modes force the determinant to zero in every $Q \neq 0$ sector, so the weighted average $\langle Q^2\rangle \to 0$. The anomalous chiral Ward identity for the singlet current makes this quantitative;

to leading order in the quark masses,

$$\chi_t^{\mathrm{QCD}} = \Big(\sum_{f=1}^{n_f} \frac{1}{m_f}\Big)^{-1} \big(-\langle \bar{q}q \rangle\big) + \cdots \xrightarrow[m_f \to 0]{} 0, \tag{42.193}$$

linear in the (harmonic mean of the) quark masses and vanishing when any quark is massless. Second, in *pure* Yang–Mills the susceptibility is nonzero, $\chi_t^{\mathrm{YM}} \neq 0$: with no quarks there are no zero modes to kill the topological sectors, and the θ-vacuum has genuine curvature. The Witten–Veneziano insight is that the gap between these two — a nonzero quenched susceptibility versus a vanishing full one — must be bridged by a hadronic state that becomes light as $N \to \infty$, and that state is the η'. Matching the η' pole contribution to the susceptibility against χ_t^{YM} gives

$$\boxed{m_{\eta'}^2 = \frac{2n_f}{f_\pi^2}\,\chi_t^{\mathrm{YM}}} \qquad \text{(chiral limit, leading order in } 1/N\text{)}. \tag{42.194}$$

The large-N scaling is what makes this consistent and what tells us how big the effect is. In 't Hooft's counting (g^2N fixed as $N \to \infty$), the pion decay constant scales as $f_\pi^2 = O(N)$, while the pure-glue susceptibility is $\chi_t^{\mathrm{YM}} = O(N^0)$ (the vacuum energy is $O(N^2)$ but its dependence on θ/N makes the second derivative at $\theta = 0$ order one). Therefore

$$m_{\eta'}^2 = \frac{2n_f}{f_\pi^2}\,\chi_t^{\mathrm{YM}} = O\Big(\frac{n_f}{N}\Big) \xrightarrow[N\to\infty]{} 0. \tag{42.195}$$

At infinite N the anomaly is $1/N$-suppressed (it is a one-loop effect, $\sim g^2 \sim 1/N$), $\mathrm{U}(1)_A$ is effectively restored, and the η' rejoins the octet as a ninth Goldstone. At finite $N = 3$ it is lifted by an amount controlled by the gauge dynamics alone. This is the precise sense in which "the η' is heavy because of the anomaly": its mass^2 is proportional to the anomaly's strength, which is $1/N$, times the gauge theory's topological activity χ_t^{YM}.

Worked Example 42.41 (The η' mass from χ_t)**.** Take $n_f = 3$ and the quenched topological susceptibility from the lattice, $\chi_t^{\mathrm{YM}} \approx (180\,\mathrm{MeV})^4$, with the pion decay constant in the normalization $f_\pi \approx 86\,\mathrm{MeV}$ used in Eq. (42.194) (this is the chiral-limit decay constant F_π; conventions for f_π differ by $\sqrt{2}$—the alternative normalization $f_\pi \approx 130\,\mathrm{MeV}$ corresponds to $f_\pi/\sqrt{2} \approx 92\,\mathrm{MeV}$—and one must keep Eq. (42.194) and the input consistent). Then

$$m_{\eta'}^2 = \frac{2 \times 3}{(86\,\mathrm{MeV})^2}\,(180\,\mathrm{MeV})^4 = \frac{6 \times (1.05 \times 10^9)}{7.4 \times 10^3}\,\mathrm{MeV}^2 \approx 8.5 \times 10^5\,\mathrm{MeV}^2,$$

so $m_{\eta'} \approx 9.2 \times 10^2\,\mathrm{MeV} \approx 920\,\mathrm{MeV}$, against the measured $958\,\mathrm{MeV}$. The agreement to within ten percent — the size of the leading $1/N$ correction one

expects — is the quantitative vindication of the picture: the η' mass is not a chiral-symmetry effect at all (it survives the chiral limit) but a measure of the topological activity of the gluon vacuum, the same activity the instanton makes visible. A more complete treatment combines the singlet with the η through the relation $m_{\eta'}^2 + m_\eta^2 - 2m_K^2 = (2n_f/f_\pi^2)\chi_t^{\rm YM}$, which incorporates the octet–singlet mixing induced by the strange-quark mass and is satisfied at a comparable level of accuracy.

Caution: What the Witten–Veneziano relation does and does not assume

The relation Eq. (42.194) is not a low-energy theorem of QCD in the sense the Gell-Mann–Oakes–Renner relation is. It is exact only at leading order in $1/N$, it uses the *quenched* (pure-glue) susceptibility as an external input rather than computing it, and the matching of the η' pole assumes the η' saturates the relevant spectral function — an approximation that the same large-N limit justifies but that receives corrections at $N = 3$. Its enduring value is conceptual: it shows, in a controlled limit, that the entire η' mass comes from the topological structure of the gauge vacuum and vanishes when that structure is switched off, turning the qualitative resolution of the $U(1)_A$ problem into a checkable number. The dilute-instanton-gas estimate of χ_t from Section 42.5 gives the right order of magnitude but, as warned there, is not under quantitative control in QCD; the lattice value used above is.

The thread that runs through this section — the integrated anomaly $\Delta Q_5 = 2n_f Q$, the zero modes it forces, the 't Hooft vertex they generate, and the η' mass that results — has a final consequence we have already glimpsed twice and now make the subject of the next section. The same axial rotation that would remove θ from the Lagrangian is anomalous: it does not leave the measure invariant, but shifts θ by the amount Eq. (42.189). There is no field redefinition that rotates θ away while leaving the quark masses real; the physical, rephasing-invariant combination $\bar\theta = \theta + \arg\det M_q$ is observable, and it is constrained by the neutron electric dipole moment to be astonishingly small. That the anomaly which heals the $U(1)_A$ problem simultaneously makes θ physical and impossible to dismiss is precisely the strong-CP problem, to which we turn.

42.7 The Strong-CP Problem and Its Resolutions

The preceding sections forced an unwelcome conclusion. The θ-vacuum (Section 42.4) is a genuine one-parameter family of inequivalent ground states, labelled by an angle θ that weights each topological sector of the Euclidean path integral by $e^{i\theta\nu}$; the instanton is the configuration that interpolates between adjacent sec-

tors and makes the topological term $\frac{g_s^2}{32\pi^2} G^a_{\mu\nu}\widetilde{G}^{a\,\mu\nu}$ — a total derivative, invisible to every classical equation of motion and to every order of perturbation theory — physically consequential. The anomaly is what seals the conclusion: a chiral redefinition of the quark fields can shuffle θ around, but it can never remove it, because the same rotation that erases θ from the gauge sector reinstates it as a phase on the quark mass matrix. We now confront the experimental fact this collides with. The combination that survives all field redefinitions, the *physical* strong-CP angle $\bar{\theta}$, is CP-odd, and a CP-odd parameter in the strong interactions has a sharp, measurable consequence: a permanent electric dipole moment of the neutron. None has been seen, and the resulting bound, $|\bar{\theta}| \lesssim 10^{-10}$, sits in flat contradiction with the expectation — forced on us by the very anomaly that makes $\bar{\theta}$ physical — that $\bar{\theta}$ is a sum of unrelated $\mathcal{O}(1)$ phases. This is the strong-CP problem, the chapter's final and most consequential payoff. We state it precisely, prove the bound, frame it honestly as a naturalness puzzle rather than an inconsistency, and present its leading dynamical resolution, the Peccei–Quinn axion, whose mechanism is built directly on the θ-vacuum energy we computed above.

42.7.1 The physical angle from an anomalous chiral rotation

Write QCD with a general complex quark mass matrix and the topological term explicit. With N_f flavours collected into a column q, and projectors $P_{L,R} = \frac{1}{2}(1 \mp \gamma^5)$,

$$\mathcal{L}_{\rm QCD} = -\tfrac{1}{4} G^a_{\mu\nu} G^{a\,\mu\nu} + \bar{q}\, i\not{D}\, q - (\bar{q}_L\, M\, q_R + \bar{q}_R\, M^\dagger q_L) + \theta_0\, \frac{g_s^2}{32\pi^2}\, G^a_{\mu\nu}\widetilde{G}^{a\,\mu\nu}, \tag{42.196}$$

where M is an arbitrary complex $N_f \times N_f$ matrix in flavour space, $q_{L,R} = P_{L,R} q$, and θ_0 is the bare gauge angle of the θ-vacuum, the same coefficient that multiplies the winding number in Eq. (42.128). The mass term is the only place the theory remembers the Higgs couplings; in the full Standard Model M is the quark mass matrix produced by electroweak symmetry breaking, and $\arg\det M = \arg\det(M_u M_d)$ collects the up- and down-type contributions assembled in Eq. (33.85). Neither θ_0 alone nor $\arg\det M$ alone is observable; the claim of this subsection is that exactly one combination of them is, and we derive it by carrying the anomaly through a chiral rotation explicitly.

A field redefinition that does not touch the gauge sector is a chiral rotation of the quarks. The most general one is $q_L \to V_L q_L$, $q_R \to V_R q_R$ with $V_{L,R} \in \mathrm{U}(N_f)$. Decompose each unitary into its $\mathrm{SU}(N_f)$ part and its overall phase. The non-abelian $\mathrm{SU}(N_f)_L \times \mathrm{SU}(N_f)_R$ part is generated by traceless matrices; its currents have *no* $\mathrm{U}(1)_A$-type colour anomaly, because the anomaly coefficient is proportional to $\mathrm{tr}\, T^a = 0$ for traceless generators. The dangerous piece is

therefore the overall axial phase, the flavour-singlet rotation

$$q \;\longrightarrow\; e^{i\alpha\gamma^5}\, q, \qquad q_L \to e^{-i\alpha} q_L, \quad q_R \to e^{+i\alpha} q_R, \tag{42.197}$$

using $\gamma^5 q_L = -q_L$, $\gamma^5 q_R = +q_R$. We track its two effects.

Effect on the mass term. Under Eq. (42.197), $\bar{q}_L \to e^{+i\alpha}\bar{q}_L$ (the conjugate carries the opposite phase), so

$$\bar{q}_L M q_R \;\longrightarrow\; e^{+i\alpha}\,\bar{q}_L\, M\, e^{+i\alpha} q_R = e^{2i\alpha}\,\bar{q}_L M q_R, \tag{42.198}$$

that is, $M \to e^{2i\alpha} M$, and therefore

$$\arg\det M \;\longrightarrow\; \arg\det M + 2N_f\,\alpha, \tag{42.199}$$

since $\det(e^{2i\alpha} M) = e^{2iN_f\alpha}\det M$ for M an $N_f \times N_f$ matrix.

Effect on the measure. Classically the rotation Eq. (42.197) of massless quarks is a symmetry of the action. Quantum mechanically the fermion path-integral measure is *not* invariant: this is the chiral anomaly in Fujikawa's form (Theorem 36.9). The Jacobian of Eq. (42.197) for the N_f flavours, each in the fundamental of $\mathrm{SU}(3)_c$, is (Eq. (36.69))

$$\mathcal{D}\bar{q}\,\mathcal{D}q \;\longrightarrow\; \mathcal{D}\bar{q}\,\mathcal{D}q\, \exp\Big[-\, 2N_f\, i\,\alpha \int d^4x\, \frac{g_s^2}{32\pi^2}\, G^a_{\mu\nu}\widetilde{G}^{a\,\mu\nu} \Big], \tag{42.200}$$

where the integer N_f counts the flavours running in the anomaly loop and the factor 2 is the same one that appears in the singlet anomaly $\partial_\mu j^\mu_5 = 2N_f \cdot \frac{g_s^2}{32\pi^2} G\widetilde{G}$ of Eq. (36.50). The exponent is, up to the factor i of the Minkowski path integral, precisely a shift of the topological term: comparing with the θ_0-term in Eq. (42.196), the Jacobian Eq. (42.200) is identical to multiplying e^{iS} by $e^{i(-2N_f\alpha)\int (g_s^2/32\pi^2) G\widetilde{G}}$, i.e. to the replacement

$$\theta_0 \;\longrightarrow\; \theta_0 - 2N_f\,\alpha. \tag{42.201}$$

Now combine Eqs. (42.199) and (42.201). The chiral rotation drags $2N_f\alpha$ out of θ_0 and deposits exactly $2N_f\alpha$ into $\arg\det M$. The two moves cancel in the sum, which is therefore inert under any chiral redefinition of the quarks:

$$\boxed{\;\bar{\theta} \;\equiv\; \theta_0 + \arg\det(M_u M_d)\;} \qquad \bar{\theta} \xrightarrow{\;q \to e^{i\alpha\gamma^5} q\;} \bar{\theta}. \tag{42.202}$$

This is the physical strong-CP angle. The lesson is the operational content of the anomaly: θ_0 is not by itself meaningful, because a chiral rotation can set it to any value we please; what is meaningful is the rephasing-invariant combination Eq. (42.202), the same quantity stated in the Standard-Model synthesis at Eq. (33.85) and proved rephasing-invariant there in Theorem 33.16. The derivation here is the one the instanton chapter owes: it shows the cancellation as a direct consequence of the Fujikawa Jacobian, the very object that made θ physical in the first place.

Physical Insight

The cleanest way to see why $\bar{\theta}$ cannot be defined away is to use the freedom Eq. (42.197) to put all of it in *one* place. Rotate until the mass matrix is real and positive ($\arg\det M = 0$); then every trace of CP violation from the masses has been pushed into the gauge angle, which now equals $\bar{\theta}$. Or rotate the other way, until $\theta = 0$; then $\bar{\theta}$ lives entirely as a common phase on the quark masses, an irremovable complex piece of $m_u m_d \cdots$. The physics is the same: a single CP-odd number that the chiral rotation can relocate but not destroy. Only if some quark were exactly massless would the relocation become a removal — with $m_u = 0$ the rotation Eq. (42.197) acting on the up quark alone is a genuine symmetry, costing no mass-term phase, and it rotates $\bar{\theta}$ to zero outright.

42.7.2 The neutron electric dipole moment and the bound on $\bar{\theta}$

That $\bar{\theta}$ is physical would be a curiosity were it not measurable. It is measurable because it is CP-odd, and the sharpest laboratory probe of strong-sector CP violation is the electric dipole moment (EDM) of the neutron. A static EDM d_n of a spin-$\frac{1}{2}$ particle must point along its spin $\mathbf{S}$, the only intrinsic vector available; the interaction energy $-\mathbf{d}\cdot\mathbf{E} = -(d_n/S)\,\mathbf{S}\cdot\mathbf{E}$ is then odd under parity (which flips $\mathbf{E}$ but not $\mathbf{S}$) and odd under time reversal (which flips $\mathbf{S}$ but not $\mathbf{E}$), hence CP-odd by CPT. This is the argument of Fig. 33.4; a nonzero d_n is a clean signal of a fundamental CP-violating parameter, and $\bar{\theta}$ is one.

We estimate $d_n(\bar{\theta})$ with the leading chiral logic. The key structural fact comes straight from Section 42.7.1: rotate θ_0 entirely onto the masses, so that $\bar{\theta}$ appears only as a phase on M. A CP-violating observable must then vanish as any quark mass $\to 0$, because in that limit the corresponding axial rotation removes the phase. At leading order in two-flavour chiral perturbation theory the relevant combination is the reduced mass

$$m_* \;\equiv\; \frac{m_u m_d}{m_u + m_d}, \tag{42.203}$$

which vanishes if *either* light quark is massless. The $\bar{\theta}$-term, transcribed into the chiral Lagrangian of Section 39.2, induces a CP-odd pion–nucleon coupling — a πNN vertex *without* the γ^5 that the ordinary, CP-conserving coupling $g_{\pi NN}$ carries:

$$\mathcal{L}_{\pi NN} = g_{\pi NN}\,\bar{N}\,i\gamma^5\,\boldsymbol{\tau}\cdot\boldsymbol{\pi}\,N \;+\; \bar{g}_{\pi NN}\,\bar{N}\,\boldsymbol{\tau}\cdot\boldsymbol{\pi}\,N, \qquad \bar{g}_{\pi NN} \simeq \bar{\theta}\,\frac{m_*}{f_\pi}\,c_N, \tag{42.204}$$

where $c_N = \mathcal{O}(1)$ is fixed by the same chiral SU(3) analysis that reproduces the baryon mass splittings. The current-algebra evaluation of Crewther, Di Vecchia,

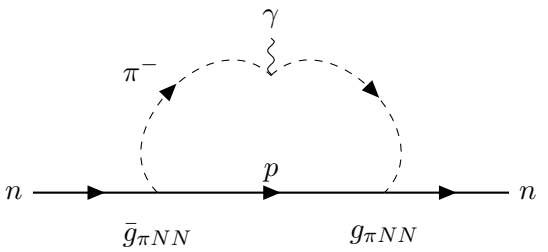

Figure 42.8: The leading chiral contribution to the neutron electric dipole moment from $\bar{\theta}$. The neutron's charged-pion cloud is dressed by a photon attaching to the π^- line. One pion–nucleon vertex is the ordinary CP-conserving coupling $g_{\pi NN}$; the other is the CP-odd coupling $\bar{g}_{\pi NN} \propto \bar{\theta}\, m_*/f_\pi$ of Eq. (42.204). The loop is logarithmically divergent in the chiral limit, cut off at the nucleon mass, producing the chiral logarithm $\ln(m_N/m_\pi)$.

Veneziano and Witten gives $\bar{g}_{\pi NN} \approx 0.027\,\bar{\theta}$ (modern reanalyses cluster around 0.015–$0.020\,\bar{\theta}$); we carry the classic value. The neutron EDM is then generated by the pion cloud: the neutron emits a π^- to become a proton at one vertex, the photon attaches to the charged pion, and the pion is reabsorbed at the other vertex, with *one* CP-even vertex $g_{\pi NN}$ and *one* CP-odd vertex $\bar{g}_{\pi NN}$. Figure 42.8 shows the diagram.

Worked Example 42.42 (The chiral-loop estimate of $d_n(\bar{\theta})$ and the bound)**.** We extract the size and the bound from Fig. 42.8.

Step 1: dimensional skeleton. An EDM operator is $\mathcal{L}_{\rm EDM} = -\frac{i}{2}\, d_n\, \bar{N}\sigma_{\mu\nu}\gamma^5 N\, F^{\mu\nu}$; d_n has dimension (charge)×(length), i.e. e/mass in natural units. The loop carries two pion–nucleon couplings (one of each parity), one factor of e from the photon on the charged pion, and a one-loop factor $1/16\pi^2$. The only mass available to make d_n dimensionful is the nucleon mass m_N running in the line. Thus

$$d_n \;\sim\; \frac{e}{m_N}\,\frac{g_{\pi NN}\,\bar{g}_{\pi NN}}{16\pi^2} \times (\text{loop integral}). \tag{42.205}$$

Step 2: the chiral logarithm. The loop momentum integral $\int d^4k$ over the pion propagators and the photon attachment is, after extracting the EDM form factor, logarithmically divergent as $m_\pi \to 0$. In the chiral effective theory the divergence is cut off at the scale where the nucleon can no longer be treated as static, $\Lambda_\chi \sim m_N$, and the infrared scale is the pion mass. The integral therefore delivers a factor $\propto \ln(m_N/m_\pi)$ — the hallmark chiral logarithm, the model-independent piece of the loop. Collecting the standard coefficient,

$$d_n \;=\; \frac{e\, g_{\pi NN}\,\bar{g}_{\pi NN}}{4\pi^2\, m_N}\,\ln\frac{m_N}{m_\pi}. \tag{42.206}$$

Step 3: numbers. Use $g_{\pi NN} \approx 13.5$, $\bar{g}_{\pi NN} \approx 0.027\,\bar{\theta}$, $m_N \approx 0.94$ GeV,

$\ln(m_N/m_\pi) = \ln(940/138) \approx 1.9$. Then

$$d_n \approx \frac{(13.5)(0.027)}{4\pi^2}\,\frac{1.9}{0.94\ \text{GeV}}\,e\,\bar\theta = 2.0\times10^{-2}\ \text{GeV}^{-1}\,e\,\bar\theta. \tag{42.207}$$

Converting with $1\ \text{GeV}^{-1} = 1.97\times10^{-14}$ cm,

$$d_n \;\approx\; 4\times10^{-16}\,\bar\theta\ \ e{\cdot}\text{cm}, \tag{42.208}$$

consistent with the order-of-magnitude estimate $d_n \sim e\,\bar\theta\,m_q/m_N^2 \sim \bar\theta\times10^{-16}\,e$cm quoted at Eq. (33.86) (the factor m_q/m_N^2 is Eq. (42.203) divided by m_N^2, with the residual numbers absorbed into the chiral coefficients).

Step 4: the bound. The experimental limit on the neutron EDM is $|d_n| < 1.8\times10^{-26}\,e{\cdot}$cm (90% C.L., mid-2020s). Dividing,

$$|\bar\theta| \;\lesssim\; \frac{1.8\times10^{-26}}{4\times10^{-16}} \;\approx\; 5\times10^{-11} \;\sim\; 10^{-10}. \tag{42.209}$$

This is the strong-CP bound, the statement quoted at Eq. (33.87): a dimensionless, marginal, $\mathcal{O}(1)$-natural parameter pinned by experiment below one part in ten billion.

42.7.3 The naturalness puzzle

The bound Eq. (42.209) is a measurement, not a contradiction. Any value of $\bar\theta$ yields a perfectly consistent, unitary, renormalizable theory; nothing is sick about $\bar\theta \neq 0$. The discomfort is one of naturalness, and it has two prongs that must be kept distinct.

First, the two summands in $\bar\theta = \theta_0 + \arg\det(M_u M_d)$ are logically independent. The gauge angle θ_0 is a pure-glue parameter, a property of the θ-vacuum with no reference to flavour; the phase $\arg\det(M_u M_d)$ lives in the Yukawa sector and is controlled by the same complex mass matrices that produce the large, confirmed CP violation of the CKM phase — the source quantified by the Jarlskog invariant of Theorem 32.20, an $\mathcal{O}(1)$ effect seen in kaon and B physics. There is no symmetry relating a glue angle to a Yukawa phase, so their cancellation to ten decimal places is an unexplained conspiracy between two unrelated sectors of the Standard Model.

Second — and this is the prong that distinguishes strong-CP from a mere small number — setting $\bar\theta = 0$ does *not* enlarge the symmetry of the theory. One might hope to protect $\bar\theta = 0$ by CP invariance: $\bar\theta$ is CP-odd, so an exact CP symmetry would forbid it. But CP is already broken, badly, by the CKM phase (Section 32.4); it is not a symmetry of the Standard Model to invoke. A technically natural small parameter, in 't Hooft's sense, is one whose vanishing restores a symmetry, so that quantum corrections to it are proportional to itself and a small value is radiatively stable. The strong-CP angle fails this test: no

symmetry of the Standard Model is recovered at $\bar{\theta} = 0$, and yet there it sits. The number is small, and nothing in the theory makes it so.

It is worth marking how unusual this puzzle is among the Standard Model's structural complaints. The hierarchy problem concerns a *relevant* coupling (the Higgs mass) whose smallness is destabilized by quantum corrections; strong-CP concerns a *marginal*, dimensionless, topological coupling that receives only tiny radiative shifts — the CKM phase feeds into $\bar{\theta}$ only at high loop order, contributing $\delta\bar{\theta} \sim 10^{-16}$, far below the bound. So $\bar{\theta}$ is not destabilized; it is simply unexplained. The problem is the value, not its stability. That is precisely why strong-CP, alone among the naturalness puzzles, admits a clean dynamical cure: there is room for a mechanism that drives $\bar{\theta}$ to its special value without any fine-tuning, because the special value is not under radiative attack.

42.7.4 Resolutions

The massless up quark (disfavoured, dated). The escape hatch is already visible in the structure of $\bar{\theta}$. If any single quark were exactly massless, the axial rotation Eq. (42.197) acting on that flavour alone would be an exact symmetry — there would be no mass-term phase for it to disturb — and it could rotate $\bar{\theta}$ to zero at no physical cost. The light up quark is the natural candidate: $m_u = 0$ would solve strong-CP outright, with no new fields and no new symmetry imposed by hand. The proposal was viable for years because m_u is small and the relevant matrix element ambiguous. It is now disfavoured. Lattice QCD determines the light-quark mass ratio cleanly, $m_u/m_d \approx 0.47$ with $m_u \approx 2.2$ MeV several standard deviations from zero (FLAG averages, mid-2020s); the up quark is light but firmly massive. The susceptibility that controls the whole problem, $\chi_{\text{top}} \propto m_u m_d/(m_u + m_d)^2$ (the two-flavour result of Eq. (35.82)), is the same combination Eq. (42.203) and would vanish only at $m_u = 0$; lattice says it does not vanish, and the escape is closed.

The Peccei–Quinn axion (the leading resolution). The remaining strategy is to make $\bar{\theta}$ *dynamical*. If the constant $\bar{\theta}$ is replaced by a field that can relax to the bottom of the vacuum-energy curve $E(\theta)$, the field will roll to wherever E is minimized, and we already know where that is. The construction rests on a single structural fact about the θ-vacuum, which the instanton machinery of this chapter establishes directly.

The θ-dependence of the vacuum energy density is defined by the Euclidean partition function in a four-volume V_4, with the topological term carrying the factor i characteristic of a continued total-derivative term,

$$e^{-V_4\,E(\theta)} = \int \mathcal{D}A\,\mathcal{D}q\,\mathcal{D}\bar{q}\;\exp\Big(-S_E + i\theta\int d^4x\,\frac{g_s^2}{32\pi^2}G\widetilde{G}\Big) = \big\langle e^{i\theta\nu}\big\rangle_0\, e^{-V_4 E(0)}, \tag{42.210}$$

where $\nu = \frac{g_s^2}{32\pi^2}\int G\widetilde{G} \in \mathbb{Z}$ is the integer winding number of Theorem 41.10 and $\langle\cdot\rangle_0$ is the expectation in the $\theta = 0$ ensemble. Two exact properties follow. Because ν is an integer, $E(\theta)$ is periodic with period 2π. And because the $\theta = 0$ measure is real and positive in a vector-like theory while $e^{i\theta\nu}$ is a pure phase, $|\langle e^{i\theta\nu}\rangle_0| \le 1$, so

$$E(\theta) \;\ge\; E(0) \qquad \text{for all } \theta. \tag{42.211}$$

This is the Vafa–Witten result: in QCD the vacuum energy is globally minimized at $\theta = 0$, with positive curvature there. The curvature is the topological susceptibility $\chi_{\text{top}} = E''(0) = \langle\nu^2\rangle/V_4 \ge 0$ of Eq. (42.162). In the dilute-instanton-gas approximation (Section 42.4), where the partition function is dominated by independent single (anti-)instantons each contributing a factor $e^{\pm i\theta}$, the cumulant sum exponentiates to the simple periodic form

$$E(\theta) \;=\; E(0) - \chi_{\text{top}}(\cos\theta - 1) \;+\; \cdots \;=\; E(0) + \tfrac{1}{2}\chi_{\text{top}}\,\theta^2 + \mathcal{O}(\theta^4), \tag{42.212}$$

a convex well at the CP-conserving point. (The full chiral-Lagrangian computation softens $-\cos\theta$ into the more accurate $\sqrt{m_u^2 + m_d^2 + 2m_u m_d\cos\theta}$ form derived in Theorem 35.7; the curvature at the origin, χ_{top}, is the same.) The well in Fig. 42.9 is all the Peccei–Quinn mechanism needs.

The mechanism promotes θ to a field. Postulate a global $\mathrm{U}(1)_{\text{PQ}}$ symmetry that is (i) spontaneously broken at a large scale f_a, delivering a Goldstone boson a — the *axion* — with a shift symmetry $a \to a + \text{const}$, and (ii) colour-anomalous, so that the anomaly Eq. (42.200) ties the shift of a to a shift of the effective θ-angle. Then the axion enters QCD in exactly the slot occupied by $\bar\theta$: the coefficient of $\frac{g_s^2}{32\pi^2}G\widetilde{G}$ becomes

$$\theta_{\text{eff}} \;=\; \bar\theta + \frac{a}{f_a}. \tag{42.213}$$

The shift symmetry guarantees that a appears only through this combination, so the constant $\bar\theta$ can be absorbed into the origin of a. What value a takes is not free, however, because θ_{eff} is physical and QCD generates a potential for it. Integrating out the gluons, the axion potential is nothing but the vacuum energy Eq. (42.212) evaluated at the dynamical argument:

$$V(a) \;=\; E\Big(\bar\theta + \frac{a}{f_a}\Big) \;\simeq\; -\,\chi_{\text{top}}\cos\Big(\bar\theta + \frac{a}{f_a}\Big). \tag{42.214}$$

Worked Example 42.43 (Relaxation of $\bar\theta$ and the axion mass)**.** *Step 1: minimize.* The potential Eq. (42.214) is stationary where

$$\frac{dV}{da} = \frac{\chi_{\text{top}}}{f_a}\,\sin\Big(\bar\theta + \frac{a}{f_a}\Big) = 0, \tag{42.215}$$

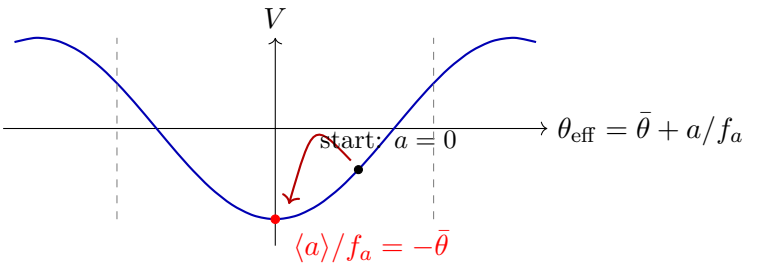

Figure 42.9: The axion potential $V(a) = -\chi_{\text{top}} \cos(\bar{\theta} + a/f_a)$ of Eq. (42.214), the QCD vacuum-energy curve Eq. (42.212) read as a function of the dynamical field. Whatever the bare $\bar{\theta}$ (the field begins at $a = 0$, where $\theta_{\text{eff}} = \bar{\theta} \neq 0$), the axion rolls to the minimum at $\theta_{\text{eff}} = 0$, i.e. $\langle a \rangle = -f_a \bar{\theta}$, switching off strong CP. The curvature at the minimum is the axion mass-squared, $m_a^2 = \chi_{\text{top}}/f_a^2$.

and, since $\chi_{\text{top}} > 0$ by Eq. (42.211), the minimum (not the maximum) is the solution with $\cos(\cdots) = +1$, namely

$$\left\langle \frac{a}{f_a} \right\rangle = -\bar{\theta} \qquad \Longrightarrow \qquad \theta_{\text{eff}}\big|_{\text{vac}} = \bar{\theta} + \left\langle \frac{a}{f_a} \right\rangle = 0. \tag{42.216}$$

The axion field rolls until the *effective* strong-CP angle is exactly zero, whatever the bare $\bar{\theta}$ was. Strong CP is not tuned away; it is dynamically relaxed away. The residual neutron EDM is set by θ_{eff}, driven to zero up to the negligible electroweak feed-through $\delta\theta_{\text{eff}} \sim 10^{-16}$, well below the bound Eq. (42.209).

Step 2: the mass. The same potential that relaxes $\bar{\theta}$ gives the axion a mass — it is a pseudo-Goldstone boson, massless only in the absence of the QCD anomaly. The mass is the curvature at the minimum:

$$m_a^2 = \frac{d^2 V}{da^2}\bigg|_{\text{min}} = \frac{\chi_{\text{top}}}{f_a^2} \cos(0) = \frac{\chi_{\text{top}}}{f_a^2}, \qquad \Longrightarrow \qquad \boxed{m_a = \frac{\chi_{\text{top}}^{1/2}}{f_a}} \tag{42.217}$$

The axion mass is fixed entirely by the QCD topological susceptibility and the breaking scale; everything model-dependent has dropped out. Inserting the two-flavour value $\chi_{\text{top}} = f_\pi^2 m_\pi^2 \, m_u m_d/(m_u + m_d)^2$ of Eq. (35.82) reproduces the numerical mass–coupling relation $m_a \approx 5.7 \ \mu\text{eV} \, (10^{12}\,\text{GeV}/f_a)$ computed in full at Theorem 35.7.

Equation Eq. (42.217) is the signature of the solution: the axion mass scales *inversely* with the symmetry-breaking scale. A high f_a means a very light, very weakly coupled axion — every coupling, being that of a pseudo-Goldstone, is suppressed by $1/f_a$. This is what makes the axion at once an economical fix for strong-CP and a distinctive experimental target: not a heavy particle for a collider but an ultralight, feebly interacting relic. And that relic is a leading dark-matter candidate. In the early universe the field is frozen at a

random misalignment $\theta_{\text{eff}} = \theta_i$ until the topological susceptibility switches on near Λ_{QCD} (Theorem 27.14); the coherent oscillations of the field about the minimum Eq. (42.216) are a cold, pressureless condensate — cold dark matter produced by the very mechanism that solves strong-CP.

Alternatives (honest scope). The axion is the leading but not the only proposal. A second class spontaneously breaks CP at a high scale and arranges the vacuum so that $\theta_0 = 0$ is enforced by the symmetry while the observed CKM phase arises from the breaking — the Nelson–Barr mechanism, which trades the axion for a structured, often baroque, flavour sector and the burden of keeping radiative corrections to $\bar{\theta}$ below 10^{-10}. The massless-up-quark option is, as noted, disfavoured by the lattice. As of the mid-2020s no resolution is experimentally confirmed: the axion remains a hypothesis under active search, and strong-CP remains, strictly, an open problem with a compelling but unverified favourite.

This closes the chapter. We have carried Yang–Mills theory to its full non-perturbative reach — classical Yang–Mills and the Wilson loop, the Faddeev–Popov and BRST quantization, asymptotic freedom, the monopoles of Chapter 41, and here the instanton, the θ-vacuum, the resolution of the $\mathrm{U}(1)_A$ problem, and the strong-CP problem it exposes — and we have shown that an entire layer of physics, weighted by $e^{-8\pi^2/g^2}$ and invisible to every order of perturbation theory, reorganizes the vacuum. The model-building of the strong-CP problem and its axion — the KSVZ and DFSZ realizations of $\mathrm{U}(1)_{\text{PQ}}$ (Section 35.4.5) and the cosmology of the misalignment relic abundance (Section 35.6) — is the province of the BSM chapter (Section 35.4), and the broader naturalness landscape that of the frontier survey of Chapter 57.

Further reading

The instanton was discovered as a self-dual Yang–Mills solution by Belavin et al. [55], and its quantum effects—the collective-coordinate measure, the running-coupling size integral, and the multi-fermion vertex—were computed in 't Hooft [464]. The definitive pedagogical account remains Coleman's Erice lectures [128], reprinted in his collected lectures [129]; a comprehensive modern review of the instanton calculus and its phenomenology is Schäfer and Shuryak [428]. The resolution of the $U(1)_A$ problem in the large-N limit and the η' mass formula are due to Witten [518] and Veneziano [486]. For the strong-CP problem and its resolutions: the Peccei–Quinn mechanism is Peccei and Quinn [388, 389] with the axion identified by Weinberg [497] and Wilczek [511], and the invisible-axion models are KSVZ [294] and DFSZ [149]; the Vafa–Witten theorem that CP is unbroken in vector-like QCD is Vafa and Witten [480]; the chiral estimate of the neutron electric dipole moment is Crewther et al. [140], with the current

experimental bound from Abel et al. [2] and the light-quark masses that close the $m_u = 0$ option reviewed in Aoki and others [27].

Chapter 43

Lattice Field Theory

Every regulator in this book so far has been provisional. Dimensional continuation, Pauli–Villars masses, the Wilsonian momentum shell — each tamed the ultraviolet long enough to extract a finite answer, and each was meant to be removed at the end. None of them is a *definition* of a quantum field theory: each presupposes the perturbative expansion it regulates, and that expansion, as the Borel analysis of Chapter 5 made plain, is at best asymptotic. It does not sum to a function, and it is blind to the one phenomenon that organizes the strong interaction, confinement. The recurring question of the book — what *is* an interacting quantum field theory, exactly, beyond a recipe for a divergent series? — has so far been deferred. This chapter answers it. Following Wilson, we place the theory on a finite hypercubic Euclidean lattice, where the path integral becomes an ordinary, manifestly convergent, finite-dimensional integral, and we ask what survives as the spacing is sent to zero.

The construction draws together threads from across the book. The Euclidean path integral and the statistical-mechanical reading of e^{-S_E} as a Boltzmann weight are imported from Chapter 10; Grassmann integration and the fermion determinant from Chapter 12; the gauge connection, curvature, and Wilson loop from Chapter 25; and the entire language of the continuum limit — relevant couplings, the critical surface, flow into a renormalization-group fixed point — from the Wilsonian picture of Chapter 23 and the beta functions of Chapter 24. The decisive physical input is the asymptotic freedom of Chapter 27, which is what allows a four-dimensional non-abelian gauge theory to be defined all the way to zero spacing. The representation-theoretic vocabulary of Chapter 2 runs throughout, and the chiral anomaly of Chapter 36 reappears, unexpectedly, as the obstruction that makes lattice fermions hard.

The arc is the following. We first build the lattice as a constructive regulator and show that the discretized measure is genuinely finite, that it carries a positive transfer matrix and hence reconstructs a Hamiltonian, and that reflection positivity is the lattice shadow of the Osterwalder–Schrader axioms (Section 43.1).

We then study the scalar in detail and learn the central lesson of the subject: the continuum limit is not a naive $a \to 0$ but the approach to a second-order critical point, an RG fixed point at which the correlation length in lattice units diverges (Section 43.2). With the framework fixed, we turn to gauge fields, where the gauge potential is replaced by group-valued link variables and exact gauge invariance is achieved with no gauge fixing at all (Section 43.3); the payoff is the first analytic proof of confinement, the strong-coupling area law and its linear potential (Section 43.4).

Fermions are the hard case, and we treat them honestly. Naively discretized, a single Dirac field becomes sixteen, and the Nielsen–Ninomiya theorem shows this doubling is no accident but a topological necessity tied to the anomaly (Section 43.5). We survey the responses — Wilson's explicit symmetry breaking, staggered fermions, and the Ginsparg–Wilson relation that restores an exact lattice chiral symmetry through overlap and domain-wall constructions (Section 43.6). We then show what the finished machine actually delivers: expectation values as Monte Carlo ensemble averages, masses read off the spectral decomposition of Euclidean correlators, and the controlled removal of the cutoff by asymptotic scaling (Section 43.7). The chapter closes by assembling these pieces into a single claim and weighing it carefully: the lattice is, as of the mid-2020s, the only known fully non-perturbative, gauge-invariant definition of an interacting quantum field theory — and we separate cleanly what it has *proved* from what it has only *computed*, ending on the frontiers where the definition itself is still being built (Section 43.8).

43.1 The Euclidean lattice as a constructive regulator

The chapter introduction made a promise that the rest of the book has earned but never quite cashed: that after the Wick rotation of Chapter 10 the weight e^{-S_E} is not a formal device but a genuine positive measure, so that a quantum field theory is, in disguise, a problem in classical statistical mechanics. We saw there (Section 10.6) that the rotated generating functional

$$Z_E = \int \mathcal{D}\phi \, e^{-S_E[\phi]} \tag{43.1}$$

has a positive, bounded integrand, with none of the conditional-convergence delicacy of the Minkowski e^{iS}. What we did *not* do there is say what the symbol $\int \mathcal{D}\phi$ means. It is a product of uncountably many ordinary integrals, one for each point of spacetime, and as written it is not a mathematical object at all. Every manipulation we have performed on it—completing the square, expanding $e^{-S_{\text{int}}}$ in a perturbation series, Legendre-transforming—has been a manipulation of a symbol whose existence we postponed.

The lattice discharges that debt in the most direct way imaginable: it replaces continuous spacetime by a finite grid of points, so that $\int \mathcal{D}\phi$ becomes

a finite-dimensional integral over $\mathbb{R}^V$ that any first course in analysis certifies as convergent. There is no other regulator, no $i\varepsilon$, no analytic continuation in dimension, no subtraction of infinities—the integral is simply finite because it is an ordinary integral over finitely many real variables. This is the sense in which the lattice is not a numerical approximation bolted onto a pre-existing theory but a *definition* of one. The continuum theory, when it exists, will be recovered as a limit of these honest integrals; until then, the lattice integral is the only fully non-perturbative thing on the table that we are entitled to call "the theory."

We carry out the construction for ϕ^4 theory: the same single real scalar with the Lagrangian frozen in Chapter 6 and quantized perturbatively in Chapter 9, now defined with no reference to perturbation theory at all. The Euclidean action is the one fixed in Theorem 10.27, Eq. (10.161). The goals of this section are four, and they are exactly the things every later section will lean on. First, to define the lattice, its fields, and its measure precisely. Second, to read off the dictionary that turns e^{-S_E}/Z into a Boltzmann distribution and the theory into statistical mechanics. Third, to prove that the resulting integral is finite—that the lattice is a complete ultraviolet regulator—for the massive scalar. Fourth, and most importantly, to reconstruct from the lattice integral a Hilbert space and a Hamiltonian: to build the transfer matrix T, prove it is a positive self-adjoint operator, and exhibit $T = e^{-aH}$, so that the statistical system genuinely *is* a quantum theory in imaginary time. Reflection (Osterwalder–Schrader) positivity, stated in general in Theorem 10.32, is what makes this reconstruction possible, and we prove it for the lattice scalar.

43.1.1 The hypercubic Euclidean lattice

We work in four Euclidean dimensions; the construction is identical in any number. Continuous spacetime $\mathbb{R}^4$ is replaced by a finite, regular grid.

Definition 43.1 (Hypercubic Euclidean lattice)**.** Fix a length $a > 0$, the *lattice spacing*, and an integer N, the number of sites per direction; the *physical extent* is $L = Na$. The *lattice* is the finite set of *sites*

$$\Lambda = \{\, n = (n_0, n_1, n_2, n_3) \;:\; n_\mu \in \{0, 1, \dots, N-1\} \,\}, \qquad x_\mu = a\, n_\mu, \tag{43.2}$$

identified pairwise across opposite faces, $n_\mu \equiv n_\mu + N$ (periodic boundary conditions), so that Λ is a discrete four-torus with $V = N^4$ sites. Let $\hat{\mu}$ denote the unit vector in direction μ. The ordered pairs $(n, n+\hat{\mu})$ of nearest-neighbour sites are the *links*; the elementary squares spanned by two directions, with corners $\{n,\ n+\hat{\mu},\ n+\hat{\nu},\ n+\hat{\mu}+\hat{\nu}\}$, are the *plaquettes*. A (real scalar) *field configuration* is a map $\phi : \Lambda \to \mathbb{R}$, written ϕ_n, an element of the finite-dimensional space $\mathbb{R}^V$.

The site/link/plaquette vocabulary is not pedantry: it is the skeleton on which every field in this chapter is hung. A scalar lives on sites; a gauge field will

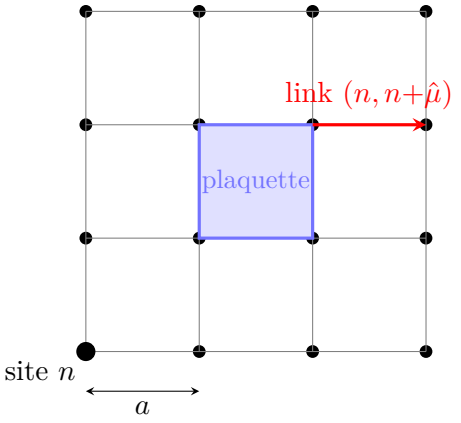

Figure 43.1: A two-dimensional slice of the hypercubic lattice Λ. Sites carry the scalar field ϕ_n; links connect nearest neighbours; the shaded unit square is a plaquette. The spacing a is the only length in the problem and, as Theorem 43.4 shows, plays the role of an ultraviolet cutoff: no fluctuation of wavelength shorter than a exists.

live on links (Section 43.3, where this becomes the whole point); the field strength will live on plaquettes. Figure 43.1 shows the three objects on a two-dimensional slice.

To put dynamics on Λ we need a discrete version of the derivative. The natural choice is the *forward difference*

$$(\partial_\mu^{\mathrm{lat}}\phi)_n := \frac{\phi_{n+\hat{\mu}} - \phi_n}{a}, \tag{43.3}$$

which reduces to $\partial_\mu\phi$ as $a \to 0$ for a smooth field, by Taylor expansion: $\phi_{n+\hat{\mu}} = \phi_n + a\,\partial_\mu\phi + \tfrac{1}{2}a^2\partial_\mu^2\phi + O(a^3)$, so $(\partial_\mu^{\mathrm{lat}}\phi)_n = \partial_\mu\phi + \tfrac{1}{2}a\,\partial_\mu^2\phi + O(a^2)$. The discretization of a continuum action is then obtained by the rule

$$\int \mathrm{d}^4x \;\longmapsto\; a^4 \sum_{n\in\Lambda}, \qquad \partial_\mu\phi \;\longmapsto\; (\partial_\mu^{\mathrm{lat}}\phi)_n, \tag{43.4}$$

which is the obvious Riemann-sum prescription. Applying it to the Euclidean ϕ^4 action of Eq. (10.161) gives the central definition.

Definition 43.2 (Lattice ϕ^4 action)**.** For a configuration $\phi : \Lambda \to \mathbb{R}$, the *lattice action* of ϕ^4 theory is

$$S_E[\phi] = a^4 \sum_{n\in\Lambda} \left[\frac{1}{2} \sum_{\mu=0}^{3} \left(\frac{\phi_{n+\hat{\mu}} - \phi_n}{a} \right)^2 + \frac{1}{2} m^2 \phi_n^2 + \frac{\lambda}{4!}\phi_n^4 \right], \tag{43.5}$$

with $m^2 > 0$ and $\lambda \geq 0$ the same mass and coupling as the continuum theory. Every term is non-negative, so $S_E[\phi] \geq 0$ for all ϕ, and $S_E[\phi] \to +\infty$ as $|\phi| \to \infty$ in $\mathbb{R}^V$.

The non-negativity and the growth at large field, inherited from the all-plus sign structure of the Euclidean action (Eq. (10.161)), are exactly the two properties that will make the integral converge. We isolate them at once.

Definition 43.3 (Lattice measure and partition function)**.** The *lattice measure* is the ordinary product Lebesgue measure on $\mathbb{R}^V$,

$$\mathcal{D}\phi := \prod_{n\in\Lambda} \mathrm{d}\phi_n, \tag{43.6}$$

a finite product of one-dimensional integrals. The *partition function* is

$$Z = \int_{\mathbb{R}^V} \mathcal{D}\phi\, e^{-S_E[\phi]} = \int \Big(\prod_n \mathrm{d}\phi_n\Big)\, e^{-S_E[\phi]}, \tag{43.7}$$

and the *lattice expectation* of an observable $\mathcal{O}[\phi]$ (any function of the field configuration) is

$$\langle \mathcal{O} \rangle = \frac{1}{Z} \int \mathcal{D}\phi\, \mathcal{O}[\phi]\, e^{-S_E[\phi]}. \tag{43.8}$$

This is the whole apparatus. The formal $\int \mathcal{D}\phi$ of Eq. (43.1) has become the genuinely defined $\int_{\mathbb{R}^V} \prod_n \mathrm{d}\phi_n$ of Eq. (43.7); the limit operations of Chapter 10 are now applied to an object that exists. Everything that follows—the dictionary, the finiteness, the Hilbert space—is a property of this finite-dimensional integral.

43.1.2 The Boltzmann dictionary: a quantum field theory as a statistical system

The form of Eq. (43.7) is, letter for letter, that of the partition function of a classical statistical-mechanical system. Compare with the canonical ensemble of a system whose microstates are configurations σ with energy $E[\sigma]$ at inverse temperature $\beta = 1/k_B T$:

$$Z_{\mathrm{stat}} = \sum_{\sigma} e^{-\beta E[\sigma]}, \qquad P[\sigma] = \frac{1}{Z_{\mathrm{stat}}} e^{-\beta E[\sigma]}. \tag{43.9}$$

The correspondence is exact, not a metaphor: the microstate σ is the field configuration $\phi : \Lambda \to \mathbb{R}$; the configuration sum $\sum_\sigma$ is the integral $\int \prod_n \mathrm{d}\phi_n$; the dimensionless energy βE is the Euclidean action $S_E[\phi]$; and the Boltzmann probability of a state is

$$P[\phi] = \frac{e^{-S_E[\phi]}}{Z}. \tag{43.10}$$

That $P[\phi] \geq 0$ and $\int \mathcal{D}\phi\, P[\phi] = 1$ is automatic from $S_E \geq 0$ and the definition of Z; Eq. (43.10) is a bona fide probability density on field space. The lattice expectation Eq. (43.8) is then literally the thermal average $\langle \mathcal{O} \rangle = \int \mathcal{D}\phi\, \mathcal{O}[\phi]\, P[\phi]$. A four-dimensional Euclidean scalar field theory is a four-dimensional classical

statistical-mechanical model with a continuous spin $\phi_n \in \mathbb{R}$ at each site, nearest-neighbour ferromagnetic coupling (the gradient term favours aligned neighbours), and an on-site potential $\frac{1}{2}m^2\phi_n^2 + \frac{\lambda}{4!}\phi_n^4$.

This is the dictionary tabulated abstractly in Table 10.1, now made completely concrete by the discretization: the entries on the statistical-mechanics side are not analogies but the actual ingredients of a well-defined finite system. The single most important entry, the one that organizes the rest of the chapter, is the bottom line of that table:

$$\text{correlation length } \xi \quad \longleftrightarrow \quad \text{inverse mass } 1/m_{\text{phys}}. \tag{43.11}$$

A massive particle in the field theory is an exponentially decaying correlation in the statistical model, with decay length $\xi = 1/m_{\text{phys}}$. We will see this explicitly when we extract masses from the transfer matrix below, and it is the hinge on which the next section turns: the continuum limit will be the limit in which ξ, measured in lattice units ξ/a, diverges—a critical point of the statistical system. For now the lesson is the structural one. Having discretized, we are no longer obliged to think of the lattice integral as an approximation to something else. It is a complete statistical-mechanical problem, with a positive probability measure, and we are entitled to ask any question of it that we would ask of an Ising model.

Why the Euclidean rotation was worth the trouble

The Minkowski path integral weights configurations by a phase e^{iS}; it is an oscillatory integral, conditionally convergent at best, and it defines no probability measure—there is no such thing as "the probability of a field configuration" in real time. The Wick rotation of Theorem 5.30 and Chapter 10 converts the phase into a positive Boltzmann weight, and *that* is what makes the configuration sum a statistical-mechanics problem and lets us simulate it, bound it, and reason about it probabilistically. The price—a theory formulated in imaginary time—is paid back in full by reflection positivity (Section 43.1.5), which returns us to real-time quantum mechanics with a Hermitian Hamiltonian. The lattice is the arena in which this trade is carried out honestly.

43.1.3 The lattice is a complete ultraviolet regulator

Before extracting physics we must be sure there is something to extract: that Z in Eq. (43.7) is finite. In the continuum this is exactly the question that perturbation theory could only answer order by order, with subtractions; on the lattice it is a one-line consequence of the integral being finite-dimensional and the action growing at large field. We make it precise.

Proposition 43.4 (Finiteness of the lattice measure for the massive scalar)**.** *For $m^2 > 0$, $\lambda \geq 0$, and any finite lattice Λ with $V = N^4$ sites, the integral Z of Eq. (43.7) is finite and strictly positive, and the lattice expectation Eq. (43.8) of any polynomially bounded observable is an absolutely convergent integral. No ultraviolet divergence occurs and no regulator beyond the lattice is required.*

Proof. Split the action into its quadratic (free) and quartic (interacting) parts, $S_E = S_E^{(0)} + S_{\text{int}}$ with

$$S_E^{(0)}[\phi] = \frac{a^4}{2} \sum_n \Big[\sum_\mu \Big(\tfrac{\phi_{n+\hat{\mu}} - \phi_n}{a} \Big)^2 + m^2 \phi_n^2 \Big], \qquad S_{\text{int}}[\phi] = a^4 \sum_n \frac{\lambda}{4!} \phi_n^4. \tag{43.12}$$

Step 1: the free part is a positive-definite quadratic form. Using $\sum_n (\phi_{n+\hat{\mu}} - \phi_n)^2 = -\sum_n \phi_n (\phi_{n+\hat{\mu}} + \phi_{n-\hat{\mu}} - 2\phi_n)$ after a shift of summation index (legitimate by periodicity), we may write

$$S_E^{(0)}[\phi] = \frac{1}{2} \sum_{n,n'} \phi_n \, M_{nn'} \, \phi_{n'}, \qquad M = a^2 (-\Delta_{\text{lat}}) + a^4 m^2 \, \mathbf{1}, \tag{43.13}$$

where $(\Delta_{\text{lat}} \phi)_n = \sum_\mu (\phi_{n+\hat{\mu}} + \phi_{n-\hat{\mu}} - 2\phi_n)$ is the lattice Laplacian and $\mathbf{1}$ the identity on $\mathbb{R}^V$. The matrix M is real, symmetric, and translation invariant, so it is diagonalized by the lattice plane waves $\phi_n^{(p)} = V^{-1/2} e^{i\, p \cdot n a}$ with momenta quantized by periodicity,

$$p_\mu = \frac{2\pi k_\mu}{N a}, \qquad k_\mu \in \{0, 1, \ldots, N-1\}. \tag{43.14}$$

Acting with M on $\phi^{(p)}$ and using $e^{i p_\mu a} + e^{-i p_\mu a} - 2 = -4 \sin^2(p_\mu a / 2)$ gives the eigenvalues

$$\lambda_p = a^2 \sum_\mu 4 \sin^2\Big(\frac{p_\mu a}{2} \Big) + a^4 m^2 \;\geq\; a^4 m^2 \;>\; 0. \tag{43.15}$$

Every eigenvalue is bounded below by $a^4 m^2 > 0$: the mass term lifts the would-be zero mode, and M is positive definite. Crucially, the eigenvalues are also bounded *above*, $\lambda_p \leq 16 a^2 + a^4 m^2$, because $\sin^2 \leq 1$ and the momenta Eq. (43.14) are confined to the first Brillouin zone $|p_\mu| \leq \pi / a$. There is no large-momentum tail to diverge: modes of wavelength shorter than $2a$ simply do not exist on Λ. *This is the lattice acting as an ultraviolet cutoff*, $\Lambda_{\text{UV}} \sim \pi / a$, built into the kinematics rather than imposed by hand.

Step 2: the free integral is a finite Gaussian. Since M is symmetric positive definite, the standard V-dimensional Gaussian integral converges:

$$Z_0 = \int_{\mathbb{R}^V} \mathcal{D}\phi \; e^{-\frac{1}{2} \phi^{\mathsf{T}} M \phi} = \frac{(2\pi)^{V/2}}{\sqrt{\det M}} = (2\pi)^{V/2} \Big(\prod_p \lambda_p \Big)^{-1/2}, \tag{43.16}$$

and $\det M = \prod_p \lambda_p \geq (a^4 m^2)^V > 0$ is a finite, strictly positive number because it is a finite product of the strictly positive eigenvalues Eq. (43.15). Hence $0 < Z_0 < \infty$.

Step 3: the interaction only helps. For $\lambda \geq 0$ the quartic term is non-negative, $S_{\text{int}}[\phi] \geq 0$, so $0 < e^{-S_{\text{int}}[\phi]} \leq 1$ pointwise. Therefore the full integrand is dominated by the convergent Gaussian,

$$0 < e^{-S_E[\phi]} = e^{-S_E^{(0)}[\phi]}\, e^{-S_{\text{int}}[\phi]} \leq e^{-S_E^{(0)}[\phi]}, \tag{43.17}$$

and integrating gives $0 < Z \leq Z_0 < \infty$. The integral is absolutely convergent; in fact Z is strictly positive because the integrand is strictly positive and continuous. *Step 4: observables.* For a polynomially bounded observable $|\mathcal{O}[\phi]| \leq C\,(1+|\phi|)^k$, the integrand $|\mathcal{O}|\; e^{-S_E} \leq C(1+|\phi|)^k e^{-S_E^{(0)}}$ is dominated by a polynomial times the convergent Gaussian, whose moments are all finite; hence Eq. (43.8) converges absolutely. □

Three features of this proof deserve emphasis because they are the entire conceptual payload of "the lattice as a regulator." First, no subtraction occurred: Z is finite as it stands, in contrast to dimensional regularization or Pauli–Villars, which render individual divergent integrals finite only after a regulator parameter is introduced and counterterms are arranged to cancel poles. Second, the cutoff is the spacing a itself, visible in Eq. (43.14) as the boundary π/a of the Brillouin zone; the theory at finite a is complete and self-contained, and the continuum is a *limit* of well-defined theories rather than a divergent object to be tamed. Third—and this is the property that no other regulator shares—nothing in the construction broke any symmetry we will want to keep. The product measure Eq. (43.6) and the action Eq. (43.5) are manifestly invariant under the lattice translations and the discrete hypercubic rotations, and, as the next section's gauge generalization will show, the lattice can be set up to preserve *exact* gauge invariance without gauge fixing. The price is the breaking of continuous rotational invariance down to the hypercubic point group, a defect that heals in the continuum limit; we pay it gladly in exchange for a manifestly gauge-invariant, manifestly finite definition.

43.1.4 The transfer matrix and the reconstruction of a Hamiltonian

We have a finite, positive, statistical-mechanical measure. We now show that hidden inside it is a quantum mechanics: a Hilbert space, a Hamiltonian, and the operator that propagates states one lattice spacing in imaginary time. The device is the *transfer matrix*, the same object that diagonalizes the one-dimensional Ising model, generalized to a field on each site of a time slice. It is the lattice incarnation of the relation $e^{-S_E} \leftrightarrow e^{-\beta H}$, and it is the machine that Section 43.7.2

(and Sections 43.1.4 onward of this chapter) will use to read masses off correlation functions.

Single out one direction, say $\mu = 0$, as Euclidean time. A site is $n = (t, \mathbf{n})$ with $t \in \{0, \dots, N-1\}$ the time coordinate and $\mathbf{n}$ a site of the three-dimensional *spatial* lattice Λ_s ($V_s = N^3$ sites). The field restricted to a fixed time is a *time-slice configuration* $\Phi_t = \{\phi_{(t,\mathbf{n})}\}_{\mathbf{n}\in\Lambda_s} \in \mathbb{R}^{V_s}$. Splitting the time and space derivatives in Eq. (43.5), the action becomes a sum over time slices,

$$S_E[\phi] = \sum_t \Big[\underbrace{\frac{a^2}{2} \sum_{\mathbf{n}} \big(\phi_{t+1,\mathbf{n}} - \phi_{t,\mathbf{n}}\big)^2}_{\text{couples slices } t,\, t+1} + a^4\, W(\Phi_t) \Big], \tag{43.18}$$

where the temporal hopping term couples adjacent slices, and everything intrinsic to a single slice is collected in the *slice potential*

$$W(\Phi) = \sum_{\mathbf{n}} \Big[\frac{1}{2} \sum_{i=1}^{3} \Big(\frac{\phi_{\mathbf{n}+\hat{\imath}} - \phi_{\mathbf{n}}}{a} \Big)^2 + \frac{1}{2} m^2 \phi_{\mathbf{n}}^2 + \frac{\lambda}{4!} \phi_{\mathbf{n}}^4 \Big]. \tag{43.19}$$

We now write the Boltzmann weight e^{-S_E} as a product of identical factors, one per temporal link, by sharing each slice's potential symmetrically between the two temporal links that touch it (under the periodic identification each slice t has neighbours $t \pm 1$). The factor associated with the link from slice t to slice $t+1$ defines an integral kernel on slice configurations.

Definition 43.5 (Transfer matrix of the lattice scalar)**.** Let $\mathcal{H} = L^2(\mathbb{R}^{V_s}, \mathrm{d}\Phi)$ with $\mathrm{d}\Phi = \prod_{\mathbf{n}} \mathrm{d}\phi_{\mathbf{n}}$ be the Hilbert space of square-integrable functionals of one spatial slice. The *transfer matrix* T is the integral operator on $\mathcal{H}$ with kernel

$$\langle \Phi' | T | \Phi \rangle = e^{-\frac{1}{2} a^4 W(\Phi')}\, \mathcal{K}(\Phi', \Phi)\, e^{-\frac{1}{2} a^4 W(\Phi)}, \qquad \mathcal{K}(\Phi', \Phi) = \Big(\tfrac{a^2}{2\pi} \Big)^{V_s/2} e^{-\frac{a^2}{2} \sum_{\mathbf{n}} (\phi'_{\mathbf{n}} - \phi_{\mathbf{n}})^2}, \tag{43.20}$$

the normalization of $\mathcal{K}$ chosen so that $\int \mathrm{d}\Phi\, \mathcal{K}(\Phi', \Phi) = 1$.

The point of the symmetric splitting is the following identity, which is the lattice statement that "the partition function is a trace over states."

Proposition 43.6 (Partition function as a trace)**.** *With periodic time of extent N, $Z = \mathrm{Tr}_{\mathcal{H}}\, T^N$, and more generally any correlator of slice observables is a trace of the corresponding multiplication operators interleaved with powers of T.*

Proof. The kernel product over the temporal links reassembles the Boltzmann weight: the Gaussian factors $\mathcal{K}(\Phi_{t+1}, \Phi_t)$ reproduce the temporal hopping terms of Eq. (43.18) (the normalization constant is a ϕ-independent prefactor that contributes only to the overall constant in Z), while each slice potential $a^4 W(\Phi_t)$

is supplied as two halves, $e^{-\frac{1}{2}a^4 W(\Phi_t)}$ from the link below and another from the link above. Hence

$$\int \prod_t \mathrm{d}\Phi_t \; \prod_t \langle \Phi_{t+1}|T|\Phi_t\rangle = \int \prod_t \mathrm{d}\Phi_t \; e^{-S_E[\phi]} \cdot (\text{const}) = Z \cdot (\text{const}), \tag{43.21}$$

and the left side, with the periodic identification $\Phi_N \equiv \Phi_0$, is by definition $\operatorname{Tr} T^N = \int \prod_t \mathrm{d}\Phi_t \; \prod_t \langle \Phi_{t+1}|T|\Phi_t\rangle$. Absorbing the constant into the normalization of T (equivalently of $\mathcal{K}$, as in Eq. (43.20)) gives $Z = \operatorname{Tr} T^N$. Inserting a slice observable $\mathcal{O}(\Phi_t)$ multiplies the integrand by the corresponding multiplication operator $\hat{\mathcal{O}}$ at position t in the product, yielding $\langle \mathcal{O} \rangle = Z^{-1} \operatorname{Tr}(\hat{\mathcal{O}}\, T^N)$, and similarly for several insertions. □

Everything now hinges on the operator properties of T. The next theorem is the central analytic result of the section: T is a positive self-adjoint operator, so its logarithm is a self-adjoint operator, and that operator, divided by $-a$, is the Hamiltonian.

Theorem 43.7 (The transfer matrix is positive and defines a Hamiltonian)**.** *The operator T of Theorem 43.5 is bounded, self-adjoint, and strictly positive on $\mathcal{H} = L^2(\mathbb{R}^{V_s})$. Consequently there is a self-adjoint operator*

$$H := -\frac{1}{a} \ln T, \qquad \textit{i.e.} \qquad T = e^{-aH}, \tag{43.22}$$

with real spectrum bounded below. The ground state of H (the lowest eigenvector of T) is unique and may be chosen strictly positive; identifying it with the vacuum $|0\rangle$, the spectrum of H above it gives the energy levels of the reconstructed quantum theory.

Proof. Self-adjointness. The kernel Eq. (43.20) is real and symmetric, $\langle \Phi'|T|\Phi\rangle = \langle \Phi|T|\Phi'\rangle$, because $W(\Phi')$ and $W(\Phi)$ enter symmetrically and $\mathcal{K}(\Phi', \Phi) = \mathcal{K}(\Phi, \Phi')$. A real symmetric kernel defines a (formally) self-adjoint integral operator; boundedness, proved next, makes it genuinely self-adjoint on $\mathcal{H}$.

Boundedness. Write $T = A\,K\,A$ with A the multiplication operator $(A\psi)(\Phi) = e^{-\frac{1}{2}a^4 W(\Phi)}\psi(\Phi)$ and K the integral operator with kernel $\mathcal{K}$. Since $W(\Phi) \geq 0$ (it is a sum of squares and even powers), A is a bounded multiplication operator with $0 < A \leq \mathbf{1}$, hence $\|A\| \leq 1$. The operator K is a Gaussian convolution: $\mathcal{K}(\Phi', \Phi)$ depends only on $\Phi' - \Phi$ and is a normalized probability density, so K is a Markov (averaging) operator with $\|K\| \leq 1$ (its Fourier symbol, computed below, lies in $(0, 1]$). Therefore $\|T\| \leq \|A\|^2 \, \|K\| \leq 1$, and T is bounded.

Positivity. This is the crux. The convolution operator K is diagonalized by the spatial plane waves $\Phi \mapsto e^{i\,\mathbf{k}\cdot\Phi}$ in the conjugate (momentum) variables of the V_s field components; equivalently, recognizing the Gaussian as a heat kernel, one

has

$$\mathcal{K}(\Phi',\Phi)=\Big\langle\Phi'\Big|\,\exp\Big(\frac{1}{2a^2}\sum_{\mathbf{n}}\frac{\partial^2}{\partial\phi_{\mathbf{n}}^2}\Big)\Big|\Phi\Big\rangle=\Big\langle\Phi'\Big|\,e^{-\frac{1}{2a^2}\hat{\mathbf{p}}^2}\,\Big|\Phi\Big\rangle,\qquad \hat{p}_{\mathbf{n}}=-i\frac{\partial}{\partial\phi_{\mathbf{n}}},\tag{43.23}$$

where $\hat{\mathbf{p}}^2=\sum_{\mathbf{n}}\hat{p}_{\mathbf{n}}^2$. The identity is the standard heat-kernel formula $\langle x'|e^{(s/2)\partial_x^2}|x\rangle=(2\pi s)^{-1/2}e^{-(x'-x)^2/2s}$ with $s=1/a^2$, applied componentwise. Thus $K=e^{-\frac{1}{2a^2}\hat{\mathbf{p}}^2}$ is the exponential of the negative semidefinite operator $-\frac{1}{2a^2}\hat{\mathbf{p}}^2$; its spectrum is $\{e^{-\mathbf{k}^2/2a^2}:\mathbf{k}\in\mathbb{R}^{V_s}\}\subset(0,1]$, so K is strictly positive: $\langle\psi|K|\psi\rangle=\int\frac{\mathrm{d}^{V_s}\mathbf{k}}{(2\pi)^{V_s}}\,e^{-\mathbf{k}^2/2a^2}\left|\tilde{\psi}(\mathbf{k})\right|^2>0$ for $\psi\neq0$. Positivity is preserved under congruence by a self-adjoint operator: for any $\psi\in\mathcal{H}$,

$$\langle\psi|T|\psi\rangle=\langle\psi|AKA|\psi\rangle=\langle A\psi|K|A\psi\rangle>0\tag{43.24}$$

whenever $A\psi\neq0$; and $A\psi=0$ forces $\psi=0$ because A is multiplication by the strictly positive function $e^{-\frac{1}{2}a^4W}$. Hence $T>0$ strictly.

The Hamiltonian. A bounded strictly positive self-adjoint operator has, by the spectral theorem, a self-adjoint logarithm $\ln T$ with spectrum $\ln(\operatorname{spec}T)\subset(-\infty,0]$ (since $\|T\|\leq1$). Define $H=-\frac{1}{a}\ln T$; it is self-adjoint, its spectrum is real and bounded below by $-\frac{1}{a}\ln\|T\|\geq0$, and by construction $T=e^{-aH}$, which is Eq. (43.22). Because T has a strictly positive kernel on $\mathcal{H}$ (both factors A and K are positivity-improving), the Perron–Frobenius theorem for integral operators applies: the largest eigenvalue of T is simple and its eigenfunction can be chosen strictly positive. That eigenfunction is the lowest-energy state of H, the vacuum $|0\rangle$; its uniqueness is the statement that the reconstructed theory has a unique ground state. □

Theorem 43.7 is the reconstruction in miniature. The statistical-mechanical measure e^{-S_E}/Z has handed us, with no further input, a Hilbert space $\mathcal{H}$, a self-adjoint Hamiltonian H with a real spectrum bounded below, and a unique vacuum. The relation $T=e^{-aH}$ says that advancing one slice in Euclidean time is imaginary-time evolution by a, exactly the Euclidean analogue of e^{-iHt}. The trace formula $Z=\operatorname{Tr}e^{-NaH}=\operatorname{Tr}e^{-\beta H}$ with $\beta=Na=L$ identifies the temporal extent of the lattice with an inverse temperature, sharpening the dictionary of Section 43.1.2: a Euclidean field theory in a box of temporal size L is the thermal ensemble of the reconstructed quantum theory at temperature $1/L$, and the zero-temperature quantum theory is recovered as $L\to\infty$. The energy gaps of H are physical particle masses, extracted in lattice units from the exponential decay of two-point functions $\big\langle\hat{\mathcal{O}}(t)\hat{\mathcal{O}}(0)\big\rangle\sim e^{-(E_1-E_0)\,at}$, the precise mechanism the spectroscopy of Section 43.7.2 relies on. This is the concrete content of the correspondence Eq. (43.11).

Positivity of the measure is not yet positivity of the Hilbert space

Theorem 43.4 gave a positive, convergent measure, and Theorem 43.7 gave a positive operator T. These are logically distinct positivities, and the second does not follow from the first for an arbitrary action. A higher-derivative or improperly chosen temporal discretization can produce a perfectly convergent positive measure whose transfer matrix is *not* a positive operator—its "Hamiltonian" $-\frac{1}{a}\ln T$ would then have complex eigenvalues, and there would be no unitary continuation to real time. What guarantees positivity of T for the nearest-neighbour scalar is the structure we used in the proof—the temporal coupling appears only through the Gaussian heat kernel $\mathcal{K}$—and this structural fact is precisely reflection positivity, to which we now turn.

43.1.5 Reflection positivity and the unitary continuation to Minkowski

Theorem 43.7 built a Hamiltonian by assuming the slicing and computing. We now connect that computation to the criterion that Theorem 10.32 identified as the general guarantee of a sensible Lorentzian theory: reflection (Osterwalder–Schrader) positivity. For the lattice the criterion takes a sharp, checkable form, and we prove it for the scalar. The payoff is conceptual closure: positivity of T, hence the existence of a Hermitian H with real spectrum, hence a unitary real-time evolution e^{-iHt}, all follow from a single inequality satisfied by the lattice action.

Fix a reflection plane. The cleanest choice is *link reflection* about the hyperplane lying halfway between time slices $t = 0$ and $t = 1$; we work on the temporally infinite lattice ($t \in \mathbb{Z}$, Λ_s finite) so that the reflection is exact, and remark afterward on the periodic case. The reflection Θ acts on configurations by exchanging slices across the plane,

$$(\Theta\phi)_{(t,\mathbf{n})} = \phi_{(1-t,\,\mathbf{n})}, \tag{43.25}$$

so that slice $t = 1$ maps to $t = 0$, slice $t = 2$ to $t = -1$, and so on. Call a functional $F[\phi]$ *supported at positive time* if it depends on ϕ only through the slices $t \geq 1$; denote by $\mathcal{A}_+$ the algebra of such functionals. Reflection acts on functionals antilinearly by $(\Theta F)[\phi] := \overline{F[\Theta\phi]}$, mapping $\mathcal{A}_+$ to functionals of the slices $t \leq 0$.

Definition 43.8 (Reflection positivity)**.** The lattice action S_E is *reflection positive* (about the chosen plane) if

$$\langle (\Theta F)\, F \rangle \geq 0 \qquad \text{for every } F \in \mathcal{A}_+. \tag{43.26}$$

This is the lattice transcription of the abstract inequality Eq. (10.180): the Euclidean expectation of a positive-time functional paired with its reflection is non-negative. Its meaning, unpacked at length in Section 10.6.6, is that the reconstructed inner product $\langle F, F' \rangle := \langle (\Theta F) F' \rangle$ is positive semidefinite, so the quotient by its null space is a genuine Hilbert space with no negative-norm states. We now prove the lattice scalar satisfies Eq. (43.26), and that this is equivalent to the positivity of T established above.

Theorem 43.9 (Reflection positivity of the lattice scalar)**.** *The lattice ϕ^4 action Eq. (43.5) with $m^2 > 0$, $\lambda \geq 0$ is reflection positive about any temporal link-reflection plane. Equivalently, the transfer matrix T of Theorem 43.5 is a positive operator. Consequently the Osterwalder–Schrader reconstruction (Theorem 10.32) applies: the lattice data define a Hilbert space of positive norm, a self-adjoint Hamiltonian $H \geq 0$, and a unitary real-time evolution e^{-iHt} obtained by continuing the lattice (imaginary-time) correlators back to Minkowski signature.*

Proof. Decompose the action with respect to the reflection plane. Because the only term in Eq. (43.5) that couples a slice to its temporal neighbour is the temporal hopping term, and the plane sits between slices 0 and 1, the action splits as

$$S_E[\phi] = S_+[\phi_+] \; + \; S_-[\phi_-] \; + \; S_0, \qquad S_0 = \frac{a^2}{2} \sum_{\mathbf{n}} (\phi_{1,\mathbf{n}} - \phi_{0,\mathbf{n}})^2, \tag{43.27}$$

where ϕ_+ denotes the fields on slices $t \geq 1$, ϕ_- those on $t \leq 0$, $S_\pm$ collect all terms supported entirely on one side (every slice potential and every temporal link strictly to one side of the plane), and S_0 is the *single* crossing link. The quartic, mass, and spatial-gradient terms are intrinsic to slices and therefore split cleanly into S_+ and S_-; this is what makes the argument work for the interacting theory exactly as for the free one. Reflection symmetry of the action gives $S_-[\phi_-] = S_+[\Theta\phi_+]$, i.e. $S_- = \Theta S_+$.

The crossing weight e^{-S_0} is Gaussian in the difference $\phi_{1,\mathbf{n}} - \phi_{0,\mathbf{n}}$, and we represent it as a manifestly positive pairing of a positive-time factor with its reflection by Fourier transform. For each spatial site, $e^{-\frac{a^2}{2}x^2} = \frac{1}{a\sqrt{2\pi}} \int_{\mathbb{R}} \mathrm{d}k \; e^{-k^2/2a^2} \, e^{ikx}$; with $x = \phi_{1,\mathbf{n}} - \phi_{0,\mathbf{n}}$ and a product over $\mathbf{n}$,

$$e^{-S_0} = \int \mathrm{d}\mu(\mathbf{k}) \, \Big(\prod_{\mathbf{n}} e^{ik_{\mathbf{n}} \phi_{1,\mathbf{n}}} \Big) \Big(\prod_{\mathbf{n}} e^{-ik_{\mathbf{n}} \phi_{0,\mathbf{n}}} \Big), \qquad \mathrm{d}\mu(\mathbf{k}) = \prod_{\mathbf{n}} \frac{\mathrm{d}k_{\mathbf{n}}}{a\sqrt{2\pi}} \, e^{-k_{\mathbf{n}}^2/2a^2}, \tag{43.28}$$

where $\mathrm{d}\mu$ is a *positive* measure on the auxiliary variables $\mathbf{k} = \{k_{\mathbf{n}}\}$. The first product, $h_{\mathbf{k}}[\phi_+] := \prod_{\mathbf{n}} e^{ik_{\mathbf{n}}\phi_{1,\mathbf{n}}}$, depends only on the slice-1 field and so belongs to $\mathcal{A}_+$; the second product equals $\overline{(\Theta h_{\mathbf{k}})[\phi_-]}$ because Θ exchanges slice 1 with slice 0 and Θ conjugates. Thus the only coupling between the two halves has been written as $\int \mathrm{d}\mu(\mathbf{k}) \, h_{\mathbf{k}}[\phi_+] \, \overline{(\Theta h_{\mathbf{k}})[\phi_-]}$ with $\mathrm{d}\mu \geq 0$.

Now compute the reflected expectation for any $F \in \mathcal{A}_+$. With the field measure factorizing as $\mathcal{D}\phi = \mathcal{D}\phi_+ \, \mathcal{D}\phi_-$ (the slices on the two sides are independent variables) and using $(\Theta F)[\phi] = \overline{F[\Theta\phi]}$, which depends only on ϕ_-,

$$\begin{aligned} Z \, \langle (\Theta F) F \rangle &= \int \mathcal{D}\phi_+ \, \mathcal{D}\phi_- \; \overline{F[\Theta\phi]} \, F[\phi] \; e^{-S_+[\phi_+]} \, e^{-S_-[\phi_-]} \, e^{-S_0} \\ &= \int \mathrm{d}\mu(\mathbf{k}) \int \mathcal{D}\phi_+ \, \mathcal{D}\phi_- \; \overline{F[\Theta\phi]} \, \overline{(\Theta h_{\mathbf{k}})[\phi_-]} \, e^{-\Theta S_+[\phi_-]} \;\cdot\; F[\phi] \, h_{\mathbf{k}}[\phi_+] \, e^{-S_+[\phi_+]}. \end{aligned} \tag{43.29}$$

The integrand factorizes into a piece depending only on ϕ_- and a piece depending only on ϕ_+, so the double integral is a product. Define the single functional integral over positive-time fields

$$I(\mathbf{k}) := \int \mathcal{D}\phi_+ \; F[\phi_+] \, h_{\mathbf{k}}[\phi_+] \, e^{-S_+[\phi_+]}. \tag{43.30}$$

The ϕ_- integral is the complex conjugate of the same object: substituting $\phi_- = \Theta\phi'_+$ (a measure-preserving change of variables, since Θ permutes slices) turns $\overline{F[\Theta\phi]} \to \overline{F[\phi'_+]}$, $\overline{(\Theta h_{\mathbf{k}})[\phi_-]} \to \overline{h_{\mathbf{k}}[\phi'_+]}$, and $e^{-\Theta S_+[\phi_-]} \to e^{-S_+[\phi'_+]}$, giving $\int \mathcal{D}\phi_-(\dots) = \overline{I(\mathbf{k})}$. Therefore

$$\langle (\Theta F) F \rangle = \frac{1}{Z} \int \mathrm{d}\mu(\mathbf{k}) \; \overline{I(\mathbf{k})} \, I(\mathbf{k}) = \frac{1}{Z} \int \mathrm{d}\mu(\mathbf{k}) \; |I(\mathbf{k})|^2 \;\geq\; 0, \tag{43.31}$$

because $\mathrm{d}\mu \geq 0$, $Z > 0$, and the integrand is a non-negative real number. This is Eq. (43.26); the action is reflection positive.

Equivalence with positivity of T. The same slicing that produced Eq. (43.31) is the slicing of Section 43.1.4: the crossing Gaussian e^{-S_0} is precisely the kernel $\mathcal{K}$ of Eq. (43.20) (up to the slice-potential factors absorbed into $S_\pm$), and the Fourier representation Eq. (43.28) is the spectral representation Eq. (43.23) of $K = e^{-\hat{\mathbf{p}}^2/2a^2}$ as a positive operator. A monomial positive-time functional, evaluated through Theorem 43.6, gives $\langle (\Theta F) F \rangle = \langle \Omega | \, \hat{F}^\dagger \, T^m \, \hat{F} \, | \Omega \rangle / \langle \Omega | T^N | \Omega \rangle$ for appropriate insertions, and the right side is ≥ 0 for all F iff $T \geq 0$. Thus reflection positivity Eq. (43.26) and positivity of the transfer matrix (Theorem 43.7) are the same statement viewed two ways; we have now established it from both ends.

Continuation to Minkowski. Given Eq. (43.26), the reconstruction theorem Theorem 10.32 produces a positive-norm Hilbert space (the completion of $\mathcal{A}_+$ in the inner product $\langle F, F' \rangle = \langle (\Theta F) F' \rangle$, modulo null vectors), a vacuum (the constant functional), and a self-adjoint Hamiltonian $H \geq 0$ generating Euclidean time translation—which is exactly the H of Eq. (43.22). Because H is self-adjoint with real, bounded-below spectrum, e^{-iHt} is a one-parameter unitary group: the lattice (imaginary-time) correlators, continued in the time variable $at \to it_{\mathrm{Mink}}$, are the Wightman functions of a unitary Lorentzian quantum field theory. The Wick rotation of Chapter 10 has been run in reverse, rigorously, on a fully defined object. □

We pause on what has been achieved, because it is the justification for the entire chapter. Starting from nothing but an ordinary finite-dimensional integral—a positive measure on $\mathbb{R}^V$ with no perturbative expansion in sight—we have reconstructed every structural ingredient of a quantum field theory: a Hilbert space of positive norm, a Hermitian Hamiltonian bounded below, a unique vacuum, a particle spectrum encoded in the decay of correlations, and a unitary evolution back in Minkowski signature. The lattice is therefore not merely a regulator that happens to be finite; it is a self-contained, non-perturbative *definition* of an interacting quantum field theory that satisfies the axioms a quantum theory must satisfy. This is the precise sense in which the lattice answers the question "what is a quantum field theory, exactly?"

43.1.6 Worked example: the lattice scalar in zero space dimensions is the harmonic oscillator

The relation $T = e^{-aH}$ is abstract until one sees the Hamiltonian come out by hand. The cleanest case is the lattice scalar with no spatial directions at all—a single degree of freedom ϕ_t on a one-dimensional time lattice. This is the lattice path integral for ordinary quantum mechanics, and its transfer matrix is the imaginary-time propagator. Carrying it out makes Theorem 43.7 completely explicit and shows the continuum Hamiltonian, with its spectrum, emerging from the lattice as $a \to 0$.

Worked Example 43.10 (Transfer matrix of the $(0+1)$-dimensional free scalar)**.** Take $\Lambda = \{0, 1, \dots, N-1\}$ with one real variable ϕ_t per site, free ($\lambda = 0$), mass m. In one dimension the discretization rule Eq. (43.4) carries $a^4 \to a$, and the action Eq. (43.5) reduces to

$$S_E[\phi] = \sum_t \Big[\frac{1}{2a}(\phi_{t+1} - \phi_t)^2 + \frac{a}{2} m^2 \phi_t^2 \Big]. \tag{43.32}$$

There is no slice potential beyond the on-site mass term, so $W(\phi) = \frac{1}{2}m^2\phi^2$, and the transfer kernel Eq. (43.20) on $\mathcal{H} = L^2(\mathbb{R}, \mathrm{d}\phi)$ is

$$\langle \phi' | T | \phi \rangle = \frac{1}{\sqrt{2\pi a}} \exp\Big[-\frac{am^2}{4}\phi'^2 - \frac{1}{2a}(\phi' - \phi)^2 - \frac{am^2}{4}\phi^2 \Big]. \tag{43.33}$$

We extract H from $T = e^{-aH}$ in the small-a regime, then verify the spectrum. By the heat-kernel identity Eq. (43.23) the Gaussian middle factor is the kernel of $e^{-\frac{a}{2}\hat{p}^2}$ with $\hat{p} = -i\,\mathrm{d}/\mathrm{d}\phi$, and the two outer factors are multiplication by $e^{-\frac{a}{4}m^2\hat{\phi}^2}$ with $\hat{\phi}$ the position operator. Hence T is the operator

$$T = e^{-\frac{a}{4}m^2\hat{\phi}^2}\; e^{-\frac{a}{2}\hat{p}^2}\; e^{-\frac{a}{4}m^2\hat{\phi}^2}, \tag{43.34}$$

a symmetric (Strang) splitting of the evolution. This factored form is manifestly the structure $T = AKA$ of Theorem 43.7, with $A = e^{-\frac{a}{4}m^2\hat{\phi}^2} > 0$ and $K =$

$e^{-\frac{a}{2}\hat{p}^2} > 0$; positivity and self-adjointness are visible by inspection. To read off H, use the Baker–Campbell–Hausdorff formula for a symmetric product: for operators X, Y,

$$e^{X/2}e^{Y}e^{X/2} = \exp\Big(X+Y-\tfrac{1}{24}\,[X,[X,Y]]+\tfrac{1}{12}\,[Y,[X,Y]]+\cdots\Big) = \exp(X+Y+O(\text{triple commutato} \tag{43.35}$$

where the leading correction to $X+Y$ is of *third* order in the small quantities—the symmetric ordering cancels the second-order commutator $\frac{1}{2}\,[X,Y]$ that spoils the naive product $e^{X}e^{Y}$. With $X = -\frac{a}{2}m^2\hat{\phi}^2$ and $Y = -\frac{a}{2}\hat{p}^2$, both of order a, we obtain

$$T = \exp\Big[-a\big(\tfrac{1}{2}\hat{p}^2 + \tfrac{1}{2}m^2\hat{\phi}^2\big) + O(a^3)\Big] = e^{-aH}, \qquad H = \frac{1}{2}\hat{p}^2 + \frac{1}{2}m^2\hat{\phi}^2 + O(a^2). \tag{43.36}$$

The reconstructed Hamiltonian is the harmonic oscillator of angular frequency $\omega = m$. Its spectrum, from the ladder operators of nonrelativistic quantum mechanics, is $E_n = m\big(n+\frac{1}{2}\big)$, $n = 0, 1, 2, \ldots$, so the transfer-matrix eigenvalues are $\tau_n = e^{-aE_n} = e^{-am(n+1/2)}$, with the largest, $\tau_0 = e^{-am/2}$, simple and belonging to the strictly positive Gaussian ground state $\psi_0(\phi) \propto e^{-m\phi^2/2}$—exactly the unique positive vacuum guaranteed in general by Perron–Frobenius in Theorem 43.7.

The lattice corrections are now explicit and instructive. The exact transfer matrix Eq. (43.33) can be diagonalized in closed form (it is a Mehler kernel), giving $\tau_n = R^{\,n+1/2}$ with R fixed by the a-dependent coefficients; expanding, the gap is

$$a\,(E_1 - E_0) = -\ln\frac{\tau_1}{\tau_0} = \operatorname{arccosh}\Big(1+\tfrac{1}{2}a^2m^2\Big) = a\,m\Big(1-\tfrac{1}{24}a^2m^2 + O(a^4m^4)\Big), \tag{43.37}$$

so the physical mass measured from the decay of the lattice two-point function, $E_1 - E_0 = m(1+O(a^2m^2))$, equals the input m up to a discretization error that vanishes as $a \to 0$. The correlation length in lattice units is $\xi/a = 1/[a(E_1 - E_0)] = 1/(am) + O(am)$, diverging as $a \to 0$ at fixed physical m—the first concrete instance of the criterion Eq. (43.11) that the next section elevates to the organizing principle of the continuum limit.

This single-site example is the whole reconstruction in a form one can hold in the hand: a positive measure on $\mathbb{R}^N$, a positive transfer matrix, a Hermitian Hamiltonian read off by Baker–Campbell–Hausdorff, an exact spectrum, and a continuum limit reached by sending the lattice correlation length to infinity. Adding spatial sites changes none of the logic; it only replaces the oscillator H by the field Hamiltonian of Theorem 43.7 on the larger Hilbert space $L^2(\mathbb{R}^{V_s})$, and the Fock structure of Section 9.3 reappears in the continuum limit as the spectrum of that H organizes into multiparticle states.

We now have exactly what the rest of the chapter needs: a finite, positive, reflection-positive lattice measure e^{-S_E}/Z on the field configurations of Theorem 43.1, on which a scalar field is already in place and which reconstructs a Hilbert space and a Hamiltonian through the transfer matrix $T = e^{-aH}$. The next section places the free and $\lambda\phi^4$ scalar on this measure in earnest, recovers the continuum propagator as $a \to 0$, and confronts the central lesson that the discretization makes unavoidable—that the continuum limit is not $a \to 0$ at fixed couplings but the tuning of the statistical system to a critical point where the correlation length Eq. (43.11) diverges in lattice units, a second-order phase transition that is, in the language of Chapter 23, a Wilsonian renormalization-group fixed point.

43.2 The lattice scalar and the continuum limit as an RG fixed point

Section 43.1 turned the Euclidean path integral of Chapter 10 into a genuine, finite, positive measure: a real scalar field defined on the sites of a hypercubic lattice, with weight e^{-S_E}/Z over an ordinary (if astronomically high-dimensional) integral, and with a transfer matrix whose ground state and spectral gap reconstruct a physical Hilbert space and Hamiltonian. We now have a constructive, regulator-free *definition* of a quantum field theory and a dictionary back to physics. The obvious next question is whether this object actually contains the continuum theory we set out to define, and if so, how the continuum is reached. The answer is the conceptual heart of this chapter, and it is not the naive one. Putting $a \to 0$ at fixed bare couplings does *not* give the continuum theory; it gives nothing at all. The continuum limit is instead a limit in which the lattice is tuned to a critical point, where the correlation length measured in lattice spacings diverges, and that critical point is precisely a fixed point of the Wilsonian renormalization group of Chapter 23. We will establish this for the carried ϕ^4 theory scalar, recovering the continuum propagator with its leading lattice artifact along the way, and we will state honestly — and date — what is by now a theorem: in four dimensions the resulting continuum theory is free.

43.2.1 The lattice action for the free and $\lambda\phi^4$ scalar

We work on the Euclidean hypercubic lattice

$$\Lambda_a \;=\; a\,\mathbb{Z}^4 \;=\; \{\, x = a\,n \;:\; n = (n_1, n_2, n_3, n_4) \in \mathbb{Z}^4 \,\}, \tag{43.38}$$

with lattice spacing $a > 0$ and unit vectors $\hat{\mu}$ along the four axes, so that $x + a\hat{\mu}$ is the neighbour of x in direction μ. (We take the infinite lattice throughout this section; the finite periodic volume of Section 43.1 is recovered by restricting n to $\{0, \ldots, N-1\}^4$ and is what one actually simulates. All sums over x below mean

$\sum_{n\in\mathbb{Z}^4}$.) The dynamical variable is a real number $\phi(x) \equiv \phi_n$ attached to each site, the discretization of the continuum field $\phi(x)$ of ϕ^4 theory, Chapter 6.

A continuum derivative must become a finite difference. The two simplest choices are the *forward* and *backward* differences,

$$(\Delta_\mu^+\phi)(x) \;=\; \frac{\phi(x+a\hat{\mu})-\phi(x)}{a}, \qquad (\Delta_\mu^-\phi)(x) \;=\; \frac{\phi(x)-\phi(x-a\hat{\mu})}{a}. \tag{43.39}$$

Each reduces to $\partial_\mu\phi$ as $a\to 0$ with an error of order a. Their average, the symmetric difference $\frac{1}{2}(\Delta_\mu^+ + \Delta_\mu^-)\phi = (\phi(x+a\hat{\mu}) - \phi(x-a\hat{\mu}))/2a$, is accurate to order a^2 but, as we will see, has a defect of its own for the second derivative. For the kinetic term either one-sided difference will do, because the action symmetrizes the choice. The discretized Euclidean action of ϕ^4 theory, the lattice version of the Euclidean $S_E = \int d^4x\,[\frac{1}{2}(\partial\phi)^2 + \frac{1}{2}m^2\phi^2 + \frac{\lambda}{4!}\phi^4]$ fixed for the thread in Chapter 10, is

$$S_E[\phi] \;=\; a^4 \sum_{x\in\Lambda_a} \left[\frac{1}{2}\sum_{\mu=1}^{4} \big((\Delta_\mu^+\phi)(x)\big)^2 \;+\; \frac{1}{2}\,m^2\,\phi(x)^2 \;+\; \frac{\lambda}{4!}\,\phi(x)^4 \right], \tag{43.40}$$

where the factor a^4 is the volume of one hypercube and turns the site sum into a Riemann approximation of $\int d^4x$. As $a\to 0$ with ϕ a smooth profile, Eq. (43.5) converges termwise to the continuum S_E; the content of the rest of this section is that this naive pointwise statement is *not* how the continuum theory is recovered.

It is convenient to expose the lattice Laplacian hiding in the kinetic term. The key tool is *summation by parts*, the lattice avatar of integration by parts. For any two fields f, g that decay at infinity (or on the periodic torus, with no boundary at all),

$$a^4 \sum_x (\Delta_\mu^+ f)(x)\, g(x) \;=\; -\,a^4 \sum_x f(x)\,(\Delta_\mu^- g)(x), \tag{43.41}$$

which follows from relabelling the shifted sum: writing out the left side,

$$a^4 \sum_x \frac{f(x+a\hat{\mu})-f(x)}{a}\, g(x) = \frac{a^4}{a}\Big[\sum_x f(x+a\hat{\mu})g(x) - \sum_x f(x)g(x)\Big] = \frac{a^4}{a}\sum_x f(x)\big[g(x-a\hat{\mu}) - g(x$$

where in the first sum we shifted the summation index $x \to x - a\hat{\mu}$ (legitimate because the sum is over all of Λ_a), and the bracket is $-a\,(\Delta_\mu^- g)(x)$, giving Eq. (43.41). Applying it to the kinetic term with $f = \phi$ and $g = \Delta_\mu^+\phi$,

$$a^4 \sum_x (\Delta_\mu^+\phi)^2 = -\,a^4 \sum_x \phi\,(\Delta_\mu^-\Delta_\mu^+\phi) = -\,a^4 \sum_x \phi\,(\Delta_\mu\phi), \tag{43.42}$$

where the second-difference operator $\Delta_\mu \equiv \Delta_\mu^-\Delta_\mu^+ = \Delta_\mu^+\Delta_\mu^-$ (the two one-sided differences commute) acts as

$$(\Delta_\mu\phi)(x) = \frac{\phi(x+a\hat{\mu}) + \phi(x-a\hat{\mu}) - 2\phi(x)}{a^2}. \tag{43.43}$$

Summing over μ defines the *lattice Laplacian*

$$(\Delta\phi)(x) \;=\; \sum_{\mu=1}^{4}(\Delta_\mu\phi)(x) \;=\; \frac{1}{a^2}\sum_{\mu=1}^{4}\big[\phi(x+a\hat{\mu})+\phi(x-a\hat{\mu})-2\phi(x)\big], \quad (43.44)$$

the nearest-neighbour "hopping" operator familiar from statistical mechanics: it couples each site to its $2\times 4=8$ neighbours and subtracts $8\phi(x)/a^2$. In terms of it the free part of the action is the manifestly quadratic form

$$S_E^{(0)}[\phi] \;=\; \frac{a^4}{2}\sum_x \phi(x)\,(-\Delta+m^2)\phi(x), \quad (43.45)$$

exactly the lattice transcription of $\frac{1}{2}\int d^4x\,\phi(-\partial^2+m^2)\phi$, with the continuum $-\partial^2$ replaced by the discrete $-\Delta$. The operator $-\Delta+m^2$ is positive (it is a sum of squares plus $m^2>0$), so the Gaussian integral built on it converges — the positivity that Section 43.1 required of the whole measure, here visible in the free sector.

43.2.2 The lattice free propagator

The operator $-\Delta+m^2$ has constant coefficients — it commutes with lattice translations — so it is diagonalized by plane waves, and the propagator follows by inversion in momentum space. This is the lattice instance of the momentum-space inversion that produced the continuum propagator in Chapter 10.

Because the lattice resolves no structure finer than a, momenta are defined only modulo $2\pi/a$: the plane waves $e^{ip\cdot x}$ and $e^{i(p+2\pi\hat{\mu}/a)\cdot x}$ coincide on every site $x=an$, since $e^{i(2\pi/a)\hat{\mu}\cdot an}=e^{2\pi i n_\mu}=1$. The independent momenta therefore fill one period, the *first Brillouin zone*

$$\mathrm{BZ} \;=\; \Big(-\tfrac{\pi}{a},\,\tfrac{\pi}{a}\Big]^4, \quad (43.46)$$

and the lattice Fourier transform and its inverse read

$$\tilde{\phi}(p)=a^4\sum_x e^{-ip\cdot x}\,\phi(x), \qquad \phi(x)=\int_{\mathrm{BZ}}\frac{d^4p}{(2\pi)^4}\,e^{ip\cdot x}\,\tilde{\phi}(p), \quad (43.47)$$

with the completeness relations $a^4\sum_x e^{-i(p-q)\cdot x}=(2\pi)^4\delta^{(4)}(p-q)$ for $p,q\in\mathrm{BZ}$ and $\int_{\mathrm{BZ}}\frac{d^4p}{(2\pi)^4}e^{ip\cdot(x-y)}=a^{-4}\delta_{xy}$. Acting on a plane wave the one-sided differences are diagonal,

$$\Delta_\mu^{\pm}\,e^{ip\cdot x}=\frac{e^{\pm iap_\mu}-1}{\pm a}\,e^{ip\cdot x}, \quad (43.48)$$

so the lattice Laplacian Eq. (43.44) has eigenvalue

$$-\Delta\,e^{ip\cdot x}=-\frac{1}{a^2}\sum_\mu\big(e^{iap_\mu}+e^{-iap_\mu}-2\big)\,e^{ip\cdot x}=\frac{2}{a^2}\sum_\mu\big(1-\cos ap_\mu\big)\,e^{ip\cdot x}=\hat{p}^2\,e^{ip\cdot x}, \quad (43.49)$$

where, using $1-\cos\theta = 2\sin^2(\theta/2)$, we have defined the *lattice momentum*

$$\boxed{\hat{p}_\mu \;=\; \frac{2}{a}\sin\!\Big(\frac{a p_\mu}{2}\Big), \qquad \hat{p}^2 \;=\; \sum_{\mu=1}^{4}\hat{p}_\mu^{\,2} \;=\; \frac{4}{a^2}\sum_{\mu=1}^{4}\sin^2\!\Big(\frac{a p_\mu}{2}\Big).} \tag{43.50}$$

The lattice Laplacian is thus exactly $-\partial^2$ with p_μ^2 replaced by $\hat{p}_\mu^2$. The quantity $\hat{p}_\mu$ is real, periodic in $p_\mu \to p_\mu + 2\pi/a$ as it must be, and vanishes not only at $p_\mu = 0$ but also at the zone boundary $p_\mu = \pi/a$ — a fact innocuous for the scalar but, as Section 43.1's successor sections will exploit, fatal for naive fermions, where it is the origin of doubling.

To get the propagator, diagonalize the free action. Inserting Eq. (43.47) into Eq. (43.45) and using Eq. (43.49) with the completeness relation,

$$S_E^{(0)}[\phi] = \frac{1}{2}\int_{\mathrm{BZ}} \frac{d^4p}{(2\pi)^4}\,(\hat{p}^2+m^2)\,\tilde{\phi}(-p)\,\tilde{\phi}(p), \qquad \tilde{\phi}(-p) = \tilde{\phi}(p)^*, \tag{43.51}$$

the last equality holding because $\phi(x)$ is real. The action is a sum of decoupled Gaussians, one per momentum mode, with stiffness $\hat{p}^2+m^2$. Coupling to a source J through $a^4\sum_x J\phi = \int_{\mathrm{BZ}}\frac{d^4p}{(2\pi)^4}\tilde{J}(-p)\tilde{\phi}(p)$ and completing the square mode by mode — the well-defined finite-dimensional Gaussian integral guaranteed by Section 43.1, and the exact lattice replica of the continuum manipulation in Chapter 10 — gives the connected two-point function as the inverse stiffness. We record the result as a proposition.

Proposition 43.11 (Lattice free propagator)**.** *For the free lattice scalar with action Eq. (43.45) on Λ_a, the two-point function is, in momentum and in position space,*

$$\tilde{G}(p) \;=\; \frac{1}{\hat{p}^2+m^2}, \qquad G(x-y) \;=\; \langle\phi(x)\phi(y)\rangle \;=\; \int_{\mathrm{BZ}}\frac{d^4p}{(2\pi)^4}\,\frac{e^{ip\cdot(x-y)}}{\hat{p}^2+m^2}, \tag{43.52}$$

with $\hat{p}^2$ given by Eq. (43.50). The denominator obeys $\hat{p}^2+m^2 \geq m^2 > 0$ for all $p \in \mathrm{BZ}$, so G is finite with no $i\epsilon$ prescription and no ultraviolet divergence: the lattice has cut the momentum integration off at the zone boundary.

Proof. Completing the square in Eq. (43.51) shifts $\tilde{\phi}(p) \to \tilde{\phi}(p) + \tilde{J}(p)/(\hat{p}^2+m^2)$, a translation of the integration variable with unit Jacobian, leaving

$$\ln Z[J] - \ln Z[0] = \frac{1}{2}\int_{\mathrm{BZ}}\frac{d^4p}{(2\pi)^4}\,\frac{\tilde{J}(-p)\,\tilde{J}(p)}{\hat{p}^2+m^2}.$$

Two functional derivatives with respect to the source, evaluated at $J=0$, extract $\tilde{G}(p) = 1/(\hat{p}^2+m^2)$; transforming back with Eq. (43.47) gives the position-space form. Positivity of the denominator is immediate from $\hat{p}^2 \geq 0$ and $m^2 > 0$, and the integration region is the bounded set Eq. (43.46), so the

integral converges absolutely. The Gaussian integral itself is finite-dimensional and absolutely convergent because $-\Delta + m^2$ is a positive operator, which is exactly the statement that the lattice measure of Section 43.1 restricted to the free sector is a normalizable Gaussian. □

This is the central object. The momentum integral is over a compact region and the integrand is bounded, so every quantity built from G — in particular the loop integrals of the interacting theory, where $\int_{\mathrm{BZ}} d^4p$ replaces $\int d^4p$ — is finite from the start. The lattice is a complete ultraviolet regulator, and unlike dimensional regularization or Pauli–Villars it is non-perturbative: it regulates the measure, not a diagram.

43.2.3 The continuum limit of the propagator and its $O(a^2)$ artifact

Fix a physical momentum p and let $a \to 0$. Then $ap_\mu \to 0$, so $\hat{p}_\mu = (2/a)\sin(ap_\mu/2) \to p_\mu$, the Brillouin zone Eq. (43.46) opens up to all of $\mathbb{R}^4$, and Eq. (43.52) becomes

$$G(x) \xrightarrow{a\to 0} \int_{\mathbb{R}^4} \frac{d^4p}{(2\pi)^4}\, \frac{e^{ip\cdot x}}{p^2+m^2}, \tag{43.53}$$

which is exactly the Euclidean (Schwinger) propagator of the free scalar, Eq. (10.168), the Wick rotation of the Feynman propagator Eq. (10.30). The naive continuum limit of the free two-point function is therefore correct: site-field discretization reproduces the right propagator. The interesting physics lives in the rate of approach, which we now extract.

Worked Example 43.12 (The lattice propagator to $O(a^2)$: the leading discretization error)**.** We expand $\hat{p}_\mu^2$ in powers of a and read off how the lattice propagator deviates from the continuum one. From the Taylor series $\sin\theta = \theta - \theta^3/6 + O(\theta^5)$ with $\theta = ap_\mu/2$,

$$\hat{p}_\mu = \frac{2}{a}\Big[\frac{ap_\mu}{2} - \frac{1}{6}\Big(\frac{ap_\mu}{2}\Big)^3 + O(a^5)\Big] = p_\mu - \frac{a^2}{24}\,p_\mu^3 + O(a^4),$$

and squaring (the cross term is $2\cdot p_\mu \cdot (-a^2 p_\mu^3/24) = -a^2 p_\mu^4/12$),

$$\hat{p}_\mu^2 = p_\mu^2 - \frac{a^2}{12}\,p_\mu^4 + O(a^4), \qquad \hat{p}^2 = \sum_\mu \hat{p}_\mu^2 = p^2 - \frac{a^2}{12}\sum_\mu p_\mu^4 + O(a^4), \tag{43.54}$$

where $p^2 = \sum_\mu p_\mu^2$. The leading correction $-\frac{a^2}{12}\sum_\mu p_\mu^4$ is suppressed by a^2 relative to p^2 — the forward/backward kinetic term is automatically $O(a^2)$-accurate, the $O(a)$ error of a single one-sided difference having cancelled in the symmetric

second difference Eq. (43.43). Inserting Eq. (43.54) into the propagator and expanding the geometric series,

$$\tilde{G}(p) = \frac{1}{\hat{p}^2 + m^2} = \frac{1}{(p^2 + m^2) - \frac{a^2}{12}\sum_\mu p_\mu^4 + O(a^4)} = \frac{1}{p^2 + m^2}\left[1 + \frac{a^2}{12}\frac{\sum_\mu p_\mu^4}{p^2 + m^2} + O(a^4)\right]. \tag{43.55}$$

The bracket exhibits the continuum propagator times 1 plus a fractional lattice artifact of order a^2p^2 (for $p \gg m$), exactly the behaviour plotted in Fig. 43.2.

The structure of the artifact carries a physical lesson. The continuum denominator $p^2 = \sum_\mu p_\mu^2$ is invariant under the Euclidean rotation group $O(4)$ (the rotation to Minkowski Lorentz invariance), but the correction $\sum_\mu p_\mu^4$ is *not*: it is invariant only under the hypercubic point group, the 48-element symmetry of the lattice cell that permutes and reflects the axes. The lattice breaks continuous rotations down to this finite subgroup, and the breaking shows up first at $O(a^2)$. This is the generic fate of a lattice observable: continuum (here $O(4)$) symmetry is recovered only as $a \to 0$, restored by the irrelevance — in the precise RG sense of Section 43.2.6 below — of the symmetry-breaking operators. One can engineer the leading $O(a^2)$ error away by adding further-neighbour terms to the action chosen to cancel Eq. (43.54) (Symanzik improvement, [463]); the resulting "improved" actions converge as $O(a^4)$ and are the workhorse of modern simulations. The point of principle, however, stands: the artifacts are there at finite a and vanish only in the limit.

43.2.4 Dimensionless variables: the lattice as a pure statistical system

A lattice simulation manipulates numbers, and a number cannot carry a dimension; the lattice spacing a is the only scale in sight and is itself just a label until something physical sets it. It is therefore essential to recast Eq. (43.5) in dimensionless variables, which also makes the upcoming criticality argument transparent. In four dimensions the canonical mass dimensions (in units $\hbar = c = 1$, with $[a] = -1$) are $[\phi] = 1$, $[m] = 1$, $[\lambda] = 0$. Define the dimensionless field, mass, and coupling

$$\hat{\phi}(n) \;=\; a\,\phi(an), \qquad \hat{m} \;=\; a\,m, \qquad \hat{\lambda} \;=\; \lambda, \tag{43.56}$$

(the quartic coupling is already dimensionless in $d = 4$, the marginality that will matter for triviality). Substituting $\phi(an) = \hat{\phi}(n)/a$ into Eq. (43.5), every explicit a cancels: the gradient term carries $a^4 \cdot a^{-2} \cdot a^{-2} = a^0$, the mass term $a^4 \cdot m^2 \cdot a^{-2} = (am)^2 = \hat{m}^2$, the quartic $a^4 \cdot a^{-4} = a^0$. The result is a purely

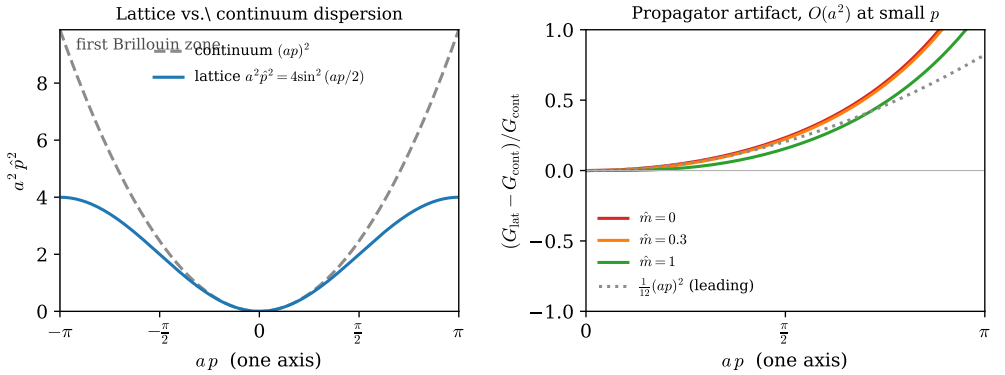

Figure 43.2: The lattice scalar at finite spacing. *Left:* the dispersion of the lattice Laplacian, $a^2\hat{p}^2 = 4\sin^2(ap/2)$ along one axis (solid), against the continuum $(ap)^2$ (dashed), over the first Brillouin zone $ap \in (-\pi, \pi]$. The two agree near $p = 0$ and separate toward the zone boundary; $\hat{p}$ even bends back to zero at $p = \pi/a$. *Right:* the resulting fractional error of the free propagator, $(G_{\rm lat} - G_{\rm cont})/G_{\rm cont}$, versus ap for several dimensionless masses $\hat{m} = am$, with the leading $\frac{1}{12}(ap)^2$ envelope (dotted). The artifact is $O(a^2)$ at small momentum and grows where the lattice can no longer resolve the wave.

numerical action over the integer lattice,

$$S_E[\hat{\phi}] \;=\; \sum_{n\in\mathbb{Z}^4} \left[\frac{1}{2} \sum_{\mu} \big(\hat{\phi}(n+\hat{\mu}) - \hat{\phi}(n)\big)^2 + \frac{1}{2}\,\hat{m}^2\,\hat{\phi}(n)^2 + \frac{\hat{\lambda}}{4!}\,\hat{\phi}(n)^4 \right]. \qquad (43.57)$$

This is the whole content of the regularized theory: a classical statistical-mechanics model of a real spin $\hat{\phi}(n)$ at each site of $\mathbb{Z}^4$, with nearest-neighbour ferromagnetic coupling and an on-site double-well-or-single-well potential, whose Boltzmann weight is $e^{-S_E[\hat{\phi}]}$. It depends on exactly two dimensionless parameters, $(\hat{m}^2, \hat{\lambda})$. (The traditional parametrization rescales $\hat{\phi}$ to make the hopping coefficient unity, trading $(\hat{m}^2, \hat{\lambda})$ for a *hopping parameter* κ and a quartic u; this is a change of variables, not of content, and we keep $(\hat{m}^2, \hat{\lambda})$.) The lattice scalar field theory *is* this statistical model. Every physical prediction must be a function of the two numbers $(\hat{m}^2, \hat{\lambda})$ alone — and this is precisely what forces the continuum limit to be a critical point.

43.2.5 Correlation length, the mass gap, and why the continuum limit is critical

The transfer matrix of Section 43.1 expresses the Euclidean two-point function as a sum over its eigenvalues; the leading large-separation behaviour is governed by the spectral gap. Taking the separation along a lattice axis (say direction 4,

"time"), with n_4 the number of time slices,

$$\left\langle \hat{\phi}(n)\,\hat{\phi}(0) \right\rangle \;\sim\; C\,e^{-\hat{m}\,n_4} \qquad (n_4 \to \infty), \tag{43.58}$$

where $\hat{m} = aE_1$ is the dimensionless energy gap (the mass gap of the reconstructed Hamiltonian, in lattice units), agreeing at leading order with the bare $\hat{m}$ for small coupling and renormalized by interactions in general. Equivalently, restoring physical length $x_4 = a\,n_4$, the correlator decays as $e^{-x_4/\xi_{\text{phys}}}$ with

$$\xi_{\text{phys}} \;=\; \frac{a}{\hat{m}} \;=\; \frac{1}{m_{\text{phys}}}, \qquad m_{\text{phys}} \;=\; \frac{\hat{m}}{a}, \tag{43.59}$$

where m_{phys} is the physical particle mass extracted from the exponential falloff and $\xi_{\text{phys}} = 1/m_{\text{phys}}$ is its Compton wavelength. The dimensionless number actually measured on the lattice is the correlation length *in lattice units*,

$$\hat{\xi} \;=\; \frac{\xi_{\text{phys}}}{a} \;=\; \frac{1}{\hat{m}}, \tag{43.60}$$

the number of lattice spacings over which correlations survive. It is a pure function of $(\hat{m}^2, \hat{\lambda})$ — consistent with Section 43.2.4, since it is dimensionless — and it is the bridge between the statistical model and continuum physics.

Proposition 43.13 (A finite physical mass forces tuning to criticality)**.** *Fix a target physical mass $m_{\text{phys}} > 0$. A continuum limit, defined as $a \to 0$ at fixed m_{phys}, exists only if the bare lattice parameters $(\hat{m}^2, \hat{\lambda})$ are tuned, as $a \to 0$, toward a point where the lattice correlation length diverges,*

$$\hat{\xi} \;=\; \frac{1}{a\,m_{\text{phys}}} \;\xrightarrow{a\to 0}\; \infty. \tag{43.61}$$

A divergent $\hat{\xi}$ is the defining feature of a second-order (continuous) phase transition: the continuum limit of the lattice scalar exists only at a critical point *of the statistical model Eq. (43.57).*

Proof. By Eq. (43.59), $a = \hat{\xi}^{-1}/m_{\text{phys}}$, so at fixed m_{phys} the lattice spacing in physical units is controlled entirely by $\hat{\xi}$: shrinking a is the same as growing $\hat{\xi}$, and $a \to 0 \iff \hat{\xi} \to \infty$. Since $\hat{\xi} = \hat{\xi}(\hat{m}^2, \hat{\lambda})$ is a function of the bare parameters alone (Section 43.2.4), driving $\hat{\xi} \to \infty$ requires moving $(\hat{m}^2, \hat{\lambda})$ to the locus where this function diverges. In the language of statistical mechanics a diverging correlation length is precisely the signature of a continuous phase transition — at a first-order transition $\hat{\xi}$ stays finite, while at a critical point it diverges as a power of the distance to criticality. Hence the bare couplings must be tuned to the critical surface; there is the continuum limit, and nowhere else.

The contrapositive is the more striking statement. Suppose instead one holds the bare couplings $(\hat{m}^2, \hat{\lambda})$ *fixed* (away from criticality) and lets $a \to 0$ — the

"naive" continuum limit. Then $\hat{\xi}$ is a fixed finite number, and Eq. (43.59) gives $\xi_{\text{phys}} = a\,\hat{\xi} \to 0$: the physical Compton wavelength shrinks to zero, equivalently $m_{\text{phys}} = \hat{m}/a \to \infty$. Every particle becomes infinitely heavy in physical units, every correlation collapses to a single site, and the limit is empty — it describes ultra-local, non-interacting fluctuations with no propagation, not a field theory. The naive limit does not fail to converge; it converges to nothing. This is the precise sense in which "the continuum limit is not $a \to 0$ at fixed couplings." □

Why the lattice spacing has no absolute meaning

The lattice spacing a never appears in the dimensionless action Eq. (43.57); it enters physics only through Eq. (43.59), which *defines* a in physical units once a measured mass is matched to its lattice value: $a = \hat{m}/m_{\text{phys}}$. Choosing a smaller a is not a separate operation from tuning the bare couplings closer to criticality — it *is* that tuning, read through the correlation length. "Approaching the continuum" and "approaching the critical point" are two descriptions of one motion in the space of bare couplings.

43.2.6 The continuum limit as a Wilsonian RG fixed point

Theorem 43.13 located the continuum limit at a critical point. The renormalization group of Chapter 23 now tells us what that critical point *is* and organizes the approach to it. Recall the Wilsonian picture: integrating out lattice fluctuations between scale a and a coarser scale ba ($b > 1$) and rescaling back induces a flow on the space of (dimensionless) couplings, $\hat{g} \mapsto R_b(\hat{g})$, with fixed points $\hat{g}_* = R_b(\hat{g}_*)$ (Theorem 23.19, Section 23.5). The correlation length transforms simply under a blocking by factor b: lengths measured in the coarsened lattice units are b times smaller, so $\hat{\xi} \mapsto \hat{\xi}/b$. A fixed point, being invariant under blocking, must therefore have $\hat{\xi} = \hat{\xi}/b$, which for $b > 1$ forces

$$\hat{\xi}_* \in \{0, \infty\}. \tag{43.62}$$

The trivial alternative $\hat{\xi} = 0$ describes a completely disordered or completely ordered sink with no fluctuations on any scale; the physically interesting fixed points have $\hat{\xi} = \infty$. These are exactly the critical points of Theorem 43.13. *A critical point of the lattice statistical model is a fixed point of the RG, and the continuum limit of the field theory lives there.* This is the identification promised in the section title, and it converts the construction of a continuum QFT into the study of the RG flow near a fixed point.

The flow near the fixed point is controlled by its linearization, classified in Theorem 23.23 into relevant ($y_i > 0$), marginal ($y_i = 0$), and irrelevant ($y_i < 0$) directions according to the eigenvalues of the linearized blocking transformation, with scaling dimensions $\Delta_i = d - y_i$ (Theorem 23.22). The implications for the lattice scalar are immediate and physical:

- The *relevant* directions are the couplings that must be *tuned* to reach the critical surface, because a generic point flows away from the fixed point along them. For the scalar there is one relevant coupling, the mass parameter $\hat{m}^2$ (scaling dimension 2, hence $y = d - 2 = 2 > 0$ in $d = 4$): the statement that $\hat{m}^2$ must be tuned to a critical value $\hat{m}_c^2(\hat{\lambda})$ to make $\hat{\xi}$ diverge is the RG statement that the relevant coupling must be set to its fixed-point value. This single tuning is the lattice incarnation of mass renormalization.

- The *irrelevant* directions die out under coarsening; they are the operators that the continuum limit forgets. The $O(a^2)$ lattice artifacts of Theorem 43.12 — the hypercubic-symmetry-breaking term $\sum_\mu p_\mu^4$, the higher-derivative and further-neighbour operators generated by blocking — are all irrelevant. Their decay under the flow is exactly why those artifacts vanish as $a \to 0$ and why full $O(4)$ (Lorentz) symmetry, broken at finite a, is restored in the continuum. It is also the origin of *universality*: lattice actions differing by irrelevant terms (a different difference scheme, an added Symanzik term, a different short-distance regulator entirely) flow to the same fixed point and yield the same continuum theory.

- The *marginal* coupling is $\hat{\lambda}$ ($\Delta = 4$, $y = 0$ in $d = 4$), whose fate is decided not at tree level but by loops. This is the case that decides whether ϕ_4^4 has any nontrivial continuum limit at all.

The practical face of this analysis is the notion of a *line of constant physics*. To take the continuum limit one does not pick bare couplings once; one moves along a trajectory $(\hat{m}^2(a), \hat{\lambda}(a))$ in bare-coupling space, indexed by a, chosen so that a fixed set of physical quantities (a mass ratio, say $m_{\text{phys}}\,\xi_{\text{phys}'}$, or a renormalized coupling defined at a physical scale) stays constant while $a \to 0$ and $\hat{\xi} \to \infty$. By construction this trajectory is a renormalized-trajectory of the RG flowing into the fixed point along its relevant direction; the irrelevant couplings are dragged to their fixed-point values automatically. The lattice thereby *realizes*, non-perturbatively and concretely, the abstract renormalized trajectory of Chapter 23: "renormalizing" a lattice theory means following a line of constant physics toward criticality.

The continuum limit, in one sentence

Defining a continuum quantum field theory *is* finding a fixed point of the renormalization group of a regularized statistical system and approaching it along a line of constant physics; the lattice makes both the system and the approach completely explicit, turning the question "does this QFT exist?" into the question "does the underlying statistical model have a suitable second-order critical point?".

43.2.7 The fate of ϕ^4 in four dimensions: triviality, stated and dated

We can now complete ϕ^4 theory at the non-perturbative layer. The question Section 43.2.6 leaves open is which fixed point the four-dimensional scalar flows to. There is always the *Gaussian fixed point* $\hat{\lambda}_* = 0$ (Theorem 23.20), the free theory, sitting at the origin of coupling space with $\hat{\xi} = \infty$ (a free massless scalar is scale invariant). The marginal coupling $\hat{\lambda}$ decides whether any *other*, interacting, fixed point exists with a continuum limit. Marginality is broken at one loop by the ϕ^4 beta function computed in ϕ^4 theory,

$$\beta_{\hat{\lambda}} \;=\; \frac{3\hat{\lambda}^2}{16\pi^2} + O(\hat{\lambda}^3) \;>\; 0 \tag{43.63}$$

(Eq. (24.40), Section 24.2). The sign is positive: $\hat{\lambda}$ is *marginally irrelevant* — it grows toward the ultraviolet and shrinks toward the infrared. Integrating Eq. (43.63) with the bare coupling $\hat{\lambda}$ held fixed at the lattice cutoff $1/a$, the renormalized coupling λ_R at a fixed physical scale μ behaves, as $a \to 0$, as

$$\lambda_R(\mu) \;\approx\; \frac{16\pi^2}{3\,\ln(1/a\mu)} \;\xrightarrow{a\to 0}\; 0, \tag{43.64}$$

so holding the bare coupling fixed and sending the cutoff up drives the renormalized coupling to zero (the Landau pole / triviality story of Section 24.7.2, Theorem 24.29, read here through the cutoff $1/a$). The complementary reading runs the other way: holding λ_R fixed at μ while $a \to 0$ would force the bare coupling $\hat{\lambda}(1/a)$ to *grow*, and Eq. (43.63) sends it through a Landau pole at a finite a — so that route reaches no continuum limit at all. In RG language: in $d = 4$ the only fixed point the flow of Eq. (43.57) can reach with $\hat{\xi} = \infty$ is the Gaussian one, and any continuum limit built on it is non-interacting. An interacting nontrivial fixed point does exist, but only away from four dimensions — the Wilson–Fisher fixed point in $d = 4 - \epsilon$, where $\hat{\lambda}$ becomes relevant and is balanced by the loop term at $\hat{\lambda}_* = \frac{16\pi^2}{3}\epsilon + O(\epsilon^2)$ (Section 24.7.5, ϕ^4 theory's eventual handoff to the conformal bootstrap). In strictly four dimensions, there is no such balance.

This is the content of the *triviality* of ϕ^4_4, and it deserves to be stated as a result of the lattice program rather than a perturbative extrapolation, because that is now what it is.

ϕ^4_4 triviality: status as of the mid-2020s

The perturbative argument above (a positive $\beta_{\hat{\lambda}}$, a Landau pole, a vanishing renormalized coupling as the cutoff is removed) is suggestive but not a proof: it could in principle be overturned by strong-coupling behaviour beyond the reach of Eq. (43.63). The non-perturbative evidence comes

from the lattice formulation of this very section. For dimensions $d > 4$ the triviality of the continuum limit of lattice ϕ^4 (and of the closely related Ising model) was proved rigorously by Aizenman and by Fröhlich around 1981–82 [10, 202], using correlation inequalities directly on the statistical model Eq. (43.57). The borderline and physically decisive case $d = 4$ — the marginal case, where the logarithms of Eq. (43.64) make the analysis delicate — resisted until the 2021 theorem of Aizenman and Duminil-Copin [11], which established that the scaling limit of the critical four-dimensional ϕ^4 (and Ising) model is Gaussian. As of the mid-2020s, then, it is a *theorem* that $\lambda\phi^4$ in four dimensions has no interacting continuum limit of the kind sought here: tuned to its critical point and taken to $a \to 0$, it yields a free field.

The physical reading is the one this book has stressed since the renormalization-group chapters. A nonzero measured ϕ^4 coupling — the Higgs self-coupling, a scalar order parameter near a critical point — is not a sign of a fundamental ϕ^4 field valid to arbitrarily short distances. It is the low-energy shadow of a theory that must possess a finite ultraviolet cutoff $1/a$, below which $\hat{\lambda}$ is appreciable and above which new physics, or a different fixed point, takes over. ϕ^4 in four dimensions is a textbook *effective* field theory, complete and predictive at long distances and silent about its own ultraviolet completion — exactly the status Chapter 23 taught us to expect of a theory governed by an irrelevant interaction near the Gaussian fixed point. The lattice has turned that expectation into a proved structural fact about the carried example we have followed since Chapter 6.

The scalar has thus served its purpose. It fixed the framework — discretize the Euclidean action, read the propagator off the diagonalized lattice Laplacian, recover the continuum as a critical point that is an RG fixed point — and delivered, as ϕ^4 theory's non-perturbative stage, the honest verdict of triviality in four dimensions. But the construction leaned on one feature peculiar to a scalar: the field lives on *sites*, and there was never any question of a local internal symmetry to protect. The moment we try to discretize a gauge field $A^a_\mu(x)$ the same way — a vector attached to each site — local gauge invariance is destroyed, because a gauge transformation relates the field at *neighbouring* sites and a site-by-site variable has no way to compensate the difference across a link. Preserving exact gauge invariance on the lattice forces a genuinely different fundamental variable: not the algebra-valued A_μ on a site, but the group-valued parallel transporter on the link between two sites. That is the subject of the next section, where the link variable U_μ, the plaquette, and Wilson's gauge action are built and shown to reduce to $\frac{1}{4}F^2$ in the continuum.

43.3 Gauge fields on the lattice: link variables and the Wilson action

The previous section taught us how to put a scalar field on a lattice and read the continuum limit off a critical point, but it also delivered a warning. The naive recipe that worked for the scalar — sample the field ϕ at the sites $x \in \Lambda$ of the hypercubic lattice $\Lambda = a\mathbb{Z}^4$ and replace derivatives by finite differences — destroys local gauge invariance the instant it is applied to a charged or non-abelian field. The reason is structural. A gauge transformation rotates the matter field by a *different* group element at every site, $\psi(x) \to \Omega(x)\psi(x)$ with $\Omega(x) \in \mathrm{SU}(N)$, and the only finite-difference object built from the field at two sites,

$$\bar{\psi}(x)\,\frac{\psi(x+a\hat{\mu})-\psi(x)}{a}, \tag{43.65}$$

contains the bilinear $\bar{\psi}(x)\psi(x+a\hat{\mu})$, which under the transformation becomes $\bar{\psi}(x)\,\Omega^\dagger(x)\Omega(x+a\hat{\mu})\,\psi(x+a\hat{\mu})$. The mismatched factor $\Omega^\dagger(x)\Omega(x+a\hat{\mu})$ does not cancel: it is the identity only if $\Omega(x) = \Omega(x+a\hat{\mu})$, i.e. only for a *global* transformation. At finite a the naive lattice action is not gauge invariant, and no amount of cleverness with the *site* field $A_\mu(x)$ repairs this, because $A_\mu(x)$ inherits the same disease: it is the connection sampled at a point, and a connection is precisely the object whose transformation law is inhomogeneous. The lesson, due to Wilson, is that on a lattice the fundamental gauge variable cannot be $A_\mu(x)$ at all. It must be the object that already knows how to carry a field from one site to its neighbour while compensating the gauge rotation in between — the parallel transporter of Chapter 25, evaluated on the elementary link. Everything in this section follows from taking that single idea seriously.

We work throughout in Euclidean signature, the Wick-rotated framework of Section 10.6 in which the path-integral weight e^{-S_E} is a genuine statistical measure; the previous section carried out the rotation explicitly for the scalar. All spacetime indices $\mu, \nu \in \{1,2,3,4\}$ are Euclidean, raised and lowered with $\delta_{\mu\nu}$, so contractions are ordinary sums of squares and there are no signature signs to track. We keep the frozen Yang–Mills theory conventions: gauge group $\mathrm{SU}(N)$, Hermitian fundamental generators T^a with $\mathrm{tr}(T^aT^b) = \frac{1}{2}\delta^{ab}$, matrix-valued connection $A_\mu = A_\mu^a T^a$, coupling g, covariant derivative $D_\mu = \partial_\mu - igA_\mu$, and the field strength

$$F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu - ig[A_\mu, A_\nu], \qquad F^a_{\mu\nu} = \partial_\mu A^a_\nu - \partial_\nu A^a_\mu + g f^{abc} A^b_\mu A^c_\nu, \tag{43.66}$$

of Eqs. (25.48) and (25.49). The hat $\hat{\mu}$ denotes the unit vector in direction μ, so $x + a\hat{\mu}$ is the lattice neighbour of x in that direction.

43.3.1 The link variable as a lattice parallel transporter

In the continuum the device that compensates the gauge rotation between two points is the Wilson line of Theorem 25.22, the path-ordered exponential $\mathcal{P}\exp(ig\int_C A_\mu\,dx^\mu)$. On the lattice the shortest nontrivial path is the elementary link joining a site x to its neighbour $x+a\hat{\mu}$. We promote the Wilson line on that one link to a dynamical variable in its own right.

Definition 43.14 (Link variable)**.** To each oriented link of the lattice, running from x to $x+a\hat{\mu}$, assign a group element $U_\mu(x)\in \mathrm{SU}(N)$, the *link variable*. It is the lattice incarnation of the Wilson line of Eq. (25.124) along that link,

$$U_\mu(x) \;=\; \mathcal{P}\exp\Big(ig\int_x^{x+a\hat{\mu}} A_\rho\,dx^\rho\Big) \;=\; \exp\big(iag\,A_\mu(x)\big)+O(a^2), \tag{43.67}$$

the second form being the leading short-link expansion, with the connection evaluated on the link. The reversed link carries the inverse, $U_{-\mu}(x+a\hat{\mu})\equiv U_\mu(x)^\dagger$, since traversing the link backward path-orders the comparator the other way and $U\in\mathrm{SU}(N)$ is unitary.

The crucial point is what we keep and what we discard. The continuum field $A_\mu(x)$ appears in Eq. (43.67) only inside the exponential and only as a way of writing a particular group element; the lattice theory's degree of freedom is the *group element* $U_\mu(x)$ itself, ranging over all of $\mathrm{SU}(N)$. We never again use $A_\mu(x)$ as an independent variable. This is not a notational nicety. The map $A_\mu\mapsto e^{iagA_\mu}$ is many-to-one (it is the exponential map onto a compact group), so a single U_μ corresponds to a whole family of A_μ's differing by the lattice analogue of a large gauge transformation; insisting on U as fundamental builds in compactness of the gauge group from the start, with consequences we exploit in Section 43.3.5.

The transformation law of the link variable is dictated entirely by its origin as a Wilson line. Under a lattice gauge transformation, an independent group element $\Omega(x)\in\mathrm{SU}(N)$ is assigned to every site, and matter rotates by $\psi(x)\to\Omega(x)\psi(x)$. The Wilson line of Theorem 25.25 transforms by conjugation at its endpoints, $W_C\to\Omega(x_f)\,W_C\,\Omega^\dagger(x_i)$ (this is Eq. (25.137), with the gauge matrix there written U and here written Ω to free the symbol U for the link). Applied to the elementary link, whose endpoints are x and $x+a\hat{\mu}$, this is the defining transformation rule of lattice gauge theory:

$$\boxed{\;U_\mu(x)\;\longrightarrow\;\Omega(x)\,U_\mu(x)\,\Omega^\dagger(x+a\hat{\mu})\;} \tag{43.68}$$

The link carries the gauge rotation of the site it starts at on the left and of the site it ends at on the right. Its entire purpose is to make the matter bilinear gauge invariant: the lattice-covariant hopping term is $\bar{\psi}(x)\,U_\mu(x)\,\psi(x+a\hat{\mu})$, which under the combined transformation becomes $\bar{\psi}(x)\Omega^\dagger(x)\cdot\Omega(x)U_\mu(x)\Omega^\dagger(x+a\hat{\mu})\cdot$

$\Omega(x+a\hat{\mu})\psi(x+a\hat{\mu}) = \bar{\psi}(x)U_\mu(x)\psi(x+a\hat{\mu})$, exactly invariant. The mismatched factor that ruined Eq. (43.65) is absorbed by the link. This is the whole point, and it works at *any* lattice spacing, not merely as $a \to 0$.

Notation Watch

In Chapter 25 the gauge transformation matrix was denoted $U(x)$ and the parallel transporter W_C. On the lattice the universal convention reverses the roles of the letters: the parallel transporter on a link is $U_\mu(x)$ — the dynamical field — while the gauge transformation is $\Omega(x)$. We adopt the lattice convention here. The objects are unchanged; only the names are swapped, and we have stated the dictionary explicitly so no reader confuses the field with the symmetry acting on it.

Physical Insight

A lattice gauge field is a discretized *geometry*. The continuum gauge field is a connection on a principal $\mathrm{SU}(N)$ bundle; its content is the rule for parallel transport, and that rule lives on paths, not points. Discretizing the manifold to a lattice discretizes the paths to links, and the connection becomes a collection of group-valued parallel transporters — one per edge — exactly as a discrete differential geometer would assign holonomies to the edges of a graph. Gauge invariance is then automatic for the right reason: physical (gauge-invariant) quantities are built only from *closed* loops of links, whose conjugation factors at the basepoint cancel under the trace, and from open lines capped at both ends by matter, whose endpoint rotations are absorbed by the fields. There is no gauge-variant quantity left to worry about, because we never wrote one down.

43.3.2 The plaquette and its exact gauge invariance

To build a pure gauge action we need a gauge-invariant functional of the links alone, with no matter fields. By the geometric principle just stated it must be a closed loop, and the smallest closed loop on the lattice is the elementary square — the *plaquette* — bounding one unit cell of the $\mu\nu$ plane.

Definition 43.15 (Plaquette variable)**.** The plaquette variable in the $\mu\nu$ plane based at x is the ordered product of the four link variables around the unit square $x \to x+a\hat{\mu} \to x+a\hat{\mu}+a\hat{\nu} \to x+a\hat{\nu} \to x$, traversed counterclockwise,

$$U_{\mu\nu}(x) \;=\; U_\mu(x)\, U_\nu(x+a\hat{\mu})\, U_\mu(x+a\hat{\nu})^\dagger\, U_\nu(x)^\dagger, \tag{43.69}$$

where the daggers implement the two backward links (Theorem 43.14). It is an element of $\mathrm{SU}(N)$.

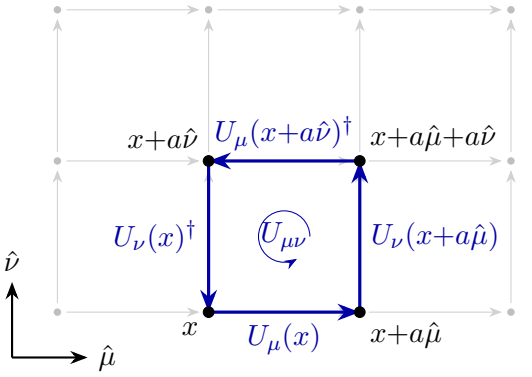

Figure 43.3: A slice of the hypercubic lattice. Each oriented edge carries a link variable $U_\mu(x) \in \mathrm{SU}(N)$, the parallel transporter from x to $x + a\hat{\mu}$ (Theorem 43.14); the reversed edge carries $U_\mu(x)^\dagger$. The highlighted unit square is the plaquette $U_{\mu\nu}(x)$ of Eq. (43.69), the ordered product of its four edge links read counterclockwise. Under a gauge transformation $U_\mu(x) \to \Omega(x)U_\mu(x)\Omega^\dagger(x + a\hat{\mu})$ the interior corner factors telescope and $U_{\mu\nu}(x) \to \Omega(x)U_{\mu\nu}(x)\Omega^\dagger(x)$, so $\mathrm{Re}\,\mathrm{tr}\,U_{\mu\nu}$ is exactly gauge invariant at every lattice spacing.

The ordering reads counterclockwise around the square (Fig. 43.3): forward along $\hat{\mu}$ at the bottom, forward along $\hat{\nu}$ at the right, backward along $\hat{\mu}$ at the top (hence the dagger of the link $U_\mu(x + a\hat{\nu})$, which is the *forward* link on the top edge traversed in reverse), and backward along $\hat{\nu}$ on the left. It is the lattice realization of the small Wilson loop of Section 25.6.5, with the abstract loop $\mathcal{C}$ taken to be one unit cell.

Proposition 43.16 (Gauge transformation of the plaquette)**.** *Under the lattice gauge transformation Eq. (43.68), the plaquette variable transforms by conjugation at its basepoint x,*

$$U_{\mu\nu}(x) \;\longrightarrow\; \Omega(x)\, U_{\mu\nu}(x)\, \Omega^\dagger(x), \tag{43.70}$$

and consequently its trace, and the real part of its trace, are exactly gauge invariant at any lattice spacing a.

Proof. Substitute the transformation Eq. (43.68) into each of the four factors of Eq. (43.69). The forward links transform as written; the backward links (daggers) transform as the daggers of Eq. (43.68), namely $U_\mu(x + a\hat{\nu})^\dagger \to \Omega(x + a\hat{\nu} + a\hat{\mu})\, U_\mu(x + a\hat{\nu})^\dagger\, \Omega^\dagger(x + a\hat{\nu})$ and $U_\nu(x)^\dagger \to \Omega(x + a\hat{\nu})\, U_\nu(x)^\dagger\, \Omega^\dagger(x)$. Writing the four transformed factors in order and inserting brackets around the gauge matrices that meet at each shared corner,

$$U_{\mu\nu}(x) \to \Omega(x)U_\mu(x)\underbrace{\Omega^\dagger(x+a\hat{\mu})\,\Omega(x+a\hat{\mu})}_{=\mathbf{1}}U_\nu(x+a\hat{\mu})\underbrace{\Omega^\dagger(x+a\hat{\mu}+a\hat{\nu})\,\Omega(x+a\hat{\nu}+a\hat{\mu})}_{=\mathbf{1}}$$

$$\times\, U_\mu(x{+}a\hat\nu)^\dagger \underbrace{\Omega^\dagger(x{+}a\hat\nu)\,\Omega(x{+}a\hat\nu)}_{=\mathbf{1}} U_\nu(x)^\dagger\,\Omega^\dagger(x)$$

$$= \Omega(x)\,U_\mu(x)U_\nu(x{+}a\hat\mu)U_\mu(x{+}a\hat\nu)^\dagger U_\nu(x)^\dagger\,\Omega^\dagger(x) = \Omega(x)\,U_{\mu\nu}(x)\,\Omega^\dagger(x). \tag{43.71}$$

Every interior corner of the square contributes a pair $\Omega^\dagger\Omega = \mathbf{1}$: the gauge matrix attached to a site by the link arriving there is exactly cancelled by the one attached by the link leaving it. Only the basepoint x, where the loop opens and closes, survives, leaving the conjugation Eq. (43.70). Taking the trace and using cyclicity together with $\Omega^\dagger\Omega = \mathbf{1}$,

$$\operatorname{tr} U_{\mu\nu}(x) \to \operatorname{tr}\big(\Omega(x)U_{\mu\nu}(x)\Omega^\dagger(x)\big) = \operatorname{tr}\big(\Omega^\dagger(x)\Omega(x)U_{\mu\nu}(x)\big) = \operatorname{tr} U_{\mu\nu}(x), \tag{43.72}$$

and the real part of an invariant is invariant. No expansion in a was used: the cancellation is algebraic, exact at finite spacing. □

This is the lattice version of the trace invariance of the Wilson loop, Theorem 25.26: the untraced plaquette is gauge *covariant*, conjugated at its basepoint, and the trace removes the residual conjugation. Equation Eq. (43.72) is the foundation of everything that follows. It says that $\operatorname{Re}\operatorname{tr} U_{\mu\nu}(x)$ is a legitimate gauge-invariant building block at every value of a, with no continuum limit invoked and — as we will see — no gauge fixing required.

43.3.3 The Wilson gauge action

We now assemble the simplest gauge-invariant action from plaquettes. Summing $\operatorname{Re}\operatorname{tr} U_{\mu\nu}$ over all plaquettes of the lattice gives a real, gauge-invariant functional of the links; subtracting it from its maximal value normalizes the action to vanish on the trivial configuration $U_{\mu\nu} = \mathbf{1}$ (no field), which corresponds to the zero-action vacuum.

Definition 43.17 (Wilson gauge action)**.** The *Wilson action* for an $\mathrm{SU}(N)$ gauge field on the lattice is

$$\boxed{S_W[U] \;=\; \beta \sum_x \sum_{\mu<\nu} \Big(1 - \tfrac{1}{N}\,\operatorname{Re}\operatorname{tr}\, U_{\mu\nu}(x)\Big), \qquad \beta = \frac{2N}{g^2},} \tag{43.73}$$

where the first sum runs over all sites $x \in \Lambda$ and the second over all distinct oriented planes $\mu < \nu$, so that each plaquette is counted once. The dimensionless parameter $\beta = 2N/g^2$ is the *lattice coupling* (the inverse coupling, in the language of statistical mechanics, where it plays the role of an inverse temperature).

Three features are immediate. First, S_W is exactly gauge invariant at any a, by Theorem 43.16 applied term by term. Second, the normalization $1 - \frac{1}{N}\operatorname{Re}\operatorname{tr} U_{\mu\nu}$

is non-negative — since $\operatorname{tr} U_{\mu\nu}$ for a unitary matrix has real part at most N, attained only at $U_{\mu\nu} = \mathbf{1}$ — so the action is bounded below by zero, and e^{-S_W} is bounded above by one, a property we will lean on when we argue convergence of the path integral. Third, the value of the constant β has been chosen, not derived; we now show that this particular choice is the one for which S_W reduces to the continuum Yang–Mills action.

43.3.4 The classical continuum limit

The decisive test of Eq. (43.73) is that as the lattice is refined, with the link variables set to their continuum values Eq. (43.67), the Wilson action collapses to the Euclidean Yang–Mills action $\frac{1}{4}\int F^a_{\mu\nu}F^a_{\mu\nu}$. The engine is the Baker–Campbell–Hausdorff (BCH) expansion of the plaquette, which we carry out in full.

Worked Example 43.18 (BCH expansion of the plaquette)**.** Set the links to their leading short-link form $U_\mu(x) = \exp(iag\,A_\mu(x))$ and compute $U_{\mu\nu}(x)$ to second order in the spacing a. We will find $U_{\mu\nu}(x) = \exp\big(ia^2 g\,F_{\mu\nu}(x) + O(a^3)\big)$.

Step 1: the four exponents. Each factor in Eq. (43.69) is the exponential of a Lie-algebra element of order a. The two daggers flip the sign of the exponent. Taylor-expanding the connection of the displaced factors about the basepoint x, $A_\nu(x + a\hat{\mu}) = A_\nu + a\,\partial_\mu A_\nu + O(a^2)$ and $A_\mu(x + a\hat{\nu}) = A_\mu + a\,\partial_\nu A_\mu + O(a^2)$ (with all fields on the right evaluated at x), the four exponents are

$$\begin{aligned} X_1 &= iag\,A_\mu, & X_2 &= iag\big(A_\nu + a\,\partial_\mu A_\nu\big) + O(a^3),\\ X_3 &= -iag\big(A_\mu + a\,\partial_\nu A_\mu\big) + O(a^3), & X_4 &= -iag\,A_\nu, \end{aligned} \tag{43.74}$$

so that $U_{\mu\nu} = e^{X_1}e^{X_2}e^{X_3}e^{X_4}$. Each X_i is $O(a)$.

Step 2: the BCH combination. For a product of exponentials,

$$e^{X_1}e^{X_2}e^{X_3}e^{X_4} = \exp\Big(\sum_i X_i + \tfrac{1}{2}\sum_{i<j}[X_i, X_j] + \cdots\Big), \tag{43.75}$$

where the omitted terms are nested double commutators, each of order a^3 since every X_i is $O(a)$. We need the exponent only to $O(a^2)$, so we keep the linear sum (to $O(a^2)$) and the single-commutator sum (using the $O(a)$ leading parts of the X_i), and drop the rest.

Step 3: the linear sum. The $O(a)$ pieces cancel because the loop closes: $iag(A_\mu + A_\nu - A_\mu - A_\nu) = 0$. The surviving $O(a^2)$ pieces come from the Taylor shifts in X_2 and X_3,

$$\sum_i X_i = ia^2 g\,\partial_\mu A_\nu - ia^2 g\,\partial_\nu A_\mu + O(a^3) = ia^2 g\big(\partial_\mu A_\nu - \partial_\nu A_\mu\big) + O(a^3). \tag{43.76}$$

This is the abelian curl — the first two terms of the field strength.

Step 4: the commutator sum. For the commutators we may use the $O(a)$ leading parts $X_1 \simeq iag\,A_\mu$, $X_2 \simeq iag\,A_\nu$, $X_3 \simeq -iag\,A_\mu$, $X_4 \simeq -iag\,A_\nu$ (the Taylor shifts would contribute at $O(a^3)$). Write $\alpha \equiv iag\,A_\mu$ and $\gamma \equiv iag\,A_\nu$, so $X_1 = \alpha$, $X_2 = \gamma$, $X_3 = -\alpha$, $X_4 = -\gamma$. The six ordered pairs give

$$\begin{aligned} &[X_1,X_2] = [\alpha,\gamma], && [X_1,X_3] = [\alpha,-\alpha] = 0, && [X_1,X_4] = [\alpha,-\gamma] = -[\alpha,\gamma], \\ &[X_2,X_3] = [\gamma,-\alpha] = [\alpha,\gamma], && [X_2,X_4] = [\gamma,-\gamma] = 0, && [X_3,X_4] = [-\alpha,-\gamma] = [\alpha,\gamma], \end{aligned} \tag{43.77}$$

using $[\gamma,\alpha] = -[\alpha,\gamma]$. Their sum is $(1-1+1+1)[\alpha,\gamma] = 2[\alpha,\gamma]$, so

$$\tfrac{1}{2}\sum_{i<j}[X_i,X_j] = [\alpha,\gamma] = (iag)^2[A_\mu,A_\nu] = -a^2g^2\,[A_\mu,A_\nu]. \tag{43.78}$$

Step 5: assemble. Adding Eqs. (43.76) and (43.78), the exponent of $U_{\mu\nu}$ is

$$\begin{aligned} \sum_i X_i + \tfrac{1}{2}\sum_{i<j}[X_i,X_j] &= ia^2g(\partial_\mu A_\nu - \partial_\nu A_\mu) - a^2g^2[A_\mu,A_\nu] + O(a^3) \\ &= ia^2g(\partial_\mu A_\nu - \partial_\nu A_\mu - ig[A_\mu,A_\nu]) + O(a^3) = ia^2g\,F_{\mu\nu}(x) + O(a^3), \end{aligned} \tag{43.79}$$

where in the second equality we factored out ia^2g from the commutator term using $-a^2g^2 = ia^2g\cdot(-ig)$, and in the third recognized $F_{\mu\nu}$ from Eq. (43.66). Therefore

$$\boxed{U_{\mu\nu}(x) = \exp\!\big(ia^2g\,F_{\mu\nu}(x) + O(a^3)\big) = \mathbf{1} + ia^2g\,F_{\mu\nu}(x) + O(a^3).} \tag{43.80}$$

This is precisely the small-loop holonomy of Eq. (25.149), $W(\mathcal{C}) = \mathbf{1} + ig\,a^\mu b^\nu F_{\mu\nu}$, specialized to the unit plaquette with edge vectors $a^\mu = a\hat{\mu}$ and $b^\nu = a\hat{\nu}$ and area element a^2: the full non-abelian curvature, self-coupling commutator included, emerges automatically from the ordered product of the four links. The plaquette *measures the curvature through the cell it bounds*, which is why it is the right object to build the action from.

With Eq. (43.80) in hand the continuum reduction is a short computation.

Theorem 43.19 (Classical continuum limit of the Wilson action)**.** *With the link variables set to their continuum values Eq. (43.67) and a smooth gauge field A_μ, the Wilson action Eq. (43.73) reduces to the Euclidean Yang–Mills action,*

$$S_W[U] \;\xrightarrow{a\to 0}\; \frac{1}{4}\int d^4x\; F^a_{\mu\nu}(x)\,F^a_{\mu\nu}(x) \;+\; O(a^2), \tag{43.81}$$

the choice $\beta = 2N/g^2$ being exactly what makes the prefactor unity.

Proof. Abbreviate $X \equiv a^2 g\, F_{\mu\nu}(x)$, a Hermitian matrix (since $F_{\mu\nu} = F^a_{\mu\nu} T^a$ with real components and Hermitian T^a), so that $U_{\mu\nu} = e^{iX}$ by Eq. (43.80). Expanding the exponential,

$$\operatorname{tr} U_{\mu\nu} = \operatorname{tr}\Big(\mathbf{1} + iX - \tfrac{1}{2}X^2 - \tfrac{i}{6}X^3 + \cdots\Big) = N + i\,\operatorname{tr} X - \tfrac{1}{2}\operatorname{tr} X^2 + \cdots . \tag{43.82}$$

Because X is Hermitian, $\operatorname{tr} X$ is real, so $i\,\operatorname{tr} X$ is pure imaginary and drops out of the real part; in fact $\operatorname{tr} X = a^2 g\, F^a_{\mu\nu} \operatorname{tr} T^a = 0$ since the generators are traceless, but we do not even need this. Likewise $\operatorname{tr} X^2$ is real. Hence

$$\operatorname{Re}\operatorname{tr} U_{\mu\nu} = N - \tfrac{1}{2}\operatorname{tr} X^2 + O(a^6) = N - \tfrac{1}{2} a^4 g^2\, \operatorname{tr}(F_{\mu\nu}F_{\mu\nu}) + O(a^6), \tag{43.83}$$

with no sum on μ, ν. The plaquette term in the action is therefore

$$1 - \tfrac{1}{N}\operatorname{Re}\operatorname{tr} U_{\mu\nu} = \frac{a^4 g^2}{2N}\, \operatorname{tr}(F_{\mu\nu}F_{\mu\nu}) + O(a^6). \tag{43.84}$$

Now sum over sites and planes and insert $\beta = 2N/g^2$, so that the explicit coupling factor collapses, $\beta \cdot \frac{g^2}{2N} = 1$:

$$S_W = \frac{2N}{g^2} \sum_x \sum_{\mu<\nu} \frac{a^4 g^2}{2N}\, \operatorname{tr}(F_{\mu\nu}F_{\mu\nu}) + \cdots = \sum_x a^4 \sum_{\mu<\nu} \operatorname{tr}(F_{\mu\nu}F_{\mu\nu}) + \cdots . \tag{43.85}$$

Three reductions finish the proof. The site sum becomes an integral by the definition of the lattice measure, $\sum_x a^4 \to \int d^4x$. The restricted plane sum becomes a full sum, $\sum_{\mu<\nu} = \frac{1}{2}\sum_{\mu,\nu}$, because $\operatorname{tr}(F_{\mu\nu}F_{\mu\nu})$ is symmetric in $\mu \leftrightarrow \nu$ (and the diagonal $\mu = \nu$ terms vanish). And the color trace is evaluated with the normalization $\operatorname{tr}(T^a T^b) = \frac{1}{2}\delta^{ab}$,

$$\operatorname{tr}(F_{\mu\nu}F_{\mu\nu}) = F^a_{\mu\nu} F^b_{\mu\nu}\, \operatorname{tr}(T^a T^b) = \tfrac{1}{2} F^a_{\mu\nu} F^a_{\mu\nu}. \tag{43.86}$$

Combining,

$$S_W \to \int d^4x\, \tfrac{1}{2} \sum_{\mu,\nu} \cdot \tfrac{1}{2} F^a_{\mu\nu} F^a_{\mu\nu} = \frac{1}{4}\int d^4x\, F^a_{\mu\nu} F^a_{\mu\nu}, \tag{43.87}$$

which is Eq. (43.81). The corrections are $O(a^2)$: the leading omitted terms in the BCH exponent are $O(a^3)$ inside $U_{\mu\nu}$, raising $\operatorname{Re}\operatorname{tr}$ corrections to relative order a^2 beyond the displayed a^4, which after the $\sum_x a^4 \to \int$ becomes an $O(a^2)$ correction to the continuum action — the hallmark of the Wilson action's leading discretization error. □

Two remarks tie this to the broader story. First, the result Eq. (43.87) is the *Euclidean* Yang–Mills action, $+\frac{1}{4}\int F^2$ with all indices down and summed with $\delta_{\mu\nu}$; it is the Wick rotation (Section 10.6) of the Minkowski $-\frac{1}{4}\int F^a_{\mu\nu} F^{a\,\mu\nu}$ of Yang–Mills theory, and it enters the statistical weight as e^{-S_W}. Second, the

appearance of the *bare* lattice coupling g inside β is not the end of the matter: as in the scalar case of the previous section, the physical continuum limit $a \to 0$ is not taken at fixed g but along a trajectory on which $g \to 0$, dictated by the renormalization group. For Yang–Mills that trajectory is governed by asymptotic freedom (Theorem 27.7 and Section 27.5): the bare coupling must be tuned to zero as $a \to 0$, so the continuum theory sits at the Gaussian ultraviolet fixed point, the gauge-theory instance of "the continuum limit is an RG fixed point" established in Section 23.6. We return to this when we ask, in the next section, whether the confinement found at large g survives the journey to $g \to 0$.

43.3.5 The Haar measure: exact gauge invariance with no gauge fixing

We can now write the lattice gauge theory's defining object, the partition function, and confront the feature that most sharply distinguishes the lattice from every continuum construction. The path integral is an ordinary integral over one copy of the compact group $\mathrm{SU}(N)$ for each link,

$$\boxed{Z = \int \prod_{x,\mu} dU_\mu(x)\, e^{-S_W[U]}, \qquad \langle \mathcal{O} \rangle = \frac{1}{Z} \int \prod_{x,\mu} dU_\mu(x)\, \mathcal{O}[U]\, e^{-S_W[U]},} \tag{43.88}$$

where dU is the *Haar measure* on $\mathrm{SU}(N)$. On a finite lattice this is a finite product of integrals over a compact manifold of fixed, finite dimension — in the most literal sense an ordinary (if enormous) multidimensional integral, with no functional analysis and no further regulator required. The choice of dU as the Haar measure is what makes Eq. (43.88) both well defined and exactly gauge invariant, so we state its properties precisely.

Proposition 43.20 (Haar measure on a compact group)**.** *On a compact Lie group G (here $G = \mathrm{SU}(N)$) there exists a unique normalized, bi-invariant integration measure dU, the* Haar measure*, characterized by:*

(i) Normalization: $\displaystyle\int_G dU = 1.$

(ii) Left and right invariance: *for any fixed $V \in G$ and any integrable f,*

$$\int_G f(VU)\, dU = \int_G f(UV)\, dU = \int_G f(U)\, dU. \tag{43.89}$$

(iii) Inversion invariance: $\displaystyle\int_G f(U^{-1})\, dU = \int_G f(U)\, dU.$

The existence and uniqueness of such a measure are guaranteed precisely by the compactness of G: a left-invariant measure exists on any locally compact group,

compactness makes its total mass finite so it can be normalized to (i), and on a compact group left invariance forces right invariance and inversion invariance as well.

We do not reprove the existence theorem here — it is a standard result of the theory of compact groups, and a self-contained construction (building dU from a bi-invariant volume form, or as the unique invariant mean) is recorded in [98, 139]. What we *do* need, and prove, is its consequence for the path integral.

Theorem 43.21 (Exact gauge invariance of the lattice path integral)**.** *The product measure $\prod_{x,\mu} dU_\mu(x)$ is invariant under any lattice gauge transformation Eq. (43.68). Consequently Z and every expectation value $\langle \mathcal{O} \rangle$ are gauge invariant, and no gauge fixing, Faddeev–Popov determinant, or Gribov choice is needed to define them.*

Proof. Fix a gauge transformation, i.e. a choice of $\Omega(x) \in \mathrm{SU}(N)$ at every site, and let it act on the links by $U_\mu(x) \mapsto U_\mu^\Omega(x) = \Omega(x) U_\mu(x) \Omega^\dagger(x + a\hat{\mu})$. For each link separately this is left multiplication by the fixed element $\Omega(x)$ followed by right multiplication by the fixed element $\Omega^\dagger(x + a\hat{\mu})$. By the left and right invariance Eq. (43.89) of the Haar measure, applied to that link's integration variable,

$$\int dU_\mu(x)\, f(U_\mu^\Omega(x)) = \int dU_\mu(x)\, f(U_\mu(x)), \tag{43.90}$$

for any integrand f. The full measure is the product of one such factor per link, and the transformation acts on each link's variable independently (the Ω's are external constants for the purpose of integration), so the product measure is invariant: $\prod_{x,\mu} dU_\mu^\Omega(x) = \prod_{x,\mu} dU_\mu(x)$. The Wilson action is invariant by Theorem 43.16, $S_W[U^\Omega] = S_W[U]$. Changing integration variables from U to U^Ω in Eq. (43.88) therefore leaves both the measure and the integrand unchanged, so Z is gauge invariant, and for any observable $\langle \mathcal{O}[U^\Omega] \rangle = \langle \mathcal{O}[U] \rangle$. Crucially, this required *no* restriction of the integration domain to a single representative per gauge orbit: we integrate over all links freely. □

The contrast with the continuum construction of Chapter 26 is the conceptual payoff of the entire link-variable formalism, and it deserves to be drawn explicitly.

Physical Insight: why the lattice needs no gauge fixing

In the continuum, the gauge field A_μ is a noncompact variable: at each point it ranges over the whole Lie algebra $\mathbb{R}^{\dim G}$. The path-integral measure $\mathcal{D}A$ then integrates over infinitely many physically identical copies of each configuration — the gauge orbit — and that orbit has *infinite* volume. The integral $\int \mathcal{D}A\, e^{-S}$ diverges through this redundant volume, and the Faddeev–Popov procedure of Section 26.2 is the surgery that

divides it out: insert $1 = \Delta_{\mathrm{FP}} \int \mathcal{D}\Omega\, \delta(G[A^{\Omega}])$, factor off the orbit volume, and pay for it with the determinant $\Delta_{\mathrm{FP}} = \det(\delta G/\delta\Omega)$, re-exponentiated as the ghost fields. On the lattice none of this arises. The link variable U_μ ranges over the *compact* group $\mathrm{SU}(N)$, whose total Haar volume per link is $\int dU = 1$; the gauge group at each site is the same compact $\mathrm{SU}(N)$, of finite volume. The redundant gauge-orbit volume is therefore finite — it is $\prod_x \mathrm{vol}(\mathrm{SU}(N))$, a finite constant — and in the normalized expectation value $\langle \mathcal{O} \rangle = Z^{-1} \int \mathcal{O}\, e^{-S_W}$ it cancels identically between numerator and denominator. There is nothing to divide out, hence no Faddeev–Popov determinant, no ghost fields, and no need to impose a gauge condition $G[A] = 0$ at all. The price the continuum pays for working with the noncompact A_μ is exactly the price the lattice avoids by working with the compact U_μ.

This evasion is not merely an economy; it removes a genuine pathology. The Faddeev–Popov construction is exact only locally in field space. A gauge-fixing surface $G[A] = 0$ generally intersects each orbit more than once — the *Gribov ambiguity* of Section 26.1.4 — so the continuum path integral, taken at face value, either overcounts or must be restricted to a Gribov region whose boundary is itself subtle. The lattice formulation Eq. (43.88) has no gauge-fixing surface, hence no Gribov copies: it is a manifestly gauge-invariant, manifestly finite definition of the integral, with no choices left to make and no ambiguity to resolve. This is the precise sense in which the lattice is a *constructive* definition of a gauge theory and the continuum gauge-fixed path integral is not.

Remark 43.22 (Local gauge symmetry cannot break; Elitzur's theorem). One might worry that, without gauge fixing, the expectation value of a gauge-variant quantity is ill defined or ambiguous. It is neither: it is automatically zero. By Theorem 43.21 the measure averages over the whole gauge orbit at each point, so any quantity that is not invariant integrates to zero against e^{-S_W} — for instance $\langle U_\mu(x) \rangle = 0$, since $\int d\Omega(x)\, \Omega(x) = 0$ over the group. The sharp statement is *Elitzur's theorem*: a local gauge symmetry can never be spontaneously broken, so the expectation value of any local non-gauge-invariant operator vanishes identically, with or without an explicit symmetry-breaking source taken to zero afterwards [174]. This is not needed for any computation below, but it explains why the absence of gauge fixing is harmless: the only quantities that can be nonzero are the gauge-invariant ones — Wilson loops, plaquette averages, and the like — which are exactly the quantities we wish to compute.

Caution

The fundamental variable is the group element $U_\mu(x)$, not the algebra element $A_\mu(x)$. At finite a the relation $U_\mu = e^{iagA_\mu}$ is not invertible to

a single A_μ, and there is no sense in which "$A_\mu(x)$ on the lattice" is a well-defined field; expressions like $\partial_\mu A_\nu$ on the lattice are meaningful only as the $a \to 0$ shorthand exhibited in Theorem 43.18. All exact lattice statements — gauge invariance, the action, the measure — are statements about the U's. Forgetting this and trying to gauge-fix "A" on the lattice reintroduces every problem the link formulation was designed to avoid.

We have, with no approximation and no gauge fixing, a manifestly gauge-invariant definition of a non-abelian gauge theory: links valued in SU(N), the Wilson action Eq. (43.73), and the Haar-measure integral Eq. (43.88) whose invariance is exact at every spacing. The decisive virtue of this formulation is that the weight e^{-S_W} depends on the links only through the bounded, group-valued plaquette traces, so for large g — small β — the exponential can be expanded and the link integrals done term by term using nothing more than the Haar orthogonality relations of Theorem 43.20. That strong-coupling expansion, carried out on exactly this Haar-measure path integral, is what the next section uses to extract an area law for the Wilson loop and, with it, the first analytic demonstration of confinement.

43.4 Confinement at strong coupling: the area law and the string tension

The previous section reduced the gauge sector of the lattice theory to a single, completely explicit object: an ordinary integral over one copy of the compact group SU(N) for every link of the lattice, weighted by the Wilson action and the invariant Haar measure (Section 43.3). No gauge fixing, no Faddeev–Popov determinant, no Gribov ambiguity — the integral is finite, manifestly gauge invariant, and, crucially for what follows, factorizes into a product over links that are coupled only through the plaquettes. This is the rare circumstance in which a four-dimensional interacting gauge theory can be computed *by hand*. We now exploit it. Expanding the Boltzmann weight in powers of the inverse coupling and performing the link integrals one at a time, we will derive — with every Haar integral done explicitly and every combinatorial factor accounted for — that the expectation value of a large Wilson loop falls off as the exponential of the *area* it spans. By the criterion built in Chapter 27 this is exactly the statement that the static quark–antiquark potential rises linearly and the charges are permanently confined. It is the first and cleanest analytic demonstration of confinement in any four-dimensional gauge theory, and it is the non-perturbative payoff that Yang–Mills theory has been driving toward since Chapter 25. The section closes by asking, with care, whether the result survives the continuum limit — and explaining honestly why that last step is, as of the mid-2020s,

established numerically rather than proved.

Notation Watch

Throughout this chapter β denotes the *lattice inverse coupling* $\beta = 2N/g^2$ appearing in the Wilson action, *not* a renormalization-group beta function. This is universal lattice usage. The two notions are related only indirectly — through the dependence of g^2 on the lattice spacing a, which is the subject of Section 43.4.6. Strong coupling means *large* bare g^2, hence *small* β, and the expansion of this section is a power series in β.

43.4.1 The single-link integrals: moments of the Haar measure

Everything in the strong-coupling expansion is built from a short list of integrals of products of matrix elements of a single link variable $U \in \mathrm{SU}(N)$ against its normalized Haar measure $\mathrm{d}U$. Recall from Section 43.3 the two defining properties of that measure that we will use repeatedly: it is *normalized*,

$$\int \mathrm{d}U \;=\; 1, \tag{43.91}$$

and it is *left- and right-invariant*: for any fixed $V, W \in \mathrm{SU}(N)$ and any integrable function f,

$$\int \mathrm{d}U\, f(U) \;=\; \int \mathrm{d}U\, f(VU) \;=\; \int \mathrm{d}U\, f(UW). \tag{43.92}$$

These two properties, together with elementary representation theory, fix every integral we need. The substantive content is collected in the following lemma; its last identity, the "two-U" integral, is the workhorse of the entire expansion.

Lemma 43.23 (Single-link moments)**.** *Let $U \in \mathrm{SU}(N)$ ($N \geq 2$) carry the normalized Haar measure. Then*

$$\int \mathrm{d}U\; U_{ij} \;=\; 0, \tag{43.93}$$

$$\int \mathrm{d}U\; U_{ij}\,(U^\dagger)_{kl} \;=\; \frac{1}{N}\,\delta_{il}\,\delta_{jk}, \tag{43.94}$$

$$\int \mathrm{d}U\; U_{ij}\,U_{kl} \;=\; 0 \quad (N \geq 3). \tag{43.95}$$

Proof. The first moment, Eq. (43.93). Set $M_{ij} = \int \mathrm{d}U\, U_{ij}$. The centre of $\mathrm{SU}(N)$ contains the elements $V = \omega\,\mathbf{1}$ with $\omega = e^{2\pi i/N}$, since $\det(\omega\mathbf{1}) = \omega^N = 1$. Left-invariance Eq. (43.89) with this V gives

$$M_{ij} = \int \mathrm{d}U\,(VU)_{ij} = \omega \int \mathrm{d}U\, U_{ij} = \omega\, M_{ij}, \tag{43.96}$$

so $(\omega-1)M_{ij}=0$. For $N\geq 2$ we have $\omega\neq 1$, hence $M_{ij}=0$. (For the abelian group U(1), where $U=e^{i\theta}$, the same conclusion is the trivial $\int_0^{2\pi}\frac{d\theta}{2\pi}\,e^{i\theta}=0$.)

The two-U integral, Eq. (43.94). Define the rank-four tensor

$$T_{ij,kl} \;=\; \int \mathrm{d}U\; U_{ij}\,(U^\dagger)_{kl}. \tag{43.97}$$

We determine it by invariance, in two steps: first its index structure, then its single overall constant. Apply left-invariance Eq. (43.89) with an arbitrary $V\in \mathrm{SU}(N)$, using $(VU)_{ij}=V_{ia}U_{aj}$ and $\big((VU)^\dagger\big)_{kl}=(U^\dagger V^\dagger)_{kl}=(U^\dagger)_{km}(V^\dagger)_{ml}$:

$$T_{ij,kl}=\int \mathrm{d}U\,(VU)_{ij}\big((VU)^\dagger\big)_{kl}=V_{ia}\,(V^\dagger)_{ml}\,T_{aj,km}. \tag{43.98}$$

This says that, regarded as acting on the index pair (i,l), the tensor T commutes with the simultaneous transformation $V\otimes V^\dagger$ of the fundamental $\mathbf{N}$ and the antifundamental $\bar{\mathbf{N}}$, for *every* V. The invariant tensors of $\mathbf{N}\otimes\bar{\mathbf{N}}$ form a one-dimensional space — the singlet in the decomposition $\mathbf{N}\otimes\bar{\mathbf{N}}=\mathbf{1}\oplus(\mathbf{N}^2{-}\mathbf{1})$ (Chapter B), whose invariant tensor is the Kronecker delta δ_{il}. Hence the dependence of T on (i,l) is through δ_{il} alone. Applying right-invariance, $U_{ij}\to U_{ib}W_{bj}$ and $(U^\dagger)_{kl}\to(W^\dagger)_{kc}(U^\dagger)_{cl}$, the identical argument forces the dependence on (j,k) to be through δ_{jk}. The only tensor built from these two deltas is

$$T_{ij,kl} \;=\; c\,\delta_{il}\,\delta_{jk}, \tag{43.99}$$

with a single constant c to be fixed. (No competing structure $\delta_{ik}\delta_{jl}$ is allowed: it would contract two fundamental indices i,k with a delta, which is not an $\mathrm{SU}(N)$ invariant for $N\geq 2$; the only other invariant tensors, the Levi-Civita symbols, carry N indices, not two.) To fix c, contract Eqs. (43.97) and (43.99) with $\delta_{jk}\delta_{li}$ and sum — i.e. set $k=j$, $l=i$ and sum over i,j. The left side becomes

$$\sum_{i,j}\int \mathrm{d}U\,U_{ij}(U^\dagger)_{ji}=\int \mathrm{d}U\;\mathrm{tr}(UU^\dagger)=\int \mathrm{d}U\;\mathrm{tr}\,\mathbf{1}=N, \tag{43.100}$$

where unitarity $UU^\dagger=\mathbf{1}$ and normalization Eq. (43.91) were used. The right side becomes $c\sum_{i,j}\delta_{ii}\delta_{jj}=cN^2$. Equating, $cN^2=N$, so $c=1/N$, which is Eq. (43.94).

The two-U integral without a dagger, Eq. (43.95). Repeat the centre argument on $S_{ij,kl}=\int \mathrm{d}U\,U_{ij}U_{kl}$: with $V=\omega\mathbf{1}$, left-invariance gives $S=\omega^2 S$, so $S=0$ unless $\omega^2=1$, i.e. unless $N\leq 2$. For $N\geq 3$ the integral vanishes. (For SU(2) it is proportional to the invariant $\varepsilon_{ik}\varepsilon_{jl}$, since $\bar{\mathbf{2}}\cong\mathbf{2}$ there; this special case plays no role below.) □

The pattern behind Theorem 43.23 is the only fact we need to remember: *the Haar integral of a product of link variables vanishes unless every fundamental index can be paired with a conjugate one carried by a $U^\dagger$ on the same link.* A

bare U integrates to zero Eq. (43.93); a U paired with a $U^\dagger$ survives and ties their colour indices together with the weight $1/N$ Eq. (43.94); two un-conjugated U's integrate to zero for $N \geq 3$ Eq. (43.95). This pairing rule is what will force the Wilson loop to be "filled in" by a surface of plaquettes.

Physical Insight

The pairing rule is the lattice avatar of charge conservation. A single link variable $U_\mu(x)$ carries one unit of fundamental colour flux across the link; an isolated unit of flux averages to nothing over the gauge group. Only when the flux is returned — a U matched by a $U^\dagger$ on the same link — does the average survive. A Wilson loop deposits one unit of unmatched flux on each of its boundary links, and the only way the path integral can return that flux is to grow a sheet of plaquettes whose own links supply the missing conjugates. The cheapest sheet, in powers of the small coupling, is the minimal surface spanning the loop. The area law is the statement that paying for that surface costs an amount proportional to its area.

43.4.2 The strong-coupling expansion

Recall the Wilson action from Eq. (43.73),

$$S_{\text{lat}} \;=\; \beta \sum_{p} \Big(1 - \tfrac{1}{N}\, \operatorname{Re}\operatorname{tr} U_p \Big), \qquad \beta = \frac{2N}{g^2}, \tag{43.101}$$

where the sum runs over all elementary plaquettes p and $U_p = U_\mu(x)\, U_\nu(x+\hat{\mu})\, U_\mu^\dagger(x+\hat{\nu})\, U_\nu^\dagger(x)$ is the ordered product of the four link variables around p. The constant $\beta \sum_p 1$ is field-independent and cancels between numerator and denominator of any expectation value, so we drop it and work with the reduced Boltzmann weight

$$e^{-S_{\text{lat}}} \;\doteq\; \prod_{p} \exp\Big(\tfrac{\beta}{2N} \big(\operatorname{tr} U_p + \operatorname{tr} U_p^\dagger \big) \Big), \tag{43.102}$$

using $\operatorname{Re}\operatorname{tr} U_p = \tfrac{1}{2}(\operatorname{tr} U_p + \operatorname{tr} U_p^\dagger)$ and writing $\doteq$ for equality up to the cancelled constant. Each factor is now expanded as a power series in the small parameter β:

$$\exp\Big(\tfrac{\beta}{2N} \big(\operatorname{tr} U_p + \operatorname{tr} U_p^\dagger \big) \Big) \;=\; 1 \;+\; \frac{\beta}{2N} \big(\operatorname{tr} U_p + \operatorname{tr} U_p^\dagger \big) \;+\; \mathcal{O}(\beta^2). \tag{43.103}$$

This is the lattice analogue of the high-temperature expansion of statistical mechanics: β plays the role of inverse temperature, each plaquette is a small "bond," and the expectation value of any observable becomes a sum of geometric configurations of activated plaquettes, weighted by powers of β. (The systematic resummation organizes Eq. (43.103) not in powers of $\operatorname{tr} U_p$ but in the irreducible

characters of SU(N), the *character expansion*; at the leading order we need, the two coincide, the fundamental character being $\chi_{\mathbf{N}}(U_p) = \operatorname{tr} U_p$, and we use the simpler form Eq. (43.103).) The full expectation value is

$$\langle \mathcal{O} \rangle = \frac{1}{Z} \int \Big(\prod_l \mathrm{d}U_l \Big)\, \mathcal{O} \prod_p \Big[1 + \tfrac{\beta}{2N} \big(\operatorname{tr} U_p + \operatorname{tr} U_p^\dagger \big) + \mathcal{O}(\beta^2) \Big], \tag{43.104}$$

with Z the same integral with $\mathcal{O} \to 1$. Expanding the product over plaquettes, each term is a choice of a finite set of plaquettes whose $\operatorname{tr} U_p$ or $\operatorname{tr} U_p^\dagger$ factors are "pulled down," and the link integrals are then performed with Theorem 43.23. By the pairing rule, only those terms survive in which every link carries a matched $U/U^\dagger$ pair. We now apply this to the Wilson loop.

43.4.3 The area law from minimal-area tiling

The Wilson loop on the lattice is the normalized trace of the ordered product of link variables around a closed contour $\mathcal{C}$ (the discretization of Eq. (25.139)):

$$W(\mathcal{C}) = \frac{1}{N} \operatorname{tr} \prod_{l \in \mathcal{C}} U_l. \tag{43.105}$$

We take $\mathcal{C}$ to be a planar $R \times T$ rectangle, with R/a links along the spatial direction and T/a links along the temporal direction. Each of its $2(R+T)/a$ boundary links carries exactly one un-conjugated link variable from Eq. (43.105). By Eq. (43.93) every one of those integrals vanishes on its own; to rescue them we must supply, from the plaquette expansion Eq. (43.103), a conjugate variable on each boundary link. Each plaquette pulled down to do so carries three *further* link variables, which themselves vanish under Eq. (43.93) unless paired, requiring yet more plaquettes, and so on. The chain of forced pairings terminates only when the activated plaquettes tile a connected surface Σ whose boundary is exactly $\mathcal{C}$. Each tile costs one power of $\beta/2N$; the leading, lowest-order term is therefore the one with the *fewest* plaquettes, i.e. the *minimal* spanning surface. For a planar rectangle that is the flat rectangle itself, tiled by

$$n_p = \frac{\mathcal{A}}{a^2} = \frac{RT}{a^2} \tag{43.106}$$

elementary plaquettes (Fig. 43.4).

It remains to evaluate the corresponding integral exactly. We do the single-tile case first, in full, and then assemble the general rectangle by a colour-index count.

One plaquette. Take $\mathcal{C}$ to be the boundary of a single plaquette, so $W = \frac{1}{N} \operatorname{tr} U_p$ with $U_p = U_1 U_2 U_3^\dagger U_4^\dagger$ (links $1, 2$ traversed forward, $3, 4$ backward). The

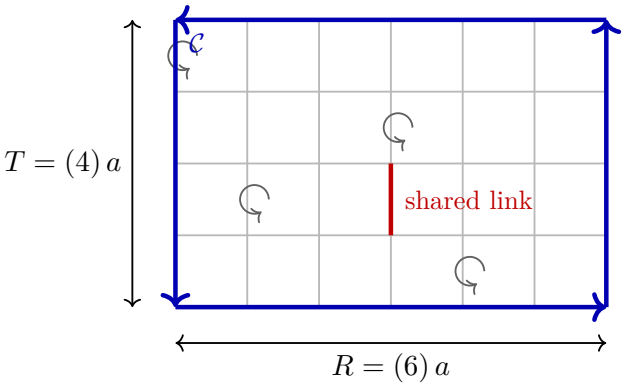

Figure 43.4: The minimal surface Σ spanning a rectangular Wilson loop $\mathcal{C}$ (blue, oriented), tiled by $n_p = RT/a^2$ elementary plaquettes (grey). Each boundary link carries one link variable from $W(\mathcal{C})$, paired by the adjacent plaquette; each interior link (red) is shared by two plaquettes whose orientations are opposite, so it carries a matched $U/U^\dagger$ pair. Every link of Σ is thereby saturated, and the leading strong-coupling weight is the product over tiles.

only surviving term of the expansion pairs each of the four loop variables with a conjugate, which the action supplies through the single factor $\frac{\beta}{2N}\operatorname{tr} U_p^\dagger$:

$$\langle W\rangle = \frac{1}{N}\cdot\frac{\beta}{2N}\int\Big(\prod_{m=1}^{4}\mathrm{d}U_m\Big)(\operatorname{tr}U_p)(\operatorname{tr}U_p^\dagger) + \mathcal{O}(\beta^2). \tag{43.107}$$

Write the two traces in indices,

$$\operatorname{tr}U_p = (U_1)_{i_1 i_2}(U_2)_{i_2 i_3}(U_3^\dagger)_{i_3 i_4}(U_4^\dagger)_{i_4 i_1}, \tag{43.108}$$

$$\operatorname{tr}U_p^\dagger = (U_4)_{j_1 j_2}(U_3)_{j_2 j_3}(U_2^\dagger)_{j_3 j_4}(U_1^\dagger)_{j_4 j_1}, \tag{43.109}$$

and integrate each link with Eq. (43.94). Link 1 carries $(U_1)_{i_1 i_2}(U_1^\dagger)_{j_4 j_1} \to \frac{1}{N}\delta_{i_1 j_1}\delta_{i_2 j_4}$; link 2 carries $(U_2)_{i_2 i_3}(U_2^\dagger)_{j_3 j_4} \to \frac{1}{N}\delta_{i_2 j_4}\delta_{i_3 j_3}$; link 3 carries $(U_3)_{j_2 j_3}(U_3^\dagger)_{i_3 i_4} \to \frac{1}{N}\delta_{j_2 i_4}\delta_{j_3 i_3}$; link 4 carries $(U_4)_{j_1 j_2}(U_4^\dagger)_{i_4 i_1} \to \frac{1}{N}\delta_{j_1 i_1}\delta_{j_2 i_4}$. The four factors of $1/N$ give $(1/N)^4$. The deltas impose $j_1 = i_1$, $j_4 = i_2$, $j_3 = i_3$, $j_2 = i_4$, after which i_1, i_2, i_3, i_4 run freely from 1 to N; summing gives N^4. Hence

$$\int\prod_m \mathrm{d}U_m\,(\operatorname{tr}U_p)(\operatorname{tr}U_p^\dagger) = \Big(\frac{1}{N}\Big)^4 N^4 = 1, \tag{43.110}$$

and therefore, for the single plaquette,

$$\langle W\rangle = \frac{1}{N}\cdot\frac{\beta}{2N}\cdot 1 = \frac{\beta}{2N^2} + \mathcal{O}(\beta^2). \tag{43.111}$$

Each tile contributes the factor $\beta/2N^2$. The colour bookkeeping that produced $N^4 = N^{\#\text{sites}}$ from the four index loops — one circling each corner of the plaquette — is the seed of the general count.

The full rectangle. For the rectangle of Fig. 43.4 the leading surviving term activates every one of the n_p tiles once (with the orientation that pairs interior links). Three facts assemble the answer.

(i) Plaquette factors. Each activated tile brings one factor $\beta/2N$ from Eq. (43.103), giving $(\beta/2N)^{n_p}$.

(ii) Link factors. Every link of Σ — boundary or interior — ends up carrying exactly one matched $U/U^\dagger$ pair: a boundary link is paired between the loop W and its single adjacent tile; an interior link is shared by two tiles whose opposite orientations supply a U from one and a $U^\dagger$ from the other (Fig. 43.4). Each link integral therefore yields a factor $1/N$ and a pair of Kronecker deltas, by Eq. (43.94). Writing L for the number of links of Σ, this gives $(1/N)^L$.

(iii) Colour-index loops. The Kronecker deltas, contracted through the whole network, organize the colour indices into closed loops, each contributing a free sum $\sum_{i=1}^{N} 1 = N$. In the double-line (ribbon) bookkeeping of these contractions, the closed index loops are in one-to-one correspondence with the *sites* of Σ: at each site, the index lines of the links meeting there close into a single small loop encircling the site. (The one-plaquette computation verifies the correspondence directly: four sites, four index loops, factor N^4.) Writing V for the number of sites of Σ, the index loops give N^V, including the overall $1/N$ from the normalization of W in Eq. (43.105) which we account for separately below.

Collecting (i)–(iii) and the loop normalization,

$$\langle W(\mathcal{C})\rangle = \frac{1}{N}\left(\frac{\beta}{2N}\right)^{n_p}\left(\frac{1}{N}\right)^{L} N^{V} = \frac{\beta^{\,n_p}}{2^{\,n_p}}\, N^{\,V-L-n_p-1}. \tag{43.112}$$

Now use the Euler characteristic of the tiled disk. A rectangle of $m \times n$ plaquettes ($m = R/a$, $n = T/a$, $n_p = mn$) has $V = (m{+}1)(n{+}1)$ sites and $L = m(n{+}1) + (m{+}1)n = 2mn + m + n$ links, so

$$V - L + n_p = (mn{+}m{+}n{+}1) - (2mn{+}m{+}n) + mn = 1, \tag{43.113}$$

the Euler characteristic of a disk, $\chi = 1$. Hence $V - L = 1 - n_p$, and the exponent of N in Eq. (43.112) is $V - L - n_p - 1 = (1 - n_p) - n_p - 1 = -2n_p$. The two factors of $1/N$ per tile (one from the link integrals, one from the index-loop deficit relative to the plaquette count) combine, and we obtain the clean result

$$\boxed{\langle W(\mathcal{C})\rangle \;=\; \left(\frac{\beta}{2N^2}\right)^{n_p}\!\left[1+\mathcal{O}(\beta)\right] \;=\; \left(\frac{\beta}{2N^2}\right)^{\mathcal{A}/a^2}\!\left[1+\mathcal{O}(\beta)\right].} \tag{43.114}$$

The Euler-characteristic identity Eq. (43.113) is precisely what makes the single-plaquette factor $\beta/2N^2$ exponentiate cleanly into the area, with no leftover boundary or normalization powers of N.

Theorem 43.24 (Strong-coupling area law)**.** *For lattice* SU(N) *gauge theory with the Wilson action Eq. (43.101) at small inverse coupling β, the expectation value*

of a large planar rectangular Wilson loop obeys an area law (Theorem 27.18),

$$\langle W(\mathcal{C})\rangle = e^{-\sigma\,\mathcal{A}}\big[1+\mathcal{O}(\beta)\big], \qquad \sigma a^2 = -\ln\frac{\beta}{2N^2} = \ln\frac{2N^2}{\beta}, \tag{43.115}$$

with $\mathcal{A} = RT$ the enclosed area and a strictly positive string tension $\sigma > 0$ for $\beta < 2N^2$. In particular the lattice theory confines, for every N and in every spacetime dimension $d \geq 2$.

Proof. Rewrite Eq. (43.114) as $\langle W\rangle = \exp\big[\, n_p \ln(\beta/2N^2)\,\big] = \exp\big[-(\mathcal{A}/a^2)\ln(2N^2/\beta)\big]$, using Eq. (43.106). Comparison with the area-law form Eq. (27.175) identifies $\sigma a^2 = \ln(2N^2/\beta)$, which is positive exactly when $\beta < 2N^2$, i.e. for sufficiently strong bare coupling. The derivation used only the pairing rule Theorem 43.23 and the combinatorics of tiling a disk, neither of which referred to the dimension or to the number of colours beyond $N \geq 2$. □

43.4.4 The string tension and the linear potential

Theorem 43.24 is the analytic heart of the chapter, but its physical meaning is delivered only by reconnecting it to the static potential. That bridge was built in Chapter 27: the rectangular Wilson loop with a long temporal extent T measures the energy of a static quark–antiquark pair held at spatial separation R. We restate the link in the lattice language of Section 43.1.4, where it is exact rather than formal.

The Euclidean lattice has a positive, self-adjoint *transfer matrix* $\hat{\mathcal{T}} = e^{-a\hat{H}}$ (constructed in Section 43.1.4 from reflection positivity of the Wilson action), with $\hat{H}$ the lattice Hamiltonian. A correlation function separated by $T = N_t a$ lattice steps in Euclidean time is the matrix element of $\hat{\mathcal{T}}^{N_t} = e^{-\hat{H}T}$. Inserting a complete set of eigenstates of $\hat{H}$ *in the presence of the two static colour sources at separation R* — exactly the spectral decomposition carried out in Theorem 27.19 — the rectangular Wilson loop has the exact representation

$$\langle W(\mathcal{C}_{R,T})\rangle = \sum_{n} |c_n|^2\; e^{-E_n(R)\,T}, \qquad V(R) \equiv E_0(R) = -\lim_{T\to\infty}\frac{1}{T}\ln\langle W(\mathcal{C}_{R,T})\rangle\,, \tag{43.116}$$

where $E_0(R) = V(R)$ is the static quark–antiquark potential (the ground-state energy of the gauge field bound to the sources) and the higher $E_n(R)$ are excited flux-tube states. This is Eq. (27.183); nothing in it was perturbative.

Now feed the strong-coupling result Eq. (43.115) into Eq. (43.116). The area law gives, at leading order, $\langle W(\mathcal{C}_{R,T})\rangle = e^{-\sigma RT}$, so

$$V(R) = -\lim_{T\to\infty}\frac{1}{T}\ln e^{-\sigma RT} = \sigma R. \tag{43.117}$$

The potential is linear, the force $-dV/dR = -\sigma$ is constant and never vanishes, and the energy to separate the pair grows without bound: a single colour charge

cannot be isolated. This is confinement, in the sharp sense of Theorem 27.20, and it has now been *derived* — not assumed, modelled, or imported as a criterion — directly from the lattice path integral. The criterion of Section 27.7 (area law $\Leftrightarrow$ linear confinement) is satisfied, with the string tension supplied explicitly by Eq. (43.115).

Worked Example 43.25 (Leading string tension and linear potential for SU(N))**.** We extract the dimensionful string tension and the potential for general N, then specialize to SU(3).

String tension. From Eq. (43.115), with $\beta = 2N/g^2$ so that $2N^2/\beta = Ng^2$,

$$\sigma a^2 = \ln\frac{2N^2}{\beta} = \ln(Ng^2) + \mathcal{O}(\beta^2), \tag{43.118}$$

in exact agreement with the leading lattice result quoted in Chapter 27 (Eq. (27.192)). For SU(3) at, say, $\beta = 1$ (deep in the strong-coupling regime), $\sigma a^2 = \ln(2\cdot 9/1) = \ln 18 \approx 2.89$, so the correlation length $1/\sqrt{\sigma} \approx 0.59\,a$ is well under one lattice spacing — a self-consistency check that the expansion is being used where it converges (the flux tube is fat in lattice units only near the continuum, at large β).

Linear potential and its slope. By Eq. (43.117) the static potential at leading order is purely linear,

$$V(R) = \sigma R = \frac{\ln(2N^2/\beta)}{a^2}\,R, \tag{43.119}$$

with no Coulombic $1/R$ piece at this order — the one-gluon-exchange tail of the Cornell potential Eq. (27.186) is a *weak*-coupling effect, recovered only by summing the strong-coupling series or, in practice, by approaching the continuum. The number of flux quanta the loop encloses is $\sigma\mathcal{A}$ in natural units, and the energy stored in a tube of length R is σR: a string of constant tension σ. The first excited state in Eq. (43.116), $E_1(R) - E_0(R)$, is the gap to a deformed flux tube; in the strong-coupling expansion it corresponds to the cheapest *non-minimal* tiling (a tile bumped out of the plane), suppressed by extra powers of β, which is why Eq. (43.116) is dominated by its ground state and the limit defining $V(R)$ converges exponentially fast in T.

Why every N confines here. Nothing in Eq. (43.118) singled out $N = 3$, or four dimensions, or even non-abelian structure: the same computation with U(1) link variables $U = e^{i\theta}$ gives $\int \frac{d\theta}{2\pi} e^{i\theta}e^{-i\theta} = 1$ and $\int \frac{d\theta}{2\pi} e^{i\theta} = 0$, the abelian instances of Theorem 43.23, and reproduces $\sigma a^2 = \ln(2/\beta)$ (here $N \to 1$, $2N^2 \to 2$). The strong-coupling lattice confines abelian and non-abelian gauge theories alike. That this is *too* good — compact U(1) is *not* confining in the continuum — is the warning we take up next.

43.4.5 Convergence and the leading corrections

Two points sharpen the status of Theorem 43.24. First, the strong-coupling expansion is genuinely *convergent*, not merely asymptotic. Like the high-temperature expansion of a lattice spin system, it is a power series in β whose coefficients count geometric configurations of activated plaquettes; the number of surfaces of a given area grows only geometrically (a connected surface of n_p plaquettes can be built in at most C^{n_p} ways for some lattice-dependent constant C), while each carries β^{n_p}, so the series has a finite radius of convergence $\beta_0 > 0$. For $\beta < \beta_0$ the area law, including the existence of a positive string tension, is a rigorous theorem about the lattice theory, with controlled error bounds. Confinement at strong coupling is proved, not conjectured.

Second, the corrections to Eq. (43.114) are themselves instructive. The $\mathcal{O}(\beta)$ terms come from (a) decorating the minimal surface with extra plaquettes that pair among themselves (vacuum fluctuations renormalizing the tension) and (b) replacing the flat minimal surface by a slightly deformed one of larger area — a "bumped" tiling. Resumming the deformations dresses the rigid tile sum into a fluctuating surface and yields, beyond leading order, the corrected tension

$$\sigma a^2 = \ln\frac{2N^2}{\beta} - \frac{1}{N^2}\left(\frac{\beta}{2N^2}\right)^4 + \cdots , \tag{43.120}$$

the first correction arising from the smallest deformation (a single displaced plaquette costs four extra tiles). The qualitative lesson survives all orders within the radius of convergence: σ remains positive and the area law remains intact. The flux tube acquires a finite width and transverse fluctuations — the seeds of the effective string description and of the roughening phenomenon that becomes important as β is increased toward the continuum.

43.4.6 Does it survive to the continuum? Honest scope

We must now be exact about what Theorem 43.24 does and does not establish, because this is the precise point at which a careful account of confinement diverges from a careless one. The theorem is a statement about the lattice theory at *large bare coupling*, i.e. small β and coarse lattice spacing. Physics, however, lives in the continuum limit $a \to 0$ taken at fixed physical quantities — fixed $\sqrt{\sigma}$, fixed hadron masses. The lattice is a regulator, and the question of confinement *in the continuum theory* is the question of whether the area law survives that limit. It need not.

Asymptotic freedom puts the continuum at weak coupling. The continuum limit is reached not at any value of β but at the renormalization-group fixed point that defines the theory. For an asymptotically free theory that fixed point is at *vanishing* bare coupling: as $a \to 0$, the bare coupling at the

cutoff scale $1/a$ must run to zero, $g^2(a) \to 0$, which is $\beta = 2N/g^2 \to \infty$ — the *weak*-coupling regime, the opposite end of the axis from where Theorem 43.24 holds. The required scaling is dictated by the Yang–Mills beta function of Chapter 27 (Eq. (27.101)): integrating $a\,dg/da = -\beta_{\mathrm{YM}}(g)$ near $g = 0$ gives the asymptotic-scaling law

$$\sigma a^2 \;\propto\; \exp\!\Big[-\frac{1}{b_0\, g^2(a)}\Big] \;\xrightarrow{a\to 0}\; 0, \qquad b_0 = \frac{1}{16\pi^2}\Big(\tfrac{11}{3}C_A - \tfrac{4}{3}T_F n_f\Big), \quad (43.121)$$

the essential singularity that makes $\sqrt{\sigma} \sim \Lambda_{\mathrm{QCD}}$ a genuine continuum quantity exponentially below the cutoff (dimensional transmutation, Section 27.6). The strong-coupling formula $\sigma a^2 = \ln(2N^2/\beta)$ of Eq. (43.115) looks nothing like Eq. (43.121): it is a lattice artefact, large precisely where the lattice is coarse. For the lattice to define a confining *continuum* theory, the measured σa^2 must cross over from the strong-coupling logarithm to the weak-coupling exponential Eq. (43.121) *without* the string tension ever passing through zero.

The nontrivial requirement: no bulk phase transition. A vanishing σ at some intermediate β would be a *deconfining (bulk) phase transition* separating a strong-coupling confined phase from a weak-coupling deconfined one. If such a transition existed, the analytic area law of Theorem 43.24 would describe only a lattice phase with no continuum counterpart, and the continuum theory — approached from the weak-coupling side — could perfectly well be deconfined. The entire force of the strong-coupling argument for *continuum* confinement therefore rests on a single statement that the strong-coupling expansion itself cannot supply: that SU(N) Yang–Mills has no bulk phase transition along the β axis, so that strong and weak coupling are analytically connected and σa^2 interpolates smoothly between the two scaling forms.

Compact U(1) shows the requirement has teeth. That this is a real gap, and not a technicality, is proved by a theory in which the requirement *fails*. Compact U(1) lattice gauge theory in four dimensions confines at strong coupling by the very computation of Theorem 43.25 (its abelian Haar integrals are the $N \to 1$ case of Theorem 43.23), yet it is known — analytically by the duality to a monopole-gas/Coulomb-gas representation, and numerically — to undergo a phase transition at a critical coupling β_c. For $\beta < \beta_c$ the photon is confined (area law, a plasma of condensed magnetic monopoles disorders the loop); for $\beta > \beta_c$ the monopoles are dilute, the area law gives way to a perimeter law, and the continuum limit taken from the weak-coupling side is the *deconfined Coulomb phase*: free, massless photons — ordinary electrodynamics, which manifestly does not confine. The strong-coupling area law is therefore demonstrably *not* a guarantee of continuum confinement. Any argument that confines SU(3) must distinguish it from compact U(1), and the strong-coupling expansion alone cannot: it confines both.

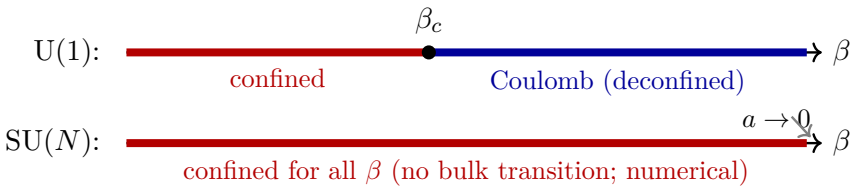

Figure 43.5: The coupling axis. *Top:* compact U(1) in four dimensions has a bulk transition at β_c: the strong-coupling area law (red) does not reach the weak-coupling continuum, which is the deconfined Coulomb phase (blue). *Bottom:* for SU(N) the strong-coupling area law of Theorem 43.24 is believed — on the basis of Monte Carlo evidence, not proof — to connect smoothly to the weak-coupling continuum ($\beta \to \infty$, $a \to 0$) with no intervening transition, so that confinement persists. The contrast is what makes the SU(N) statement nontrivial.

Where the SU(N) statement actually stands. For SU(N) Yang–Mills the required smooth connection appears to hold: large-scale Monte Carlo simulations (Section 43.4.6 anticipates the methods of Section 43.7) compute $\langle W(\mathcal{C})\rangle$ at couplings ranging continuously from strong to weak and find (i) no bulk deconfining transition along the β axis at zero temperature; (ii) the measured σa^2 crossing over from the strong-coupling logarithm to the asymptotic-scaling exponential Eq. (43.121), the signature of a true continuum quantity; and (iii) a physical string tension $\sqrt{\sigma} \approx 440\,\text{MeV}$ consistent with the Regge slope of the hadron spectrum and with quarkonium phenomenology (Eq. (27.193)). This is overwhelming evidence, but it is numerical. The statement that four-dimensional SU(N) Yang–Mills exists as a non-perturbative quantum field theory with a positive mass gap, and confines in the continuum, remains *unproved*: it is one of the Clay Mathematics Institute Millennium Prize Problems and is open as of the mid-2020s, the same honest boundary drawn at the end of Chapter 27. What strong coupling supplies is an existence proof in a regime — a clean, convergent, dimension-independent demonstration that an area law and a linear potential are genuine features of a non-perturbatively defined gauge theory. What it cannot supply, and what no analytic method yet supplies, is the uniform control from lattice to continuum that would close the gap.

Caution

The area law is the statement of confinement only for *static external sources in pure gauge theory* (or the quenched approximation). With light dynamical quarks the chromoelectric string breaks once stretched far enough to pop a $q\bar{q}$ pair from the vacuum, the potential flattens beyond $r_{\text{break}} \sim 1.2$–$1.5\,\text{fm}$, and the large-loop behaviour reverts to a perimeter law. The precise area-law confinement of Theorem 43.24 is thus a property

of the gluonic sector; the physical statement in full QCD is the weaker, observed fact that only colour singlets appear in the spectrum. Including those dynamical quarks is the problem of the next section.

We have now computed a complete gauge sector from first principles: the gauge-invariant lattice measure of Section 43.3 has yielded, by explicit Haar integration and surface combinatorics, an area law, a positive string tension, and a linear confining potential — Yang–Mills theory's non-perturbative payoff, with its continuum status framed honestly against the asymptotic freedom of Chapter 27. The temporal-Wilson-loop and transfer-matrix machinery assembled in Eq. (43.116) is also exactly what Section 43.7.2 will turn into lattice spectroscopy. What is still missing from this picture is matter: the moment we try to put a Dirac field on the lattice, the discretization fights back, and the fermion-doubling problem of Section 43.5 forces genuinely new constructions, to which we turn next.

43.5 Fermion doubling and the Nielsen–Ninomiya no-go theorem

The gauge sector is now complete. Wilson's plaquette action put the connection on links, preserved exact gauge invariance with no gauge fixing, and handed us an area law—the first analytic demonstration of confinement—essentially for free in the strong-coupling expansion of Section 43.4. What remains, to have a lattice definition of QCD rather than of pure glue, is to put *matter* on the lattice: the quarks. We already have everything we need in principle. The Dirac field was quantized in Chapter 11, its Euclidean path integral is a Berezin integral over Grassmann variables (Section 12.3), and integrating those variables out produces the fermion determinant (Theorem 12.26) that weights each gauge configuration. One would expect discretizing the Dirac action to be no harder than discretizing the scalar of Section 43.2: replace derivatives by finite differences and be done.

It is not. The naive discretization is a disaster of a very specific and instructive kind. A single continuum Dirac field, discretized by the obvious symmetric difference, describes not one fermion on the lattice but $2^d = 16$ of them in four dimensions. These extra species—the *doublers*—are not a coding error or a poor choice of difference scheme that a cleverer one would remove. They are forced. The Nielsen–Ninomiya theorem will show that any lattice fermion action that is simultaneously local, translation-invariant, hermitian, and *exactly chirally symmetric* must produce doublers in chirality-balanced pairs, so that no such action can describe a single chiral (Weyl) fermion. The obstruction is topological, and—this is the deep point—it is the lattice's faithful bookkeeping of the chiral anomaly of Chapter 36. The very feature that makes the lattice a clean gauge

regulator (it is a regulator, not a continuum trick, and it respects every exact symmetry of the action) is what forbids it from quietly representing a chiral theory. This section discretizes the Dirac action, exhibits the sixteen doublers explicitly with their chiralities, explains their anomaly-cancelling role, and states and proves the topological core of Nielsen–Ninomiya.

Throughout we work in the Euclidean formulation of the lattice path integral set up in Section 43.1, descending from the Wick rotation $t \to -i\tau$ of Chapter 10. Fermions enter this section for the first time in the chapter, so we begin by fixing the Euclidean Dirac conventions.

Notation Watch

On the Euclidean lattice the gamma matrices are taken *hermitian* and satisfy the Euclidean Clifford algebra

$$\{\gamma_\mu, \gamma_\nu\} = 2\,\delta_{\mu\nu}\,\mathbf{1}, \qquad \gamma_\mu^\dagger = \gamma_\mu, \qquad \mu, \nu = 1, \ldots, d, \tag{43.122}$$

with all indices down and the Kronecker $\delta_{\mu\nu}$ in place of the Minkowski $\eta_{\mu\nu}$. They are obtained from the mostly-minus matrices of Appendix C and Chapter 11 by $\gamma_d^{\mathrm{E}} = \gamma^0$, $\gamma_j^{\mathrm{E}} = -i\gamma^j$ $(j = 1, \ldots, d-1)$; one checks Eq. (43.122) directly from $\{\gamma^\mu, \gamma^\nu\} = 2\eta^{\mu\nu}$. The chirality matrix is $\gamma_5 = \gamma_1\gamma_2\gamma_3\gamma_4$ in $d = 4$, which is hermitian, squares to $\mathbf{1}$, and anticommutes with every γ_μ. We drop the superscript "E" from here on; within this section γ_μ always means the Euclidean matrix. The spinor field $\bar\psi$ is treated as an independent Grassmann variable, not as $\psi^\dagger\gamma^0$—the standard and necessary convention in the Euclidean functional integral (Section 12.3).

43.5.1 The naive lattice Dirac action

Take a hypercubic lattice of spacing a, with sites labelled by integer vectors $n \in \mathbb{Z}^d$ (so the physical coordinate is $x = an$) and unit lattice vectors $\hat\mu$ in each of the d directions. Place a Grassmann-valued Dirac spinor ψ_n and an independent conjugate $\bar\psi_n$ at every site. The continuum Euclidean Dirac action $S_F = \int d^dx\, \bar\psi(\gamma_\mu\partial_\mu + m)\psi$ (the Euclidean rotation of the Lagrangian of Section 11.1.4) requires a lattice stand-in for ∂_μ.

The first derivative has two one-sided lattice realizations, the forward and backward differences $(\psi_{n+\hat\mu} - \psi_n)/a$ and $(\psi_n - \psi_{n-\hat\mu})/a$. Neither is a hermitian operation on the lattice, and a non-hermitian kinetic term would spoil the reality of the Euclidean action and the positivity of the transfer matrix. The unique antisymmetric—hence, paired with the i that the first-order Dirac operator carries, hermitian—first difference is their average, the *symmetric difference*

$$(\partial_\mu\psi)_n \;\longmapsto\; \frac{\psi_{n+\hat\mu} - \psi_{n-\hat\mu}}{2a}. \tag{43.123}$$

This is the obvious, "naive" choice: it is the most symmetric local approximation to ∂_μ, accurate to $O(a^2)$ just as the symmetric Laplacian was for the scalar. The corresponding *naive lattice Dirac action* is

$$S_F^{\text{naive}} = a^d \sum_n \left[\bar\psi_n \sum_{\mu=1}^{d} \gamma_\mu \frac{\psi_{n+\hat\mu} - \psi_{n-\hat\mu}}{2a} \;+\; m\,\bar\psi_n \psi_n \right]. \tag{43.124}$$

The prefactor a^d is the lattice cell volume that turns $\sum_n$ into the discretized $\int d^d x$. The hopping term connects nearest neighbours only: Eq. (43.124) is manifestly *ultralocal* (finite range), translation-invariant, and—because the symmetric difference is antisymmetric under $n \leftrightarrow n \pm \hat\mu$ while γ_μ is hermitian—hermitian. It is also, crucially, *exactly chirally symmetric* when $m = 0$: under $\psi_n \to e^{i\alpha\gamma_5}\psi_n$, $\bar\psi_n \to \bar\psi_n e^{i\alpha\gamma_5}$, each $\bar\psi_n \gamma_\mu (\cdots)$ bilinear is invariant because γ_5 anticommutes with γ_μ (the two factors of $e^{i\alpha\gamma_5}$ combine to $e^{i\alpha\gamma_5}\gamma_\mu e^{i\alpha\gamma_5} = \gamma_\mu e^{-i\alpha\gamma_5} e^{i\alpha\gamma_5} = \gamma_\mu$). These four properties—locality, translation invariance, hermiticity, exact chiral symmetry—are exactly the hypotheses of Nielsen–Ninomiya, and Eq. (43.124) satisfies all of them. The theorem will tell us that it must therefore pay a price, and the price is the doublers we now expose.

43.5.2 The momentum-space propagator and its poles

Diagonalize Eq. (43.124) by Fourier transform. Because the lattice is discrete, momenta live on the *Brillouin torus*

$$p_\mu \in \Big(-\frac{\pi}{a}, \frac{\pi}{a}\Big], \qquad \text{BZ} = \Big(-\tfrac{\pi}{a}, \tfrac{\pi}{a}\Big]^d \cong T^d, \tag{43.125}$$

a compact set with opposite faces identified—a d-torus, the single most important geometric fact in this section. Expand

$$\psi_n = \int_{\text{BZ}} \frac{d^d p}{(2\pi)^d}\, e^{\,i a\, n\cdot p}\, \tilde\psi(p), \qquad \bar\psi_n = \int_{\text{BZ}} \frac{d^d p}{(2\pi)^d}\, e^{-i a\, n\cdot p}\, \tilde{\bar\psi}(p), \tag{43.126}$$

with the lattice completeness relation $a^d \sum_n e^{i a\, n\cdot(p-p')} = (2\pi)^d\, \delta^d(p - p')$ for $p, p' \in \text{BZ}$. Shifting a site by $\hat\mu$ multiplies the plane wave by a phase, $\psi_{n\pm\hat\mu} \leftrightarrow e^{\pm i a p_\mu} \tilde\psi(p)$, so the symmetric difference becomes

$$\frac{\psi_{n+\hat\mu} - \psi_{n-\hat\mu}}{2a} \;\longleftrightarrow\; \frac{e^{\,i a p_\mu} - e^{-i a p_\mu}}{2a}\, \tilde\psi(p) = \frac{i \sin(a p_\mu)}{a}\, \tilde\psi(p). \tag{43.127}$$

Substituting Eqs. (43.126) and (43.127) into Eq. (43.124) and using completeness to collapse one momentum integral, the action becomes diagonal in p,

$$S_F^{\text{naive}} = \int_{\text{BZ}} \frac{d^d p}{(2\pi)^d}\, \tilde{\bar\psi}(p)\, \widetilde{D}(p)\, \tilde\psi(p), \tag{43.128}$$

with the *naive lattice Dirac operator* in momentum space

$$\boxed{\widetilde{D}(p) = \frac{i}{a}\sum_{\mu=1}^{d}\gamma_\mu \sin(ap_\mu) + m\,\mathbf{1}\,.} \tag{43.129}$$

This is the central object. As $a \to 0$ at fixed physical p, $\sin(ap_\mu)/a \to p_\mu$ and $\widetilde{D}(p) \to i\gamma_\mu p_\mu + m$, the correct Euclidean continuum inverse propagator: the naive action has the right *naive* continuum limit, which is precisely why the doubling is so insidious. Inverting Eq. (43.129) uses the Clifford algebra Eq. (43.122). Writing $s_\mu \equiv \sin(ap_\mu)/a$ and multiplying numerator and denominator by $(m - i\gamma_\nu s_\nu)$,

$$\Big(i\gamma_\mu s_\mu + m\Big)\Big(m - i\gamma_\nu s_\nu\Big) = m^2 + \gamma_\mu\gamma_\nu s_\mu s_\nu = m^2 + \tfrac{1}{2}\{\gamma_\mu,\gamma_\nu\}s_\mu s_\nu = m^2 + \sum_\mu s_\mu^2, \tag{43.130}$$

where the cross terms $im\gamma_\nu s_\nu - im\gamma_\mu s_\mu$ cancel and the symmetric $s_\mu s_\nu$ projects onto $\delta_{\mu\nu}$. The denominator is a c-number, so

$$\widetilde{D}(p)^{-1} = \frac{m - \dfrac{i}{a}\sum_\mu \gamma_\mu \sin(ap_\mu)}{m^2 + \dfrac{1}{a^2}\displaystyle\sum_\mu \sin^2(ap_\mu)}. \tag{43.131}$$

The propagator's poles—the propagating particles of the theory—sit where its denominator vanishes. In the massless ($m = 0$) case relevant to chirality, this requires

$$\sum_\mu \sin^2(ap_\mu) = 0 \quad\Longleftrightarrow\quad \sin(ap_\mu) = 0 \;\text{ for } \textit{every}\ \mu, \tag{43.132}$$

since each term is non-negative. Within the Brillouin zone Eq. (43.125), $\sin(ap_\mu) = 0$ has not one but *two* solutions per direction: $p_\mu = 0$ and $p_\mu = \pi/a$. The continuum operator $i\gamma_\mu p_\mu$ vanished only at $p = 0$; the lattice sine, being periodic, vanishes again at the zone boundary. Figure 43.6 (left) shows this in one dimension: the line $f = p$ crosses zero once, the curve $f = \sin(ap)/a$ crosses zero twice inside the zone.

43.5.3 Counting and identifying the doublers

Definition 43.26 (Doublers)**.** The *doublers* of the naive lattice fermion are the propagator poles of Eq. (43.131) (at $m = 0$) located at momenta other than the physical $p = 0$. Each pole is a separate propagating Dirac species in the continuum limit.

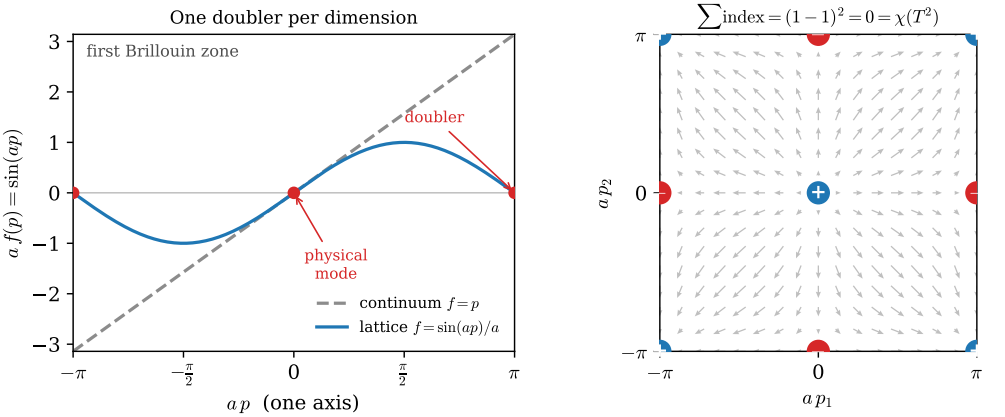

Figure 43.6: *Left:* the naive fermion dispersion $f(p) = \sin(ap)/a$ along one axis over the first Brillouin zone. Unlike the continuum line $f = p$ (which vanishes only at $p = 0$), the lattice sine vanishes a *second* time at the zone boundary $ap = \pi$: one physical mode and one doubler per dimension. *Right:* the $d = 2$ Brillouin torus with the $2^2 = 4$ zeros of $V(p) = (\sin(ap_1)/a, \sin(ap_2)/a)$. The Poincaré–Hopf index at each zero, $\operatorname{sign}\det(\partial V_\mu/\partial p_\nu) = \prod_\mu \cos(ap_\mu) = (-1)^{|A|}$, is the chirality of that species; the signs form a checkerboard summing to $(1-1)^2 = 0 = \chi(T^2)$.

Proposition 43.27 (Sixteen species in four dimensions)**.** *The massless naive lattice Dirac operator Eq. (43.129) has exactly 2^d poles in the Brillouin zone, located at the corner momenta*

$$p^{(A)} = \frac{\pi}{a} \sum_{\mu \in A} \hat{\mu}, \qquad A \subseteq \{1, 2, \ldots, d\}, \tag{43.133}$$

one for each subset A of the d directions. In $d = 4$ there are $2^4 = 16$ species: one physical fermion ($A = \varnothing$) and 15 doublers. Near each pole the theory is a relativistic Dirac fermion, but its chirality alternates: the species at $p^{(A)}$ has chirality $(-1)^{|A|}$ relative to the physical one, giving $2^{d-1} = 8$ left-handed and 8 right-handed species, of net chirality zero.

Proof. The pole condition Eq. (43.132) requires $ap_\mu \in \{0, \pi\}$ independently in each direction, since these are the only zeros of sin in $(-\pi, \pi]$. A choice of $\{0, \pi\}$ in each of d directions is exactly a choice of the subset A of directions carrying π, whence Eq. (43.133) and the count 2^d.

To read off the physics near a pole, expand about $p^{(A)}$ by writing $p = p^{(A)} + k$ with $|ak_\mu| \ll 1$. For a direction $\mu \notin A$ ($ap_\mu^{(A)} = 0$),

$$\frac{1}{a} \sin(ap_\mu^{(A)} + ak_\mu) = \frac{1}{a} \sin(ak_\mu) \simeq k_\mu. \tag{43.134}$$

For $\mu \in A$ ($ap_\mu^{(A)} = \pi$), using $\sin(\pi + \theta) = -\sin\theta$,

$$\frac{1}{a}\sin(\pi + ak_\mu) = -\frac{1}{a}\sin(ak_\mu) \simeq -k_\mu. \tag{43.135}$$

Collecting both cases, the Dirac operator near the pole is, to linear order in k,

$$\widetilde{D}(p^{(A)} + k) \simeq i\sum_\mu s_\mu^{(A)}\,\gamma_\mu\,k_\mu + m, \qquad s_\mu^{(A)} = \begin{cases} +1, & \mu \notin A, \\ -1, & \mu \in A. \end{cases} \tag{43.136}$$

This is again a Dirac operator, but with γ_μ replaced by the rescaled set

$$\gamma'_\mu \equiv s_\mu^{(A)}\,\gamma_\mu, \qquad \{\gamma'_\mu, \gamma'_\nu\} = s_\mu^{(A)} s_\nu^{(A)}\{\gamma_\mu, \gamma_\nu\} = 2\delta_{\mu\nu}, \tag{43.137}$$

which obeys the *same* Clifford algebra Eq. (43.122) (the signs square away on the diagonal). So each pole is genuinely a relativistic Dirac fermion—the doublers are real particles, not lattice junk. What distinguishes them is chirality. The chirality matrix built from the primed gammas is

$$\gamma'_5 = \gamma'_1\gamma'_2\gamma'_3\gamma'_4 = \Big(\textstyle\prod_\mu s_\mu^{(A)}\Big)\gamma_1\gamma_2\gamma_3\gamma_4 = (-1)^{|A|}\,\gamma_5, \tag{43.138}$$

because exactly $|A|$ of the factors carry a minus sign. The species at $p^{(A)}$ therefore couples to γ_5 with the opposite sign whenever $|A|$ is odd: its left- and right-handed components are interchanged relative to the physical fermion. Counting by parity of $|A|$,

$$\sum_{A \subseteq \{1,\dots,d\}} (-1)^{|A|} = \sum_{k=0}^{d} \binom{d}{k} (-1)^k = (1-1)^d = 0. \tag{43.139}$$

In $d = 4$ this is $\binom{4}{0} - \binom{4}{1} + \binom{4}{2} - \binom{4}{3} + \binom{4}{4} = 1 - 4 + 6 - 4 + 1 = 0$, i.e. $1 + 6 + 1 = 8$ species of one chirality and $4 + 4 = 8$ of the other. The net chirality vanishes. □

The combinatorial identity Eq. (43.139) is the heart of the matter, and it is worth seeing in a single explicit doubler before we lift it to its topological meaning.

Worked Example 43.28 (The chirality of one corner doubler)**.** Take $d = 4$ and the doubler at the single-direction corner $A = \{1\}$, i.e. $p^{(A)} = (\pi/a, 0, 0, 0)$, and show directly that its chirality is opposite to that of the physical fermion at the origin.

Setup. By Eq. (43.136) the sign vector is $s^{(A)} = (-1, +1, +1, +1)$, so near this pole

$$\widetilde{D}(p^{(A)} + k) \simeq i\big(-\gamma_1 k_1 + \gamma_2 k_2 + \gamma_3 k_3 + \gamma_4 k_4\big) + m = i\,\gamma'_\mu k_\mu + m, \tag{43.140}$$

with $\gamma'_1 = -\gamma_1$ and $\gamma'_{2,3,4} = \gamma_{2,3,4}$.

Two ways to see the flipped chirality. First, algebraically: the projectors onto definite chirality for this species are $P'_\pm = \frac{1}{2}(\mathbf{1} \pm \gamma'_5)$ with

$$\gamma'_5 = \gamma'_1\gamma'_2\gamma'_3\gamma'_4 = (-\gamma_1)\gamma_2\gamma_3\gamma_4 = -\gamma_5, \tag{43.141}$$

so $P'_\pm = \frac{1}{2}(\mathbf{1} \mp \gamma_5) = P_\mp$. What the doubler calls "right-handed" is what the physical fermion calls "left-handed."

Second, and more invariantly: the sign flip on the single matrix γ_1 can be realized by a similarity transformation that leaves the Clifford algebra intact. Conjugation by γ_5 flips *every* γ_μ, $\gamma_5\gamma_\mu\gamma_5 = -\gamma_\mu$; to flip only γ_1 we conjugate instead by the unitary $W = \gamma_2\gamma_3\gamma_4$ built from the *untouched* directions. Using Eq. (43.122), $W\gamma_1 W^{-1} = -\gamma_1$ while $W\gamma_j W^{-1} = +\gamma_j$ for $j = 2, 3, 4$ (each γ_j anticommutes with the two other factors in W and commutes with itself, an even number of sign changes for j, an odd number for γ_1). Hence $\gamma'_\mu = W\gamma_\mu W^{-1}$, and the doubler is unitarily a standard Dirac fermion—but the map W is anti-chiral, $W\gamma_5 W^{-1} = -\gamma_5$ (three anticommutations), confirming $\gamma'_5 = -\gamma_5$. Either way the corner $A = \{1\}$ carries chirality $(-1)^{|A|} = -1$, opposite the physical fermion.

Why the net must cancel. The physical fermion ($A = \varnothing$) contributes $+1$; this single doubler contributes -1. Running over all 16 corners reproduces Eq. (43.139): the four single-direction doublers each cancel against the physical mode and against the three-direction doublers, the six two-direction doublers pair up, and the lone four-direction doubler ($p = (\pi/a, \pi/a, \pi/a, \pi/a)$, chirality $(-1)^4 = +1$) restores balance. The lattice does not contain a single chiral fermion; it contains eight of each handedness, exactly cancelling.

43.5.4 Why the doublers are the anomaly

It is tempting to read Theorem 43.27 as a defect of the symmetric difference and to hope a smarter difference scheme removes the unwanted fifteen species while keeping the one. The next subsection proves no such scheme exists under the stated hypotheses. But first it pays to understand *why* nature forbids it, because the reason is one of the most beautiful facts in the subject: the doublers are the lattice's way of being honest about the chiral anomaly of Chapter 36.

Recall the structure of that anomaly. A single massless Dirac fermion coupled to a gauge field has a classically conserved axial current $j_5^\mu = \bar\psi\gamma^\mu\gamma_5\psi$. Quantum mechanically the conservation law fails—the Adler–Bell–Jackiw result of Section 36.2,

$$\partial_\mu j_5^\mu = \frac{1}{16\pi^2}\,\epsilon^{\mu\nu\rho\sigma}F_{\mu\nu}F_{\rho\sigma} \quad \text{(per unit charge)}, \tag{43.142}$$

an effect that no regulator can remove because it is a genuine property of the continuum theory. The anomaly is intrinsically tied to chirality: it is the

contribution of a *single* Weyl (definite-chirality) fermion that fails to cancel, and the sign of the anomaly is the sign of the chirality.

Now confront this with the naive lattice action Eq. (43.124). At $m = 0$ it has an *exact*, non-anomalous chiral symmetry: it is invariant under $\psi_n \to e^{i\alpha\gamma_5}\psi_n$, $\bar{\psi}_n \to \bar{\psi}_n e^{i\alpha\gamma_5}$ for any constant α, with no anomaly possible, because the symmetry is a symmetry of a perfectly well-defined finite-dimensional Grassmann integral and the Berezin measure (Section 12.3) is invariant. The lattice is a complete, gauge-invariant regulator; if its chiral symmetry is exact, the axial current it defines is *exactly* conserved. But Eq. (43.142) says a continuum theory of one chiral fermion cannot have an exactly conserved axial current. The only escape—the only way the lattice can host an exact chiral symmetry and still be a legitimate regulator of relativistic fermions—is for its particle content to be anomaly-free, i.e. to have *net zero chirality*. And that is exactly Eq. (43.139). The eight left-handed and eight right-handed species each contribute their anomaly $(-1)^{|A|} \times (\text{ABJ } \epsilon FF)$, and these cancel in pairs, leaving the total axial current conserved, consistent with the exact lattice symmetry.

Physical Insight

Doubling is not a bug; it is anomaly cancellation enforced by a faithful regulator. A regulator that exactly preserves chiral symmetry *cannot* reproduce the chiral anomaly of an odd number of Weyl fermions—and since the anomaly is unavoidable in the continuum, such a regulator can only describe anomaly-free (chirality-balanced) content. The lattice with naive fermions chooses to keep chiral symmetry exact and pays by doubling. Dimensional regularization and Pauli–Villars make the opposite choice: they describe a single fermion and pay by breaking chiral symmetry (the γ_5 problem in $d = 4 - 2\varepsilon$; the chirality-violating PV mass), which is how *they* make room for the anomaly. There is no free lunch, and the lattice's version of the bill is the doublers.

This anomaly viewpoint also reveals the doublers' deeper geometric character. Each massless species is a point in the Brillouin torus where the inverse propagator vanishes; near it the Dirac structure $i\gamma'_\mu k_\mu$ is, in the language of topological band theory, a *Weyl point*—a monopole of Berry curvature in momentum space, with magnetic charge equal to its chirality. Gauss's law on a closed manifold forces the total monopole charge enclosed to vanish: there is no boundary through which net flux can escape the torus. The sum of chiralities over the Brillouin zone is therefore zero *for the same reason that the total magnetic charge inside a closed surface is zero*. We now make this topology precise.

43.5.5 The topological obstruction: Poincaré–Hopf on the Brillouin torus

Strip the massless naive operator Eq. (43.129) to its content. Writing $\widetilde{D}(p) = i\sum_\mu \gamma_\mu V_\mu(p)$, all of the physics of the zeros lives in the real vector field

$$V:\ T^d \longrightarrow \mathbb{R}^d, \qquad V_\mu(p) = \frac{\sin(ap_\mu)}{a}, \tag{43.143}$$

on the Brillouin torus: the species are exactly the zeros of V, and—we will show—the chirality of each species is exactly the topological index of V at that zero. The constraint Eq. (43.139) is then not an accident of sin but the Poincaré–Hopf theorem, which we now recall and apply.

Theorem 43.29 (Poincaré–Hopf index theorem)**.** *Let V be a smooth tangent vector field on a closed (compact, boundaryless) oriented manifold M of dimension d, with only isolated, nondegenerate zeros. At a zero p_* define the* index

$$\operatorname{ind}_{p_*} V = \operatorname{sign}\det\left[\left.\frac{\partial V_\mu}{\partial p_\nu}\right|_{p_*}\right] \in \{+1,-1\}. \tag{43.144}$$

Then the sum of indices over all zeros equals the Euler characteristic of M,

$$\sum_{p_*:\,V(p_*)=0} \operatorname{ind}_{p_*} V = \chi(M). \tag{43.145}$$

The geometric content is that the index counts how many times the normalized field $V/|V|$ wraps the unit sphere S^{d-1} as p circles a small sphere around the zero (the degree of the local Gauss map); summing these local winding numbers over M gives a global topological invariant that cannot depend on the particular field, only on M. We take Theorem 43.29 as an established result of differential topology—its proof (triangulate M, or deform V to the gradient of a Morse function and identify indices with critical-point signatures) is standard and outside the physics this book builds; what we owe is the two facts that turn it into Nielsen–Ninomiya.

Fact 1: the index equals the chirality. For the naive field Eq. (43.143) the Jacobian is diagonal,

$$\frac{\partial V_\mu}{\partial p_\nu} = \delta_{\mu\nu}\cos(ap_\mu), \tag{43.146}$$

so at a corner zero $p^{(A)}$ of Eq. (43.133), where $ap_\mu = \pi$ for $\mu \in A$ and $ap_\mu = 0$ otherwise,

$$\operatorname{ind}_{p^{(A)}} V = \operatorname{sign}\prod_\mu \cos(ap_\mu^{(A)}) = \prod_{\mu\in A}(-1) = (-1)^{|A|}. \tag{43.147}$$

Comparing with Eq. (43.138), the index of the vector field at a zero is *identically* the chirality of the corresponding fermion species. This is not a coincidence of the naive model: for any $\widetilde{D}(p) = i\gamma_\mu V_\mu(p)$ satisfying $\{\gamma_5, \widetilde{D}\} = 0$, the relative sign of γ_5' at a zero is the sign of the determinant of the linearized V, because $\gamma_5' = \det(\partial V/\partial p)/|\det(\partial V/\partial p)| \cdot \gamma_5$ follows from the same rescaling-of-gammas computation Eq. (43.137)–Eq. (43.138) applied to the eigenvalues of the Jacobian. Chirality *is* a Poincaré–Hopf index.

Fact 2: the torus has Euler characteristic zero. The Euler characteristic is multiplicative under products, $\chi(X \times Y) = \chi(X)\chi(Y)$, and the circle has $\chi(S^1) = 0$ (a circle triangulated into V vertices and V edges has $\chi = V - V = 0$; equivalently it admits the nowhere-vanishing tangent field ∂_θ). Since $T^d = (S^1)^{\times d}$,

$$\chi(T^d) = \chi(S^1)^d = 0. \tag{43.148}$$

Putting the two facts into Poincaré–Hopf Eq. (43.145) gives, with no reference to the specific form of V,

$$\sum_{\text{species}} \text{chirality} = \sum_{p_*\colon V(p_*)=0} \operatorname{ind}_{p_*} V = \chi(T^d) = 0. \tag{43.149}$$

The net chirality of the massless lattice fermion's particle content is forced to vanish by the topology of the Brillouin zone alone. For the naive field this reproduces Eq. (43.139) term by term—Fig. 43.6 (right) shows the $d = 2$ case, four zeros with indices $+, -, -, +$ arranged in a checkerboard whose sum is $(1-1)^2 = 0$—but Eq. (43.149) holds for *any* smooth V on the torus, i.e. for any local, translation-invariant, chirally symmetric, hermitian lattice fermion. Changing the difference scheme deforms V, moves the zeros around, perhaps merges or splits them, but can never change the signed total. That invariance is the theorem.

43.5.6 The Nielsen–Ninomiya theorem

We can now state the no-go result precisely. It comes in two equivalent guises: the original Hamiltonian formulation of Nielsen and Ninomiya, phrased in terms of Weyl particles and a conserved charge, and the Euclidean "vector field on the torus" formulation just proved. We give the Euclidean version as the theorem, since it is what Theorem 43.29 establishes, and state the Hamiltonian version as a remark.

Theorem 43.30 (Nielsen–Ninomiya no-go)**.** *Let a free lattice fermion be defined by a bilinear Euclidean action $S = \sum_{n,m} \bar\psi_n D_{nm} \psi_m$ on the hypercubic lattice, with Fourier-transformed Dirac operator $\widetilde{D}(p)$ on the Brillouin torus T^d. Suppose*

(L) Locality: $\widetilde{D}(p)$ *is a continuously differentiable (indeed real-analytic) periodic function on* T^d*; equivalently the real-space kernel* D_{nm} *decays faster than any power of* $|n-m|$ *(e.g. finite range or exponentially bounded).*

(T) Translation invariance: $D_{nm} = D(n-m)$*, so* $\widetilde{D}$ *depends only on* p*.*

(H) Hermiticity: *the action is hermitian, with* γ_5*-hermiticity* $\widetilde{D}(p)^\dagger = \gamma_5\,\widetilde{D}(p)\,\gamma_5$*, guaranteeing real, bounded single-particle energies.*

(C) Exact chiral symmetry: $\{\gamma_5, \widetilde{D}(p)\} = 0$ *for all* p*, so the massless action is invariant under* $\psi \to e^{i\alpha\gamma_5}\psi$*,* $\bar\psi \to \bar\psi\, e^{i\alpha\gamma_5}$*.*

(R) Right relativistic content: $\widetilde{D}$ *has isolated nondegenerate zeros, near each of which* $\widetilde{D}(p_* + k) \simeq i\,\gamma_\mu C^{(*)}_{\mu\nu} k_\nu$ *with* $\det C^{(*)} \neq 0$*, describing a Weyl fermion of definite chirality* $\operatorname{sign}\det C^{(*)}$*; and at least one zero reproduces a standard fermion.*

Then the zeros come in chirality-balanced sets: the number of left-handed Weyl species equals the number of right-handed ones,

$$\sum_{\text{species } j} \chi_j = 0. \tag{43.150}$$

In particular, no *such lattice action describes a single Weyl fermion, nor any chirally asymmetric (anomalous) fermion content. The minimal anomaly-free content has an even number of species; the naive action realizes the maximal* 2^d*.*

Proof (topological core). By (C) and (H), at $m = 0$ the operator anticommutes with γ_5 and is γ_5-hermitian; expanding in the Clifford basis, the only structures consistent with $\{\gamma_5, \widetilde{D}\} = 0$ are the chirality-odd matrices, and (H) forces their coefficients to assemble into $\widetilde{D}(p) = i\sum_\mu \gamma_\mu V_\mu(p)$ with $V_\mu(p)$ real. (For the naive action, $V_\mu = \sin(ap_\mu)/a$.) By (L), V is a smooth field on T^d; by (T), it is single-valued on the torus; by (R), its zeros are isolated and nondegenerate, with the chirality of species j equal to $\operatorname{sign}\det(\partial V/\partial p)|_{p_j} = \operatorname{ind}_{p_j} V$, the identification of Fact 1 (Eq. (43.147)). Poincaré–Hopf, Theorem 43.29, applied to V on the closed manifold T^d, gives $\sum_j \chi_j = \sum_j \operatorname{ind}_{p_j} V = \chi(T^d) = 0$ by Fact 2 (Eq. (43.148)). This is Eq. (43.150). □

Remark 43.31 (Honest scope of this proof). What is proved above is the topological *index-summation* core: under hypotheses (L), (T), (H), (C), (R) the chiralities sum to zero. This is the content is needed here and the content that matters for physics. The original Nielsen–Ninomiya argument [365, 366] is set in the Hamiltonian (transfer-matrix) framework: one assumes a lattice Hamiltonian $H(p)$ that is a smooth periodic function of crystal momentum on the Brillouin torus (locality), hermitian (real energies), with a conserved, locally defined, integer-quantized charge Q commuting with H; the conclusion is that

the low-energy Weyl excitations carrying any given value of Q occur in equal numbers of left- and right-movers. Their proof tracks the Fermi points where energy bands cross zero and shows, by a homotopy/degree argument on the band structure, that left- and right-crossings must balance—the same topology, dressed as the statement that the net Berry-monopole charge over a closed Brillouin zone vanishes (the insight of Section 43.5.4). The full functional-analytic theorem additionally controls the most general local $\widetilde{D}$—fields V with more than d real components, degenerate or non-isolated zeros—by perturbing to the generic case; we do not reproduce that machinery, but Theorem 43.29 is exactly the invariant it computes.

The theorem is sharp about which hypothesis must give way. One cannot abandon locality (L) without destroying the regulator: a non-local action reintroduces, through the back door, the ultraviolet ambiguities the lattice was meant to tame, and spoils the cluster/positivity properties that make the Euclidean measure a probability measure (Section 43.1). One cannot abandon translation invariance (T) or hermiticity (H) without losing momentum conservation or unitarity of the continuum limit. Hypothesis (R) is just the demand that we get relativistic fermions at all. The single negotiable assumption is (C), *exact* chiral symmetry. Every practical lattice fermion is a different answer to the question "how do I weaken (C) the least?"

Caution

The no-go theorem forbids a single *chiral* (Weyl) fermion with exact chiral symmetry; it does not forbid lattice fermions outright, and it does not say chiral gauge theories cannot be discretized—only that doing so naively, with exact $\{\gamma_5, \widetilde{D}\} = 0$, fails. The loophole that Section 43.6 exploits is precisely that (C) can be *deformed* rather than violated: the Ginsparg–Wilson relation replaces $\{\gamma_5, D\} = 0$ by $\{\gamma_5, D\} = aD\gamma_5 D$, which reduces to exact chiral symmetry as $a \to 0$ but evades the index theorem at finite a by allowing a modified, lattice-deformed chiral rotation. That is not a violation of Nielsen–Ninomiya; it is a careful walk around its single load-bearing hypothesis.

This last point sets up the matter stage of QED and Yang–Mills theory at the non-perturbative level. The Dirac field of Chapter 11, and with it the electron of QED and the quarks of Yang–Mills theory, can be placed on the lattice—but only by confronting Theorem 43.30 head on. We make no new perturbative calculation here: the doubling/anomaly structure is a genuinely deeper, non-perturbative layer of the same fermion fields the threads carry, linking the lattice directly to the chiral anomaly of Chapter 36. Having established the precise constraint that any acceptable lattice fermion must evade, we turn in Section 43.6 to the explicit constructions—Wilson's term, which removes the doublers by breaking

chiral symmetry; staggered fermions, which thin the species to four while keeping a remnant symmetry; and the Ginsparg–Wilson realization of an exact *lattice* chiral symmetry through overlap and domain-wall fermions—each one a distinct, principled response to the no-go theorem just proved.

43.6 Lattice fermions: Wilson, staggered, and the Ginsparg–Wilson resolution

The no-go theorem of the previous section is not a defect of one clumsy discretization; it is a theorem. Theorem 43.30 states that no lattice Dirac operator can simultaneously be local, translation-invariant, Hermitian, free of doublers, *and* chirally symmetric in the textbook sense $\{D, \gamma_5\} = 0$. Something on that list must give. The history of lattice fermions is the history of choosing, with eyes open, what to surrender. Wilson surrenders chiral symmetry outright and pays for it with tuning; Kogut and Susskind surrender most of the chiral symmetry but keep a sliver, trading it against a residual species multiplicity; Ginsparg and Wilson found the subtle move that surrenders the precise *algebraic form* of the symmetry while keeping a genuine, exact, continuous chiral invariance of the lattice action — and so evade the theorem without breaking locality. This section develops all three, in that order, because that is the order in which the difficulty is understood: first the brute-force fix, then the clever economy, then the principled resolution that turns the index theorem and the anomaly of Chapter 36 into exact lattice statements.

Throughout we work on the Euclidean lattice set up earlier in this chapter: sites $x \in a\mathbb{Z}^4$, lattice spacing a, gauge fields carried by link variables $U_\mu(x) \in \mathrm{SU}(N)$, and the Euclidean Dirac algebra

$$\{\gamma_\mu, \gamma_\nu\} = 2\delta_{\mu\nu}, \qquad \gamma_\mu^\dagger = \gamma_\mu, \qquad \gamma_5 \equiv \gamma_1\gamma_2\gamma_3\gamma_4 = \gamma_5^\dagger, \qquad \gamma_5^2 = \mathbf{1}, \tag{43.151}$$

with $\{\gamma_5, \gamma_\mu\} = 0$. We write γ_5 with a lowered index throughout this section, as is universal in the lattice literature; it is the Euclidean continuation of the γ^5 of Chapter 11 and Appendix C and carries the same physics. Recall from Section 43.5.1 the naive massless lattice Dirac operator obtained by replacing ∂_μ with the symmetric difference, whose momentum-space kernel on the Brillouin zone $p_\mu \in (-\pi/a, \pi/a]$ is

$$\widetilde{D}_{\mathrm{naive}}(p) = m + \frac{i}{a}\sum_\mu \gamma_\mu \sin(a p_\mu). \tag{43.152}$$

For $m = 0$ this vanishes not only at $p = 0$ but at every corner of the Brillouin zone where each $a p_\mu \in \{0, \pi\}$, giving $2^4 = 16$ massless species: one physical fermion and fifteen doublers. The doublers split eight-and-eight into the two chiralities and, by the Poincaré–Hopf argument of Section 43.5.5, their chiralities

sum to zero — which is exactly why a chirally symmetric naive action cannot have a chiral anomaly, and exactly the obstruction Nielsen and Ninomiya turned into a theorem.

43.6.1 The Wilson term: lifting the doublers by hand

Wilson's idea is the most direct imaginable. The doublers live at the zone corners because $\sin(ap_\mu)$ has a second zero there; the physical mode lives at the origin. If we add to the operator a term that vanishes at the origin but is large and positive at every corner, it will leave the physical fermion alone while giving each doubler a mass that grows without bound as $a \to 0$, decoupling it from the continuum theory. The function $1-\cos(ap_\mu)$ does precisely this: it is $\tfrac{1}{2}a^2p_\mu^2 + O(a^4)$ near the origin and equals 2 at $ap_\mu = \pi$. In position space it is (minus) the lattice Laplacian, so the operator we add is a second difference.

Definition 43.32 (Wilson–Dirac operator)**.** Let $r > 0$ be the *Wilson parameter* (conventionally $r = 1$). The free Wilson–Dirac operator is the naive operator plus the Wilson term

$$D_W \;=\; D_{\text{naive}} - \frac{ra}{2}\,\Box_{\text{lat}}, \qquad (\Box_{\text{lat}}\psi)(x) = \frac{1}{a^2}\sum_{\mu}\big[\psi(x+a\hat{\mu}) - 2\psi(x) + \psi(x-a\hat{\mu})\big], \tag{43.153}$$

where $\Box_{\text{lat}}$ is the (gauge-covariant, when the differences carry link variables) lattice Laplacian. Equivalently, in momentum space,

$$\widetilde{D}_W(p) \;=\; \underbrace{m + \frac{r}{a}\sum_{\mu}\big(1-\cos(ap_\mu)\big)}_{\equiv\, M(p)} \;+\; \frac{i}{a}\sum_{\mu}\gamma_\mu \sin(ap_\mu). \tag{43.154}$$

That the two forms agree is a one-line Fourier check: the second difference of $e^{ip\cdot x}$ contributes $a^{-2}\sum_\mu(e^{iap_\mu} - 2 + e^{-iap_\mu}) = a^{-2}\sum_\mu(2\cos ap_\mu - 2)$, so $-\frac{ra}{2}\Box_{\text{lat}} \to -\frac{r}{2a}\sum_\mu(2\cos ap_\mu - 2) = \frac{r}{a}\sum_\mu(1-\cos ap_\mu)$, the scalar piece of $M(p)$. The object $M(p)$ acts as a *momentum-dependent mass*: it carries no γ matrix, so it adds to m rather than to the kinetic γ structure.

The physical mode is untouched; the operator is irrelevant. Expanding Eq. (43.154) for $ap_\mu \to 0$,

$$M(p) = m + \frac{r}{a}\sum_{\mu}\Big(\tfrac{1}{2}a^2p_\mu^2 + O(a^4)\Big) = m + \frac{ra}{2}\,p^2 + O(a^3), \qquad \frac{i}{a}\sum_{\mu}\gamma_\mu\sin(ap_\mu) = i\not{p} + O(a^2), \tag{43.155}$$

so $\widetilde{D}_W(p) \to m + i\not{p}$, the continuum Euclidean Dirac operator, and the Wilson correction $\frac{ra}{2}p^2$ is suppressed by one power of a relative to the mass. In the language of Chapter 23, the Wilson term is a dimension-five operator $\bar\psi\,\partial^2\psi$:

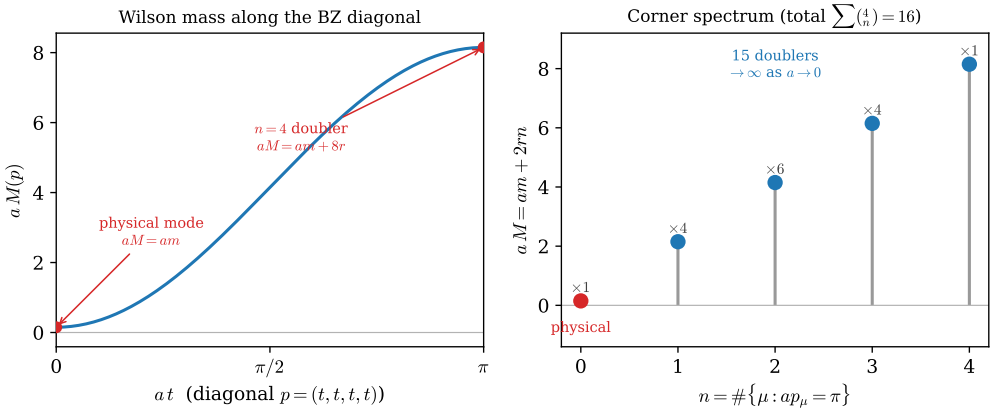

Figure 43.7: The Wilson term lifts the doublers. *Left:* the scalar Wilson mass $aM(p)$ along the Brillouin-zone diagonal $p = (t,t,t,t)$; the physical mode sits at $aM = am$ near the origin, the $n = 4$ doubler at the far corner sits at $aM = am + 8r$. *Right:* the corner spectrum $aM = am + 2rn$ versus the number n of components equal to π/a, with multiplicities $\binom{4}{n} = 1, 4, 6, 4, 1$. The fifteen doublers (blue) run off to infinity as $a \to 0$; only the physical mode (red) survives.

irrelevant, it scales away at the fixed point and does not change the continuum physics of the physical mode. (Its only lasting effect, discussed below, is to introduce $O(a)$ discretization errors — the reason "improved" Wilson actions add a further dimension-five term, the clover term, to cancel them.)

The doublers get masses of order $1/a$. At a Brillouin-zone corner the sine term vanishes identically, so the entire operator collapses to its scalar part $M(p)$. Let the corner have n of its four components equal to π/a and the rest zero. Then $\cos(ap_\mu) = -1$ for those n components and $+1$ for the others, so

$$M(\text{corner with } n \text{ components} = \pi/a) = m + \frac{r}{a}\big[n\cdot 2 + (4-n)\cdot 0\big] = m + \frac{2rn}{a}, \qquad n \in \{0,1,2,3,4\}. \tag{43.156}$$

The $n = 0$ corner is the physical fermion with mass m. The other fifteen corners carry masses $2r/a$, $4r/a$, $6r/a$, $8r/a$ with multiplicities $\binom{4}{1} = 4$, $\binom{4}{2} = 6$, $\binom{4}{3} = 4$, $\binom{4}{4} = 1$ respectively, summing to $\sum_{n=1}^{4}\binom{4}{n} = 15$. Every doubler mass diverges as $a \to 0$: the doublers become infinitely heavy and decouple, leaving a single Dirac fermion in the continuum. Figure 43.7 shows this staircase.

Worked Example 43.33 (Doubler masses at the zone corners)**.** We verify Eq. (43.156) by evaluating the full Wilson operator, not just its scalar part, at a representative corner and reading off the pole of the propagator. Take $m = 0$, $r = 1$, and the corner $p_\star = (\pi/a, 0, 0, 0)$ ($n = 1$). The sine term has components $\sin(ap_{\star,\mu})$; since $\sin(\pi) = 0$ and $\sin(0) = 0$, every component

vanishes and the γ piece of Eq. (43.154) is zero at $p_\star$. The scalar piece is $M(p_\star) = \frac{1}{a}[(1-\cos\pi)+3(1-\cos 0)] = \frac{1}{a}[2+0] = 2/a$. Hence $\widetilde{D}_W(p_\star) = 2/a$.

To see that this is genuinely a mass, expand around the corner: write $p = p_\star + k$ with ak_μ small. For the first component, $\sin(ap_1) = \sin(\pi + ak_1) = -\sin(ak_1) = -ak_1 + O(a^3)$ and $\cos(ap_1) = \cos(\pi + ak_1) = -\cos(ak_1) = -1 + \frac{1}{2}a^2k_1^2 + \dots$; for the transverse components $\sin(ak_j) = ak_j + O(a^3)$, $\cos(ak_j) = 1 - \frac{1}{2}a^2k_j^2 + \dots$. Therefore

$$\begin{aligned}\widetilde{D}_W(p_\star + k) &= \frac{1}{a}\Big[(1-\cos ap_1) + \sum_{j=2}^{4}(1-\cos ak_j)\Big] + \frac{i}{a}\Big[\gamma_1 \sin ap_1 + \sum_{j=2}^{4}\gamma_j \sin ak_j\Big] \\ &= \frac{1}{a}\Big[2 - \tfrac{1}{2}a^2k_1^2 + \tfrac{1}{2}a^2\sum_{j\geq 2}k_j^2 + \dots\Big] + i\Big[-\gamma_1 k_1 + \sum_{j\geq 2}\gamma_j k_j\Big] + O(a) \\ &= \frac{2}{a} \;+\; i\,\tilde{\not{k}} \;+\; O(a), \qquad \tilde{k} \equiv (-k_1, k_2, k_3, k_4). \end{aligned} \tag{43.157}$$

This is exactly a continuum Dirac operator $i\tilde{\not{k}} + M$ with mass $M = 2/a$ (the sign flip $k_1 \to -k_1$ is a harmless reflection of the local Dirac basis, absorbed by $\gamma_1 \to -\gamma_1$, a unitary change of variables that does not affect the physics). The propagator $\widetilde{D}_W^{-1}$ has its pole at $\tilde{k}^2 = -(2/a)^2$, i.e. a particle of mass $2/a$, confirming $n = 1 \Rightarrow 2r/a$. Repeating at a corner with n entries equal to π/a adds $2/a$ for each, giving $M = 2rn/a$ and reproducing Eq. (43.156). As $a \to 0$ each such pole is pushed to infinite mass and the corresponding species leaves the spectrum.

The price: explicit chiral-symmetry breaking. The Wilson term is, by construction, a momentum-dependent mass, and a mass term breaks chiral symmetry. We can make this exact. The continuum chiral rotation is $\psi \to e^{i\alpha\gamma_5}\psi$, $\bar\psi \to \bar\psi\, e^{i\alpha\gamma_5}$, an invariance of the massless naive action because γ_5 anticommutes with every γ_μ in the kinetic term, so $\bar\psi\,\gamma_\mu \to \bar\psi\, e^{i\alpha\gamma_5}\gamma_\mu = \bar\psi\,\gamma_\mu e^{-i\alpha\gamma_5}$ and the two exponentials cancel against $\psi \to e^{i\alpha\gamma_5}\psi$. The cleanest invariant statement is that the kinetic operator anticommutes with γ_5 while a mass commutes through. Computing the anticommutator of the Wilson operator with γ_5 in momentum space,

$$\Big\{\widetilde{D}_W(p), \gamma_5\Big\} = \{M(p), \gamma_5\} + \frac{i}{a}\sum_\mu \sin(ap_\mu)\;\{\gamma_\mu, \gamma_5\} = 2\,M(p)\,\gamma_5 + 0 = 2\gamma_5\Big[m + \frac{r}{a}\sum_\mu (1-\cos a \tag{43.158}$$

The kinetic γ term drops out because $\{\gamma_\mu, \gamma_5\} = 0$; the scalar term survives because $\{\mathbf{1}, \gamma_5\} = 2\gamma_5$. Even at $m = 0$, the Wilson contribution $\frac{2r}{a}\gamma_5 \sum_\mu (1 - \cos ap_\mu)$ is nonzero everywhere except the origin. Thus D_W violates the chiral hypothesis $\{D, \gamma_5\} = 0$ identically; chiral symmetry is broken not spontaneously and not anomalously but *explicitly*, by the regulator, at every nonzero momentum.

Consequences: additive mass renormalization and κ_c. In the continuum, chiral symmetry forbids an additively generated fermion mass: the massless point $m = 0$ is protected because m is the order parameter of a symmetry. Wilson fermions have no such protection. Radiative corrections generate a mass shift $\delta m \sim 1/a$ (a linear divergence, the worst kind), so the bare mass that yields a massless physical quark is not $m = 0$ but some a-dependent critical value $m_c(g)$ that must be *tuned*. It is conventional to package this in the *hopping parameter* form of the action. Rescaling the field to dimensionless variables $\psi \to \sqrt{2\kappa}\,\psi$ with

$$\kappa \equiv \frac{1}{2(am + 4r)}, \tag{43.159}$$

the gauged Wilson action Eq. (43.153) becomes the standard nearest-neighbour "hopping" form

$$S_W = \sum_x \bar\psi_x \psi_x - \kappa \sum_{x,\mu} \Big[\bar\psi_x (r - \gamma_\mu) U_\mu(x) \psi_{x+\hat\mu} + \bar\psi_{x+\hat\mu}(r + \gamma_\mu) U_\mu^\dagger(x) \psi_x\Big], \tag{43.160}$$

in which κ multiplies the hopping (kinetic) term and tunes the mass: large κ is light. At tree level $am = 0$ corresponds to $\kappa = \kappa_c = 1/8r$, but interactions push κ_c to a nontrivial function of the coupling, determined in practice by demanding that the pion mass (or the axial Ward identity) vanish. The matrices $(r \mp \gamma_\mu)$ are, for $r = 1$, twice the projectors $\frac{1}{2}(1 \mp \gamma_\mu)$ onto the γ_μ eigenspaces along each direction — the algebraic fingerprint of the broken chiral symmetry. This tuning, and the $O(a)$ artifacts left by the dimension-five term, are the full bill for Wilson's directness; it is paid routinely, and improved (clover) Wilson fermions remain a workhorse of the field.

Caution

The Wilson term is sometimes mis-stated as "giving the doublers a mass while preserving chiral symmetry on the physical mode." Equation (43.158) shows the chiral breaking is present at *all* nonzero momenta, including arbitrarily soft ones; it is $O(a)$ on soft modes but never zero. What survives the continuum limit is a chirally symmetric theory only because the breaking term is irrelevant, not because it is absent. The distinction matters the moment one wants chiral symmetry at finite a — for instance to control mixing of lattice operators — which is exactly what staggered and Ginsparg–Wilson fermions deliver and Wilson fermions do not.

43.6.2 Staggered (Kogut–Susskind) fermions: keeping a remnant chiral symmetry

Wilson removes all fifteen doublers and all chiral symmetry. The Kogut–Susskind construction is an economy in the opposite spirit: it does not fight the doubling at

all but *reorganizes* it, spreading the sixteen naive components over the corners of a hypercube so that, after discarding redundant spinor structure, only four species ("tastes") remain — and, crucially, an exact $U(1)$ chiral symmetry survives at finite a to protect the mass. The trick is that the naive operator Eq. (43.129) is, in a precise sense, four identical copies of a one-component problem.

Spin diagonalization. Perform the site-dependent change of Grassmann variables

$$\psi(x) = T(x)\,\chi(x), \qquad \bar\psi(x) = \bar\chi(x)\,T^\dagger(x), \qquad T(x) \equiv \gamma_1^{x_1/a}\,\gamma_2^{x_2/a}\,\gamma_3^{x_3/a}\,\gamma_4^{x_4/a}, \tag{43.161}$$

where the exponents are the integer coordinates in lattice units. Since each $\gamma_\mu^2 = \mathbf{1}$, $T(x)$ is unitary and $T^\dagger(x)T(x) = \mathbf{1}$. The only nontrivial input is how T behaves under a unit hop. Going from x to $x + a\hat\mu$ increments the exponent of γ_μ by one, i.e. inserts one extra γ_μ at slot μ of the ordered product. Bringing that extra γ_μ out to the left so it can meet the explicit γ_μ of the kinetic term requires anticommuting it past the factors $\gamma_1^{x_1/a}\cdots\gamma_{\mu-1}^{x_{\mu-1}/a}$ sitting to its left, each anticommutation costing a sign. The result is the central identity

$$T^\dagger(x)\,\gamma_\mu\,T(x + a\hat\mu) = \eta_\mu(x)\,\mathbf{1}, \qquad \eta_\mu(x) \equiv (-1)^{(x_1+\cdots+x_{\mu-1})/a}, \tag{43.162}$$

with $\eta_1(x) \equiv 1$. To see it, note $T^\dagger(x)\gamma_\mu T(x+a\hat\mu) = T^\dagger(x)\gamma_\mu T(x)\cdot[T^{-1}(x)T(x+a\hat\mu)]$; the bracket is γ_μ moved to slot μ, and $T^\dagger(x)\gamma_\mu T(x)\cdot\gamma_\mu^{(\text{at slot }\mu)}$ leaves $\eta_\mu(x)\,\mathbf{1}$ after all γ's square to unity. The phase $\eta_\mu(x)$ counts the parity of the coordinates *preceding* direction μ. Substituting Eq. (43.161) into the naive action and using Eq. (43.162),

$$S_{\text{naive}} = \sum_x \Big[\frac{1}{2a}\sum_\mu \eta_\mu(x)\,\bar\chi(x)\big(\chi(x+a\hat\mu) - \chi(x-a\hat\mu)\big) + m\,\bar\chi(x)\chi(x)\Big]\otimes \mathbf{1}_{4\times 4}. \tag{43.163}$$

Every explicit γ_μ has been replaced by the scalar phase $\eta_\mu(x)$, and the action is now diagonal in the (suppressed) Dirac index: it is four identical, decoupled copies of a single-component theory. Keeping one component — a single Grassmann field $\chi(x)$ per site — discards a factor of four of redundancy and defines the staggered fermion. The sixteen naive species become $16/4 = 4$ *tastes*, an internal flavour quartet that becomes four degenerate Dirac fermions in the continuum, assembled from the sixteen corners of the elementary hypercube (one taste-times-spin index per corner).

The remnant chiral symmetry. The decisive payoff is that a continuous chiral symmetry survives at $a \neq 0$. The site parity

$$\epsilon(x) \equiv (-1)^{(x_1+x_2+x_3+x_4)/a} \tag{43.164}$$

splits the lattice into even and odd sublattices, and the transformation

$$\chi(x) \to e^{i\alpha\,\epsilon(x)}\chi(x), \qquad \bar{\chi}(x) \to e^{i\alpha\,\epsilon(x)}\bar{\chi}(x) \tag{43.165}$$

is an exact symmetry of the *massless* staggered action and is broken only by the mass term. The verification is immediate. The hopping term connects x to its neighbour $x \pm a\hat{\mu}$, which lies on the opposite sublattice, so $\epsilon(x+a\hat{\mu}) = -\epsilon(x)$; under Eq. (43.165) the hopping bilinear picks up $e^{i\alpha(\epsilon(x)+\epsilon(x+a\hat{\mu}))} = e^{i\alpha(\epsilon(x)-\epsilon(x))} = 1$ and is invariant. The mass term, by contrast, joins $\chi(x)$ to $\bar{\chi}(x)$ on the *same* site and picks up $e^{2i\alpha\epsilon(x)} \neq 1$. Thus $\epsilon(x)$ plays exactly the role γ_5 plays in the continuum: it anticommutes with the kinetic operator (here, in the sense that it flips sign across a hop) and commutes through the mass. This $U(1)_\epsilon$ is a genuine remnant of the continuum $\mathrm{SU}(4) \times \mathrm{SU}(4)$ taste-chiral group — the lattice keeps one of its sixteen generators exactly — and because it is an exact symmetry at finite spacing, it forbids additive mass renormalization. The massless point is $m = 0$ with no tuning: this is the cardinal advantage of staggered over Wilson fermions, and it is why staggered fermions are the method of choice for problems where cheap near-chiral fermions matter, such as high-precision determinations of the light-quark masses and the equation of state at finite temperature.

Physical Insight

The two finite-a chiral symmetries on offer are mirror images. Wilson keeps the doubler count at one and throws away the chiral symmetry; staggered keeps an exact $U(1)$ chiral symmetry and pays with a residual fourfold taste multiplicity. Neither is the continuum symmetry: Wilson recovers it only as $a \to 0$, staggered realizes only a one-dimensional subgroup of it at $a \neq 0$. The Ginsparg–Wilson construction of the next subsection is the statement that one can, in fact, have the full continuous chiral symmetry exactly at finite a — provided one is willing to let the *operator* that generates it be deformed by the lattice.

The fourth-root trick, honestly. Four tastes is the wrong number for almost every physical application: nature has one up quark, not four. The standard remedy is to take the fourth root of the staggered determinant in the path integral, replacing $\det D_{\mathrm{stag}}$ for the four-taste operator by $(\det D_{\mathrm{stag}})^{1/4}$ for each physical flavour, so that N_f physical flavours enter as $(\det D_{\mathrm{stag}})^{N_f/4}$. Heuristically this divides the four degenerate tastes back down to one. The difficulty is that, at finite a, the four tastes are *not* exactly degenerate — they are split by lattice artifacts (taste-breaking interactions of order a^2) — and $(\det D_{\mathrm{stag}})^{1/4}$ is provably not the determinant of any local, one-taste lattice Dirac operator. The rooted theory is therefore nonlocal and non-unitary at $a \neq 0$; the open question is whether locality and unitarity are restored in the continuum limit, i.e. whether rooted staggered fermions lie in the correct universality class. As of the mid-2020s the weight

of evidence — analytic arguments controlling the taste splittings, and a large body of numerical tests against experiment and against other discretizations — supports the conclusion that the continuum limit is correct, and rooted staggered ensembles underpin many of the field's most precise results. But it is not a theorem, and a residual minority of the community regards the construction as not fully justified. The honest statement is: rooting works in practice, is believed to give the right continuum theory, and remains without rigorous proof.

43.6.3 The Ginsparg–Wilson relation and an exact lattice chiral symmetry

We now reach the principled resolution. The Nielsen–Ninomiya theorem forbids $\{D, \gamma_5\} = 0$ for a local, doubler-free D. Ginsparg and Wilson asked the right question: what is the *weakest* deformation of $\{D, \gamma_5\} = 0$ consistent with a sensible continuum limit, and does it still encode a chiral symmetry? Their answer, obtained originally by blocking a chirally symmetric continuum theory onto the lattice, is a relation in which the right-hand side is not zero but a local term that vanishes as $a \to 0$.

Definition 43.34 (Ginsparg–Wilson relation)**.** A lattice Dirac operator D satisfies the Ginsparg–Wilson (GW) relation if

$$\boxed{\{D, \gamma_5\} \;=\; a\, D\, \gamma_5\, D} \tag{43.166}$$

We assume in addition γ_5-Hermiticity $D^\dagger = \gamma_5 D \gamma_5$, the lattice version of the reality property of the Euclidean Dirac operator (it guarantees a real, positive fermion determinant for degenerate pairs and underlies reflection positivity).

The right-hand side of Eq. (43.166) is $O(a)$: it carries an explicit factor of a and is built from D, which has a smooth continuum limit. So as $a \to 0$ the relation collapses to $\{D, \gamma_5\} = 0$, the continuum chiral algebra. At finite a the deformation is real but mild, and — this is the content of the construction — it is exactly the deformation that converts the chiral *symmetry* from the naive one into a lattice-corrected one that the action still respects.

The relation localizes chiral breaking to a contact term. Multiplying Eq. (43.166) on the left and right by D^{-1} (assume for now D is invertible, i.e. no zero modes; the zero-mode case is the index theorem, taken up below) gives a statement about the propagator $S \equiv D^{-1}$:

$$D^{-1}\,\{D, \gamma_5\}\,D^{-1} = a\,\gamma_5 \quad\Longrightarrow\quad \left\{D^{-1}, \gamma_5\right\} = \gamma_5 D^{-1} + D^{-1}\gamma_5 = a\,\gamma_5. \tag{43.167}$$

The anticommutator of the propagator with γ_5 is a pure *contact term*: $a\gamma_5$ is an ultralocal operator (a multiple of the identity in position space, $a\gamma_5\,\delta_{xy}$). At any

nonzero separation $x \neq y$ the propagator anticommutes with γ_5 exactly, just as in the continuum. Chiral symmetry is broken only at coincident points, where a regulator is always entitled to act, and the breaking vanishes with a. This is the precise sense in which GW fermions are "as chiral as a lattice can be."

Eigenvalues live on a circle. The single most useful consequence of Eq. (43.166) together with γ_5-Hermiticity is the location of the spectrum of D. Multiply the GW relation on the left by γ_5:

$$\gamma_5 \{D, \gamma_5\} = \gamma_5(\gamma_5 D + D\gamma_5) = D + \gamma_5 D \gamma_5 = a\, \gamma_5 D \gamma_5 D. \tag{43.168}$$

By γ_5-Hermiticity $\gamma_5 D \gamma_5 = D^\dagger$, so this reads

$$D + D^\dagger = a\, D^\dagger D. \tag{43.169}$$

Now compute the combination $(\mathbf{1} - aD)^\dagger(\mathbf{1} - aD)$:

$$(\mathbf{1}-aD)^\dagger(\mathbf{1}-aD) = \mathbf{1}-aD-aD^\dagger+a^2D^\dagger D = \mathbf{1}-a(D+D^\dagger)+a^2D^\dagger D = \mathbf{1}-a(aD^\dagger D)+a^2D^\dagger D = \mathbf{1}, \tag{43.170}$$

using Eq. (43.169) at the third step. Therefore

$$V \equiv \mathbf{1} - aD \quad \text{is unitary:} \quad V^\dagger V = \mathbf{1}, \qquad D = \frac{1}{a}(\mathbf{1} - V). \tag{43.171}$$

The eigenvalues of the unitary V are phases $e^{i\theta}$, so the eigenvalues of D are

$$\lambda = \frac{1}{a}(1 - e^{i\theta}), \qquad \theta \in (-\pi, \pi], \tag{43.172}$$

which trace out the circle $|1 - a\lambda| = 1$ of radius $1/a$ centered at $1/a$ in the complex plane — the *Ginsparg–Wilson circle* (Fig. 43.8). It passes through the origin ($\theta = 0$, $\lambda = 0$) and through $\lambda = 2/a$ ($\theta = \pi$), the only two real points; everywhere else the eigenvalues come in complex-conjugate pairs because D is γ_5-Hermitian. As $a \to 0$ the circle flattens onto the imaginary axis near the origin, reproducing the continuum spectrum $\lambda = i\not{p}$. The two real points are special: $\lambda = 0$ will host the exact chiral zero modes, and $\lambda = 2/a$ the heavy lattice-artifact real modes that play the role of the would-be doublers.

Lüscher's exact lattice chiral symmetry. The deformation Eq. (43.166) is not a loss of chiral symmetry but a redefinition of it. Lüscher observed that the GW relation is precisely the integrability condition for the action $S = \bar\psi D \psi$ to be invariant under a modified, lattice-deformed chiral rotation. Define the *lattice chirality operator*

$$\hat\gamma_5 \equiv \gamma_5\,(\mathbf{1} - aD) = \gamma_5 V, \tag{43.173}$$

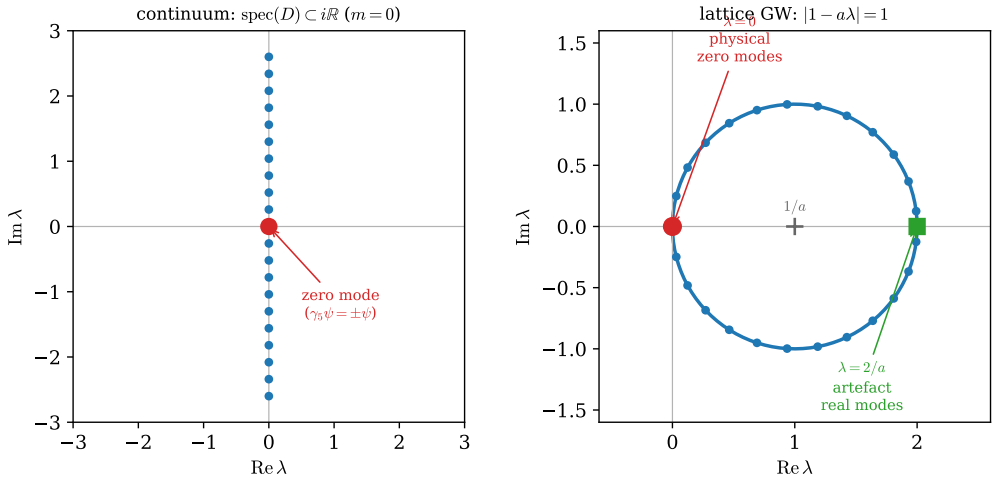

Figure 43.8: The Ginsparg–Wilson circle. *Left:* the continuum massless Dirac spectrum lies on the imaginary axis, with chiral zero modes at the origin in a topological background. *Right:* a GW operator has $1 - aD$ unitary, so spec(D) lies on the circle $|1 - a\lambda| = 1$ of radius $1/a$ centered at $1/a$. The two real eigenvalues — the physical zero modes at $\lambda = 0$ and the artifact real modes at $\lambda = 2/a$ — are where ordinary γ_5 is an exact symmetry; in between, the deformed chirality $\hat{\gamma}_5 = \gamma_5(1 - aD)$ takes over.

which is the natural lattice object replacing γ_5 in the chiral rotation of the field. We first record its key algebraic properties, which the index theorem below will use. It is Hermitian and squares to one:

$$\hat{\gamma}_5^\dagger = (\gamma_5 V)^\dagger = V^\dagger \gamma_5 = \gamma_5 V = \hat{\gamma}_5, \qquad \hat{\gamma}_5^2 = \gamma_5 V \gamma_5 V = V^\dagger V = \mathbf{1}, \tag{43.174}$$

where we used $\gamma_5 V \gamma_5 = \gamma_5(\mathbf{1} - aD)\gamma_5 = \mathbf{1} - aD^\dagger = V^\dagger$ (from γ_5-Hermiticity) twice. So $\hat{\gamma}_5$ is a legitimate chirality: Hermitian, involutive, with eigenvalues ± 1, and it reduces to γ_5 as $a \to 0$. The associated chiral projectors are $\hat{P}_\pm = \frac{1}{2}(\mathbf{1} \pm \hat{\gamma}_5)$ for the field ψ and $P_\pm = \frac{1}{2}(\mathbf{1} \pm \gamma_5)$ for $\bar{\psi}$. The worked example below verifies that the rotation built from $\hat{\gamma}_5$ is an exact symmetry.

Worked Example 43.35 (Lüscher's modified chiral rotation is an exact symmetry)**.** We show that, for any D obeying the GW relation Eq. (43.166), the bilinear lattice action $S = \bar{\psi}\, D\, \psi$ is exactly invariant — at finite a, to all orders, not merely as $a \to 0$ — under the infinitesimal chiral rotation

$$\delta\psi = i\alpha\, \gamma_5(\mathbf{1} - aD)\, \psi = i\alpha\, \hat{\gamma}_5\, \psi, \qquad \delta\bar{\psi} = i\alpha\, \bar{\psi}\, \gamma_5, \tag{43.175}$$

with α a constant infinitesimal parameter. Note the deliberate asymmetry: the field ψ rotates with the *deformed* chirality $\hat{\gamma}_5$, while $\bar{\psi}$ rotates with the ordinary

γ_5. Varying the action and keeping the two contributions,

$$\begin{aligned}\delta S &= (\delta\bar\psi)\, D\,\psi + \bar\psi\, D\,(\delta\psi) = i\alpha\,\bar\psi\,\gamma_5 D\,\psi + i\alpha\,\bar\psi\, D\,\gamma_5(\mathbf{1} - aD)\,\psi \\ &= i\alpha\,\bar\psi[\gamma_5 D + D\gamma_5 - a\,D\gamma_5 D]\psi = i\alpha\,\bar\psi[\{D,\gamma_5\} - a\,D\gamma_5 D]\psi. \end{aligned} \tag{43.176}$$

The bracket is exactly the GW relation Eq. (43.166) rearranged: $\{D,\gamma_5\} - aD\gamma_5 D = 0$. Hence

$$\delta S = 0 \tag{43.177}$$

identically. The action is invariant under Eq. (43.175) *because* D satisfies the Ginsparg–Wilson relation, and conversely the relation is the necessary and sufficient condition for this rotation to be a symmetry. This is the exact lattice chiral symmetry: a continuous $U(1)$ invariance of the regularized, doubler-free action at finite lattice spacing, evading Nielsen–Ninomiya not by violating any of its analytic hypotheses but by deforming the algebraic form of the chirality from γ_5 to $\hat\gamma_5$.

A symmetric, manifestly $\psi \leftrightarrow \bar\psi$-balanced form distributes the deformation evenly: $\delta\psi = i\alpha\,\gamma_5(\mathbf{1} - \frac{a}{2}D)\psi$, $\delta\bar\psi = i\alpha\,\bar\psi(\mathbf{1} - \frac{a}{2}D)\gamma_5$. The same computation gives $\delta S = i\alpha\,\bar\psi[\gamma_5 D + D\gamma_5 - \frac{a}{2}D\gamma_5 D - \frac{a}{2}D\gamma_5 D]\psi = i\alpha\,\bar\psi[\{D,\gamma_5\} - aD\gamma_5 D]\psi = 0$, again by GW. The two forms differ by a field redefinition and define the same symmetry; the asymmetric form Eq. (43.175) is algebraically lighter and the symmetric form makes the chiral charge manifestly real.

43.6.4 The lattice index theorem and the anomaly

The exact symmetry of Theorem 43.35 is a classical statement about the action. Its quantum fate — whether the path-integral *measure* respects it — is where the anomaly and the index theorem of Chapter 36 reappear, now as exact lattice identities. This is the deepest payoff of the GW construction: it places the Atiyah–Singer index theorem and the chiral anomaly on the lattice with no continuum limit required.

Zero modes are exact chirality eigenstates. Let ϕ be a zero mode, $D\phi = 0$. Acting with the GW relation, $\{D,\gamma_5\}\,\phi = aD\gamma_5 D\phi = 0$, so $D(\gamma_5\phi) = -\gamma_5 D\phi = 0$: the space of zero modes is γ_5-invariant. Since $\gamma_5^2 = \mathbf{1}$ we may diagonalize γ_5 on it and choose every zero mode to have definite chirality $\gamma_5\phi = \pm\phi$. On a zero mode the deformed and ordinary chiralities coincide, $\hat\gamma_5\phi = \gamma_5(\mathbf{1} - aD)\phi = \gamma_5\phi = \pm\phi$. Write n_+ and n_- for the numbers of zero modes with $\gamma_5 = +1$ and $\gamma_5 = -1$ respectively. This chirality grading of the exact zero modes is the lattice analogue of the continuum statement that Dirac zero modes in an instanton background are chiral.

The index is a trace of $\hat{\gamma}_5$. Consider the trace of the lattice chirality over the whole Dirac space (Dirac, colour, and site indices),

$$\operatorname{Tr}\hat{\gamma}_5 = \operatorname{Tr}\big[\gamma_5(\mathbf{1} - aD)\big] = \operatorname{Tr}\gamma_5 - a\,\operatorname{Tr}(\gamma_5 D) = -a\,\operatorname{Tr}(\gamma_5 D), \tag{43.178}$$

where $\operatorname{Tr}\gamma_5 = 0$ because γ_5 is traceless on Dirac indices and the identity on the others. We now evaluate $\operatorname{Tr}\hat{\gamma}_5$ a second way, by its spectrum, using the unitary $V = \mathbf{1} - aD$ of Eq. (43.171). The eigenspaces of V are labeled by phases $e^{i\theta}$. The relation $\gamma_5 V \gamma_5 = V^\dagger$ means γ_5 maps the $e^{i\theta}$-eigenspace of V to its $e^{-i\theta}$-eigenspace: if $Vv = e^{i\theta}v$ then $V(\gamma_5 v) = \gamma_5 V^\dagger v = e^{-i\theta}(\gamma_5 v)$. Consequently, for $\theta \neq 0, \pi$ the eigenspaces at $\pm\theta$ are distinct and γ_5 — hence $\hat{\gamma}_5 = \gamma_5 V$ — is strictly off-diagonal between them, contributing *nothing* to the trace. Only the two real points survive:

- at $\theta = 0$ ($V = +\mathbf{1}$, $D = 0$): the zero-mode space, where $\hat{\gamma}_5 = \gamma_5$, contributing $n_+ - n_-$;
- at $\theta = \pi$ ($V = -\mathbf{1}$, $D = 2/a$): the artifact real-mode space, where $\hat{\gamma}_5 = -\gamma_5$, contributing $-(n_+^{(2/a)} - n_-^{(2/a)})$.

Therefore

$$\operatorname{Tr}\hat{\gamma}_5 = (n_+ - n_-) - (n_+^{(2/a)} - n_-^{(2/a)}). \tag{43.179}$$

The trace of the deformed chirality counts exact zero modes by chirality, corrected by the chirality of the heavy real modes at the top of the circle. For smooth gauge backgrounds carrying topological charge the index is saturated by the physical zero modes at the origin, the artifact modes at $2/a$ being absent or canceling in pairs; defining the lattice index as the physical zero-mode count,

$$\operatorname{index}(D) \equiv n_- - n_+, \tag{43.180}$$

and combining Eqs. (43.178) and (43.179), we obtain the exact lattice identity

$$\boxed{\operatorname{index}(D) = n_- - n_+ = -\tfrac{1}{2}\operatorname{Tr}\hat{\gamma}_5 = \frac{a}{2}\operatorname{Tr}(\gamma_5 D)} \tag{43.181}$$

(in the absence of $2/a$ real modes). This is the Ginsparg–Wilson form of the index theorem: an integer, computable on a finite lattice from the eigenvalues of a single operator, expressed as a trace that is the lattice transcription of the continuum $\frac{1}{32\pi^2}\int d^4x\,\epsilon^{\mu\nu\rho\sigma}\operatorname{Tr}F_{\mu\nu}F_{\rho\sigma}$.

The anomaly as a measure Jacobian. The continuum chiral anomaly is the failure of the path-integral measure to be invariant under a chiral rotation — the Fujikawa Jacobian computed in Chapter 36. The lattice reproduces this exactly. Under the Lüscher rotation, take the symmetric form $\delta\psi = i\alpha\,\gamma_5(\mathbf{1} - \frac{a}{2}D)\psi$,

$\delta\bar\psi = i\alpha\,\bar\psi(\mathbf{1}-\frac{a}{2}D)\gamma_5$. The Grassmann measure transforms with the inverse-Jacobian rule: $\psi\to(\mathbf{1}+M)\psi$ contributes $\det(\mathbf{1}+M)^{-1}\simeq e^{-\operatorname{Tr}M}$, and likewise for $\bar\psi$. With $M=i\alpha\gamma_5(\mathbf{1}-\frac{a}{2}D)$ and $\bar M = i\alpha(\mathbf{1}-\frac{a}{2}D)\gamma_5$,

$$\mathcal{D}\bar\psi\,\mathcal{D}\psi \;\longrightarrow\; \mathcal{D}\bar\psi\,\mathcal{D}\psi\;\exp\Big(-\operatorname{Tr}M-\operatorname{Tr}\bar M\Big),\qquad \operatorname{Tr}M+\operatorname{Tr}\bar M = 2i\alpha\;\operatorname{Tr}\Big[\gamma_5(\mathbf{1}-\tfrac{a}{2}D)\Big]. \tag{43.182}$$

Using $\operatorname{Tr}\gamma_5=0$ this is $\operatorname{Tr}M+\operatorname{Tr}\bar M = 2i\alpha(-\frac{a}{2})\operatorname{Tr}(\gamma_5 D) = -i\alpha\,a\;\operatorname{Tr}(\gamma_5 D)$, so the measure picks up the anomalous phase

$$\mathcal{D}\bar\psi\,\mathcal{D}\psi \;\longrightarrow\; \mathcal{D}\bar\psi\,\mathcal{D}\psi\;\exp\Big(i\alpha\,a\;\operatorname{Tr}(\gamma_5 D)\Big) = \mathcal{D}\bar\psi\,\mathcal{D}\psi\;\exp\Big(-2i\alpha\,(n_- - n_+)\Big), \tag{43.183}$$

where the last step used Eq. (43.181). The classically exact chiral symmetry of Theorem 43.35 is anomalous at the quantum level: the measure is not invariant, and its variation is precisely $2(n_- - n_+)$ times the rotation angle — an integer topological quantity, not a regulator-dependent number. This is the chiral anomaly of Chapter 36, derived here without a single continuum manipulation. In the continuum limit $-\frac{a}{2}\operatorname{Tr}(\gamma_5 D)$ tends to the topological charge $Q=\frac{1}{32\pi^2}\int d^4x\,\epsilon^{\mu\nu\rho\sigma}\operatorname{Tr}F_{\mu\nu}F_{\rho\sigma}$, and Eq. (43.181) becomes the Atiyah–Singer statement $n_- - n_+ = Q$ established in Section 36.5. The lattice has thus turned the anomaly — the very obstruction that, through Nielsen–Ninomiya, made doublers unavoidable for a chirally symmetric naive action — into an exact, finite, computable identity, while keeping one species and an exact (if deformed) chiral symmetry. The circle closes: the anomaly is not evaded but realized.

43.6.5 Realizations: overlap and domain-wall fermions

The GW relation is a constraint; it does not by itself exhibit an operator. Two explicit, widely used solutions exist, and they turn out to be two faces of the same construction.

The overlap operator (Neuberger). Neuberger gave a closed-form solution of Eq. (43.166):

$$D_{\mathrm{ov}} = \frac{1}{a}\Big(\mathbf{1}+\gamma_5\;\operatorname{sgn}(H)\Big) = \frac{1}{a}\Big(\mathbf{1}+\gamma_5\,\frac{H}{\sqrt{H^2}}\Big),\qquad H\equiv\gamma_5(aD_W-\rho), \tag{43.184}$$

where D_W is the Wilson–Dirac operator of Theorem 43.32, $\rho\in(0,2)$ is a negative "domain-wall mass" parameter that selects the physical mode, and sgn is the matrix sign function. The Wilson operator does double duty: its doubler-lifting property ensures that H has no near-zero eigenvalues coming from the corners, so $\operatorname{sgn}(H)$ is well defined, and the single physical mode survives the sign function as the chiral fermion. Writing $\epsilon\equiv\operatorname{sgn}(H)$, which is Hermitian and satisfies $\epsilon^2=\mathbf{1}$

(and, with the γ_5-Hermiticity of D_W, $\gamma_5\epsilon\gamma_5 = \epsilon^\dagger = \epsilon$ in the combination entering below), one checks the GW relation directly. With $aD_{\rm ov} = \mathbf{1} + \gamma_5\epsilon$,

$$\{D_{\rm ov}, \gamma_5\} = \frac{1}{a}\{\mathbf{1} + \gamma_5\epsilon, \gamma_5\} = \frac{1}{a}\Big(\{\mathbf{1}, \gamma_5\} + \{\gamma_5\epsilon, \gamma_5\}\Big) = \frac{1}{a}\Big(2\gamma_5 + \gamma_5\epsilon\gamma_5 + \gamma_5\gamma_5\epsilon\Big) = \frac{1}{a}\Big(2\gamma_5 \tag{43.185}$$

$$\begin{aligned} a\, D_{\rm ov}\gamma_5 D_{\rm ov} &= \frac{1}{a}(\mathbf{1} + \gamma_5\epsilon)\,\gamma_5\,(\mathbf{1} + \gamma_5\epsilon) = \frac{1}{a}(\gamma_5 + \gamma_5\epsilon\gamma_5)(\mathbf{1} + \gamma_5\epsilon) \\ &= \frac{1}{a}\Big(\gamma_5 + \gamma_5\gamma_5\epsilon + \gamma_5\epsilon\gamma_5 + \gamma_5\epsilon\gamma_5\gamma_5\epsilon\Big) = \frac{1}{a}\Big(\gamma_5 + \epsilon + \gamma_5\epsilon\gamma_5 + \gamma_5\epsilon^2\Big) = \frac{1}{a}\Big(2\gamma_5 + \epsilon - \end{aligned} \tag{43.186}$$

using $\gamma_5^2 = \mathbf{1}$ and $\epsilon^2 = \mathbf{1}$. The two right-hand sides are identical, so $\{D_{\rm ov}, \gamma_5\} = aD_{\rm ov}\gamma_5 D_{\rm ov}$: the overlap operator satisfies the Ginsparg–Wilson relation exactly. Its spectrum sits on the GW circle of Fig. 43.8 by construction, since $\mathbf{1} - aD_{\rm ov} = -\gamma_5\epsilon$ is manifestly unitary ($(\gamma_5\epsilon)^\dagger(\gamma_5\epsilon) = \epsilon\gamma_5\gamma_5\epsilon = \epsilon^2 = \mathbf{1}$). All the chiral structure of the previous subsections — Lüscher's symmetry, the exact zero modes, the index theorem — is therefore realized by a concrete, simulable operator.

Domain-wall fermions (Kaplan). The domain-wall construction reaches the same place by a physical route: it borrows a fifth dimension. Kaplan observed that a Dirac fermion in five dimensions with a mass that changes sign across a four-dimensional "wall" — a domain wall in the fifth coordinate $s \in \{1, \dots, L_5\}$ — binds a single chiral zero mode, exponentially localized on the wall (the Jackiw–Rebbi mechanism of Chapter 41). With a finite slab of fifth dimension and a wall at each end, a left-handed mode localizes on one wall and a right-handed mode on the other; the four-dimensional theory at low energy is a single Dirac fermion whose two chiralities live at opposite ends of the fifth dimension and therefore have exponentially small overlap. Their residual coupling, the "residual mass" $m_{\rm res}$, breaks chiral symmetry by an amount $\propto e^{-cL_5}$ that one sends to zero by taking $L_5 \to \infty$. In that limit the effective four-dimensional operator obtained by integrating out the bulk is *exactly* the overlap operator Eq. (43.184): domain-wall and overlap fermions are the same chiral lattice fermion, presented respectively as a five-dimensional local theory and its four-dimensional reduction. Domain-wall fermions trade the explicit matrix sign function for the simulation of an extra dimension of extent L_5 — often the more convenient bargain in practice, since it keeps the action local in five dimensions.

How Ginsparg–Wilson evades Nielsen–Ninomiya. It is worth stating cleanly which hypothesis of Theorem 43.30 is given up. The theorem assumes locality, translation invariance, Hermiticity (γ_5-Hermiticity), the absence of doublers, and chiral symmetry in the form $\{D, \gamma_5\} = 0$. The overlap operator keeps the first four: it is translation-invariant, γ_5-Hermitian, doubler-free, and *local*

— not ultralocal (it couples all sites, since $\mathrm{sgn}(H)$ is a nonpolynomial function of D_W), but local in the sufficient sense that its kernel decays exponentially, $|D_{\mathrm{ov}}(x,y)| \lesssim e^{-|x-y|/\xi}$ with a fixed range $\xi = O(a)$ for smooth gauge fields, which is all universality requires. What it gives up is the precise algebraic form of the fifth hypothesis: instead of $\{D,\gamma_5\}=0$ it satisfies $\{D,\gamma_5\} = aD\gamma_5 D$, and the exact chiral symmetry it possesses is generated not by γ_5 but by the deformed $\hat{\gamma}_5$ of Eq. (43.173). Nielsen–Ninomiya is not violated; its chirality hypothesis is *deformed*, in exactly the way that still admits an anomaly (Eq. (43.183)) and an index theorem (Eq. (43.181)) while keeping locality intact. This is the principled resolution of the doubling problem.

Physical Insight

The corollary of Nielsen–Ninomiya that no *ultralocal* GW operator exists is not a loophole but the cost made explicit. Chirality on the lattice cannot be packaged into a finite-range difference operator; it requires the infinite-range (yet exponentially localized) reach of the sign function or, equivalently, the extra dimension of the domain wall. The anomaly, which lives in the deep ultraviolet, forces the chiral operator to "feel" the whole lattice. That nonlocality-in-detail, locality-in-bulk is the precise mathematical price of an exact lattice anomaly.

Caution

Ginsparg–Wilson fermions are correct but expensive. The matrix sign function in Eq. (43.184) must be approximated — by rational (Zolotarev) functions or Lanczos methods — and each application costs an inner iterative solve, so an overlap inversion is one to two orders of magnitude more costly than a Wilson inversion; domain-wall fermions carry the multiplicative cost of the fifth dimension L_5. As of the mid-2020s this expense is why chiral lattice fermions, despite their theoretical supremacy, are deployed selectively — for quantities where chiral symmetry is essential (e.g. certain weak matrix elements, ϵ'/ϵ, topological susceptibility) — while the bulk of large-volume spectroscopy still runs on improved Wilson (clover) or rooted staggered ensembles. The choice of fermion discretization remains a genuine cost–correctness trade-off, not a solved problem.

With the doubling problem resolved — pragmatically by Wilson and staggered fermions, in principle by Ginsparg–Wilson — the lattice now offers a complete, positive, gauge-invariant measure for both gauge fields and matter. Every ingredient of the regulator is in hand: a discretized action, a doubler-free fermion sector, and a probability weight e^{-S_E} on a finite-dimensional configuration space. What remains is to extract numbers from it, which is the task of Section 43.7: importance sampling of the gauge measure, integration over the Grassmann fields

to the fermion determinant, the extraction of hadron masses from the exponential decay of Euclidean correlators, and the continuum extrapolation governed by asymptotic freedom.

43.7 What the lattice computes: Monte Carlo, the spectrum, and the continuum limit

The previous sections finished the hard constructive work. We have a finite-dimensional integral over compact link variables $U_\mu(x) \in \mathrm{SU}(3)$ and Grassmann quark fields, weighted by a positive, manifestly gauge-invariant Euclidean action assembled from the Wilson gauge action of Section 43.3 and a doubler-free fermion action of Section 43.6, on a finite hypercubic lattice with spacing a and volume $L^3 \times T$. Reflection positivity (Section 43.1.4) guarantees that this Euclidean system is the imaginary-time face of a genuine quantum theory with a self-adjoint, positive transfer matrix. Everything is now well defined. What remains is the question that justifies the entire construction: *how does one turn this object into numbers*—a proton mass, a quark mass, a transition temperature, a contribution to the muon anomaly—and in what sense do those numbers belong to continuum QCD rather than to the scaffolding we erected to define it? This section answers both. We compute expectation values by importance sampling, extract physical masses from the exponential decay of Euclidean correlators using the spectral decomposition the transfer matrix supplies, and remove the regulator by an extrapolation $a \to 0$ whose form is dictated by asymptotic freedom. We then survey, honestly and with dates, what the lattice has and has not delivered.

43.7.1 Expectation values as ensemble averages

The lattice path integral assigns to any observable $\mathcal{O}$—a product of fields and link variables—the Euclidean expectation value

$$\langle \mathcal{O} \rangle \;=\; \frac{1}{Z} \int \Big(\prod_{x,\mu} \mathrm{d}U_\mu(x) \Big)\, \mathrm{d}\bar{\psi}\, \mathrm{d}\psi \;\; \mathcal{O}\, e^{-S_g[U] - S_F[\bar{\psi},\psi,U]}, \qquad Z = \int \mathrm{d}U\, \mathrm{d}\bar{\psi}\, \mathrm{d}\psi \; e^{-S_g - S_F}, \tag{43.187}$$

where $\mathrm{d}U_\mu(x)$ is the normalized Haar measure on the group (the unique left- and right-invariant probability measure, used already in the strong-coupling expansion of Section 27.7), and $\mathrm{d}\bar{\psi}\,\mathrm{d}\psi$ is the Grassmann measure of Chapter 12. The normalization Z is the partition function; only ratios $\langle \mathcal{O} \rangle = (\text{numerator})/Z$ are physical, exactly as for any statistical-mechanical average. This is the content of the chapter's thesis made operational: after Wick rotation the weight e^{-S} is non-negative, so Eq. (43.187) is the average of $\mathcal{O}$ over a probability distribution on field configurations. A quantum field theory has become a problem in classical statistical mechanics on a finite (if astronomically large) configuration space.

Integrating out the fermions. The fermion action is bilinear in the Grassmann fields,

$$S_F[\bar\psi,\psi,U] = \sum_{x,y} \bar\psi(x)\, D[U]_{xy}\, \psi(y) \;\equiv\; \bar\psi\, D[U]\, \psi, \tag{43.188}$$

with $D[U]$ the lattice Dirac operator (Wilson, staggered, or overlap) built from the gauge links; it is a finite matrix carrying Dirac, colour, and lattice-site indices. Because the action is quadratic in $\psi,\bar\psi$, the Grassmann integral is the fermionic Gaussian of Chapter 12, and the master formula proved there—that integrating out anticommuting variables produces the *determinant* of the kinetic matrix in the numerator, not the inverse square root—applies verbatim. For a single Dirac flavour,

$$\int \mathrm{d}\bar\psi\, \mathrm{d}\psi\; e^{-\bar\psi D[U]\psi} = \det D[U], \tag{43.189}$$

the lattice incarnation of the functional determinant $\det(i\not{D} - m)$ obtained in Section 12.7 (Eq. (12.155)). Observables built from fermion bilinears bring down propagators: by the same Wick combinatorics, the Grassmann average of $\psi(x)\bar\psi(y)$ inside the integral is $D[U]^{-1}_{xy}$, the quark propagator *on the fixed background* U. For a generic fermionic observable, integrating out the quarks therefore turns Eq. (43.187) into a purely bosonic integral over gauge fields,

$$\langle \mathcal{O} \rangle \;=\; \frac{1}{Z}\int \mathrm{d}U\;\; \widehat{\mathcal{O}}[U]\;\det D[U]\; e^{-S_g[U]}, \qquad Z = \int \mathrm{d}U\;\det D[U]\, e^{-S_g[U]}, \tag{43.190}$$

where $\widehat{\mathcal{O}}[U]$ is $\mathcal{O}$ with every quark bilinear replaced by the appropriate string of background propagators $D[U]^{-1}$ and signed Wick contractions (the lattice version of the contraction rules of Chapter 12). The price of removing the Grassmann variables is that the effective gauge weight is no longer local: $\det D[U]$ couples every link to every other, and the propagators $D[U]^{-1}$ require inverting a sparse but enormous matrix on each configuration. For N_f degenerate flavours the weight carries $\big(\det D[U]\big)^{N_f}$.

Positivity and the role of the determinant. For the Monte Carlo method to apply, the integrand of Eq. (43.190) must be a genuine probability weight: $\det D[U]\, e^{-S_g[U]} \geq 0$. The gauge factor e^{-S_g} is positive by construction. The determinant is not automatically positive for a single flavour, but the Wilson and staggered operators satisfy a γ_5-Hermiticity relation $D^\dagger = \gamma_5 D \gamma_5$, which forces the eigenvalues to be real or to occur in complex-conjugate pairs, so $\det D$ is real. For an even number of degenerate flavours one writes $(\det D)^2 = \det(D^\dagger D)$, which is manifestly non-negative because $D^\dagger D$ is a positive operator. Two degenerate light flavours—a good approximation to the physical up and down quarks—are thus simulated with a strictly positive weight, and this is why the two-flavour theory was the workhorse of the field for a generation. A single

flavour, or the residual phase of an odd-flavour or rooted-staggered setup, is handled by writing the weight as $|\det D|$ times a phase and folding the phase into the observable by *reweighting*,

$$\langle \mathcal{O} \rangle = \frac{\left\langle \widehat{\mathcal{O}}\, e^{i\theta[U]} \right\rangle_{|\det D|}}{\left\langle e^{i\theta[U]} \right\rangle_{|\det D|}}, \qquad \det D[U] = |\det D[U]|\, e^{i\theta[U]}, \tag{43.191}$$

where $\langle \cdot \rangle_{|\det D|}$ is the average over the positive ensemble defined by $|\det D|\, e^{-S_g}$. Reweighting is exact and harmless when the phase $e^{i\theta}$ stays near unity; when it fluctuates wildly it destroys the method, and that catastrophe—the sign problem—is the subject of Section 43.7.5.

Configurations as a Markov chain. The integral in Eq. (43.190) runs over millions of link variables; it cannot be tabulated, and ordinary quadrature is hopeless in such dimension. The way out is *importance sampling*: rather than evaluate the weight everywhere, generate a finite sequence of gauge configurations $\{U^{(1)}, U^{(2)}, \dots, U^{(N)}\}$ drawn from the probability distribution

$$P[U] \;=\; \frac{1}{Z}\, \det D[U]\, e^{-S_g[U]}, \tag{43.192}$$

and estimate the expectation value as a simple ensemble average,

$$\langle \mathcal{O} \rangle \;\approx\; \frac{1}{N} \sum_{i=1}^{N} \widehat{\mathcal{O}}\,[U^{(i)}], \qquad \text{with statistical error} \;\sim \frac{1}{\sqrt{N}}\, \sqrt{2\tau_{\mathcal{O}}}\, \sigma_{\mathcal{O}}, \tag{43.193}$$

the unknown Z having cancelled because it is the same normalization for every configuration. The error is the central-limit $1/\sqrt{N}$ of any Monte Carlo estimator, inflated by the integrated autocorrelation time $\tau_{\mathcal{O}}$ that measures how many successive configurations it takes to produce one statistically independent sample, and by the intrinsic variance $\sigma_{\mathcal{O}}^2$ of the observable. The configurations are produced by a Markov chain: a stochastic update $U \to U'$ with transition probability $W(U \to U')$ engineered so that its unique stationary distribution is exactly Eq. (43.192). It suffices that the chain be ergodic (able to reach any configuration) and satisfy *detailed balance*,

$$P[U]\, W(U \to U') = P[U']\, W(U' \to U), \tag{43.194}$$

which guarantees P is stationary: summing Eq. (43.194) over U gives $\sum_U P[U] W(U \to U') = P[U'] \sum_U W(U' \to U) = P[U']$. The classic realization is the *Metropolis* algorithm: propose a local change to a link, compute the resulting action change ΔS, and accept the proposal with probability $\min(1, e^{-\Delta S})$; the acceptance ratio satisfies Eq. (43.194) by inspection, because for $\Delta S > 0$ the forward step is accepted with $e^{-\Delta S}$ and the reverse with 1, and $P[U']/P[U] = e^{-\Delta S}$. Metropolis

is efficient for pure gauge theory, where ΔS depends only on the few plaquettes touching the changed link. With dynamical fermions it is crippling, because the nonlocal $\det D[U]$ changes under every local move and recomputing it costs an inversion of D.

Hybrid Monte Carlo and pseudofermions. The algorithm that made full QCD with dynamical quarks tractable is *Hybrid (or Hamiltonian) Monte Carlo* (HMC). One first removes the determinant from the weight by re-expressing it as a bosonic Gaussian integral over auxiliary complex fields—*pseudofermions* ϕ—using, for two flavours,

$$\det(D^\dagger D) \;\propto\; \int \mathrm{d}\phi^\dagger\, \mathrm{d}\phi \;\exp\!\big(-\phi^\dagger (D^\dagger D)^{-1}\phi\big), \tag{43.195}$$

which is the ordinary bosonic Gaussian (the determinant now sits in the numerator because the exponent carries the *inverse* of $D^\dagger D$). The full weight $e^{-S_g}\det(D^\dagger D)$ is thereby written as $e^{-S_{\mathrm{eff}}[U,\phi]}$ with a local-in-U but ϕ-dependent effective action whose only nonlocality is the matrix inverse $(D^\dagger D)^{-1}\phi$, computed once per update by a sparse linear solver. HMC then introduces a fictitious conjugate momentum π for every link, defines a fictitious Hamiltonian $H = \tfrac{1}{2}\sum \pi^2 + S_{\mathrm{eff}}$, and evolves (U,π) along a trajectory of Hamilton's equations in a fictitious "molecular-dynamics" time using a reversible, area-preserving leapfrog integrator. The integrator's finite step makes H change by a small ΔH; a concluding Metropolis accept/reject with probability $\min(1, e^{-\Delta H})$ corrects exactly for that discretization error, so the algorithm samples Eq. (43.192) without bias regardless of step size. The genius of HMC is that the global molecular-dynamics move changes every link at once—essential for moving through configuration space when the fermion determinant resists local updates—while remaining exact. For a single flavour, or for the fourth root of the staggered determinant, the square root $(D^\dagger D)^{1/4}$ is realized by a rational approximation (the rational-HMC variant). We state these algorithms at the level of their defining properties; their convergence and efficiency are the engineering core of the field, but the physics content is exhausted by Eq. (43.193): *a lattice prediction is an average over a finite, importance-sampled ensemble of gauge configurations, carrying a statistical error that falls as* $1/\sqrt{N}$.

Physical Insight

The deepest conceptual payoff of Eqs. (43.187) and (43.193) is that the path integral, which in the continuum is a formal symbol manipulated by Feynman rules, is here a literal probability average that a computer evaluates by drawing samples. There is no perturbation series, no gauge fixing, no Faddeev–Popov determinant, and no Gribov ambiguity (contrast Chapter 26): the configurations are sampled directly from the gauge-invariant

measure on SU(3) link variables. Confinement, chiral symmetry breaking, and the hadron spectrum are not summed up diagram by diagram—they are present in the ensemble, and one measures them.

43.7.2 Extracting masses: spectral decomposition of a Euclidean correlator

The single most important class of lattice observable is the two-point function of a local operator, because its Euclidean-time dependence encodes the mass spectrum. Let $\mathcal{O}$ be a gauge-invariant operator with the quantum numbers of a state one wishes to study—for a pion, $\mathcal{O} = \bar{d}\,\gamma_5 u$; for the proton, a gauge-invariant three-quark operator; for a glueball, a trace of plaquettes. Build the zero-momentum operator by summing over a spatial timeslice, $\mathcal{O}(t) = \sum_{\mathbf{x}} \mathcal{O}(\mathbf{x}, t)$, projecting onto vanishing spatial momentum. The object measured is the connected correlator

$$C(t) = \left\langle \mathcal{O}(t)\, \mathcal{O}^\dagger(0) \right\rangle - \langle \mathcal{O} \rangle \left\langle \mathcal{O}^\dagger \right\rangle . \tag{43.196}$$

We now prove that $C(t)$ decays as a sum of pure exponentials whose rates are the energies of the states $\mathcal{O}^\dagger$ creates, with the lightest dominating at large t.

Theorem 43.36 (Spectral decomposition of a Euclidean correlator)**.** *Let $\mathcal{T} = e^{-aH}$ be the positive self-adjoint transfer matrix of Section 43.1.4, with eigenstates $\mathcal{T}\,|n\rangle = e^{-aE_n}\,|n\rangle$, $E_0 \le E_1 \le \cdots$, normalized $\langle m|n\rangle = \delta_{mn}$, and let $\widehat{\mathcal{O}}$ be the operator on the transfer-matrix Hilbert space corresponding to $\mathcal{O}$. Writing the Euclidean separation as $t = n_t\, a$ with integer n_t, the connected correlator Eq. (43.196) on a lattice of temporal extent $L_t = N_t\, a$ with periodic boundary conditions is*

$$C(t) = \frac{1}{Z} \sum_{m,n} \left| \left\langle m \middle| \widehat{\mathcal{O}} \middle| n \right\rangle \right|^2 e^{-E_n t}\, e^{-E_m (L_t - t)}, \tag{43.197}$$

and, in the limit $L_t \to \infty$ with the vacuum $|0\rangle$ unique and the disconnected piece removed,

$$C(t) = \sum_{n \ge 1} \left| \left\langle 0 \middle| \widehat{\mathcal{O}} \middle| n \right\rangle \right|^2 e^{-(E_n - E_0)\, t} \;\equiv\; \sum_{n \ge 1} |c_n|^2\; e^{-M_n t}, \qquad M_n \equiv E_n - E_0. \tag{43.198}$$

Every coefficient $|c_n|^2 \ge 0$, so $C(t)$ is a sum of decaying exponentials with positive weights; at large t it is dominated by the lightest state $|1\rangle$ that $\widehat{\mathcal{O}}^\dagger$ overlaps, and $C(t) \to |c_1|^2\; e^{-M_1 t}$.

Proof. Euclidean time evolution is implemented by powers of the transfer matrix: an operator inserted n_t steps apart is conjugated by $\mathcal{T}^{n_t} = e^{-n_t a H} = e^{-Ht}$, so the lattice Heisenberg operator is $\widehat{\mathcal{O}}(t) = e^{Ht}\, \widehat{\mathcal{O}}\, e^{-Ht}$, exactly the imaginary-time

continuation of the Minkowski Heisenberg picture. The thermal trace that the periodic path integral computes is

$$C(t) = \frac{1}{Z}\,\mathrm{Tr}\big[\,e^{-(L_t-t)H}\,\widehat{\mathcal{O}}\,e^{-tH}\,\widehat{\mathcal{O}}^\dagger\,\big], \qquad Z = \mathrm{Tr}\;e^{-L_tH}, \tag{43.199}$$

the partition function Z being the trace of $\mathcal{T}^{N_t} = e^{-L_tH}$. This identity—that the Euclidean path integral on a torus of temporal circumference L_t equals the thermal trace at inverse temperature $\beta = L_t$—is the operator content of reflection positivity established in Section 43.1.4; we use it here. Insert the resolution of the identity $\mathbf{1} = \sum_n |n\rangle\langle n|$ twice, once on each side of $\widehat{\mathcal{O}}$:

$$\mathrm{Tr}\big[e^{-(L_t-t)H}\widehat{\mathcal{O}}\,e^{-tH}\widehat{\mathcal{O}}^\dagger\big] = \sum_{m,n} \Big\langle m\Big|\widehat{\mathcal{O}}\Big|n\Big\rangle\; e^{-E_nt}\;\Big\langle n\Big|\widehat{\mathcal{O}}^\dagger\Big|m\Big\rangle\; e^{-E_m(L_t-t)}. \tag{43.200}$$

Using $\Big\langle n\Big|\widehat{\mathcal{O}}^\dagger\Big|m\Big\rangle = \Big\langle m\Big|\widehat{\mathcal{O}}\Big|n\Big\rangle^*$ gives the modulus-squared and establishes Eq. (43.197). Now take $L_t \to \infty$. Every term carries $e^{-E_m(L_t-t)}$, which is exponentially suppressed unless $E_m = E_0$; with a unique vacuum the sum over m collapses to $m = 0$, and dividing by $Z \to e^{-E_0L_t}$ converts the surviving $e^{-E_0(L_t-t)}$ and e^{-E_nt} into $e^{+E_0t}e^{-E_nt} = e^{-(E_n-E_0)t}$. The $n = 0$ term is the disconnected piece $\Big|\Big\langle 0\Big|\widehat{\mathcal{O}}\Big|0\Big\rangle\Big|^2$, removed by the subtraction in Eq. (43.196); what remains is Eq. (43.198). Positivity of every $|c_n|^2 = \Big|\Big\langle 0\Big|\widehat{\mathcal{O}}\Big|n\Big\rangle\Big|^2$ is automatic. Since $M_n = E_n - E_0$ increases with n, the slowest-decaying surviving exponential is $n = 1$, which dominates as $t \to \infty$. □

Theorem 43.36 is the lattice counterpart of the Källén–Lehmann spectral representation of Theorem 14.23: both express a two-point function as a positively-weighted sum over the physical spectrum. The continuum version is an integral over a spectral density $\rho(M^2)$; the finite lattice, with its discrete transfer-matrix spectrum, gives a discrete sum. The key practical consequence is the same in both: *the lightest state with the chosen quantum numbers governs the long-distance (here, large Euclidean-time) behaviour*, so a hadron mass is read off as the asymptotic exponential decay rate of the corresponding correlator.

The effective mass. To expose the dominant exponential without fitting, define the *effective mass*

$$a\,M_{\mathrm{eff}}(t) \;\equiv\; \ln\frac{C(t)}{C(t+a)}. \tag{43.201}$$

If C were a single exponential $|c_1|^2\,e^{-M_1t}$, then Eq. (43.201) would return aM_1 exactly, for every t. With sub-leading states present, substitute Eq. (43.198)

and factor out the ground state, $C(t) = |c_1|^2 e^{-M_1 t}[1 + r\,e^{-\Delta t} + \cdots]$ with $r = |c_2|^2/|c_1|^2$ and gap $\Delta = M_2 - M_1 > 0$. Then

$$a\,M_{\text{eff}}(t) = \ln \frac{|c_1|^2 e^{-M_1 t}(1 + re^{-\Delta t})}{|c_1|^2 e^{-M_1(t+a)}(1 + re^{-\Delta(t+a)})} = aM_1 + \ln \frac{1 + re^{-\Delta t}}{1 + re^{-\Delta(t+a)}}$$
$$= aM_1 + r(1 - e^{-a\Delta})\, e^{-\Delta t} + O(r^2 e^{-2\Delta t}), \tag{43.202}$$

where the second line expands the logarithm for large t. The effective mass therefore approaches the true ground-state mass from above (if $r > 0$), with the excited-state contamination dying *exponentially* at the rate of the energy gap Δ. The signature of a clean measurement is a *plateau*: a range of t over which $M_{\text{eff}}(t)$ is constant within statistical errors, before the noise of Eq. (43.193) (which grows with t as the signal decays) swamps it. The plateau value is the mass.

Worked Example 43.37 (Reading a mass off the effective-mass plateau)**.** Take the two-state model correlator in lattice units ($a = 1$)

$$C(t) = A_0\, e^{-M_0 t} + A_1\, e^{-M_1 t}, \qquad M_0 = 0.5,\ M_1 = 1.2,\ A_0 = 1,\ A_1 = 0.8, \tag{43.203}$$

which mimics a correlator with a ground state at $aM_0 = 0.5$ and one excited state. We evaluate $C(t)$ and the effective mass Eq. (43.201) step by step. Directly,

$$C(0) = 1 + 0.8 = 1.8000, \qquad C(1) = e^{-0.5} + 0.8\,e^{-1.2} = 0.6065$$
$$C(2) = e^{-1.0} + 0.8\,e^{-2.4} = 0.36788 + 0.07257 = 0.44045, \qquad C(3) = e^{-1.5} + 0.8\,e^{-3.6} = 0.2231$$
$$C(4) = e^{-2.0} + 0.8\,e^{-4.8} = 0.13534 + 0.00658 = 0.14192, \qquad C(5) = e^{-2.5} + 0.8\,e^{-6.0} = 0.0820$$

and so on. The effective masses follow from ratios of consecutive entries:

t	0	1	2	3	4	5	6
$M_{\text{eff}}(t)$	0.7533	0.6545	0.5866	0.5460	0.5236	0.5120	0.5060

(43.204)

The sequence falls monotonically toward $aM_0 = 0.5$. The rate of approach is exactly Eq. (43.202): with $r = A_1/A_0 = 0.8$ and $\Delta = M_1 - M_0 = 0.7$, the leading correction is $r(1 - e^{-\Delta})e^{-\Delta t} = 0.8(1 - e^{-0.7})e^{-0.7t} = 0.4027\,e^{-0.7t}$. At $t = 4$ this predicts $0.5 + 0.4027\,e^{-2.8} = 0.5 + 0.0245 = 0.5245$, against the exact 0.5236; the small residual is the $O(r^2)$ term. By $t = 6$ the contamination has fallen below 0.6% and the plateau is established. In a real computation one fits the plateau region—here $t \gtrsim 5$—to a constant (or fits $C(t)$ itself to one or two exponentials over the same window), and the fitted value is the hadron mass in lattice units, aM. Figure 43.9 plots the approach and the analytic contamination curve together.

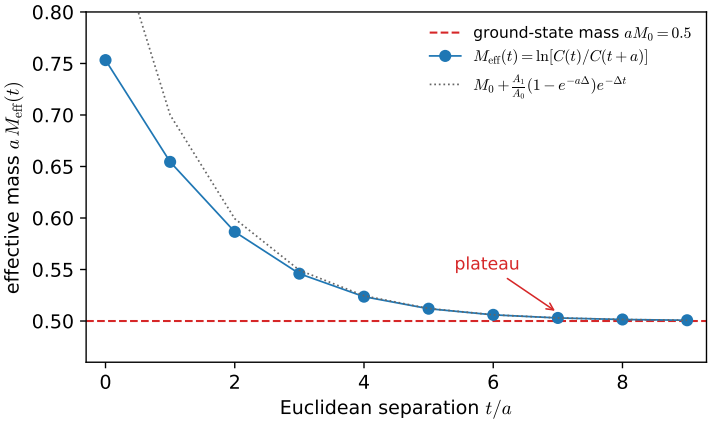

Figure 43.9: The effective mass $aM_{\rm eff}(t) = \ln[C(t)/C(t+a)]$ for the model correlator Eq. (43.203) of Theorem 43.37. It descends toward the ground-state value $aM_0 = 0.5$ (dashed) as the excited-state contamination dies at the gap rate $\Delta = M_1 - M_0$; the dotted curve is the leading analytic estimate Eq. (43.202). The flat region at large t is the plateau from which the mass is read.

Caution

On a torus of finite temporal extent L_t the full Eq. (43.197) is not a single exponential but a symmetric combination. For a single dominant state the dominant terms are $n{=}1, m{=}0$ and $n{=}0, m{=}1$, giving $C(t) \propto e^{-M_1 t} + e^{-M_1(L_t - t)} = 2e^{-M_1 L_t/2}\cosh\!\left[M_1(L_t/2 - t)\right]$ for a bosonic operator (and a sinh, or a forward/backward-propagating split, for baryons whose forward and backward states differ). The effective mass is then defined by solving $C(t)/C(t+a) = \cosh[\cdot]/\cosh[\cdot]$ rather than by the naive logarithm, and the plateau sits near the midpoint $t = L_t/2$. Forgetting the backward-propagating image is a classic way to misread a mass at small L_t.

43.7.3 Removing the regulator: scale setting and the continuum limit

Every number computed so far is dimensionless: Eq. (43.193) produces pure numbers, and the masses of Theorem 43.37 come out as the dimensionless products aM. The lattice spacing a is the only dimensionful quantity in the simulation, and it is *not* an input one dials in physical units—it is an output, fixed implicitly by the bare coupling g_0 (equivalently the inverse-coupling $\beta_{\rm lat} = 2N/g_0^2$ of the Wilson action) and the bare quark masses. To produce a physical prediction one must (i) determine a in physical units at each bare coupling—*scale setting*—and

(ii) extrapolate to $a \to 0$—the *continuum limit*. Both steps are governed by the renormalization group, and the form of the continuum limit is dictated by asymptotic freedom.

The continuum limit is an ultraviolet fixed point. The lattice spacing is the ultraviolet cutoff: momenta are bounded by π/a. Sending $a \to 0$ at fixed physical quantities is therefore the statement that the cutoff is removed while the physics is held fixed—precisely the renormalization-group flow toward an ultraviolet fixed point (Chapter 23). A physical mass M_{phys} is held fixed only if the dimensionless lattice mass scales as $aM_{\text{phys}} \to 0$, i.e. the correlation length $\xi = 1/(aM_{\text{phys}})$ in lattice units diverges. A divergent correlation length is the defining feature of a *critical point* of a statistical system. The continuum limit of a lattice field theory is thus a second-order critical point of the corresponding statistical mechanics, and which critical point QCD flows to is fixed by asymptotic freedom: the relevant fixed point is the *Gaussian* (free) fixed point at $g_0 = 0$, approached from the asymptotically free side. We now make this quantitative by importing the Yang–Mills beta function.

Asymptotic scaling from the two-loop beta function. The bare lattice coupling g_0 runs with the cutoff scale $\mu \sim 1/a$ exactly as the renormalized coupling runs with μ, because the lattice is just one more regularization scheme. Recall from Theorem 27.7 the renormalization-group equation $\mu \frac{dg}{d\mu} = \beta(g)$ with the two-loop beta function (Eqs. (27.101) and (27.171))

$$\beta(g) = -\beta_0\, g^3 - \beta_1\, g^5 + O(g^7), \qquad \beta_0 = \frac{1}{16\pi^2}\Big(\tfrac{11}{3}C_A - \tfrac{4}{3}T_F n_f\Big), \quad \beta_1 = \frac{1}{(16\pi^2)^2}\Big(\tfrac{34}{3}C_A^2 - (\tfrac{20}{3}C \tag{43.205}$$

Because $\mu \sim 1/a$ we have $\mathrm{d}\ln\mu = -\mathrm{d}\ln a$, so $a\,\frac{dg_0}{da} = -\beta(g_0) = \beta_0 g_0^3 + \beta_1 g_0^5 + \cdots$. As $a \to 0$ this drives $g_0 \to 0$: the bare coupling vanishes at the continuum limit, the hallmark of asymptotic freedom. Separating variables,

$$\frac{\mathrm{d}a}{a} = \frac{\mathrm{d}g_0}{\beta_0 g_0^3 + \beta_1 g_0^5 + \cdots} = \frac{\mathrm{d}g_0}{\beta_0 g_0^3}\Big(1 - \frac{\beta_1}{\beta_0} g_0^2 + \cdots\Big) = \Big(\frac{1}{\beta_0 g_0^3} - \frac{\beta_1}{\beta_0^2 g_0} + \cdots\Big)\mathrm{d}g_0. \tag{43.206}$$

Integrating term by term,

$$\ln a = -\frac{1}{2\beta_0 g_0^2} - \frac{\beta_1}{\beta_0^2}\ln g_0 + \text{const} + O(g_0^2), \tag{43.207}$$

and exponentiating, the lattice spacing is tied to the bare coupling by the *asymptotic-scaling formula*

$$\boxed{a\,\Lambda_{\text{lat}} = (\beta_0 g_0^2)^{-\beta_1/(2\beta_0^2)} \exp\Big(-\frac{1}{2\beta_0 g_0^2}\Big)\,[1 + O(g_0^2)],} \tag{43.208}$$

where the integration constant has been packaged into a dimensionful scale $\Lambda_{\rm lat}$. One checks directly that $\Lambda_{\rm lat}$ is a renormalization-group invariant: differentiating $a\Lambda_{\rm lat} = f(g_0)$ and using $a\,\mathrm{d}g_0/\mathrm{d}a = -\beta(g_0)$ gives $a\,\mathrm{d}\Lambda_{\rm lat}/\mathrm{d}a = 0$ to the order worked. This is precisely the dimensional transmutation of Theorem 27.14: a dimensionless coupling traded for a dimensionful scale through the logarithmic running of the quantum theory, here producing the lattice version $\Lambda_{\rm lat}$ of the continuum $\Lambda_{\rm QCD}$ (Eq. (27.153)). The two are related by a fixed, computable one-loop conversion factor $\Lambda_{\rm QCD}/\Lambda_{\rm lat}$, scheme matching being a one-loop calculation of the kind in Eq. (27.161). The decisive content of Eq. (43.208) is the essential singularity $e^{-1/(2\beta_0 g_0^2)}$: the lattice spacing shrinks *exponentially fast* as $g_0 \to 0$, so a modest decrease in the bare coupling buys a large reduction in a. This exponential approach to the continuum, with no power-law freedom, is the gift of asymptotic freedom; were the beta function positive, no such limit would exist and the lattice could not define the theory.

Worked Example 43.38 (How much must the coupling change to halve the lattice spacing?)**.** Take pure SU(3) gauge theory ($n_f = 0$, $C_A = N = 3$), so $\beta_0 = \frac{1}{16\pi^2}\cdot 11 = 11/(16\pi^2) = 0.06966$. Keep only the leading exponential in Eq. (43.208), $a\Lambda_{\rm lat} \simeq e^{-1/(2\beta_0 g_0^2)}$. The ratio of spacings at two couplings is

$$\frac{a'}{a} = \exp\Big[-\frac{1}{2\beta_0}\Big(\frac{1}{g_0'^2} - \frac{1}{g_0^2}\Big)\Big]. \tag{43.209}$$

To halve the spacing, $a'/a = \frac{1}{2}$, requires $\frac{1}{g_0'^2} - \frac{1}{g_0^2} = 2\beta_0 \ln 2 = 2(0.06966)(0.6931) = 0.0966$. Starting from $g_0^2 = 1$ (Wilson inverse-coupling $\beta_{\rm lat} = 6/g_0^2 = 6.0$), the new coupling satisfies $1/g_0'^2 = 1.0966$, i.e. $g_0'^2 = 0.9119$ and $\beta'_{\rm lat} = 6/0.9119 = 6.58$. Thus an increase of the simulation parameter from $\beta_{\rm lat} = 6.0$ to ≈ 6.6 halves the lattice spacing—in good qualitative accord with the empirical fact that $a \approx 0.094\,\mathrm{fm}$ at $\beta_{\rm lat} = 6.0$ and roughly half that near $\beta_{\rm lat} = 6.6$. The exponential in Eq. (43.208) is what makes the continuum reachable: each step of $a \to a/2$ costs only a finite increment in $\beta_{\rm lat}$, not an exponentially large one. (Quantitatively the two-loop prefactor and higher corrections shift these numbers; Eq. (43.208) is the leading systematics, and the onset of the regime where it holds is called the scaling window.)

Scale setting and lines of constant physics. Equation (43.208) fixes how *a scales* with g_0 but not its absolute value: the constant $\Lambda_{\rm lat}$ must be pinned to experiment. *Scale setting* does this by computing one chosen dimensionful quantity on the lattice—in pure numbers, as $a\,Q_{\rm lat}$—and dividing by its measured physical value to read off a:

$$a = \frac{(a\,Q)_{\rm lat}}{Q_{\rm phys}}. \tag{43.210}$$

Good scale-setting quantities are precisely measured, weakly dependent on the quark masses, and cheap to compute: common choices are a hadron mass or

decay constant (the Ω^- baryon mass, the pion or kaon decay constant f_π, f_K), the static-quark force scales r_0, r_1 extracted from the heavy-quark potential, or the purely gluonic gradient-flow scales t_0, w_0. Once $a(g_0)$ is known, every other lattice number is converted to physical units by multiplying by the appropriate power of $1/a$. The bare quark masses must also be tuned: at each g_0 one adjusts them so that a set of dimensionless ratios—typically the ratios of pseudoscalar masses to the scale-setting quantity, e.g. m_π/m_Ω and m_K/m_Ω—equal their physical values. A curve in the space of bare parameters $(g_0, m_{0,u}, m_{0,d}, m_{0,s}, \dots)$ along which all such dimensionless ratios are held fixed while a varies is a *line of constant physics*: it is the lattice realization of an RG trajectory, the path one walks toward the continuum while keeping the theory physically the same.

The continuum extrapolation. With a known at several couplings along a line of constant physics, any predicted dimensionless ratio R is computed at each a and extrapolated to $a = 0$. The cutoff dependence is governed by the lattice analogue of irrelevant operators (Chapter 23): the leading discretization error is a power of a set by the action. The Wilson fermion action of Section 43.6 has $O(a)$ errors, removable by the Symanzik improvement programme (adding higher-dimension operators tuned to cancel the linear term) to leave $O(a^2)$; staggered and many improved actions are $O(a^2)$ from the outset. One therefore fits

$$R(a) = R_{\text{cont}} + c_1\, a + c_2\, a^2 + \cdots \tag{43.211}$$

(omitting the c_1 term for an $O(a^2)$-improved action) and takes the intercept R_{cont} as the continuum prediction. Figure 43.10 shows the geometry: dimensionless data computed at several squared lattice spacings, with a straight-line extrapolation in a^2 to the continuum value on the axis. The honesty of a lattice result lives in this plot—in the spread of lattice spacings, the smallness of the slope, and whether several different discretizations extrapolate to the same intercept. A modern result quotes a continuum-extrapolated number with a statistical error from Eq. (43.193) and a systematic error dominated by the continuum and infinite-volume extrapolations.

Physical Insight

The continuum limit is the moment the regulator disappears and the answer becomes a property of quantum field theory rather than of the lattice. That this limit exists at all, and is reached by an exponentially fast flow of the bare coupling toward zero, is asymptotic freedom doing double duty: in Chapter 27 it explained why short-distance QCD is calculable in perturbation theory; here it guarantees that a non-perturbative lattice definition possesses a continuum limit. The same negative beta function that liberates quarks at high energy is what lets us *define* the theory by

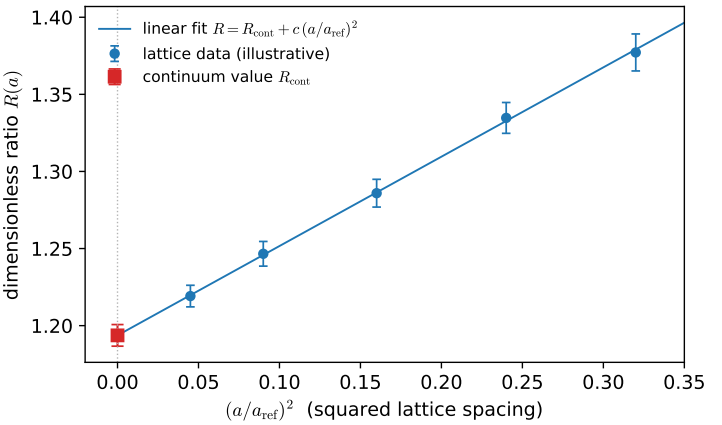

Figure 43.10: Continuum extrapolation of a dimensionless ratio R computed at several lattice spacings along a line of constant physics. For an $O(a^2)$-improved discretization the cutoff dependence is linear in $(a/a_{\rm ref})^2$ per Eq. (43.211); the intercept on the axis ($a \to 0$, red square) is the continuum value. Data points are illustrative.

taking $a \to 0$.

43.7.4 What the lattice has delivered (mid-2020s)

We can now state, honestly and with dates, what the machine of Eqs. (43.193), (43.198) and (43.208) has produced. The following are established results of lattice QCD as of the mid-2020s, computed from the QCD Lagrangian with no input beyond the quark masses and the overall scale.

The light-hadron spectrum from first principles. The masses of the lightest mesons and baryons—$\pi, K, \rho, K^*, N, \Lambda, \Sigma, \Xi, \Omega, \ldots$—have been computed with full dynamical u, d, s (and increasingly c) quarks, extrapolated to the continuum and to physical quark masses and infinite volume, in agreement with experiment at the percent level. This is the carried payoff of Yang–Mills theory: the proton mass, $\approx 938\,\text{MeV}$, emerges almost entirely from the gluonic field energy and dimensional transmutation—the bare light-quark masses contribute only a few percent—so the nucleon mass is a prediction of the dynamics, set by $\Lambda_{\rm QCD}$ (Theorem 27.14) and not by any mass written into the Lagrangian. The same ensembles deliver the string tension σ of the confining potential, whose strong-coupling estimate $\sqrt{\sigma} \sim 440\,\text{MeV}$ in Eq. (27.193) is confirmed and made precise, converting the analytic strong-coupling area law into a measured physical scale.

Quark masses and the strong coupling. Because the quark masses are not observable in isolation (quarks are confined), their values are *defined* by matching

lattice hadron masses to experiment and are quoted as renormalized parameters in a continuum scheme, e.g. the $\overline{\text{MS}}$ masses m_u, m_d, m_s, m_c, m_b at $\mu = 2\,\text{GeV}$ or at their own scale. Lattice QCD provides the most precise determinations of several of these, and competitive determinations of $\alpha_s(M_Z)$ via short-distance lattice quantities matched to perturbation theory—feeding the world average that Eq. (27.155) runs.

The finite-temperature transition and the QCD phase structure. Repeating the construction at temporal extent $L_t = 1/T$ (so the temporal circumference sets the temperature T, in natural units with $k_B = 1$) probes QCD thermodynamics. Lattice computations establish that the transition from confined hadronic matter to the deconfined quark–gluon plasma at zero baryon density is a smooth *crossover*, not a true phase transition, at a pseudocritical temperature $T_c \approx 155\,\text{MeV}$, and they map the equation of state $p(T)$, $\epsilon(T)$ used to interpret heavy-ion collisions. The deconfinement transition is diagnosed by the Polyakov loop (the temporal Wilson line, a gauge-invariant order parameter for the centre symmetry) and the chiral transition by the chiral condensate.

The hadronic vacuum polarization for the muon $g-2$. This is the live retouch of QED. The leading hadronic contribution a_μ^{HVP} to the muon anomaly of Eq. (20.120) is the non-perturbative quark-loop dressing of the photon vacuum polarization (Fig. 20.6a), intrinsically beyond perturbation theory at the muon scale. Lattice QCD computes it directly, as a weighted Euclidean integral of the electromagnetic-current correlator—an instance of Eq. (43.198) for the vector current. As recounted in Section 20.4.4, the first sub-percent lattice computation (BMW 2021) came out larger than the long-standing data-driven dispersive value, shifting the Standard-Model prediction toward the measured a_μ and turning a 4σ experiment-versus-theory "anomaly" into a theory-versus-theory tension; the 2023 CMD-3 $e^+e^- \to \pi^+\pi^-$ remeasurement and the 2025 white-paper update have since moved the consensus toward the lattice. That a lattice determination of a single non-perturbative number can adjudicate the most precise confrontation between theory and experiment in particle physics is the clearest demonstration that the lattice computes physics, not artefacts.

Physical Insight

The throughline of this survey is that lattice QCD has graduated from confirming known masses to *providing* numbers that no other method can: hadronic matrix elements for flavour physics (decay constants, form factors, bag parameters feeding the CKM tests of Chapter 32), the HVP for $g-2$, the equation of state of the quark–gluon plasma. Where perturbation theory and the lattice overlap they agree; where perturbation theory fails—the confining, chiral-symmetry-breaking infrared—the lattice stands alone and is checked against experiment.

43.7.5 What it has not delivered: the sign problem

The Monte Carlo method of Section 43.7.1 rests on one load-bearing assumption: that the weight $\det D[U]\, e^{-S_g[U]}$ is real and non-negative, so that Eq. (43.192) is a probability and Eq. (43.193) is an honest average. Two physically central regimes violate this assumption irreparably, and they bound what the lattice can presently do.

Finite baryon density. Introducing a baryon chemical potential μ_B to study dense matter—the interior of neutron stars, the conjectured colour-superconducting and critical-point structure of the QCD phase diagram—enters the Dirac operator as $D(\mu_B)$ with the temporal links weighted by $e^{\pm a\mu_B}$. The γ_5-Hermiticity that made $\det D$ real becomes, at $\mu_B \neq 0$,

$$\big[\det D(\mu_B)\big]^* = \det D(-\mu_B^*), \tag{43.212}$$

so for real μ_B the determinant is genuinely *complex*: $\det D(\mu_B) \neq [\det D(\mu_B)]^*$. The weight is no longer a probability, importance sampling has nothing to sample from, and one is forced into the reweighting of Eq. (43.191). There the failure becomes quantitative. The average phase that must be divided out scales as

$$\left\langle e^{i\theta} \right\rangle_{|\det D|} = \frac{Z}{Z_{|\det D|}} = e^{-V\,\Delta f/T}, \tag{43.213}$$

the ratio of the true partition function to the phase-quenched one, which is the exponential of (minus) a free-energy difference times the spacetime volume V. Because $\Delta f > 0$ generically, the signal-to-noise ratio of Eq. (43.191) falls *exponentially* in the volume: extracting a result to fixed accuracy requires a number of configurations growing like $e^{+V\Delta f/T}$, which is prohibitive for any interesting volume. This is the *sign problem*. It is not a defect of a particular algorithm; the generic complex-weight sampling problem is NP-hard, so a general efficient cure would collapse a complexity class widely believed not to collapse. Partial workarounds—Taylor expansion in μ_B/T about zero density, analytic continuation from imaginary chemical potential (where the weight is real), reweighting at small μ_B, and the more speculative complex-Langevin and Lefschetz-thimble methods—extend the reach a little way from $\mu_B = 0$, enough to constrain the curvature of the crossover line and bound where a critical point could lie, but the cold dense interior of the phase diagram remains beyond first-principles reach as of the mid-2020s.

Real-time dynamics. The same obstruction, in a different guise, blocks real-time and transport quantities. Everything above lives in Euclidean (imaginary) time, where e^{-S_E} is real and positive. Physical real-time evolution, e^{iS}, is a pure oscillatory phase—the worst possible sign problem. Quantities defined by real-time correlators (transport coefficients such as the shear viscosity of the quark–gluon plasma, jet-quenching parameters, the spectral functions that encode

particle widths and thermalization, and any genuinely out-of-equilibrium process) are accessible on the lattice only indirectly, by the ill-posed analytic continuation of Euclidean correlators back to real frequencies—inverting Eq. (43.198) for the full spectral density rather than just its lowest pole, a numerically unstable problem. Improving these reconstructions is an active frontier, but real-time QCD dynamics is not solved.

These two frontiers—finite baryon density and real-time dynamics—are the principal standing limitations of the lattice programme. They are honest boundaries of the method, not of the definition: the theory is perfectly well defined by Eq. (43.187) at any μ_B and in real time; it is the *stochastic evaluation* that fails when the weight ceases to be positive. Whether a fundamentally different sampling strategy—or quantum simulation, which evolves the real-time dynamics natively—will dissolve the sign problem is one of the genuine open questions of computational field theory.

Having turned the positive gauge-invariant measure into reproducible numbers, watched the hadron spectrum and the muon anomaly emerge from first principles, and marked the precise places where the method runs out, we have assembled the full evidence base for the chapter's concluding claim. The next section steps back from technique to thesis: that this constructive, regulator-complete, manifestly gauge-invariant, non-perturbative procedure is not merely a way to compute QCD but a *definition* of quantum field theory—and it weighs, with the honesty these results demand, exactly which theories are thereby proven to exist and which remain, for now, numerical.

43.8 Synthesis: the lattice as a definition of quantum field theory

We have, by this point, assembled every piece of the machine. The scalar discretization fixed the framework and showed that the continuum limit *is* the approach to a renormalization-group fixed point; gauge invariance forced the field onto links and handed us the first analytic proof of confinement in the strong-coupling phase; the Nielsen–Ninomiya theorem forced genuinely new constructions for fermions; and importance sampling turned the resulting finite-dimensional measure into hadron masses with quantified errors. The individual results are in hand. What remains is to step back and ask what they amount to *together*. The claim of this chapter — promised in its opening and now to be defended — is not the modest one that the lattice is a useful numerical scheme. It is the strong one: the lattice is, as of the mid-2020s, the only known fully non-perturbative, first-principles, manifestly gauge-invariant *definition* of an interacting quantum field theory. It is a constructive answer to the question that has shadowed the entire book, "what is a QFT, exactly, beyond a recipe for an asymptotic series?" This section states that thesis precisely, shows how the

earlier sections combine to support it, and then — because honesty is part of the contract — separates cleanly what the lattice has *proved* from what it has only *computed*, and lays out the frontiers where even the definition is not yet under control.

43.8.1 The lattice as a complete definition

Begin with what a definition of a QFT must supply. Perturbation theory does not supply it: the Feynman expansion is at best an asymptotic series (the Borel analysis of Chapter 5, Section 5.7), so the sum of all orders does not define a function, and the defining phenomenon of QCD — confinement — is invisible to every finite order. A genuine definition must produce, from a finite set of inputs, a complete and self-consistent set of correlation functions, with no appeal to a series and no hidden regulator left undefined. The lattice does exactly this, in three logically separate steps that the earlier sections established one at a time.

Definition 43.39 (Lattice-regularized field theory)**.** Fix a lattice spacing $a > 0$ and a finite hypercubic lattice $\Lambda_a = a\,(\mathbb{Z}/L\mathbb{Z})^d$ of $N_{\mathrm{s}} = L^d$ sites. A *lattice field theory* is the data of

1. finitely many real integration variables — a field value $\phi_x \in \mathbb{R}^k$ at each site $x \in \Lambda_a$ for matter, or a group element $U_\ell \in G$ on each oriented link ℓ for gauge fields;
2. a real action $S[\phi, U]$ that is bounded below and grows fast enough at large field that e^{-S} is integrable against the product of Lebesgue measures $\prod_x \mathrm{d}^k\phi_x$ and Haar measures $\prod_\ell \mathrm{d}U_\ell$;

together with the resulting probability measure and its expectation values

$$\mathrm{d}\mu_a \;=\; \frac{1}{Z_a}\, e^{-S[\phi,U]} \prod_x \mathrm{d}^k\phi_x \prod_\ell \mathrm{d}U_\ell, \qquad \langle \mathcal{O}_1 \cdots \mathcal{O}_n \rangle \;=\; \int \mathcal{O}_1 \cdots \mathcal{O}_n \,\mathrm{d}\mu_a, \tag{43.214}$$

with $Z_a = \int e^{-S} \prod \mathrm{d}\phi \prod \mathrm{d}U$ finite and nonzero.

This is the first and most important point, and it is the one that distinguishes the lattice from every other regulator in the book. The object in Eq. (43.214) is an *ordinary integral* over a finite-dimensional space. It is completely well defined: there are no ultraviolet divergences to subtract, because the spacing a is a hard momentum cutoff π/a built into the kinematics; there is no need for dimensional continuation, Pauli–Villars fields, or any analytic-continuation crutch; and — the decisive virtue for gauge theory — there is no gauge fixing. The Haar measure $\prod_\ell \mathrm{d}U_\ell$ is finite on the compact group G, so the integral over the entire gauge orbit converges without dividing by an infinite orbit volume. There is no Faddeev–Popov determinant, no ghost, and therefore no Gribov ambiguity of the

kind that obstructs a globally valid gauge choice in the continuum (Chapter 26, Section 26.1.4). The price — the loss of manifest Lorentz invariance, broken to the hypercubic point group — is paid up front and is recovered only in the continuum limit, and we accept it because gauge invariance, not Lorentz invariance, is the symmetry whose violation is fatal to a regulator. This is what "regulator-complete" means: Eq. (43.214) needs nothing outside itself to be a number.

Physical Insight

The Euclidean weight e^{-S_E} of Chapter 10 (Section 10.6) is, after Wick rotation, real and positive, so $\mathrm{d}\mu_a$ is a genuine probability measure and a QFT is literally a problem in classical statistical mechanics: a Boltzmann distribution on field configurations at "temperature" set by the couplings. Every continuum question becomes a question about a statistical-mechanical system — correlation lengths, phase transitions, critical exponents. This is not an analogy. It is an identity, and it is the reason the renormalization group of Chapter 23, invented for critical phenomena, governs the continuum limit of field theory verbatim.

The second step is that this statistical system carries, hidden inside its positivity, the entire Lorentzian content of a quantum theory. Section 1 established *reflection positivity*: for observables $\mathcal{O}$ supported on one side of a reflection plane and $\Theta\mathcal{O}$ its reflected conjugate, $\langle(\Theta\mathcal{O})\,\mathcal{O}\rangle \geq 0$. This single inequality is the lattice incarnation of Osterwalder–Schrader positivity, and it does two things at once. On the lattice it guarantees a self-adjoint, positive transfer matrix $\hat{T} = e^{-a\hat{H}}$ with $\hat{H} \geq 0$, whose spectral decomposition is exactly what Section 43.7 used to read hadron masses off the exponential decay of Euclidean correlators. In the continuum limit it is the hypothesis of the reconstruction theorem.

Theorem 43.40 (Osterwalder–Schrader reconstruction; imported, stated)**.** *A family of Euclidean correlation (Schwinger) functions that is Euclidean-invariant, reflection positive, symmetric, suitably regular, and clustering determines a unique Wightman quantum field theory: a separable Hilbert space with a positive-energy unitary representation of the Poincaré group, a unique vacuum, and Wightman fields whose vacuum correlators are the analytic continuations of the Schwinger functions. This is the content of Theorem 10.32; we use it here as an imported result.*

We do not reprove Theorem 43.40 — it is owned by the constructive-QFT framing of Chapter 10 — but we lean on it for the precise sense of "definition." It tells us that to construct a relativistic quantum field theory it suffices to construct a reflection-positive set of Euclidean correlators with the right symmetry and decay. The lattice produces exactly such correlators at every finite a; what is left is to remove the cutoff.

That removal is the third step, and it is where Chapter 23 enters. Sending $a \to 0$ at fixed physics is not a naive limit of Eq. (43.214) — taken at fixed bare couplings it gives back free or trivial physics. It is the approach to a *second-order critical point* of the statistical system, a point where the correlation length in lattice units, ξ/a, diverges. There the lattice forgets its microscopic details (universality, Section 23.6); a physical mass $m = (\xi/a)^{-1} \cdot a^{-1} = 1/\xi_{\text{phys}}$ can be held fixed while $a \to 0$ only if $\xi/a \to \infty$, which is precisely criticality. Tuning the relevant couplings (the mass, Eq. (23.177)) onto the critical surface (Theorem 23.24) and flowing into a renormalization-group fixed point is the continuum limit (Section 23.6.6, Eq. (23.178)). Assembling the three steps gives the thesis in one sentence.

Physical Insight

The lattice definition of a quantum field theory. A non-perturbative quantum field theory *is* the continuum limit of a reflection-positive lattice measure Eq. (43.214) taken along a renormalization-group trajectory into a fixed point: a finite, manifestly gauge-invariant statistical-mechanical measure (Theorem 43.39); reflection positivity (Section 1) so that Theorem 43.40 applies; and a critical point (Chapter 23) at which the cutoff can be removed. When such a limit exists and its Schwinger functions satisfy the Osterwalder–Schrader axioms, the theory *exists* in the constructive sense of Chapter 10; perturbation theory is then a controlled asymptotic expansion *about* this definition, not a substitute for it.

Two clauses in that statement carry the entire honesty of the chapter, and the rest of this section is devoted to them: "when such a limit exists" (which theories provably exist?), and the gap between "the strong-coupling measure confines" (proved) and "the continuum theory confines" (computed).

43.8.2 The existence dichotomy: triviality versus asymptotic freedom

Whether the continuum limit of a given lattice theory exists as a nontrivial interacting theory is governed by a single asymptotic fact: the behavior of the running coupling as the cutoff is removed, i.e. the sign of the leading coefficient of the beta function. The reason is now transparent from the fixed-point picture. Removing the cutoff means $a \to 0$, i.e. flowing toward the ultraviolet. A nontrivial continuum limit exists precisely when the ultraviolet end of the flow lands on a fixed point at which the theory is interacting — or, for the perturbatively accessible case, when the *Gaussian* fixed point at the origin of coupling space is approached from a direction along which the coupling is marginally relevant in the right sense. This is the criterion, and it sorts the threads of the book cleanly.

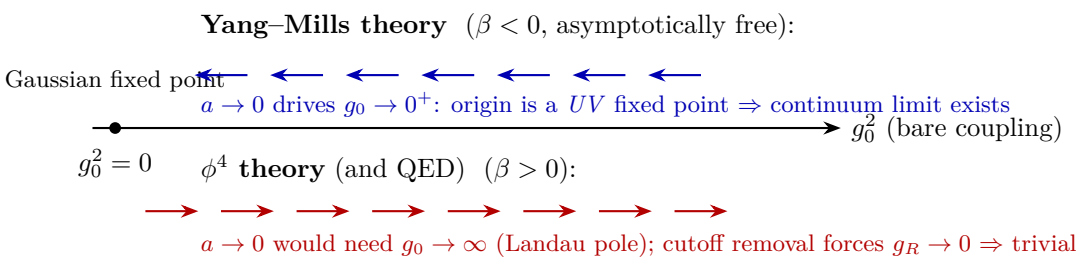

Figure 43.11: The continuum limit as a flow in bare coupling. For an asymptotically free theory (Chapter 27) the origin is an ultraviolet fixed point: as $a \to 0$ the bare coupling is driven *into* it, $g_0 \to 0^+$, and the limit exists with a dynamically generated scale. For a theory with $\beta > 0$ the flow runs the bare coupling *up* toward a Landau pole; no ultraviolet fixed point is reachable, and removing the cutoff at fixed physics squeezes the renormalized coupling to zero — triviality.

The asymptotically free side is the one that works, and the worked computation below makes "the continuum limit is a UV fixed point" fully quantitative. We continue Yang–Mills theory from the asymptotic freedom of Chapter 27 (Theorem 27.11).

Worked Example 43.41 (Asymptotic scaling: the continuum limit of Yang–Mills as a UV fixed point)**.** On the lattice the only scale is a, so the bare coupling g_0 runs with a. Holding physical quantities fixed, the Callan–Symanzik content of Chapter 27 reads, with $\mu = 1/a$ identified as the cutoff scale and $\beta(g) = \mathrm{d}g/\mathrm{d}\ln\mu$,

$$a\,\frac{\mathrm{d}g_0}{\mathrm{d}a} \;=\; b_0\,g_0^3 + b_1\,g_0^5 + \cdots, \qquad b_0 = \frac{1}{(4\pi)^2}\Big(\tfrac{11}{3}C_A - \tfrac{4}{3}T_F n_f\Big), \tag{43.215}$$

where the sign is fixed by $\beta = -b_0 g^3 - \cdots < 0$ (Eq. (27.101)) and $\mathrm{d}\ln\mu = -\mathrm{d}\ln a$. For $SU(3)$ with n_f flavors, $b_0 = (11 - \frac{2}{3}n_f)/(4\pi)^2 > 0$ as long as $n_f < \frac{33}{2}$, so the right-hand side is positive: *as a decreases, g_0 decreases.* The continuum limit $a \to 0$ is the limit $g_0 \to 0^+$, and the origin is a UV fixed point.

Integrate Eq. (43.215) to find exactly how fast. Separate variables,

$$\frac{\mathrm{d}a}{a} = \frac{\mathrm{d}g_0}{b_0 g_0^3 + b_1 g_0^5} = \frac{\mathrm{d}g_0}{b_0 g_0^3}\,\frac{1}{1 + (b_1/b_0)g_0^2} = \frac{1}{b_0}\Big[g_0^{-3} - \frac{b_1}{b_0}\,g_0^{-1} + O(g_0)\Big]\mathrm{d}g_0, \tag{43.216}$$

where in the last step we expanded $(1 + (b_1/b_0)g_0^2)^{-1} = 1 - (b_1/b_0)g_0^2 + \cdots$ for small g_0. Integrate term by term:

$$\ln a = \frac{1}{b_0}\Big[-\frac{1}{2g_0^2} - \frac{b_1}{b_0}\ln g_0\Big] + \text{const} = -\frac{1}{2b_0 g_0^2} - \frac{b_1}{b_0^2}\ln g_0 + \text{const}. \tag{43.217}$$

Exponentiating, and absorbing the constant into an integration scale Λ_L with the dimensions of inverse length (the lattice analogue of Λ_{QCD}, Eq. (27.152)),

gives the *two-loop asymptotic-scaling formula*

$$\boxed{a\,\Lambda_L \;=\; (b_0 g_0^2)^{-b_1/(2b_0^2)}\,\exp\!\Big(-\frac{1}{2b_0\,g_0^2}\Big)\,[1+O(g_0^2)].} \tag{43.218}$$

The content is the boxed exponential. As $g_0 \to 0^+$ the right-hand side vanishes faster than any power, so $a \to 0$: the continuum is reached by sending the bare coupling to the Gaussian fixed point, exactly as Fig. 43.11 draws it. The combination Λ_L is renormalization-group invariant by construction — it is what is held fixed while a and g_0 both run — so every physical mass is $m_i = c_i\,\Lambda_L$ with c_i a pure dimensionless number. This is *dimensional transmutation* (Section 27.6.2) realized on the lattice: a classically scale-free, parameter-free pure gauge theory generates a physical scale out of the cutoff, and all of its spectrum is fixed in units of that one scale. That the simulated masses, extracted as in Section 43.7, indeed approach finite multiples of a single Λ_L as $g_0 \to 0$ — "asymptotic scaling" — is the numerical signature that the continuum limit is being taken correctly.

Now the other side of the dichotomy, which closes the non-perturbative arc of ϕ^4 theory. The scalar coupling runs the opposite way: from Chapter 24 the one-loop beta function is $\beta_\lambda = 3\lambda^2/16\pi^2 > 0$. Integrating $\mathrm{d}\lambda/\mathrm{d}\ln\mu = 3\lambda^2/16\pi^2$ from the cutoff scale $\Lambda = 1/a$, where the bare coupling is $\lambda_0 = \lambda(\Lambda)$, down to a fixed physical scale μ_R,

$$\frac{1}{\lambda_R} = \frac{1}{\lambda_0} + \frac{3}{16\pi^2}\,\ln\frac{\Lambda}{\mu_R}. \tag{43.219}$$

The sign is decisive. As the cutoff is removed, $\Lambda \to \infty$ (that is, $a \to 0$) at fixed finite bare coupling λ_0, the logarithm drives $1/\lambda_R \to +\infty$, hence $\lambda_R \to 0$: the interacting theory collapses to the free one. The only escape would be to let $\lambda_0 \to \infty$ as $a \to 0$ to chase a nonzero λ_R, but that is the Landau pole, the statement that no ultraviolet fixed point lies in reach. The perturbative picture is exactly Fig. 43.11: with $\beta > 0$ the origin is an infrared fixed point, and there is no nontrivial UV fixed point to anchor a continuum limit. The Wilson–Fisher fixed point of Theorem 23.36 that rescues ϕ^4 exists only in $d = 4-\epsilon < 4$; precisely at $d = 4$ it merges with the Gaussian fixed point and the interacting theory has nowhere to go.

The lattice converts this perturbative heuristic into a theorem, because ϕ^4 in the lattice formulation is the Ising universality class and is amenable to the rigorous methods of statistical mechanics. The verdict, with its date, is the following.

Theorem 43.42 (Triviality of ϕ^4 in four dimensions; stated, dated)**.** *For lattice ϕ^4 theory (equivalently the Ising and ϕ^4 models in the same universality class) in $d \geq 4$ dimensions, every continuum limit obtained by tuning to the critical point is Gaussian: the limiting Schwinger functions are those of a generalized*

free field, with all connected n-point functions for $n \geq 4$ vanishing. For $d > 4$ this was established by Aizenman and by Fröhlich (1981–82); the marginal case $d = 4$ — the physical one — was closed by Aizenman and Duminil-Copin in 2021. Consequently $\lambda\phi^4$ in four dimensions does not *exist as an interacting continuum quantum field theory: as a fundamental theory it is trivial, and as written it can only be an effective theory below a finite cutoff.*

This is the honest non-perturbative fate of the book's workhorse scalar, and it is not a defect of the lattice but a discovery made through it: the lattice definition is sharp enough to prove that a famous Lagrangian fails to define a theory. The same fate applies to QED, whose $\beta_e > 0$ (Chapter 24) places it on the trivial side of Fig. 43.11; the Landau pole of QED is the statement that it, too, is an effective theory, consistent only up to a finite (astronomically high) cutoff. The contrast with Yang–Mills theory could not be cleaner: asymptotic freedom is not a convenience, it is the property that lets a four-dimensional gauge theory be a complete, cutoff-independent definition.

For Yang–Mills the optimistic verdict is, however, still a *conjecture supported by overwhelming evidence*, not a theorem. The construction of four-dimensional non-abelian gauge theory as a genuine continuum quantum field theory satisfying the Osterwalder–Schrader (Wightman) axioms, together with the proof that its spectrum has a strictly positive mass gap $\Delta > 0$, is the Yang–Mills existence and mass-gap problem — one of the Clay Mathematics Institute Millennium Problems, open as of the mid-2020s. The asymptotic-scaling computation of Theorem 43.41 shows the construction has the right shape, and lattice simulations exhibit the gap numerically with controlled errors, but no proof exists that the limit Eq. (43.218) converges to an OS-positive theory or that the gap survives. This is the precise sense in which Yang–Mills theory hands its non-perturbative existence question forward as an open frontier.

43.8.3 What is proved and what is computed

The most important discipline in reporting lattice results is to keep the line between theorem and measurement sharp. Three statements about confinement and the spectrum illustrate exactly where it falls.

First, *strong-coupling confinement is analytic.* The Wilson-action section proved, by the convergent strong-coupling (large bare g_0, small $\beta = 2N/g_0^2$) character expansion, that the Wilson loop obeys an area law $\langle W(C)\rangle \sim e^{-\sigma\,\mathrm{Area}(C)}$ with a nonzero string tension $\sigma = -a^{-2}\ln(\beta/2N\cdots) + \cdots$, and that the static quark–antiquark potential rises linearly. This is a bona fide theorem about the lattice measure at large coupling: the series converges, every coefficient is computed, and the area law is the order parameter for confinement (Chapter 27, Theorem 27.18). It was the first analytic demonstration of confinement in any formulation, and it remains the clearest one.

Second, *that confinement survives to the continuum is, as of the mid-2020s, established numerically, not proved.* The strong-coupling expansion converges only for β below a finite radius; the continuum limit lives at $\beta \to \infty$ (i.e. $g_0 \to 0$, the opposite end). A pure $SU(N)$ gauge theory has no bulk phase transition separating the two regimes — numerically the string tension in physical units $\sigma\, a^2$ tracks the asymptotic-scaling prediction Eq. (43.218) smoothly down to small a — so the area law is seen to persist into the continuum. But "seen to persist" is a statement about Monte Carlo data with statistical and systematic uncertainties, not an analytic continuation of the strong-coupling proof. Bridging the two ends rigorously is exactly the unsolved part of the mass-gap problem.

Caution

The strong-coupling area-law proof does *not* by itself prove continuum confinement. It establishes confinement in a regime that, for the abelian compact $U(1)$ lattice theory, is separated from the weak-coupling Coulomb phase by a genuine phase transition — there compact $U(1)$ confines at strong coupling and deconfines (becomes ordinary photons) at weak coupling, so strong-coupling confinement says nothing about the continuum. That non-abelian $SU(N)$ has no such intervening transition, and therefore confines all the way to $a \to 0$, is an empirical, numerical fact, not a corollary of the strong-coupling expansion.

Third, *the spectrum is numerical with controlled errors.* Hadron masses, decay constants, the glueball spectrum, and matrix elements are obtained by the Monte Carlo and transfer-matrix techniques of Section 43.7: extracted from Euclidean correlator decay, extrapolated to the continuum using the asymptotic-freedom-governed scaling of Theorem 43.41, and to physical quark masses and infinite volume. Each step carries a quantified uncertainty — statistical from the finite sample, systematic from the extrapolations — and modern lattice QCD reports few-percent or better total errors on many quantities, with the light hadron spectrum reproduced from first principles. These are genuine first-principles predictions of QCD, but they are computations with error bars, not closed-form theorems. The honest summary is that the lattice has *delivered* QCD as a quantitative theory of the strong interaction while *not yet delivering* a proof that the theory it is computing exists.

43.8.4 Open frontiers

Three problems mark the boundary of what the lattice definition currently reaches, and they are the right note on which to close the non-perturbative part of the book, because they are where the very framework of Theorem 43.39 is under strain.

Chiral gauge theories on the lattice. The Standard Model is chiral: left- and

right-handed fermions transform differently under $\mathrm{SU}(3)_c \times \mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$. The Nielsen–Ninomiya theorem, established earlier in this chapter, forbids a local, undoubled, chirally symmetric lattice fermion, and the Ginsparg–Wilson relation evades it for *vector-like* theories (where left and right pair up) by realizing an exact lattice chiral symmetry through overlap or domain-wall constructions. Defining a genuinely *chiral* gauge theory non-perturbatively on the lattice — with anomaly cancellation, the correct chiral fermion content, and gauge invariance all simultaneously — remains only partially solved. There exist constructions (notably for anomaly-free theories) and a substantial body of work, but no turnkey, simulable definition of the electroweak sector as a lattice theory exists as of the mid-2020s. The non-perturbative definition of the Standard Model itself is therefore still incomplete.

The sign problem. The entire edifice of Theorem 43.39 rests on e^{-S} being a positive weight, so that Eq. (43.214) is a probability measure and importance sampling applies. This positivity fails in physically central situations: at nonzero baryon chemical potential the fermion determinant becomes complex, and a real-time (Minkowski) weight e^{iS} is a pure phase. When the weight is not positive the configurations cannot be sampled by their probability, and naive reweighting suffers a variance that grows exponentially in the volume — the sign problem. It is known to be NP-hard in general, so a universal solution is not expected; partial remedies (complex Langevin, Lefschetz thimbles, dual variables for special cases, tensor-network and quantum-computing approaches) are active but not general. The phase diagram of dense QCD — the interior of neutron stars, the deconfinement transition at finite density — lies behind this wall.

Real-time dynamics. The lattice is intrinsically Euclidean: it computes imaginary-time correlators, from which Lorentzian, real-time quantities (spectral functions, transport coefficients, scattering at finite energy, thermalization) must be obtained by analytic continuation — an ill-posed inverse problem from noisy data. This limits direct access to dynamical quantities even where the Euclidean measure is perfectly positive. Quantum simulation of lattice gauge theories, which would evolve e^{iHt} directly, is the most promising route past both the sign problem and the real-time barrier, and is an early-stage frontier.

These are not failures of the thesis but its honest boundary. Where the Euclidean weight is positive and the theory is asymptotically free, the lattice is a complete, first-principles, gauge-invariant definition of quantum field theory, and it has made QCD a quantitative science. Where positivity fails or chirality intervenes, the definition itself is still being built.

This closes Part XII and, with it, the recurring question of the book — what is a quantum field theory, non-perturbatively? — with a constructive answer and a candid account of its reach. The Euclidean, measure-theoretic viewpoint developed here connects directly to the constructive and axiomatic program framed in Chapter 10, and it sets up the complementary non-perturbative handle

of Part XIV: the conformal bootstrap (Chapter 49), which dispenses with a Lagrangian altogether and constrains the same correlation functions by symmetry and consistency, picking up the ϕ^4 theory endpoint — the Wilson–Fisher fixed point of Theorem 23.36, surviving in $d < 4$ exactly where four-dimensional triviality forbids it — as the three-dimensional Ising CFT.

Further reading

The constructive viewpoint and the Osterwalder–Schrader axioms that give the lattice its claim to "definition" are developed in Glimm and Jaffe [225] and the original papers of Osterwalder and Schrader [372]; reflection positivity on the lattice is treated carefully in Montvay and Münster [351] and Seiler [437]. Wilson's lattice formulation, link variables, and the strong-coupling confinement argument are Wilson and Kogut [516], with the staggered construction in Kogut and Susskind [300]; thorough modern textbook treatments are Gattringer and Lang [211], Rothe [420], and the classic monograph by Creutz [139]. The fermion-doubling no-go theorem is Nielsen and Ninomiya [365] and Nielsen and Ninomiya [366], and the exact lattice chiral symmetry of the Ginsparg–Wilson relation, with its overlap and domain-wall realizations, is surveyed in Lüscher [327]. The non-perturbative triviality of four-dimensional ϕ^4 is proved in Aizenman and Duminil-Copin [11], building on the high-dimensional results of Aizenman [10] and Fröhlich [202]; the Yang–Mills existence and mass-gap problem is stated precisely in Jaffe and Witten [281]. For the open frontiers, the sign problem and its computational complexity are analyzed in Troyer and Wiese [474], and quantum-simulation approaches to lattice gauge theory are reviewed in Bañuls et al. [43].

Part XIII

Supersymmetry

Chapter 44

Supersymmetry: Algebra and Representations

Every continuous symmetry we have met so far has been built from two non-overlapping pieces: the spacetime symmetries of the Poincaré group, fixed once and for all in Chapter 3, and the internal symmetries that act on field indices and commute with spacetime, the gauge groups of Chapter 25. The Coleman–Mandula theorem makes this separation a law rather than a habit: under mild assumptions any symmetry of a nontrivial relativistic S-matrix must be a direct product of the Poincaré group with an internal group whose generators are Lorentz scalars. There is, however, a single hypothesis in that theorem that can be loosened without contradiction — the assumption that every conserved charge is bosonic. This chapter is the story of what happens when we allow *fermionic* generators, charges that carry a spinor index and exchange bosons with fermions, and find that relativistic quantum field theory admits exactly one further symmetry beyond Coleman–Mandula: supersymmetry.

The development is deliberately self-contained and algebra-first. We open (Section 44.1) by stating and motivating Coleman–Mandula, carrying the forward-scattering argument far enough to see precisely where it uses bosonic statistics, and then defining the $\mathbb{Z}_2$-graded Lie superalgebra that the loophole demands, with its graded Jacobi identity checked in all four parity sectors. The Haag–Łopuszański–Sohnius theorem (Section 44.2) then elevates the natural guess — supercharges in the $(\tfrac{1}{2},0)\oplus(0,\tfrac{1}{2})$ representation of the Lorentz group of Chapter 3 — to a uniqueness statement, and we derive the complete $\mathcal{N}=1$ super-Poincaré algebra one (anti)commutator at a time in the two-component spinor language inherited from Chapter 11, fixing the central relation $\{Q_\alpha,\bar{Q}_{\dot\beta}\}=2\sigma^\mu_{\alpha\dot\beta}P_\mu$ by Lorentz covariance and positivity alone. With the algebra closed and every super-Jacobi identity verified, we squeeze the physics out of it directly (Section 44.3): the energy is non-negative, the vacuum energy is the exact order parameter for spontaneous SUSY breaking, every supermultiplet is mass-degenerate, and it

contains equal numbers of bosonic and fermionic states — all proved from the brackets, and all made concrete in Witten's supersymmetric quantum mechanics.

The middle of the chapter turns from the algebra to its representations. Wigner's construction of one-particle states from Chapter 3 is the template: in Section 44.4 the supercharges become fermionic creation and annihilation operators acting on a Clifford vacuum, and the massless and massive supermultiplets, the $2^{\mathcal{N}}$ state count, the spin-2 bound on $\mathcal{N}$, central charges, and BPS shortening all follow. We then ask the obvious next question — which interacting field theory realizes the simplest multiplet — and answer it in Section 44.5 with the Wess–Zumino model, discovering that the naive transformations close only on shell, that an auxiliary field F restores off-shell closure and balances the off-shell degrees of freedom, and that supersymmetry forces the interactions to derive from a single holomorphic superpotential.

That the component-field treatment needs a transformation rule per field, an auxiliary field introduced by hand, and Fierz gymnastics to verify closure is a sign that we are describing a geometric object in non-geometric language. The final two sections build the geometry. Section 44.6 enlarges spacetime to $\mathcal{N} = 1$ superspace, realized as a coset of the super-Poincaré group, on which the supercharges and the covariant derivatives $D_\alpha, \bar{D}_{\dot\alpha}$ act as differential operators in anticommuting coordinates — here we lean on the Grassmann calculus and Berezin integration of Chapter 12. Section 44.7 imposes the chiral constraint $\bar{D}_{\dot\alpha}\Phi = 0$, collapses the general superfield into the irreducible chiral multiplet (ϕ, ψ, F), and reassembles the entire Wess–Zumino model — Kähler kinetic term plus holomorphic superpotential — in a few manifestly supersymmetric lines, with the auxiliary field and the superpotential now emerging automatically from the measure. The chiral superfield and the F-term/D-term grammar established here are the working vocabulary for the supersymmetric gauge theories of Chapter 45 and the exact results of Chapter 46.

44.1 From Coleman–Mandula to Graded Symmetry

The standing question with which this chapter opened was whether the Poincaré algebra admits any *nontrivial* extension. The word "nontrivial" is doing all the work. There is always a cheap way to enlarge a symmetry: take the direct product of the Poincaré group with some internal group G, so that the new generators commute with everything spacetime-related and merely relabel particles within a fixed mass and spin. This is the structure realized by every flavour, colour, and electroweak symmetry built in Parts II through VIII — the internal charges are Lorentz scalars, blind to where and how a particle moves. Such a direct product is no fusion at all; the two factors live in separate rooms. The genuine question is whether the rooms can be opened into one another: can there be a conserved charge that is *not* a Lorentz scalar, one that mixes a particle's internal identity

with its spacetime quantum numbers, so that boosting a state and applying the charge fail to commute? If such a charge existed it would weld the external and internal symmetries into a single simple structure, and the representation theory of that structure — the pattern of allowed particles — would be far more rigid than anything a direct product can impose.

The answer, within the framework of relativistic quantum mechanics with a sensible S-matrix, is a sharp and famous *no*, provided one insists that all conserved charges be *bosonic* — that they form an ordinary Lie algebra under commutators. This is the content of the Coleman–Mandula theorem, which we state precisely and prove at the load-bearing two-particle level below. The theorem is not a vague folk warning; it is a kinematic obstruction with a completely concrete mechanism, and seeing the mechanism is what reveals the single loophole through which a nontrivial extension can after all slip. That loophole is the subject of the entire chapter: the conserved charges need not all be bosonic. If one admits *fermionic* charges — generators that are odd elements of a $\mathbb{Z}_2$-graded algebra, closing not under commutators but under anticommutators — then the hypotheses of Coleman–Mandula simply do not apply to them, and the obstruction evaporates. The graded extension of the Poincaré algebra that results is supersymmetry. This section establishes the frame: it states the no-go theorem with its hypotheses, carries the forward-scattering argument that proves it, defines the graded Lie superalgebra and its generalized Jacobi identity, and shows exactly where the fermionic generators escape the net. Throughout we keep the chapter conventions: the metric is mostly-minus, $\eta_{\mu\nu} = \mathrm{diag}(+,-,-,-)$, and $\hbar = c = 1$.

44.1.1 Symmetries of the S-matrix

To state Coleman–Mandula precisely we must first say what we mean by a symmetry, and the right arena is not the Lagrangian but the S-matrix. A *symmetry of the S-matrix* is a Hermitian operator Q on the Hilbert space of asymptotic states that commutes with the scattering operator, $[Q, \mathbf{S}] = 0$, and that maps single-particle states to single-particle states. The Poincaré generators P^μ and $M^{\mu\nu}$ (Section 3.5, with the algebra recorded in Eqs. (3.147) to (3.149)) are the prototypes: they commute with $\mathbf{S}$ because scattering is Poincaré invariant, and they act on one-particle states without changing the particle number. An ordinary internal symmetry charge — electric charge, isospin, colour — is another example, distinguished by the fact that it is a Lorentz scalar: $[M^{\mu\nu}, Q] = 0$, so it carries no spacetime index and assigns to each particle a number that is the same in every frame.

Two structural facts about such generators are used in the proof, and both are honest consequences of the defining properties rather than extra assumptions. The first is that a symmetry generator acts *additively* on multi-particle states. An asymptotic n-particle state is, by construction, the tensor product of n single-particle states (the particles are infinitely separated and noninteracting in the

far past or far future), and a conserved charge generated by a local current is an extensive quantity: its value on the whole is the sum of its values on the parts. Symbolically, if Q acts on a one-particle state of momentum p and internal label r by some matrix $q(p)_r{}^s$ in the (finite) space of states at that momentum, then on a two-particle state

$$Q\,|p_1, r_1;\, p_2, r_2\rangle \;=\; \big(q(p_1)_{r_1}{}^{s_1}\,\delta^{s_2}_{r_2} + \delta^{s_1}_{r_1}\,q(p_2)_{r_2}{}^{s_2}\big)\,|p_1, s_1;\, p_2, s_2\rangle\,, \tag{44.1}$$

the sum of a one-body operator acting on each particle in turn. The second fact is that because Q commutes with the translation generators, $[Q, P^\mu] = 0$, it cannot change the momentum of the state it acts on: it maps the space of one-particle states at fixed momentum p into itself. By the finite-degeneracy hypothesis stated below, that space is finite dimensional, so $q(p)$ is a finite Hermitian matrix for each p, depending smoothly on p.

44.1.2 The Coleman–Mandula theorem

We can now state the theorem. The hypotheses are physical and we list them with care, because the entire force of the result — and the location of the loophole — lives in exactly which assumptions are made.

Theorem 44.1 (Coleman–Mandula)**.** *Let $\mathcal{G}$ be the Lie algebra of all symmetries of the S-matrix of a relativistic quantum field theory in four spacetime dimensions, in the sense of Section 44.1.1, and suppose that*

(H1) (Poincaré invariance.) *$\mathcal{G}$ contains the Poincaré algebra (Theorem 3.30), and the S-matrix is Poincaré invariant.*

(H2) (Particle finiteness.) *For any finite mass M there are only finitely many one-particle species with mass below M, and each corresponds to a finite-dimensional (discrete-spin) representation of the little group; the one-particle states are thus a discrete spectrum with finite degeneracy at each mass.*

(H3) (Nontrivial analytic scattering.) *The S-matrix is nontrivial — some two-particle elastic amplitude differs from the identity at almost all energies — and the two-body elastic amplitude is an analytic function of the centre-of-momentum scattering angle in a neighbourhood of the forward direction, except at isolated kinematic singularities.*

(H4) (Lie structure.) *The generators of $\mathcal{G}$ are bosonic: they close under* commutators *into a finite-dimensional Lie algebra (Theorem 2.39).*

Then $\mathcal{G}$ is, necessarily, the direct sum of the Poincaré algebra and a finite-dimensional internal Lie algebra of Lorentz-scalar *charges:*

$$\mathcal{G} \;=\; \mathfrak{iso}(1,3) \,\oplus\, \mathfrak{g}_{\mathrm{int}}, \qquad [M^{\mu\nu}, Q_A] = 0 \;\; \textit{for every internal generator } Q_A. \tag{44.2}$$

In particular every conserved charge beyond energy, momentum, and angular momentum must commute with the Lorentz generators; no conserved charge carries a nontrivial Lorentz index.

The conclusion Eq. (44.2) is exactly the statement that spacetime and internal symmetry can be combined only trivially, as a direct product. The full proof, due to Coleman and Mandula, is a careful argument involving the analytic structure of the S-matrix in all its variables; it is standard, and we cite it for completeness [131, 502]. What we carry on the page is the load-bearing kinematic core: the demonstration that a single extra conserved charge carrying two Lorentz indices already over-constrains two-body scattering so severely that the only Lorentz-covariant, analytic, nontrivial possibility is no scattering at all. This is the heart of the theorem, and it is the part whose mechanism we need in order to see the loophole.

44.1.3 The forward-scattering argument

Suppose, contrary to the conclusion, that $\mathcal{G}$ contains a conserved charge $B^{\mu\nu}$ that is a symmetric, traceless Lorentz tensor of rank two and is *not* a function of P^μ and $M^{\mu\nu}$ alone — a genuinely new charge carrying spacetime indices. (Rank two is the cleanest case; we comment on higher and lower rank at the end.) Being a symmetry generator, $B^{\mu\nu}$ acts on one-particle states by a matrix $b^{\mu\nu}(p)$ in the internal/spin labels, and being conserved it is additive on multi-particle states as in Eq. (44.1).

The eigenvalue is fixed by Lorentz covariance. Diagonalize $B^{\mu\nu}$ on the one-particle states (it is Hermitian, hence diagonalizable). On an eigenstate of momentum p its eigenvalue is a symmetric, traceless two-index tensor that depends only on the data available to a single particle. For a particle in an irreducible little-group multiplet the only Lorentz vector at hand is its own momentum p^μ, and the only symmetric traceless rank-two tensors one can build from a single vector p^μ and the metric are multiples of

$$b^{\mu\nu}(p) \;=\; \alpha\Big(p^\mu p^\nu - \tfrac{1}{4}\,\eta^{\mu\nu}\,p^2\Big), \tag{44.3}$$

where $p^2 = m^2$ on shell and α is a real constant that may depend on the particle species but not on its momentum (a smooth Lorentz-scalar function of p^2, hence constant on a mass shell). The trace subtraction enforces $\eta_{\mu\nu}b^{\mu\nu} = 0$. Any antisymmetric part would be a separate charge of the type of $M^{\mu\nu}$ and is excluded by assumption; the symmetric traceless part is the new content. The crucial feature is that Eq. (44.3) is *quadratic* in the momentum, in contrast to the energy–momentum charge P^μ, whose eigenvalue is linear.

Conservation in two-body elastic scattering. Consider an elastic collision of two particles of the same species and mass m,

$$p_1 + p_2 \;\longrightarrow\; p_1' + p_2', \tag{44.4}$$

which the nontrivial S-matrix (H3) supports at generic angle. Three conservation laws constrain the final momenta. First, energy–momentum conservation, the additivity of P^μ,

$$p_1^\mu + p_2^\mu \;=\; p_1'^\mu + p_2'^\mu. \tag{44.5}$$

Second, the on-shell conditions $p_i^2 = p_i'^2 = m^2$. Third — and this is the new constraint — conservation of the tensor charge $B^{\mu\nu}$, whose eigenvalue on the two-particle in- and out-states is the sum of the one-particle eigenvalues Eq. (44.3) with a common α (same species):

$$p_1^\mu p_1^\nu + p_2^\mu p_2^\nu \;=\; p_1'^\mu p_1'^\nu + p_2'^\mu p_2'^\nu, \tag{44.6}$$

where the trace terms $-\frac{1}{4}\eta^{\mu\nu}m^2$ have cancelled between the two sides (two particles on each side, equal mass) and the overall α has divided out. We now read off what Eq. (44.5) and Eq. (44.6) together permit.

The kinematics collapse to the forward direction. Work in the centre-of-momentum frame of the collision, the cleanest place to expose the constraint. There the spatial momenta are equal and opposite,

$$p_1 = (E, \mathbf{p}), \quad p_2 = (E, -\mathbf{p}), \qquad p_1' = (E, \mathbf{p}'), \quad p_2' = (E, -\mathbf{p}'), \tag{44.7}$$

with $|\mathbf{p}'| = |\mathbf{p}|$ fixed by energy conservation and the common mass, so that Eq. (44.5) is automatically satisfied for any direction of $\mathbf{p}'$. The scattering angle θ is the angle between $\mathbf{p}$ and $\mathbf{p}'$, and a nontrivial S-matrix must produce scattering at generic θ. Now impose the tensor law Eq. (44.6). Its purely spatial components $\mu\nu = ij$ read

$$p_1^i p_1^j + p_2^i p_2^j = \mathbf{p}^i\mathbf{p}^j + (-\mathbf{p}^i)(-\mathbf{p}^j) = 2\,\mathbf{p}^i\mathbf{p}^j, \tag{44.8}$$

and likewise the right-hand side equals $2\,\mathbf{p}'^i\mathbf{p}'^j$. Conservation therefore demands

$$\mathbf{p}^i\,\mathbf{p}^j \;=\; \mathbf{p}'^i\,\mathbf{p}'^j \qquad \text{for all } i,j \in \{1,2,3\}. \tag{44.9}$$

This is a far stronger statement than $|\mathbf{p}'| = |\mathbf{p}|$: it equates two rank-one spatial matrices. Contracting $i = j$ and summing recovers $|\mathbf{p}'|^2 = |\mathbf{p}|^2$, which we already had; but the off-diagonal and direction-resolving content of Eq. (44.9) forces the *directions* to agree up to sign. Concretely, the matrix $\mathbf{p}^i\mathbf{p}^j$ has a single nonzero eigenvalue $|\mathbf{p}|^2$ with eigenvector $\hat{\mathbf{p}}$; equality of the two matrices forces their eigenvectors to coincide, $\hat{\mathbf{p}}' = \pm\hat{\mathbf{p}}$. Hence

$$\mathbf{p}' \;=\; \pm\,\mathbf{p}, \qquad \text{i.e.} \qquad \theta \in \{0, \pi\}. \tag{44.10}$$

The only kinematically allowed outcomes are $\theta = 0$ (forward, no scattering) and $\theta = \pi$ (backward, which for identical particles is the same final state relabelled). Scattering through any intermediate angle is forbidden by the existence of the tensor charge. The scattering amplitude $\mathcal{M}(s, \theta)$ is thereby forced to vanish for all θ outside the discrete set $\{0, \pi\}$.

Analyticity finishes the contradiction. A function of the scattering angle that vanishes everywhere except on a discrete set of isolated points is, if it is analytic in θ in a neighbourhood of the forward direction, identically zero — the zeros of a nonzero analytic function are isolated, so a function whose *nonzeros* are isolated must be the zero function. By hypothesis (H3) the elastic amplitude is analytic in $\cos\theta$ near the forward direction. Therefore $\mathcal{M}(s, \theta) \equiv 0$ as a function of θ: the interaction produces no scattering at all. But a vanishing elastic amplitude is in direct conflict with a nontrivial S-matrix; through the optical theorem (Theorem 14.37), the imaginary part of the forward amplitude controls the total cross section,

$$\operatorname{Im} \mathcal{M}(s, \theta = 0) \;\propto\; \sqrt{s}\, \sigma_{\mathrm{tot}}(s), \tag{44.11}$$

the precise relation being Eq. (14.200), so a theory that scatters anything into anything has a nonzero forward amplitude and hence, by analyticity, a nonzero amplitude at generic angle. The two requirements — the tensor charge demanding $\mathcal{M} \equiv 0$, the nontrivial unitary S-matrix demanding $\mathcal{M} \not\equiv 0$ — are incompatible. The only escape is that no such tensor charge $B^{\mu\nu}$ exists. This is the assertion of the theorem for rank-two charges.

Worked Example 44.2 (A conserved Lorentz vector charge is also excluded)**.** The same mechanism disposes of a hypothetical conserved charge C^μ carrying a single Lorentz index but distinct from P^μ. By the argument of Eq. (44.3) its one-particle eigenvalue must be the only vector available, $c^\mu(p) = \beta\, p^\mu$ with β a species constant. For two species a, b with constants $\beta_a \neq \beta_b$, additivity and conservation in the elastic process $p_1 + p_2 \to p_1' + p_2'$ (species preserved) give

$$\beta_a\, p_1^\mu + \beta_b\, p_2^\mu \;=\; \beta_a\, p_1'^\mu + \beta_b\, p_2'^\mu. \tag{44.12}$$

Subtracting β_a times momentum conservation Eq. (44.5) leaves $(\beta_b - \beta_a)(p_2^\mu - p_2'^\mu) = 0$, so $p_2' = p_2$ and hence $p_1' = p_1$: again only forward scattering, again contradicting analyticity and a nontrivial S-matrix. The sole way out is $\beta_a = \beta_b$ for all species, but then $C^\mu = \beta\, P^\mu$ is just a multiple of the momentum and carries no new information. Thus a conserved Lorentz *vector* must coincide with energy–momentum, and a conserved Lorentz *scalar* (rank zero, eigenvalue an arbitrary constant q_a per species) is unconstrained — precisely the internal charges. Charges of rank two or higher are excluded outright. This is the complete rank-by-rank census that yields Eq. (44.2): only scalars survive.

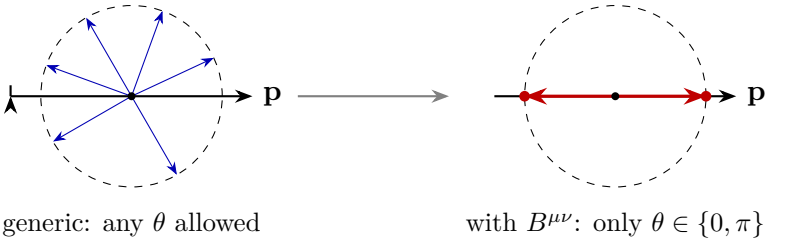

Figure 44.1: The Coleman–Mandula collapse in the centre-of-momentum frame. A nontrivial S-matrix scatters the incoming relative momentum $\mathbf{p}$ into a continuum of directions on the energy shell (left). A conserved symmetric tensor charge $B^{\mu\nu}$ imposes $\mathbf{p}^i\mathbf{p}^j = \mathbf{p}'^i\mathbf{p}'^j$ (Eq. (44.9)), pinching the allowed final directions to the two antipodal points $\theta = 0, \pi$ (right). Analyticity in $\cos\theta$ then forces the amplitude to vanish identically.

Physical Insight

The engine of Coleman–Mandula is dimensional, in the most literal sense. Momentum conservation supplies four linear equations, just enough to fix the two outgoing momenta up to a one-parameter family — the scattering angle, the freedom on which all interesting dynamics lives. *Any* additional conserved charge that depends on momentum nonlinearly (rank two: quadratically) or that distinguishes species linearly (rank one with unequal coefficients) adds equations that consume that last freedom and freeze the angle. Bosonic conserved tensors are too rigid: they leave no room for an analytic, nontrivial scattering function. The escape, when it comes, will not be to weaken conservation but to change the *type* of the extra generator, so that it never enters the conservation balance as an additive c-number tensor in the first place.

Figure 44.1 summarizes the kinematic collapse: the locus of allowed final momenta, a full sphere of directions for a generic interaction, is pinched by the tensor charge down to two antipodal points.

44.1.4 Where the theorem does not reach: graded generators

The proof just given leaned, at three separate points, on the generators being *bosonic*. The eigenvalue Eq. (44.3) was a c-number tensor because $B^{\mu\nu}$ was an ordinary observable with real eigenvalues; the additive conservation law Eq. (44.6) treated the charge as a number summed over particles; and the closure into a Lie algebra (H4) was what allowed Coleman and Mandula to enumerate all such charges in the first place. Strip away hypothesis (H4) — allow generators that are *not* elements of a Lie algebra under commutators — and the census no longer

applies.

The precise way to do this is to admit generators that anticommute. A fermionic charge Q_α carrying a spinor index changes the spin of the state it acts on by half a unit, turning a boson into a fermion and vice versa. It is odd under the $\mathbb{Z}_2$ grading inherited from the Grassmann structure of fermionic fields (Theorem 12.7): two such charges combine naturally not through a commutator but through an *anticommutator*, and the result $\{Q_\alpha, Q_\beta\}$ is bosonic. The content of the supersymmetry escape, which we will make exact in the next section, is that this anticommutator closes onto the translation generator P^μ — a rank-*one* object, the momentum itself — and not onto any new rank-two tensor charge. The forward-scattering obstruction never engages: there is no symmetric c-number tensor $B^{\mu\nu}$ to conserve, because the only bosonic charge produced by the fermionic generators is the one rank-one charge, P^μ, that the kinematics already accommodates. The fermionic charges sit outside the hypotheses of Theorem 44.1 from the start, and the no-go theorem says nothing about them.

To make "closes under anticommutators" a precise algebraic statement we need the notion of a graded Lie algebra. We develop it now, in the generality the chapter requires, and verify its internal consistency.

44.1.5 Graded Lie superalgebras

The Grassmann calculus of Chapter 12 taught us to track a single bookkeeping datum — the parity $|X| \in \{0, 1\}$ of an object, even or odd — and to attach a sign $(-1)^{|X||Y|}$ whenever two homogeneous objects are interchanged (Theorem 12.8). A Lie superalgebra is the structure obtained by demanding that a bracket respect exactly this sign rule.

Definition 44.3 ($\mathbb{Z}_2$-graded Lie superalgebra)**.** A *Lie superalgebra* is a $\mathbb{Z}_2$-graded vector space

$$\mathfrak{g} \;=\; \mathfrak{g}_{\bar{0}} \,\oplus\, \mathfrak{g}_{\bar{1}}, \tag{44.13}$$

the *even* (bosonic) part $\mathfrak{g}_{\bar{0}}$ and the *odd* (fermionic) part $\mathfrak{g}_{\bar{1}}$, equipped with a bilinear *graded bracket* $[\cdot,\cdot\}$ that respects the grading,

$$[\mathfrak{g}_a, \mathfrak{g}_b\} \subseteq \mathfrak{g}_{a+b} \qquad (a, b \in \mathbb{Z}_2, \text{ indices added mod 2}), \tag{44.14}$$

and that on homogeneous elements is a commutator unless both arguments are odd, in which case it is an anticommutator:

$$[X, Y\} \;=\; \begin{cases} [X,Y] = XY - YX, & |X|\,|Y| = 0 \quad \text{(at least one even)}, \\ \{X,Y\} = XY + YX, & |X| = |Y| = 1 \quad \text{(both odd)}. \end{cases} \tag{44.15}$$

The bracket obeys the *graded antisymmetry* (or grade-dependent symmetry) rule

$$[X, Y\} \;=\; -(-1)^{|X|\,|Y|}\,[Y, X\}, \tag{44.16}$$

and the *generalized (graded) Jacobi identity*: for all homogeneous X, Y, Z,

$$(-1)^{|X||Z|}\,[X,[Y,Z\}\} + (-1)^{|Y||X|}\,[Y,[Z,X\}\} + (-1)^{|Z||Y|}\,[Z,[X,Y\}\} \;=\; 0. \tag{44.17}$$

The grade-dependent rule Eq. (44.16) unifies the two familiar statements: for at least one even argument the sign $(-1)^{|X||Y|}$ equals $+1$ and Eq. (44.16) reads $[X,Y] = -\,[Y,X]$, ordinary antisymmetry; for two odd arguments the sign is -1 and it reads $\{X,Y\} = +\,\{Y,X\}$, the symmetry of the anticommutator. An ordinary Lie algebra (Theorem 2.39) is the special case $\mathfrak{g}_{\bar{1}} = 0$, all generators even, the graded bracket reducing to the commutator and Eq. (44.17) to the ordinary Jacobi identity.

It is worth pausing on the structural picture before checking the identities, because it already encodes the physics of supermultiplets. The even part $\mathfrak{g}_{\bar{0}}$ is an ordinary Lie algebra (the even–even bracket is a commutator landing in the even part), and the odd part $\mathfrak{g}_{\bar{1}}$ is a representation of it (the even–odd bracket $[\text{even}, \text{odd}]$ is again odd, so $\mathfrak{g}_{\bar{0}}$ acts on $\mathfrak{g}_{\bar{1}}$). The genuinely new ingredient is the odd–odd bracket, the symmetric pairing $\{\cdot,\cdot\} : \mathfrak{g}_{\bar{1}} \otimes_{\text{sym}} \mathfrak{g}_{\bar{1}} \to \mathfrak{g}_{\bar{0}}$, which feeds the fermionic generators back into the bosonic algebra. In the super-Poincaré case of the next section, $\mathfrak{g}_{\bar{0}}$ is the Poincaré algebra (plus R-symmetry), $\mathfrak{g}_{\bar{1}}$ is the spinorial supercharges, and the symmetric pairing is exactly the anticommutator that produces P^μ.

44.1.6 Consistency of the graded Jacobi identity

The generalized Jacobi identity Eq. (44.17) is not an extra axiom pulled from the air; like the ordinary Jacobi identity, it is automatically satisfied whenever the bracket is realized by (anti)commutators of associative operators, which is the only realization we ever use — the generators are concrete operators on a Hilbert space. To see this, and to confirm that the four parity sectors are mutually consistent, we write the identity out in each case. There are four inequivalent assignments of parities to the triple (X, Y, Z), up to the relabelling permitted by Eq. (44.16): all even; two even and one odd; one even and two odd; all odd. We treat them in turn.

Worked Example 44.4 (The graded Jacobi identity in its four parity sectors)**.** We verify that Eq. (44.17) reduces, in each parity sector, to a genuine identity satisfied by operators on a Hilbert space, where the bracket is the appropriate (anti)commutator.

(i) Even–even–even, $|X| = |Y| = |Z| = 0$. Every sign $(-1)^{|\cdot||\cdot|} = +1$ and every bracket is a commutator, so Eq. (44.17) is the ordinary Jacobi identity

$$[X,[Y,Z]] + [Y,[Z,X]] + [Z,[X,Y]] = 0, \tag{44.18}$$

which holds identically for associative operators: expanding all six double commutators, the twelve resulting triple products cancel in pairs. This is the content of Theorem 2.39 and needs no grading.

(ii) Even–even–odd, $|X| = |Y| = 0$, $|Z| = 1$. The parity products in the exponents are $|X||Z| = 0$, $|Y||X| = 0$, $|Z||Y| = 0$, so again every sign is $+1$. All three brackets are commutators ($[Y, Z]$ and $[Z, X]$ pair an even with an odd element; $[X, Y]$ is even–even), and the identity is once more the ordinary Jacobi relation Eq. (44.18) with Z odd. It expresses the statement that the odd space carries a representation of the even algebra: writing the even action as $\rho(X)Z := [X, Z]$, Eq. (44.18) rearranges to $\rho([X, Y]) = [\rho(X), \rho(Y)]$, the homomorphism property of the representation.

(iii) Even–odd–odd, $|X| = 0$, $|Y| = |Z| = 1$. Now the parities matter, and so do the bracket types. The exponents are $|X||Z| = 0$, $|Y||X| = 0$, $|Z||Y| = 1$, so the third term acquires a sign $(-1)^1 = -1$ while the first two keep $+1$. The inner bracket of the first term, $\{Y, Z\}$, pairs two odd elements and is an anticommutator landing in the even part; the inner brackets $[Z, X]$ and $[X, Y]$ each pair an odd with an even element and are commutators that land in the *odd* part. Consequently the outer brackets are not all commutators: in the first term the outer pair X (even) and $\{Y, Z\}$ (even) gives a commutator, but in the second and third terms the outer pairs $Y, [Z, X]$ and $Z, [X, Y]$ are both odd–odd and are therefore *anticommutators*. Reading Eq. (44.17) with these assignments,

$$[X, \{Y, Z\}] + \{Y, [Z, X]\} - \{Z, [X, Y]\} = 0. \tag{44.19}$$

We check it by direct expansion. With X even and Y, Z odd, writing out each (anti)commutator as operator products,

$$[X, \{Y, Z\}] = X(YZ + ZY) - (YZ + ZY)X = XYZ + XZY - YZX - ZYX, \tag{44.20}$$

$$\{Y, [Z, X]\} = Y(ZX - XZ) + (ZX - XZ)Y = YZX - YXZ + ZXY - XZY, \tag{44.21}$$

$$-\{Z, [X, Y]\} = -Z(XY - YX) - (XY - YX)Z = -ZXY + ZYX - XYZ + YXZ. \tag{44.22}$$

Collecting the six distinct orderings, each appears exactly once with a $+$ and once with a $-$:

$$\begin{aligned} XYZ &: \ +(\mathrm{t1}) - (\mathrm{t3}) = 0, & XZY &: \ +(\mathrm{t1}) - (\mathrm{t2}) = 0, \\ YZX &: \ -(\mathrm{t1}) + (\mathrm{t2}) = 0, & ZYX &: \ -(\mathrm{t1}) + (\mathrm{t3}) = 0, \\ YXZ &: \ -(\mathrm{t2}) + (\mathrm{t3}) = 0, & ZXY &: \ +(\mathrm{t2}) - (\mathrm{t3}) = 0, \end{aligned} \tag{44.23}$$

so the sum vanishes identically. The two anticommutators in the second and third terms are forced by the grading — replacing them by commutators would leave the XYZ ordering with coefficient $+2$ rather than 0, and the identity

would fail. Rearranged using $[Z,X] = -[X,Z]$, Eq. (44.19) reads $[X,\{Y,Z\}] = \{[X,Y],Z\} + \{Y,[X,Z]\}$, the statement that the even generator X acts as a derivation on the odd pairing. Physically this is the relation that will force $\{Q,Q\} \sim P$ to transform correctly as a four-vector under Lorentz rotations in the next section: taking X a Lorentz generator and $Y = Z = Q$ a supercharge, it says the spacetime transformation of the bosonic anticommutator is induced by the spinorial transformation of Q on each factor.

(iv) Odd–odd–odd, $|X| = |Y| = |Z| = 1$. Every exponent $|X||Z| = |Y||X| = |Z||Y| = 1$, so all three terms carry a sign -1, an overall factor that drops out of the equation. Each inner bracket pairs two odd elements and is an anticommutator (even result), while the outer bracket pairs the even result with the remaining odd element and is a commutator. The identity becomes

$$[X,\{Y,Z\}] + [Y,\{Z,X\}] + [Z,\{X,Y\}] = 0, \tag{44.24}$$

the so-called *graded Jacobi identity for three odd generators*. Expanding with all of X, Y, Z odd,

$$\begin{aligned} [X,\{Y,Z\}] &= XYZ + XZY - YZX - ZYX, \\ [Y,\{Z,X\}] &= YZX + YXZ - ZXY - XZY, \\ [Z,\{X,Y\}] &= ZXY + ZYX - XYZ - YXZ. \end{aligned} \tag{44.25}$$

Adding the three lines, every one of the six monomials cancels: XYZ ($+$ in line 1, $-$ in line 3); XZY ($+$ in line 1, $-$ in line 2); YZX ($-$ in line 1, $+$ in line 2); ZYX ($-$ in line 1, $+$ in line 3); YXZ ($+$ in line 2, $-$ in line 3); ZXY ($-$ in line 2, $+$ in line 3). The sum is identically zero. This is the nontrivial sector — it has no analogue in an ordinary Lie algebra — and its automatic satisfaction is what guarantees that the supercharges can be adjoined consistently.

The four cases of Theorem 44.4 exhaust the parity assignments and each holds identically when the bracket is realized by (anti)commutators of operators. We have therefore established that a Lie superalgebra built from honest operators on a Hilbert space automatically satisfies Eqs. (44.16) and (44.17): the graded structure is consistent, not merely postulated. The crucial qualitative lesson is that the odd generators enter the algebra only through their *anticommutators*, and an anticommutator is not a Lie bracket — it never appears in the hypotheses of Coleman–Mandula. The even part of any Lie superalgebra extending Poincaré is still constrained by Theorem 44.1 to be Poincaré plus a Lorentz-scalar internal algebra, but the odd part is entirely free of that constraint. Supersymmetry is the unique nontrivial fusion of spacetime and internal symmetry precisely because it is the unique structural way to add generators that the no-go theorem cannot see.

Caution

The freedom opened by grading is real but narrow. Admitting odd generators does not license arbitrary new charges: the odd part must still be a representation of the Poincaré algebra (case (ii) of Theorem 44.4), its anticommutators must close back into the even algebra in a Lorentz-covariant way (case (iii)), and the triple-odd identity (case (iv)) must hold. These requirements are stringent enough to fix the odd generators almost completely. The companion no-go theorem of Haag, Łopuszański, and Sohnius — the subject of the next section — shows that the *only* admissible fermionic charges are spinorial, transforming in the $(\frac{1}{2},0)$ and $(0,\frac{1}{2})$ representations of the Lorentz group, with anticommutators fixed up to normalization. The grading is a loophole, not a free-for-all.

This pins down what the next section must do. The forward-scattering census of Theorem 44.1 kills every bosonic charge of rank two or higher; the graded structure of Theorem 44.3 reopens the door for fermionic charges, but the consistency requirements of Theorem 44.4 demand that those charges transform as a definite Lorentz representation and close under anticommutation onto the bosonic algebra. The natural hypothesis — which the Haag–Łopuszański–Sohnius theorem will elevate to a uniqueness statement — is that the admissible fermionic charges transform in the $(\frac{1}{2},0)$ representation of the Lorentz group (and its conjugate $(0,\frac{1}{2})$), the smallest nontrivial spinor. With that hypothesis in hand we turn, in the next section, to deriving the complete $\mathcal{N}=1$ super-Poincaré algebra, fixing every (anti)commutator in two-component spinor notation.

44.2 The Haag–Łopuszański–Sohnius Theorem and the SUSY Algebra

The previous section closed the bosonic door and pointed at the one crack of light left open. Coleman–Mandula forbids any *bosonic* generator that mixes spacetime and internal symmetry nontrivially: under the hypotheses of the theorem, the symmetry algebra of an interacting relativistic quantum field theory with a mass gap is forced to be a direct sum of the Poincaré algebra and an internal Lie algebra of Lorentz scalars. The single loophole is that the no-go theorem assumed all conserved charges close under *commutators*—that the symmetry is an ordinary Lie algebra. If we admit conserved charges that close under *anticommutators*, and that transform as Lorentz spinors rather than tensors, the proof no longer applies, because spinorial charges cannot be diagonalised against the momentum eigenstates in the way Coleman–Mandula requires. We saw that Lorentz covariance restricts such fermionic charges to the lowest spin that does the job: a charge in the $(\frac{1}{2},0)$ representation (and its conjugate in $(0,\frac{1}{2})$). The

task of this section is to take that structural observation and turn it into an algebra. We state the theorem of Haag, Łopuszański and Sohnius, which says that the spinorial loophole is not merely allowed but *essentially unique*, and then we derive, bracket by bracket, the complete $\mathcal{N} = 1$ super-Poincaré algebra, fixing every coefficient by Lorentz covariance, closure, and positivity, and identifying the one outer automorphism the structure admits.

44.2.1 Graded Lie algebras and the precise statement

To even phrase the theorem we must enlarge the notion of a symmetry algebra. An ordinary symmetry algebra is a Lie algebra in the sense of Theorem 2.39: a vector space with an antisymmetric bracket obeying the Jacobi identity. Fermionic charges demand a $\mathbb{Z}_2$-graded generalisation.

Definition 44.5 (Graded (super) Lie algebra)**.** A *graded Lie algebra* (synonymously a super Lie algebra) is a vector space $\mathfrak{g} = \mathfrak{g}_{\bar{0}} \oplus \mathfrak{g}_{\bar{1}}$ with a $\mathbb{Z}_2$ grading—elements of $\mathfrak{g}_{\bar{0}}$ are called *even* (bosonic), those of $\mathfrak{g}_{\bar{1}}$ *odd* (fermionic), with degree $|X| \in \{0, 1\}$—equipped with a bilinear *graded bracket* $[\,\cdot\,,\,\cdot\,\}$ that respects the grading, $|[X, Y\}| = |X| + |Y| \bmod 2$, is graded-antisymmetric,

$$[X, Y\} = -(-1)^{|X||Y|}\,[Y, X\}, \tag{44.26}$$

and satisfies the *graded (super-)Jacobi identity*

$$(-1)^{|X||Z|}\,[X, [Y, Z\}\} + (-1)^{|Y||X|}\,[Y, [Z, X\}\} + (-1)^{|Z||Y|}\,[Z, [X, Y\}\} = 0. \tag{44.27}$$

Concretely the graded bracket is the ordinary commutator $[X, Y]$ unless both arguments are odd, in which case it is the anticommutator $\{X, Y\}$. The even part $\mathfrak{g}_{\bar{0}}$ is an ordinary Lie algebra; the odd part $\mathfrak{g}_{\bar{1}}$ is a representation of $\mathfrak{g}_{\bar{0}}$; and the anticommutator of two odd elements lands back in the even part.

The grading is forced on us physically by spin-statistics: a charge that turns a boson into a fermion must itself carry half-integer spin and obey Fermi statistics, so it is natural to compose two such charges with an anticommutator. The bracket $\{Q, Q\}$ of two fermionic charges is symmetric and produces a bosonic operator; that this bosonic operator is forced to be the energy–momentum is the heart of supersymmetry. With Theorem 44.5 in hand the no-go landscape is sharpened to a uniqueness statement.

Theorem 44.6 (Haag–Łopuszański–Sohnius)**.** *Let $\mathfrak{g}$ be the graded symmetry algebra of the S-matrix of a nontrivial, unitary, relativistic quantum field theory in four spacetime dimensions, subject to the regularity and mass-gap hypotheses of Coleman–Mandula, and suppose the odd generators act on asymptotic multiparticle states. Then:*

1. *the even part $\mathfrak{g}_{\bar{0}}$ is, as Coleman–Mandula already dictates, the direct sum of the Poincaré algebra $\mathfrak{iso}(1,3)$ and a compact internal Lie algebra of Lorentz scalars (together with possible central charges);*

2. *the odd generators sit in the spin-$\frac{1}{2}$ representation only—copies of $(\frac{1}{2},0)\oplus(0,\frac{1}{2})$ under the Lorentz group; no higher-spin odd generators are admissible;*

3. *writing the $\mathcal{N}$ left-handed odd generators as Q^I_α ($\alpha=1,2$; $I=1,\dots,\mathcal{N}$) with conjugates $\bar{Q}^I_{\dot\alpha}=(Q^I_\alpha)^\dagger$, their graded brackets are fixed up to normalisation to be*

$$\left\{Q^I_\alpha,\bar{Q}^J_{\dot\beta}\right\}=2\,\sigma^\mu_{\alpha\dot\beta}\,P_\mu\,\delta^{IJ}, \tag{44.28}$$

$$\left\{Q^I_\alpha,Q^J_\beta\right\}=\varepsilon_{\alpha\beta}\,Z^{IJ},\qquad Z^{IJ}=-Z^{JI}, \tag{44.29}$$

where the Z^{IJ} are central charges*, commuting with everything in $\mathfrak{g}$ and forming an antisymmetric matrix in the internal indices; and the odd generators commute with translations and rotate as spinors under Lorentz transformations.*

The theorem is stated here at the level required for a self-contained development of the algebra; its proof is a refinement of the Coleman–Mandula argument that carries the spinor index structure through the same analyticity and cluster-decomposition machinery, and we use the result as the starting point for what follows rather than reproving the S-matrix analysis. What we *do* prove in full is everything downstream: that, once Theorem 44.6 licenses spinorial charges at all, Lorentz covariance, closure and positivity fix the algebra completely. For the rest of this chapter we restrict to $\mathcal{N}=1$: a single Weyl supercharge Q_α and its conjugate $\bar{Q}_{\dot\alpha}$. With only one internal index the antisymmetric matrix Z^{IJ} in Eq. (44.29) has no components, so the central charge vanishes identically and $\{Q_\alpha,Q_\beta\}=0$; the extended case $\mathcal{N}>1$, where Z is the engine of BPS shortening, is opened only far enough in Chapter 46 to count states.

44.2.2 Two-component conventions

The whole of supersymmetry is cleanest in two-component (Weyl, or van der Waerden) spinor language, and we now fix that notation, importing the content from Section 3.4.3 and dressing it with the dotted/undotted index bookkeeping that the algebra demands. A left-handed Weyl spinor in $(\frac{1}{2},0)$ carries an undotted index ψ_α, $\alpha=1,2$; a right-handed spinor in $(0,\frac{1}{2})$ carries a dotted index $\bar\chi_{\dot\alpha}$. Complex conjugation exchanges the two representations (Eq. (3.107) and Section 11.7.6), $(\psi_\alpha)^\dagger=\bar\psi_{\dot\alpha}$, so the conjugate of an undotted object is a dotted one.

Indices are raised and lowered with the antisymmetric Levi-Civita symbols, which play the role of a metric on spinor space. We use the north-west–south-east

convention

$$\varepsilon^{12} = -\varepsilon^{21} = +1, \qquad \varepsilon_{12} = -\varepsilon_{21} = -1, \qquad \varepsilon^{\alpha\beta}\varepsilon_{\beta\gamma} = \delta^{\alpha}_{\gamma}, \tag{44.30}$$

and identically for the dotted symbols $\varepsilon^{\dot\alpha\dot\beta}$, $\varepsilon_{\dot\alpha\dot\beta}$. As a 2×2 matrix the upper-index symbol $\varepsilon^{\alpha\beta}$ equals $i\sigma^2$, the invariant form of Eq. (3.107); the lower-index symbol is its inverse with the sign fixed by $\varepsilon^{\alpha\beta}\varepsilon_{\beta\gamma} = \delta^{\alpha}_{\gamma}$. Raising and lowering then read

$$\psi^{\alpha} = \varepsilon^{\alpha\beta}\psi_{\beta}, \qquad \psi_{\alpha} = \varepsilon_{\alpha\beta}\psi^{\beta}, \qquad \bar\psi^{\dot\alpha} = \varepsilon^{\dot\alpha\dot\beta}\bar\psi_{\dot\beta}, \qquad \bar\psi_{\dot\alpha} = \varepsilon_{\dot\alpha\dot\beta}\bar\psi^{\dot\beta}. \tag{44.31}$$

We adopt the standard summation conventions $\psi\chi \equiv \psi^{\alpha}\chi_{\alpha}$ (descending undotted) and $\bar\psi\bar\chi \equiv \bar\psi_{\dot\alpha}\bar\chi^{\dot\alpha}$ (ascending dotted); for anticommuting (Grassmann) spinors, which is the case of interest, antisymmetry of ε together with anticommutativity makes these products *symmetric*, $\psi\chi = \chi\psi$ and $\bar\psi\bar\chi = \bar\chi\bar\psi$.

The Lorentz-vector content is carried by the sigma matrices imported from Eqs. (3.79) and (3.106),

$$\sigma^{\mu}_{\alpha\dot\beta} = (\mathbf{1}, \vec\sigma)_{\alpha\dot\beta}, \qquad \bar\sigma^{\mu\,\dot\alpha\beta} = (\mathbf{1}, -\vec\sigma)^{\dot\alpha\beta} = \varepsilon^{\dot\alpha\dot\gamma}\varepsilon^{\beta\delta}\sigma^{\mu}_{\delta\dot\gamma}, \tag{44.32}$$

the index heights being exactly those that make the contractions in Eq. (44.28) consistent: $\sigma^{\mu}_{\alpha\dot\beta}$ has one lower undotted and one lower dotted index, while $\bar\sigma^{\mu\,\dot\alpha\beta}$ has both raised. They satisfy the Clifford-type identities, proved blockwise in Section 3.4.3,

$$(\sigma^{\mu}\bar\sigma^{\nu} + \sigma^{\nu}\bar\sigma^{\mu})_{\alpha}{}^{\beta} = 2\eta^{\mu\nu}\delta^{\beta}_{\alpha}, \qquad (\bar\sigma^{\mu}\sigma^{\nu} + \bar\sigma^{\nu}\sigma^{\mu})^{\dot\alpha}{}_{\dot\beta} = 2\eta^{\mu\nu}\delta^{\dot\alpha}_{\dot\beta}. \tag{44.33}$$

The Lorentz generators in the two spinor representations are the (anti-self-dual and self-dual) combinations

$$(\sigma^{\mu\nu})_{\alpha}{}^{\beta} = \tfrac{i}{4}\big(\sigma^{\mu}\bar\sigma^{\nu} - \sigma^{\nu}\bar\sigma^{\mu}\big)_{\alpha}{}^{\beta}, \qquad (\bar\sigma^{\mu\nu})^{\dot\alpha}{}_{\dot\beta} = \tfrac{i}{4}\big(\bar\sigma^{\mu}\sigma^{\nu} - \bar\sigma^{\nu}\sigma^{\mu}\big)^{\dot\alpha}{}_{\dot\beta}, \tag{44.34}$$

which are precisely the left and right blocks $S_L^{\mu\nu}$, $S_R^{\mu\nu}$ of the Dirac generator computed in Section 3.4.3; they satisfy the Lorentz algebra Eq. (3.149) on each spinor index. That the two-spinor catalogue $(\tfrac12, 0)$, $(0, \tfrac12)$ is exactly the list of building blocks for a spin-$\tfrac12$ charge is the content of Theorems 3.17 and 3.19: the supercharge must be one of these, and the conjugation $(Q_\alpha)^\dagger = \bar Q_{\dot\alpha}$ ties them together.

Notation Watch

Beyond the supercharges $Q_\alpha, \bar Q_{\dot\alpha}$ and the Grassmann coordinates $\theta^\alpha, \bar\theta_{\dot\alpha}$ (which use existing notation), the superspace machinery of Section 44.2.7 onward requires three new shorthands, used from Chapter 44 on: the superspace covariant derivatives D_α and $\bar D_{\dot\alpha}$, the Grassmann measures

$\int \mathrm{d}^2\theta$, $\int \mathrm{d}^2\bar\theta$ and $\int \mathrm{d}^4\theta$ built by Berezin integration (Theorem 12.17), and the superpotential symbol W. These are geometric packaging only; no physical convention is introduced beyond the metric, sigma and gamma conventions of Appendices A and C.

44.2.3 The central anticommutator $\left\{Q_\alpha, \bar Q_{\dot\beta}\right\}$

The defining relation of supersymmetry is the anticommutator of Q with its conjugate. We derive it from three inputs: Lorentz covariance, the closure requirement of Theorem 44.5, and positivity of the Hilbert-space norm.

Index structure. The object $\left\{Q_\alpha, \bar Q_{\dot\beta}\right\}$ carries one undotted and one dotted lower index, so it transforms in $(\tfrac12,0)\otimes(0,\tfrac12) = (\tfrac12,\tfrac12)$, the Lorentz four-vector representation. By closure it must be a bosonic generator already present in $\mathfrak{g}_{\bar 0}$, and by the first clause of Theorem 44.6 the bosonic generators are the Poincaré generators $P_\mu, M_{\mu\nu}$ together with Lorentz-scalar internal charges. Of these, only one transforms as a four-vector: the translation generator P_μ. The internal charges are scalars, hence carry no Lorentz index and cannot appear; the Lorentz generator $M_{\mu\nu}$ is an antisymmetric two-tensor, the reducible $(\tfrac12,\tfrac12)\otimes(\tfrac12,\tfrac12) \supset (1,0)\oplus(0,1)$ content, not the irreducible $(\tfrac12,\tfrac12)$, so it cannot supply a single vector index either. The unique covariant possibility is therefore

$$\left\{Q_\alpha, \bar Q_{\dot\beta}\right\} = c\,\sigma^\mu_{\alpha\dot\beta}\,P_\mu, \tag{44.35}$$

with $\sigma^\mu_{\alpha\dot\beta}$ the invariant tensor of Eq. (44.32) that converts a vector index μ into the pair $(\alpha,\dot\beta)$, and c a single constant to be fixed. (No term $c'\,\sigma^\mu_{\alpha\dot\beta}\partial_\mu(\dots)$ or higher can appear: the right-hand side must be a fixed element of the finite-dimensional algebra, and P_μ exhausts the available vectors.)

Reality of the coefficient. Taking the Hermitian adjoint of Eq. (44.35) and using $(Q_\alpha)^\dagger = \bar Q_{\dot\alpha}$, $P_\mu^\dagger = P_\mu$, and the Hermiticity $(\sigma^\mu_{\alpha\dot\beta})^* = \sigma^\mu_{\beta\dot\alpha}$ of the sigma matrices, the anticommutator $\left\{Q_\alpha, \bar Q_{\dot\beta}\right\}^\dagger = \left\{\bar Q_{\dot\beta}, Q_\alpha\right\} = \left\{Q_\alpha, \bar Q_{\dot\beta}\right\}$ (relabelled) returns the same equation with $c \to c^*$. Hence c is real.

Positivity fixes the sign. Contract Eq. (44.35) with $\bar\sigma_\nu^{\dot\beta\alpha}$ and use the trace $\bar\sigma_\nu^{\dot\beta\alpha}\sigma^\mu_{\alpha\dot\beta} = \mathrm{tr}(\bar\sigma_\nu\sigma^\mu) = 2\delta^\mu_\nu$ from Eq. (44.33); this inverts Eq. (44.35) to $P_\nu = \frac{c}{2c}\dots$, but the cleanest route to the sign is to set $\mu=\nu=0$ and sum over $\alpha=\dot\beta$. With $\sigma^0 = \mathbf{1}$,

$$\sum_{\alpha=1,2}\left\{Q_\alpha, (Q_\alpha)^\dagger\right\} = \left\{Q_1, Q_1^\dagger\right\} + \left\{Q_2, Q_2^\dagger\right\} = c\,(\sigma^0_{1\dot1} + \sigma^0_{2\dot2})P_0 = 2c\,P_0 = 2c\,H, \tag{44.36}$$

where $H = P^0 = P_0$ is the Hamiltonian. The left-hand side is a sum of operators of the form $\{A, A^\dagger\} = AA^\dagger + A^\dagger A$, each of which is positive semidefinite, since for any state $|\psi\rangle$, $\langle\psi|AA^\dagger + A^\dagger A|\psi\rangle = \|A^\dagger|\psi\rangle\|^2 + \|A|\psi\rangle\|^2 \geq 0$. Therefore $2c\,H \geq 0$ as an operator. Because the energy spectrum of a relativistic theory is bounded below and contains states of positive energy (the vacuum and excitations above it), consistency requires $c > 0$. We *define* the normalisation of the supercharges by choosing

$$\boxed{\{Q_\alpha, \bar{Q}_{\dot\beta}\} = 2\,\sigma^\mu_{\alpha\dot\beta}\,P_\mu} \tag{44.37}$$

i.e. $c = 2$. The factor of 2 is a convention—it could be absorbed into a rescaling $Q \to Q/\sqrt{2}$—but it is the universal choice, and it makes Eq. (44.36) read $\sum_\alpha \{Q_\alpha, Q_\alpha^\dagger\} = 4H$, the relation from which the next section reads off energy positivity and the supersymmetry-breaking order parameter. The relation Eq. (44.37) is the algebraic core of the entire subject: the anticommutator of a supercharge with its conjugate is the energy–momentum. Spacetime translations are, in this precise sense, the "square" of a supersymmetry transformation.

44.2.4 The vanishing of $\{Q_\alpha, Q_\beta\}$ for $\mathcal{N} = 1$

Next consider the anticommutator of two left-handed supercharges. It carries two undotted indices, transforming in $(\tfrac{1}{2}, 0) \otimes (\tfrac{1}{2}, 0) = (1, 0) \oplus (0, 0)$. Decomposing on the symmetry of the index pair, the symmetric part sits in $(1, 0)$ and the antisymmetric part in the singlet $(0, 0)$. Because the anticommutator is symmetric under exchange of its arguments *together with* their indices, $\{Q_\alpha, Q_\beta\} = \{Q_\beta, Q_\alpha\}$, only certain covariant tensors can appear. The general Lorentz-covariant ansatz built from the available invariant tensors and bosonic generators is

$$\{Q_\alpha, Q_\beta\} = k\,(\sigma^{\mu\nu})_{\alpha\beta}\,M_{\mu\nu} + \varepsilon_{\alpha\beta}\,Z, \tag{44.38}$$

where $(\sigma^{\mu\nu})_{\alpha\beta} = (\sigma^{\mu\nu})_\alpha{}^\gamma \varepsilon_{\gamma\beta}$ is symmetric in $\alpha\beta$ (it carries the $(1, 0)$ part), and $\varepsilon_{\alpha\beta}$ is antisymmetric (the singlet). We dispose of each term.

The singlet coefficient Z would be a Lorentz scalar central charge. But $\varepsilon_{\alpha\beta}$ is antisymmetric while the anticommutator is symmetric, so the term $\varepsilon_{\alpha\beta}Z$ is consistent with Eq. (44.38) only if Z itself is antisymmetric in some additional index that compensates. For $\mathcal{N}$ supercharges this is exactly the antisymmetric internal matrix $Z^{IJ} = -Z^{JI}$ of Eq. (44.29): the combined object $\varepsilon_{\alpha\beta}Z^{IJ}$ is symmetric under the simultaneous exchange $(\alpha, I) \leftrightarrow (\beta, J)$, as required of $\{Q^I_\alpha, Q^J_\beta\}$. For $\mathcal{N} = 1$ there is no internal index, Z^{IJ} collapses to a single antisymmetric 1×1 matrix, which vanishes identically. Hence the central term is absent.

The tensor coefficient k would couple $\{Q, Q\}$ to the Lorentz generators $M_{\mu\nu}$. This term is killed by translation invariance, which we establish independently

in Section 44.2.5 below but may anticipate here: once $[Q_\alpha, P_\rho] = 0$, the left-hand side of Eq. (44.38) commutes with every P_ρ,

$$[\{Q_\alpha, Q_\beta\}, P_\rho] = \{[Q_\alpha, P_\rho], Q_\beta\} + \{Q_\alpha, [Q_\beta, P_\rho]\} = 0, \tag{44.39}$$

using the graded Leibniz rule (a special case of Eq. (44.27)). But the right-hand side does *not* commute with P_ρ if $k \neq 0$, because $[M_{\mu\nu}, P_\rho] = i(\eta_{\nu\rho}P_\mu - \eta_{\mu\rho}P_\nu) \neq 0$ by Eq. (3.148). The only way Eq. (44.38) can have a translation-invariant left-hand side and a translation-covariant right-hand side is $k = 0$. (A dimensional check confirms the verdict from another angle: Q has mass dimension $\frac{1}{2}$, so $\{Q, Q\}$ has dimension 1, matching P_μ; but $M_{\mu\nu}$ is dimensionless, so k would carry dimension 1, and the algebra of a theory with no built-in mass scale offers no such invariant constant.) Therefore, for $\mathcal{N} = 1$,

$$\boxed{\{Q_\alpha, Q_\beta\} = 0, \qquad \left\{\bar{Q}_{\dot\alpha}, \bar{Q}_{\dot\beta}\right\} = 0} \tag{44.40}$$

the second relation being the Hermitian conjugate of the first.

44.2.5 Translations commute with the supercharges

We owe the proof that $[Q_\alpha, P_\mu] = 0$, on which Section 44.2.4 leaned. This is the cleanest illustration of how the super-Jacobi identity, applied to a carefully chosen triple, forces a coefficient to vanish.

Proposition 44.7. *In the $\mathcal{N} = 1$ super-Poincaré algebra the supercharges commute with translations,*

$$[Q_\alpha, P_\mu] = 0, \qquad \left[\bar{Q}_{\dot\alpha}, P_\mu\right] = 0. \tag{44.41}$$

Proof. The commutator $[Q_\alpha, P_\mu]$ carries one undotted spinor index and one lower vector index, so it transforms in $(\frac{1}{2}, 0) \otimes (\frac{1}{2}, \frac{1}{2}) = (1, \frac{1}{2}) \oplus (0, \frac{1}{2})$. A fermionic generator of the algebra must, by Theorem 44.6, lie in $(\frac{1}{2}, 0) \oplus (0, \frac{1}{2})$; the $(1, \frac{1}{2})$ piece corresponds to no admissible generator and must be absent. The only fermionic object of the algebra that fits the surviving $(0, \frac{1}{2})$ slot, with the correct index structure to balance Eq. (44.41), is $\bar{Q}$ contracted with a sigma matrix. Hence the most general covariant ansatz is

$$[Q_\alpha, P_\mu] = a\, \sigma_{\mu\,\alpha\dot\beta}\, \bar{Q}^{\dot\beta}, \tag{44.42}$$

for a single constant a (the index $\dot\beta$ is raised with $\varepsilon^{\dot\beta\dot\gamma}$ as in Eq. (44.31)). Taking the Hermitian conjugate gives the partner relation $\left[\bar{Q}_{\dot\alpha}, P_\mu\right] = a^*\, \bar\sigma_\mu{}^{\dot\beta}{}_? \ldots$; written with consistent index heights it reads

$$\left[\bar{Q}^{\dot\alpha}, P_\mu\right] = a^*\, \bar\sigma_\mu^{\dot\alpha\beta}\, Q_\beta. \tag{44.43}$$

Now impose the super-Jacobi identity Eq. (44.27) on the triple (Q_α, P_μ, P_ν). Here Q_α is odd and P_μ, P_ν are even, so all gradings are even except those involving Q, and every bracket reduces to an ordinary commutator. The identity reads

$$[Q_\alpha, [P_\mu, P_\nu]] + [P_\mu, [P_\nu, Q_\alpha]] + [P_\nu, [Q_\alpha, P_\mu]] = 0. \tag{44.44}$$

The first term vanishes because $[P_\mu, P_\nu] = 0$ by Eq. (3.147). The remaining two combine into the statement that $[[Q_\alpha, P_\mu], P_\nu]$ is symmetric under $\mu \leftrightarrow \nu$. Substituting Eq. (44.42) and then Eq. (44.43),

$$[[Q_\alpha, P_\mu], P_\nu] = a\,\sigma_{\mu\,\alpha\dot\alpha}\left[\bar Q^{\dot\alpha}, P_\nu\right] = a\,\sigma_{\mu\,\alpha\dot\beta}\,a^*\,\bar\sigma_\nu^{\dot\beta\gamma}\,Q_\gamma = |a|^2\,(\sigma_\mu\bar\sigma_\nu)_\alpha{}^\gamma\,Q_\gamma. \tag{44.45}$$

Requiring this to be symmetric in $\mu\nu$—equivalently, that its antisymmetric part vanish—gives

$$0 = |a|^2\,(\sigma_\mu\bar\sigma_\nu - \sigma_\nu\bar\sigma_\mu)_\alpha{}^\gamma\,Q_\gamma = |a|^2\,(-4i)(\sigma_{\mu\nu})_\alpha{}^\gamma\,Q_\gamma, \tag{44.46}$$

using $\sigma_\mu\bar\sigma_\nu - \sigma_\nu\bar\sigma_\mu = -4i\,\sigma_{\mu\nu}$ from the definition Eq. (44.34). The tensor $(\sigma_{\mu\nu})_\alpha{}^\gamma$ is nonzero (it is the spin-$\frac{1}{2}$ Lorentz generator, which acts nontrivially on Q), and the supercharges Q_γ are linearly independent operators, so the only solution is $|a|^2 = 0$, i.e. $a = 0$. Substituting back into Eqs. (44.42) and (44.43) yields Eq. (44.41). □

The result has a sharp physical reading. The would-be term Eq. (44.42) is precisely the $(1, \frac{1}{2})$ "Lorentz-spin-$\frac{3}{2}$" object that the higher-spin clause of Theorem 44.6 forbids; the super-Jacobi identity is the algebraic mechanism that enforces the prohibition, by tying the coefficient of the forbidden structure to the nonvanishing antisymmetric tensor $\sigma_{\mu\nu}$. Physically, $[Q, P] = 0$ says the supercharge is translation-invariant: it is the same operator at every point of spacetime, exactly as a conserved charge should be, and supersymmetry transformations commute with going from one inertial frame's origin to another's.

44.2.6 The Lorentz action and the closed $\mathcal{N} = 1$ algebra

The last brackets to record are the action of the Lorentz generators on the supercharges. These are not derived from closure—they are dictated by the statement that Q_α *is* a $(\frac{1}{2}, 0)$ spinor and $\bar Q_{\dot\alpha}$ a $(0, \frac{1}{2})$ spinor, which is part of Theorem 44.6. An operator carrying a spinor index transforms under an infinitesimal Lorentz rotation with the spinor generator Eq. (44.34), with the sign fixed by the convention that operators carry the representation through a commutator,

$$[M^{\mu\nu}, Q_\alpha] = -(\sigma^{\mu\nu})_\alpha{}^\beta\,Q_\beta, \tag{44.47}$$

$$\left[M^{\mu\nu}, \bar{Q}_{\dot{\alpha}}\right] = -(\bar{\sigma}^{\mu\nu})_{\dot{\alpha}}{}^{\dot{\beta}}\, \bar{Q}_{\dot{\beta}}. \tag{44.48}$$

That these are the right matrices, and the right sign, is most easily checked against the Poincaré algebra itself: Eq. (44.47) must reproduce, on the spinor index α, the same $[M, \cdot] \sim \sigma^{\mu\nu}$ action that Section 3.4.3 found for the left Weyl block of a Dirac field, and the consistency of Eq. (44.47) with the central relation Eq. (44.37) is verified explicitly in Theorem 44.8.

Collecting Eqs. (44.37), (44.40), (44.41), (44.47) and (44.48) together with the imported Poincaré relations Eqs. (3.147) to (3.149) gives the complete $\mathcal{N} = 1$ super-Poincaré algebra:

$$\begin{aligned}
[P^{\mu}, P^{\nu}] &= 0, \\
[M^{\mu\nu}, P^{\rho}] &= i(\eta^{\nu\rho} P^{\mu} - \eta^{\mu\rho} P^{\nu}), \\
[M^{\mu\nu}, M^{\rho\sigma}] &= i(\eta^{\nu\rho} M^{\mu\sigma} - \eta^{\mu\rho} M^{\nu\sigma} - \eta^{\nu\sigma} M^{\mu\rho} + \eta^{\mu\sigma} M^{\nu\rho}), \\
[M^{\mu\nu}, Q_{\alpha}] &= -(\sigma^{\mu\nu})_{\alpha}{}^{\beta}\, Q_{\beta}, \qquad \left[M^{\mu\nu}, \bar{Q}_{\dot{\alpha}}\right] = -(\bar{\sigma}^{\mu\nu})_{\dot{\alpha}}{}^{\dot{\beta}}\, \bar{Q}_{\dot{\beta}}, \\
[Q_{\alpha}, P_{\mu}] &= 0, \qquad \left[\bar{Q}_{\dot{\alpha}}, P_{\mu}\right] = 0, \\
\{Q_{\alpha}, Q_{\beta}\} &= 0, \qquad \left\{\bar{Q}_{\dot{\alpha}}, \bar{Q}_{\dot{\beta}}\right\} = 0, \\
\left\{Q_{\alpha}, \bar{Q}_{\dot{\beta}}\right\} &= 2\, \sigma^{\mu}_{\alpha\dot{\beta}}\, P_{\mu}.
\end{aligned} \tag{44.49}$$

This is the object the rest of the chapter studies. Its structure is best seen as a $\mathbb{Z}_2$-graded extension of Poincaré, sketched in Fig. 44.2: the even sector is the Poincaré algebra acting on itself and on the odd sector, and the single nontrivial new relation, the anticommutator Eq. (44.37), sends a pair of odd generators back into the even translations.

44.2.7 The $\mathrm{U}(1)_R$ outer automorphism

The algebra Eq. (44.49) admits one continuous symmetry of its own structure that is not generated by any of its elements: an *outer automorphism*. Consider the phase rotation of the supercharges

$$Q_{\alpha} \;\longmapsto\; e^{-i\lambda}\, Q_{\alpha}, \qquad \bar{Q}_{\dot{\alpha}} \;\longmapsto\; e^{+i\lambda}\, \bar{Q}_{\dot{\alpha}}, \qquad \lambda \in \mathbb{R}, \tag{44.50}$$

with the Poincaré generators held fixed. This map preserves every bracket of Eq. (44.49): the relations $\{Q, Q\} = 0$ and $[M, Q] \sim Q$ are homogeneous of degree $+1$ in Q and so transform covariantly, while the central relation Eq. (44.37) carries one Q and one $\bar{Q}$, accruing a net phase $e^{-i\lambda} e^{+i\lambda} = 1$, and so is left invariant, consistent with P_{μ} being unrotated. Because the transformation acts nontrivially on the generators yet leaves the bracket structure unchanged, it is an automorphism of the super-Poincaré algebra; because no element of the algebra generates it through the adjoint action (it commutes with all of Poincaré but

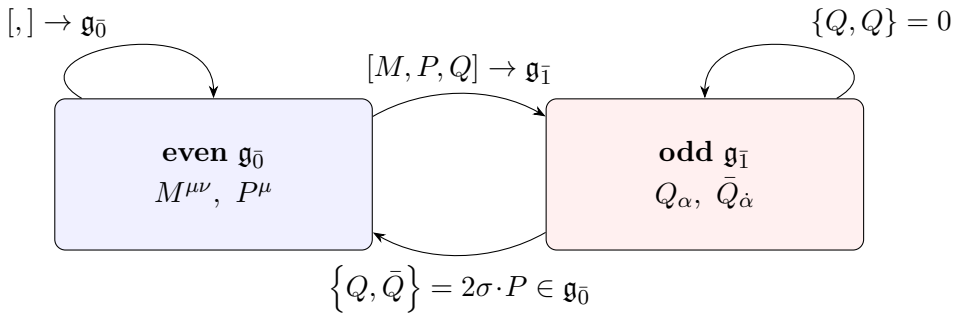

Figure 44.2: The $\mathbb{Z}_2$-graded structure of the $\mathcal{N}=1$ super-Poincaré algebra. The even (bosonic) sector contains the Lorentz and translation generators and closes on itself; it acts on the odd (fermionic) sector, rotating $Q,\bar{Q}$ as spinors and leaving them translation-invariant. The single new content is that the anticommutator of the odd generators returns the bosonic momentum, $\left\{Q,\bar{Q}\right\} = 2\sigma\cdot P$, while $\{Q,Q\}=0$.

rephases the supercharges), it is *outer*. The transformations Eq. (44.50) form a group U(1), called *R-symmetry* and denoted $\mathrm{U}(1)_R$.

When $\mathrm{U}(1)_R$ is promoted to an actual symmetry of a theory it is generated by a Hermitian charge R acting through the commutators

$$\boxed{[R,Q_\alpha] = -\,Q_\alpha, \qquad \left[R,\bar{Q}_{\dot\alpha}\right] = +\,\bar{Q}_{\dot\alpha}, \qquad [R,P_\mu] = [R,M_{\mu\nu}] = 0.} \tag{44.51}$$

The infinitesimal form of Eq. (44.50) is $\delta Q_\alpha = i\lambda\,[R,Q_\alpha] = -i\lambda\,Q_\alpha$, reproducing the phase. The supercharge carries R-charge -1 and its conjugate R-charge $+1$. Consistency with the algebra is immediate from the graded Leibniz rule: acting with R on Eq. (44.37),

$$\left[R,\left\{Q_\alpha,\bar{Q}_{\dot\beta}\right\}\right] = \left\{[R,Q_\alpha],\bar{Q}_{\dot\beta}\right\} + \left\{Q_\alpha,\left[R,\bar{Q}_{\dot\beta}\right]\right\} = (-1+1)\left\{Q_\alpha,\bar{Q}_{\dot\beta}\right\} = 0 = 2\sigma^{\mu}_{\alpha\dot\beta}\,[R,P_\mu]\,, \tag{44.52}$$

and the right-hand side vanishes because $[R,P_\mu]=0$. The two sides agree, so Eq. (44.51) is compatible with the central relation; the same check on $\{Q,Q\}=0$ is trivially satisfied since both sides scale by $e^{-2i\lambda}$. The R-symmetry is special to supersymmetry: it acts on the spinorial directions of the algebra and has no analogue in the ordinary Poincaré structure. Its presence or absence—whether a given supersymmetric theory respects $\mathrm{U}(1)_R$, and whether it is anomalous—is a powerful organising principle in the analysis of Chapters 45 and 46; for now we record it as the unique continuous outer automorphism of the $\mathcal{N}=1$ algebra.

Physical Insight

The single relation $\left\{Q, \bar{Q}\right\} = 2\sigma \cdot P$ already contains the two headline consequences supersymmetry is famous for, and it is worth seeing why before the next section extracts them carefully. First, energy is non-negative: Eq. (44.36) expresses $4H$ as a sum of squared-norm operators, so $H \geq 0$ in any supersymmetric theory, with $H|\psi\rangle = 0$ if and only if $Q_\alpha|\psi\rangle = \bar{Q}_{\dot{\alpha}}|\psi\rangle = 0$—a supersymmetric vacuum has exactly zero energy. Second, because Q commutes with P^μ and hence with the mass operator P^2, acting with Q on a one-particle state of mass m produces another state of the *same* mass but spin differing by $\frac{1}{2}$: bosons and fermions are paired into mass-degenerate multiplets. Both statements are read directly off the algebra, with no Lagrangian and no perturbation theory in sight; this is the sense in which the algebra is the theory's backbone.

44.2.8 Verifying the super-Jacobi identities

A graded Lie algebra is only consistent if its brackets satisfy the super-Jacobi identity Eq. (44.27) on every triple of generators. For the Poincaré subalgebra this is inherited from Chapter 3. What must be checked are the mixed triples involving the supercharges; we verify the three structurally distinct cases in full.

Worked Example 44.8 (The super-Jacobi identities of the $\mathcal{N} = 1$ algebra)**.** We verify Eq. (44.27) for the triples (Q, Q, Q), (Q, Q, P), and (M, Q, Q), and as the substantive covariance test the mixed triple $(M, Q, \bar{Q})$.

(i) The all-fermionic triple $(Q_\alpha, Q_\beta, Q_\gamma)$. All three are odd, $|Q| = 1$, so each cyclic sign in Eq. (44.27) is $(-1)^{1\cdot 1} = -1$ and each inner bracket of two odd generators is an anticommutator, itself feeding an outer commutator with the third odd generator. The identity reads

$$[Q_\alpha, \{Q_\beta, Q_\gamma\}] + [Q_\beta, \{Q_\gamma, Q_\alpha\}] + [Q_\gamma, \{Q_\alpha, Q_\beta\}] = 0, \tag{44.53}$$

after the common overall sign -1 is dropped. Every inner anticommutator vanishes by Eq. (44.40), so the identity holds trivially, $0 + 0 + 0 = 0$. The check is not vacuous: it confirms that setting $\{Q, Q\} = 0$ introduces no obstruction, which would not have been automatic had a nonzero $(1, 0)$ piece survived in Eq. (44.38).

(ii) The triple $(Q_\alpha, Q_\beta, P_\mu)$. Two odd, one even. Writing out Eq. (44.27) with $|Q| = 1, |P| = 0$, the signs are $(-1)^{|Q||P|} = +1$ for the term beginning with Q_α, $(-1)^{|Q||Q|} = -1$ for the term beginning with Q_β, and $(-1)^{|P||Q|} = +1$ for the term beginning with P_μ:

$$[Q_\alpha, [Q_\beta, P_\mu]] - [Q_\beta, [P_\mu, Q_\alpha]] + [P_\mu, \{Q_\alpha, Q_\beta\}] = 0. \tag{44.54}$$

The first two terms vanish by $[Q,P]=0$ (Eq. (44.41)); the third vanishes by $\{Q,Q\}=0$ (Eq. (44.40)), since $[P_\mu,0]=0$. The identity is satisfied. This triple is the consistency statement that the supercharges' translation-invariance and their vanishing self-anticommutator are mutually compatible—precisely the input combination used in Eq. (44.39).

(iii) The triple $(M_{\mu\nu},Q_\alpha,Q_\beta)$. One even, two odd. With M even the relevant rearrangement of Eq. (44.27) states that the Lorentz variation of $\{Q_\alpha,Q_\beta\}$ equals the sum of the variations of its factors:

$$[M_{\mu\nu},\{Q_\alpha,Q_\beta\}]=\{[M_{\mu\nu},Q_\alpha]\,,Q_\beta\}+\{Q_\alpha,[M_{\mu\nu},Q_\beta]\}\,. \tag{44.55}$$

The left-hand side is $[M_{\mu\nu},0]=0$. The right-hand side, using Eq. (44.47), is

$$-(\sigma_{\mu\nu})_\alpha{}^\gamma\ \{Q_\gamma,Q_\beta\}-(\sigma_{\mu\nu})_\beta{}^\gamma\ \{Q_\alpha,Q_\gamma\}=0, \tag{44.56}$$

again by Eq. (44.40). Both sides vanish, so the identity holds. The content is that $\{Q,Q\}=0$ is a Lorentz-invariant statement: the spinor rotation Eq. (44.47) maps the (vanishing) $(1,0)$ tensor to itself, confirming that no Lorentz transformation can generate a nonzero $\{Q,Q\}$ from zero.

(iv) The covariance test $(M_{\mu\nu},Q_\alpha,\bar{Q}_{\dot\beta})$. This is the only triple whose super-Jacobi identity is not automatically satisfied by vanishing brackets, and it is the genuine check that the central relation Eq. (44.37) is Lorentz-covariant with the coefficient we fixed. With M even, the identity again takes Leibniz form:

$$\left[M_{\mu\nu},\left\{Q_\alpha,\bar{Q}_{\dot\beta}\right\}\right]=\left\{[M_{\mu\nu},Q_\alpha]\,,\bar{Q}_{\dot\beta}\right\}+\left\{Q_\alpha,\left[M_{\mu\nu},\bar{Q}_{\dot\beta}\right]\right\}. \tag{44.57}$$

Evaluate both sides. The left-hand side, using Eq. (44.37) and the Poincaré bracket Eq. (3.148),

$$\left[M_{\mu\nu},2\sigma^\rho_{\alpha\dot\beta}P_\rho\right]=2\sigma^\rho_{\alpha\dot\beta}\,[M_{\mu\nu},P_\rho]=2\sigma^\rho_{\alpha\dot\beta}\,i(\eta_{\nu\rho}P_\mu-\eta_{\mu\rho}P_\nu)=2i(\sigma_{\nu\,\alpha\dot\beta}P_\mu-\sigma_{\mu\,\alpha\dot\beta}P_\nu). \tag{44.58}$$

The right-hand side, using Eqs. (44.47) and (44.48) and then Eq. (44.37) on each surviving anticommutator,

$$\begin{aligned}\text{RHS}&=-(\sigma_{\mu\nu})_\alpha{}^\gamma\left\{Q_\gamma,\bar{Q}_{\dot\beta}\right\}-(\bar\sigma_{\mu\nu})_{\dot\beta}{}^{\dot\gamma}\left\{Q_\alpha,\bar{Q}_{\dot\gamma}\right\}\\&=-2(\sigma_{\mu\nu})_\alpha{}^\gamma\,\sigma^\rho_{\gamma\dot\beta}P_\rho-2(\bar\sigma_{\mu\nu})_{\dot\beta}{}^{\dot\gamma}\,\sigma^\rho_{\alpha\dot\gamma}P_\rho.\end{aligned} \tag{44.59}$$

The two expressions agree if and only if the spinor matrices satisfy the intertwining identity

$$(\sigma_{\mu\nu})_\alpha{}^\gamma\,\sigma^\rho_{\gamma\dot\beta}+(\bar\sigma_{\mu\nu})_{\dot\beta}{}^{\dot\gamma}\,\sigma^\rho_{\alpha\dot\gamma}=-i(\delta^\rho_\mu\,\sigma_{\nu\,\alpha\dot\beta}-\delta^\rho_\nu\,\sigma_{\mu\,\alpha\dot\beta}). \tag{44.60}$$

This is nothing but the infinitesimal form of the Lorentz-equivariance of the invariant tensor σ^ρ established in Section 3.4.3: there the finite statement $A\,(x_\mu\sigma^\mu)\,A^\dagger=(\Lambda x)_\mu\sigma^\mu$ said that conjugating σ^ρ by the spinor representation

matrices reproduces the vector transformation of its index ρ. Differentiating that relation at the identity, with the spinor generators Eq. (44.34) on the α and $\dot\beta$ indices and the vector generator $(\mathcal{M}_{\mu\nu})^\rho{}_\sigma = i(\eta_\mu{}^\rho\eta_{\nu\sigma} - \dots)$ on ρ, yields exactly Eq. (44.60). Substituting it into Eq. (44.59) gives $-2P_\rho \cdot \left[-i(\delta^\rho_\mu\sigma_\nu - \delta^\rho_\nu\sigma_\mu)_{\alpha\dot\beta}\right] = 2i(\sigma_{\nu\,\alpha\dot\beta}P_\mu - \sigma_{\mu\,\alpha\dot\beta}P_\nu)$, which is precisely the left-hand side Eq. (44.58). The super-Jacobi identity is satisfied, and it is satisfied *only* because the coefficient on the right of Eq. (44.37) is a Lorentz scalar multiple of σ^μ—confirming both the index structure and the internal consistency of the normalisation chosen in Section 44.2.3.

With every bracket fixed and every Jacobi identity verified, the $\mathcal{N} = 1$ super-Poincaré algebra Eq. (44.49) stands as a closed, consistent graded Lie algebra. We now have a rigid algebraic object whose representations are the supermultiplets of physical states and whose internal relations already encode deep dynamical facts. The next section squeezes the physics out of the algebra itself—energy positivity, the order parameter for supersymmetry breaking, and the exact boson–fermion degeneracy and equal state counts within a multiplet—before we turn, in Section 44.2 onward, to constructing the multiplets explicitly.

44.3 Immediate Consequences of the Algebra

The previous section closed the super-Poincaré algebra: alongside the familiar Poincaré brackets we now have the fermionic supercharges Q_α and their conjugates $\bar Q_{\dot\alpha} = (Q_\alpha)^\dagger$, transforming as $(\frac12, 0)$ and $(0, \frac12)$ of $\mathrm{SL}(2,\mathbb{C})$ (Section 3.4.3), and obeying

$$\left\{Q_\alpha, \bar Q_{\dot\beta}\right\} = 2\,\sigma^\mu_{\alpha\dot\beta}\,P_\mu, \tag{44.61}$$

$$\{Q_\alpha, Q_\beta\} = 0, \qquad \left\{\bar Q_{\dot\alpha}, \bar Q_{\dot\beta}\right\} = 0, \tag{44.62}$$

$$[Q_\alpha, P_\mu] = 0, \qquad \left[\bar Q_{\dot\alpha}, P_\mu\right] = 0, \tag{44.63}$$

with $\sigma^\mu = (\mathbf{1}, \vec\sigma)$ in the conventions of Eqs. (3.79) and (3.106). (These are the $N = 1$ relations established in the preceding section; we take them as given here and cite them by label.) It is a remarkable feature of supersymmetry that a great deal of physics follows from these brackets *alone*, before a single representation has been built. The reason is structural: Eq. (44.61) ties the supercharges directly to the energy–momentum operator, so anticommuting a supercharge with its own conjugate *is* the Hamiltonian. Hilbert-space positivity then does the rest. In this section we extract three such consequences — the positivity of energy and the vacuum-energy order parameter for supersymmetry breaking, the exact equality of masses inside a multiplet, and the equality of bosonic and fermionic state counts — each proved in full from Eqs. (44.61) to (44.63). These are precisely the constraints that the explicit representation theory of the next section must realise.

44.3.1 Energy is non-negative

The first and most important consequence is that the spectrum of the Hamiltonian is bounded below by zero. To see it, we isolate $H = P^0$ from Eq. (44.61) by tracing over the spinor indices. Set $\dot\beta$ equal numerically to α and sum over $\alpha = 1, 2$; the left-hand side becomes $\sum_\alpha \left\{Q_\alpha, \bar Q_{\dot\alpha}\right\}$, and the right-hand side becomes $2\,(\operatorname{tr}\sigma^\mu)\,P_\mu$. Since the Pauli matrices are traceless, $\operatorname{tr}\sigma^\mu = (\operatorname{tr}\mathbf{1}, \operatorname{tr}\vec\sigma) = (2, \vec 0)$, so only $P_0 = H$ survives:

$$\sum_{\alpha=1,2} \left\{Q_\alpha, \bar Q_{\dot\alpha}\right\} \;=\; 2\,(\operatorname{tr}\sigma^\mu)\,P_\mu \;=\; 4\,P_0 \;=\; 4H. \tag{44.64}$$

Notice what has happened: the spatial momentum $\vec P$ has dropped out entirely, killed by the tracelessness of $\vec\sigma$. The combination of supercharges that closes on H is insensitive to $\vec P$. Solving Eq. (44.64) and inserting $\bar Q_{\dot\alpha} = Q_\alpha^\dagger$,

$$H \;=\; \tfrac{1}{4}\sum_{\alpha=1,2} \left\{Q_\alpha, Q_\alpha^\dagger\right\} \;=\; \tfrac{1}{4}\Big(Q_1 Q_1^\dagger + Q_1^\dagger Q_1 + Q_2 Q_2^\dagger + Q_2^\dagger Q_2\Big). \tag{44.65}$$

This is the central identity of the section. The Hamiltonian is a sum of an operator and its adjoint times that adjoint — a manifestly non-negative form.

Theorem 44.9 (Positivity of energy)**.** *In any unitary representation of the $N = 1$ super-Poincaré algebra on a Hilbert space with positive-definite inner product, the Hamiltonian satisfies $H \geq 0$. Consequently every state has energy $E \geq 0$.*

Proof. Let $|\psi\rangle$ be any normalisable state. Taking the expectation value of Eq. (44.65),

$$\langle\psi|H|\psi\rangle = \tfrac{1}{4}\sum_{\alpha=1,2}\Big(\big\langle\psi\big|Q_\alpha Q_\alpha^\dagger\big|\psi\big\rangle + \big\langle\psi\big|Q_\alpha^\dagger Q_\alpha\big|\psi\big\rangle\Big). \tag{44.66}$$

Unitarity makes $Q_\alpha^\dagger$ the genuine Hermitian adjoint of Q_α with respect to the inner product, so each term is the squared norm of a state:

$$\big\langle\psi\big|Q_\alpha^\dagger Q_\alpha\big|\psi\big\rangle = \|Q_\alpha\,|\psi\rangle\|^2 \geq 0, \qquad \big\langle\psi\big|Q_\alpha Q_\alpha^\dagger\big|\psi\big\rangle = \big\|Q_\alpha^\dagger\,|\psi\rangle\big\|^2 \geq 0. \tag{44.67}$$

Hence $\langle\psi|H|\psi\rangle = \tfrac{1}{4}\sum_\alpha\big(\big\|Q_\alpha^\dagger\,|\psi\rangle\big\|^2 + \|Q_\alpha\,|\psi\rangle\|^2\big) \geq 0$ for every $|\psi\rangle$, which is the statement $H \geq 0$. Diagonalising H on energy eigenstates gives $E \geq 0$. □

The economy of this argument is worth dwelling on. In an ordinary quantum field theory the positivity of the energy is a contingent fact, established case by case from the explicit Hamiltonian and the requirement that the theory be stable; nothing in the Poincaré algebra forces it. Supersymmetry promotes it to

a kinematic identity. Because H is built as a sum of squares of the supercharges, no choice of dynamics consistent with the algebra can produce a negative-energy state. The same identity also forbids the energy from being merely bounded below by some negative constant: the bound is exactly zero, and it is saturated precisely when the supercharges annihilate the state. That sharp threshold is what makes the vacuum energy an exact order parameter, to which we now turn.

44.3.2 The vacuum energy as the order parameter for SUSY breaking

A symmetry is said to be *spontaneously broken* when it is a symmetry of the dynamics but not of the ground state: the charges generating it fail to annihilate the vacuum (Chapter 29). For an ordinary internal symmetry the order parameter is the vacuum expectation value of some field; for supersymmetry the algebra hands us a far more rigid diagnostic, directly in terms of energy.

Theorem 44.10 (Vacuum energy detects SUSY breaking)**.** *Let* $|0\rangle$ *be a Poincaré-invariant vacuum, so that* $\vec{P}\,|0\rangle = 0$ *and* $E_{\text{vac}} = \langle 0|H|0\rangle$*. Then supersymmetry is unbroken — meaning* $Q_\alpha\,|0\rangle = \bar{Q}_{\dot\alpha}\,|0\rangle = 0$ *for all* $\alpha, \dot\alpha$ *— if and only if* $E_{\text{vac}} = 0$*. Equivalently,* $E_{\text{vac}} > 0$ *holds if and only if supersymmetry is spontaneously broken.*

Proof. ($\Rightarrow$) If $Q_\alpha\,|0\rangle = \bar{Q}_{\dot\alpha}\,|0\rangle = 0$, then Eq. (44.65) annihilates the vacuum term by term, so $H\,|0\rangle = 0$ and in particular $E_{\text{vac}} = \langle 0|H|0\rangle = 0$.

($\Leftarrow$) Conversely, suppose $E_{\text{vac}} = 0$. By Eq. (44.66) applied to $|0\rangle$,

$$0 = E_{\text{vac}} = \langle 0|H|0\rangle = \tfrac{1}{4}\sum_{\alpha=1,2}\Big(\big\|Q_\alpha^\dagger\,|0\rangle\big\|^2 + \|Q_\alpha\,|0\rangle\|^2\Big). \tag{44.68}$$

This is a sum of four non-negative terms equal to zero, so each term vanishes individually: $\|Q_\alpha\,|0\rangle\|^2 = 0$ and $\big\|Q_\alpha^\dagger\,|0\rangle\big\|^2 = 0$ for $\alpha = 1, 2$. In a Hilbert space with positive-definite inner product a vector of zero norm is the zero vector, hence $Q_\alpha\,|0\rangle = 0$ and $\bar{Q}_{\dot\alpha}\,|0\rangle = 0$ for all indices: supersymmetry is unbroken. The contrapositive of the two implications gives the final statement. □

Two features make this order parameter exceptional. First, it is exact and non-perturbative. The vanishing of the vacuum energy is equivalent to the existence of a supersymmetric vacuum as an operator statement, valid to all orders and beyond perturbation theory; it does not rely on a small coupling or on a classical approximation. Second, it inverts the usual logic of the cosmological-constant problem. In a generic quantum field theory the zero-point energy of every mode contributes to E_{vac} and the total is quartically sensitive to the cutoff. Here the same supercharge algebra that guarantees $E \geq 0$ also guarantees that an unbroken supersymmetry sets E_{vac} to exactly zero: the bosonic and fermionic zero-point energies cancel. We saw the mechanism of that cancellation

in miniature in Theorem 12.50, where the bosonic and fermionic functional determinants entered with opposite powers and cancelled mode by mode; the algebra above is the abstract reason it had to happen.

Physical Insight

The logic runs in a direction worth stating plainly. *Unbroken* supersymmetry forces $E_{\text{vac}} = 0$ — a statement about the ground state. A *positive* vacuum energy is therefore not a small perturbation to be tuned away but a sharp, qualitative signal that the symmetry is spontaneously broken. There is no halfway: either the supercharges annihilate the vacuum and $E_{\text{vac}} = 0$ exactly, or they do not and $E_{\text{vac}} > 0$. This is why the search for supersymmetry-breaking mechanisms is, equivalently, a search for theories whose lowest energy is strictly positive — the Goldstino and the explicit field-theoretic mechanisms (O'Raifeartaigh and Fayet–Iliopoulos breaking) are developed in Chapter 45.

We have deliberately stopped at the order parameter and deferred the dynamics. Whether a given model has $E_{\text{vac}} = 0$ or $E_{\text{vac}} > 0$ is a question about its potential and its quantum corrections, taken up in Chapter 45; here the algebra tells us only what the answer *means*.

44.3.3 Mass degeneracy within a multiplet

We now turn from the vacuum to the excited states and ask what the algebra forces on the particles that fill a single irreducible representation. The first Casimir of the Poincaré algebra is $P^2 = P_\mu P^\mu$, whose eigenvalue m^2 labels the mass of a one-particle state (Theorem 3.36). The question is whether P^2 remains a Casimir of the *enlarged* super-Poincaré algebra — that is, whether it also commutes with the supercharges. If it does, Schur's lemma fixes a single mass for an entire irreducible supermultiplet.

Proposition 44.11 (P^2 commutes with the supercharges)**.** *The first Casimir P^2 commutes with Q_α and $\bar{Q}_{\dot\alpha}$:*

$$\left[P^2, Q_\alpha\right] = 0, \qquad \left[P^2, \bar{Q}_{\dot\alpha}\right] = 0. \tag{44.69}$$

Hence P^2 is a Casimir of the full $N = 1$ super-Poincaré algebra.

Proof. Write $P^2 = P^\mu P_\mu$ and use the Leibniz rule for the commutator,

$$\left[P^2, Q_\alpha\right] = \left[P^\mu P_\mu, Q_\alpha\right] = P^\mu \left[P_\mu, Q_\alpha\right] + \left[P^\mu, Q_\alpha\right] P_\mu. \tag{44.70}$$

By Eq. (44.63) each commutator on the right vanishes, $[P_\mu, Q_\alpha] = 0$, so $\left[P^2, Q_\alpha\right] = 0$. The conjugate relation $\left[P^2, \bar{Q}_{\dot\alpha}\right] = 0$ follows identically from $\left[P_\mu, \bar{Q}_{\dot\alpha}\right] = 0$.

Since P^2 already commutes with all of P_μ and the Lorentz generators $M_{\mu\nu}$ (it is the Poincaré Casimir of Theorem 3.36), it commutes with every generator of the super-Poincaré algebra. □

Theorem 44.12 (Equal masses within a supermultiplet)**.** *All one-particle states in an irreducible representation of the $N = 1$ super-Poincaré algebra have the same eigenvalue of P^2, hence the same mass. In particular, the bosonic and fermionic superpartners related by the action of the supercharges are exactly mass-degenerate.*

Proof. On an irreducible representation P^2 commutes with every generator (Theorem 44.11), so by Schur's lemma in the form Theorem 2.23 it acts as a scalar multiple of the identity, $P^2 = m^2\,\mathbf{1}$. Concretely: the states of the multiplet are generated from any one of them by repeated application of Q_α and $\bar{Q}_{\dot\alpha}$. If $|p, s\rangle$ is an eigenstate with $P^2\,|p, s\rangle = m^2\,|p, s\rangle$, then

$$P^2\,Q_\alpha\,|p, s\rangle = Q_\alpha\,P^2\,|p, s\rangle = m^2\,Q_\alpha\,|p, s\rangle\,, \tag{44.71}$$

using $[P^2, Q_\alpha] = 0$ to pull P^2 through the supercharge. So $Q_\alpha\,|p, s\rangle$ carries the same eigenvalue m^2, and inductively every state reached from $|p, s\rangle$ does too. All members of the irreducible multiplet share one value of m^2. □

This is the algebraic origin of the slogan that "every boson has a fermionic partner of equal mass." It is also exactly the statement that confronts experiment: no scalar with the mass and charges of the electron has been observed, so if supersymmetry is realised in nature it must be *broken*, lifting the degeneracy. The breaking, by Theorem 44.10, is the same phenomenon as a positive vacuum energy; the structural payoff is that mass splittings and vacuum energy are not independent inputs but two faces of one order parameter.

Caution

It is essential that the degeneracy is in P^2 and not in the *spin*. The second Poincaré Casimir is built from the Pauli–Lubański vector W_μ, and W^2 does *not* commute with the supercharges — if it did, every state in a multiplet would carry the same spin and supersymmetry would relate bosons only to bosons. It is precisely because $[W^2, Q_\alpha] \neq 0$ that a supercharge can change the spin by half a unit, turning a boson into a fermion. The mass is rigidly shared; the spin is deliberately not. The explicit spin content of each multiplet is worked out in Section 44.4.

44.3.4 Equal numbers of bosons and fermions

The third consequence counts states. A supercharge maps a bosonic state to a fermionic one and vice versa; one expects this pairing to make the two

counts equal. Turning the expectation into a theorem requires an operator that distinguishes bosons from fermions, and a trace identity that exploits its interplay with the algebra.

Definition 44.13 (Fermion-number parity)**.** The *fermion-number parity* operator $(-1)^F$ is the unitary, Hermitian, involutive operator that acts as $+1$ on every bosonic state and -1 on every fermionic state:

$$(-1)^F\,|\text{boson}\rangle = +\,|\text{boson}\rangle\,, \qquad (-1)^F\,|\text{fermion}\rangle = -\,|\text{fermion}\rangle\,, \qquad \big((-1)^F\big)^2 = \mathbf{1}. \tag{44.72}$$

"Bosonic" and "fermionic" here mean the two superselection sectors of integer and half-integer spin; by the spin–statistics connection these coincide with even and odd fermion number F, so $(-1)^F$ is well defined.

The defining property we actually use is not the eigenvalues but how $(-1)^F$ commutes past a supercharge.

Proposition 44.14 ($(-1)^F$ anticommutes with the supercharges)**.**

$$\Big\{(-1)^F, Q_\alpha\Big\} = 0, \qquad \Big\{(-1)^F, \bar{Q}_{\dot\alpha}\Big\} = 0. \tag{44.73}$$

Proof. A supercharge Q_α carries half-integer spin, so it maps the bosonic sector into the fermionic sector and the fermionic sector into the bosonic sector; it changes the eigenvalue of $(-1)^F$ by a sign. We verify $\Big\{(-1)^F, Q_\alpha\Big\} = 0$ on each sector. On a bosonic state $|b\rangle$, with $(-1)^F\,|b\rangle = +\,|b\rangle$ and $Q_\alpha\,|b\rangle = |f\rangle$ a fermionic state with $(-1)^F\,|f\rangle = -\,|f\rangle$,

$$\big((-1)^F Q_\alpha + Q_\alpha (-1)^F\big)\,|b\rangle = (-1)^F\,|f\rangle + Q_\alpha\,|b\rangle = -\,|f\rangle + |f\rangle = 0. \tag{44.74}$$

On a fermionic state $|f\rangle$, with $(-1)^F\,|f\rangle = -\,|f\rangle$ and $Q_\alpha\,|f\rangle = |b\rangle$ bosonic,

$$\big((-1)^F Q_\alpha + Q_\alpha (-1)^F\big)\,|f\rangle = (-1)^F\,|b\rangle + Q_\alpha(-\,|f\rangle) = |b\rangle - |b\rangle = 0. \tag{44.75}$$

Since every state is a superposition of bosonic and fermionic states, $\Big\{(-1)^F, Q_\alpha\Big\} = 0$ as an operator. Taking the Hermitian adjoint and using $\big((-1)^F\big)^\dagger = (-1)^F$ gives $\Big\{(-1)^F, \bar{Q}_{\dot\alpha}\Big\} = 0$. □

We can now state and prove the counting theorem. The natural object is the supertrace $\mathrm{Tr}\big[(-1)^F(\cdots)\big]$: weighting a trace by $(-1)^F$ counts bosons with a plus sign and fermions with a minus sign, so $\mathrm{Tr}(-1)^F = n_B - n_F$, the difference of the two counts.

Theorem 44.15 ($n_B = n_F$)**.** *In any finite-dimensional representation of the $N = 1$ super-Poincaré algebra on which P_μ acts as a fixed nonzero four-momentum p_μ (for example, the states of a supermultiplet at a fixed on-shell momentum, massive or massless), the number of bosonic states equals the number of fermionic states:*

$$n_B = n_F. \tag{44.76}$$

Proof. Because the supercharges commute with P_μ (Eq. (44.63)), they preserve the fixed-momentum subspace and act as honest finite-dimensional operators on it; the trace over this subspace is finite and cyclic. Consider, for fixed spinor indices $\alpha, \dot\beta$, the weighted trace of the basic anticommutator Eq. (44.61):

$$\mathrm{Tr}\Big[(-1)^F \left\{Q_\alpha, \bar Q_{\dot\beta}\right\}\Big] = \mathrm{Tr}\big[(-1)^F Q_\alpha \bar Q_{\dot\beta}\big] + \mathrm{Tr}\big[(-1)^F \bar Q_{\dot\beta} Q_\alpha\big]. \tag{44.77}$$

In the second term, use cyclicity of the trace to move Q_α to the front,

$$\mathrm{Tr}\big[(-1)^F \bar Q_{\dot\beta} Q_\alpha\big] = \mathrm{Tr}\big[Q_\alpha (-1)^F \bar Q_{\dot\beta}\big], \tag{44.78}$$

and then anticommute $(-1)^F$ past Q_α using Eq. (44.73), $Q_\alpha (-1)^F = -(-1)^F Q_\alpha$:

$$\mathrm{Tr}\big[Q_\alpha (-1)^F \bar Q_{\dot\beta}\big] = -\,\mathrm{Tr}\big[(-1)^F Q_\alpha \bar Q_{\dot\beta}\big]. \tag{44.79}$$

The two contributions in Eq. (44.77) are therefore equal and opposite, and the weighted trace of the anticommutator vanishes:

$$\mathrm{Tr}\Big[(-1)^F \left\{Q_\alpha, \bar Q_{\dot\beta}\right\}\Big] = 0. \tag{44.80}$$

Now use the algebra on the left of Eq. (44.80). By Eq. (44.61) the anticommutator is $2\sigma^\mu_{\alpha\dot\beta} P_\mu$, and on the fixed-momentum representation P_μ acts as the c-number p_μ, so

$$0 = \mathrm{Tr}\Big[(-1)^F 2\sigma^\mu_{\alpha\dot\beta} P_\mu\Big] = 2\,\sigma^\mu_{\alpha\dot\beta}\, p_\mu\, \mathrm{Tr}\big[(-1)^F\big] = 2\,(p\cdot\sigma)_{\alpha\dot\beta}\,(n_B - n_F), \tag{44.81}$$

where $(p\cdot\sigma)_{\alpha\dot\beta} = p_\mu \sigma^\mu_{\alpha\dot\beta}$ and we used $\mathrm{Tr}(-1)^F = n_B - n_F$. The 2×2 matrix $p\cdot\sigma$ is not the zero matrix whenever $p_\mu \neq 0$: its determinant is $\det(p\cdot\sigma) = p^2 = m^2$ for a massive momentum, and even for a massless $p_\mu \neq 0$ at least one entry is nonzero. Choosing any index pair $(\alpha, \dot\beta)$ for which $(p\cdot\sigma)_{\alpha\dot\beta} \neq 0$, Eq. (44.81) forces $n_B - n_F = 0$, that is $n_B = n_F$. □

The result is exactly the one the representation theory must respect: when we build the massless and massive multiplets in Section 44.4 we will count their states explicitly and find boson and fermion totals matching at every step — two real bosonic and two real fermionic states in the massless chiral multiplet, and so on. The trace identity above is the reason the counts are guaranteed to match before any multiplet is constructed.

Caution

The hypothesis $p_\mu \neq 0$ is not cosmetic. At exactly $p_\mu = 0$ — the vacuum, or a state at rest only in a degenerate sense — the matrix $p\cdot\sigma$ vanishes and the argument gives no constraint; bosonic and fermionic ground states

need not pair up. This loophole is exactly where supersymmetry breaking can hide, and it is what the *Witten index* $\mathrm{Tr}(-1)^F$ taken over the *full* Hilbert space (with a regulator $e^{-\beta H}$) is designed to probe: nonzero-energy states pair off and cancel by Theorem 44.15, so the index counts only the zero-energy states, $\mathrm{Tr}(-1)^F = n_B^{E=0} - n_F^{E=0}$, and a nonzero value certifies that a supersymmetric vacuum survives. We develop the Witten index as a tool for deciding whether supersymmetry is dynamically broken in Chapter 46.

44.3.5 A solvable laboratory: supersymmetric quantum mechanics

All three results — $E \geq 0$, the vacuum-energy order parameter, and $n_B = n_F$ away from zero energy — can be seen at once in the simplest system carrying a supersymmetry algebra: a single particle on the line with one fermionic degree of freedom. This is the $0+1$-dimensional reduction of the algebra, and it is exactly solvable, so nothing is hidden.

Worked Example 44.16 (Witten's supersymmetric quantum mechanics)**.** Work on the Hilbert space $\mathcal{H} = L^2(\mathbb{R}) \otimes \mathbb{C}^2$, the tensor product of a bosonic coordinate Hilbert space and a two-state fermionic factor. Introduce fermionic operators $b, b^\dagger$ acting on $\mathbb{C}^2$ with $\{b, b^\dagger\} = 1$ and $b^2 = (b^\dagger)^2 = 0$, and the bosonic position and momentum x, p with $[x, p] = i$ (here $p = -i\,\mathrm{d}/\mathrm{d}x$). Fix a smooth real function $W(x)$, the *superpotential*, and define a single complex supercharge

$$Q = (p - i\,W'(x))\,b, \qquad Q^\dagger = (p + i\,W'(x))\,b^\dagger, \tag{44.82}$$

where $W' = \mathrm{d}W/\mathrm{d}x$. This is the dimensional reduction of Eq. (44.61) to one supercharge: there is one "time" direction, so P_μ reduces to H alone.

The algebra closes. Because $b^2 = 0$, the supercharge is nilpotent, $Q^2 = (p - iW')^2\, b^2 = 0$, and likewise $(Q^\dagger)^2 = 0$ — the analogues of Eq. (44.62). The nontrivial bracket is $\{Q, Q^\dagger\}$. Compute the two operator products. Using $[p, W'(x)] = -i\,W''(x)$,

$$(p - iW')(p + iW') = p^2 + W'^2 + i\,[p, W'] = p^2 + W'^2 + W'', \tag{44.83}$$

$$(p + iW')(p - iW') = p^2 + W'^2 - i\,[p, W'] = p^2 + W'^2 - W''. \tag{44.84}$$

Then, since $\{Q, Q^\dagger\} = (p - iW')(p + iW')\,bb^\dagger + (p + iW')(p - iW')\,b^\dagger b$ and $bb^\dagger = \mathbf{1} - b^\dagger b$,

$$\begin{aligned}\{Q, Q^\dagger\} &= (p^2 + W'^2)(bb^\dagger + b^\dagger b) + W''(bb^\dagger - b^\dagger b) \\ &= (p^2 + W'^2)\,\mathbf{1} + W''(\mathbf{1} - 2b^\dagger b) = (p^2 + W'^2)\,\mathbf{1} + W''\,(-1)^F,\end{aligned} \tag{44.85}$$

where in the last step we identified the fermion-parity operator $(-1)^F = \mathbf{1} - 2b^\dagger b$ (eigenvalue $+1$ on the empty fermionic state, -1 on the occupied one), exactly as in Theorem 44.13. Defining $2H \equiv \left\{Q, Q^\dagger\right\}$, the algebra is the reduced super-Poincaré algebra $Q^2 = 0$, $\left\{Q, Q^\dagger\right\} = 2H$, $[H, Q] = 0$ — the last following because $\left[\left\{Q, Q^\dagger\right\}, Q\right] = 0$ by the Jacobi identity together with $Q^2 = 0$.

Two partner Hamiltonians. In the basis where $(-1)^F = \mathrm{diag}(+1, -1) = \sigma_3$, Eq. (44.85) reads $H = \mathrm{diag}(H_+, H_-)$ with

$$H_\pm = \tfrac{1}{2}p^2 + \tfrac{1}{2}W'(x)^2 \pm \tfrac{1}{2}W''(x). \tag{44.86}$$

The bosonic $(+)$ and fermionic $(-)$ sectors are governed by the two "partner potentials" $V_\pm = \frac{1}{2}W'^2 \pm \frac{1}{2}W''$, which differ only by the $\pm\frac{1}{2}W''$ term.

Positivity. For any $|\psi\rangle$, $\langle\psi|H|\psi\rangle = \frac{1}{2}(\|Q\,|\psi\rangle\|^2 + \left\|Q^\dagger\,|\psi\rangle\right\|^2) \geq 0$, the one-supercharge form of Theorem 44.9. Energies are non-negative.

The order parameter. A zero-energy state must be annihilated by both Q and $Q^\dagger$, by the same sum-of-squares argument as in Theorem 44.10. Writing $|\psi\rangle = \psi_+(x)\,|+\rangle + \psi_-(x)\,|-\rangle$ with $|\pm\rangle$ the fermion-parity eigenstates, $Q\,|\psi\rangle = 0$ and $Q^\dagger\,|\psi\rangle = 0$ reduce to the first-order equations $(\mathrm{d}_x + W')\psi_- = 0$ and $(\mathrm{d}_x - W')\psi_+ = 0$, solved by

$$\psi_+(x) \propto e^{+W(x)}, \qquad \psi_-(x) \propto e^{-W(x)}. \tag{44.87}$$

At most one of these is normalisable, depending on whether $W(x) \to \pm\infty$ as $x \to \pm\infty$. If, say, $W \to +\infty$ at both ends, then $\psi_- \propto e^{-W}$ is normalisable and $\psi_+ \propto e^{+W}$ is not, giving exactly one zero-energy ground state and $E_{\mathrm{vac}} = 0$: supersymmetry is unbroken. If instead $W \to +\infty$ at one end and $-\infty$ at the other (for example W odd and growing), *neither* solution is normalisable, no zero-energy state exists, $E_{\mathrm{vac}} > 0$, and supersymmetry is spontaneously broken — a completely explicit instance of Theorem 44.10.

Pairing and $n_B = n_F$. For any eigenstate with $E > 0$, the operator $Q^\dagger$ maps it to a state of the same energy in the opposite fermion sector (and Q maps back), because $\left[H, Q^\dagger\right] = 0$; the map is invertible on $E > 0$ states since $\left\{Q, Q^\dagger\right\} = 2H = 2E \neq 0$ there. Hence every positive-energy level appears once in the bosonic sector and once in the fermionic sector: $n_B = n_F$ level by level, the $0+1$-dimensional shadow of Theorem 44.15. The pairing fails only at $E = 0$, precisely the loophole flagged above, and the difference of the *unpaired* zero-energy counts is the Witten index $\mathrm{Tr}(-1)^F = n_B^{E=0} - n_F^{E=0}$, which equals $+1$, -1, or 0 in the three asymptotic cases just discussed — a topological invariant of W that decides whether a supersymmetric ground state exists.

This toy model is more than an illustration: it is the conceptual germ of the index theorems and the non-renormalisation results developed in Chapter 46, and

it shows in a setting with no field-theoretic subtleties that the three consequences proved abstractly above are forced, simultaneously, by one nilpotent supercharge.

With the kinematic constraints in hand — a single mass per multiplet (Theorem 44.12) and equal boson and fermion counts away from zero momentum (Theorem 44.15) — the question becomes which collections of one-particle states actually realise them. The next section answers it by classifying the irreducible representations Wigner-style, constructing the massless and massive supermultiplets explicitly and counting their states, and showing concretely that the equalities anticipated here are met multiplet by multiplet.

44.4 Supermultiplets: Massless and Massive Representations

The previous section read physics directly off the algebra without ever constructing a single state. From the positivity relation and the basic anticommutator (Eqs. (44.37) and (44.49)) we already know three rigid facts about *any* unitary representation on which the supercharges act: the energy is bounded below and vanishes only on a supersymmetric vacuum; every state in an irreducible multiplet shares one mass (Theorem 44.12); and the multiplet contains equally many bosonic and fermionic states, $n_B = n_F$ (Theorem 44.15). These are powerful constraints, but they are constraints *on* representations we have not yet built. We now build them. The task is the supersymmetric analogue of what Chapter 3 did for the Poincaré group: classify the one-particle irreducible representations of the full algebra and list their state content. The method is Wigner's (Theorem 3.44)—fix a standard momentum, find the subalgebra that stabilizes it, and induce the whole representation from a representation of that little algebra—adapted to the fact that the stabilizer now contains fermionic generators as well as the little group of Theorem 3.43. The fermionic generators turn out to form a Clifford algebra, and the multiplet is a Clifford module built on a "Clifford vacuum" that carries an ordinary little-group label. Everything in this section is an honest consequence of that single observation. We treat the massless case first, where one of the two fermionic oscillators decouples and the multiplets are remarkably small, then the massive case, where both survive and the multiplets are correspondingly larger.

Throughout we work in two-component (Weyl) notation. The supercharges are Q_α, transforming in $(\frac{1}{2},0)$, and their Hermitian conjugates $\bar{Q}_{\dot\alpha} = (Q_\alpha)^\dagger$, transforming in $(0,\frac{1}{2})$; the index conventions, the Pauli matrices $\sigma^\mu_{\alpha\dot\beta} = (\mathbf{1},\vec\sigma)$ and $\bar\sigma^\mu = (\mathbf{1},-\vec\sigma)$, and the spinor calculus are those fixed in Section 3.4.3 and Eqs. (3.79) and (3.106). We restrict to $\mathcal{N}=1$ for the detailed constructions and turn on extended $\mathcal{N}$ only far enough to count states and to flag where central

charges enter. The two anticommutators we use are

$$\left\{Q_\alpha, \bar{Q}_{\dot\beta}\right\} = 2\,\sigma^\mu_{\alpha\dot\beta}\,P_\mu, \qquad \{Q_\alpha, Q_\beta\} = 0 = \left\{\bar{Q}_{\dot\alpha}, \bar{Q}_{\dot\beta}\right\}, \tag{44.88}$$

the first of which is Eq. (44.37) and the second the $\mathcal{N} = 1$, central-charge-free form of Eq. (44.49). The supercharges commute with P^2 (they carry no momentum, $[Q_\alpha, P_\mu] = 0$), which is the algebraic reason a whole multiplet sits at one mass; that is exactly Theorem 44.12, and it licenses us to diagonalize P_μ first and let the Q's move us *within* a fixed-momentum sector.

44.4.1 The massless multiplet as a Clifford module

For a massless particle there is no rest frame, so following Section 3.7.3 we fix a standard null momentum along the z-axis,

$$P^\mu = (E, 0, 0, E), \qquad E > 0, \tag{44.89}$$

and ask how the supercharges act on the one-particle states of this momentum. Everything is controlled by the right-hand side of the first anticommutator in Eq. (44.88) evaluated on Eq. (44.89). Lowering the index with the mostly-minus metric gives $P_\mu = (E, 0, 0, -E)$, so

$$\sigma^\mu_{\alpha\dot\beta} P_\mu = E\,\sigma^0 + (-E)\,\sigma^3 = E(\mathbf{1} - \sigma^3) = E\begin{pmatrix} 0 & 0 \\ 0 & 2 \end{pmatrix}_{\alpha\dot\beta}, \tag{44.90}$$

where the first equality uses $\sigma^\mu P_\mu = P_\mu \sigma^\mu = P_0\sigma^0 + P_3\sigma^3$ with $P_0 = E$, $P_3 = -E$, and $\sigma^3 = \mathrm{diag}(1, -1)$. The crucial feature of Eq. (44.90) is that the matrix is rank one: only the $(\alpha, \dot\beta) = (2, \dot 2)$ entry survives. Written out, the supercharge anticommutators in this frame are therefore

$$\left\{Q_2, \bar{Q}_{\dot 2}\right\} = 4E, \qquad \left\{Q_1, \bar{Q}_{\dot 1}\right\} = 0, \qquad \left\{Q_1, \bar{Q}_{\dot 2}\right\} = \left\{Q_2, \bar{Q}_{\dot 1}\right\} = 0, \tag{44.91}$$

together with $\{Q_\alpha, Q_\beta\} = \left\{\bar{Q}_{\dot\alpha}, \bar{Q}_{\dot\beta}\right\} = 0$.

The second relation in Eq. (44.91) forces Q_1 and $\bar{Q}_{\dot 1}$ to act trivially on every physical state. This is the same positivity argument that gave energy positivity in the previous section, applied locally: for any normalized physical state $|\psi\rangle$ in this momentum sector, $\bar{Q}_{\dot 1} = (Q_1)^\dagger$ gives

$$0 = \langle\psi| \left\{Q_1, \bar{Q}_{\dot 1}\right\} |\psi\rangle = \|Q_1\,|\psi\rangle\|^2 + \left\|\bar{Q}_{\dot 1}\,|\psi\rangle\right\|^2, \tag{44.92}$$

a sum of two non-negative numbers that vanishes only if each does. Hence $Q_1\,|\psi\rangle = \bar{Q}_{\dot 1}\,|\psi\rangle = 0$ for all $|\psi\rangle$: the operators Q_1 and $\bar{Q}_{\dot 1}$ are identically zero on the representation. One of the two fermionic oscillator pairs has *decoupled*. This is the algebraic origin of the smallness of massless multiplets, and it is special to the lightlike kinematics: it happened because $\sigma^\mu P_\mu$ degenerated to rank one when $P^2 = 0$.

Caution

The vanishing of $Q_1, \bar{Q}_{\dot{1}}$ is an operator statement *on this representation*, not a redefinition of the abstract algebra. The supercharges $Q_1, \bar{Q}_{\dot{1}}$ are perfectly nonzero generators of the $\mathcal{N} = 1$ algebra; what Eq. (44.92) shows is that they are represented by zero on a single massless one-particle irrep. On a massive irrep, or on a different massless momentum sector, they act nontrivially. This is the precise analogue of the massless little group collapsing from a non-compact ISO(2) to its SO(2) part in Section 3.7.3.

Only the pair $Q_2, \bar{Q}_{\dot{2}}$ remains, and Eq. (44.91) tells us it is a single fermionic creation/annihilation pair. Normalize it: define

$$a \equiv \frac{\bar{Q}_{\dot{2}}}{2\sqrt{E}}, \qquad a^\dagger \equiv \frac{Q_2}{2\sqrt{E}}, \tag{44.93}$$

so that the surviving anticommutator becomes the canonical fermionic oscillator relation

$$\left\{a, a^\dagger\right\} = \frac{1}{4E}\left\{\bar{Q}_{\dot{2}}, Q_2\right\} = 1, \qquad \{a, a\} = \left\{a^\dagger, a^\dagger\right\} = 0, \tag{44.94}$$

the last two following from $\left\{\bar{Q}_{\dot{2}}, \bar{Q}_{\dot{2}}\right\} = 0$ and $\{Q_2, Q_2\} = 0$. (The choice of which member of the pair to call a and which $a^\dagger$ is a convention; the one made here will put the Clifford vacuum at the *lower* helicity, which is the standard bookkeeping and matches the chiral-multiplet labelling below.) Equation (44.94) is the Clifford algebra of a single fermionic mode. Its unique irreducible unitary representation is two-dimensional: there is a normalized vacuum $|\Omega\rangle$ with $a\,|\Omega\rangle = 0$, the one excited state $a^\dagger\,|\Omega\rangle$, and nothing else because $(a^\dagger)^2 = 0$ truncates the tower after one step. This two-state structure is the entire massless multiplet, once we attach the helicity label.

Helicity of the oscillator. To say *which* helicities the two states carry, we need the J_3 charge of $a^\dagger = Q_2/2\sqrt{E}$, where J_3 generates rotations about the momentum axis $\hat{z}$ and hence measures helicity for our standard momentum Eq. (44.89). Because Q_α is a Lorentz spinor in $(\frac{1}{2}, 0)$, the algebra fixes its commutator with the rotation generator,

$$[J_3, Q_\alpha] = -\tfrac{1}{2}\,(\sigma^3)_\alpha{}^\beta\, Q_\beta, \tag{44.95}$$

the spin-$\frac{1}{2}$ action in the $(\frac{1}{2}, 0)$ representation. With $\sigma^3 = \mathrm{diag}(1, -1)$ this reads $[J_3, Q_1] = -\frac{1}{2}Q_1$ and $[J_3, Q_2] = +\frac{1}{2}Q_2$; taking the Hermitian conjugate of these and using $J_3^\dagger = J_3$ gives $\left[J_3, \bar{Q}_{\dot{1}}\right] = +\frac{1}{2}\bar{Q}_{\dot{1}}$ and $\left[J_3, \bar{Q}_{\dot{2}}\right] = -\frac{1}{2}\bar{Q}_{\dot{2}}$. The

operator content is then immediate: read the sign carefully from Eq. (44.95): $[J_3, Q_2] = +\frac{1}{2}Q_2$ means that if $J_3\,|h\rangle = h\,|h\rangle$ then

$$J_3(Q_2\,|h\rangle\,) = (\,[J_3, Q_2] + Q_2 J_3)\,|h\rangle = (h + \tfrac{1}{2})\,Q_2\,|h\rangle\,. \tag{44.96}$$

Thus Q_2, and with it $a^\dagger$, *raises* the helicity by $\frac{1}{2}$; correspondingly $a = \bar{Q}_{\dot{2}}/2\sqrt{E}$ *lowers* helicity by $\frac{1}{2}$. With the convention of Eq. (44.93), the Clifford vacuum $|\Omega\rangle$ is annihilated by $a = \bar{Q}_{\dot{2}}/2\sqrt{E}$, the helicity-*lowering* member of the pair, so it already sits at the bottom of the helicity ladder; the helicity-*raising* member, $b^\dagger \equiv Q_2/2\sqrt{E} = a^\dagger$, satisfies the same Clifford algebra Eq. (44.94) and builds the partner one half-unit up, at helicity $+\frac{1}{2}$ relative to the vacuum. This fixes a uniform convention: the *Clifford vacuum has the lower helicity λ, and its superpartner sits at $\lambda + \frac{1}{2}$.*

Definition 44.17 (Clifford vacuum and the massless multiplet)**.** On a massless one-particle irrep with standard momentum Eq. (44.89), the *Clifford vacuum* $|\Omega_\lambda\rangle$ is the state of definite helicity λ annihilated by the surviving helicity-lowering supercharge. The massless $\mathcal{N} = 1$ *supermultiplet of base helicity* λ is the two-dimensional Clifford module

$$\{\ |\Omega_\lambda\rangle\,,\quad \left|\Omega_{\lambda+1/2}\right\rangle \equiv b^\dagger\,|\Omega_\lambda\rangle\ \},\qquad b^\dagger = \frac{Q_2}{2\sqrt{E}}, \tag{44.97}$$

with helicities λ and $\lambda + \frac{1}{2}$ and one state at each.

Proposition 44.18 (Massless $\mathcal{N} = 1$ irreducibles)**.** *Every massless one-particle irreducible representation of the $\mathcal{N} = 1$ super-Poincaré algebra is, before imposing CPT, a pair of helicity states $(\lambda, \lambda + \frac{1}{2})$ for some λ, with exactly one state of each helicity. A CPT-invariant theory contains, in addition, the conjugate multiplet $(-\lambda - \frac{1}{2}, -\lambda)$; the full CPT-complete multiplet has four states with helicities $\{-\lambda - \frac{1}{2},\ -\lambda,\ \lambda,\ \lambda + \frac{1}{2}\}$, two bosonic and two fermionic.*

Proof. The first sentence is Theorem 44.17: by Eq. (44.92) one oscillator pair vanishes, the survivor obeys Eq. (44.94), and the unique irreducible Clifford module is two-dimensional with the helicities computed above. Each of the two states is a single helicity eigenstate, hence a one-dimensional rep of the surviving little-group generator J_3, exactly as for an ordinary massless particle (Section 3.7.3); irreducibility of the super-multiplet is the statement that the two helicities are linked by $b^\dagger$ and cannot be split into invariant subspaces. For the CPT statement, recall from Section 3.7.3 that CPT (like parity) reverses helicity, $h \mapsto -h$, and is an antiunitary symmetry that any local relativistic theory must possess. A multiplet $(\lambda, \lambda + \frac{1}{2})$ is not CPT-symmetric unless $\lambda + \frac{1}{2} = -\lambda$, i.e. $\lambda = -\frac{1}{4}$, which is not an allowed helicity by Eq. (3.217); therefore in every case CPT maps the multiplet to a distinct conjugate multiplet with helicities $(-\lambda - \frac{1}{2}, -\lambda)$, and a CPT-invariant theory must contain both.

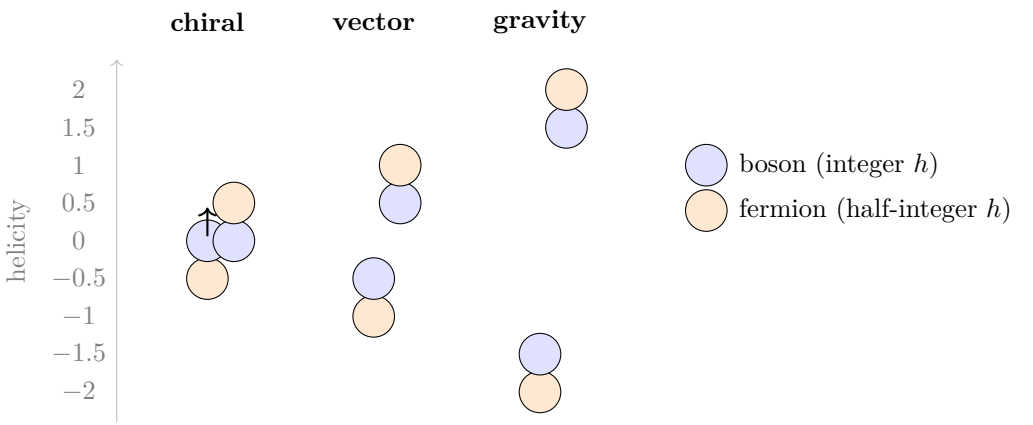

Figure 44.3: The three named CPT-complete massless $\mathcal{N}=1$ multiplets as helicity ladders. Each column shows the four helicity states of Theorem 44.18: a multiplet $(\lambda, \lambda+\frac{1}{2})$ (right pair in each column) together with its CPT conjugate $(-\lambda-\frac{1}{2}, -\lambda)$ (left pair). *Chiral* ($\lambda=0$): a Weyl fermion $\pm\frac{1}{2}$ and a complex scalar $0, 0$. *Vector* ($\lambda=\frac{1}{2}$): a gauge boson ±1 and a gaugino $\pm\frac{1}{2}$. *Gravity* ($\lambda=\frac{3}{2}$): a graviton ±2 and a gravitino $\pm\frac{3}{2}$.

The combined four states have helicities as listed. Counting bosons and fermions: half-integer helicities are fermionic and integer helicities bosonic, and the four values $\{-\lambda-\frac{1}{2}, -\lambda, \lambda, \lambda+\frac{1}{2}\}$ contain exactly two integers and two half-integers regardless of whether λ is integer or half-integer (if $\lambda\in\mathbb{Z}$ then $\lambda, -\lambda$ are bosonic and $\lambda\pm\frac{1}{2}$ fermionic; if $\lambda\in\mathbb{Z}+\frac{1}{2}$ the roles swap), so $n_B=n_F=2$, in agreement with Theorem 44.15. □

The proposition is the whole massless classification; the named multiplets are simply its small-λ instances. Figure 44.3 displays them as helicity ladders.

Worked Example 44.19 (The chiral and vector multiplets from the Clifford vacuum)**.** We build the two phenomenologically central $\mathcal{N}=1$ multiplets explicitly, in each case listing the Clifford-module states, applying CPT, and tabulating helicities and counts.

The chiral multiplet, $\lambda=0$. Take the Clifford vacuum to be a helicity-zero state, $|\Omega_0\rangle$. Equation (44.97) gives the two states

$$|\Omega_0\rangle \;\; (h=0), \qquad b^\dagger\,|\Omega_0\rangle \;\; (h=+\tfrac{1}{2}), \tag{44.98}$$

a scalar and a positive-helicity Weyl state. This pair is not CPT-complete: CPT produces the conjugate multiplet with helicities $(-\frac{1}{2}, 0)$, namely a negative-helicity Weyl state and a second scalar. Assembling both,

$$\text{chiral multiplet:} \qquad \underbrace{\{\,0,\;0\,\}}_{\text{complex scalar}} \;\cup\; \underbrace{\{\,+\tfrac{1}{2},\;-\tfrac{1}{2}\,\}}_{\text{Weyl fermion}}, \tag{44.99}$$

which is precisely one *complex* scalar field (its two real components are the two helicity-zero states, or equivalently a particle and its distinct antiparticle) and one Weyl fermion (the two helicities $\pm\frac{1}{2}$). The two helicity-0 states being a genuine complex scalar—rather than two unrelated reals—is the CPT statement that the scalar and its conjugate sit in conjugate multiplets; that the scalar carries no little-group index follows from Schur applied to the trivial helicity rep (Theorem 2.23). The state count is

$$n_B = \underbrace{2}_{\text{cplx scalar}} = n_F = \underbrace{2}_{\text{Weyl}}, \tag{44.100}$$

verifying $n_B = n_F$ (Theorem 44.15) on the nose.

The vector multiplet, $\lambda = \frac{1}{2}$. Now take the Clifford vacuum to carry helicity $\frac{1}{2}$, $\left|\Omega_{1/2}\right\rangle$. The two states are

$$\left|\Omega_{1/2}\right\rangle \ (h = +\tfrac{1}{2}), \qquad b^\dagger \left|\Omega_{1/2}\right\rangle \ (h = +1). \tag{44.101}$$

CPT adjoins the conjugate $(-1, -\frac{1}{2})$, and the complete multiplet is

$$\text{vector multiplet:} \quad \underbrace{\{+1,\ -1\}}_{\text{gauge boson}} \cup \underbrace{\{+\tfrac{1}{2},\ -\tfrac{1}{2}\}}_{\text{gaugino}}, \tag{44.102}$$

a massless vector (the two transverse helicities ± 1 of a gauge field) together with a single Weyl—equivalently Majorana—fermion in the same representation of any internal gauge group, the *gaugino*. (That the gaugino is forced into the adjoint, the same representation as the gauge boson, is a dynamical statement we establish when we gauge the theory in Chapter 45; here we have only the kinematic helicity content.) Again

$$n_B = \underbrace{2}_{\text{gauge boson}} = n_F = \underbrace{2}_{\text{gaugino}}. \tag{44.103}$$

For completeness, the next case $\lambda = \frac{3}{2}$ gives the $\mathcal{N} = 1$ *supergravity multiplet*: states $(\frac{3}{2}, 2)$ plus the CPT conjugate $(-2, -\frac{3}{2})$, i.e. helicities $\{\pm 2\} \cup \{\pm\frac{3}{2}\}$—a *graviton* (the two helicities of a massless spin-2 field) and a *gravitino* (a massless spin-$\frac{3}{2}$ field). It is the unique massless multiplet whose top helicity reaches 2, and it is the one the local version of supersymmetry—supergravity—is built on.

The chiral multiplet of Eq. (44.99)—a complex scalar plus a Weyl fermion—is the smallest nontrivial supermultiplet, and it is the one we will turn into an interacting field theory in the next section. Before that we record how the count grows with the number of supercharges, since the same Clifford-module logic dictates the entire menu of extended-supersymmetry multiplets and, with it, the famous upper bound on $\mathcal{N}$.

44.4.2 Extended supersymmetry: state counting and the spin bound

With $\mathcal{N}$ supercharges Q^I_α, $I = 1, \ldots, \mathcal{N}$ (and conjugates $\bar{Q}_{\dot\alpha I}$), the massless analysis repeats verbatim per index I. In the frame Eq. (44.89) the anticommutator $\left\{Q^I_\alpha, \bar{Q}_{\dot\beta J}\right\} = 2\,\sigma^\mu_{\alpha\dot\beta} P_\mu\, \delta^I_J$ again degenerates to rank one in the spinor indices, so for each I the pair $Q^I_1, \bar{Q}^I_{\dot 1}$ decouples by the positivity argument of Eq. (44.92), and we are left with $\mathcal{N}$ independent fermionic oscillators

$$b^\dagger_I \equiv \frac{Q^I_2}{2\sqrt{E}}, \qquad \left\{b_I, b^\dagger_J\right\} = \delta_{IJ}, \qquad \{b_I, b_J\} = \left\{b^\dagger_I, b^\dagger_J\right\} = 0, \tag{44.104}$$

each raising the helicity by $\frac{1}{2}$. (Massless central charges drop out: the $\left\{Q^I, Q^J\right\} \propto Z^{IJ}$ terms carry the rank-one $\epsilon_{\alpha\beta}$ structure that, contracted against the single surviving component, gives zero, so massless multiplets never feel Z^{IJ}.) The representation is the Fock space of $\mathcal{N}$ fermionic modes built on a Clifford vacuum $|\Omega_\lambda\rangle$ of helicity λ, with $b_I\,|\Omega_\lambda\rangle = 0$.

A fermionic Fock space on $\mathcal{N}$ modes has dimension $2^{\mathcal{N}}$: a state is specified by which subset of the $b^\dagger_I$ act on the vacuum, and there are $2^{\mathcal{N}}$ subsets. Organizing by the number k of creation operators, the states with k excitations are the $\binom{\mathcal{N}}{k}$ totally antisymmetric products $b^\dagger_{[I_1} \cdots b^\dagger_{I_k]}$, and they all carry helicity $\lambda + \frac{k}{2}$. Hence

$$\dim(\text{multiplet}) = \sum_{k=0}^{\mathcal{N}} \binom{\mathcal{N}}{k} = 2^{\mathcal{N}}, \qquad (\#\text{ states at helicity } \lambda + \tfrac{k}{2}) = \binom{\mathcal{N}}{k}. \tag{44.105}$$

The helicities run from λ (the vacuum) to $\lambda + \frac{\mathcal{N}}{2}$ (all oscillators excited), a range of $\frac{\mathcal{N}}{2}$. Bosons and fermions alternate with k, so the boson/fermion split is $n_B = \sum_{k\ \text{even}} \binom{\mathcal{N}}{k}$ and $n_F = \sum_{k\ \text{odd}} \binom{\mathcal{N}}{k}$; the binomial identity $\sum_k (-1)^k \binom{\mathcal{N}}{k} = (1-1)^{\mathcal{N}} = 0$ gives $n_B = n_F = 2^{\mathcal{N}-1}$, so $n_B = n_F$ holds for every $\mathcal{N}$, as it must.

Worked Example 44.20 (The $2^{\mathcal{N}}$ count and the spin-2 bound, for $\mathcal{N} = 1, 2, 4, 8$)**.** We carry the count explicitly for the four physically important cases and read off the bound on $\mathcal{N}$.

$\mathcal{N} = 1$ ($2^1 = 2$ states before CPT). One oscillator, helicities $(\lambda, \lambda + \frac{1}{2})$: the multiplets of Section 44.4.1.

$\mathcal{N} = 2$ ($2^2 = 4$ states). Helicities $\lambda, \lambda + \frac{1}{2}$ (twice), $\lambda + 1$, with multiplicities $\binom{2}{0}, \binom{2}{1}, \binom{2}{2} = 1, 2, 1$. Choosing the Clifford vacuum at $\lambda = -\frac{1}{2}$ gives helicities $\{-\frac{1}{2}, 0, 0, +\frac{1}{2}\}$—already CPT-self-conjugate—which is the $\mathcal{N} = 2$ *hypermultiplet*: two complex scalars and a Dirac fermion ($n_B = n_F = 4$). Choosing $\lambda = 0$ gives $\{0, \frac{1}{2}, \frac{1}{2}, 1\}$, whose CPT completion is the $\mathcal{N} = 2$ *vector multiplet*: a gauge boson, two Weyl fermions, and a complex scalar.

$\mathcal{N}=4$ *($2^4=16$ states).* Multiplicities $\binom{4}{k}=1,4,6,4,1$ for $k=0,\dots,4$. Putting the vacuum at $\lambda=-1$ centres the ladder on zero: helicities -1 (one state), $-\frac{1}{2}$ (four), 0 (six), $+\frac{1}{2}$ (four), $+1$ (one). This is already CPT-self-conjugate and is the unique $\mathcal{N}=4$ multiplet with maximal helicity 1: a single gauge boson ±1, four Weyl fermions ($\pm\frac{1}{2}$, four each by the $\binom{4}{1}=4$ degeneracy), and six real scalars (the $\binom{4}{2}=6$ states at $h=0$). It is the field content of $\mathcal{N}=4$ super-Yang–Mills. Note $n_B=1+1+6=8=4+4=n_F$. Because its top helicity is exactly 1, $\mathcal{N}=4$ is the largest extended supersymmetry whose multiplets contain no spin above 1: any larger $\mathcal{N}$ forces a helicity $\geq\frac{3}{2}$.

$\mathcal{N}=8$ *($2^8=256$ states).* Multiplicities $\binom{8}{k}=1,8,28,56,70,56,28,8,1$. With the vacuum at $\lambda=-2$ the helicities run symmetrically from -2 to $+2$: one graviton helicity $+2$ and one -2 (the $k=8$ and $k=0$ states), eight gravitini at each of $\pm\frac{3}{2}$, 28 vectors at each of ±1, 56 Weyl fermions at each of $\pm\frac{1}{2}$, and 70 real scalars at $h=0$. This is $\mathcal{N}=8$ supergravity. Its top helicity is exactly 2.

The bound. The pattern is now forced. A CPT-complete massless multiplet built on a Clifford vacuum spans a helicity range of width $\frac{\mathcal{N}}{2}$ on each side of the centre once CPT doubling is taken into account, so its maximal helicity can be made no smaller than $\frac{\mathcal{N}}{4}$ by the most symmetric choice of λ (centre the ladder on zero: $\lambda=-\frac{\mathcal{N}}{4}$, top helicity $+\frac{\mathcal{N}}{4}$). A consistent *interacting* theory of massless particles cannot contain a helicity exceeding 2: a massless particle of helicity $|h|>2$ admits no consistent long-range coupling. The argument is a soft-theorem one, carried out in full in this book in Section 63.6.1. A massless helicity-h quantum emitted softly off the external legs of an amplitude attaches with a universal factor $\sum_i g_i\,\epsilon_{\mu_1\cdots\mu_h}p_i^{\mu_1}\cdots p_i^{\mu_h}/(p_i\cdot q)$; invariance of the S-matrix under the longitudinal (pure-gauge) polarizations $\epsilon\to q$ demands that the residue $\sum_i g_i\,p_i^{\mu_1}\cdots p_i^{\mu_{h-1}}$ vanish for every configuration of the hard momenta. For $h=1$ this is $\sum_i g_i=0$, charge conservation, which *can* be satisfied (Eq. (63.73)); for $h=2$ it is $\sum_i g_i\,p_i^{\mu}=0$, satisfied by overall momentum conservation provided every g_i is equal—the universality of gravity (Eq. (63.77)). But for $h\geq3$ the condition $\sum_i g_i\,p_i^{\mu_1}\cdots p_i^{\mu_{h-1}}=0$ is an independent constraint on the hard momenta that no choice of nonzero couplings can meet for generic on-shell kinematics: there is no conserved current of rank >2 to which the particle could couple, and the soft limit is incompatible with a nontrivial S-matrix. We use only this conclusion here; the spin-1 and spin-2 cases are established in Section 63.6.1, and the classic statements are Weinberg's soft theorems and the Weinberg–Witten theorem [500]. Imposing $\frac{\mathcal{N}}{4}\leq2$ yields

$$\boxed{\mathcal{N}\leq8}\qquad\text{(local supersymmetry, spin}\leq2\text{, supergravity)},\tag{44.106}$$

saturated by $\mathcal{N}=8$ supergravity. If one insists on a theory *without* gravity—no helicity above 1—the same argument with $\frac{\mathcal{N}}{4}\leq1$ gives $\mathcal{N}\leq4$, saturated by $\mathcal{N}=4$ super-Yang–Mills. These two numbers, 4 and 8, are the reason

extended supersymmetry is so rigidly constrained: there are only finitely many supersymmetric theories of bounded spin, and the most symmetric ones are essentially unique.

Physical Insight

The spin bound is the supersymmetric echo of a theme from Chapter 3: the little group dictates everything. There, the non-compactness of the massless little group forced a massless particle to carry at most two helicity states. Here, each supercharge is a helicity-$\frac{1}{2}$ raising operator, so $\mathcal{N}$ of them necessarily generate a helicity spread of $\frac{\mathcal{N}}{2}$; the only way to keep all helicities physical ($|h| \leq 2$) is to limit $\mathcal{N}$. Supersymmetry cannot be made arbitrarily large precisely because spacetime has spin-2 gravity as its ceiling. Larger $\mathcal{N}$ would demand fundamental higher-spin massless particles, which the consistency of the S-matrix forbids.

44.4.3 Massive multiplets

For $m > 0$ there is a rest frame, and following Section 3.7.2 we fix the standard momentum

$$P^\mu = (m, 0, 0, 0), \qquad m > 0, \tag{44.107}$$

whose little group is the full SU(2) of spatial rotations. Now the right-hand side of the anticommutator does *not* degenerate: with $P_\mu = (m, 0, 0, 0)$,

$$\sigma^\mu_{\alpha\dot\beta} P_\mu = m\, \sigma^0_{\alpha\dot\beta} = m\, \delta_{\alpha\dot\beta}, \tag{44.108}$$

since $\sigma^0 = \mathbf{1}$, so

$$\left\{Q_\alpha, \bar Q_{\dot\beta}\right\} = 2m\, \delta_{\alpha\dot\beta}, \qquad \{Q_\alpha, Q_\beta\} = \left\{\bar Q_{\dot\alpha}, \bar Q_{\dot\beta}\right\} = 0. \tag{44.109}$$

Both spinor components survive: there is no positivity collapse because the diagonal entries $\left\{Q_1, \bar Q_{\dot 1}\right\} = \left\{Q_2, \bar Q_{\dot 2}\right\} = 2m$ are both nonzero. This is the algebraic reason massive multiplets are larger than massless ones—the light-like degeneration that killed half the oscillators is gone. Define two fermionic oscillators

$$a_\alpha \equiv \frac{Q_\alpha}{\sqrt{2m}}, \qquad a^\dagger_{\dot\alpha} \equiv \frac{\bar Q_{\dot\alpha}}{\sqrt{2m}}, \qquad \left\{a_\alpha, a^\dagger_{\dot\beta}\right\} = \delta_{\alpha\dot\beta}, \tag{44.110}$$

with all like-type anticommutators vanishing. We now have the Clifford algebra of *two* fermionic modes, whose irreducible module has dimension $2^2 = 4$. Crucially, the two creation operators $a^\dagger_{\dot 1}, a^\dagger_{\dot 2}$ carry the dotted spinor index of $(0, \frac{1}{2})$, so under the rest-frame little group SU(2) they form a spin-$\frac{1}{2}$ doublet. The multiplet is therefore not just four states but four states organized into definite SU(2) spins, built on a Clifford vacuum that is itself an SU(2) irrep.

Proposition 44.21 (Massive $\mathcal{N}=1$ irreducibles)**.** *Let the Clifford vacuum carry little-group spin j, i.e. be a $(2j+1)$-dimensional* SU(2) *irrep $|\Omega; j, m_j\rangle$ annihilated by both a_α. The massive $\mathcal{N}=1$ multiplet built on it has $4(2j+1)$ states, decomposing under spin as*

$$\underbrace{(j)}_{\text{vacuum}} \oplus \underbrace{(j+\tfrac{1}{2}) \oplus (j-\tfrac{1}{2})}_{\text{one } a^\dagger} \oplus \underbrace{(j)}_{\text{two } a^\dagger}, \tag{44.111}$$

where the $(j-\frac{1}{2})$ summand is absent when $j=0$, and $n_B = n_F = 2(2j+1)$.

Proof. The module is spanned by $|\Omega\rangle$, by $a^\dagger_{\dot\alpha}|\Omega\rangle$ ($\dot\alpha = 1,2$), and by $a^\dagger_{\dot 1} a^\dagger_{\dot 2}|\Omega\rangle$; the would-be states with three or more creation operators vanish because $(a^\dagger_{\dot 1})^2 = (a^\dagger_{\dot 2})^2 = 0$. Each level is a tensor product of the vacuum's SU(2) rep with the rep formed by the creation operators acting at that level. At zero excitations the states transform as the vacuum, spin j. At one excitation the single dotted index supplies a spin-$\frac{1}{2}$ factor, so the states transform as $(j)\otimes(\frac{1}{2}) = (j+\frac{1}{2})\oplus(j-\frac{1}{2})$ by the standard Clebsch–Gordan decomposition of SU(2) (with the lower branch absent at $j=0$, where $0\otimes\frac{1}{2} = \frac{1}{2}$ only). At two excitations the product $a^\dagger_{\dot 1} a^\dagger_{\dot 2}$ is antisymmetric in its two dotted indices; the antisymmetric part of $\frac{1}{2}\otimes\frac{1}{2}$ is the singlet, $\epsilon^{\dot\alpha\dot\beta} a^\dagger_{\dot\alpha} a^\dagger_{\dot\beta}$, so the two-excitation states again transform as the vacuum's spin j. Summing dimensions, $(2j+1) + 2(2j+1) + (2j+1) = 4(2j+1)$, which is the announced total. The level with one $a^\dagger$ is fermionic relative to the vacuum and the levels with zero or two are bosonic relative to it; the fermion number flips by one with each $a^\dagger$, so half the states—those with an odd number of excitations—are fermionic, giving $n_F = 2(2j+1) = n_B$, consistent with Theorem 44.15. Irreducibility under the full algebra is the statement that the supercharges link all four levels; that the little-group content at each level is as stated uses only that an intertwiner between SU(2) irreps is a multiple of the identity (Theorem 2.23), pinning the Clebsch–Gordan multiplicities to one. □

Worked Example 44.22 (The massive chiral and massive vector multiplets)**.** We instantiate Theorem 44.21 at the two smallest vacua.

Spin-0 vacuum: the massive chiral multiplet (4 states). With $j=0$, Eq. (44.111) reduces to $(0)\oplus(\frac{1}{2})\oplus(0)$: a spin-0 vacuum, a spin-$\frac{1}{2}$ doublet at one excitation, and a second spin-0 at two excitations. The content is therefore

$$\text{massive chiral:}\quad \underbrace{2\times\text{spin } 0}_{\text{2 real scalars}} \oplus \underbrace{\text{spin } \tfrac{1}{2}}_{\text{2 states}}, \tag{44.112}$$

i.e. two real scalars (equivalently one complex scalar) of mass m and one massive Majorana fermion of the same mass. The count is $n_B = 2$ (the two scalar states) and $n_F = 2$ (the spin-$\frac{1}{2}$ doublet), so $n_B = n_F = 2$. This is the massive avatar of the massless chiral multiplet Eq. (44.99): the same physical fields—a complex

scalar and a Weyl/Majorana fermion—now all massive and degenerate, exactly the degeneracy Theorem 44.12 demands.

Spin-$\frac{1}{2}$ vacuum: the massive vector multiplet (8 states). With $j = \frac{1}{2}$, Eq. (44.111) gives $(\frac{1}{2}) \oplus [(1) \oplus (0)] \oplus (\frac{1}{2})$: counting dimensions $2 + (3 + 1) + 2 = 8$. The content is

$$\text{massive vector:} \quad \underbrace{\text{spin } 1}_{3 \text{ states}} \oplus \underbrace{\text{spin } 0}_{1 \text{ state}} \oplus \underbrace{2 \times \text{spin } \tfrac{1}{2}}_{4 \text{ states}}, \tag{44.113}$$

a *massive* vector (three polarizations, including the longitudinal one absent in the massless case), one real scalar, and a massive Dirac fermion (the two spin-$\frac{1}{2}$ doublets combine into four fermionic states). The count is $n_B = 3 + 1 = 4$ and $n_F = 4$, so $n_B = n_F = 4$.

The contrast with the massless vector multiplet Eq. (44.102) is instructive and physically central. The massless vector multiplet has $2+2 = 4$ states; the massive one has $4 + 4 = 8$. The extra states are exactly a massless chiral multiplet's worth: a real scalar and an extra fermionic doublet, which supply the longitudinal polarization of the now-massive vector and the Dirac partner of the gaugino. This is the supersymmetric Higgs mechanism in embryo—a massless vector multiplet "eats" a chiral multiplet to become a massive vector multiplet, $4+4 = 8$ states all the way through—and it is the representation- theoretic reason a supersymmetric mass for a gauge field comes packaged with extra matter.

44.4.4 Central charges and BPS shortening

The massive analysis above used the $\mathcal{N} = 1$ algebra, where $\{Q_\alpha, Q_\beta\} = 0$. With extended supersymmetry the like-chirality anticommutator can acquire a Lorentz-scalar, internal-symmetry-antisymmetric piece, the *central charge*,

$$\left\{Q^I_\alpha, Q^J_\beta\right\} = 2\,\epsilon_{\alpha\beta}\,Z^{IJ}, \qquad Z^{IJ} = -Z^{JI}, \tag{44.114}$$

with Z^{IJ} commuting with everything in the algebra (hence "central"; that it must be a c-number on an irrep is again Schur, Theorem 2.23). Diagonalizing the antisymmetric Z^{IJ} into skew 2×2 blocks with skew-eigenvalues $Z_n \geq 0$, the rest-frame algebra organizes into oscillators whose anticommutators are shifted by $\pm Z_n$ relative to the $2m$ of Eq. (44.109). Positivity of the resulting oscillator norms—the same $\|\cdot\|^2 \geq 0$ argument as in Eq. (44.92), now applied block by block—forces the *Bogomolny–Prasad–Sommerfield (BPS) bound*

$$m \;\geq\; \max_n |Z_n|. \tag{44.115}$$

When the bound is saturated, $m = |Z_n|$ for one or more n, the corresponding oscillator anticommutator vanishes and that oscillator pair decouples *exactly as the second pair decoupled in the massless case* (Eq. (44.92)). The Clifford

module is then built on fewer oscillators and is correspondingly *shortened*: a BPS multiplet has fewer states than a generic massive multiplet of the same spin, interpolating in size between the generic massive ($2^{2\mathcal{N}}$) and massless ($2^{\mathcal{N}}$) counts. We will not need the detailed BPS representation theory here; we record only that the shortening is an algebraic consequence of saturating Eq. (44.115), that BPS states are stable for this reason, and that the quantitative theory of BPS spectra—and its spectacular use in extracting exact non-perturbative results—is developed in Chapter 46.

Physical Insight

The unifying picture across this section is a single dichotomy: an oscillator pair survives or it decouples, according to whether the relevant entry of the right-hand side of the anticommutator is nonzero or zero. Massless $\mathcal{N} = 1$: one pair survives (2 states). Massive $\mathcal{N} = 1$: both survive (4 states). Extended massive, generic: all $2\mathcal{N}$ pairs survive ($2^{2\mathcal{N}}$ states). Extended massive, BPS: some pairs decouple, shortening the multiplet. The massless multiplet is simply the extreme case where the degeneration is maximal because $P^2 = 0$, and the BPS multiplet is the intermediate case where it is partial because $m = |Z|$. The state counting, the $n_B = n_F$ equality, and the spin bound are all readings of this one mechanism.

With the representation theory in hand, the simplest multiplet is no longer an abstraction. The massless $\mathcal{N} = 1$ chiral multiplet of Eq. (44.99)—a single complex scalar together with a single Weyl fermion—is the minimal nontrivial supermultiplet, and it is the exact field content we must now endow with dynamics. In the next section we write down the free theory of a complex scalar and a Weyl fermion, ask what interactions are compatible with the supersymmetry algebra closing on these fields, and discover both the necessity of an auxiliary field for off-shell closure and the superpotential that organizes the interactions: the Wess–Zumino model.

44.5 The Wess–Zumino Model: On-Shell and Off-Shell SUSY

The representation theory of Section 44.4 handed us the smallest nontrivial package of supersymmetry: the *chiral multiplet* of Eq. (44.99), a complex scalar together with a single Weyl fermion, with equal numbers of bosonic and fermionic states. So far this is kinematics — a list of one-particle states forced to sit together by the algebra. The obvious next question is dynamical: can we write down a local field theory whose fields are exactly this multiplet, whose action is invariant under a symmetry that rotates the scalar into the fermion, and which realises the algebra Eqs. (44.61) to (44.63) on the fields? The answer

is the *Wess–Zumino model*, the hydrogen atom of supersymmetric field theory. Building it teaches three lessons that recur everywhere in the subject. First, that a transformation mixing a boson and a fermion is fixed almost entirely by dimensional analysis and Lorentz covariance, with only a handful of constants left to pin down by invariance. Second — and this is the central surprise — that the naive transformations close into a translation, as the algebra demands, *only when the fields obey their equations of motion*; off-shell the algebra fails by a term proportional to the Dirac operator. The cure is to enlarge the multiplet by a non-propagating *auxiliary field*, restoring the boson–fermion balance off-shell and closing the algebra identically. Third, that once the kinetic theory is in hand, all renormalisable interactions are governed by a single holomorphic function, the *superpotential* $W(\phi)$, whose first derivative squared is the scalar potential and whose second derivative is the Yukawa coupling — so that boson and fermion masses are locked together, exactly as the degeneracy theorem Theorem 44.12 promised.

Throughout we work in the two-component conventions fixed in Section 44.4: undotted indices are contracted descending, $\psi\chi \equiv \psi^{\alpha}\chi_{\alpha}$, dotted indices ascending, $\bar{\psi}\bar{\chi} \equiv \bar{\psi}_{\dot{\alpha}}\bar{\chi}^{\dot{\alpha}}$, with $\sigma^{\mu} = (\mathbf{1}, \vec{\sigma})$ and $\bar{\sigma}^{\mu} = (\mathbf{1}, -\vec{\sigma})$ of Eqs. (3.79) and (3.106), indices raised and lowered by the antisymmetric symbol ε of Eq. (3.107). The metric is mostly-minus and units are natural. The fermion ψ is a left-handed Weyl spinor in $(\tfrac{1}{2}, 0)$, ψ_{α}, with conjugate $\bar{\psi}_{\dot{\alpha}} = (\psi_{\alpha})^{\dagger}$; we will treat it as Grassmann-valued at the classical (anticommuting-field) level, exactly the algebra of Theorem 12.3, and its single-Weyl mass term is the Majorana mass of Sections 11.7.2 and 11.7.6.

44.5.1 The free Lagrangian and the SUSY transformations

The field content is a complex scalar ϕ and a left-handed Weyl fermion ψ_{α}. The unique Lorentz-invariant, renormalisable, free Lagrangian built from them is the sum of the canonical complex-scalar kinetic term and the canonical Weyl kinetic term,

$$\mathcal{L}_{\text{free}} \;=\; \partial_{\mu}\phi^{*}\,\partial^{\mu}\phi \;+\; i\,\bar{\psi}\,\bar{\sigma}^{\mu}\,\partial_{\mu}\psi, \tag{44.116}$$

where $\bar{\psi}\bar{\sigma}^{\mu}\partial_{\mu}\psi = \bar{\psi}_{\dot{\alpha}}\,\bar{\sigma}^{\mu\,\dot{\alpha}\beta}\,\partial_{\mu}\psi_{\beta}$ is the two-component reduction of the Dirac kinetic term of Chapter 11 for a single left-handed field. In mostly-minus natural units the canonical dimensions are $[\phi] = 1$ and $[\psi] = \tfrac{3}{2}$, as one reads off by demanding that each term in Eq. (44.116) have dimension 4.

We now look for an infinitesimal transformation that mixes ϕ and ψ and leaves the action invariant. The transformation must be a symmetry of fermionic type: it carries a constant spinor parameter ξ_{α}, anticommuting and of dimension $[\xi] = -\tfrac{1}{2}$, so that ξ multiplied into ψ has the dimension of ϕ and into ϕ has the dimension of ψ. (We write the parameter ξ rather than ε to avoid collision with the spinor metric $\varepsilon_{\alpha\beta}$.) The lowest-dimension covariant possibilities are essentially forced. A scalar of dimension 1 can be made from ξ and ψ only as

the invariant contraction $\xi\psi$; a spinor of dimension $\frac{3}{2}$ can be made from $\bar\xi$ and ϕ only by spending one derivative, as $(\sigma^\mu\bar\xi)\,\partial_\mu\phi$, which carries the correct single undotted index. We therefore postulate

$$\delta\phi = \sqrt{2}\,\xi\psi, \qquad \delta\psi_\alpha = \sqrt{2}\,c\;i\,(\sigma^\mu\bar\xi)_\alpha\,\partial_\mu\phi, \tag{44.117}$$

with $(\sigma^\mu\bar\xi)_\alpha = \sigma^\mu_{\alpha\dot\beta}\bar\xi^{\dot\beta}$, the overall $\sqrt{2}$ a conventional normalisation of $\delta\phi$, and a single real constant c to be fixed by invariance. The conjugate rules follow by Hermitian conjugation, using $(\xi\psi)^\dagger = \bar\psi\bar\xi = \bar\xi\bar\psi$ and the Hermiticity of σ^μ:

$$\delta\phi^* = \sqrt{2}\,\bar\xi\bar\psi, \qquad \delta\bar\psi_{\dot\alpha} = \sqrt{2}\,c\,(-i)\,(\xi\sigma^\mu)_{\dot\alpha}\,\partial_\mu\phi^*, \tag{44.118}$$

with $(\xi\sigma^\mu)_{\dot\alpha} = \xi^\beta\sigma^\mu_{\beta\dot\alpha}$.

Proposition 44.23 (Invariance of the free action fixes $c=-1$)**.** *With the choice $c=-1$ in Eq. (44.117), the action $S_{\text{free}} = \int \mathrm{d}^4x\,\mathcal{L}_{\text{free}}$ of Eq. (44.116) is invariant under Eqs. (44.117) and (44.118); the Lagrangian changes by a total derivative. No other value of c gives a symmetry.*

Proof. We track every term. The variation splits cleanly into two complex-conjugate sectors: one holding $(\bar\xi,\bar\psi,\phi)$ and the other (ξ,ψ,ϕ^*); they are conjugates, so it suffices to show one of them is a total derivative. Take the $(\bar\xi,\bar\psi,\phi)$ sector. It receives two contributions, one from varying ϕ^* in the scalar kinetic term and one from varying ψ in the fermion kinetic term:

$$\delta_D\mathcal{L}_{\text{free}} = \partial_\mu(\delta\phi^*)\,\partial^\mu\phi = \sqrt{2}\,\bar\xi\,(\partial_\mu\bar\psi)\,\partial^\mu\phi, \tag{44.119}$$

$$\begin{aligned}\delta_A\mathcal{L}_{\text{free}} &= i\,\bar\psi\bar\sigma^\mu\partial_\mu(\delta\psi) = i\,\bar\psi_{\dot\alpha}\bar\sigma^{\mu\,\dot\alpha\beta}\,\partial_\mu(\sqrt{2}\,c\,i\,\sigma^\nu_{\beta\dot\gamma}\bar\xi^{\dot\gamma}\partial_\nu\phi)\\ &= -\sqrt{2}\,c\,\bar\psi_{\dot\alpha}\,(\bar\sigma^\mu\sigma^\nu)^{\dot\alpha}{}_{\dot\gamma}\,\bar\xi^{\dot\gamma}\,\partial_\mu\partial_\nu\phi.\end{aligned} \tag{44.120}$$

The constant parameter $\bar\xi$ passes through the derivative. In Eq. (44.120) the two derivatives are symmetric in $\mu\nu$, so only the symmetric part of $\bar\sigma^\mu\sigma^\nu$ survives. The two-component Clifford identity (proved blockwise in Section 3.4.3)

$$(\bar\sigma^\mu\sigma^\nu + \bar\sigma^\nu\sigma^\mu)^{\dot\alpha}{}_{\dot\gamma} = 2\,\eta^{\mu\nu}\,\delta^{\dot\alpha}{}_{\dot\gamma} \tag{44.121}$$

then collapses the structure to $\eta^{\mu\nu}\partial_\mu\partial_\nu = \Box$, giving $\delta_A\mathcal{L}_{\text{free}} = -\sqrt{2}\,c\;\bar\psi\bar\xi\,\Box\phi = -\sqrt{2}\,c\;\bar\xi\bar\psi\,\Box\phi$, where we used the symmetry $\bar\psi\bar\xi = \bar\xi\bar\psi$ of Grassmann-spinor contractions. Now integrate Eq. (44.119) by parts inside the action, moving ∂_μ off $\bar\psi$:

$$\int \mathrm{d}^4x\,\delta_D\mathcal{L}_{\text{free}} = -\sqrt{2}\int \mathrm{d}^4x\,\bar\xi\,\bar\psi\,\Box\phi. \tag{44.122}$$

Adding the two,

$$\int \mathrm{d}^4x\,(\delta_A+\delta_D)\mathcal{L}_{\text{free}} = -\sqrt{2}\,(c+1)\int \mathrm{d}^4x\,\bar\xi\,\bar\psi\,\Box\phi. \tag{44.123}$$

This vanishes for all field configurations if and only if $c = -1$, and then the two terms combine into the total derivative $\partial_\mu(\sqrt{2}\,\bar\xi\,\bar\psi\,\partial^\mu\phi)$ as one checks by reversing the integration by parts. The conjugate sector (ξ, ψ, ϕ^*) is the complex conjugate of this computation and likewise reduces to a total derivative when $c = -1$. Hence the action is invariant, and only for $c = -1$. □

From here on we fix $c = -1$ and write the *on-shell* Wess–Zumino transformations

$$\boxed{\delta\phi = \sqrt{2}\,\xi\psi, \qquad \delta\psi_\alpha = -\sqrt{2}\,i\,(\sigma^\mu\bar\xi)_\alpha\,\partial_\mu\phi} \tag{44.124}$$

together with their conjugates. The label *on-shell* anticipates the defect we now expose.

Why a derivative is unavoidable

The transformation $\delta\psi$ *must* carry a derivative of ϕ. A SUSY parameter has dimension $-\frac{1}{2}$, the scalar has dimension 1, and the fermion has dimension $\frac{3}{2}$; the arithmetic $-\frac{1}{2}+1 = \frac{1}{2}$ falls short of $\frac{3}{2}$ by exactly one unit of dimension, which only a ∂_μ can supply. This is the seed of the entire structure: because one side of the transformation carries a derivative and the other does not, composing two transformations produces a single net derivative — a translation. Supersymmetry is, quite literally, a square root of spacetime translation, and Eq. (44.61) is that statement at the level of the algebra.

44.5.2 On-shell closure, and its failure

The algebra Eq. (44.61) demands that the commutator of two supersymmetry transformations, with parameters ξ_1 and ξ_2, be a translation. On fields, a translation by a^μ acts as $a^\mu\partial_\mu$. We test this directly. It is convenient to abbreviate the translation parameter that should emerge,

$$a^\mu \;\equiv\; 2i(\xi_1\sigma^\mu\bar\xi_2 - \xi_2\sigma^\mu\bar\xi_1), \tag{44.125}$$

which is real and antisymmetric under $1 \leftrightarrow 2$, exactly the structure $\{Q, \bar Q\} = 2\sigma^\mu P_\mu$ produces when sandwiched between two parameters.

Closure on the scalar. Using Eq. (44.124),

$$\delta_1\delta_2\,\phi = \sqrt{2}\,\xi_2\,\delta_1\psi = \sqrt{2}\,\xi_2^\alpha(-\sqrt{2}\,i\,\sigma^\mu_{\alpha\dot\beta}\bar\xi_1^{\dot\beta}\partial_\mu\phi) = -2i\,(\xi_2\sigma^\mu\bar\xi_1)\,\partial_\mu\phi. \tag{44.126}$$

Antisymmetrising in $1 \leftrightarrow 2$,

$$[\delta_1, \delta_2]\,\phi = -2i(\xi_2\sigma^\mu\bar\xi_1 - \xi_1\sigma^\mu\bar\xi_2)\partial_\mu\phi = a^\mu\,\partial_\mu\phi. \tag{44.127}$$

The algebra closes on ϕ *identically* — no equation of motion was used. The commutator is precisely the translation Eq. (44.125).

Closure on the fermion. Here the story changes. With $\delta_2\psi_\alpha = -\sqrt{2}\, i\,(\sigma^\mu\bar\xi_2)_\alpha\partial_\mu\phi$ and $\delta_1\phi = \sqrt{2}\,\xi_1\psi$,

$$\delta_1\delta_2\,\psi_\alpha = -\sqrt{2}\, i\,\sigma^\mu_{\alpha\dot\beta}\bar\xi_2^{\dot\beta}\,\partial_\mu(\delta_1\phi) = -2i\,\sigma^\mu_{\alpha\dot\beta}\bar\xi_2^{\dot\beta}\,\xi_1^\gamma\,\partial_\mu\psi_\gamma. \tag{44.128}$$

The obstruction is that $\partial_\mu\psi_\gamma$ carries its spinor index γ contracted into ξ_1, not free; to compare with $a^\mu\partial_\mu\psi_\alpha$ we must move the free index onto ψ. This rearrangement is a Fierz identity. The clean tool is the *Schouten identity*: for any three anticommuting two-component spinors λ,χ,ρ,

$$\lambda_\alpha(\chi\rho) + \chi_\alpha(\rho\lambda) + \rho_\alpha(\lambda\chi) = 0, \tag{44.129}$$

which holds because the left-hand side is totally antisymmetric in the three two-valued indices it would take to write all spinors with a lower index, and no nonzero totally antisymmetric object exists on three values of a two-dimensional index. Apply Eq. (44.129) with $\lambda_\alpha = (\sigma^\mu\bar\xi_2)_\alpha$, $\chi = \xi_1$, $\rho = \partial_\mu\psi$:

$$(\sigma^\mu\bar\xi_2)_\alpha\,(\xi_1\partial_\mu\psi) = -\,\xi_{1\alpha}\,(\partial_\mu\psi\,\sigma^\mu\bar\xi_2) - (\partial_\mu\psi)_\alpha\,(\sigma^\mu\bar\xi_2\,\xi_1). \tag{44.130}$$

In the last factor $(\sigma^\mu\bar\xi_2\,\xi_1) = (\sigma^\mu\bar\xi_2)^\gamma\xi_{1\gamma} = \xi_1\sigma^\mu\bar\xi_2$ by Grassmann symmetry of the undotted contraction. In the middle factor we use the standard reordering identity for anticommuting spinors,

$$\chi\,\sigma^\mu\,\bar\eta = -\,\bar\eta\,\bar\sigma^\mu\,\chi, \tag{44.131}$$

(the minus sign is the Grassmann reordering, traced through the ε-symbols in Eq. (3.107)), so that $\partial_\mu\psi\,\sigma^\mu\bar\xi_2 = -\bar\xi_2\bar\sigma^\mu\partial_\mu\psi$. Inserting Eq. (44.130) into Eq. (44.128) and antisymmetrising, the piece proportional to $(\partial_\mu\psi)_\alpha$ assembles into the translation, while the piece proportional to ξ_α assembles into the Dirac operator:

$$[\delta_1,\delta_2]\,\psi_\alpha = a^\mu\,\partial_\mu\psi_\alpha \;+\; 2i\Big[\,\xi_{2\alpha}\,(\bar\xi_1\bar\sigma^\mu\partial_\mu\psi) - \xi_{1\alpha}\,(\bar\xi_2\bar\sigma^\mu\partial_\mu\psi)\Big]. \tag{44.132}$$

The first term is the translation Eq. (44.125), identical to that on ϕ. The second term is the defect: it is proportional to $\bar\sigma^\mu\partial_\mu\psi$, which is *nothing but the free Weyl equation of motion* obtained by varying Eq. (44.116), $i\,\bar\sigma^\mu\partial_\mu\psi = 0$. On-shell the defect vanishes and the algebra closes; off-shell it does not.

Theorem 44.24 (On-shell-only closure of the naive algebra)**.** *Under the transformations Eq. (44.124), the commutator of two supersymmetry variations reproduces the translation Eq. (44.125) on the scalar identically (Eq. (44.127)) and on the fermion only up to a term proportional to the fermion equation of motion (Eq. (44.132)). The supersymmetry algebra therefore closes on the field ψ only when ψ obeys its Dirac equation.*

This is not a defect of our particular ansatz; it is structural, and counting reveals why. A complex scalar has two real off-shell components; the equation of motion is second order and removes none of them at the level of field content (it propagates two real on-shell degrees of freedom). A Weyl fermion ψ_α has four real off-shell components — two complex components — but its equation of motion is first order, halving the count to two real on-shell degrees of freedom. Thus on-shell the multiplet balances, $2_B = 2_F$, exactly as the representation theory of Section 44.4 demanded; but off-shell it does not, $2_B \neq 4_F$. A symmetry that rotates bosons into fermions cannot close on a mismatched set of fields, because the commutator of two such rotations must map the field content back into itself without invoking the dynamics. The missing two bosonic components are exactly what we must supply.

44.5.3 The auxiliary field and off-shell closure

We restore the balance by adjoining a second complex scalar F, of canonical dimension $[F] = 2$ — one unit higher than ϕ — whose kinetic term we deliberately omit. The free Lagrangian becomes

$$\mathcal{L}_{\text{free}} = \partial_\mu \phi^* \partial^\mu \phi + i\,\bar\psi \bar\sigma^\mu \partial_\mu \psi + F^* F. \tag{44.133}$$

The term F^*F carries no derivatives, so F is *auxiliary*: its Euler–Lagrange equation is the purely algebraic $F = 0$ in the free theory, and it propagates no states. Off-shell, however, it contributes two real bosonic components, restoring $4_B = 4_F$ and giving us exactly the slack needed to close the algebra. The transformations must be augmented so that F is part of the multiplet. Dimensional analysis again narrows the choice: δF has the dimension of F, namely 2, and since the parameter $\bar\xi$ carries dimension $-\tfrac{1}{2}$ the remaining factor must have dimension $\tfrac{5}{2}$. The only Lorentz-scalar of that dimension built from $\bar\xi$ and ψ is $\bar\xi \bar\sigma^\mu \partial_\mu \psi$, in which the single derivative supplies the extra unit. We take the off-shell transformations

$$\boxed{\delta\phi = \sqrt{2}\,\xi\psi, \qquad \delta\psi_\alpha = \sqrt{2}\,\xi_\alpha F - \sqrt{2}\,i\,(\sigma^\mu \bar\xi)_\alpha \partial_\mu \phi, \qquad \delta F = -\sqrt{2}\,i\,\bar\xi \bar\sigma^\mu \partial_\mu \psi,} \tag{44.134}$$

the new pieces being the inhomogeneous $\sqrt{2}\,\xi_\alpha F$ added to $\delta\psi$ and the transformation of F itself, with coefficients we now justify by demanding (i) invariance of Eq. (44.133) and (ii) off-shell closure.

Invariance. The pieces of Eq. (44.134) not involving F already leave Eq. (44.116) invariant by Theorem 44.23. The new contributions are: from the ξF piece of $\delta\psi$ and the $\bar\xi F^*$ piece of $\delta\bar\psi$ acting on the fermion kinetic term, and from $\delta(F^*F)$. Collecting them,

$$i\,\bar\psi\bar\sigma^\mu \partial_\mu(\sqrt{2}\,\xi F) + i\,(\sqrt{2}\,\bar\xi F^*)\bar\sigma^\mu\partial_\mu\psi = i\sqrt{2}\,(\bar\psi\bar\sigma^\mu\xi)\,\partial_\mu F + i\sqrt{2}\,F^*(\bar\xi\bar\sigma^\mu\partial_\mu\psi), \tag{44.135}$$

$$\delta(F^*F) = (\delta F^*)F + F^*\delta F = i\sqrt{2}\,(\partial_\mu\bar\psi\,\bar\sigma^\mu\xi)\,F - i\sqrt{2}\,F^*(\bar\xi\bar\sigma^\mu\partial_\mu\psi), \tag{44.136}$$

where $\delta F^* = (\delta F)^\dagger = +i\sqrt{2}\,\partial_\mu\bar\psi\,\bar\sigma^\mu\xi$ follows from $(\bar\xi\bar\sigma^\mu\chi)^\dagger = \bar\chi\bar\sigma^\mu\xi$. The two terms carrying F^* cancel between Eqs. (44.135) and (44.136), and the two terms carrying F combine into the total derivative $i\sqrt{2}\,\partial_\mu\big[(\bar\psi\bar\sigma^\mu\xi)\,F\big]$. Hence Eq. (44.133) is supersymmetric, and the coefficient of δF is fixed (up to the sign we are about to need for closure).

Closure. Recompute the commutator on ψ, now with the F-term present. The derivative piece of $\delta\psi$ reproduces Eq. (44.132) exactly — translation plus the equation-of-motion defect — and the new ξF piece contributes

$$\delta_1\delta_2\,\psi_\alpha\Big|_F = \sqrt{2}\,\xi_{2\alpha}\,\delta_1 F = \sqrt{2}\,\xi_{2\alpha}(-\sqrt{2}\,i\,\bar\xi_1\bar\sigma^\mu\partial_\mu\psi) = -2i\,\xi_{2\alpha}\,(\bar\xi_1\bar\sigma^\mu\partial_\mu\psi). \tag{44.137}$$

Antisymmetrising in $1 \leftrightarrow 2$ gives $-2i\big[\xi_{2\alpha}(\bar\xi_1\bar\sigma^\mu\partial_\mu\psi) - \xi_{1\alpha}(\bar\xi_2\bar\sigma^\mu\partial_\mu\psi)\big]$, which is precisely the negative of the defect term in Eq. (44.132). The two cancel, and

$$[\delta_1,\delta_2]\,\psi_\alpha = a^\mu\,\partial_\mu\psi_\alpha \qquad \text{(off-shell, no equation of motion used).} \tag{44.138}$$

The sign of δF in Eq. (44.134) is exactly the one that makes this cancellation occur; this is what fixed it. It remains to check that the algebra also closes on F. Using Eq. (44.134),

$$\begin{aligned}\delta_1\delta_2\,F &= -\sqrt{2}\,i\,\bar\xi_2\bar\sigma^\mu\partial_\mu(\delta_1\psi) = -\sqrt{2}\,i\,\bar\xi_2\bar\sigma^\mu\partial_\mu(\sqrt{2}\,\xi_1 F - \sqrt{2}\,i\,\sigma^\nu\bar\xi_1\partial_\nu\phi)\\ &= -2i\,(\bar\xi_2\bar\sigma^\mu\xi_1)\,\partial_\mu F - 2\,(\bar\xi_2\bar\sigma^\mu\sigma^\nu\bar\xi_1)\,\partial_\mu\partial_\nu\phi.\end{aligned} \tag{44.139}$$

In the second term the symmetric-in-$\mu\nu$ derivatives project onto $\bar\sigma^\mu\sigma^\nu \to \eta^{\mu\nu}$ by Eq. (44.121), giving $-2(\bar\xi_2\bar\xi_1)\Box\phi$; under antisymmetrisation $\bar\xi_2\bar\xi_1 - \bar\xi_1\bar\xi_2 = 0$ and it drops out entirely. In the first term, using $\bar\xi\bar\sigma^\mu\xi' = -\xi'\sigma^\mu\bar\xi$ (the identity Eq. (44.131)),

$$[\delta_1,\delta_2]\,F = -2i(\bar\xi_2\bar\sigma^\mu\xi_1 - \bar\xi_1\bar\sigma^\mu\xi_2)\partial_\mu F = 2i(\xi_1\sigma^\mu\bar\xi_2 - \xi_2\sigma^\mu\bar\xi_1)\partial_\mu F = a^\mu\,\partial_\mu F. \tag{44.140}$$

The same translation a^μ closes on all three fields, with no recourse to any equation of motion.

Definition 44.25 (Off-shell chiral multiplet and its degree-of-freedom count)**.** The *off-shell chiral multiplet* is the triple (ϕ,ψ_α,F) of a complex scalar ϕ, a left-handed Weyl fermion ψ_α, and a complex auxiliary scalar F, transforming under Eq. (44.134). Its real component counts are

$$\underbrace{\phi:2 \;+\; F:2}_{n_B=4\ \text{(off-shell)}} = \underbrace{\psi:4}_{n_F=4\ \text{(off-shell)}}, \qquad \underbrace{\phi:2}_{n_B=2\ \text{(on-shell)}} = \underbrace{\psi:2}_{n_F=2\ \text{(on-shell)}}, \tag{44.141}$$

the auxiliary field carrying the two bosonic components needed to match the off-shell fermion and disappearing on-shell, where $F = 0$.

What the auxiliary field buys

The price of F is one non-dynamical complex field; the payoff is that supersymmetry becomes an *off-shell* symmetry — a symmetry of the action realised on the fields irrespective of the dynamics. This matters far beyond bookkeeping. An off-shell symmetry can be used in the path integral before the equations of motion are imposed, it survives quantum corrections in a controlled way, and it allows the algebra to be represented *linearly* on a fixed set of fields. The geometric repackaging of Section 44.6 will make the auxiliary field appear automatically, as the highest component of a superfield; here we have discovered it the hard way, by demanding closure.

44.5.4 The superpotential, the Yukawa coupling, and the scalar potential

With an off-shell-closing free theory in hand we can add interactions. The remarkable fact is that renormalisable, supersymmetric self-interactions of a single chiral multiplet are governed entirely by one holomorphic function of ϕ alone, the *superpotential* $W(\phi)$. We add to Eq. (44.133) the interaction Lagrangian

$$\mathcal{L}_W = F\,W'(\phi) - \tfrac{1}{2}\,W''(\phi)\,\psi\psi + \text{h.c.}, \qquad W' \equiv \frac{\mathrm{d}W}{\mathrm{d}\phi}, \quad W'' \equiv \frac{\mathrm{d}^2W}{\mathrm{d}\phi^2}, \tag{44.142}$$

where "h.c." adds the Hermitian conjugate $F^*\,\overline{W'} - \tfrac{1}{2}\,\overline{W''}\,\bar\psi\bar\psi$. The structure is fixed by dimensions and covariance: FW' is the unique dimension-4 scalar linear in F, and $W''\psi\psi$ the unique dimension-4 scalar bilinear in ψ, provided W is a function of ϕ but not of ϕ^*. That last requirement — holomorphy of the superpotential — is not an assumption but a consequence of supersymmetry, as the invariance proof reveals.

Proposition 44.26 (SUSY invariance forces W holomorphic)**.** *The action $\int \mathrm{d}^4x\,(\mathcal{L}_{\text{free}} + \mathcal{L}_W)$ is invariant under Eq. (44.134) if and only if W depends on ϕ alone. When it does, $\mathcal{L}_W$ changes by a total derivative.*

Proof. Vary Eq. (44.142), holding the free-action invariance already established. Using $\delta(W') = W''\,\delta\phi = \sqrt{2}\,W''(\xi\psi)$, $\delta(W'') = \sqrt{2}\,W'''(\xi\psi)$, and $\delta(\psi\psi) = 2\,\psi^\alpha\delta\psi_\alpha = 2\sqrt{2}\,\psi^\alpha(\xi_\alpha F - i(\sigma^\mu\bar\xi)_\alpha\partial_\mu\phi)$,

$$\delta\mathcal{L}_W = (\delta F)W' + F\,\delta W' - \tfrac{1}{2}(\delta W'')\psi\psi - \tfrac{1}{2}W''\,\delta(\psi\psi). \tag{44.143}$$

Group the terms. *(i) The F-dependent terms.* These are $F\,\delta W' - \tfrac{1}{2}W''\,\delta(\psi\psi)\big|_F = \sqrt{2}\,FW''(\xi\psi) - \sqrt{2}\,W''\,F\,(\psi^\alpha\xi_\alpha)$. Since $\psi^\alpha\xi_\alpha = \psi\xi = \xi\psi$, these cancel exactly.

(ii) The W''' term. This is $-\frac{\sqrt{2}}{2}\,W'''\,(\xi\psi)(\psi\psi)$, and it vanishes identically: the product contains three factors of the two-component anticommuting spinor ψ, and any product of three such (with only two independent components) is zero. *(iii) The derivative terms.* What remains is

$$(\delta F)W' - \tfrac{1}{2}W''\,\delta(\psi\psi)\big|_{\partial\phi} = -\sqrt{2}\,i\,W'\,(\bar{\xi}\bar{\sigma}^{\mu}\partial_{\mu}\psi) + \sqrt{2}\,i\,W''\,(\psi\sigma^{\mu}\bar{\xi})\,\partial_{\mu}\phi. \tag{44.144}$$

Use $\psi\sigma^{\mu}\bar{\xi} = -\bar{\xi}\bar{\sigma}^{\mu}\psi$ from Eq. (44.131) and the chain rule $W''\,\partial_{\mu}\phi = \partial_{\mu}(W'(\phi))$ — valid precisely because W' is a function of ϕ only, so that $\partial_{\mu}W'$ has no $\partial_{\mu}\phi^{*}$ piece. Then

$$\delta\mathcal{L}_{W}\big|_{\partial} = -\sqrt{2}\,i\Big[W'\,(\bar{\xi}\bar{\sigma}^{\mu}\partial_{\mu}\psi) + (\partial_{\mu}W')\,(\bar{\xi}\bar{\sigma}^{\mu}\psi)\Big] = -\sqrt{2}\,i\,\partial_{\mu}\big[\,W'\,(\bar{\xi}\bar{\sigma}^{\mu}\psi)\,\big], \tag{44.145}$$

a total derivative. Had W contained any ϕ^{*}, the chain rule in Eq. (44.145) would have produced an extra term $(\partial W'/\partial\phi^{*})(\partial_{\mu}\phi^{*})(\bar{\xi}\bar{\sigma}^{\mu}\psi)$ with no partner to cancel it, spoiling invariance. The h.c. part is the conjugate of this computation and is separately a total derivative. Hence the interacting action is supersymmetric exactly when $W = W(\phi)$. □

Integrating out the auxiliary field. The field F appears in $\mathcal{L}_{\text{free}} + \mathcal{L}_{W}$ only algebraically:

$$\mathcal{L} \supset F^{*}F + F\,W'(\phi) + F^{*}\,\overline{W'(\phi)}. \tag{44.146}$$

Its equation of motion is purely algebraic. Varying with respect to F^{*},

$$\frac{\partial\mathcal{L}}{\partial F^{*}} = F + \overline{W'(\phi)} = 0 \qquad\Longrightarrow\qquad F = -\,\overline{W'(\phi)}, \quad F^{*} = -\,W'(\phi). \tag{44.147}$$

Substituting back into Eq. (44.146), $F^{*}F \to |W'|^{2}$, $FW' \to -|W'|^{2}$, $F^{*}\overline{W'} \to -|W'|^{2}$, so the three terms collapse to $-|W'(\phi)|^{2}$. Since the Lagrangian contains the potential as $\mathcal{L} \supset -V$, we read off the central result.

Theorem 44.27 (Scalar potential of the Wess–Zumino model)**.** *After eliminating the auxiliary field through its equation of motion Eq. (44.147), the Wess–Zumino model is the theory of (ϕ, ψ) with Lagrangian*

$$\mathcal{L} = \partial_{\mu}\phi^{*}\partial^{\mu}\phi + i\,\bar{\psi}\bar{\sigma}^{\mu}\partial_{\mu}\psi - \Big(\tfrac{1}{2}\,W''(\phi)\,\psi\psi + h.c.\Big) - V(\phi,\phi^{*}), \tag{44.148}$$

with scalar potential

$$\boxed{V(\phi,\phi^{*}) = \big|W'(\phi)\big|^{2} = \left|\frac{\partial W}{\partial\phi}\right|^{2}.} \tag{44.149}$$

The fermion mass and self-interactions are carried by the Yukawa term $-\frac{1}{2}W''(\phi)\psi\psi+$ h.c.

Three features of Eq. (44.149) deserve emphasis. First, $V \geq 0$ automatically, manifesting at the Lagrangian level the positivity of energy proved abstractly from the algebra in Theorem 44.9: the scalar potential of any $\mathcal{N} = 1$ theory is a sum of squares. Second, supersymmetry is unbroken in a vacuum ϕ_0 if and only if $V(\phi_0) = 0$, i.e. $W'(\phi_0) = 0$ — the algebraic condition $F = 0$ of Eq. (44.147) is precisely the statement that the auxiliary field's expectation value, the order parameter $\langle F \rangle$, vanishes. This is the same diagnostic as Theorem 44.10, now concrete: SUSY breaks when W' has no zero. Third, the Yukawa coupling W'' and the scalar potential $|W'|^2$ are not independent — both descend from the single function W — which is why boson and fermion masses will turn out locked together.

44.5.5 The cubic Wess–Zumino model

The simplest interacting choice is a cubic superpotential, the unique renormalisable option: a quartic or higher W would give a scalar potential $|W'|^2$ of degree six or more, non-renormalisable in four dimensions. We carry the cubic model in full.

Worked Example 44.28 (The cubic superpotential and boson–fermion mass degeneracy)**.** Take

$$W(\phi) = \frac{m}{2}\,\phi^2 + \frac{g}{3}\,\phi^3, \qquad W'(\phi) = m\phi + g\phi^2, \qquad W''(\phi) = m + 2g\phi, \tag{44.150}$$

with m a mass and g a dimensionless coupling. We extract the component interactions and verify that the boson and fermion masses coincide.

Scalar potential. From Eq. (44.149),

$$\begin{aligned} V = \left|m\phi + g\phi^2\right|^2 &= (m\phi + g\phi^2)(m\phi^* + g\phi^{*2}) \\ &= m^2\,|\phi|^2 \;+\; mg\,|\phi|^2(\phi + \phi^*) \;+\; g^2\,|\phi|^4. \end{aligned} \tag{44.151}$$

The quadratic piece $m^2|\phi|^2$ is the mass term of a complex scalar; reading off the coefficient against the canonical $m^2_{\text{scalar}}|\phi|^2$, the scalar mass is $m_{\text{scalar}} = m$. The cubic term $mg\,|\phi|^2(\phi + \phi^*)$ is a scalar self-interaction of strength mg, and the quartic term is $g^2|\phi|^4$.

Yukawa and fermion mass. From the Yukawa term in Eq. (44.148),

$$-\tfrac{1}{2}\,W''(\phi)\,\psi\psi + \text{h.c.} = -\frac{m}{2}\,\psi\psi - g\,\phi\,\psi\psi - \frac{m}{2}\,\bar\psi\bar\psi - g\,\phi^*\,\bar\psi\bar\psi. \tag{44.152}$$

The ϕ-independent piece $-\frac{m}{2}(\psi\psi + \bar\psi\bar\psi)$ is a Majorana mass term for the Weyl fermion (Sections 11.7.2 and 11.7.6) of magnitude m: the fermion mass is $m_{\text{fermion}} = m$. The remaining $-g\,\phi\,\psi\psi + \text{h.c.}$ is a genuine Yukawa coupling of strength g between the scalar and the fermion bilinear.

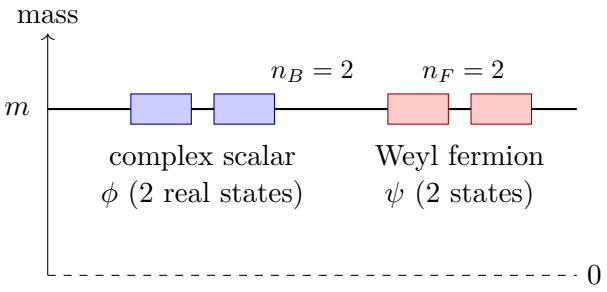

Figure 44.4: On-shell spectrum of the cubic Wess–Zumino model. The complex scalar ϕ and the Weyl fermion ψ are degenerate at the single mass m, with equal state counts $n_B = n_F = 2$ — the field-theoretic face of the multiplet degeneracy Theorem 44.12 and the equal-count theorem Theorem 44.15.

Mass degeneracy. Comparing,

$$m_{\text{scalar}} = m = m_{\text{fermion}}, \tag{44.153}$$

the complex scalar (both real components) and the Weyl fermion share the single mass m. This is the field-theoretic realisation of the multiplet degeneracy Theorem 44.12: every state in a multiplet of unbroken supersymmetry carries the same mass, here visible directly in the Lagrangian as the common coefficient m tying W' and W'' together. The degeneracy is no accident of the cubic choice; it follows from $V = |W'|^2$ and Yukawa $= W''$ sharing the single function W, so that $\partial^2 V/\partial\phi\partial\phi^*\big|_{\phi=0} = |W''(0)|^2 = m^2$ is exactly the square of the fermion mass $W''(0) = m$.

The mass spectrum is summarised in Fig. 44.4: a single level m shared by two real bosonic states and the two fermionic states.

The Wess–Zumino model as a supersymmetric completion of $\lambda\phi^4$

The quartic term $g^2|\phi|^4$ in Eq. (44.151) is a self-interaction of exactly the type carried since Chapter 6 as ϕ^4 theory. Writing the complex scalar in real components, $\phi = (\phi_1 + i\phi_2)/\sqrt{2}$, gives $g^2|\phi|^4 = \frac{g^2}{4}(\phi_1^2 + \phi_2^2)^2$, a quartic potential for the two real scalars with coupling set by g^2. The Wess–Zumino model is thus a supersymmetric completion of the scalar quartic theory: it contains the $\lambda\phi^4$-type interaction, but with the quartic coupling no longer free. Supersymmetry rigidly ties the quartic strength g^2 to the Yukawa coupling g of Eq. (44.152) and to the cubic scalar coupling mg, all descending from the single superpotential coefficient g. This rigidity is the source of the celebrated ultraviolet softness of supersymmetric theories: the same coupling controlling the boson self-interaction also controls the

fermion loop that cancels much of its divergence, a structural cancellation we return to in Chapters 35 and 46. The free quartic coupling λ of ϕ^4 theory has become, in its supersymmetric form, the square of a coupling shared with the fermion sector.

We have now realised the chiral multiplet as a fully interacting field theory, discovered the auxiliary field F as the price of off-shell closure, and seen all interactions flow from the single holomorphic superpotential, with $V = |W'|^2$ and Yukawa $= W''$ locking boson and fermion masses together. What is conspicuous is how much bookkeeping this cost: a separate transformation rule for each component, an auxiliary field introduced by hand, and Fierz gymnastics to verify closure. Every one of these features is a symptom of representing a *geometric* structure in non-geometric language. The next section removes the redundancy at a stroke by enlarging spacetime itself: in the superspace of Section 44.6, the fields (ϕ, ψ, F) become the Taylor coefficients of a single *superfield* in anticommuting coordinates $\theta, \bar{\theta}$, the transformations Eq. (44.134) become a single translation in the fermionic directions, and the auxiliary field appears automatically as the top component — closure guaranteed by construction.

44.6 Superspace and Superfields

The Wess–Zumino model of Section 44.5 taught us two lessons at once. The first is that supersymmetry organizes a complex scalar ϕ, a Weyl fermion ψ_α, and a complex auxiliary field F into a single irreducible packet that closes under the transformations only when F is kept off shell. The second is that, written out in components, those transformations are a tangle of σ-matrices and derivatives whose invariance we verified by a page of index gymnastics, term by term. Both lessons point to the same need. If a fermionic charge Q_α really shifts bosons into fermions and back into the *derivative* of a boson, then it is behaving like a translation — but in a direction that ordinary spacetime does not contain. The honest way to make a translation manifest is to give it a coordinate. We therefore enlarge spacetime by adjoining anticommuting coordinates, one for each component of the supercharge, and demand that supersymmetry act on the enlarged space as nothing more exotic than a shift. Every component transformation of Section 44.5 will then follow from a single line — the Taylor expansion of a field in the new directions — and invariance of an action will reduce to the statement that an integral over the whole space is unchanged by a shift of its variable of integration. This is the geometry of superspace, and it is the subject of this section.

The anticommuting coordinates are Grassmann numbers in the exact sense built from scratch in Theorem 12.3, and the integral over them is the Berezin integral of Theorem 12.17. We use those constructions as established machinery;

what is new here is the spacetime-spinor structure they acquire when we attach them to the $(\tfrac{1}{2},0)\oplus(0,\tfrac{1}{2})$ Lorentz data of Section 3.4.3. Throughout we work with the two-component conventions fixed in Section 44.2.2: undotted indices $\alpha,\beta=1,2$ for the $(\tfrac{1}{2},0)$ representation, dotted indices $\dot\alpha,\dot\beta=1,2$ for $(0,\tfrac{1}{2})$, the antisymmetric symbols $\varepsilon^{\alpha\beta},\varepsilon_{\alpha\beta}$ (with $\varepsilon^{12}=-\varepsilon_{12}=1$) raising and lowering them, the suppressed-index contractions

$$\theta\psi \;\equiv\; \theta^{\alpha}\psi_{\alpha} \;=\; -\,\theta_{\alpha}\psi^{\alpha}, \qquad \bar\theta\bar\psi \;\equiv\; \bar\theta_{\dot\alpha}\bar\psi^{\dot\alpha} \;=\; -\,\bar\theta^{\dot\alpha}\bar\psi_{\dot\alpha}, \tag{44.154}$$

and the Pauli-matrix data $\sigma^{\mu}_{\alpha\dot\alpha}=(\mathbf{1},\sigma^{i})$ of Eq. (3.79) together with $\bar\sigma^{\mu\,\dot\alpha\alpha}=(\mathbf{1},-\sigma^{i})=\varepsilon^{\dot\alpha\dot\beta}\varepsilon^{\alpha\beta}\sigma^{\mu}_{\beta\dot\beta}$ of Eq. (3.106). The metric is mostly-minus and units are natural, as everywhere in this chapter; the momentum operator is realized on fields as $P_{\mu}=i\partial_{\mu}$, the convention of Section 3.5.

44.6.1 Superspace as a coset

Spacetime itself is a coset. The Poincaré group acts transitively on $\mathbb{R}^{1,3}$, the stabilizer of the origin is the Lorentz group, and the quotient Poincaré/Lorentz is precisely Minkowski space; a point x^{μ} is the name of the coset represented by the pure translation $g(x)=e^{-ix^{\mu}P_{\mu}}$. Translations then act on points by group multiplication, $g(a)g(x)=g(x+a)$, which is the abstract content of "a translation shifts the coordinate." Supersymmetry extends the Poincaré algebra by the odd generators $Q_{\alpha},\bar Q_{\dot\alpha}$ satisfying (Eq. (44.49))

$$\left\{Q_{\alpha},\bar Q_{\dot\beta}\right\} \;=\; 2\,\sigma^{\mu}_{\alpha\dot\beta}\,P_{\mu}, \qquad \{Q_{\alpha},Q_{\beta}\}=\left\{\bar Q_{\dot\alpha},\bar Q_{\dot\beta}\right\}=0, \qquad [Q_{\alpha},P_{\mu}]=0. \tag{44.155}$$

The natural thing to quotient by is again the Lorentz group, leaving a coset spanned by the even translations *and* the odd charges. We coordinatize it by attaching a Grassmann parameter to each odd generator: a point of *superspace* is the coset represented by

$$g(x,\theta,\bar\theta) \;=\; \exp\!\big(\,-i\,x^{\mu}P_{\mu}\;+\;i\,\theta^{\alpha}Q_{\alpha}\;+\;i\,\bar\theta_{\dot\alpha}\bar Q^{\dot\alpha}\,\big), \tag{44.156}$$

where θ^{α} and $\bar\theta_{\dot\alpha}$ are constant anticommuting numbers carrying, respectively, an undotted and a dotted spinor index. They anticommute among themselves and with $Q,\bar Q$, so that products such as $\theta^{\alpha}Q_{\alpha}$ are Grassmann-*even* and the exponential is well defined. The triple $(x^{\mu},\theta^{\alpha},\bar\theta_{\dot\alpha})$ is a point of $\mathcal{N}=1$ superspace, a space of four commuting (bosonic) and four anticommuting (fermionic) coordinates.

Definition 44.29 ($\mathcal{N}=1$ superspace)**.** $\mathcal{N}=1$ superspace is the set of points $z^{M}=(x^{\mu},\theta^{\alpha},\bar\theta_{\dot\alpha})$, with x^{μ} ordinary real spacetime coordinates and $\theta^{\alpha},\bar\theta_{\dot\alpha}$ constant generators of a Grassmann algebra (Theorem 12.3) transforming as the $(\tfrac{1}{2},0)$ and $(0,\tfrac{1}{2})$ representations of the Lorentz group. Complex conjugation acts by $(\theta^{\alpha})^{\dagger}=\bar\theta^{\dot\alpha}$, so that $\theta\psi$ and $\bar\theta\bar\psi$ are conjugate scalars.

The whole point of the coset construction is that supersymmetry now acts by left multiplication. Multiply the representative Eq. (44.156) on the left by a finite supersymmetry transformation $g(\xi,\bar\xi)=\exp(i\xi Q+i\bar\xi\bar Q)$ with constant Grassmann parameters $\xi^\alpha,\bar\xi_{\dot\alpha}$. Because the only nontrivial bracket among the exponents is the anticommutator Eq. (44.155), the Baker–Campbell–Hausdorff series truncates after one term: the commutator of the two exponents is proportional to P_μ, which is central with respect to Q, so all higher nested brackets vanish. Explicitly,

$$\begin{aligned} g(\xi,\bar\xi)\,g(x,\theta,\bar\theta) &= \exp\!\Big(i\xi Q+i\bar\xi\bar Q\Big)\,\exp\!\Big(-ixP+i\theta Q+i\bar\theta\bar Q\Big) \\ &= \exp\!\Big(-ixP+i(\theta+\xi)Q+i(\bar\theta+\bar\xi)\bar Q\;-\;\tfrac12\big[\,i\xi Q+i\bar\xi\bar Q\,,\,i\theta Q+i\bar\theta\bar Q\,\big]\Big), \end{aligned} \tag{44.157}$$

and the leftover bracket, evaluated with Eq. (44.155), is

$$-\tfrac12\big[\,i\xi Q+i\bar\xi\bar Q\,,\,i\theta Q+i\bar\theta\bar Q\,\big] \;=\; \tfrac12\Big(\theta^\alpha\bar\xi_{\dot\beta}-\xi^\alpha\bar\theta_{\dot\beta}\Big)\Big\{Q_\alpha,\bar Q^{\dot\beta}\Big\} \;=\; (\theta\sigma^\mu\bar\xi-\xi\sigma^\mu\bar\theta)\,P_\mu. \tag{44.158}$$

Comparing the two exponentials and reading off the coefficient of each generator, the product is the representative of a new point with the same Lorentz frame but shifted coordinates,

$$\boxed{\;\theta^\alpha\;\to\;\theta^\alpha+\xi^\alpha,\qquad \bar\theta_{\dot\alpha}\;\to\;\bar\theta_{\dot\alpha}+\bar\xi_{\dot\alpha},\qquad x^\mu\;\to\;x^\mu\;+\;i\,\theta\sigma^\mu\bar\xi\;-\;i\,\xi\sigma^\mu\bar\theta\,.\;} \tag{44.159}$$

This is the geometric heart of the subject. *A supersymmetry transformation is a constant shift of the fermionic coordinates, accompanied by a definite x-translation whose amount is bilinear in ξ and θ.* The translation piece is exactly what one expects from $\{Q,\bar Q\}\sim P$: two infinitesimal odd shifts fail to commute, and their failure is a spacetime translation. The Wess–Zumino transformation rules, which looked like an intricate coincidence in components, are simply the statement that a field carried along this shift changes by the corresponding Taylor expansion.

Remark 44.30 (Reality of the shift). The bosonic shift in Eq. (44.159) is real. Taking the Hermitian conjugate and using $(\theta\sigma^\mu\bar\xi)^\dagger=\xi\sigma^\mu\bar\theta$ (a standard reordering identity for two-component spinors, proved in Section 44.2.2) shows that $i\,\theta\sigma^\mu\bar\xi-i\,\xi\sigma^\mu\bar\theta$ equals its own conjugate. Superspace is therefore a real manifold in its bosonic directions, as it must be for x^μ to remain an honest spacetime coordinate.

44.6.2 The supercharges as differential operators

A field theory lives not on the group but on functions over superspace. The action of supersymmetry on such functions is generated by differential operators, obtained by demanding that an infinitesimal version of Eq. (44.159) be

reproduced. Define the fermionic partial derivatives by the left-derivative rule of Theorem 12.17,

$$\partial_\alpha \equiv \frac{\partial}{\partial\theta^\alpha}, \qquad \bar\partial_{\dot\alpha} \equiv \frac{\partial}{\partial\bar\theta^{\dot\alpha}}, \qquad \left\{\partial_\alpha, \theta^\beta\right\} = \delta_\alpha^{\ \beta}, \quad \left\{\bar\partial_{\dot\alpha}, \bar\theta^{\dot\beta}\right\} = \delta_{\dot\alpha}^{\ \dot\beta}, \tag{44.160}$$

with all other anticommutators among $\partial_\alpha, \bar\partial_{\dot\alpha}, \theta, \bar\theta$ vanishing. The infinitesimal form of the shift Eq. (44.159) acts on a function $F(x,\theta,\bar\theta)$ as $\delta_\xi F = (\xi^\alpha Q_\alpha + \bar\xi_{\dot\alpha}\bar Q^{\dot\alpha})F$ with the representation

$$\boxed{Q_\alpha \;=\; \partial_\alpha \;-\; i\,\sigma^\mu_{\alpha\dot\alpha}\,\bar\theta^{\dot\alpha}\,\partial_\mu, \qquad \bar Q_{\dot\alpha} \;=\; -\,\bar\partial_{\dot\alpha} \;+\; i\,\theta^\alpha\sigma^\mu_{\alpha\dot\alpha}\,\partial_\mu\,.} \tag{44.161}$$

The first term in each operator generates the pure θ- (respectively $\bar\theta$-) shift; the second generates the compensating x-translation read off from Eq. (44.159), with ∂_μ the ordinary spacetime derivative. One checks directly that (ξQ) shifts $\theta^\alpha \to \theta^\alpha + \xi^\alpha$ and $x^\mu \to x^\mu - i\xi\sigma^\mu\bar\theta$, while $(\bar\xi\bar Q)$ shifts $\bar\theta \to \bar\theta + \bar\xi$ and $x^\mu \to x^\mu + i\theta\sigma^\mu\bar\xi$; summing the two and using the reordering of Theorem 44.30 reproduces Eq. (44.159) up to the overall orientation fixed by our sign of δ_ξ.

We must now prove that these differential operators close into the algebra Eq. (44.155). This is the central consistency check of the section: if the operator forms did *not* satisfy the algebra, the geometric picture would be a fiction.

Proposition 44.31 (The differential operators realize the SUSY algebra)**.** *With $P_\mu = i\partial_\mu$, the operators Eq. (44.161) satisfy*

$$\left\{Q_\alpha, \bar Q_{\dot\beta}\right\} \;=\; 2\,\sigma^\mu_{\alpha\dot\beta}\,P_\mu \;=\; 2i\,\sigma^\mu_{\alpha\dot\beta}\,\partial_\mu, \qquad \{Q_\alpha, Q_\beta\} = \left\{\bar Q_{\dot\alpha}, \bar Q_{\dot\beta}\right\} = 0, \qquad [Q_\alpha, \partial_\mu] = 0, \tag{44.162}$$

which is the $\mathcal{N} = 1$ super-Poincaré algebra of Eq. (44.155).

Proof. Every bracket is computed by pushing the fermionic derivatives through the Grassmann coordinates with the rules Eq. (44.160); the spacetime derivative ∂_μ is Grassmann-even and commutes with everything, so it rides along as a passive factor.

The mixed anticommutator. Write the two operators with distinct dummy indices,

$$Q_\alpha = \partial_\alpha - i\,\sigma^\mu_{\alpha\dot\gamma}\,\bar\theta^{\dot\gamma}\,\partial_\mu, \qquad \bar Q_{\dot\beta} = -\,\bar\partial_{\dot\beta} + i\,\theta^\gamma\sigma^\nu_{\gamma\dot\beta}\,\partial_\nu,$$

and expand $\left\{Q_\alpha, \bar Q_{\dot\beta}\right\}$ into four anticommutators. Two of them vanish identically. The derivative–derivative term $\left\{\partial_\alpha, -\bar\partial_{\dot\beta}\right\} = 0$ because the two fermionic derivatives act on independent variables. The translation–translation term also vanishes: it is $\left\{-i\sigma^\mu_{\alpha\dot\gamma}\bar\theta^{\dot\gamma}\partial_\mu,\, i\theta^\gamma\sigma^\nu_{\gamma\dot\beta}\partial_\nu\right\} = \sigma^\mu_{\alpha\dot\gamma}\sigma^\nu_{\gamma\dot\beta}\,\partial_\mu\partial_\nu\,\left\{\bar\theta^{\dot\gamma}, \theta^\gamma\right\} = 0$, since $\bar\theta$ and θ anticommute to zero and the bosonic $\partial_\mu\partial_\nu$ factors out. The two surviving cross terms are

$$\left\{\partial_\alpha,\, i\,\theta^\gamma\sigma^\nu_{\gamma\dot\beta}\partial_\nu\right\} = i\,\sigma^\nu_{\gamma\dot\beta}\,\partial_\nu\;\{\partial_\alpha, \theta^\gamma\} = i\,\sigma^\nu_{\gamma\dot\beta}\,\partial_\nu\,\delta_\alpha^{\ \gamma} = i\,\sigma^\nu_{\alpha\dot\beta}\,\partial_\nu, \tag{44.163}$$

$$\left\{-i\,\sigma^{\mu}_{\alpha\dot\gamma}\bar\theta^{\dot\gamma}\partial_\mu,\,-\bar\partial_{\dot\beta}\right\} = i\,\sigma^{\mu}_{\alpha\dot\gamma}\,\partial_\mu\,\left\{\bar\theta^{\dot\gamma},\bar\partial_{\dot\beta}\right\} = i\,\sigma^{\mu}_{\alpha\dot\gamma}\,\partial_\mu\,\delta^{\dot\gamma}_{\dot\beta} = i\,\sigma^{\mu}_{\alpha\dot\beta}\,\partial_\mu. \tag{44.164}$$

Adding Eqs. (44.163) and (44.164),

$$\left\{Q_\alpha,\bar Q_{\dot\beta}\right\} \;=\; 2i\,\sigma^{\mu}_{\alpha\dot\beta}\,\partial_\mu \;=\; 2\,\sigma^{\mu}_{\alpha\dot\beta}\,P_\mu, \tag{44.165}$$

exactly the right-hand side of Eq. (44.155). The coefficient 2 is not inserted by hand; it is the sum of two equal contributions, one from shifting θ against the $\bar\theta$-translation and one from shifting $\bar\theta$ against the θ-translation. This is the operator incarnation of the geometric fact that closing two fermionic shifts produces one bosonic translation.

The like anticommutators. For $\{Q_\alpha,Q_\beta\}$, expand again. The $\{\partial_\alpha,\partial_\beta\}=0$ by Eq. (44.160). The two cross terms $\left\{\partial_\alpha,-i\sigma^{\mu}_{\beta\dot\gamma}\bar\theta^{\dot\gamma}\partial_\mu\right\}$ and its $\alpha\leftrightarrow\beta$ partner vanish because ∂_α anticommutes with $\bar\theta^{\dot\gamma}$ *to zero* — they are derivatives and coordinates of different chirality, so $\left\{\partial_\alpha,\bar\theta^{\dot\gamma}\right\}=0$ rather than a Kronecker delta. The translation–translation term carries $\left\{\bar\theta^{\dot\gamma},\bar\theta^{\dot\delta}\right\}=0$. Hence $\{Q_\alpha,Q_\beta\}=0$, and by complex conjugation $\left\{\bar Q_{\dot\alpha},\bar Q_{\dot\beta}\right\}=0$.

Commutation with translations. Since Q_α is built from ∂_α, $\bar\theta^{\dot\alpha}$, and ∂_μ, and the spacetime derivative commutes with all three (constant-coefficient operators on flat superspace), $[Q_\alpha,\partial_\mu]=0$, i.e. $[Q_\alpha,P_\nu]=0$. This completes the verification. □

The proposition does more than reassure us. It shows that the differential operators Eq. (44.161) are a faithful realization of the abstract algebra on the function space of superspace, so that questions about representations of supersymmetry — which fields sit in a multiplet, how they transform — become questions about functions of $(x,\theta,\bar\theta)$. That is the program of the rest of the section.

44.6.3 Covariant derivatives

To carve out *irreducible* representations we will impose constraints on functions over superspace, such as "this field does not depend on $\bar\theta$." A constraint is only admissible if it is preserved by supersymmetry; otherwise acting with Q would take a solution out of the constrained set, and the constraint would not define a representation. The naive derivatives $\partial_\alpha,\bar\partial_{\dot\alpha}$ are useless for this purpose because they do not anticommute with the supercharges — indeed ∂_α is the leading piece of Q_α itself. We need a different set of fermionic derivatives that anticommute with all of $Q,\bar Q$. They are the *covariant derivatives*, and finding them requires only a sign flip relative to Eq. (44.161).

Definition 44.32 (Superspace covariant derivatives)**.** The covariant spinor derivatives are

$$\boxed{D_\alpha \;=\; \partial_\alpha \;+\; i\,\sigma^\mu_{\alpha\dot\alpha}\,\bar\theta^{\dot\alpha}\,\partial_\mu, \qquad \bar D_{\dot\alpha} \;=\; -\,\bar\partial_{\dot\alpha} \;-\; i\,\theta^\alpha\sigma^\mu_{\alpha\dot\alpha}\,\partial_\mu\,,} \tag{44.166}$$

differing from $Q_\alpha, \bar Q_{\dot\alpha}$ of Eq. (44.161) only in the sign of the ∂_μ term.

The defining virtue of these operators is covariance: they anticommute with every supercharge, so they map a representation to a representation.

Proposition 44.33 ($D, \bar D$ are covariant and close among themselves)**.** *The operators Eq. (44.166) satisfy*

$$\{D_\alpha, Q_\beta\} = \left\{D_\alpha, \bar Q_{\dot\beta}\right\} = \left\{\bar D_{\dot\alpha}, Q_\beta\right\} = \left\{\bar D_{\dot\alpha}, \bar Q_{\dot\beta}\right\} = 0, \tag{44.167}$$

$$\left\{D_\alpha, \bar D_{\dot\beta}\right\} \;=\; -\,2i\,\sigma^\mu_{\alpha\dot\beta}\,\partial_\mu, \qquad \{D_\alpha, D_\beta\} = \left\{\bar D_{\dot\alpha}, \bar D_{\dot\beta}\right\} = 0. \tag{44.168}$$

Proof. Anticommutation with the supercharges. Take $\left\{D_\alpha, \bar Q_{\dot\beta}\right\}$ with

$$D_\alpha = \partial_\alpha + i\,\sigma^\mu_{\alpha\dot\gamma}\bar\theta^{\dot\gamma}\partial_\mu, \qquad \bar Q_{\dot\beta} = -\bar\partial_{\dot\beta} + i\,\theta^\gamma\sigma^\nu_{\gamma\dot\beta}\partial_\nu.$$

The structure is identical to the calculation Eqs. (44.163) and (44.164), but the sign of the translation term in D_α is reversed. The two surviving cross terms are now

$$\left\{\partial_\alpha,\, i\theta^\gamma\sigma^\nu_{\gamma\dot\beta}\partial_\nu\right\} = +\,i\,\sigma^\nu_{\alpha\dot\beta}\partial_\nu, \qquad \left\{i\,\sigma^\mu_{\alpha\dot\gamma}\bar\theta^{\dot\gamma}\partial_\mu,\, -\bar\partial_{\dot\beta}\right\} = -\,i\,\sigma^\mu_{\alpha\dot\beta}\partial_\mu,$$

and they *cancel*: $\left\{D_\alpha, \bar Q_{\dot\beta}\right\} = 0$. The same cancellation, with the roles of θ and $\bar\theta$ exchanged, gives $\left\{\bar D_{\dot\alpha}, Q_\beta\right\} = 0$. The remaining two, $\{D_\alpha, Q_\beta\}$ and $\left\{\bar D_{\dot\alpha}, \bar Q_{\dot\beta}\right\}$, vanish for the same reason the like-anticommutators of Q vanished in Theorem 44.31: the only fermionic derivative that could contract is paired with a coordinate of the wrong chirality, so $\left\{\partial_\alpha, \bar\theta^{\dot\gamma}\right\} = 0$ and every term dies. Hence Eq. (44.167).

The D algebra. Repeating the computation of Eq. (44.165) for the two operators of Eq. (44.166), both surviving cross terms come with the flipped sign, so they add rather than canceling:

$$\left\{D_\alpha, \bar D_{\dot\beta}\right\} = -\,i\,\sigma^\mu_{\alpha\dot\beta}\partial_\mu \;-\; i\,\sigma^\mu_{\alpha\dot\beta}\partial_\mu = -\,2i\,\sigma^\mu_{\alpha\dot\beta}\,\partial_\mu. \tag{44.169}$$

The like-anticommutators $\{D_\alpha, D_\beta\}$ and $\left\{\bar D_{\dot\alpha}, \bar D_{\dot\beta}\right\}$ vanish by the chirality argument used for Q. This is Eq. (44.168). □

Theorem 44.33 is the workhorse identity of superspace. Equation Eq. (44.167) says that imposing a D- or $\bar{D}$-constraint on a field is supersymmetric: if $\bar{D}_{\dot\alpha}F = 0$, then for any supersymmetry variation $\delta_\xi F = (\xi Q + \bar\xi \bar Q)F$ we have $\bar D_{\dot\alpha}(\delta_\xi F) = \bar D_{\dot\alpha}(\xi Q + \bar\xi\bar Q)F = (\xi Q + \bar\xi \bar Q)\,\bar D_{\dot\alpha}F = 0$, because $\bar D$ anticommutes past the supercharges (the two minus signs from moving $\bar D$ through the two odd factors of ξQ cancel, leaving the operators effectively commuting on the even combination). The constrained field stays constrained: the constraint $\bar D_{\dot\alpha}\Phi = 0$ therefore defines a subrepresentation. This is precisely the chiral superfield that Section 44.7 is built on. Equation Eq. (44.168) records that the covariant derivatives close on translations with the opposite sign to the supercharges, a fact we will use repeatedly when integrating by parts in superspace.

Notation Watch

The symbols $D_\alpha = D_\alpha$ and $\bar D_{\dot\alpha} = \bar D_{\dot\alpha}$ denote the *superspace* covariant derivatives of Eq. (44.166) throughout this chapter. They are unrelated to the gauge-covariant derivative $D_\mu = \partial_\mu - igA^a_\mu T^a$ of the rest of the book; the latter always carries a spacetime vector index μ, the former a two-component spinor index. The gauge-covariant superspace derivative that fuses the two ideas appears only in Chapter 45.

44.6.4 The general superfield and its components

A field on superspace is called a superfield. Because θ^α and $\bar\theta_{\dot\alpha}$ are each two anticommuting numbers, any power higher than the second in either vanishes: $\theta^\alpha\theta^\beta\theta^\gamma = 0$ by the pigeonhole of two Grassmann generators, and similarly for $\bar\theta$. A function of superspace is therefore not an infinite Taylor series but a *polynomial* of finite degree, with at most two θ's and two $\bar\theta$'s. This finiteness is the structural reason supersymmetry yields finite multiplets.

Definition 44.34 (General scalar superfield)**.** A general (scalar) superfield $F(x,\theta,\bar\theta)$ is the most general function on $\mathcal{N}=1$ superspace,

$$\begin{aligned} F(x,\theta,\bar\theta) = {} & f(x) + \theta\psi(x) + \bar\theta\bar\chi(x) + \theta\theta\, m(x) + \bar\theta\bar\theta\, n(x) + \theta\sigma^\mu\bar\theta\, v_\mu(x) \\ & + \theta\theta\,\bar\theta\bar\lambda(x) + \bar\theta\bar\theta\,\theta\rho(x) + \theta\theta\,\bar\theta\bar\theta\, d(x), \end{aligned} \tag{44.170}$$

where the contractions follow Eq. (44.154) and $\theta\theta \equiv \theta^\alpha\theta_\alpha$, $\bar\theta\bar\theta \equiv \bar\theta_{\dot\alpha}\bar\theta^{\dot\alpha}$. The component fields are: complex scalars f, m, n, d; Weyl fermions $\psi_\alpha, \bar\chi_{\dot\alpha}, \bar\lambda_{\dot\alpha}, \rho_\alpha$; and a complex vector v_μ.

That Eq. (44.170) is the most general expansion follows from the Grassmann-degree truncation: there are exactly nine monomials in $\theta, \bar\theta$ that are nonvanishing and Lorentz-covariant, listed in Fig. 44.5, and the expansion attaches one spacetime field to each. Counting bosonic versus fermionic degrees of freedom (off

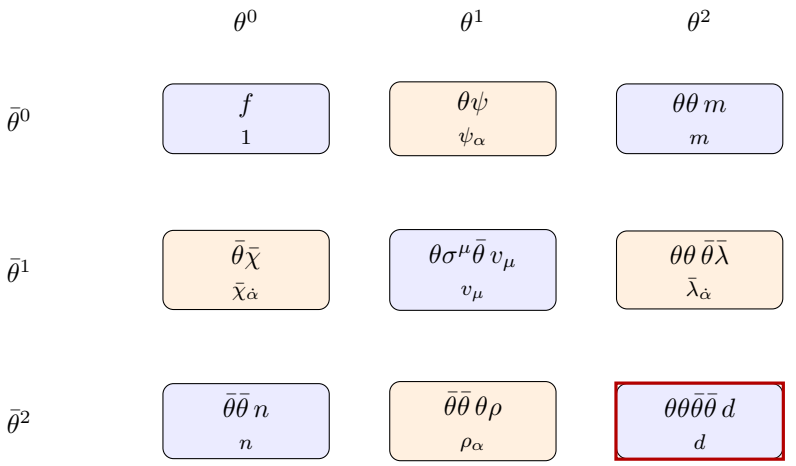

Figure 44.5: Component content of the general scalar superfield Eq. (44.170), organized by the power of θ (columns) and $\bar\theta$ (rows). Blue cells are bosonic components (f, m, n, v_μ, d), orange cells fermionic $(\psi, \bar\chi, \bar\lambda, \rho)$. The top component d (heavy red border) multiplies $\theta\theta\,\bar\theta\bar\theta$; its supersymmetry variation is a total spacetime derivative, the fact that makes $\int \mathrm{d}^4x\, \mathrm{d}^4\theta\, F$ an invariant (Theorem 44.36).

shell): the four complex scalars f, m, n, d carry $4 \times 2 = 8$ real bosonic components, and the complex four-vector v_μ carries $4 \times 2 = 8$ more, for 16 real bosonic components in all; the four Weyl fermions $\psi, \bar\chi, \bar\lambda, \rho$ carry $4 \times (2 \times 2) = 16$ real fermionic components. The boson and fermion counts match, $16 = 16$, as the algebra Eq. (44.155) forces. (We prove the equality of off-shell boson and fermion counts in any supermultiplet abstractly in Section 44.4; here it is visible by inspection.)

The general superfield is a perfectly good representation of supersymmetry — act with Q of Eq. (44.161) and the components rotate into one another — but it is a *reducible* one. The transformation Eq. (44.159) never mixes, for instance, the lowest component f with a component of higher θ-degree without also producing spacetime derivatives, and the nine components in Fig. 44.5 can be consistently truncated to smaller invariant sets. The cleanest such truncation is the chiral constraint $\bar D_{\dot\alpha}\Phi = 0$, which (as Section 44.7 shows) collapses the nine components down to the scalar-fermion-auxiliary triple (ϕ, ψ, F) of the Wess–Zumino multiplet. That a single covariant constraint extracts an irreducible piece is the practical payoff of Theorem 44.33, and the reason we built $D, \bar D$ before doing anything else with superfields.

Physical Insight

Reducibility here is the superspace echo of an old story. In Theorem 3.17 the finite-dimensional Lorentz representations were built and then *decomposed* into irreducible (j_-, j_+) blocks; a Dirac field, for instance, is the reducible sum $(\tfrac{1}{2},0)\oplus(0,\tfrac{1}{2})$. A general superfield is the analogous reducible object for the super-Poincaré algebra, and the covariant derivatives play the role that the projectors $\tfrac{1}{2}(1\pm\gamma^5)$ played there: they are the supersymmetric instruments that split a fat multiplet into its irreducible chiral and vector constituents.

44.6.5 Berezin integration on superspace and invariant measures

To build actions we must integrate over superspace. Integration over the bosonic coordinates is the ordinary $\int \mathrm{d}^4x$. Integration over the fermionic coordinates is the Berezin integral of Theorem 12.17, applied once to each Grassmann generator. We package the four fermionic integrations into Lorentz-covariant measures.

Definition 44.35 (Grassmann measures on superspace)**.** The chiral, antichiral, and full superspace measures are

$$\mathrm{d}^2\theta \;=\; -\tfrac{1}{4}\,\mathrm{d}\theta^\alpha\,\mathrm{d}\theta^\beta\,\varepsilon_{\alpha\beta}, \qquad \mathrm{d}^2\bar\theta \;=\; -\tfrac{1}{4}\,\mathrm{d}\bar\theta_{\dot\alpha}\,\mathrm{d}\bar\theta_{\dot\beta}\,\varepsilon^{\dot\alpha\dot\beta}, \qquad \mathrm{d}^4\theta \;=\; \mathrm{d}^2\theta\,\mathrm{d}^2\bar\theta, \tag{44.171}$$

normalized by the convention that they pick out the top Grassmann coefficient,

$$\int \mathrm{d}^2\theta\;\theta\theta = 1, \qquad \int \mathrm{d}^2\bar\theta\;\bar\theta\bar\theta = 1, \qquad \int \mathrm{d}^4\theta\;\theta\theta\,\bar\theta\bar\theta = 1. \tag{44.172}$$

The normalizations Eq. (44.172) are forced by Eq. (44.171) together with the one-variable Berezin rules $\int \mathrm{d}\theta\,\theta = 1$, $\int \mathrm{d}\theta\,1 = 0$ of Eq. (12.55); the prefactor $-\tfrac{1}{4}$ is chosen exactly so that the covariant combination $\theta\theta = \theta^\alpha\theta_\alpha$ integrates to unity. To see it, reduce both the integrand and the measure to the basis θ^1,θ^2. Expanding the contraction with $\varepsilon_{12} = -1$,

$$\theta\theta \;=\; \theta^\alpha\theta_\alpha \;=\; \varepsilon_{\alpha\beta}\,\theta^\alpha\theta^\beta \;=\; \varepsilon_{12}\,\theta^1\theta^2 + \varepsilon_{21}\,\theta^2\theta^1 \;=\; -2\,\theta^1\theta^2, \tag{44.173}$$

while the measure Eq. (44.171), using $\mathrm{d}\theta^2\,\mathrm{d}\theta^1 = -\mathrm{d}\theta^1\,\mathrm{d}\theta^2$, collapses to

$$\mathrm{d}^2\theta = -\tfrac{1}{4}\,\varepsilon_{\alpha\beta}\,\mathrm{d}\theta^\alpha\,\mathrm{d}\theta^\beta = -\tfrac{1}{4}(-\,\mathrm{d}\theta^1\,\mathrm{d}\theta^2 + \mathrm{d}\theta^2\,\mathrm{d}\theta^1) = \tfrac{1}{2}\,\mathrm{d}\theta^1\,\mathrm{d}\theta^2. \tag{44.174}$$

Composing the two and performing the nested Berezin integral $\int \mathrm{d}\theta^1\,\mathrm{d}\theta^2\,\theta^1\theta^2 = -1$ (integrate θ^2 first, then θ^1, picking up one sign from the anticommuting reorder),

$$\int \mathrm{d}^2\theta\,\theta\theta = \tfrac{1}{2}\int \mathrm{d}\theta^1\,\mathrm{d}\theta^2\,(-2\,\theta^1\theta^2) = -\int \mathrm{d}\theta^1\,\mathrm{d}\theta^2\,\theta^1\theta^2 = -(-1) = 1, \tag{44.175}$$

as claimed; the antichiral and full-superspace normalizations follow identically. The practical upshot, which is all we use below, is contained in Eq. (44.172): *integrating over* $\mathrm{d}^2\theta$ *extracts the* $\theta\theta$ *coefficient, integrating over* $\mathrm{d}^4\theta$ *extracts the* $\theta\theta\,\bar\theta\bar\theta$ *coefficient*, and all lower components integrate to zero because the Berezin integral of anything not saturating every Grassmann variable vanishes (Eq. (12.55)).

Two integrals build all supersymmetric actions. The first, the integral of a general superfield over the *full* superspace,

$$\int \mathrm{d}^4x\,\mathrm{d}^4\theta\; F(x,\theta,\bar\theta) \;=\; \int \mathrm{d}^4x\; d(x), \tag{44.176}$$

projects out the top component d of Eq. (44.170) and is called a *D-term*. The second, the integral of a chiral superfield over the chiral half $\mathrm{d}^2\theta$ only, projects out its highest $\theta\theta$ component and is called an *F-term*; we construct it in Section 44.7, where chiral superfields are defined. The remarkable fact, which makes these projections the right building blocks, is that both are supersymmetry invariants. We prove the D-term case in full now; the F-term case uses the same mechanism on a constrained field and is dispatched in Section 44.7.

Theorem 44.36 (D-term invariance)**.** *For any general superfield F, the full-superspace integral $\int \mathrm{d}^4x\,\mathrm{d}^4\theta\, F$ is invariant under supersymmetry: its variation δ_ξ is the spacetime integral of a total derivative, hence vanishes for fields decaying at infinity.*

Proof. The variation of F under an infinitesimal supersymmetry transformation is $\delta_\xi F = (\xi^\alpha Q_\alpha + \bar\xi_{\dot\alpha}\bar Q^{\dot\alpha})F$ with the operators Eq. (44.161). We integrate this over $\mathrm{d}^4x\,\mathrm{d}^4\theta$ and treat the two pieces of each supercharge in turn.

The ∂_θ pieces integrate to zero. The first term of $\xi^\alpha Q_\alpha$ is $\xi^\alpha\partial_\alpha F$, a fermionic derivative of F. The Berezin integral of a fermionic derivative vanishes:

$$\int \mathrm{d}^4\theta\; \xi^\alpha\partial_\alpha F \;=\; 0. \tag{44.177}$$

The reason is the one-variable identity $\int \mathrm{d}\theta\,\partial_\theta(\cdots) = 0$ from Eq. (12.55): $\partial_\alpha F$ lowers the θ-degree of every monomial by one, so it cannot contain the full top monomial $\theta\theta\,\bar\theta\bar\theta$ that $\mathrm{d}^4\theta$ requires for a nonzero answer. Equivalently, integration and differentiation are the same operation on Grassmann variables (Eq. (12.56)), and an integral of a derivative is a boundary term, which is empty for the polynomial F. The same argument kills $-\bar\xi_{\dot\alpha}\bar\partial^{\dot\alpha}F$, the leading piece of $\bar\xi\bar Q$.

The ∂_x pieces are spacetime total derivatives. The remaining terms in the supercharges all carry an explicit ∂_μ:

$$\delta_\xi F\big|_{\partial_x} = -\,i\,\xi^\alpha\sigma^\mu_{\alpha\dot\alpha}\bar\theta^{\dot\alpha}\,\partial_\mu F \;+\; i\,\bar\xi_{\dot\alpha}\,\theta^\alpha\sigma^{\mu\dot\alpha}_{\alpha}\,\partial_\mu F \;=\; \partial_\mu\Big[(-i\,\xi\sigma^\mu\bar\theta + i\,\theta\sigma^\mu\bar\xi)F\Big], \tag{44.178}$$

where the last equality holds because the bracket multiplying $\partial_\mu F$ is itself x-independent (it depends only on the constant parameters $\xi, \bar\xi$ and the coordinates $\theta, \bar\theta$), so it can be pulled inside the derivative. Integrating over d^4x, this is the integral of a spacetime total divergence and vanishes for fields falling off at infinity:

$$\int \mathrm{d}^4x\, \partial_\mu\Big[(-i\,\xi\sigma^\mu\bar\theta + i\,\theta\sigma^\mu\bar\xi)F\Big] \;=\; 0. \tag{44.179}$$

(The Grassmann factor $\theta, \bar\theta$ rides along untouched by $\int \mathrm{d}^4x$; the subsequent $\mathrm{d}^4\theta$ integration of zero is still zero.)

Combining the two pieces, the entire variation $\delta_\xi \int \mathrm{d}^4x\, \mathrm{d}^4\theta\, F$ is a sum of a Berezin boundary term Eq. (44.177) and a spacetime boundary term Eq. (44.179), both vanishing. Therefore

$$\delta_\xi \int \mathrm{d}^4x\, \mathrm{d}^4\theta\; F \;=\; 0, \tag{44.180}$$

and $\int \mathrm{d}^4x\, \mathrm{d}^4\theta\, F$ is supersymmetric. □

The mechanism is worth restating in one breath, because it is the engine of every superspace action. The top component of a superfield is the only one with nothing above it in Fig. 44.5; a supersymmetry transformation can only move it *sideways or down* into other components multiplied by ∂_μ, never up, because there is no higher monomial to receive it. Its variation is therefore forced to be a total spacetime derivative, and its spacetime integral is an invariant. The same statement holds for the top $(\theta\theta)$ component of a chiral superfield, which is why F-terms work. Supersymmetric Lagrangians are nothing but superfields whose top components we integrate.

Worked Example 44.37 (The top-component variation, by hand)**.** To see the abstract argument of Theorem 44.36 concretely, we compute the supersymmetry variation of the top component $d(x)$ of the general superfield Eq. (44.170) directly and confirm it is a total derivative.

Act with $\delta_\xi = \xi^\alpha Q_\alpha + \bar\xi_{\dot\alpha}\bar Q^{\dot\alpha}$ on F and collect everything proportional to the top monomial $\theta\theta\,\bar\theta\bar\theta$; that coefficient is $\delta_\xi d$. The ∂_α and $\bar\partial_{\dot\alpha}$ pieces of the supercharges lower the Grassmann degree, so to *reach* degree $(\theta^2\bar\theta^2)$ they must act on a monomial of degree $(\theta^3\bar\theta^2)$ or $(\theta^2\bar\theta^3)$ — which do not exist, since no field carries three θ's. Hence the pure-∂_θ pieces contribute *nothing* to $\delta_\xi d$: this is Eq. (44.177) seen component-by-component. Only the ∂_μ pieces survive. They act on the next-to-top components, $\theta\theta\,\bar\theta\bar\lambda$ and $\bar\theta\bar\theta\,\theta\rho$, supplying the missing Grassmann factor through the explicit $\bar\theta$ or θ they carry. Extracting the $\theta\theta\,\bar\theta\bar\theta$ coefficient from

$$-\,i\,\xi\sigma^\mu\bar\theta\,\partial_\mu(\bar\theta\bar\theta\,\theta\rho) \;+\; i\,\theta\sigma^\mu\bar\xi\,\partial_\mu(\theta\theta\,\bar\theta\bar\lambda)$$

and using the Fierz reorderings of Section 44.2.2 ($\theta^\alpha\theta^\beta = -\tfrac12\varepsilon^{\alpha\beta}\theta\theta$ and its dotted analogue), one finds

$$\delta_\xi d \;=\; -\tfrac{i}{2}\,\partial_\mu(\,\xi\sigma^\mu\bar\lambda \;-\; \rho\sigma^\mu\bar\xi\,). \tag{44.181}$$

The right-hand side is manifestly ∂_μ(something) — a total spacetime derivative, exactly as Theorem 44.36 promised. Whatever the detailed coefficients (they depend on the bilinear conventions of Section 44.2.2), the *form* is guaranteed: d sits at the top of the staircase, so its variation can only spill downward into derivatives of the rung below it. This is the component shadow of the theorem, and it is the calculation the Wess–Zumino action of Section 44.5 was secretly performing every time we checked invariance term by term.

Worked Example 44.38 (Integration by parts on superspace)**.** A second identity we will lean on in Chapters 45 and 46 is that the covariant derivatives can be integrated by parts under the full measure, just like ordinary derivatives. We show

$$\int \mathrm{d}^4x\,\mathrm{d}^4\theta\;(D_\alpha A)\,B \;=\; -\,(-1)^{|A|}\int \mathrm{d}^4x\,\mathrm{d}^4\theta\;A\,(D_\alpha B), \tag{44.182}$$

where $|A| = 0, 1$ is the Grassmann parity of A and the sign is the usual one for moving an odd operator past an object of definite parity. Write $D_\alpha = \partial_\alpha + i\sigma^\mu_{\alpha\dot\alpha}\bar\theta^{\dot\alpha}\partial_\mu$. The first piece, $\int \mathrm{d}^4\theta\,(\partial_\alpha A)B$, is handled by the Leibniz rule for the Grassmann derivative, $\partial_\alpha(AB) = (\partial_\alpha A)B + (-1)^{|A|}A(\partial_\alpha B)$, together with the vanishing of the Berezin integral of a total θ-derivative (Eq. (44.177)): $\int \mathrm{d}^4\theta\,\partial_\alpha(AB) = 0$, so $\int \mathrm{d}^4\theta\,(\partial_\alpha A)B = -(-1)^{|A|}\int \mathrm{d}^4\theta\,A(\partial_\alpha B)$. The second piece carries the spacetime derivative ∂_μ, which integrates by parts under $\int \mathrm{d}^4x$ with a relative minus and no Grassmann sign, since $\bar\theta^{\dot\alpha}$ is inert under ∂_μ: $\int \mathrm{d}^4x\,(i\sigma^\mu\bar\theta\,\partial_\mu A)B = -\int \mathrm{d}^4x\,(i\sigma^\mu\bar\theta)\,A\,\partial_\mu B = -(-1)^{|A|}\int \mathrm{d}^4x\,A\,(i\sigma^\mu\bar\theta\,\partial_\mu B)$ (the extra $(-1)^{|A|}$ from commuting the odd factor $i\sigma^\mu\bar\theta$ past A). Adding the two pieces reassembles D_α on B and gives Eq. (44.182). The identical computation with the flipped sign holds for $\bar D_{\dot\alpha}$. These rules let us freely move covariant derivatives across a superspace action, which is the manipulation that, in Chapter 46, turns a chiral integral into a full-superspace integral and underlies the nonrenormalization theorems.

With covariant derivatives that anticommute with the supercharges, a clean criterion for an irreducible constraint, and a pair of manifestly invariant measures in hand, every ingredient of a superspace action is now in place. The chiral constraint $\bar D_{\dot\alpha}\Phi = 0$ singled out by Theorem 44.33 will, in the next section, collapse the reducible nine-component superfield of Fig. 44.5 into the irreducible chiral multiplet (ϕ, ψ, F); its F-term and the D-term Eq. (44.176) of $\Phi^\dagger\Phi$ will reassemble the entire Wess–Zumino model of Section 44.5 in a single supersymmetric line, with the auxiliary field F and the superpotential W emerging automatically from the geometry we have just built.

44.7 Chiral Superfields and the Superspace Wess–Zumino Action

The previous section gave superspace its calculus. Supersymmetry became translation along the Grassmann directions, the supercharges Q_α, $\bar{Q}_{\dot\alpha}$ were realized as first-order differential operators on the coordinates $(x^\mu, \theta^\alpha, \bar\theta^{\dot\alpha})$, and a second pair of operators — the covariant derivatives D_α and $\bar D_{\dot\alpha}$ — was constructed precisely so as to *anticommute* with every supercharge (Section 44.6, Eq. (44.166)). Alongside them the Berezin measures $\mathrm{d}^2\theta$, $\mathrm{d}^2\bar\theta$ and $\mathrm{d}^4\theta$ were defined, inheriting from Theorem 12.17 the single rule that an integral over an anticommuting variable extracts the coefficient of the top form. We now put this machinery to work. A general superfield is a hugely reducible object: expanded in θ and $\bar\theta$ it contains far more component fields than any one irreducible multiplet of Section 44.5. The art is to impose a *covariant constraint* — one that commutes with supersymmetry, so that the constrained object is still a representation — which truncates the superfield down to an irreducible piece. The simplest such constraint singles out exactly the off-shell Wess–Zumino multiplet (ϕ, ψ, F) built by hand in Section 44.5, and reassembling that multiplet into a single superfield is what finally makes the Wess–Zumino model manifestly supersymmetric: its action becomes an integral over superspace, invariance becoming as automatic as Lorentz invariance is for $\int d^4x\, \mathcal{F}^2$. Along the way we will meet the two ways to extract a Lagrangian from superfields — the F-term and the Kähler (D-) term — and we will see the structural fact, holomorphy of the superpotential, that seeds the nonrenormalization theorems of Chapters 45 and 46.

Throughout we keep the chapter conventions: mostly-minus metric $\eta_{\mu\nu} = \mathrm{diag}(+,-,-,-)$, natural units, and the two-component spinor calculus of Section 3.4.3 with $\sigma^\mu_{\alpha\dot\beta} = (\mathbf{1}, \vec\sigma)$ (Eq. (3.79)) and $\bar\sigma^{\mu\,\dot\alpha\alpha} = (\mathbf{1}, -\vec\sigma)$ (Eq. (3.106)). Undotted indices are raised and lowered with $\epsilon^{\alpha\beta}, \epsilon_{\alpha\beta}$ ($\epsilon^{12} = -\epsilon_{12} = 1$), dotted ones likewise, and we use the standard summation shorthands $\theta\psi = \theta^\alpha\psi_\alpha$, $\bar\theta\bar\psi = \bar\theta_{\dot\alpha}\bar\psi^{\dot\alpha}$, $\theta\theta = \theta^\alpha\theta_\alpha$, $\bar\theta\bar\theta = \bar\theta_{\dot\alpha}\bar\theta^{\dot\alpha}$ fixed in Section 44.6.

44.7.1 The chiral constraint

The covariant derivatives recorded in Eq. (44.166) are, in the representation acting on superfields,

$$D_\alpha = \partial_\alpha + i\,\sigma^\mu_{\alpha\dot\beta}\,\bar\theta^{\dot\beta}\,\partial_\mu, \qquad \bar D_{\dot\alpha} = -\bar\partial_{\dot\alpha} - i\,\theta^\beta\,\sigma^\mu_{\beta\dot\alpha}\,\partial_\mu, \tag{44.183}$$

where $\partial_\alpha = \partial/\partial\theta^\alpha$ and $\bar\partial_{\dot\alpha} = \partial/\partial\bar\theta^{\dot\alpha}$, and $\partial_\mu = \partial/\partial x^\mu$. Their defining virtue, established in Section 44.6, is that they anticommute with the supercharges,

$$\{D_\alpha, Q_\beta\} = \left\{D_\alpha, \bar Q_{\dot\beta}\right\} = 0, \qquad \left\{\bar D_{\dot\alpha}, Q_\beta\right\} = \left\{\bar D_{\dot\alpha}, \bar Q_{\dot\beta}\right\} = 0, \tag{44.184}$$

while among themselves they reproduce the algebra $\left\{D_\alpha, \bar{D}_{\dot\beta}\right\} = -2i\,\sigma^\mu_{\alpha\dot\beta}\,\partial_\mu$ and $\{D_\alpha, D_\beta\} = \left\{\bar{D}_{\dot\alpha}, \bar{D}_{\dot\beta}\right\} = 0$ (Eq. (44.168)). Property Eq. (44.184) is the whole point: any equation built from the D's is supersymmetric, because a supersymmetry variation $\delta_\xi = \xi Q + \bar\xi \bar Q$ passes through a covariant derivative without obstruction.

Definition 44.39 (Chiral and antichiral superfields)**.** A superfield $\Phi(x, \theta, \bar\theta)$ is *chiral* if it is annihilated by every antiholomorphic covariant derivative,

$$\bar{D}_{\dot\alpha}\,\Phi \;=\; 0 \qquad (\dot\alpha = \dot1, \dot2). \tag{44.185}$$

It is *antichiral* if $D_\alpha\,\Phi^\dagger = 0$; the Hermitian conjugate of a chiral superfield is antichiral.

That Eq. (44.185) is consistent — that it does not collapse Φ to a constant — is guaranteed by the algebra: since $\left\{\bar{D}_{\dot\alpha}, \bar{D}_{\dot\beta}\right\} = 0$, imposing $\bar{D}_{\dot1}\Phi = \bar{D}_{\dot2}\Phi = 0$ involves no integrability obstruction. That it is supersymmetric — that the chiral subspace is preserved by the algebra — is Eq. (44.184): if $\bar{D}\Phi = 0$ then $\bar{D}(\delta_\xi\Phi) = \bar{D}(\xi Q + \bar\xi\bar Q)\Phi = -(\xi Q + \bar\xi\bar Q)\bar{D}\Phi = 0$, so $\delta_\xi\Phi$ is again chiral. The constraint therefore cuts out an honest sub-representation, and it is this sub-representation we now identify.

44.7.2 Solving the constraint: chiral coordinates

The constraint Eq. (44.185) looks awkward because $\bar{D}_{\dot\alpha}$ in Eq. (44.183) mixes a $\bar\theta$-derivative with an x-derivative. The remedy is a change of bosonic coordinate that absorbs the mixing. Define the *chiral coordinate*

$$y^\mu \;\equiv\; x^\mu + i\,\theta\sigma^\mu\bar\theta \;=\; x^\mu + i\,\theta^\alpha\sigma^\mu_{\alpha\dot\beta}\bar\theta^{\dot\beta}, \tag{44.186}$$

and its complex conjugate, the *antichiral coordinate* $y^{\dagger\mu} = x^\mu - i\,\theta\sigma^\mu\bar\theta$. The claim is that $\bar{D}_{\dot\alpha}$ annihilates both y^μ and θ^α, so that any function of y and θ alone automatically satisfies Eq. (44.185). The first is immediate: $\bar{D}_{\dot\alpha}\theta^\beta = 0$, since θ^β contains no $\bar\theta$ and no x. The second is a one-line computation. Using $\bar\partial_{\dot\alpha}\bar\theta^{\dot\gamma} = \delta^{\dot\gamma}_{\dot\alpha}$ and the anticommutativity of $\bar\partial_{\dot\alpha}$ with the θ^α to its left,

$$-\bar\partial_{\dot\alpha}\,y^\nu = -\bar\partial_{\dot\alpha}(i\,\theta^\beta\sigma^\nu_{\beta\dot\gamma}\bar\theta^{\dot\gamma}) = -i\,(-\theta^\beta\sigma^\nu_{\beta\dot\gamma}\delta^{\dot\gamma}_{\dot\alpha}) = +i\,\theta^\beta\sigma^\nu_{\beta\dot\alpha}, \tag{44.187}$$

while the explicit x-derivative piece of $\bar{D}_{\dot\alpha}$ acts on the x^ν in y^ν,

$$-i\,\theta^\beta\sigma^\mu_{\beta\dot\alpha}\,\partial_\mu\,y^\nu = -i\,\theta^\beta\sigma^\mu_{\beta\dot\alpha}\,\delta^\nu_\mu = -i\,\theta^\beta\sigma^\nu_{\beta\dot\alpha}, \tag{44.188}$$

the ∂_μ of the $i\theta\sigma^\nu\bar\theta$ term vanishing because it has no x-dependence. The two contributions Eq. (44.187) and Eq. (44.188) cancel:

$$\bar{D}_{\dot\alpha}\,y^\nu = i\,\theta^\beta\sigma^\nu_{\beta\dot\alpha} - i\,\theta^\beta\sigma^\nu_{\beta\dot\alpha} = 0. \tag{44.189}$$

Hence $\bar{D}_{\dot\alpha}$ kills y and θ, and any $\Phi = \Phi(y,\theta)$ obeys $\bar{D}_{\dot\alpha}\Phi = 0$. Conversely, in the coordinate system $(y,\theta,\bar\theta)$ the operator $\bar{D}_{\dot\alpha}$ reduces to $-\bar\partial_{\dot\alpha}\big|_{y,\theta}$ (the chain rule moves the mixing into the definition of y), so $\bar{D}_{\dot\alpha}\Phi = 0$ says nothing other than $\partial\Phi/\partial\bar\theta^{\dot\alpha} = 0$ at fixed (y,θ): a chiral superfield is precisely a superfield independent of $\bar\theta$ when written in terms of y. This is the general solution of the constraint.

44.7.3 The component expansion and the off-shell multiplet

A function of θ^α (two anticommuting components) and y terminates at order θ^2, because any product of three θ's vanishes. The most general chiral superfield is therefore the finite expansion

$$\boxed{\Phi(y,\theta) \;=\; \phi(y) \;+\; \sqrt{2}\,\theta\psi(y) \;+\; \theta\theta\, F(y).} \tag{44.190}$$

The factor $\sqrt{2}$ is conventional, chosen so that the kinetic terms below come out canonically normalized. The three component fields are exactly the content of the off-shell Wess–Zumino multiplet of Section 44.5: a complex scalar ϕ, a left-handed Weyl fermion ψ_α, and a complex auxiliary scalar F. The constraint $\bar{D}\Phi = 0$ has done its work, truncating the bloated general superfield down to this single irreducible multiplet. Counting confirms it: off shell, ϕ has 2 real bosonic components and F has 2, four bosonic in all, matching the four real components of the unconstrained Weyl spinor ψ — the boson–fermion balance demanded by Section 44.4.

To compare with the component transformations of Section 44.5, which were written as functions of x, we re-expand Eq. (44.190) about x^μ using $y^\mu = x^\mu + i\theta\sigma^\mu\bar\theta$. The shift is nilpotent — $(y-x)^\mu(y-x)^\nu(y-x)^\rho = 0$ since it is cubic in θ and $\bar\theta$ — so the Taylor series stops at second order. Two Grassmann identities, both established in Section 44.6, organize the result:

$$(\theta\sigma^\mu\bar\theta)(\theta\sigma^\nu\bar\theta) = \tfrac{1}{2}\,\eta^{\mu\nu}\,\theta\theta\,\bar\theta\bar\theta, \tag{44.191}$$

$$(\theta\sigma^\mu\bar\theta)(\theta\chi) = -\tfrac{1}{2}\,\theta\theta\,(\chi\sigma^\mu\bar\theta). \tag{44.192}$$

Applying them, $\phi(y) = \phi(x) + i\theta\sigma^\mu\bar\theta\,\partial_\mu\phi - \tfrac{1}{4}\theta\theta\bar\theta\bar\theta\,\Box\phi$ from Eq. (44.191), and $\sqrt{2}\,\theta\psi(y) = \sqrt{2}\,\theta\psi - \tfrac{i}{\sqrt{2}}\theta\theta\,\partial_\mu\psi\,\sigma^\mu\bar\theta$ from Eq. (44.192), while $\theta\theta F(y) = \theta\theta F$ to the order that survives. Collecting,

$$\Phi = \phi + \sqrt{2}\,\theta\psi + \theta\theta\,F + i\,\theta\sigma^\mu\bar\theta\,\partial_\mu\phi - \tfrac{i}{\sqrt{2}}\,\theta\theta\,\partial_\mu\psi\,\sigma^\mu\bar\theta - \tfrac{1}{4}\,\theta\theta\,\bar\theta\bar\theta\,\Box\phi, \tag{44.193}$$

all fields now functions of x. The chiral superfield has only the components (ϕ,ψ,F); the remaining terms in Eq. (44.193) are their spacetime derivatives, forced by the constraint, not independent fields.

It remains to verify that the supersymmetry variation of the components reproduces, term by term, the off-shell Wess–Zumino transformations of Eq. (44.134)

— closing the loop opened in Section 44.5. The variation of a chiral superfield is $\delta_\xi \Phi = (\xi Q + \bar{\xi}\bar{Q})\Phi$. In chiral coordinates the supercharges take a simple form on $\Phi(y,\theta)$: from Eq. (44.183) and the chain rule one finds $Q_\alpha \to \partial_\alpha$ acting at fixed y, while $\bar{Q}_{\dot\alpha} \to 2i\,\theta^\beta \sigma^\mu_{\beta\dot\alpha}\partial_\mu$, so that

$$\delta_\xi \Phi = \xi^\alpha \partial_\alpha \Phi - 2i\,(\theta\sigma^\mu\bar{\xi})\,\partial_\mu \Phi. \tag{44.194}$$

Inserting Eq. (44.190) and reading off the coefficients of 1, θ, and $\theta\theta$ (using $\partial_\alpha(\theta\theta) = 2\theta_\alpha$ and Eq. (44.192)) gives

$$\delta_\xi \phi = \sqrt{2}\,\xi\psi, \tag{44.195}$$

$$\delta_\xi \psi_\alpha = \sqrt{2}\,\xi_\alpha\, F - i\sqrt{2}\,\sigma^\mu_{\alpha\dot\beta}\,\bar{\xi}^{\dot\beta}\,\partial_\mu \phi, \tag{44.196}$$

$$\delta_\xi F = i\sqrt{2}\,\partial_\mu(\psi\sigma^\mu\bar{\xi}) \;=\; -i\sqrt{2}\,\bar{\xi}\,\bar{\sigma}^\mu\,\partial_\mu\psi. \tag{44.197}$$

These are precisely Eq. (44.134): the scalar rotates into the fermion, the fermion into the auxiliary field and the gradient of the scalar, and — the structurally decisive fact — *the auxiliary field rotates into a total derivative*. The off-shell multiplet built by trial and error in Section 44.5 is nothing but the component content of a constrained superfield, and superspace has reproduced its transformation law mechanically. The loop is closed.

Physical Insight

The miracle of Eq. (44.197) — that $\delta_\xi F$ is a pure divergence — is not an accident of the Wess–Zumino multiplet; it is the top of every chiral ladder. A supersymmetry transformation Eq. (44.194) raises the θ-degree by one (the $\xi^\alpha\partial_\alpha$ piece) or shifts the argument (the ∂_μ piece). The highest component $F = \Phi|_{\theta\theta}$ has nowhere higher to go: the only thing δ_ξ can do to it is move it in spacetime. This is why $\int d^4x\, F$ is supersymmetric, and it is the whole reason superspace integrals build invariant actions. The same logic, applied to the highest component of a general *real* superfield, will give the D-term below.

44.7.4 Products of chiral superfields and the superpotential

Chiral superfields form a *ring*, and this single algebraic fact is what makes interactions possible in superspace. Since $\bar{D}_{\dot\alpha}$ is a first-order differential operator, it acts on a product as a (graded) derivation; acting on two bosonic chiral superfields Φ_1, Φ_2,

$$\bar{D}_{\dot\alpha}(\Phi_1\Phi_2) = (\bar{D}_{\dot\alpha}\Phi_1)\Phi_2 + \Phi_1(\bar{D}_{\dot\alpha}\Phi_2) = 0, \tag{44.198}$$

so the product is again chiral. By induction any polynomial in the Φ_i with constant coefficients is chiral, and more generally any *holomorphic* function — a

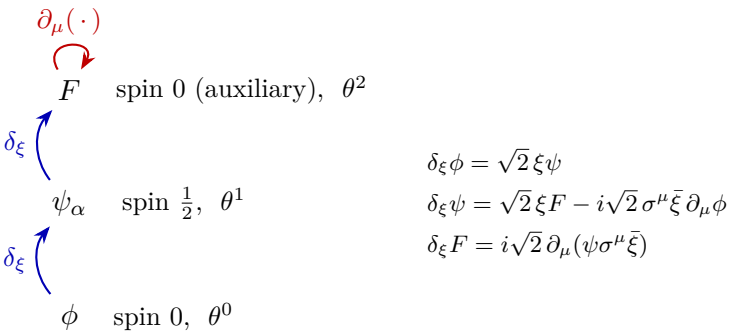

Figure 44.6: The chiral multiplet as a ladder in θ-degree. Supersymmetry δ_ξ climbs the ladder $\phi \to \psi \to F$, raising the θ-degree by one rung. The top rung F has nowhere higher to go, so δ_ξ can only move it by a total spacetime derivative (the looped red arrow, Eq. (44.197)). This is exactly what makes $\int d^4x\, F$ a supersymmetric invariant and underlies the F-term construction of actions.

power series in the Φ_i alone, with no $\Phi_i^\dagger$ — is chiral. (A function involving both Φ and $\Phi^\dagger$ is neither chiral nor antichiral; $\Phi^\dagger$ satisfies $D_\alpha\Phi^\dagger = 0$, not $\bar{D}_{\dot\alpha}\Phi^\dagger = 0$.) The cleanest way to see chirality of a product is in chiral coordinates: each $\Phi_i = \Phi_i(y,\theta)$ is $\bar\theta$-independent, and a product of $\bar\theta$-independent functions is $\bar\theta$-independent.

Definition 44.40 (Superpotential)**.** A *superpotential* $W(\Phi)$ is any holomorphic function of the chiral superfields of the theory — for a single field, a power series $W(\Phi) = \sum_n \frac{1}{n}\lambda_n\Phi^n$ with constant coefficients. By Eq. (44.198) the composite superfield $W(\Phi)$ is itself chiral.

Because $W(\Phi)$ is chiral, it has a component expansion of the form Eq. (44.190), and we will need its components. Expanding the holomorphic function about its lowest component ϕ and using $\Phi - \phi = \sqrt{2}\,\theta\psi + \theta\theta F$ together with the bilinear identity $(\theta\psi)(\theta\chi) = -\frac{1}{2}\,\theta\theta\,(\psi\chi)$,

$$W(\Phi) = W(\phi) + W'(\phi)\,(\Phi-\phi) + \tfrac{1}{2}\,W''(\phi)\,(\Phi-\phi)^2 + \dots, \tag{44.199}$$

the quadratic term contributing $(\Phi-\phi)^2\big|_{\theta\theta} = 2(\theta\psi)(\theta\psi) = -\theta\theta\,(\psi\psi)$. Collecting the coefficient of $\theta\theta$ gives the highest component of the superpotential,

$$\boxed{W(\Phi)\big|_{\theta\theta} = W'(\phi)\,F - \tfrac{1}{2}\,W''(\phi)\,\psi\psi.} \tag{44.200}$$

Here $W' = \partial W/\partial\phi$ and $W'' = \partial^2 W/\partial\phi^2$ are ordinary derivatives of the function W evaluated on the scalar ϕ.

44.7.5 The F-term and its supersymmetry invariance

The Berezin rule $\int \mathrm{d}^2\theta\,\theta\theta = 1$ (Theorem 44.35, inherited from Theorem 12.17) means that integrating a chiral superfield over the chiral measure extracts precisely

its highest component:

$$\int \mathrm{d}^2\theta\, W(\Phi) = W(\Phi)\big|_{\theta\theta} = W'(\phi)\, F - \tfrac{1}{2}\, W''(\phi)\, \psi\psi. \tag{44.201}$$

Such an integral is called an *F-term*. We must check that adding it to a Lagrangian preserves supersymmetry; this is the central invariance statement of the construction.

Theorem 44.41 (F-terms are supersymmetric)**.** *Let Λ be any chiral superfield, with highest component $F_\Lambda = \Lambda|_{\theta\theta}$ (in chiral coordinates). Then under a supersymmetry transformation δ_ξ, the highest component varies into a total spacetime derivative,*

$$\delta_\xi F_\Lambda = i\sqrt{2}\,\partial_\mu(\psi_\Lambda\,\sigma^\mu\bar{\xi}), \tag{44.202}$$

where $\psi_\Lambda = \Lambda|_\theta/\sqrt{2}$ is the fermionic component of Λ. Consequently the action contribution

$$S_F = \int d^4x \left[\int \mathrm{d}^2\theta\ \Lambda\ +\ \text{h.c.}\right] = \int d^4x\ (F_\Lambda + F_\Lambda^*) \tag{44.203}$$

is invariant, $\delta_\xi S_F = 0$.

Proof. The expansion Eq. (44.190) and the transformation rules Eq. (44.195)–Eq. (44.197) were derived for a generic chiral superfield; nothing in them used the field content beyond chirality. Writing $\Lambda = A + \sqrt{2}\,\theta\psi_\Lambda + \theta\theta\, F_\Lambda$ in chiral coordinates, Eq. (44.197) reads exactly Eq. (44.202). Now Λ is chiral, so its highest component is a function of y; but $\int d^4x\, f(y) = \int d^4y\, f(y) = \int d^4x\, f(x)$, since the shift $y = x + i\theta\sigma\bar{\theta}$ has unit Jacobian and merely relabels the integration variable. Therefore $\delta_\xi S_F = \int d^4x\,(\delta_\xi F_\Lambda + \text{c.c.}) = \int d^4x\,\partial_\mu(\cdots) = 0$, the integral of a total derivative over all of spacetime vanishing for fields decaying at infinity. □

Applied to $\Lambda = W(\Phi)$, Theorem 44.41 establishes that the superpotential term

$$S_W = \int d^4x \left[\int \mathrm{d}^2\theta\ W(\Phi) + \text{h.c.}\right] \tag{44.204}$$

is a supersymmetric invariant for *any* holomorphic W. This is the superspace origin of every Yukawa coupling and scalar self-interaction in a supersymmetric theory: they are not added by hand but are the components of a single holomorphic function.

44.7.6 The Kähler term: kinetic energy in superspace

The superpotential supplies masses and interactions but no derivatives of the scalar and no kinetic term for the fermion: Eq. (44.200) contains F, $\psi\psi$, and ϕ algebraically, never $\partial_\mu\phi$. Kinetic terms must come from an integral over the

full superspace, $\int \mathrm{d}^4\theta = \int \mathrm{d}^2\theta\, \mathrm{d}^2\bar\theta$, of a quantity that is real and contains both Φ and $\Phi^\dagger$. The minimal, canonical choice is the *Kähler term*

$$S_K = \int d^4x \int \mathrm{d}^4\theta\; \Phi^\dagger\Phi. \tag{44.205}$$

The combination $\Phi^\dagger\Phi$ is a general real superfield (neither chiral nor antichiral), so it has a nonzero highest component $\theta\theta\bar\theta\bar\theta$, and the Berezin rule $\int \mathrm{d}^4\theta\, \theta\theta\bar\theta\bar\theta = 1$ extracts it. Invariance is guaranteed by the same logic as the F-term: the highest component of any superfield transforms into a total derivative under δ_ξ (the D-term theorem, Theorem 44.36), because there is no higher component to receive the variation. What we must do now is reduce Eq. (44.205) to components and confirm that it delivers exactly the canonical kinetic Lagrangian.

We extract the $\theta\theta\bar\theta\bar\theta$ coefficient of $\Phi^\dagger\Phi$ by multiplying the x-expansion Eq. (44.193) with its conjugate and keeping only terms of total Grassmann bidegree $(2,2)$ in $(\theta,\bar\theta)$. Organizing Φ and $\Phi^\dagger$ by bidegree, the pairings that reach $(2,2)$ are few. The purely bosonic ones are

$$\begin{aligned}
&\phi^*\Big(-\tfrac14\Box\phi\Big) + \Big(-\tfrac14\Box\phi^*\Big)\phi && \text{from (lowest)} \times \text{(highest)},\\
&F^*F && \text{from } (\bar\theta\bar\theta F^*)(\theta\theta F),\\
&(\partial_\mu\phi^*\partial_\nu\phi)\,(\theta\sigma^\mu\bar\theta)(\theta\sigma^\nu\bar\theta) = \tfrac12\,\partial_\mu\phi^*\partial^\mu\phi\;\theta\theta\bar\theta\bar\theta && \text{from the two } (1,1) \text{ pieces, via Eq. (44.191)}.
\end{aligned}$$

Collecting the bosonic coefficient of $\theta\theta\bar\theta\bar\theta$ and integrating the $\Box$ terms by parts under $\int d^4x$ (so that $-\tfrac14\phi^*\Box\phi \to +\tfrac14\partial_\mu\phi^*\partial^\mu\phi$, and likewise for its conjugate),

$$[\Phi^\dagger\Phi]^{\text{bos}}_{\theta\theta\bar\theta\bar\theta} \;\longrightarrow\; \Big(\tfrac14+\tfrac14+\tfrac12\Big)\partial_\mu\phi^*\partial^\mu\phi + F^*F = \partial_\mu\phi^*\,\partial^\mu\phi + F^*F. \tag{44.206}$$

The two halves of the kinetic term — one quarter each from the $\Box\phi$ descendants of ϕ and ϕ^*, one half from the $(\theta\sigma\bar\theta)$-cross term — assemble into the single canonically normalized $\partial_\mu\phi^*\partial^\mu\phi$, and the auxiliary field contributes its modulus squared F^*F with no derivative, confirming that F is non-propagating.

The fermionic contributions come from the two pairings that carry one ψ and one $\bar\psi$ and reach bidegree $(2,2)$: the lowest fermion of $\Phi^\dagger$ with the $\theta\theta$-cross term of Φ, and the conjugate pairing. Using the reduction identities Eq. (44.192) and its conjugate $(\bar\theta\bar\eta)(\partial_\mu\psi\,\sigma^\mu\bar\theta) = -\tfrac12\,\bar\theta\bar\theta\,(\partial_\mu\psi\,\sigma^\mu\bar\eta)$, together with $\chi\sigma^\mu\bar\eta = -\bar\eta\,\bar\sigma^\mu\chi$ from Section 44.6, the two terms combine into the Hermitian Weyl bilinear

$$[\Phi^\dagger\Phi]^{\text{ferm}}_{\theta\theta\bar\theta\bar\theta} = \tfrac{i}{2}\,(\bar\psi\,\bar\sigma^\mu\partial_\mu\psi - \partial_\mu\bar\psi\,\bar\sigma^\mu\psi) \;\xrightarrow{\text{by parts}}\; i\,\bar\psi\,\bar\sigma^\mu\partial_\mu\psi, \tag{44.207}$$

which is exactly the canonical kinetic Lagrangian for a left-handed Weyl fermion fixed in Section 3.4.3 and quantized in Chapter 11. Assembling Eq. (44.206) and Eq. (44.207), the Kähler term reduces to

$$\boxed{\int \mathrm{d}^4\theta\; \Phi^\dagger\Phi = \partial_\mu\phi^*\,\partial^\mu\phi + i\,\bar\psi\,\bar\sigma^\mu\partial_\mu\psi + F^*F} \tag{44.208}$$

up to a total derivative — the free, massless, canonically normalized kinetic energy of the scalar and the fermion, plus the algebraic F^*F that marks F as auxiliary.

44.7.7 The full superspace Wess–Zumino action

We can now write the Wess–Zumino model of Section 44.5 in one line of superspace. Combining the Kähler term Eq. (44.205) with the superpotential term Eq. (44.204),

$$\boxed{S_{\mathrm{WZ}} = \int d^4x \left[\int \mathrm{d}^4\theta\, \Phi^\dagger \Phi \;+\; \left(\int \mathrm{d}^2\theta\, W(\Phi) + \mathrm{h.c.} \right) \right].} \tag{44.209}$$

This is manifestly supersymmetric: the Kähler term is a D-term and the superpotential term is an F-term, and both classes are invariant by Theorem 44.41 and Theorem 44.36. No component computation is needed to certify invariance — supersymmetry of Eq. (44.209) is as automatic as Lorentz invariance of a scalar action, and this economy is the entire payoff of the superspace formalism.

Reducing Eq. (44.209) to components by Eq. (44.208) and Eq. (44.201) gives the off-shell component Lagrangian

$$\mathcal{L}_{\mathrm{WZ}} = \partial_\mu \phi^* \partial^\mu \phi + i\,\bar\psi\,\bar\sigma^\mu \partial_\mu \psi + F^*F + \Big[W'(\phi)\, F - \tfrac{1}{2} W''(\phi)\, \psi\psi + \mathrm{h.c.} \Big], \tag{44.210}$$

which is, term for term, the Lagrangian assembled by hand in Eqs. (44.133) and (44.142). The fermion kinetic term and the scalar kinetic term are the components of the same Kähler term; the Yukawa coupling $W''\psi\psi$ and the auxiliary coupling $W'F$ are the components of the same superpotential. Supersymmetry, which related these by hand in Section 44.5 only after a page of algebra, is here built into the geometry.

The auxiliary field F appears without derivatives, so its Euler–Lagrange equation is algebraic. Varying Eq. (44.210) with respect to F^* and F,

$$\frac{\partial \mathcal{L}}{\partial F^*} = F + \overline{W'} = 0 \quad \Longrightarrow \quad F = -\,\overline{W'(\phi)}, \qquad F^* = -\,W'(\phi), \tag{44.211}$$

where $\overline{W'} = (\partial W/\partial\phi)^*$. Substituting back, the auxiliary sector $F^*F + W'F + \overline{W'}F^*$ collapses to $|W'|^2 - |W'|^2 - |W'|^2 = -|W'(\phi)|^2$, so the on-shell Lagrangian is

$$\mathcal{L}_{\mathrm{WZ}}^{\text{on-shell}} = \partial_\mu \phi^* \partial^\mu \phi + i\,\bar\psi\,\bar\sigma^\mu \partial_\mu \psi - \tfrac{1}{2}\big[W''(\phi)\, \psi\psi + \mathrm{h.c.} \big] - V(\phi, \phi^*), \tag{44.212}$$

with the *scalar potential*

$$\boxed{V(\phi,\phi^*) = \big|W'(\phi)\big|^2 = \Big|\frac{\partial W}{\partial \phi}\Big|^2 \;\geq\; 0.} \tag{44.213}$$

The potential is the modulus-squared of the holomorphic derivative of the superpotential, and it is manifestly non-negative — the component-level shadow of the energy positivity $H \geq 0$ derived from the algebra in Section 44.3.1. Supersymmetric vacua are the zeros of V, i.e. the critical points $W'(\phi) = 0$ of the superpotential, where the energy vanishes exactly.

Worked Example 44.42 (The cubic Wess–Zumino model: Yukawa and potential from $\int \mathrm{d}^2\theta\, W$)**.** Take the renormalizable cubic superpotential of the Wess–Zumino model,

$$W(\Phi) = \tfrac{1}{2}\, m\, \Phi^2 + \tfrac{1}{3}\, g\, \Phi^3, \tag{44.214}$$

with a mass parameter m and a dimensionless coupling g. (A constant and a linear term are the only other renormalizable options: a constant drops out of Eq. (44.201), and a linear "Fayet–Iliopoulos-like" term shifts F and is treated in Chapter 45.) We extract the component Lagrangian directly from the superspace expression and exhibit the supersymmetric relations among its couplings.

Derivatives of the superpotential. From Eq. (44.214),

$$W'(\phi) = m\,\phi + g\,\phi^2, \qquad W''(\phi) = m + 2g\,\phi. \tag{44.215}$$

The F-term. Substituting Eq. (44.215) into Eq. (44.201),

$$\int \mathrm{d}^2\theta\, W(\Phi) = (m\phi + g\phi^2)\, F - \tfrac{1}{2}(m + 2g\phi)\, \psi\psi. \tag{44.216}$$

Adding the Hermitian conjugate and the Kähler term Eq. (44.208), the off-shell Lagrangian is Eq. (44.210) with these explicit couplings. The fermion bilinear splits into a *Majorana mass term* $-\frac{1}{2}m\,\psi\psi + \text{h.c.}$ and a *Yukawa coupling* $-g\,\phi\,\psi\psi + \text{h.c.}$; the mass that appears here is the same m that sits in front of Φ^2.

The scalar potential. Integrating out F via Eq. (44.211) and using Eq. (44.213),

$$V(\phi, \phi^*) = |m\phi + g\phi^2|^2 = m^2\,|\phi|^2 + mg\,(\phi^*\phi^2 + \phi\,\phi^{*2}) + g^2\,|\phi|^4. \tag{44.217}$$

Reading off the spectrum and the SUSY relations. The scalar mass term is $m^2|\phi|^2$, so the complex scalar ϕ has mass m; the Majorana mass term is $-\frac{1}{2}m\,\psi\psi$, so the Weyl fermion ψ has the *same* mass m. Boson and fermion are exactly degenerate — the hallmark of unbroken supersymmetry, which in Section 44.4 was forced by $\left\{Q, \bar{Q}\right\} \sim P$. The quartic scalar coupling $g^2|\phi|^4$ and the cubic scalar coupling $mg(\phi^*\phi^2 + \text{h.c.})$ are not independent of the Yukawa coupling g: they are fixed by it, because all three descend from the *single* holomorphic function Eq. (44.214). The familiar non-supersymmetric freedom to choose a scalar quartic independently of the Yukawa is gone; supersymmetry ties $\lambda_{\phi^4} = g^2$ to the Yukawa g. This rigidity — one holomorphic W controlling masses, Yukawas, and the scalar potential at once — is exactly what will make the loop corrections of Chapter 45 so tightly constrained.

44.7.8 Holomorphy and the seed of nonrenormalization

The split of the action Eq. (44.209) into a Kähler term and a superpotential term is not merely organizational; it is the structural fact behind the most celebrated quantum properties of supersymmetric theories. The superpotential $W(\Phi)$ is *holomorphic* — a function of the chiral superfields alone, with no dependence on the conjugates $\Phi^\dagger$ — whereas the Kähler potential $K = \Phi^\dagger\Phi$ depends on both. Holomorphy is a powerful constraint because the couplings in W can be promoted to background chiral superfields ("spurions"): the mass m and coupling g of Eq. (44.214) are themselves the lowest components of chiral spurion superfields, and any quantum-corrected effective superpotential must again be a *holomorphic* function of the dynamical fields and these spurions. Together with the symmetries (including an R-symmetry that assigns charges to θ and hence to W) and the weak-coupling limits, holomorphy is so restrictive that it forbids the superpotential from receiving *any* perturbative corrections at all: the renormalized W equals the classical W to all orders in perturbation theory. This is the *nonrenormalization theorem*, and it is the reason the boson–fermion mass degeneracy found in Theorem 44.42 survives quantization — the cancellation of quadratic divergences that motivates supersymmetry as a response to the hierarchy problem (Chapter 35).

Caution

Nonrenormalization protects the *superpotential*, not the whole theory. The Kähler term $\int \mathrm{d}^4\theta\, \Phi^\dagger\Phi$ is a D-term and is *not* holomorphic; it does receive corrections, which renormalize the kinetic terms and hence wave-function-renormalize the fields. Physical (canonically normalized) couplings therefore do run, but only through the universal wave-function factors, not through independent vertex renormalizations. Disentangling "holomorphic" from "physical" couplings is the technical heart of Chapters 45 and 46; here we only plant the flag that the superpotential's protection comes from its holomorphy and the F-term structure isolated in Theorem 44.41.

We have now built the full $\mathcal{N} = 1$ chiral toolkit: the chiral constraint and its solution, the component multiplet matched to Section 44.5, the F-term and Kähler-term constructions, the superspace Wess–Zumino action, and the holomorphy that protects it. What remains, to reach realistic supersymmetric theories, is to add gauge interactions. That requires a second kind of superfield — the real *vector* superfield, whose lowest physical components are a gauge boson and its fermionic "gaugino" partner — and the supersymmetric completion of the gauge principle of Chapter 25. Chapter 45 constructs the vector superfield, gauges the chiral matter built here, and assembles super-Yang–Mills and SQCD, taking the chiral superfields and superspace actions of this section as its starting point; Chapter 46 then turns the holomorphy seeded above into exact nonperturbative

results. The chiral superfield, and the F-term/Kähler-term grammar of writing actions in superspace, are from here on assumed.

Further reading

The two no-go-and-its-loophole results that frame the chapter are Coleman and Mandula [131] and Haag et al. [247]; both repay a careful reading and are the honest source for the hypotheses we only sketch. The Wess–Zumino model first appeared in Wess and Zumino [507]. For the systematic textbook development at the level of this chapter, Wess and Bagger [505] is the classic superspace reference (compatible two-component conventions), Weinberg [502] gives the most careful treatment of the algebra, representations, and the HLS theorem, and Terning [472] is an excellent modern account weighted toward dynamics and duality. Martin [339] is the standard pedagogical introduction, especially strong on the passage from superspace to component Lagrangians and on conventions; the two-component spinor technology used throughout is laid out exhaustively in Dreiner et al. [162]. Witten's supersymmetric quantum mechanics and the index that decides whether supersymmetry is spontaneously broken are from Witten [520]. Readers heading toward supergravity will find the superspace methods continued in Freedman and Van Proeyen [199].

Chapter 45

Supersymmetric Gauge Theories

The previous chapter built supersymmetry as a graded extension of the Poincaré algebra and gave it a working language: superspace, chiral and antichiral superfields, the auxiliary F- and D-components that close the algebra off shell, and the Wess–Zumino model as the simplest interacting theory (Chapter 44). What that chapter deliberately set aside was the gauge principle. This chapter supplies it. The task is to merge the two great organizing ideas of the book so far — local gauge invariance, which produced electromagnetism in Chapter 8 and Yang–Mills theory in Chapter 25, and supersymmetry, which pairs every boson with a fermion — into a single framework. The fusion is not optional decoration: once matter is charged and the gauge parameter is promoted to a *chiral* superfield, the ordinary Kähler term ceases to be invariant, and a new object, the real vector superfield, is forced into existence to repair it. Everything in the chapter unfolds from that one demand. Throughout we keep the global conventions of Chapter A : mostly-minus signature $\eta_{\mu\nu} = \mathrm{diag}(+,-,-,-)$, natural units $\hbar = c = 1$, Hermitian generators with $\mathrm{tr}(T^a T^b) = \frac{1}{2}\delta^{ab}$ and the numerical group-theory data of Chapter B, and the covariant-derivative sign $D_\mu = \partial_\mu - igA^a_\mu T^a$.

The arc runs from the simplest realization to the most physical. We open in the abelian case (Section 45.1): the vector superfield V, its super-gauge redundancy $V \to V + \Lambda + \Lambda^\dagger$ that reduces in Wess–Zumino gauge to exactly the ordinary U(1) symmetry of Chapter 8, the chiral gauge-invariant field strength $W_\alpha = -\frac{1}{4}\bar{D}^2 D_\alpha V$, the supersymmetric Maxwell action packaged by a single holomorphic coupling, and the covariant Kähler term $\Phi^\dagger e^{2qV}\Phi$ that reproduces minimal coupling. The non-abelian generalization (Section 45.2) promotes V to a matrix in the Lie algebra, replaces the additive gauge law by the finite conjugation $e^V \to e^{-i\Lambda^\dagger} e^V e^{i\Lambda}$, and produces super Yang–Mills, whose bosonic content is precisely the classical theory of Chapter 25 and whose quantization reuses the

Faddeev–Popov and BRST machinery of Chapter 26 without modification — the gaugino simply rides along in the adjoint. Adding charged quark and antiquark flavours gives supersymmetric QCD (Section 45.3), whose scalar potential $V = \sum_f |F_f|^2 + \frac{1}{2}\sum_a (D^a)^2$ falls out of the auxiliary fields and whose flat directions trace a classical moduli space of degenerate vacua, coordinatized by gauge-invariant mesons and baryons.

With the classical theory assembled, the chapter turns to what makes these models extraordinary. Holomorphy — the statement that the superpotential and the gauge coupling τ are holomorphic functions of holomorphic data, sharpened by treating the couplings themselves as spurion background fields — forces the nonrenormalization theorems (Section 45.4): the superpotential receives *no* perturbative corrections, and the holomorphic gauge coupling runs only at one loop. Translating from the holomorphic to the canonical normalization, via the Konishi anomaly whose rescaling Jacobian is computed by the same Fujikawa method as the chiral anomaly of Chapter 36, converts that one-loop statement into the all-orders exact NSVZ beta function, which reduces at leading order to the supersymmetric version of the Yang–Mills theory coefficient of Chapter 27. These exact results are the controlled laboratory that Chapter 46 exploits.

The world is not supersymmetric, so the last two sections confront breaking and phenomenology. Soft breaking (Section 45.5) is the art of lifting the superpartners while preserving the cancellation of quadratic divergences that made supersymmetry attractive in the first place: we compute that cancellation explicitly, prove the supertrace sum rule, and classify — via the spurion method and the Girardello–Grisaru criterion — exactly which operators may be added without reintroducing the hard divergences. Instantiating the template with realistic field content gives the Minimal Supersymmetric Standard Model (Section 45.6): two Higgs doublets forced by anomaly cancellation and holomorphy, the soft-breaking Lagrangian, the tree-level bound $m_h \le m_Z |\cos 2\beta|$ on the lightest Higgs, and the improvement of gauge-coupling unification that motivated so much of the program in Chapter 35.

This chapter advances Yang–Mills theory into its supersymmetric incarnation and is, apart from the NSVZ resummation and the soft-breaking divergence structure, perturbative and symmetry-based throughout. The genuinely non-perturbative content of these theories — the quantum fate of the moduli space, Seiberg duality, gaugino condensation, and the Seiberg–Witten solution — is deferred to Chapter 46, which takes the classical moduli spaces, the holomorphic scale, and the nonrenormalization theorems established here as its starting data. Where the experimental status of supersymmetry is at stake we state it plainly and date it: as of the mid-2020s no superpartner has been observed, and the natural region of the MSSM is constrained but not excluded.

45.1 The Vector Superfield and the Abelian Gauge Multiplet

Chapter 44 left us holding one of the two massless irreducible representations of the $\mathcal{N}=1$ super-Poincaré algebra. The chiral superfield Φ (Theorem 44.39, Eq. (44.190)) packages a complex scalar, a Weyl fermion, and an auxiliary field into a single object on superspace, and the superspace measures $\mathrm{d}^2\theta$, $\mathrm{d}^4\theta$ (Theorem 44.35) turn invariant Lagrangians into Berezin integrals whose supersymmetry is as automatic as the Lorentz invariance of $\int \mathrm{d}^4x\,\mathcal{F}^2$. What is still missing is the *other* massless multiplet found in the representation theory of Theorem 44.19: the vector, or gauge, multiplet, the supersymmetric home of a spin-one field. Building it is the business of this section. The guiding principle is not aesthetic but forced: if we want to gauge an internal symmetry of the matter built in Chapter 44 — to repeat, in superspace, the Chapter 8 step that turned a global U(1) into electromagnetism (Section 8.1) — then demanding that the matter Kähler term survive a *local* phase rotation will require a new superfield to compensate, and the representation theory of that compensator will hand us, with no further input, a photon, a Majorana gaugino, and a real auxiliary scalar. We let the gauge principle do the construction and watch the abelian gauge multiplet assemble itself.

Throughout we keep the chapter conventions of Section 44.7: mostly-minus metric $\eta_{\mu\nu}=\mathrm{diag}(+,-,-,-)$, natural units, the two-component spinor calculus of Section C.9 with $\sigma^{\mu}_{\alpha\dot\beta}=(\mathbf{1},\vec\sigma)$ and $\bar\sigma^{\mu\,\dot\alpha\alpha}=(\mathbf{1},-\vec\sigma)$, undotted indices raised and lowered with $\epsilon^{\alpha\beta},\epsilon_{\alpha\beta}$ ($\epsilon^{12}=-\epsilon_{12}=1$, dotted likewise), and the contraction shorthands $\theta\psi=\theta^\alpha\psi_\alpha$, $\bar\theta\bar\psi=\bar\theta_{\dot\alpha}\bar\psi^{\dot\alpha}$, $\theta\theta=\theta^\alpha\theta_\alpha$, $\bar\theta\bar\theta=\bar\theta_{\dot\alpha}\bar\theta^{\dot\alpha}$.

45.1.1 Gauging a symmetry forces a chiral parameter

Begin with the matter we already have. A single chiral superfield Φ with the canonical Kähler term $\int \mathrm{d}^4\theta\,\Phi^\dagger\Phi$ (Eq. (44.205)) has a manifest global U(1) symmetry,

$$\Phi \longrightarrow e^{-iq\,\alpha}\,\Phi, \qquad \Phi^\dagger \longrightarrow \Phi^\dagger\, e^{+iq\,\alpha}, \tag{45.1}$$

with α a real constant and q the charge: the phases cancel in $\Phi^\dagger\Phi$ and the action is unchanged. This is the superspace lift of the global phase symmetry whose gauging produced QED in Chapter 8. The Chapter 8 move was to promote the constant α to a spacetime function $\alpha(x)$ and to repair the resulting non-invariance by introducing a connection A_μ (Section 8.1). We attempt the identical move here, with one non-negotiable constraint imposed by supersymmetry.

The constraint is that the transformed field must *remain chiral*. If Φ obeys $\bar D_{\dot\alpha}\Phi=0$ then the gauge-rotated field must obey it too, or the rotation would carry us out of the chiral representation and the transformation would not be a

symmetry of the superspace structure at all. A local parameter is now itself a superfield $\Lambda(x,\theta,\bar\theta)$, and

$$\Phi \;\longrightarrow\; e^{-2iq\,\Lambda}\,\Phi \tag{45.2}$$

is chiral if and only if $e^{-2iq\Lambda}$ is chiral, i.e. if and only if Λ is itself a chiral superfield:

$$\bar D_{\dot\alpha}\,\Lambda \;=\; 0. \tag{45.3}$$

(The factor 2 and the i are conventional, chosen to make later component formulas clean; q is the charge.) That a product of chiral superfields is chiral, so that $e^{-2iq\Lambda}\Phi$ is chiral whenever Λ and Φ are, is the ring property of Section 44.7.4. The local gauge parameter of a supersymmetric theory *cannot* be a real function: it is forced to be a complex chiral superfield, carrying not just the ordinary gauge function but an entire chiral multiplet of partners. This is the first surprise, and it propagates through everything that follows.

Now watch the Kähler term. Under Eq. (45.2),

$$\Phi^\dagger\Phi \;\longrightarrow\; \Phi^\dagger\, e^{+2iq\,\Lambda^\dagger}\, e^{-2iq\,\Lambda}\,\Phi \;=\; \Phi^\dagger\, e^{-2iq(\Lambda-\Lambda^\dagger)}\,\Phi, \tag{45.4}$$

the last equality holding because the abelian exponents commute. The combination $\Lambda-\Lambda^\dagger$ does not vanish: Λ is chiral and $\Lambda^\dagger$ antichiral, distinct superfields. The Kähler term is *not* invariant, exactly as the matter kinetic term $\bar\psi i\bar\sigma\!\cdot\!\partial\psi$ failed to be invariant under a local phase in Chapter 8. The cure is the same in spirit: introduce a compensating field that absorbs the offending factor. We postulate a real superfield V, to be called the *vector superfield*, entering the Kähler term through an exponential and transforming so as to cancel Eq. (45.4).

Definition 45.1 (Gauge-covariant Kähler term and the super-gauge transformation)**.** Let $V=V^\dagger$ be a real superfield. The *gauge-covariant Kähler term* for a charge-q chiral superfield is

$$\int \mathrm{d}^4\theta\; \Phi^\dagger\, e^{2qV}\,\Phi, \tag{45.5}$$

and the *abelian super-gauge transformation* is the pair

$$\Phi \;\longrightarrow\; e^{-2iq\Lambda}\,\Phi, \qquad V \;\longrightarrow\; V \;+\; i(\Lambda-\Lambda^\dagger), \qquad \bar D_{\dot\alpha}\Lambda = 0. \tag{45.6}$$

The transformation of V is engineered precisely so that Eq. (45.5) is invariant: under Eq. (45.6),

$$\Phi^\dagger e^{2qV}\Phi \;\longrightarrow\; \Phi^\dagger\, e^{+2iq\Lambda^\dagger}\, e^{2qV+2iq(\Lambda-\Lambda^\dagger)}\, e^{-2iq\Lambda}\,\Phi \;=\; \Phi^\dagger\, e^{2qV}\,\Phi, \tag{45.7}$$

where every exponent commutes and the four added pieces $+2iq\Lambda^\dagger + 2iq\Lambda - 2iq\Lambda^\dagger - 2iq\Lambda$ cancel. The compensator V has done its job. Writing $\Lambda+\Lambda^\dagger$ or $i(\Lambda-\Lambda^\dagger)$ is a matter of taste — both are real superfields, both shift V by a real quantity — and we adopt $\delta V = i(\Lambda-\Lambda^\dagger)$ so that the imaginary part of the lowest component of Λ becomes the ordinary gauge function below. The remainder of the section is the unpacking of what this real superfield V contains and how the redundancy Eq. (45.6) prunes it.

45.1.2 The real vector superfield

A real superfield is the most general scalar superfield (Theorem 44.34, Eq. (44.170)) subject to $V = V^\dagger$. The reality condition identifies the complex components of Eq. (44.170) in conjugate pairs, halving the bosonic count and pairing the fermions. Writing out the surviving independent components in the parametrization standard for gauge theory,

Definition 45.2 (Real vector superfield)**.** A *vector superfield* is a real superfield $V = V^\dagger$, with component expansion

$$\begin{aligned} V(x,\theta,\bar\theta) = C + i\,\theta\chi - i\,\bar\theta\bar\chi + \tfrac{i}{2}\,\theta\theta\,(M+iN) - \tfrac{i}{2}\,\bar\theta\bar\theta\,(M-iN) - \theta\sigma^\mu\bar\theta\,A_\mu \\ + i\,\theta\theta\,\bar\theta\bar\lambda - i\,\bar\theta\bar\theta\,\theta\lambda + \tfrac{1}{2}\,\theta\theta\,\bar\theta\bar\theta\,D, \end{aligned} \tag{45.8}$$

in which C, M, N, D are real scalars, A_μ is a real vector, and $\chi_\alpha, \lambda_\alpha$ are Weyl fermions. (The gaugino λ and the scalar D appearing in the top two components have absorbed, by a field redefinition of the form $\lambda \to \lambda + \frac{i}{2}\sigma^\mu\partial_\mu\bar\chi$ and $D \to D + \frac{1}{2}\Box C$, the spacetime derivatives of the lower components, so that they stand alone; this is a harmless shift by derivatives of fields already present.)

Reality is manifest term by term: $(i\theta\chi)^\dagger = -i\bar\theta\bar\chi$, $(\frac{i}{2}\theta\theta(M+iN))^\dagger = -\frac{i}{2}\bar\theta\bar\theta(M-iN)$, $(\theta\sigma^\mu\bar\theta)^\dagger = \theta\sigma^\mu\bar\theta$ for real A_μ, and $(i\theta\theta\,\bar\theta\bar\lambda)^\dagger = -i\bar\theta\bar\theta\,\theta\lambda$, so that $V = V^\dagger$ holds identically. The off-shell content is eight real bosonic components — C, M, N, D, and the four of A_μ — balanced by eight real fermionic components, the four each of χ and λ. This $8_B + 8_F$ count is the vector-multiplet counterpart of the $4_B + 4_F$ of the off-shell chiral multiplet (Eq. (44.190)), and it will be slashed in half by gauge redundancy before the physical multiplet emerges. The vector A_μ sitting at the $\theta\sigma^\mu\bar\theta$ level is the candidate photon; the rest of Eq. (45.8) is, as we now show, either pure gauge or auxiliary.

45.1.3 The super-gauge transformation in components and Wess–Zumino gauge

To see what the transformation Eq. (45.6) does to the components Eq. (45.8), expand the chiral parameter Λ. As a chiral superfield it has the form Eq. (44.190), which in the x-expansion Eq. (44.193) reads

$$\Lambda = a + \sqrt{2}\,\theta\eta + \theta\theta\,f + i\,\theta\sigma^\mu\bar\theta\,\partial_\mu a - \tfrac{i}{\sqrt{2}}\,\theta\theta\,\partial_\mu\eta\,\sigma^\mu\bar\theta - \tfrac{1}{4}\,\theta\theta\,\bar\theta\bar\theta\,\Box a, \tag{45.9}$$

with a a complex scalar, η_α a Weyl fermion, and f a complex scalar. Its conjugate $\Lambda^\dagger$ is the antichiral mirror. Forming $i(\Lambda - \Lambda^\dagger)$ and matching the result against Eq. (45.8) component by component gives the transformation laws of the components of V. The lowest few are

$$C \to C - 2\,\mathrm{Im}\,a, \quad \chi \to \chi - \sqrt{2}\,\eta, \quad M + iN \to M + iN - 2f, \tag{45.10}$$

in which $\operatorname{Im} a$, η, and f are entirely free (they are arbitrary functions parametrizing Λ). These three shifts can therefore be used to set

$$C = 0, \qquad \chi = 0, \qquad M = N = 0, \tag{45.11}$$

exhausting the real part of a's imaginary partner $\operatorname{Im} a$, the spinor η, and the complex f. What survives untouched in this gauge is the $\theta\sigma^\mu\bar\theta$ component, the gaugino, and D.

Definition 45.3 (Wess–Zumino gauge)**.** A vector superfield is in *Wess–Zumino (WZ) gauge* when $C = \chi = M = N = 0$. In this gauge Eq. (45.8) collapses to

$$\boxed{V_{\text{WZ}} = -\,\theta\sigma^\mu\bar\theta\, A_\mu + i\,\theta\theta\,\bar\theta\bar\lambda - i\,\bar\theta\bar\theta\,\theta\lambda + \tfrac{1}{2}\,\theta\theta\,\bar\theta\bar\theta\, D.} \tag{45.12}$$

Theorem 45.4 (Wess–Zumino gauge exists and leaves exactly an ordinary U(1) gauge symmetry)**.** *Every vector superfield can be brought to the form Eq. (45.12) by a super-gauge transformation Eq. (45.6). The residual transformations that preserve WZ gauge are exactly those with* $\operatorname{Im} a = \text{const}\cdot$ *removed,* $\eta = 0$*,* $f = 0$*, and* $\operatorname{Re} a \equiv \frac{1}{2}\alpha(x)$ *an arbitrary real function; under such a residual transformation the components of Eq. (45.12) transform as*

$$A_\mu \;\longrightarrow\; A_\mu + \partial_\mu\alpha, \qquad \lambda \;\longrightarrow\; \lambda, \qquad D \;\longrightarrow\; D. \tag{45.13}$$

That is, the leftover gauge freedom is precisely an ordinary abelian gauge transformation of the photon A_μ*, while the gaugino and the auxiliary field are gauge invariant.*

Proof. Existence is Eq. (45.10): the three shifts there are by free parameters and can be solved to enforce Eq. (45.11), reaching Eq. (45.12). For the residual freedom, demand that a further transformation keep $C = \chi = M = N = 0$. From Eq. (45.10), preserving $C = 0$ requires $\operatorname{Im} a = 0$ (up to the trivial constant that shifts nothing physical), preserving $\chi = 0$ requires $\eta = 0$, and preserving $M = N = 0$ requires $f = 0$. The only surviving freedom is the *real* part of the lowest component, $\operatorname{Re} a$; write $\operatorname{Re} a = \frac{1}{2}\alpha(x)$. With $\operatorname{Im} a = \eta = f = 0$ the parameter Eq. (45.9) reduces to $\Lambda = \frac{1}{2}\alpha + \frac{i}{2}\,\theta\sigma^\mu\bar\theta\,\partial_\mu\alpha - \frac{1}{8}\theta\theta\bar\theta\bar\theta\,\Box\alpha$, a real-lowest-component chiral superfield, and

$$i(\Lambda - \Lambda^\dagger) = i\Big(\tfrac{i}{2}\theta\sigma^\mu\bar\theta\,\partial_\mu\alpha - \big(-\tfrac{i}{2}\theta\sigma^\mu\bar\theta\,\partial_\mu\alpha\big)\Big) + (\text{higher},\ \propto\Box\alpha \text{ cancels}) = -\,\theta\sigma^\mu\bar\theta\,\partial_\mu\alpha, \tag{45.14}$$

where the real-$\Box\alpha$ pieces of Λ and $\Lambda^\dagger$ are equal and cancel in the difference, and the lowest real constant $\frac{1}{2}\alpha$ cancels against its own conjugate. Comparing Eq. (45.14) with the $\theta\sigma^\mu\bar\theta$ term of Eq. (45.12) (coefficient $-A_\mu$), the shift $\delta V = -\theta\sigma^\mu\bar\theta\,\partial_\mu\alpha$ is $\delta(-A_\mu) = -\partial_\mu\alpha$, i.e. $A_\mu \to A_\mu + \partial_\mu\alpha$; the $\theta\theta\bar\theta\bar\lambda$ and $\theta\theta\bar\theta\bar\theta D$ components receive no shift because Λ at this residual level has no contribution at those orders. This is Eq. (45.13). □

Theorem 45.4 is the payoff of the whole construction: the gauge principle of Chapter 8, $A_\mu \to A_\mu + \partial_\mu \alpha$, has reappeared as the residue of a much larger superspace redundancy. The complex scalar a, the spinor η, and the scalar f of the chiral parameter Λ were spent gauging away the unphysical components C, χ, M, N; the single real function $\alpha = 2\,\mathrm{Re}\, a$ that remains is the ordinary photon gauge function. The matter field's response is consistent: under the residual transformation Eq. (45.2) becomes $\Phi \to e^{-2iq\Lambda}\Phi \to e^{-iq\alpha}\Phi$ at the level of lowest components, the global rotation Eq. (45.1) now made local — exactly the Chapter 8 matter transformation $\phi \to e^{-iq\alpha}\phi$ that accompanies $A_\mu \to A_\mu + \partial_\mu \alpha$.

Physical Insight

WZ gauge is a gauge choice, not a supersymmetric statement: the conditions $C = \chi = M = N = 0$ are not preserved by a supersymmetry transformation, since acting with Q on Eq. (45.12) regenerates lower components. The practical attitude, which every component computation in supersymmetric gauge theory adopts, is to work in WZ gauge and accept that a supersymmetry variation must be followed by a compensating supergauge transformation to return to the gauge. What *is* supersymmetric and gauge invariant is the physical content (A_μ, λ, D) modulo Eq. (45.13), and the field strength of the next subsection repackages exactly that content into a manifestly covariant object.

A computational bonus of WZ gauge deserves emphasis because every matter coupling relies on it. Since V_{WZ} in Eq. (45.12) begins at order $\theta\bar\theta$, any product of three or more factors of V_{WZ} exceeds the available four Grassmann coordinates and vanishes:

$$V_{\mathrm{WZ}}^2 = -\tfrac{1}{2}\,\theta\theta\,\bar\theta\bar\theta\,A_\mu A^\mu, \qquad V_{\mathrm{WZ}}^3 = 0. \tag{45.15}$$

The exponential in the covariant Kähler term Eq. (45.5) therefore truncates exactly, $e^{2qV_{\mathrm{WZ}}} = 1 + 2qV_{\mathrm{WZ}} + 2q^2V_{\mathrm{WZ}}^2$, a polynomial of degree two. This is what makes the matter coupling computable in closed form, as we verify in Theorem 45.8.

45.1.4 The chiral field-strength superfield

WZ gauge displays the physical content but is not supersymmetric, and the photon component A_μ is not gauge invariant. We want a gauge-invariant, manifestly supersymmetric object built from V that contains the field strength $F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu$ — the superspace analog of the curvature $F_{\mu\nu}$ that Chapter 8 extracted from the connection A_μ. The covariant derivatives $D_\alpha, \bar D_{\dot\alpha}$ of Theorem 44.32 provide it.

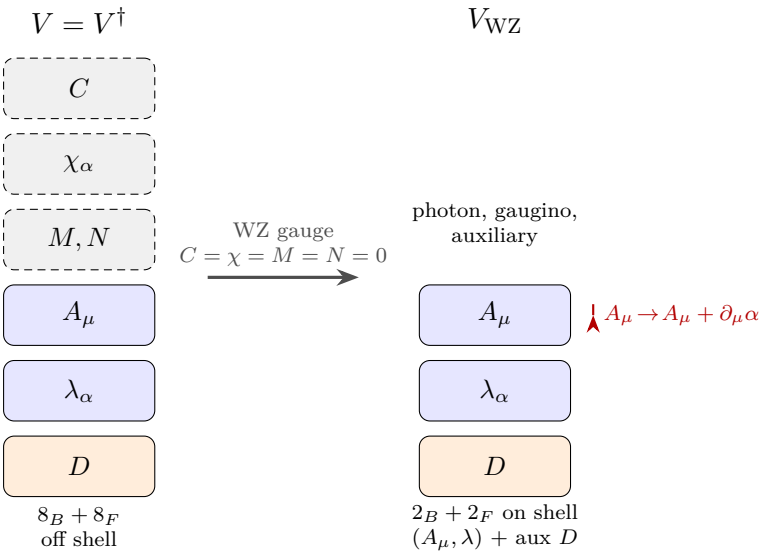

Figure 45.1: The abelian gauge multiplet. The off-shell real vector superfield V carries eight bosonic and eight fermionic components (left). The super-gauge freedom Eq. (45.6), whose parameter is a full chiral superfield Λ, gauges away the redundant lower components C, χ, M, N (dashed), landing in Wess–Zumino gauge Eq. (45.12) with content (A_μ, λ, D). The leftover real function in Λ is exactly the Chapter 8 photon gauge transformation (Theorem 45.4). On shell D is eliminated and A_μ, λ each carry two states, the photon and the Majorana gaugino.

Definition 45.5 (Abelian field-strength superfield)**.** The *field-strength superfield* of an abelian vector superfield V is the spinor-valued superfield

$$\boxed{W_\alpha \;=\; -\tfrac{1}{4}\,\bar{D}\bar{D}\,D_\alpha V \;=\; -\tfrac{1}{4}\,\bar{D}^2\,D_\alpha V,} \qquad \bar{W}_{\dot\alpha} \;=\; -\tfrac{1}{4}\,D^2\,\bar{D}_{\dot\alpha} V, \tag{45.16}$$

where $\bar{D}^2 \equiv \bar{D}^{\dot\alpha}\bar{D}_{\dot\alpha}$ and $D^2 \equiv D^\alpha D_\alpha$.

Two properties make W_α the right object, and both follow from the covariant derivative algebra of Eq. (44.168) with almost no computation.

Theorem 45.6 (W_α is chiral and gauge invariant)**.** *The field-strength superfield Eq. (45.16) satisfies*

$$\bar{D}_{\dot\beta}\, W_\alpha \;=\; 0 \qquad \textit{(chirality)}, \tag{45.17}$$

and is invariant under the abelian super-gauge transformation Eq. (45.6),

$$\delta_\Lambda W_\alpha \;=\; 0. \tag{45.18}$$

Proof. Chirality. The operator $\bar{D}^2 = \bar{D}^{\dot\alpha}\bar{D}_{\dot\alpha}$ is a product of two of the anti-holomorphic covariant derivatives, of which there are only two independent

components, $\bar{D}_{\dot{1}}, \bar{D}_{\dot{2}}$. Any product of three of them must repeat one, and since $\left\{\bar{D}_{\dot{\alpha}}, \bar{D}_{\dot{\beta}}\right\} = 0$ (Eq. (44.168)), a repeated antiholomorphic derivative anticommutes to zero. Hence

$$\bar{D}_{\dot{\beta}}\,\bar{D}^2 \;=\; 0 \qquad \text{(three } \bar{D}\text{'s vanish).} \tag{45.19}$$

Applying $\bar{D}_{\dot{\beta}}$ to Eq. (45.16), $\bar{D}_{\dot{\beta}} W_\alpha = -\frac{1}{4}(\bar{D}_{\dot{\beta}}\bar{D}^2)\, D_\alpha V = 0$ by Eq. (45.19). Thus W_α is chiral.

Gauge invariance. Under Eq. (45.6) the variation of V is $\delta V = i(\Lambda - \Lambda^\dagger)$, so $\delta_\Lambda W_\alpha = -\frac{1}{4}\bar{D}^2 D_\alpha\, i(\Lambda - \Lambda^\dagger)$. Treat the two pieces in turn. The antichiral piece $\Lambda^\dagger$ obeys $D_\alpha \Lambda^\dagger = 0$ by definition of antichirality (Theorem 44.39), so $\bar{D}^2 D_\alpha \Lambda^\dagger = 0$ outright. For the chiral piece Λ, use $\bar{D}_{\dot{\alpha}}\Lambda = 0$ and the algebra $\left\{D_\alpha, \bar{D}_{\dot{\beta}}\right\} = -2i\sigma^\mu_{\alpha\dot{\beta}}\partial_\mu$ (Eq. (44.168)) to commute D_α leftward through the two $\bar{D}$'s:

$$\bar{D}^2 D_\alpha \Lambda = \bar{D}^{\dot{\beta}}\bar{D}_{\dot{\beta}}\, D_\alpha \Lambda = \bar{D}^{\dot{\beta}}(-2i\sigma^\mu_{\alpha\dot{\beta}}\partial_\mu \Lambda) = -2i\sigma^\mu_{\alpha\dot{\beta}}\,\partial_\mu(\bar{D}^{\dot{\beta}}\Lambda) = 0, \tag{45.20}$$

where the first step replaced $\bar{D}_{\dot{\beta}} D_\alpha \Lambda = -D_\alpha \bar{D}_{\dot{\beta}}\Lambda - 2i\sigma^\mu_{\alpha\dot{\beta}}\partial_\mu\Lambda = -2i\sigma^\mu_{\alpha\dot{\beta}}\partial_\mu\Lambda$ (the first term vanishing by chirality of Λ), and the last step used chirality again, $\bar{D}^{\dot{\beta}}\Lambda = 0$. Both pieces vanish, so $\delta_\Lambda W_\alpha = 0$. □

The structure here is worth a sentence of reflection. Gauge invariance of W_α is the superspace statement that the field strength does not feel the gauge transformation, exactly as $F_{\mu\nu}$ in Chapter 8 was invariant under $A_\mu \to A_\mu + \partial_\mu\alpha$ while A_μ was not. Here the gauge parameter is an entire chiral superfield Λ, far larger than a function, yet $W_\alpha = -\frac{1}{4}\bar{D}^2 D_\alpha V$ annihilates all of it: the combination $\bar{D}^2 D_\alpha$ is the superspace projector onto the gauge-invariant curvature. That W_α is simultaneously chiral makes it a legitimate ingredient for an F-term action, which is what we build next. (Its $\mathrm{U}(1)_R$ charge is $+1$, inherited from the single uncontracted D_α, fixing the gaugino's R-charge; this is the gauge-sector entry of the R-symmetry table of Section 44.2.7.)

45.1.5 Component expansion of W_α

We now extract the components of W_α in WZ gauge. The cleanest route is the chiral coordinate $y^\mu = x^\mu + i\theta\sigma^\mu\bar{\theta}$ of Eq. (44.186), in which a chiral superfield is a function of (y, θ) alone and the covariant derivatives take the reduced form established in Section 44.7.2: since $\bar{D}_{\dot{\alpha}}$ annihilates both y^μ and θ^α (Eq. (44.189)), acting on any superfield written in $(y, \theta, \bar{\theta})$ it reduces to $\bar{D}_{\dot{\alpha}} = -\,\partial/\partial\bar{\theta}^{\dot{\alpha}}$, while the chain rule gives $D_\alpha = \partial/\partial\theta^\alpha + 2i\sigma^\mu_{\alpha\dot{\beta}}\bar{\theta}^{\dot{\beta}}\,\partial/\partial y^\mu$. Consequently $\bar{D}^2 = \bar{D}^{\dot{\alpha}}\bar{D}_{\dot{\alpha}} = \bar{\partial}^{\dot{\alpha}}\bar{\partial}_{\dot{\alpha}}$ in these coordinates, an operator that extracts the $\bar{\theta}\bar{\theta}$ coefficient: a direct

computation in the basis $\bar\theta^{\dot1},\bar\theta^{\dot2}$ with $\epsilon^{\dot1\dot2}=1$ gives $\bar\partial^{\dot\alpha}\bar\partial_{\dot\alpha}(\bar\theta\bar\theta)=4$, so for any g, $\bar D^2 g = 4\,[g]_{\bar\theta\bar\theta}$ in chiral coordinates. Therefore

$$W_\alpha = -\tfrac14\,\bar D^2\,(D_\alpha V) = -\,\big[\,D_\alpha V\,\big]_{\bar\theta\bar\theta}, \tag{45.21}$$

the (negative of the) coefficient of $\bar\theta\bar\theta$ in $D_\alpha V$.

We need $V_{\rm WZ}$ expressed in chiral coordinates. Substituting $x^\mu = y^\mu - i\theta\sigma^\mu\bar\theta$ into Eq. (45.12) and using the Fierz identity $(\theta\sigma^\mu\bar\theta)(\theta\sigma^\nu\bar\theta) = \tfrac12\eta^{\mu\nu}\theta\theta\bar\theta\bar\theta$ (Eq. (44.191)) to reduce the one cross term that survives,

$$V_{\rm WZ} = -\theta\sigma^\mu\bar\theta\,A_\mu(y) + i\,\theta\theta\,\bar\theta\bar\lambda(y) - i\,\bar\theta\bar\theta\,\theta\lambda(y) + \tfrac12\,\theta\theta\,\bar\theta\bar\theta\,\big[D(y) + i\,\partial_\mu A^\mu(y)\big], \tag{45.22}$$

all fields now functions of y. Applying $D_\alpha = \partial_\alpha + 2i\sigma^\nu_{\alpha\dot\gamma}\bar\theta^{\dot\gamma}\partial_{y\nu}$ and collecting the coefficient of $\bar\theta\bar\theta$ is a short exercise in the Grassmann identities $\bar\theta^{\dot\gamma}\bar\theta^{\dot\delta} = \tfrac12\epsilon^{\dot\gamma\dot\delta}\bar\theta\bar\theta$ and $\bar\theta^{\dot\gamma}\bar\theta_{\dot\delta} = -\tfrac12\delta^{\dot\gamma}_{\dot\delta}\bar\theta\bar\theta$. The ∂_α piece contributes, at order $\bar\theta\bar\theta$, the gaugino from $-i\bar\theta\bar\theta\,\theta\lambda$ and the D-term from $\tfrac12\theta\theta\bar\theta\bar\theta[D+i\partial A]$; the $2i\sigma\bar\theta\,\partial_y$ piece contributes the A_μ-gradient terms (from the $\theta\sigma^\mu\bar\theta A_\mu$ component) and the $\partial\bar\lambda$ term (from the $\theta\theta\bar\theta\bar\lambda$ component). Two facts organize the result. First, the antiholomorphic-derivative piece $-i\theta_\alpha\partial_\mu A^\mu$ generated by ∂_α acting on the D-component combines with the *symmetric* part of $\sigma^\nu\bar\sigma^\mu\partial_\nu A_\mu$ from the $2i\sigma\bar\theta\,\partial_y$ piece and *cancels*, since $\sigma^\nu\bar\sigma^\mu + \sigma^\mu\bar\sigma^\nu = 2\eta^{\mu\nu}$ (Section C.9) projects the symmetric part onto $\partial_\mu A^\mu$ with the opposite sign; this cancellation is the component avatar of the gauge invariance Eq. (45.18). Second, the *antisymmetric* part survives as $\tfrac12(\sigma^\mu\bar\sigma^\nu - \sigma^\nu\bar\sigma^\mu)\theta\,\partial_\mu A_\nu = (\sigma^\mu\bar\sigma^\nu\theta)\,\tfrac12 F_{\mu\nu}$, exactly the gauge-invariant field strength. Collecting,

$$\boxed{W_\alpha(y,\theta) = \lambda_\alpha(y) + \theta_\alpha\,D(y) - \tfrac{i}{2}\,(\sigma^\mu\bar\sigma^\nu\theta)_\alpha\,F_{\mu\nu}(y) + i\,\theta\theta\,(\sigma^\mu\partial_\mu\bar\lambda(y))_\alpha,} \tag{45.23}$$

with $F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu$ and $(\sigma^\mu\partial_\mu\bar\lambda)_\alpha = \sigma^\mu_{\alpha\dot\beta}\partial_\mu\bar\lambda^{\dot\beta}$. (The overall sign and normalization of the gaugino field λ are fixed once and for all by demanding that $W_\alpha|_{\theta=0} = \lambda_\alpha$ and that the kinetic term below be canonical with positive energy; this is the same convention that fixed the matter fermion's kinetic term in Eq. (44.207).) The lowest component is the gaugino, the θ-linear component carries the auxiliary D and the antisymmetric field strength $F_{\mu\nu}$, and the $\theta\theta$ component is the gaugino's equation-of-motion operator. The whole gauge-invariant content of the multiplet — λ, D, and $F_{\mu\nu}$ but *not* A_μ itself — has been assembled into one chiral spinor superfield.

45.1.6 The supersymmetric Maxwell action

Because W_α is chiral, the Lorentz scalar $W^\alpha W_\alpha$ is chiral, and its $\theta\theta$ component is a supersymmetry invariant by the F-term theorem (the chiral analog of Theorem 44.36). This is the unique dimension-three gauge-invariant chiral scalar built from one vector multiplet, hence the unique candidate for a renormalizable kinetic action. We extract its $\theta\theta$ component.

Worked Example 45.7 (The $\theta\theta$ component of $W^\alpha W_\alpha$)**.** From Eq. (45.23), multiply W^α by W_α and collect the coefficient of $\theta\theta$. Four products reach order $\theta\theta$:

- *Gaugino kinetic* (lowest $\times$ top, twice): $\lambda^\alpha \cdot i\theta\theta(\sigma^\mu\partial_\mu\bar\lambda)_\alpha$ and its mirror, summing to $2i\,\theta\theta\,\lambda\sigma^\mu\partial_\mu\bar\lambda$.
- *Auxiliary* (θ-linear D with itself): $(\theta^\alpha D)(\theta_\alpha D) = \theta\theta\, D^2$.
- *Field strength squared* (θ-linear F with itself): $-\frac{1}{4}(\sigma^\mu\bar\sigma^\nu\theta)^\alpha(\sigma^\rho\bar\sigma^\sigma\theta)_\alpha F_{\mu\nu}F_{\rho\sigma}$, which the two-component trace identities of Section C.9 reduce to $\theta\theta\big(-\frac{1}{2}F_{\mu\nu}F^{\mu\nu} - \frac{i}{4}\epsilon^{\mu\nu\rho\sigma}F_{\mu\nu}F_{\rho\sigma}\big)$.
- *Cross D–F*: proportional to $\theta\sigma^{\mu\nu}\theta\,F_{\mu\nu}$, which vanishes because $\theta^\alpha\theta_\beta = -\frac{1}{2}\delta^\alpha_\beta\,\theta\theta$ contracts the antisymmetric $F_{\mu\nu}$ against the symmetric trace δ, giving zero.

Assembling the surviving pieces,

$$\big[\,W^\alpha W_\alpha\,\big]_{\theta\theta} = D^2 \;-\; \tfrac{1}{2}F_{\mu\nu}F^{\mu\nu} \;+\; 2i\,\lambda\sigma^\mu\partial_\mu\bar\lambda \;-\; \tfrac{i}{4}\,\epsilon^{\mu\nu\rho\sigma}F_{\mu\nu}F_{\rho\sigma}. \tag{45.24}$$

The antichiral conjugate $\bar W_{\dot\alpha}\bar W^{\dot\alpha}$ has $\bar\theta\bar\theta$ component the complex conjugate of Eq. (45.24), in which F^2 and ϵFF are real (the latter multiplied by $+\frac{i}{4}$) and the gaugino term becomes $-2i\,\partial_\mu\lambda\,\sigma^\mu\bar\lambda$.

The supersymmetric Maxwell action is the F-term of Eq. (45.24) plus its conjugate. In *canonical* normalization,

$$S_{\text{Maxwell}} = \int \mathrm{d}^4x\,\Big[\tfrac{1}{4}\int \mathrm{d}^2\theta\; W^\alpha W_\alpha + \tfrac{1}{4}\int \mathrm{d}^2\bar\theta\;\bar W_{\dot\alpha}\bar W^{\dot\alpha}\Big] = \int \mathrm{d}^4x\,\Big[-\tfrac{1}{4}F_{\mu\nu}F^{\mu\nu} + i\,\bar\lambda\bar\sigma^\mu\partial_\mu\lambda + \tfrac{1}{2}D^2\Big]. \tag{45.25}$$

We verify the reduction. The F-term picks the $\theta\theta$ coefficient, so $\frac{1}{4}(W^\alpha W_\alpha|_{\theta\theta} + \text{c.c.}) = \frac{1}{2}\,\mathrm{Re}[W^\alpha W_\alpha]_{\theta\theta}$. The real parts of Eq. (45.24): the D^2 and $-\frac{1}{2}F^2$ pieces are real and survive as $\frac{1}{4}(2D^2) = \frac{1}{2}D^2$ and $\frac{1}{4}(-2\cdot\frac{1}{2}F^2) = -\frac{1}{4}F^2$; the ϵFF term, being pure imaginary in Eq. (45.24), cancels against its conjugate (the would-be θ-term is absent at $\theta = 0$); the gaugino term $\frac{1}{4}(2i\lambda\sigma^\mu\partial_\mu\bar\lambda - 2i\partial_\mu\lambda\,\sigma^\mu\bar\lambda)$ becomes, after one integration by parts and the identity $\lambda\sigma^\mu\bar\chi = -\bar\chi\bar\sigma^\mu\lambda$ of Section C.9, the canonical Weyl kinetic term $i\,\bar\lambda\bar\sigma^\mu\partial_\mu\lambda$ with the sign and normalization fixed in Eq. (44.207). The result Eq. (45.25) is exactly the photon Maxwell term of Chapter 8, $-\frac{1}{4}F_{\mu\nu}F^{\mu\nu}$, plus a kinetic term for a single Weyl fermion λ — the *gaugino* — plus the non-propagating square of the auxiliary D.

This pins down the on-shell content. The auxiliary D has algebraic equation of motion $D = 0$ (its only appearance in the pure-gauge action is $\frac{1}{2}D^2$), eliminating it; the photon A_μ contributes two physical polarizations after the gauge freedom Eq. (45.13) removes one and the equation of motion a second, and the gaugino λ, a massless Weyl fermion, carries two helicity states. Boson and fermion

counts match, $2_B = 2_F$, as supersymmetry demands on shell. The abelian gauge multiplet is precisely (A_μ, λ, D): a photon, a Majorana gaugino (the Weyl λ being the chiral half of a self-conjugate Majorana spinor, the photino), and an auxiliary real scalar.

Notation Watch

Three distinct objects in this section wear symbols built from "D" and "θ," and they must not be confused. *(i)* $D_\alpha, \bar{D}_{\dot\alpha}$ are the *superspace* covariant derivatives of Theorem 44.32, carrying spinor indices. *(ii)* D (no index) is the real *auxiliary scalar* of the vector multiplet, the top component of V in Eq. (45.12). *(iii)* $D_\mu = \partial_\mu - iqA_\mu$, appearing in Theorem 45.8 below, is the ordinary *gauge-covariant* derivative of Chapter 8, carrying a vector index. Likewise θ^α is the Grassmann *superspace coordinate*, whereas the θ inside the holomorphic coupling τ of Eq. (45.26) is the real *vacuum angle* of Chapter 42, a c-number with no index. Context and indices disambiguate; we keep the standard symbols rather than multiply notation.

Renormalizability and the freedom to absorb couplings invite a second, equivalent packaging. Rescaling the gauge field to canonical kinetic normalization moves the coupling g out of the matter term and in front of $W^\alpha W_\alpha$, and a CP-odd total-derivative term $\propto \epsilon^{\mu\nu\rho\sigma} F_{\mu\nu} F_{\rho\sigma}$ — the abelian shadow of the θ-term of Chapter 42 — may be added without spoiling supersymmetry, since it too descends from the imaginary part of $\int \mathrm{d}^2\theta\, W^\alpha W_\alpha$. Both are captured by promoting the coefficient to a single complex constant, the *holomorphic gauge coupling*

$$\tau \;\equiv\; \frac{\theta}{2\pi} \;+\; \frac{4\pi i}{g^2}, \tag{45.26}$$

in terms of which the gauge action is the manifestly supersymmetric

$$S_{\text{gauge}} = \frac{1}{8\pi}\,\mathrm{Im}\!\left[\,\tau \int \mathrm{d}^4x\, \mathrm{d}^2\theta\; W^\alpha W_\alpha\right]. \tag{45.27}$$

Expanding with Eq. (45.24) and $\mathrm{Im}[\tau X] = \mathrm{Re}\,\tau\ \mathrm{Im}\,X + \mathrm{Im}\,\tau\ \mathrm{Re}\,X$, the imaginary part $\mathrm{Im}\,\tau = 4\pi/g^2$ multiplies the real content $\mathrm{Re}[W^\alpha W_\alpha]_{\theta\theta} = D^2 - \tfrac{1}{2}F^2 + 2i\lambda\sigma\partial\bar\lambda +$ c.c., producing $-\frac{1}{4g^2}F_{\mu\nu}F^{\mu\nu} + \frac{1}{2g^2}D^2 + \frac{i}{g^2}\bar\lambda\bar\sigma^\mu\partial_\mu\lambda$, while the real part $\mathrm{Re}\,\tau = \theta/2\pi$ multiplies the imaginary ϵFF piece, producing the topological term $\frac{\theta}{32\pi^2}\,F_{\mu\nu}\widetilde{F}^{\mu\nu}$ (equivalently $\frac{\theta}{64\pi^2}\,\epsilon^{\mu\nu\rho\sigma}F_{\mu\nu}F_{\rho\sigma}$) in the normalization of Chapter 42. Setting $\theta = 0$ and $g = 1$ recovers Eq. (45.25); the prefactor $1/8\pi$ is exactly what converts $\mathrm{Im}\,\tau = 4\pi/g^2$ into the canonical $-1/4g^2$ in front of F^2. The single holomorphic constant τ thus carries both the gauge coupling and the vacuum angle, and its holomorphic dependence — $W^\alpha W_\alpha$ enters the action linearly in τ, never in $\bar\tau$ — is the structural seed of the nonrenormalization theorems to come.

45.1.7 Coupling matter and recovering the Chapter 8 covariant derivative

It remains to confirm that the covariant Kähler term Eq. (45.5) reproduces, in components, the minimal coupling of Chapter 8 — that the photon A_μ inside V couples to charged matter exactly through $D_\mu = \partial_\mu - iqA_\mu$. This both validates the construction and seeds the next section's matter coupling.

Worked Example 45.8 (Minimal coupling from $\Phi^\dagger e^{2qV}\Phi$)**.** Work in WZ gauge, where $e^{2qV} = 1 + 2qV_{\rm WZ} + 2q^2V_{\rm WZ}^2$ by Eq. (45.15). Expand $\Phi = \phi + \sqrt{2}\theta\psi + \theta\theta F$ (Eq. (44.193)) and collect the $\theta\theta\bar\theta\bar\theta$ coefficient of $\Phi^\dagger e^{2qV}\Phi$.

The order-V^0 term is the free Kähler density $\partial_\mu\phi^*\partial^\mu\phi + i\bar\psi\bar\sigma^\mu\partial_\mu\psi + F^*F$ of Eq. (44.208). The order-V^1 term, $2q\,\Phi^\dagger V_{\rm WZ}\Phi$, contributes through the photon component $-\theta\sigma^\mu\bar\theta A_\mu$. Pairing it with the $(1,1)$-bidegree pieces of $\Phi^\dagger\Phi$ and using $(\theta\sigma^\rho\bar\theta)(\theta\sigma^\mu\bar\theta) = \frac{1}{2}\eta^{\rho\mu}\theta\theta\bar\theta\bar\theta$, the bosonic part yields

$$2q(-A_\rho)\Big[i\,\phi^*\partial^\rho\phi\cdot\tfrac{1}{2} - i\,\partial^\rho\phi^*\,\phi\cdot\tfrac{1}{2}\Big] = -iqA^\mu(\phi^*\partial_\mu\phi - \partial_\mu\phi^*\,\phi), \tag{45.28}$$

the standard current–potential coupling. The order-V^2 term, $2q^2\Phi^\dagger V_{\rm WZ}^2\Phi = 2q^2\phi^*\phi\cdot(-\frac{1}{2}\theta\theta\bar\theta\bar\theta A^2)$, contributes the seagull $-q^2A_\mu A^\mu\,\phi^*\phi$. Adding the free kinetic term,

$$\partial_\mu\phi^*\partial^\mu\phi - iqA^\mu(\phi^*\partial_\mu\phi - \partial_\mu\phi^*\phi) - q^2A_\mu A^\mu\phi^*\phi = (D_\mu\phi)^*(D^\mu\phi), \quad D_\mu = \partial_\mu - iqA_\mu, \tag{45.29}$$

exactly the minimal coupling of Section 8.1 with the standard sign convention $D_\mu = \partial_\mu - iqA_\mu$. The fermion pieces assemble identically into $i\bar\psi\bar\sigma^\mu D_\mu\psi$. Beyond the gauge field, the order-V^1 term also couples matter to the *gaugino* and the *auxiliary* field: the $i\theta\theta\bar\theta\bar\lambda$ and $\frac{1}{2}\theta\theta\bar\theta\bar\theta D$ components of $V_{\rm WZ}$ produce

$$\sqrt{2}\,q\,(\phi^*\psi\lambda + \bar\lambda\bar\psi\,\phi) \;+\; q\,D\,\phi^*\phi, \tag{45.30}$$

a gaugino–matter Yukawa and a D-term coupling, both with strength fixed by the same charge q that controls the photon coupling — the rigid prediction of supersymmetry, with no independent coupling constant to adjust. Collecting,

$$\int \mathrm{d}^4\theta\;\Phi^\dagger e^{2qV}\Phi = (D_\mu\phi)^*(D^\mu\phi) + i\bar\psi\bar\sigma^\mu D_\mu\psi + F^*F + \sqrt{2}\,q(\phi^*\psi\lambda + \text{h.c.}) + q\,D\,\phi^*\phi. \tag{45.31}$$

The D-term coupling $q\,D\,\phi^*\phi$ in Eq. (45.31) is the first appearance of the scalar potential that drives supersymmetric gauge dynamics: combined with the gauge action's $\frac{1}{2}D^2$ from Eq. (45.25), the auxiliary D has equation of motion $D = -q\,\phi^*\phi$ (plus any Fayet–Iliopoulos constant), and integrating it out leaves the positive *D-term potential* $\frac{1}{2}D^2 = \frac{1}{2}q^2(\phi^*\phi)^2$. We have everything needed to state this potential and to promote the construction to a nonabelian group.

The abelian gauge multiplet is complete: a real vector superfield V with its super-gauge redundancy Eq. (45.6), the chiral gauge-invariant field strength $W_\alpha = -\frac{1}{4}\bar{D}^2 D_\alpha V$, the supersymmetric Maxwell action packaged by the holomorphic coupling τ, and the gauge-covariant matter coupling $\Phi^\dagger e^{2qV}\Phi$ that recovers Chapter 8's minimal coupling. These three building blocks — the exponential e^{2qV}, the field strength W_α, and the holomorphic action Eq. (45.27) — are exactly what Section 45.2 promotes to a nonabelian gauge group G, where $V = V^a T^a$ becomes matrix valued, the finite super-gauge transformation reads $e^V \to e^{-i\Lambda^\dagger} e^V e^{i\Lambda}$ (Eq. (45.34)), and the covariant field strength $W_\alpha = -\frac{1}{4}\bar{D}^2(e^{-V} D_\alpha e^V)$ carries the gaugino into the adjoint representation alongside the classical Yang–Mills field of Chapter 25.

45.2 Nonabelian Super Yang–Mills

The abelian construction of Section 45.1 gave us everything we need in miniature: a real vector superfield V, a super-gauge transformation $V \to V + i(\Lambda - \Lambda^\dagger)$ built from a *chiral* parameter Λ, the Wess–Zumino gauge that strips V down to the physical triple (A_μ, λ, D), the gauge-invariant chiral field-strength superfield $W_\alpha = -\frac{1}{4}\bar{D}^2 D_\alpha V$ (Eq. (45.16)), and the supersymmetric Maxwell action $\frac{1}{4}\int \mathrm{d}^2\theta\, W^\alpha W_\alpha + \text{h.c.}$ (Eq. (45.25)) whose component content is a photon, a gaugino, and an auxiliary D. Every one of these objects has a nonabelian counterpart, and the purpose of this section is to build it. The single structural change is that V becomes *matrix-valued*, $V = V^a T^a$, and the gauge transformation becomes a conjugation rather than a shift. That one change propagates through the entire construction: the field strength acquires a covariant derivative, the action acquires the cubic and quartic gluon self-interactions of Chapter 25, and the gaugino is promoted to the adjoint representation. What emerges is *super Yang–Mills theory*, the supersymmetric completion of the classical gauge theory of Chapter 25. We will see that its bosonic sector is, term for term, the classical Yang–Mills Lagrangian Eq. (25.104); that the gauge coupling and the θ-angle of Chapter 42 fuse into a single complex chiral coefficient, the holomorphic coupling $\tau = \theta/2\pi + 4\pi i/g^2$; and that quantization is carried out by feeding the Wess–Zumino-gauge component fields into the Faddeev–Popov/BRST machinery already built in Chapter 26.

Throughout we keep the chapter conventions: mostly-minus metric $\eta_{\mu\nu} = \mathrm{diag}(+,-,-,-)$, natural units, two-component spinors with $\sigma^\mu_{\alpha\dot\beta} = (\mathbf{1}, \vec\sigma)$ and $\bar\sigma^{\mu\,\dot\alpha\alpha} = (\mathbf{1}, -\vec\sigma)$, and the superspace covariant derivatives $D_\alpha, \bar{D}_{\dot\alpha}$ of Eq. (44.183) obeying $\left\{D_\alpha, \bar{D}_{\dot\beta}\right\} = -2i\,\sigma^\mu_{\alpha\dot\beta}\partial_\mu$ and $\{D_\alpha, D_\beta\} = \left\{\bar{D}_{\dot\alpha}, \bar{D}_{\dot\beta}\right\} = 0$. The gauge group is a compact simple Lie group G (default SU(N)) with Hermitian generators T^a in the representation on which the fields sit, $\left[T^a, T^b\right] = i f^{abc} T^c$ and $\mathrm{tr}(T^a T^b) = \frac{1}{2}\delta^{ab}$ in the fundamental; the structure constants f^{abc}, the dual

Coxeter number/adjoint Casimir C_A, and the index T_F are those collected in Section B.4.

45.2.1 The matrix vector superfield and the finite super-gauge transformation

The cleanest route to the nonabelian gauge multiplet is, exactly as in Chapter 25, to demand that the matter kinetic term be gauge invariant and let that requirement dictate the transformation law of the gauge superfield. Let Φ be a chiral superfield (Theorem 44.39) valued in a representation R of G, so that Φ^i carries a representation index i and the generators act as matrices $(T^a)^i{}_j$. The supersymmetric, gauge-covariant kinetic term is the Kähler integral

$$\int \mathrm{d}^4\theta\; \Phi^\dagger e^V \Phi \;=\; \int \mathrm{d}^4\theta\; \Phi^\dagger_{\bar\imath}\,(e^V)^{\bar\imath}{}_j\,\Phi^j, \qquad V \equiv V^a\,T^a, \tag{45.32}$$

the matrix exponential of the real, matrix-valued vector superfield $V = V^aT^a$ replacing the bare $\Phi^\dagger\Phi$ of Eq. (44.205). Reality of the V^a together with Hermiticity of the T^a makes V a Hermitian matrix superfield, $V = V^\dagger$, so that e^V is Hermitian and Eq. (45.32) is real. The exponential is the right object because gauge invariance is multiplicative: a chiral superfield transforms by a chiral matrix, and matrices compose by multiplication, not addition.

Concretely, generalize the abelian rule. In the abelian theory the matter field transformed by $\Phi \to e^{-i\Lambda}\Phi$ with Λ chiral (a chiral parameter preserves chirality, since $\bar D_{\dot\alpha}(e^{-i\Lambda}\Phi) = e^{-i\Lambda}\bar D_{\dot\alpha}\Phi = 0$ when $\bar D\Lambda = 0$). The nonabelian generalization is the same with $\Lambda = \Lambda^aT^a$ a matrix of chiral superfields:

$$\Phi \;\longrightarrow\; e^{-i\Lambda}\,\Phi, \qquad \Phi^\dagger \;\longrightarrow\; \Phi^\dagger\, e^{\,i\Lambda^\dagger}, \qquad \bar D_{\dot\alpha}\Lambda = 0,\;\; D_\alpha\Lambda^\dagger = 0. \tag{45.33}$$

Here $\Lambda^\dagger$ is antichiral, the Hermitian conjugate of the chiral Λ. For Eq. (45.32) to be invariant we need $\Phi^\dagger e^V\Phi \to \Phi^\dagger e^{\,i\Lambda^\dagger}\, e^{V'}\, e^{-i\Lambda}\Phi$ to equal $\Phi^\dagger e^V\Phi$, which fixes the transformation of the gauge superfield to be

$$\boxed{\;e^V \;\longrightarrow\; e^{V'} \;=\; e^{-i\Lambda^\dagger}\, e^V\, e^{\,i\Lambda}\;} \tag{45.34}$$

the *finite nonabelian super-gauge transformation*. This is the central definition of the section. It reduces to the abelian rule when everything commutes: there $e^{-i\Lambda^\dagger}e^Ve^{i\Lambda} = e^{V-i\Lambda^\dagger+i\Lambda}$, i.e. $V \to V + i(\Lambda - \Lambda^\dagger)$, the shift of Eq. (45.6). In the nonabelian case the conjugation by the chiral group element $e^{i\Lambda}$ on the right and the antichiral $e^{-i\Lambda^\dagger}$ on the left does not collapse to a shift, and the ordered structure is exactly what will produce the covariant derivative in the field strength.

Infinitesimal form. Write $\Lambda = \Lambda^a T^a$ infinitesimal and seek δV such that $e^{V+\delta V} = e^{-i\Lambda^\dagger} e^V e^{i\Lambda}$ to first order. Using the variation formula $\delta e^V = \int_0^1 e^{sV}(\delta V) e^{(1-s)V}\, ds$ and expanding the right-hand side to first order in $\Lambda, \Lambda^\dagger$ gives, after a short manipulation with the operator $\mathcal{L}_{V^\cdot} \equiv [V, \cdot]$,

$$\delta V \;=\; i(\Lambda - \Lambda^\dagger) \;+\; \tfrac{i}{2}\Big[V, \Lambda + \Lambda^\dagger\Big] \;+\; O(V^2)\,, \tag{45.35}$$

the full series being $\delta V = i\,\mathcal{L}_{V/2}\Big[\coth(\mathcal{L}_{V/2})(\Lambda - \Lambda^\dagger) + (\Lambda + \Lambda^\dagger)\Big]$, with $\mathcal{L}_{V/2^\cdot} = \frac{1}{2}[V, \cdot]$. We will never need the full series: the work below is done either with the finite law Eq. (45.34) directly, or in Wess–Zumino gauge, where V is nilpotent and the displayed terms of Eq. (45.35) are exact.

Notation Watch

The matrix superfield $V = V^a T^a$ is dimensionless in the holomorphic normalization used here: the gauge coupling g does *not* appear in V, in e^V, or in the field strength below. It is carried entirely by the single prefactor of the action, Eq. (45.55). In the alternative *canonical* normalization the component gauge field is rescaled $A_\mu \to g A_\mu$ (equivalently $V \to 2gV$) so that the kinetic term is $-\frac{1}{4} F^a_{\mu\nu} F^{a\,\mu\nu}$ with g inside the covariant derivative, as in Chapter 25. We will give the result in both normalizations and state explicitly which is which; conflating them is the single most common source of stray factors of g in this subject.

The Wess–Zumino gauge of Section 45.1 survives the promotion to nonabelian intact. The abelian shift $V \to V + i(\Lambda - \Lambda^\dagger)$ used the lower components of Λ to gauge away the lower components of V; the leading term $i(\Lambda - \Lambda^\dagger)$ of Eq. (45.35) is identical, so the same components of Λ remove the same components of V, leaving the WZ-gauge form

$$V_{\rm WZ} = -\,\theta\sigma^\mu\bar\theta\, A_\mu + i\,\theta\theta\,\bar\theta\bar\lambda - i\,\bar\theta\bar\theta\,\theta\lambda + \tfrac{1}{2}\,\theta\theta\,\bar\theta\bar\theta\, D, \tag{45.36}$$

with $A_\mu = A^a_\mu T^a$, $\lambda_\alpha = \lambda^a_\alpha T^a$, $D = D^a T^a$ all matrix-valued (and Hermitian as matrices, A_μ, D real, $\bar\lambda = \lambda^\dagger$). The commutator term in Eq. (45.35) only shuffles these surviving components among themselves and acts on A_μ as an ordinary nonabelian gauge rotation, exactly as in Chapter 25: the residual freedom after fixing WZ gauge is precisely the ordinary spacetime gauge symmetry $A_\mu \to U A_\mu U^{-1} + \frac{i}{?}\dots$ whose component form we recover below. The crucial structural fact we will use repeatedly is that Eq. (45.36) is *nilpotent*: every term carries at least one $\theta\sigma\bar\theta$, and a product of three such terms has more than two θ's or more than two $\bar\theta$'s and so vanishes. Hence

$$V_{\rm WZ}^3 = 0, \qquad V_{\rm WZ}^2 = \tfrac{1}{2}\,\theta\theta\,\bar\theta\bar\theta\; A_\mu A^\mu, \qquad e^{V_{\rm WZ}} = 1 + V_{\rm WZ} + \tfrac{1}{2} V_{\rm WZ}^2, \tag{45.37}$$

where the value of V^2 follows from $(\theta\sigma^\mu\bar\theta)(\theta\sigma^\nu\bar\theta) = \tfrac{1}{2}\theta\theta\,\bar\theta\bar\theta\,\eta^{\mu\nu}$ (the vector–vector Fierz identity Eq. (44.191)), so that the only surviving square is the gauge-field bilinear $A_\mu A^\mu$ (a matrix product, hence not symmetric in the colour indices).

45.2.2 The covariant field strength W_α

The abelian field strength $W_\alpha = -\tfrac{1}{4}\bar D^2 D_\alpha V$ is replaced by

$$\boxed{W_\alpha \;=\; -\tfrac{1}{4}\,\bar D^2\Big(e^{-V}\,D_\alpha\,e^{V}\Big)\,, \qquad W_\alpha = W_\alpha^a T^a.} \tag{45.38}$$

Here $\bar D^2 \equiv \bar D_{\dot\alpha}\bar D^{\dot\alpha}$ and $e^{-V}D_\alpha e^V$ is the supersymmetric analogue of the Maurer–Cartan form $U^{-1}\partial_\mu U$: it is the natural gauge-covariant object built from a group element, and applying $-\tfrac{1}{4}\bar D^2$ projects it onto a chiral superfield. In the abelian limit $e^{-V}D_\alpha e^V = D_\alpha V$ and Eq. (45.38) collapses to Eq. (45.16), as it must. Two properties make W_α the correct field strength: it is chiral, and it transforms in the adjoint by conjugation.

Proposition 45.9 (Chirality of W_α)**.** *The superfield W_α defined by Eq. (45.38) is chiral, $\bar D_{\dot\beta} W_\alpha = 0$.*

Proof. The dotted index $\dot\beta$ takes only two values, and $\big\{\bar D_{\dot\alpha}, \bar D_{\dot\beta}\big\} = 0$ makes the $\bar D$'s mutually anticommuting. Any product of three of them therefore vanishes: writing $\bar D_{\dot\beta}\bar D^2 = \bar D_{\dot\beta}\bar D^{\dot\gamma}\bar D_{\dot\gamma}$, the three factors live in a two-dimensional anticommuting space and so contain a repeated index, killing the product. Since W_α is $-\tfrac{1}{4}\bar D^2$ acting on something, $\bar D_{\dot\beta}W_\alpha = -\tfrac{1}{4}\bar D_{\dot\beta}\bar D^2(\cdots) = 0$. □

Chirality is exactly what is needed to use W_α in an F-term: by Theorem 44.41 the integral $\int \mathrm{d}^2\theta$ of any chiral quantity is supersymmetric, so $\int \mathrm{d}^2\theta\ \mathrm{Tr}(W^\alpha W_\alpha)$ is a candidate supersymmetric Lagrangian provided it is also gauge invariant. That is the content of the covariance theorem, the key result of this subsection.

Theorem 45.10 (Gauge covariance of W_α)**.** *Under the finite super-gauge transformation Eq. (45.34), the field strength transforms homogeneously in the adjoint,*

$$W_\alpha \;\longrightarrow\; e^{-i\Lambda}\,W_\alpha\,e^{\,i\Lambda}, \tag{45.39}$$

and consequently $\mathrm{Tr}(W^\alpha W_\alpha)$ is gauge invariant.

Proof. Write $\Omega \equiv e^{-V}D_\alpha e^V$ for the object inside the projection. Under Eq. (45.34) we have $e^V \to e^{-i\Lambda^\dagger}e^V e^{i\Lambda}$ and, taking the inverse, $e^{-V} \to e^{-i\Lambda}e^{-V}e^{i\Lambda^\dagger}$. We must transform $D_\alpha e^V$. By the Leibniz rule for the (odd) covariant derivative,

$$D_\alpha\Big(e^{-i\Lambda^\dagger}e^V e^{i\Lambda}\Big) = (D_\alpha e^{-i\Lambda^\dagger})\,e^V e^{i\Lambda} + e^{-i\Lambda^\dagger}(D_\alpha e^V)e^{i\Lambda} + e^{-i\Lambda^\dagger}e^V(D_\alpha e^{i\Lambda}). \tag{45.40}$$

The first term vanishes: $\Lambda^\dagger$ is antichiral, $D_\alpha \Lambda^\dagger = 0$ (Eq. (45.33)), hence $D_\alpha e^{-i\Lambda^\dagger} = 0$. Assembling $\Omega' = e^{-V'} D_\alpha e^{V'}$ with the transformed $e^{-V'} = e^{-i\Lambda} e^{-V} e^{i\Lambda^\dagger}$ and the surviving two terms of Eq. (45.40),

$$\begin{aligned}\Omega' &= e^{-i\Lambda} e^{-V} e^{i\Lambda^\dagger} \Big[e^{-i\Lambda^\dagger} (D_\alpha e^{V}) e^{i\Lambda} + e^{-i\Lambda^\dagger} e^{V} (D_\alpha e^{i\Lambda}) \Big] \\ &= e^{-i\Lambda}\, e^{-V} (D_\alpha e^{V})\, e^{i\Lambda} + e^{-i\Lambda}\, e^{-V} e^{V} (D_\alpha e^{i\Lambda}) \\ &= e^{-i\Lambda}\, \Omega\, e^{i\Lambda} + e^{-i\Lambda} (D_\alpha e^{i\Lambda}),\end{aligned} \tag{45.41}$$

where the cancellation $e^{i\Lambda^\dagger} e^{-i\Lambda^\dagger} = 1$ and $e^{-V} e^{V} = 1$ were used. The first term is the desired covariant piece; the second, an inhomogeneous "pure-gauge" term, must be annihilated by the projection $-\frac{1}{4}\bar{D}^2$. Apply it:

$$W'_\alpha = -\tfrac{1}{4}\bar{D}^2 (e^{-i\Lambda}\, \Omega\, e^{i\Lambda}) - \tfrac{1}{4}\bar{D}^2 (e^{-i\Lambda}\, D_\alpha e^{i\Lambda}). \tag{45.42}$$

For the first term, recall that Λ is chiral, $\bar{D}_{\dot\beta}\Lambda = 0$, so $\bar{D}_{\dot\beta} e^{\pm i\Lambda} = 0$: the chiral group elements are covariantly constant under $\bar{D}$. Because $\bar{D}_{\dot\beta}$ is a graded derivation and annihilates $e^{\pm i\Lambda}$, it passes through them untouched, and the same holds for the second $\bar{D}$; hence

$$\bar{D}^2 (e^{-i\Lambda}\, \Omega\, e^{i\Lambda}) = e^{-i\Lambda}\, (\bar{D}^2 \Omega)\, e^{i\Lambda}, \tag{45.43}$$

so the first term of Eq. (45.42) is exactly $e^{-i\Lambda}\, W_\alpha\, e^{i\Lambda}$, the claimed transformation. It remains to show the second term vanishes. We claim

$$\bar{D}^2 (D_\alpha X) = 0 \qquad \text{for any chiral } X\ (\bar{D}_{\dot\beta} X = 0), \tag{45.44}$$

which applies to $X = e^{-i\Lambda} D_\alpha e^{i\Lambda}$ being a product of chiral objects (the factor $e^{-i\Lambda}$ is chiral and $D_\alpha e^{i\Lambda}$ is chiral because $\bar{D}_{\dot\beta} D_\alpha e^{i\Lambda} = \left\{ \bar{D}_{\dot\beta}, D_\alpha \right\} e^{i\Lambda} = -2i\sigma^\mu_{\alpha\dot\beta} \partial_\mu e^{i\Lambda}$, itself chiral since $\bar{D}(\partial_\mu e^{i\Lambda}) = \partial_\mu \bar{D} e^{i\Lambda} = 0$). To prove Eq. (45.44), compute using $\bar{D}_{\dot\beta} X = 0$ and the algebra $\left\{ D_\alpha, \bar{D}_{\dot\beta} \right\} = -2i\sigma^\mu_{\alpha\dot\beta}\partial_\mu$:

$$\bar{D}_{\dot\beta}\, D_\alpha X = \left\{ \bar{D}_{\dot\beta}, D_\alpha \right\} X - D_\alpha \bar{D}_{\dot\beta} X = -2i\, \sigma^\mu_{\alpha\dot\beta}\, \partial_\mu X, \tag{45.45}$$

and then apply the second $\bar{D}^{\dot\beta}$: $\bar{D}^{\dot\beta} \bar{D}_{\dot\beta} (D_\alpha X) = -2i\sigma^\mu_{\alpha\dot\beta}\, \bar{D}^{\dot\beta} \partial_\mu X = -2i\sigma^\mu_{\alpha\dot\beta}\, \partial_\mu (\bar{D}^{\dot\beta} X) = 0$, since ∂_μ commutes with $\bar{D}$ and X is chiral. This is exactly Eq. (45.44), so the inhomogeneous term in Eq. (45.42) vanishes and Eq. (45.39) is proved. Finally, under Eq. (45.39),

$$\mathrm{Tr}(W^\alpha W_\alpha) \to \mathrm{Tr}(e^{-i\Lambda} W^\alpha e^{i\Lambda}\, e^{-i\Lambda} W_\alpha e^{i\Lambda}) = \mathrm{Tr}(e^{-i\Lambda}\, W^\alpha W_\alpha\, e^{i\Lambda}) = \mathrm{Tr}(W^\alpha W_\alpha), \tag{45.46}$$

the last equality by cyclicity of the trace (and $e^{i\Lambda} e^{-i\Lambda} = 1$). The trace of $W^\alpha W_\alpha$ is gauge invariant. □

The two mechanisms that powered this proof are worth stating plainly, because they are the supersymmetric avatars of facts familiar from Chapter 25. First, the inhomogeneous "connection" piece $e^{-i\Lambda}D_\alpha e^{i\Lambda}$ of Eq. (45.41) is the exact analogue of the $U^{-1}\partial_\mu U$ term in the gauge transformation of an ordinary connection; the field strength is curvature, and curvature transforms homogeneously. Second, the reason the inhomogeneous piece drops is purely a chirality count (Eq. (45.44)): three $\bar{D}$'s acting effectively on a chiral object cannot survive. Holomorphy, here in the guise of chirality of the gauge parameter Λ, is doing the work; the same holomorphy will, in Chapter 46, forbid quantum corrections to the form of the gauge kinetic term.

45.2.3 Component expansion in Wess–Zumino gauge

We now compute W_α in Wess–Zumino gauge and exhibit its components. The nilpotency Eq. (45.37) truncates the exponentials, so the Maurer–Cartan form is exactly

$$\begin{aligned} e^{-V}D_\alpha e^{V} &= (1 - V + \tfrac{1}{2}V^2)\, D_\alpha (V + \tfrac{1}{2}V^2) \\ &= (1 - V + \tfrac{1}{2}V^2)\Big[D_\alpha V + \tfrac{1}{2}(D_\alpha V)V + \tfrac{1}{2}V(D_\alpha V)\Big]. \end{aligned} \tag{45.47}$$

Multiplying out and discarding every term with three or more factors of V (which vanish by Eq. (45.37)), the surviving terms are $D_\alpha V$ at order V, and at order V^2 the combination $\frac{1}{2}(D_\alpha V)V + \frac{1}{2}V(D_\alpha V) - V(D_\alpha V)$. The order-$V^2$ piece is $\frac{1}{2}(D_\alpha V)V - \frac{1}{2}V(D_\alpha V) = -\frac{1}{2}\,[V, D_\alpha V]$. Hence the exact, closed-form result in WZ gauge is

$$e^{-V}D_\alpha e^{V} = D_\alpha V \;-\; \tfrac{1}{2}\,[V, D_\alpha V]\,, \tag{45.48}$$

and therefore

$$W_\alpha = \underbrace{-\tfrac{1}{4}\,\bar{D}^2\, D_\alpha V}_{\text{abelian-form}} \;+\; \underbrace{\tfrac{1}{8}\,\bar{D}^2\,[V, D_\alpha V]}_{\text{nonabelian completion}}\,. \tag{45.49}$$

The first term is precisely the abelian field-strength operator of Eq. (45.16) applied component by component; its evaluation was carried out in Section 45.1, and it produces, in chiral coordinates $y^\mu = x^\mu + i\theta\sigma\bar{\theta}$,

$$-\tfrac{1}{4}\bar{D}^2 D_\alpha V = \lambda_\alpha + \Big[\delta_\alpha{}^\beta D - i\,(\sigma^{\mu\nu})_\alpha{}^\beta\,(\partial_\mu A_\nu - \partial_\nu A_\mu)\Big]\theta_\beta + i\,\theta\theta\,(\sigma^\mu\partial_\mu\bar{\lambda})_\alpha, \tag{45.50}$$

now matrix-valued (each component carries its colour matrix). The second term of Eq. (45.49) dresses this abelian skeleton with commutators. Because the commutator $[V, D_\alpha V]$ is built from two V's, the Fierz reductions Eq. (44.191)

that produced Eq. (45.37) apply, and the surviving content is governed entirely by the gauge-field bilinear $[A_\mu, A_\nu]$ and by the gauge-field–gaugino bilinear $\left[A_\mu, \bar\lambda\right]$. Carrying out the $\bar D^2$ projection on $\frac{1}{8}[V, D_\alpha V]$ term by term (the algebra is identical to the abelian projection, with the antisymmetric matrix structure of the commutator carried along) supplies exactly the two missing pieces: the antisymmetrized derivative $\partial_\mu A_\nu - \partial_\nu A_\mu$ is completed to the nonabelian curvature, and the ordinary derivative $\partial_\mu \bar\lambda$ is completed to the adjoint covariant derivative. The result is the gauge-covariant field-strength superfield

$$\boxed{W_\alpha = \lambda_\alpha + \left[\delta_\alpha{}^\beta D - i\,(\sigma^{\mu\nu})_\alpha{}^\beta\, \mathcal{F}_{\mu\nu}\right]\theta_\beta + i\,\theta\theta\,(\sigma^\mu \mathcal{D}_\mu \bar\lambda)_\alpha,} \tag{45.51}$$

with the matrix field strength and the adjoint covariant derivative

$$\mathcal{F}_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu - i\,[A_\mu, A_\nu]\,, \tag{45.52}$$

$$\mathcal{D}_\mu \bar\lambda = \partial_\mu \bar\lambda - i\,\left[A_\mu, \bar\lambda\right]. \tag{45.53}$$

In components, with $A_\mu = A_\mu^a T^a$ and $\left[T^b, T^c\right] = i f^{bcd} T^d$, the matrix relation Eq. (45.52) reads $\mathcal{F}^a_{\mu\nu} = \partial_\mu A^a_\nu - \partial_\nu A^a_\mu + f^{abc} A^b_\mu A^c_\nu$ and the covariant derivative reads $(\mathcal{D}_\mu \bar\lambda)^a = \partial_\mu \bar\lambda^a + f^{abc} A^b_\mu \bar\lambda^c$. This is the field strength of Eq. (25.49) and the adjoint-representation covariant derivative of Chapter 25, written without the explicit g because we are in the holomorphic normalization (Section 45.2.1). The promotion of ∂_μ to $\mathcal{D}_\mu$ on the gaugino is the precise statement that *the gaugino lives in the adjoint*: it is a colour-octet (for SU(3)) Weyl fermion, transforming like the gauge field itself, as the covariance Eq. (45.39) demands. The components of W_α are therefore the physical fields of the gauge multiplet: a gaugino λ_α at order θ^0, the field strength and auxiliary D at order θ^1, and the covariant gaugino kinetic term at order θ^2.

45.2.4 The super Yang–Mills action and the holomorphic coupling

Having a chiral, gauge-covariant W_α, the unique renormalizable supersymmetric and gauge-invariant kinetic term is the F-term of $\mathrm{Tr}(W^\alpha W_\alpha)$. We package its coefficient into a single complex number, the *holomorphic gauge coupling*.

Definition 45.11 (Holomorphic gauge coupling)**.** The holomorphic gauge coupling is the complex combination

$$\tau \;\equiv\; \frac{\theta}{2\pi} + \frac{4\pi i}{g^2}, \tag{45.54}$$

where g is the Yang–Mills coupling of Chapter 25 and θ is the vacuum angle of Chapter 42. Its real part is the θ-angle (mod 2π); its imaginary part, positive for $g^2 > 0$, is $4\pi/g^2$.

Definition 45.12 (Super Yang–Mills action)**.** The pure super Yang–Mills action for gauge group G is

$$\boxed{S_{\mathrm{SYM}} = \frac{1}{4\pi}\,\mathrm{Im}\left[\,\tau \int d^4x\, \mathrm{d}^2\theta\ \mathrm{Tr}\,(W^\alpha W_\alpha)\right],} \tag{45.55}$$

the imaginary part supplying the Hermitian conjugate (F-term plus $\bar{F}$-term) automatically.

It remains to expand Eq. (45.55) into components and verify that it is the supersymmetric completion of classical Yang–Mills. The Grassmann integral $\int \mathrm{d}^2\theta$ extracts the $\theta\theta$ coefficient of $\mathrm{Tr}(W^\alpha W_\alpha)$. We compute that coefficient from Eq. (45.51).

The bosonic $\theta\theta$ coefficient. The terms in $W^\alpha W_\alpha$ that reach order $\theta\theta$ and carry no fermion come from the product of the two order-θ^1 brackets of Eq. (45.51). Writing $M_\alpha{}^\beta \equiv \delta_\alpha{}^\beta D - i(\sigma^{\mu\nu})_\alpha{}^\beta \mathcal{F}_{\mu\nu}$, the relevant product is $(\theta M)^\alpha (\theta M)_\alpha$ where $(\theta M)_\alpha \equiv M_\alpha{}^\beta \theta_\beta$. Using $\theta_\gamma\theta_\delta = -\frac{1}{2}\epsilon_{\gamma\delta}\theta\theta$ (the Grassmann identity fixed in Section 44.6), the bilinear collapses to

$$(\theta M)^\alpha (\theta M)_\alpha = -\tfrac{1}{2}\,\theta\theta\ M_\alpha{}^\beta M_\beta{}^\alpha = -\tfrac{1}{2}\,\theta\theta\ \mathrm{tr}_2(M^2), \tag{45.56}$$

where tr_2 is the trace over the two-dimensional spinor space. Expanding M^2,

$$\mathrm{tr}_2(M^2) = \mathrm{tr}_2\Big(D^2\mathbf{1} - 2iD\,\sigma^{\mu\nu}\mathcal{F}_{\mu\nu} - (\sigma^{\mu\nu}\sigma^{\rho\sigma})\,\mathcal{F}_{\mu\nu}\mathcal{F}_{\rho\sigma}\Big). \tag{45.57}$$

The first trace is $\mathrm{tr}_2(\mathbf{1}) = 2$, giving $2D^2$. The second vanishes because $\sigma^{\mu\nu}$ is traceless, $\mathrm{tr}_2(\sigma^{\mu\nu}) = 0$ (it is a Lorentz generator, Eq. (44.34)). The third requires the spinor trace of two Lorentz generators, the self-duality identity derived in Section 3.4.3 (and collected in Appendix C),

$$\mathrm{tr}_2(\sigma^{\mu\nu}\sigma^{\rho\sigma}) = \tfrac{1}{2}(\eta^{\mu\rho}\eta^{\nu\sigma} - \eta^{\mu\sigma}\eta^{\nu\rho}) - \tfrac{i}{2}\,\epsilon^{\mu\nu\rho\sigma}, \tag{45.58}$$

with $\epsilon^{0123} = +1$. Contracting with $\mathcal{F}_{\mu\nu}\mathcal{F}_{\rho\sigma}$ and using $\epsilon^{\mu\nu\rho\sigma}\mathcal{F}_{\mu\nu}\mathcal{F}_{\rho\sigma} = 2\,\mathcal{F}_{\mu\nu}\widetilde{\mathcal{F}}^{\mu\nu}$ with $\widetilde{\mathcal{F}}^{\mu\nu} = \frac{1}{2}\epsilon^{\mu\nu\rho\sigma}\mathcal{F}_{\rho\sigma}$,

$$\mathrm{tr}_2(\sigma^{\mu\nu}\sigma^{\rho\sigma})\,\mathcal{F}_{\mu\nu}\mathcal{F}_{\rho\sigma} = \mathcal{F}_{\mu\nu}\mathcal{F}^{\mu\nu} - i\,\mathcal{F}_{\mu\nu}\widetilde{\mathcal{F}}^{\mu\nu}. \tag{45.59}$$

Assembling, the bosonic $\theta\theta$ coefficient is $-\frac{1}{2}(2D^2 - \mathcal{F}_{\mu\nu}\mathcal{F}^{\mu\nu} + i\mathcal{F}_{\mu\nu}\widetilde{\mathcal{F}}^{\mu\nu}) = \frac{1}{2}\mathcal{F}_{\mu\nu}\mathcal{F}^{\mu\nu} - \frac{i}{2}\mathcal{F}_{\mu\nu}\widetilde{\mathcal{F}}^{\mu\nu} - D^2$. The crucial structural fact is the appearance of *both* $\mathcal{F}^2$ (real) and $\mathcal{F}\widetilde{\mathcal{F}}$ (imaginary): the spinor trace Eq. (45.58) has split $W^\alpha W_\alpha$ into a parity-even and a parity-odd part, and they sit in the real and imaginary parts of one chiral quantity.

The fermionic $\theta\theta$ coefficient. The product of the order-θ^0 gaugino λ_α with the order-θ^2 term $i\theta\theta(\sigma^\mu\mathcal{D}_\mu\bar\lambda)_\alpha$ (and the symmetric partner) gives, after using $\lambda^\alpha(\sigma^\mu\mathcal{D}_\mu\bar\lambda)_\alpha = \lambda\sigma^\mu\mathcal{D}_\mu\bar\lambda$, the coefficient $2i\,\lambda\sigma^\mu\mathcal{D}_\mu\bar\lambda$, which integration by parts under $\int d^4x$ and the identity $\lambda\sigma^\mu\chi = -\chi\bar\sigma^\mu\lambda$ converts to $+2i\,\bar\lambda\,\bar\sigma^\mu\mathcal{D}_\mu\lambda$. Collecting,

$$\int \mathrm{d}^2\theta\ \mathrm{Tr}\,(W^\alpha W_\alpha) = \mathrm{Tr}\Big[\tfrac{1}{2}\mathcal{F}_{\mu\nu}\mathcal{F}^{\mu\nu} - \tfrac{i}{2}\mathcal{F}_{\mu\nu}\widetilde{\mathcal{F}}^{\mu\nu} + 2i\,\bar\lambda\,\bar\sigma^\mu\mathcal{D}_\mu\lambda - D^2\Big]. \quad (45.60)$$

Taking the colour trace with $\mathrm{tr}(T^aT^b) = \frac{1}{2}\delta^{ab}$ replaces each $\mathrm{Tr}(XY)$ by $\frac{1}{2}X^aY^a$, so $\int \mathrm{d}^2\theta\ \mathrm{Tr}(W^\alpha W_\alpha) = \frac{1}{4}\mathcal{F}^a_{\mu\nu}\mathcal{F}^{a\,\mu\nu} - \frac{i}{4}\mathcal{F}^a_{\mu\nu}\widetilde{\mathcal{F}}^{a\,\mu\nu} + i\,\bar\lambda^a\bar\sigma^\mu\mathcal{D}_\mu\lambda^a - \frac{1}{2}D^aD^a$ (with the gaugino and D terms real).

Assembling the action. Insert into Eq. (45.55) and use Eq. (45.54). Writing the chiral quantity as $X = \int \mathrm{d}^2\theta\ \mathrm{Tr}(W^\alpha W_\alpha) = \mathrm{Re}\,X + i\,\mathrm{Im}\,X$, with $\mathrm{Re}\,X$ collecting $\frac{1}{4}\mathcal{F}^2 + i\bar\lambda\bar\sigma\mathcal{D}\lambda - \frac{1}{2}D^2$ (the parity-even, Hermitian terms) and $\mathrm{Im}\,X = -\frac{1}{4}\mathcal{F}^a\widetilde{\mathcal{F}}^a$,

$$\mathrm{Im}(\tau X) = \frac{4\pi}{g^2}\,\mathrm{Re}\,X + \frac{\theta}{2\pi}\,\mathrm{Im}\,X. \quad (45.61)$$

The factor $1/4\pi$ then gives

$$S_{\mathrm{SYM}} = \int d^4x\,\Big\{\frac{1}{g^2}\Big[-\tfrac{1}{4}\mathcal{F}^a_{\mu\nu}\mathcal{F}^{a\,\mu\nu} + i\,\bar\lambda^a\bar\sigma^\mu\mathcal{D}_\mu\lambda^a + \tfrac{1}{2}D^aD^a\Big] + \frac{\theta}{32\pi^2}\,\mathcal{F}^a_{\mu\nu}\widetilde{\mathcal{F}}^{a\,\mu\nu}\Big\}, \quad (45.62)$$

where we absorbed the overall sign by the conventional choice that the action be bounded below (equivalently, by matching the abelian limit to the supersymmetric Maxwell action Eq. (45.25) of the previous section, which fixes every relative coefficient). This is the super Yang–Mills Lagrangian in holomorphic normalization: a single chiral coefficient τ multiplies one chiral density, and the split into $-\frac{1}{4}\mathcal{F}^2$ and the θ-density is the split of τ into imaginary and real parts.

Canonical normalization and the bridge to Chapters 25 and 42. Rescale the gauge multiplet to canonical kinetic normalization by $A_\mu \to gA_\mu$, $\lambda \to g\lambda$, $D \to gD$ (equivalently $V \to 2gV$). Then $\mathcal{F}^a_{\mu\nu} \to g\,F^a_{\mu\nu}$ with $F^a_{\mu\nu} = \partial_\mu A^a_\nu - \partial_\nu A^a_\mu + g f^{abc}A^b_\mu A^c_\nu$ the field strength of Eq. (25.49), and the covariant derivative becomes $(D_\mu\lambda)^a = \partial_\mu\lambda^a + g f^{abc}A^b_\mu\lambda^c$. The prefactor $1/g^2$ cancels the g^2 from $(\mathcal{F})^2 = g^2F^2$, and the θ-density picks up the missing g^2 from $\mathcal{F} = gF$:

$$\boxed{\mathcal{L}_{\mathrm{SYM}} = -\tfrac{1}{4}F^a_{\mu\nu}F^{a\,\mu\nu} + i\,\bar\lambda^a\,\bar\sigma^\mu(D_\mu\lambda)^a + \tfrac{1}{2}D^aD^a + \frac{\theta g^2}{32\pi^2}\,F^a_{\mu\nu}\widetilde{F}^{a\,\mu\nu}.} \quad (45.63)$$

Read this Lagrangian one term at a time. The first term is *exactly* the classical Yang–Mills Lagrangian Eq. (25.104), with its cubic and quartic gluon

self-interactions hidden inside $F^a_{\mu\nu}$; the bosonic gauge sector of super Yang–Mills *is* the theory of Chapter 25, not an approximation to it. The second term is the kinetic energy of the gaugino, an adjoint Weyl fermion λ^a minimally coupled to the gauge field through the adjoint covariant derivative D_μ — the same covariant derivative that acts on any adjoint field, here producing a gluon–gaugino interaction with strength gf^{abc}. The third term is the auxiliary field D^a, which appears with no derivative and no source in the pure gauge theory and is therefore set to zero by its equation of motion (it becomes nonzero only once charged matter is added, in Section 45.3). The fourth term is the topological θ-density $\frac{\theta g^2}{32\pi^2} F^a_{\mu\nu}\widetilde{F}^{a\,\mu\nu}$, identical term-for-term and prefactor-for-prefactor to the θ-term whose vacuum meaning was fixed in Section 42.4 (Eq. (42.128)): a total derivative, $F\widetilde{F} = \partial_\mu K^\mu$, which is invisible in perturbation theory but records, through the instanton sectors of Chapter 42, the angle of the true θ-vacuum. Holomorphy has done something remarkable: the gauge coupling g and the topological angle θ, which look completely unrelated in Chapters 25 and 42, are revealed to be the imaginary and real parts of a single holomorphic coupling τ multiplying a single chiral operator.

Physical Insight: The coupling as the geometry of a torus

Because θ is an angle, $\theta \to \theta + 2\pi$ is a symmetry; in terms of τ it is $\tau \to \tau + 1$. The instanton expansion organizes itself in powers of $e^{2\pi i\tau} = e^{i\theta}e^{-8\pi^2/g^2}$, precisely the Boltzmann weight $e^{i\theta}e^{-S_{\text{inst}}}$ of one instanton (Section 42.4). The holomorphic coupling thus lives naturally on the upper half-plane $\operatorname{Im}\tau > 0$ with the periodicity $\tau \sim \tau + 1$, and in theories with enough supersymmetry a second generator $\tau \to -1/\tau$ (electric–magnetic duality) completes this to a modular group acting on τ as on the modular parameter of a torus. That nonperturbative story belongs to Chapter 46; here we note only that packaging g and θ into τ is what makes it possible to ask the question at all.

Worked Example 45.13 (Off-shell and on-shell degree-of-freedom counting)**.** We verify the equality $n_B = n_F$ guaranteed by the algebra (Theorem 44.15) for the vector multiplet, both off-shell and on-shell, and see why the auxiliary D is needed.

Off-shell. Count real field components before imposing equations of motion. The gauge field A^a_μ has, per colour, four components, of which one is removed by the residual ordinary gauge invariance left after fixing Wess–Zumino gauge (the residual $A_\mu \to A_\mu + D_\mu\alpha$ of Section 45.2.1); that leaves $4 - 1 = 3$ bosonic components. The auxiliary D^a is one real scalar. The bosonic total is therefore $n_B = 3 + 1 = 4$ per colour. The gaugino λ^a_α is a single Weyl spinor: two complex components, hence four real Grassmann components, $n_F = 4$ per colour, off-shell

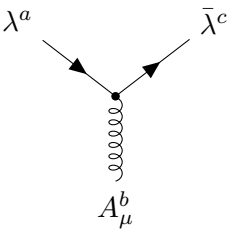

Figure 45.2: The gluon–gaugino–gaugino vertex $g f^{abc} A^b_\mu \bar{\lambda}^a \bar{\sigma}^\mu \lambda^c$ supplied by the adjoint covariant derivative in Eq. (45.63). The gaugino is an adjoint Weyl fermion, so its coupling to the gauge field carries the structure constants f^{abc} exactly as the three-gluon vertex does (Fig. 25.3a); the gluon self-interactions of Chapter 25 are inherited unchanged.

with no equation of motion imposed. Thus

$$n_B = \underbrace{3}_{A_\mu} + \underbrace{1}_{D} = 4 = \underbrace{4}_{\lambda_\alpha \text{ (complex Weyl)}} = n_F, \tag{45.64}$$

and the equality holds *only because* of the auxiliary D: without it $n_B = 3 \neq 4 = n_F$, and supersymmetry would close only on-shell. The single real D is exactly the deficit, the supersymmetric mirror of the auxiliary F of the chiral multiplet (Eq. (44.208)).

On-shell. Imposing the equations of motion, the massless gauge field A^a_μ propagates two transverse polarizations; the auxiliary D^a satisfies the algebraic equation $D^a = 0$ and carries none; so $n_B = 2$. The gaugino's Dirac equation halves its components to two real on-shell degrees of freedom (a massless Weyl/Majorana fermion has two helicity states), $n_F = 2$. Again $n_B = n_F = 2$, the count of a massless vector multiplet: a gauge boson of helicities ± 1 and a gaugino of helicities $\pm\frac{1}{2}$. This is the content already anticipated by the algebra in Section 44.3.4.

The new interaction that distinguishes super Yang–Mills from the bosonic theory of Chapter 25 is the minimal coupling of the adjoint gaugino to the gauge field, the $g f^{abc} A^b_\mu \bar{\lambda}^a \bar{\sigma}^\mu \lambda^c$ vertex hidden in the covariant derivative of Eq. (45.63). Figure 45.2 records it alongside the inherited gluon self-couplings.

Physical Insight: Why super Yang–Mills is the rigid completion of Chapter 25

Classical Yang–Mills had one free parameter, g (and the discrete-seeming θ). Super Yang–Mills adds no new parameter: the gaugino mass is forbidden by gauge invariance (an adjoint Weyl fermion has no gauge-invariant mass term) and by supersymmetry (it would split the multiplet, violating Theorem 44.12), and the gaugino coupling is fixed to be g by the covariant

derivative. There is no room for a Yukawa coupling or a quartic scalar coupling because there is no scalar. The entire dynamics is dictated by the single τ. This rigidity is what will let Chapter 46 compute the low-energy effective coupling exactly, and it is already visible here as the absence of any freedom beyond g and θ.

45.2.5 Gauge fixing and BRST in Wess–Zumino gauge

The Lagrangian Eq. (45.63) is classical and gauge invariant; quantizing it requires gauge fixing, and the apparatus for that was built in full generality in Chapter 26. Nothing in that construction is special to a purely bosonic gauge field, so we may apply it directly to the Wess–Zumino-gauge component fields, with one honest caveat about supersymmetry that we state precisely.

The route is the one of Section 26.2. We have committed to Wess–Zumino gauge, which fixed the *super*-gauge redundancy down to the ordinary spacetime gauge transformations $A^a_\mu \to A^a_\mu + (D_\mu \alpha)^a$ acting on the component gauge field of Eq. (45.36). This residual ordinary gauge invariance is exactly the redundancy of Chapter 25, and it is removed by the Faddeev–Popov procedure of Section 26.2: insert $1 = \int \mathcal{D}\alpha\, \delta(G[A^\alpha])\, \det(\delta G/\delta\alpha)$ for a gauge-fixing functional $G[A]$ (e.g. $G = \partial^\mu A^a_\mu$ in R_ξ gauge), exponentiate the determinant with a pair of adjoint anticommuting Faddeev–Popov ghosts $c^a, \bar{c}^a$, and add the gauge-fixing and ghost terms

$$\mathcal{L}_{\text{gf}} + \mathcal{L}_{\text{gh}} = -\frac{1}{2\xi}\left(\partial^\mu A^a_\mu\right)^2 + \bar{c}^a\left(-\partial^\mu D_\mu c\right)^a, \tag{45.65}$$

with $(D_\mu c)^a = \partial_\mu c^a + g f^{abc} A^b_\mu c^c$ the same adjoint covariant derivative that acts on the gaugino. The ghosts $c^a, \bar{c}^a$ are the ordinary Faddeev–Popov ghosts of Chapter 26; they are *not* part of any supermultiplet and should not be confused with the gaugino λ^a, which is a physical adjoint fermion of the gauge multiplet Eq. (45.36). The gauge-fixed theory then carries the BRST symmetry of Section 26.5: the nilpotent transformation $sA^a_\mu = (D_\mu c)^a$, $sc^a = -\frac{1}{2} g f^{abc} c^b c^c$, $s\bar{c}^a = B^a$, $sB^a = 0$ (with B^a the Nakanishi–Lautrup auxiliary), under which the gaugino transforms in the adjoint, $s\lambda^a = g f^{abc} c^b \lambda^c$, exactly as any adjoint matter field does. Physical states are the BRST cohomology classes of Section 26.6, and the Slavnov–Taylor identities of Section 26.7 control renormalization. The perturbative Feynman rules are those of Section 26.3 augmented by the gaugino propagator (a massless adjoint Weyl fermion) and the single new vertex of Fig. 45.2; the gauge sector, ghost sector, and BRST charge are imported wholesale from Chapter 26.

Caution: Wess–Zumino gauge breaks manifest supersymmetry

The price of working in Wess–Zumino gauge is that supersymmetry is no longer manifest. A supersymmetry transformation δ_ξ acting on the WZ-gauge superfield Eq. (45.36) does not preserve the WZ form: it regenerates the lower components C, χ, M, N of V that WZ gauge set to zero. To stay in WZ gauge one must follow δ_ξ by a compensating super-gauge transformation Eq. (45.34) that removes the regenerated components. The composite "δ_ξ + compensating gauge transformation" is the supersymmetry that actually acts on the physical component fields, and its algebra closes only up to a field-dependent gauge transformation, $\{\delta_{\xi_1}, \delta_{\xi_2}\} = (\text{translation}) + (\text{gauge transformation})$. This is not a defect of the theory — the off-shell algebra of Chapter 44 still holds on the unfixed superfield — but a feature of the gauge choice: WZ gauge trades manifest supersymmetry for the absence of unphysical fields. Consequently, the BRST charge Q_B of the gauge-fixed theory and the (composite, WZ-gauge) supercharge Q_α do not commute on individual fields; only a combined cohomology is well-defined.

The honest statement at the perturbative level we work to here is therefore the following. The gauge-fixed action $S_{\text{SYM}} + \int d^4x\,(\mathcal{L}_{\text{gf}} + \mathcal{L}_{\text{gh}})$ is invariant under the BRST transformation s, and the physical S-matrix is supersymmetric because the broken-then-compensated supersymmetry acts on the BRST-cohomology (physical) states as the genuine super-Poincaré symmetry of Chapter 44: the supersymmetry Ward identities hold on gauge-invariant correlators even though no single off-shell symmetry is manifest. A fully manifestly-supersymmetric quantization exists — superspace Feynman rules with a super-Faddeev–Popov determinant and a ghost-for-ghost tower, because the super-gauge parameter Λ is itself a reducible (chiral-superfield) gauge parameter — and it is the efficient tool for proving the nonrenormalization theorems of Section 45.4. But for reading off the particle content, the beta function, and the comparison to Chapter 27, the component WZ-gauge quantization just described, built directly on the Chapter 26 machinery, is the appropriate and complete framework.

This advances Yang–Mills theory one decisive step: the bosonic content of super Yang–Mills is, by Eq. (45.63), the classical Yang–Mills theory of Chapter 25; its quantization reuses, without modification, the Faddeev–Popov/BRST apparatus of Chapter 26; and the holomorphic coupling τ carries the θ-angle of Chapter 42. The one-loop beta-function coefficient $b_0 = \frac{11}{3}C_A - \frac{4}{3}T_F n_f$ computed in Eq. (27.124) will be recovered, and then sharpened to an exact formula, once we add the gaugino's adjoint contribution and the matter of the next section; that comparison is the through-line from here to Chapter 46.

With the pure-gauge dynamics in hand — a covariant field strength W_α, the component Lagrangian Eq. (45.63), and a quantization built on Chapter 26 —

the remaining ingredient is matter. The gauge-covariant Kähler term $\Phi^\dagger e^V \Phi$ of Eq. (45.32), whose invariance under Eq. (45.33) we have already established, is precisely the coupling of charged chiral superfields to this gauge multiplet. Combining it with N_f flavours of quark and antiquark chiral superfields and the super Yang–Mills action Eq. (45.55) builds supersymmetric QCD, whose scalar potential and classical moduli space are the subject of the next section.

45.3 Supersymmetric QCD: Matter, the Scalar Potential, and the Classical Moduli Space

The previous section completed the gauge sector: a nonabelian vector superfield $V = V^a T^a$ whose component content is exactly the classical Yang–Mills field of Chapter 25 together with a gaugino λ^a in the adjoint, governed by the super Yang–Mills action and packaged by the holomorphic coupling $\tau = \theta/2\pi + 4\pi i/g^2$ (Section 45.2). Along the way the finite super-gauge transformation

$$e^V \longrightarrow e^{-i\Lambda^\dagger} e^V e^{i\Lambda}, \qquad \Lambda = \Lambda^a T^a \text{ chiral}, \tag{45.66}$$

forced the gauge multiplet to carry the exponential e^V rather than V itself (Eq. (45.66)). That exponential is precisely the object a chiral matter field must lean on to be gauged covariantly. Pure super Yang–Mills is the SUSY analog of gluodynamics; to build the SUSY analog of QCD — to extend Yang–Mills theory from pure gauge to gauge + matter — we now couple charged chiral superfields to V. The result, *supersymmetric QCD* (SQCD), is the most rigidly constrained renormalizable gauge theory one can write: supersymmetry and gauge invariance together fix the matter Lagrangian completely, leaving as the only freedom the gauge group, the matter representation, and a holomorphic superpotential. Reading the scalar potential off that Lagrangian and solving for its zeros will hand us a continuous family of degenerate vacua — the classical moduli space — whose gauge-invariant coordinates (mesons and baryons) are exactly the variables on which the nonperturbative analysis of Chapter 46 will act.

45.3.1 The gauge-covariant Kähler term

Recall from Section 44.7.6 that the kinetic energy of a chiral superfield Φ comes from the Kähler term $\int \mathrm{d}^4\theta\, \Phi^\dagger \Phi$, whose component reduction Eq. (44.208) is the free, canonically normalized kinetic Lagrangian of a complex scalar and a Weyl fermion together with the algebraic $F^* F$. We now charge Φ under the gauge group: let Φ transform in a (in general reducible) unitary representation R with Hermitian generators T^a, $[T^a, T^b] = i f^{abc} T^c$, normalized by $\mathrm{tr}(T^a T^b) = \frac{1}{2}\delta^{ab}$ in the fundamental (Section B.4). The defining gauge transformation of charged

matter is the chiral rotation

$$\Phi \longrightarrow e^{i\Lambda}\Phi, \qquad \Phi^\dagger \longrightarrow \Phi^\dagger e^{-i\Lambda^\dagger}, \qquad \Lambda \equiv \Lambda^a T^a, \tag{45.67}$$

with Λ a *chiral* superfield-valued gauge parameter (so that $e^{i\Lambda}\Phi$ is again chiral: a holomorphic function of chiral superfields is chiral, Theorem 44.40). Because $\Lambda \neq \Lambda^\dagger$ in general, the naive bilinear $\Phi^\dagger\Phi$ is *not* invariant: under Eq. (45.67) it rotates to $\Phi^\dagger e^{-i\Lambda^\dagger} e^{i\Lambda}\Phi$, and the mismatched exponentials do not cancel. The cure is exactly the exponential the gauge sector already supplies.

Definition 45.14 (Gauge-covariant Kähler term)**.** For chiral matter Φ in the representation R with vector superfield $V = V^a T^a_{(R)}$, the *minimal* (canonical) gauge-invariant Kähler term is

$$S^{\text{kin}}_{\text{matter}} = \int d^4x \int \mathrm{d}^4\theta\, \Phi^\dagger\, e^V\, \Phi, \tag{45.68}$$

where $e^V = \sum_{n\geq 0} V^n/n!$ acts on Φ in the representation R.

Theorem 45.15 (Super-gauge invariance of the covariant Kähler term)**.** *The functional Eq. (45.68) is invariant under the simultaneous transformations Eq. (45.67) of the matter and Eq. (45.66) of the gauge multiplet.*

Proof. Under the two transformations the integrand becomes

$$\Phi^\dagger\, e^V\, \Phi \longrightarrow (\Phi^\dagger e^{-i\Lambda^\dagger})(e^{-i\Lambda^\dagger})^{-1}\cdots \tag{45.69}$$

which we evaluate directly. The matter factors rotate to $\Phi^\dagger e^{-i\Lambda^\dagger}$ on the left and $e^{i\Lambda}\Phi$ on the right, while the gauge factor becomes $e^{-i\Lambda^\dagger} e^V e^{i\Lambda}$. Assembling,

$$\Phi^\dagger\, e^V\, \Phi \longrightarrow \Phi^\dagger\, e^{-i\Lambda^\dagger}\, (e^{-i\Lambda^\dagger})^{-1} e^V\, e^{i\Lambda}\, (e^{i\Lambda})^{-1}\Phi \;=\; \Phi^\dagger\, e^V\, \Phi. \tag{45.70}$$

The transformation matrices cancel in conjugate pairs: $e^{-i\Lambda^\dagger}$ from the matter on the left meets its inverse inside the transformed e^V, and $e^{i\Lambda}$ on the right meets its inverse likewise. The integrand is therefore pointwise invariant, hence so is its full-superspace integral. (No total-derivative argument is needed for the integrand itself; what the D-term theorem Theorem 44.36 of the previous chapter supplies is the orthogonal statement that the $\mathrm{d}^4\theta$-integral of *any* real superfield is supersymmetric, so the term is simultaneously gauge- and SUSY-invariant.) □

Remark 45.16 (Why e^V, and why minimal)*.* Three requirements pin down Eq. (45.68) uniquely. First, *gauge invariance* forces the conjugate fields to be bridged by an object transforming as $e^V \to e^{-i\Lambda^\dagger} e^V e^{i\Lambda}$; the vector superfield's defining transformation is exactly this, and no polynomial in V shares it. Second, *the flat-space limit*: setting $V \to 0$ must return the free Kähler term Eq. (44.208), which $\Phi^\dagger e^V \Phi$ does since $e^0 = 1$. Third, *renormalizability*: the canonical Kähler

potential $K = \Phi^\dagger e^V \Phi$ has a flat (field-independent) Kähler metric $\partial^2 K/\partial\Phi^\dagger\partial\Phi = \mathbf{1}$, so the scalar kinetic term is canonically normalized and the term is marginal; any function $K(\Phi^\dagger e^V \Phi)$ beyond the linear one introduces dimensionful couplings and is non-renormalizable. The combination Eq. (45.68) is thus *the* minimal coupling, the superspace descendant of the gauge principle of Chapters 8 and 25.

45.3.2 Component expansion in Wess–Zumino gauge

To read off physics we reduce Eq. (45.68) to components. As in Eq. (45.36), work in Wess–Zumino gauge, where the residual gauge freedom has been used to set the lowest components of V to zero, leaving

$$V \;=\; -\,\theta\sigma^\mu\bar\theta\, g A_\mu^a T^a \;+\; i\,\theta\theta\,\bar\theta\bar\lambda^a T^a \;-\; i\,\bar\theta\bar\theta\,\theta\lambda^a T^a \;+\; \tfrac{1}{2}\,\theta\theta\bar\theta\bar\theta\, g D^a T^a, \tag{45.71}$$

with the coupling g displayed explicitly on the gauge field and the auxiliary D, so that the gauge field's covariant derivative will emerge as $D_\mu = \partial_\mu - igA_\mu^a T^a$ in the convention of Chapter 25 and Yang–Mills theory. The decisive simplification of WZ gauge is that V *nilpotent*: its lowest surviving piece carries one factor of $\theta\sigma\bar\theta$, so

$$V^2 = (\theta\sigma^\mu\bar\theta)(\theta\sigma^\nu\bar\theta)\, g^2 A_\mu^a A_\nu^b T^a T^b = \tfrac{1}{2}\,\theta\theta\bar\theta\bar\theta\, g^2 A_\mu^a A^{b\mu} T^a T^b, \tag{45.72}$$

where we used the Fierz reduction $(\theta\sigma^\mu\bar\theta)(\theta\sigma^\nu\bar\theta) = \tfrac{1}{2}\theta\theta\bar\theta\bar\theta\,\eta^{\mu\nu}$ (the same identity Eq. (44.191) that produced the scalar kinetic term in the free case), and $V^3 = 0$ because there is no room for three factors of $\theta\sigma\bar\theta$. Hence the exponential truncates:

$$e^V = 1 + V + \tfrac{1}{2}V^2, \tag{45.73}$$

and the entire coupling is a finite polynomial. We must extract the $\theta\theta\bar\theta\bar\theta$ component of $\Phi^\dagger e^V \Phi$. Write the chiral superfield in the y-coordinates of Section 44.7.3 with components (ϕ, ψ, F) and organize the calculation by which power of V contributes.

The V^0 piece. This is the free Kähler term, already reduced in Eq. (44.208):

$$\big[\Phi^\dagger\Phi\big]_{\theta\theta\bar\theta\bar\theta} = \partial_\mu\phi^\dagger\partial^\mu\phi + i\,\bar\psi\,\bar\sigma^\mu\partial_\mu\psi + F^\dagger F, \tag{45.74}$$

with the colour/flavour indices on ϕ, ψ, F left implicit (they are vectors in the representation space of R).

The V^1 piece. We need $[\Phi^\dagger\, V\, \Phi]_{\theta\theta\bar\theta\bar\theta}$. Only three structures in V can pair with components of $\Phi^\dagger, \Phi$ to reach Grassmann bidegree $(2,2)$:

- The gauge-field term $-\theta\sigma^\mu\bar\theta\, g A^a_\mu T^a$ must be saturated by one $(1,0)$ factor and one $(0,1)$ factor from the matter. The relevant matter pieces are the θ-linear part of Φ ($\sqrt{2}\,\theta\psi$ and the descendant $-i\,\theta\sigma^\nu\bar\theta\,\partial_\nu\phi$ in x-coordinates) and their conjugates. Collecting the cross terms and using $(\theta\sigma^\mu\bar\theta)(\theta\sigma^\nu\bar\theta) = \tfrac{1}{2}\theta\theta\bar\theta\bar\theta\,\eta^{\mu\nu}$ once more, the bosonic part assembles into

$$-\,igA^a_\mu(\phi^\dagger T^a\partial^\mu\phi - \partial^\mu\phi^\dagger\, T^a\phi), \tag{45.75}$$

  i.e. the gauge-current $\times$ gauge-field coupling, while the fermionic part gives $gA^a_\mu\,\bar\psi\,\bar\sigma^\mu T^a\psi$.

- The gaugino terms $i\theta\theta\,\bar\theta\bar\lambda^a T^a$ and $-i\bar\theta\bar\theta\,\theta\lambda^a T^a$ pair the gaugino with one matter fermion and one matter scalar. The first pairs $\bar\lambda$ with the lowest scalar $\phi^\dagger$ of $\Phi^\dagger$ and the $\sqrt{2}\,\theta\psi$ of Φ; the second is its conjugate. These produce the gaugino–matter Yukawa

$$\sqrt{2}\,i\,g\,(\phi^\dagger T^a\psi)^-\ldots \;\longrightarrow\; -\sqrt{2}\,g(\phi^\dagger T^a\psi)\lambda^a - \sqrt{2}\,g\,\bar\lambda^a(\bar\psi\,T^a\phi). \tag{45.76}$$

- The auxiliary term $\tfrac{1}{2}\theta\theta\bar\theta\bar\theta\, gD^aT^a$ is already top-component; it pairs with the two lowest scalars to give

$$\tfrac{1}{2}\,gD^a\,\phi^\dagger T^a\phi \;+\; (\text{from } V^1 \text{ symmetrization}) \;=\; gD^a\,\phi^\dagger T^a\phi. \tag{45.77}$$

  (The factor combines the explicit $\tfrac{1}{2}$ in Eq. (45.71) with the $\tfrac{1}{2}$ from $\int \mathrm{d}^4\theta\,\theta\theta\bar\theta\bar\theta = 1$ being applied to the symmetric product $\phi^\dagger\{T^a\}\phi$; we fix the net normalization below by matching to the gauge-current structure.)

The $\tfrac{1}{2}V^2$ piece. By Eq. (45.72) this is already top- component, so it pairs only with the two lowest scalars:

$$\Big[\Phi^\dagger\,\tfrac{1}{2}V^2\,\Phi\Big]_{\theta\theta\bar\theta\bar\theta} = \tfrac{1}{2}\,\phi^\dagger(g^2A^a_\mu A^{b\mu}T^aT^b)\phi = \tfrac{1}{2}\,g^2A^a_\mu A^{b\mu}\,\phi^\dagger T^aT^b\phi. \tag{45.78}$$

This is the "seagull" contact term quadratic in the gauge field.

Assembly into covariant derivatives. The point of the gauge principle is that Eq. (45.74), Eq. (45.75) and Eq. (45.78) recombine into manifestly covariant kinetic terms. For the scalar, expand

$$(D_\mu\phi)^\dagger(D^\mu\phi) = \partial_\mu\phi^\dagger\partial^\mu\phi + igA^a_\mu(\partial_\mu\phi^\dagger T^a\phi - \phi^\dagger T^a\partial^\mu\phi) + g^2A^a_\mu A^{b\mu}\,\phi^\dagger T^aT^b\phi, \tag{45.79}$$

with $D_\mu\phi = (\partial_\mu - igA^a_\mu T^a)\phi$. The three lines of Eq. (45.79) are exactly Eq. (45.74) (scalar part), Eq. (45.75), and Eq. (45.78); the abelian-current and seagull pieces supplied by the V and V^2 terms are precisely the completions that turn ∂_μ into D_μ. For the fermion, the free term $i\bar\psi\bar\sigma^\mu\partial_\mu\psi$ plus the $gA^a_\mu\bar\psi\bar\sigma^\mu T^a\psi$ of the V^1 piece

combine to $i\bar{\psi}\bar{\sigma}^{\mu}D_{\mu}\psi$ with the same covariant derivative. Collecting everything, the matter Kähler term reduces to the off-shell component Lagrangian

$$\boxed{\begin{aligned}\mathcal{L}^{\text{kin}}_{\text{matter}} &= (D_{\mu}\phi)^{\dagger}(D^{\mu}\phi) + i\,\bar{\psi}\,\bar{\sigma}^{\mu}D_{\mu}\psi + F^{\dagger}F \\ &\quad - \sqrt{2}\,g\big[(\phi^{\dagger}T^{a}\psi)\,\lambda^{a} + \bar{\lambda}^{a}(\bar{\psi}\,T^{a}\phi)\big] + g\,D^{a}\,\phi^{\dagger}T^{a}\phi.\end{aligned}} \tag{45.80}$$

Every term has a clear origin: the covariant scalar and fermion kinetic terms from the gauge completion of Eq. (44.208), the $F^{\dagger}F$ auxiliary term unchanged, the gaugino–quark–squark Yukawa $\sqrt{2}\,g\,\phi^{\dagger}T^{a}\psi\lambda^{a}$ from the gaugino components of V, and the D-dependent term $gD^{a}\phi^{\dagger}T^{a}\phi$ from the auxiliary component of V. The $\sqrt{2}$ in the Yukawa is not adjustable: it is the same $\sqrt{2}$ that appears in $\Phi = \phi + \sqrt{2}\theta\psi + \ldots$, fixed once and for all by the SUSY algebra, and it ties the strength of the gaugino–matter coupling to the gauge coupling g. This is the supersymmetric rigidity in action: gauging a chiral multiplet introduces *no* new free parameters beyond g itself.

Notation Watch

The sign and normalization of the D-dependent term depend on the conventions chosen for the components of V in Eq. (45.71) and for the super Yang–Mills auxiliary term in Eq. (45.63). We fix them so that the on-shell elimination below yields the standard non-negative potential $V = \sum|F|^2 + \frac{1}{2}\sum(D^{a})^2$; only the product of the matter D-coupling and the SYM D^2-coefficient is physical, and it is convention-independent. Throughout we write g for the canonically-normalized gauge coupling of Yang–Mills theory.

45.3.3 The full SQCD Lagrangian

We now specialize to supersymmetric QCD itself. The gauge group is $G = \mathrm{SU}(N_c)$. The matter is N_f *flavors* of *quark* chiral superfields Q_i $(i = 1, \ldots, N_f)$ in the fundamental $\mathbf{N_c}$, together with N_f *antiquark* chiral superfields $\widetilde{Q}^{\,i}$ in the antifundamental $\overline{\mathbf{N_c}}$. Writing the colour index $a = 1, \ldots, N_c$ explicitly, Q^{a}_{i} carries an upper (fundamental) colour index and $\widetilde{Q}^{\,i}_{a}$ a lower (antifundamental) one; each is a full chiral multiplet (ϕ, ψ, F) — a complex *squark* scalar, a Weyl *quark* fermion, and an auxiliary field. The vector multiplet $(A^{a}_{\mu}, \lambda^{a}, D^{a})$ lives in the adjoint of $\mathrm{SU}(N_c)$. This pairing of conjugate representations is the SUSY analog of one Dirac quark of QCD: a Dirac fermion in $\mathbf{N_c}$ is two Weyl fermions, one in $\mathbf{N_c}$ (from Q) and one in $\overline{\mathbf{N_c}}$ (from $\widetilde{Q}$), so N_f flavors of *Dirac* quark become N_f pairs $(Q, \widetilde{Q})$. The vector-like content is what allows a gauge-invariant mass term, as we will see.

Definition 45.17 (Supersymmetric QCD)**.** SQCD is the $\mathrm{SU}(N_c)$ gauge theory with N_f flavors $(Q_i, \widetilde{Q}^{\,i})$ of chiral matter in $\mathbf{N_c} \oplus \overline{\mathbf{N_c}}$, with the action

$$S_{\mathrm{SQCD}} = \int d^4x \Big[\tfrac{1}{4\pi}\,\mathrm{Im} \int \mathrm{d}^2\theta\; \tau\; \mathrm{tr}\; W^\alpha W_\alpha + \int \mathrm{d}^4\theta (Q^\dagger e^V Q + \widetilde{Q}^\dagger e^{-V^\top} \widetilde{Q}) + \Big(\int \mathrm{d}^2\theta\; W + \mathrm{h.c.} \Big) \Big], \tag{45.81}$$

where τ and W_α are the holomorphic coupling and field strength of Eqs. (45.16) and (45.54), $e^{-V^\top}$ is the representation of e^V on the antifundamental $\widetilde{Q}$, and W is a gauge-invariant superpotential. The renormalizable choice is a quark mass term

$$W = \sum_{i,j} m^{\,j}_{\,i}\, \widetilde{Q}^{\,i} Q_j \equiv \mathrm{tr}\,(m\, \widetilde{Q} Q), \tag{45.82}$$

the unique gauge-invariant holomorphic quadratic; *massless* SQCD is $W = 0$.

The antifundamental coupling deserves a word. If $Q \to e^{i\Lambda} Q$ in the fundamental, then a field in $\overline{\mathbf{N_c}}$ transforms with the conjugate matrices, $\widetilde{Q} \to \widetilde{Q}\, e^{-i\Lambda^\top}$ (acting on the row index), so its covariant Kähler term uses $e^{-V^\top}$, i.e. V in the antifundamental representation, $T^a_{\overline{\mathbf{N_c}}} = -(T^a)^\top$. With this the antiquark term is gauge invariant by the same cancellation as in Theorem 45.15, and its component reduction is Eq. (45.80) with $T^a \to -(T^a)^\top$. The superpotential Eq. (45.82) is gauge invariant because $\widetilde{Q}^{\,i} Q_j$ contracts a $\overline{\mathbf{N_c}}$ with a $\mathbf{N_c}$ into a colour singlet, and it is holomorphic, hence an admissible F-term by Theorem 44.41.

Adding the super Yang–Mills component Lagrangian Eq. (45.63) — which contains $-\frac{1}{4} F^a_{\mu\nu} F^{a\mu\nu}$, the gaugino kinetic term $i\bar\lambda^a \bar\sigma^\mu (D_\mu \lambda)^a$, the topological θ-term, and the gauge auxiliary $\frac{1}{2} D^a D^a$ — to the matter Lagrangian Eq. (45.80) summed over all N_f flavors of both Q and $\widetilde{Q}$, and to the superpotential components Eq. (44.201), gives the complete off-shell SQCD Lagrangian

$$\begin{aligned} \mathcal{L}_{\mathrm{SQCD}} = &-\tfrac{1}{4} F^a_{\mu\nu} F^{a\mu\nu} + i\,\bar\lambda^a \bar\sigma^\mu (D_\mu \lambda)^a + \tfrac{1}{2} D^a D^a \\ &+ \sum_f \Big[(D_\mu \phi_f)^\dagger (D^\mu \phi_f) + i\,\bar\psi_f \bar\sigma^\mu D_\mu \psi_f + F_f^\dagger F_f \Big] \\ &- \sqrt{2}\, g \sum_f \big[(\phi_f^\dagger T_f^a \psi_f) \lambda^a + \mathrm{h.c.} \big] + g\, D^a \sum_f \phi_f^\dagger T_f^a \phi_f \\ &+ \Big[\sum_f \frac{\partial W}{\partial \phi_f} F_f - \tfrac{1}{2} \sum_{f,f'} \frac{\partial^2 W}{\partial \phi_f \partial \phi_{f'}} \psi_f \psi_{f'} + \mathrm{h.c.} \Big], \end{aligned} \tag{45.83}$$

where the index f runs over *all* matter chiral multiplets — the N_f quarks Q_i (with $T^a_f = T^a$ in the fundamental) and the N_f antiquarks $\widetilde{Q}^{\,i}$ (with $T^a_f = -(T^a)^\top$) — and ϕ_f, ψ_f, F_f are their components. This is the full renormalizable Lagrangian SQCD: a single gauge coupling g, a single θ-angle, and the holomorphic mass matrix m, with every other coefficient — the gaugino Yukawa, the seagull, the D-coupling — fixed by supersymmetry. We have extended Yang–Mills theory from the pure-glue theory of Chapters 25 and 27 to a gauge theory with matter,

exactly as ordinary QCD extends pure Yang–Mills; the matter content $(Q, \widetilde{Q})$ is what will contribute to the beta function computed in Section 45.4.

45.3.4 The scalar potential from the auxiliary fields

The auxiliary fields F_f and D^a appear in Eq. (45.83) algebraically — quadratically, with no derivatives — exactly as F did in the ungauged Wess–Zumino model (Eq. (44.210)). They therefore carry no dynamics and may be eliminated by their algebraic equations of motion. Doing so produces the scalar potential, the central object that controls the vacuum structure.

Theorem 45.18 (SQCD scalar potential)**.** *Eliminating the auxiliary fields of Eq. (45.83) by their equations of motion yields the on-shell scalar potential*

$$\boxed{V(\phi,\phi^\dagger) = \sum_f |F_f|^2_{\text{on-shell}} + \tfrac{1}{2}\sum_a (D^a)^2_{\text{on-shell}} = \underbrace{\sum_f \Big|\frac{\partial W}{\partial \phi_f}\Big|^2}_{F\text{-term}} + \underbrace{\frac{g^2}{2}\sum_a \Big(\sum_f \phi_f^\dagger T_f^a \phi_f\Big)^2}_{D\text{-term}} \;\geq\; 0,} \tag{45.84}$$

with on-shell values

$$F_f = -\Big(\frac{\partial W}{\partial \phi_f}\Big)^*, \qquad D^a = -g\sum_f \phi_f^\dagger T_f^a \phi_f. \tag{45.85}$$

Proof. Collect from Eq. (45.83) every term containing an auxiliary field. The F-dependent terms are, for each f,

$$\mathcal{L}_F = \sum_f \Big[F_f^\dagger F_f + \frac{\partial W}{\partial \phi_f} F_f + \Big(\frac{\partial W}{\partial \phi_f}\Big)^* F_f^\dagger\Big], \tag{45.86}$$

exactly the structure of Eq. (44.210). Varying with respect to $F_f^\dagger$ gives $F_f + (\partial W/\partial\phi_f)^* = 0$, i.e. the first relation in Eq. (45.85). Substituting back,

$$\mathcal{L}_F\big|_{\text{on-shell}} = \sum_f \Big[\,|W_f|^2 - |W_f|^2 - |W_f|^2\Big] = -\sum_f \Big|\frac{\partial W}{\partial \phi_f}\Big|^2, \tag{45.87}$$

writing $W_f \equiv \partial W/\partial\phi_f$. The D-dependent terms are

$$\mathcal{L}_D = \tfrac{1}{2} D^a D^a + g D^a \sum_f \phi_f^\dagger T_f^a \phi_f. \tag{45.88}$$

Define the gauge moment map $\mu^a \equiv \sum_f \phi_f^\dagger T_f^a \phi_f$. Varying with respect to D^a gives $D^a + g\mu^a = 0$, i.e. the second relation in Eq. (45.85), $D^a = -g\mu^a$. Substituting,

$$\mathcal{L}_D\big|_{\text{on-shell}} = \tfrac{1}{2} g^2 (\mu^a)^2 - g^2 (\mu^a)^2 = -\tfrac{1}{2} g^2 \sum_a (\mu^a)^2 = -\tfrac{1}{2}\sum_a (D^a)^2. \tag{45.89}$$

The potential is minus the auxiliary Lagrangian (the Lagrangian contains $-V$ in the sign conventions of Eq. (44.212)), so $V = -\mathcal{L}_F|_{\text{on-shell}} - \mathcal{L}_D|_{\text{on-shell}}$, which is Eq. (45.84). Each summand is a modulus squared, hence $V \geq 0$. □

The structure $V = \sum_f |F_f|^2 + \frac{1}{2}\sum_a (D^a)^2$ is universal: it holds for *any* $\mathcal{N} = 1$ gauge theory with canonical Kähler terms, the F-terms set by the superpotential and the D-terms set by the gauge charges. The F-term piece is the gauge-theory generalization of Eq. (44.149), and the D-term piece is the genuinely new ingredient brought by gauging. Notice that the D-term is quartic in the scalars with coefficient g^2 fixed entirely by the gauge coupling — a scalar self-interaction that supersymmetry and gauge invariance *predict*, with no free quartic of its own.

Physical Insight: vacuum energy as the SUSY-breaking order parameter

Because $V \geq 0$ with equality iff every $F_f = 0$ and every $D^a = 0$, the scalar potential is the component-level avatar of the algebraic fact, proved from the SUSY algebra in Theorem 44.9, that the Hamiltonian is non-negative, $H = \frac{1}{4}\sum_\alpha (\{Q_\alpha, Q_\alpha^\dagger\}) \geq 0$. Supersymmetry is unbroken in a vacuum $|0\rangle$ precisely when $Q_\alpha |0\rangle = 0$, equivalently when the vacuum energy vanishes, equivalently when $\langle F_f \rangle = \langle D^a \rangle = 0$. A non-zero vacuum energy is therefore the *order parameter* for spontaneous supersymmetry breaking (Theorem 44.10): if no scalar configuration can set all F and D to zero simultaneously, then $V_{\min} > 0$ and SUSY is broken — by an F-term (the O'Raifeartaigh mechanism) or by a D-term (the Fayet–Iliopoulos mechanism). For a *simple* gauge group such as $\mathrm{SU}(N_c)$ there is no Fayet–Iliopoulos term, because a linear $\xi \int \mathrm{d}^4\theta\, V^a$ is gauge invariant only for an abelian factor (the trace $\mathrm{tr}\, T^a = 0$ kills it for $\mathrm{SU}(N_c)$); D-term breaking thus requires a U(1), and the abelian linear "Fayet–Iliopoulos-like" term flagged in Theorem 44.42 is exactly this option. In SQCD with $W = 0$ we will find that $V = 0$ has a large solution space, so classical SUSY is unbroken along an entire moduli space.

45.3.5 Classical supersymmetric vacua and the moduli space

The classical vacua of SQCD are the field configurations minimizing V. Since $V \geq 0$ and supersymmetric vacua have $V = 0$, the supersymmetric vacua are exactly the simultaneous solutions of the *F-flatness* and *D-flatness* conditions

$$F_f = -\Big(\frac{\partial W}{\partial \phi_f}\Big)^* = 0 \quad \text{for all } f, \qquad D^a = -g \sum_f \phi_f^\dagger T_f^a \phi_f = 0 \quad \text{for all } a. \tag{45.90}$$

Generically these equations have not isolated solutions but a continuous family. The set of solutions, modulo gauge equivalence, is the *classical moduli space* $\mathcal{M}_{\rm cl}$ — a space of physically inequivalent, exactly degenerate vacua. We now characterize it.

D-flatness in matrix form. Specialize to massless SQCD, $W = 0$, so F-flatness is automatic and only D-flatness constrains the squarks. Arrange the squark VEVs into colour×flavour matrices: let ϕ_i^a ($a = 1, \dots, N_c$; $i = 1, \dots, N_f$) be the scalar of Q_i, an $N_c \times N_f$ matrix, and let $\widetilde{\phi}_a^{\,i}$ be the scalar of $\widetilde{Q}^{\,i}$, an $N_f \times N_c$ matrix. The D-flatness condition $\mu^a = 0$ reads, summing the fundamental contribution of Q and the antifundamental contribution of $\widetilde{Q}$,

$$\mu^a = \sum_i \phi_i^\dagger T^a \phi_i + \sum_i \widetilde{\phi}^{\,i} \big(-(T^a)^\top\big) \widetilde{\phi}^{\,i\dagger} = \mathrm{tr}\big[T^a \big(\phi\,\phi^\dagger - \widetilde{\phi}^\dagger \widetilde{\phi}\big)\big] = 0 \quad \text{for all } a. \tag{45.91}$$

Since the T^a span all traceless Hermitian $N_c \times N_c$ matrices, the vanishing of Eq. (45.91) for every a is equivalent to the statement that the Hermitian matrix $\phi\phi^\dagger - \widetilde{\phi}^\dagger\widetilde{\phi}$ has no traceless part, i.e. is proportional to the identity:

$$\phi\,\phi^\dagger - \widetilde{\phi}^\dagger \widetilde{\phi} = \rho\, \mathbf{1}_{N_c}, \qquad \rho = \frac{1}{N_c}\,\mathrm{tr}\big(\phi\phi^\dagger - \widetilde{\phi}^\dagger\widetilde{\phi}\big) \in \mathbb{R}. \tag{45.92}$$

This single matrix equation is the complete D-flatness condition. Its solution space, modulo $\mathrm{SU}(N_c)$ gauge transformations, is the classical moduli space of massless SQCD.

Gauge-invariant coordinates: mesons and baryons. Rather than solve Eq. (45.92) and quotient by hand, it is cleaner to describe $\mathcal{M}_{\rm cl}$ by gauge invariants. The holomorphic gauge-invariant chiral operators built from Q and $\widetilde{Q}$ are

$$\text{mesons:} \quad M^i_{\ j} = \widetilde{Q}^{\,i}_a\, Q^a_j, \qquad \text{an } N_f \times N_f \text{ matrix}, \tag{45.93}$$

$$\text{baryons:} \quad B^{i_1 \cdots i_{N_c}} = \epsilon_{a_1 \cdots a_{N_c}}\, Q^{a_1}_{i_1} \cdots Q^{a_{N_c}}_{i_{N_c}}, \quad \text{antisymmetric in the } N_c \text{ flavors}, \tag{45.94}$$

$$\text{antibaryons:} \quad \widetilde{B}_{i_1 \cdots i_{N_c}} = \epsilon^{a_1 \cdots a_{N_c}}\, \widetilde{Q}^{\,i_1}_{a_1} \cdots \widetilde{Q}^{\,i_{N_c}}_{a_{N_c}}. \tag{45.95}$$

These are colour singlets (the meson by contracting $\overline{\mathbf{N_c}}$ with $\mathbf{N_c}$, the baryon by the invariant ϵ-tensor of $\mathrm{SU}(N_c)$), and being holomorphic in the chiral superfields they are themselves chiral. A foundational fact, which we use here and Chapter 46 elevates to the quantum level, is that *the gauge-invariant chiral operators provide good holomorphic coordinates on the classical moduli space*: every D-flat configuration is gauge-equivalent to one labeled by the values of $M, B, \widetilde{B}$, subject to the classical relations among them. The baryons require antisymmetrizing N_c colour indices over the flavors, which is impossible when there are fewer than N_c distinct flavors; hence baryons exist only for $N_f \geq N_c$.

Dimension count by the super-Higgs mechanism. The cleanest way to get the dimension of $\mathcal{M}_{\rm cl}$ is to count light degrees of freedom directly. We start with $2N_cN_f$ complex squark fields (N_cN_f in Q and N_cN_f in $\widetilde{Q}$). At a generic point of the moduli space the squark VEVs Higgs the gauge group, and each *broken* gauge generator eats one chiral superfield: supersymmetrically, a massless vector multiplet (2 bosonic $+2$ fermionic states) absorbs a massless chiral multiplet ($2+2$ states) to form a massive vector multiplet, the super-Higgs mechanism. Hence

$$\dim_{\mathbb{C}} \mathcal{M}_{\rm cl} = \underbrace{2N_cN_f}_{\text{squark chirals}} - \underbrace{(\dim G - \dim H)}_{\text{broken generators, each eats one chiral}}, \tag{45.96}$$

where $H \subseteq G$ is the unbroken gauge group at the generic point. Two regimes arise, distinguished by whether the squarks can break $\mathrm{SU}(N_c)$ completely.

Regime $N_f < N_c$. A generic rank-N_f squark VEV ϕ breaks $\mathrm{SU}(N_c) \to \mathrm{SU}(N_c - N_f)$ (the colour directions orthogonal to the N_f "filled" ones are untouched). The number of broken generators is

$$\dim \mathrm{SU}(N_c) - \dim \mathrm{SU}(N_c - N_f) = (N_c^2 - 1) - \big((N_c - N_f)^2 - 1\big) = 2N_cN_f - N_f^2. \tag{45.97}$$

Substituting into Eq. (45.96),

$$\dim_{\mathbb{C}} \mathcal{M}_{\rm cl} = 2N_cN_f - (2N_cN_f - N_f^2) = N_f^2. \tag{45.98}$$

These N_f^2 complex moduli are exactly the N_f^2 components of the meson matrix $M^i_{\ j}$ of Eq. (45.93); there are no baryons and no constraints, so $\mathcal{M}_{\rm cl}$ is freely parametrized by M, a copy of $\mathbb{C}^{N_f^2}$.

Regime $N_f \geq N_c$. Now a generic squark VEV breaks $\mathrm{SU}(N_c)$ *completely*, $H = \{1\}$, so all $N_c^2 - 1$ generators are broken and

$$\dim_{\mathbb{C}} \mathcal{M}_{\rm cl} = 2N_cN_f - (N_c^2 - 1). \tag{45.99}$$

The invariants are now the mesons M (N_f^2 of them) *and* the baryons and antibaryons $B, \widetilde{B}$ (each $\binom{N_f}{N_c}$ of them). These over-count Eq. (45.99), so they obey classical relations — the moduli space is the image of the map $(\phi, \widetilde{\phi}) \mapsto (M, B, \widetilde{B})$, an algebraic variety cut out by those relations. For the borderline case $N_f = N_c$ the baryons collapse to single objects $B = \det Q$, $\widetilde{B} = \det \widetilde{Q}$ (one each), and the meson, baryon and antibaryon obey the single classical constraint

$$\det M - B\,\widetilde{B} = 0, \tag{45.100}$$

since $\det(\widetilde{Q}Q) = \det \widetilde{Q} \det Q$. Counting: N_c^2 (mesons) $+2$ (baryons) -1 (constraint) $= N_c^2 + 1$, matching Eq. (45.99) at $N_f = N_c$. These dimension counts, and the distinction between the two regimes, are precisely the classical data that the exact analysis of Chapter 46 — Seiberg duality and the quantum-modified moduli space — takes as its starting point.

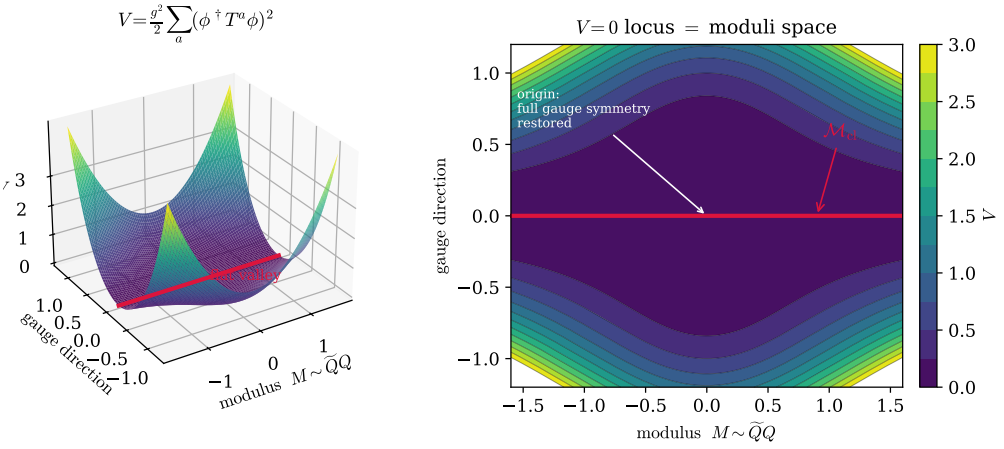

Figure 45.3: The scalar potential of massless SQCD ($W = 0$) is purely a D-term, $V = \frac{g^2}{2}\sum_a (\phi^\dagger T^a \phi)^2 \geq 0$. Its zero locus is a flat, connected valley of exactly degenerate supersymmetric vacua — the classical moduli space $\mathcal{M}_{\rm cl}$ — swept out as the gauge-invariant modulus (here the meson $M \sim \widetilde{Q}Q$) varies. Directions transverse to the valley turn on $D^a \neq 0$ and cost energy. At the origin all squark VEVs vanish and the full gauge symmetry is restored; this is where the classical description becomes singular and the nonperturbative physics of Chapter 46 takes over.

Worked Example 45.19 (SU(2) with one flavor: the simplest moduli space)**.** Take $N_c = 2$, $N_f = 1$: gauge group SU(2), one quark Q^a ($a = 1, 2$) in the doublet $\mathbf{2}$ and one antiquark $\widetilde{Q}_a$ in $\overline{\mathbf{2}}$. We solve Eq. (45.90) explicitly with $W = 0$, exhibit the surviving massless modulus, and check the dimension count Eq. (45.98), which predicts $\dim_{\mathbb{C}} \mathcal{M}_{\rm cl} = N_f^2 = 1$.

Setup. Write the squark VEVs as two-component complex column vectors: $q \equiv (\phi^1, \phi^2)^\top$ for the quark, and $\widetilde{q} \equiv (\widetilde{\phi}_1, \widetilde{\phi}_2)^\dagger$ packaging the antiquark scalar as a column. The generators are $T^a = \frac{1}{2}\sigma^a$ with σ^a the Pauli matrices (Section B.2). The D-flatness matrix equation Eq. (45.92) reads, for $N_c = 2$,

$$q\, q^\dagger - \widetilde{q}\, \widetilde{q}^\dagger = \rho\, \mathbf{1}_2, \qquad \rho = \tfrac{1}{2}(|q|^2 - |\widetilde{q}|^2). \tag{45.101}$$

Solving. Use the SU(2) gauge freedom to rotate q to the form $q = (v, 0)^\top$ with $v \geq 0$. Write $\widetilde{q} = (b, c)^\top$. Then

$$q q^\dagger = \begin{pmatrix} v^2 & 0 \\ 0 & 0 \end{pmatrix}, \qquad \widetilde{q}\widetilde{q}^\dagger = \begin{pmatrix} |b|^2 & bc^* \\ cb^* & |c|^2 \end{pmatrix}, \tag{45.102}$$

and Eq. (45.101) demands the difference be proportional to the identity: the off-diagonal entries force $bc^* = 0$, and the diagonal entries force $v^2 - |b|^2 = -|c|^2$.

The generic branch is $c = 0$, leaving $v^2 = |b|^2$, i.e. $|\widetilde{q}| = |q| = v$. Thus, up to gauge and global flavor rotations, the D-flat configurations are

$$q = \begin{pmatrix} v \\ 0 \end{pmatrix}, \qquad \widetilde{q} = \begin{pmatrix} v\, e^{i\beta} \\ 0 \end{pmatrix}, \qquad v \geq 0, \tag{45.103}$$

a two-real-parameter family (v, β) after the gauge fixing.

The modulus. The single gauge invariant is the meson

$$M = \widetilde{Q}\, Q = \widetilde{\phi}_a \phi^a = v \cdot v\, e^{-i\beta} = v^2 e^{-i\beta}, \tag{45.104}$$

one complex number that combines the modulus' magnitude v^2 and phase β. This M is the surviving massless modulus: as it varies over $\mathbb{C}$ it sweeps out the entire one-complex-dimensional moduli space, confirming $\dim_{\mathbb{C}} \mathcal{M}_{\rm cl} = 1 = N_f^2$.

Degree-of-freedom audit. The squarks carry $2 + 2 = 4$ complex $= 8$ real fields. D-flatness imposes $\dim \mathrm{SU}(2) = 3$ real conditions ($\mu^a = 0$, $a = 1, 2, 3$), leaving $8 - 3 = 5$. A nonzero VEV $q = (v, 0)^\top$ breaks SU(2) completely (a single doublet VEV has trivial stabilizer in SU(2), since $\mathrm{SU}(2) \cong S^3$ acts freely on the unit sphere in $\mathbb{C}^2$), so all three gauge directions are eaten: $5 - 3 = 2$ real $= 1$ complex modulus. Equivalently, Eq. (45.96) gives $2N_cN_f - (N_c^2 - 1) = 4 - 3 = 1$, the same answer because $\mathrm{SU}(N_c - N_f) = \mathrm{SU}(1)$ is trivial. The three broken gauge bosons acquire mass $\sim g\, v$ by the super-Higgs mechanism, each absorbing a squark chiral multiplet; what remains massless is the single chiral multiplet whose scalar is M.

The origin and its singularity. At $v = 0$ (hence $M = 0$) all squark VEVs vanish, the gauge group SU(2) is restored unbroken, and the three would-be massive vector multiplets become massless. The classical moduli space is therefore smooth away from $M = 0$ but *singular at the origin*, where extra degrees of freedom (the full gluon/gaugino multiplet) become light. Reinstating a quark mass $W = mM$ adds an F-term: $\partial W/\partial M = m$, so $V \supset |m|^2$ lifts the flat direction entirely and the unique vacuum slides to $M = 0$. With $W = 0$, however, the classical theory has an exact one-complex-dimensional valley of degenerate supersymmetric vacua — the concrete realization of the moduli-space notion, and the simplest laboratory for the quantum corrections of Chapter 46, where this very singularity at $M = 0$ is resolved by nonperturbative dynamics.

We have assembled the complete renormalizable Lagrangian of supersymmetric QCD, reduced it to the scalar potential $V = \sum_f |F_f|^2 + \frac{1}{2}\sum_a (D^a)^2$ by integrating out the auxiliary fields, and mapped out its classical moduli space of vacua in terms of the gauge-invariant mesons and baryons. The holomorphic superpotential W and the gauge coupling τ now stand exposed as the two data on which the quantum theory acts. The next section turns to the property that makes these theories extraordinary: the superpotential and the holomorphic coupling are protected by holomorphy and the global symmetries (including the R-symmetry of Section 44.2.7) so tightly that the former receives *no* perturbative

corrections at all and the latter runs only at one loop, yielding the exact NSVZ beta function that sharpens the one-loop result of Chapter 27 for Yang–Mills theory.

45.4 Nonrenormalization Theorems and the Exact NSVZ Beta Function

The preceding section assembled supersymmetric QCD: N_f flavors of chiral matter $Q, \widetilde{Q}$ coupled to SU(N_c) super-Yang–Mills, with the gauge-covariant Kähler term $Q^\dagger e^V Q + \widetilde{Q}^\dagger e^{-V}\widetilde{Q}$, the holomorphic superpotential (a possible mass or, more generally, gauge-invariant chiral interactions), and the classical scalar potential whose flat directions form the moduli space. We now ask the quantum question. In an ordinary field theory the couplings drift with scale, and there is no shortcut: one computes loop integrals order by order. Supersymmetry changes this radically. The split of the action into a *holomorphic* piece — the superpotential W and the gauge kinetic term, each an F-term integrated only over half of superspace — and a *non-holomorphic* piece — the Kähler term, a D-term integrated over all of superspace — is not bookkeeping. It is the structural fact that lets us determine the quantum corrections to the holomorphic sector *exactly*, with no loop computation at all, using only holomorphy, symmetry, and the behavior in weak-coupling limits. The flag planted in Section 44.7.8 is now made into a theorem.

The payoff is twofold. First, the superpotential receives *no* perturbative corrections: the renormalized W equals the tree-level W to all orders. Second — and this is the climactic Yang–Mills theory advance promised by the chapter — the holomorphic gauge coupling runs at one loop only, and converting it to the physical (canonically normalized) coupling through a single, controlled anomaly produces a *closed-form, all-orders* beta function: the NSVZ formula. Reducing it at one loop recovers and sharpens the coefficient $b_0 = \frac{11}{3}C_A - \frac{4}{3}T_F n_f$ that Eq. (27.1) computed for ordinary Yang–Mills, replacing it by the supersymmetric values $b_0 = 3C_A$ for pure super-Yang–Mills and $b_0 = 3N_c - N_f$ for SU(N_c) SQCD. We develop the holomorphy principle, prove the superpotential nonrenormalization theorem, show carefully why the Kähler potential is *not* protected (so that physical couplings do run), establish the one-loop-exactness of the holomorphic coupling, and assemble the NSVZ denominator from the rescaling (Konishi) anomaly.

Notation Watch

Two distinct objects in this chapter are traditionally both called "W." The *superpotential* $W(\Phi)$ is a holomorphic function of chiral matter superfields (Theorem 44.40); we always write it with an explicit field argument or

as W. The *gauge field-strength superfield* is the chiral spinor superfield $W_\alpha = -\frac{1}{4}\bar{D}\bar{D}\, e^{-V} D_\alpha e^{V}$ built from the vector superfield earlier in this chapter; it always carries a spinor index α. The two never appear without their distinguishing decoration, so no ambiguity survives.

45.4.1 Couplings as spurions: the holomorphy principle

The engine of every nonrenormalization result is a single idea due to Seiberg: *treat each coupling in the holomorphic sector as the constant value of a background chiral superfield.* A coupling λ that multiplies an F-term $\int \mathrm{d}^2\theta\, \mathcal{O}$ can be regarded as the lowest component of a non-dynamical chiral superfield Λ (a "spurion"), frozen to its vacuum value $\langle \Lambda \rangle = \lambda$ with all higher components set to zero. Because $\int \mathrm{d}^2\theta\, \Lambda\, \mathcal{O}$ is then a perfectly good supersymmetric interaction of a chiral superfield Λ with the chiral operator $\mathcal{O}$, the entire formal apparatus of superspace — in particular, the chirality of the superpotential — now applies to the couplings themselves. Three principles then pin down the quantum theory.

(H1) **Holomorphy.** The Wilsonian effective superpotential W_{eff}, obtained by integrating out modes above a scale μ, is a chiral F-term. By the ring property of chiral superfields (Eq. (44.198)), W_{eff} must be a *holomorphic* function of the dynamical chiral superfields *and* of the chiral spurions — a function of the Φ_i and the Λ_a alone, with no dependence on any conjugate $\Phi_i^\dagger$ or $\Lambda_a^\dagger$. Anti-holomorphic or mixed dependence would live in the Kähler (D-term) sector, never in W_{eff}.

(H2) **Symmetry.** Every global symmetry of the classical theory — the ordinary flavor U(1)'s and the $\mathrm{U}(1)_R$ R-symmetry of Section 44.2.7 — must be respected by W_{eff}, *provided we let the symmetries act on the spurions too.* A symmetry that is broken by a nonzero coupling becomes a symmetry of the spurion-extended theory by assigning the spurion the charge that compensates: the classical Lagrangian is then exactly invariant, and so is anything computed from it. This converts "approximate" or "softly broken" symmetries into exact selection rules on W_{eff}.

(H3) **Weak-coupling limits and regularity.** As any holomorphic coupling $\lambda \to 0$ the corresponding interaction switches off, and W_{eff} must reduce smoothly to that of the theory without the interaction. Combined with holomorphy, this is decisive: a function holomorphic in λ and known to be regular (no inverse powers, no logarithms of λ) as $\lambda \to 0$ is fixed by its Taylor coefficients there, and those coefficients are fixed by ordinary perturbation theory at low order. Demanding regularity also as the *other* couplings (e.g. a mass) tend to zero forbids would-be terms that are singular in those limits.

The logic is worth stating starkly: holomorphy says W_{eff} is an analytic function on the space of couplings; symmetry restricts which monomials can appear; weak-coupling limits fix the few surviving coefficients. Because an analytic function is rigid — determined globally by its behavior in a limit — conclusions drawn in the weak-coupling corner of coupling space hold *everywhere*, including at strong coupling. The honest scope, which we will respect throughout, is that this argument controls the *perturbative* holomorphic data exactly; genuinely nonperturbative contributions (instantons) appear as terms exponentially small in the coupling, are invisible to the Taylor expansion of (H3), and are the business of Chapter 46.

45.4.2 The perturbative nonrenormalization theorem

We prove the statement in the cleanest nontrivial setting — the cubic Wess–Zumino model carried since Theorem 44.42 — and then read off the general theorem. To avoid colliding with the gauge coupling g of this chapter, we write the cubic superpotential coupling as λ (it is the "g" of Eq. (44.214)):

$$W_{\text{tree}}(\Phi) = \tfrac{1}{2}\, m\, \Phi^2 + \tfrac{1}{3}\, \lambda\, \Phi^3. \tag{45.105}$$

Theorem 45.20 (Perturbative nonrenormalization of the superpotential)**.** *In the Wess–Zumino model with tree superpotential Eq. (45.105), the Wilsonian effective superpotential is uncorrected to all orders in perturbation theory:*

$$W_{\text{eff}}(\Phi) = W_{\text{tree}}(\Phi) = \tfrac{1}{2}\, m\, \Phi^2 + \tfrac{1}{3}\, \lambda\, \Phi^3. \tag{45.106}$$

More generally, for any set of chiral superfields with renormalizable or nonrenormalizable holomorphic superpotential, the coefficients in W receive no perturbative corrections; all scale dependence of physical couplings resides in the Kähler potential, i.e. in wavefunction renormalization.

Proof. Promote the mass m and the coupling λ to background chiral spurion superfields, each frozen to its constant lowest component. The spurion-extended classical theory has two global U(1) symmetries under which the dynamical field and the spurions carry charges chosen to make Eq. (45.105) invariant.

Charge assignments. Under an ordinary flavor rotation U(1) let Φ carry charge $+1$, $\Phi \mapsto e^{i\alpha}\Phi$. Invariance of $m\Phi^2$ and $\lambda\Phi^3$ forces the spurions to carry

$$q[\Phi] = +1, \qquad q[m] = -2, \qquad q[\lambda] = -3. \tag{45.107}$$

Under the R-symmetry $\mathrm{U}(1)_R$ the Grassmann coordinate has $R[\theta] = +1$, so the chiral measure has $R[\mathrm{d}^2\theta] = -2$ and an F-term superpotential must carry $R = +2$ to make $\int \mathrm{d}^2\theta\, W$ neutral (Section 44.2.7). Assigning Φ an R-charge $R[\Phi] \equiv r$ (its value will drop out), invariance of $\int \mathrm{d}^2\theta\, m\Phi^2$ and $\int \mathrm{d}^2\theta\, \lambda\Phi^3$ requires

$$R[m] = 2 - 2r, \qquad R[\lambda] = 2 - 3r. \tag{45.108}$$

Allowed monomials. By (H1), W_{eff} is a holomorphic function of Φ, m, λ; expand it in monomials $\Phi^a m^b \lambda^c$ with integers $a \geq 0$, $b, c \geq 0$ (negative powers of a field or of λ are excluded by regularity, (H3), as we confirm below). Such a monomial multiplies $\int \mathrm{d}^2\theta$ and so must carry total U(1) charge 0 and total R-charge +2:

$$q: \quad a - 2b - 3c = 0, \tag{45.109}$$

$$R: \quad a\,r + b(2-2r) + c(2-3r) = 2. \tag{45.110}$$

Substituting Eq. (45.109) into Eq. (45.110), the r-dependent terms collect as $r(a-2b-3c) + 2(b+c) = 2$, and the bracket vanishes by Eq. (45.109), leaving

$$b + c = 1. \tag{45.111}$$

The arbitrary choice r has cancelled, as it must — a genuine selection rule cannot depend on the free convention for $R[\Phi]$. With $b, c \geq 0$ integers, Eq. (45.111) has exactly two solutions: $(b, c) = (1, 0)$ forces $a = 2$ by Eq. (45.109), giving the term $m\Phi^2$; and $(b, c) = (0, 1)$ forces $a = 3$, giving $\lambda\Phi^3$. No other monomial is allowed. Symmetry and holomorphy alone therefore restrict

$$W_{\text{eff}}(\Phi) = A\, m\, \Phi^2 + B\, \lambda\, \Phi^3, \tag{45.112}$$

with A, B pure numbers — with one caveat to dispatch: the constraints Eq. (45.109)–Eq. (45.110) are also solved by inserting any power of the neutral combination $x \equiv \lambda\Phi/m$, which has $q[x] = 1 - 3 + 2 = 0$ and $R[x] = (2-3r) + r - (2-2r) = 0$. Symmetry alone thus permits $W_{\text{eff}} = m\Phi^2\, f(x)$ for an arbitrary holomorphic f; equivalently A, B could be replaced by power series in x.

Weak coupling fixes the function. Here (H3) closes the argument. Write $W_{\text{eff}} = m\Phi^2 \sum_{n\geq 0} a_n x^n$ with $x = \lambda\Phi/m$. The n-th term is

$$a_n\, m\, \Phi^2 \left(\frac{\lambda\Phi}{m}\right)^n = a_n\, \lambda^n\, m^{\,1-n}\, \Phi^{\,n+2}. \tag{45.113}$$

For $n \geq 2$ this carries a *negative* power m^{1-n} of the mass. But perturbation theory in λ is manifestly regular as $m \to 0$: Feynman diagrams of the massless Wess–Zumino model are finite functions of the external momenta and never generate inverse powers of a mass that was set to zero. A term singular as $m \to 0$ cannot arise at any finite order, so $a_n = 0$ for all $n \geq 2$. (The same conclusion follows from demanding regularity as $\Phi \to \infty$ at fixed λ: an effective superpotential growing faster than the classical cubic is excluded.) Only $n = 0, 1$ survive, reproducing Eq. (45.112) with constant $A = a_0$, $B = a_1$.

Fixing the constants. Take $\lambda \to 0$ at fixed m. The theory becomes a free massive chiral superfield, whose superpotential is exactly $\frac{1}{2}m\Phi^2$ with no corrections (a free theory renormalizes nothing in W). Hence $A = \frac{1}{2}$. Now take the leading nontrivial order in λ: at order λ^1, holomorphy and the $\lambda \to 0$

matching require the cubic coefficient to equal its tree value, since any correction would be of higher order in λ and thus carry a power $x^{n\geq 1}$ already excluded; concretely, expanding to first order in λ the only allowed $O(\lambda)$ term is $\lambda\Phi^3$ with the tree coefficient, so $B = \frac{1}{3}$. Therefore

$$W_{\text{eff}}(\Phi) = \tfrac{1}{2}\, m\, \Phi^2 + \tfrac{1}{3}\, \lambda\, \Phi^3 = W_{\text{tree}}(\Phi), \tag{45.114}$$

exactly, to all orders in perturbation theory. The generalization is immediate: for any holomorphic $W = \sum_a \lambda_a\, \mathcal{O}_a(\Phi)$, promote every λ_a to a chiral spurion, impose the U(1)'s and $\mathrm{U}(1)_R$ as exact selection rules, and require regularity in the weak-coupling and small-mass limits; the only holomorphic invariant available to multiply each operator is the corresponding single power of its own coupling, so every coefficient is frozen at its tree value. This is Eq. (45.106). □

Physical Insight

The theorem is often summarized by the diagrammatic "miracle" that the would-be loop corrections to the superpotential cancel between bosons and fermions. That cancellation is real, but it is a *consequence*, not the reason. The reason is holomorphy: an analytic function of the couplings that is regular at weak coupling is determined by a finite amount of low-order data, and that data is the tree-level superpotential. One never has to draw a single loop diagram. This is the prototype of "exact results from symmetry" that organizes all of supersymmetric dynamics, and it is what makes supersymmetry a candidate solution to the hierarchy problem (Chapter 35): a scalar mass that sits in W cannot be renormalized, so a small mass stays small, protected to all perturbative orders by holomorphy rather than by fine-tuning.

45.4.3 The Kähler potential is renormalized

Nonrenormalization protects only the holomorphic sector. The Kähler potential is a D-term,

$$\int \mathrm{d}^4\theta\; K(\Phi^\dagger, \Phi), \qquad K = Z\, \Phi^\dagger \Phi + \ldots, \tag{45.115}$$

and the spurion argument simply does not constrain it. The integrand depends on both Φ and $\Phi^\dagger$, so it is neither chiral nor antichiral; the coefficient Z is a *real* function of the couplings and their conjugates — it can and does depend on $|\lambda|^2$, $\ln(\mu)$, and the like — and there is no holomorphy to forbid its renormalization. Diagrammatically, the wavefunction self-energy of a chiral superfield is a genuine D-term loop effect with no cancellation: $Z \neq 1$ and Z runs with scale.

This is precisely what rescues the theory from triviality. The superpotential couplings m, λ in Eq. (45.114) are scale-*independent* as holomorphic parameters,

yet the *physical*, canonically normalized couplings run. To see how, canonically normalize the kinetic term by rescaling $\Phi \to Z^{-1/2}\Phi$, which sends $\int \mathrm{d}^4\theta\, Z\, \Phi^\dagger\Phi \to \int \mathrm{d}^4\theta\, \Phi^\dagger\Phi$ and rescales the superpotential coefficients:

$$m_{\text{phys}} = Z^{-1}\, m, \qquad \lambda_{\text{phys}} = Z^{-3/2}\, \lambda. \tag{45.116}$$

The physical mass and Yukawa coupling therefore run entirely through the wavefunction factor $Z(\mu)$. Defining the anomalous dimension of the chiral superfield by

$$\gamma \;\equiv\; -\,\frac{d\ln Z}{d\ln \mu}, \tag{45.117}$$

(the superfield analogue of the field anomalous dimension of Theorem 24.2, here carried once per superfield since all components renormalize together), we read off

$$\frac{d\ln \lambda_{\text{phys}}}{d\ln\mu} = -\tfrac{3}{2}\frac{d\ln Z}{d\ln\mu} = \tfrac{3}{2}\,\gamma, \qquad \frac{d\ln m_{\text{phys}}}{d\ln\mu} = \gamma. \tag{45.118}$$

The beta function of the physical Yukawa coupling is thus *not* zero; it is *entirely* the wavefunction anomalous dimension. This is the sharp version of the slogan "W does not renormalize but the theory still runs." All the genuine dynamics has been quarantined into a single real function $Z(\mu)$, and γ is the one piece of data perturbation theory still has to supply.

Caution

It is a frequent error to conclude from Theorem 45.20 that supersymmetric gauge theories have vanishing beta functions. They do not. The holomorphic couplings are protected, but the canonical couplings flow, driven by the unprotected Kähler renormalization. The next two subsections show how the same dichotomy — holomorphic coupling protected, canonical coupling running — plays out in the gauge sector and produces the exact NSVZ beta function, whose numerator carries exactly the anomalous dimensions γ_r defined above.

45.4.4 The holomorphic gauge coupling runs only at one loop

The gauge sector is governed by its own holomorphic coupling. Recall (from earlier in this chapter) the complexified coupling that packages the gauge coupling g with the theta angle of Section 42.4,

$$\tau \;\equiv\; \frac{\theta}{2\pi} + \frac{4\pi i}{g^2}, \tag{45.119}$$

and the gauge kinetic term written as a chiral F-term of the field-strength superfield W_α,

$$\mathcal{L}_{\text{gauge}} = \frac{1}{4\pi}\,\mathrm{Im}\Big[\tau\int \mathrm{d}^2\theta\ \mathrm{tr}\ W^\alpha W_\alpha\Big] = -\frac{1}{4g^2}F^a_{\mu\nu}F^{a\,\mu\nu} + \frac{\theta}{32\pi^2}F^a_{\mu\nu}\widetilde{F}^{a\,\mu\nu} + \dots . \tag{45.120}$$

Because $\int \mathrm{d}^2\theta\ \mathrm{tr}\, W^\alpha W_\alpha$ is holomorphic and the coefficient is linear in τ, the gauge coupling enters the action exactly as the superpotential couplings did: as the value of a background chiral object. We can therefore run the holomorphy machine on τ itself.

Two facts constrain the effective holomorphic coupling $\tau_{\text{eff}}(\mu)$. First, **holomorphy**: τ_{eff} is a holomorphic function of τ (and of any chiral matter spurions). Second, **periodicity of the theta angle**. The term $\frac{\theta}{32\pi^2}F\widetilde{F}$ integrates, on configurations of integer topological charge ν (Section 42.4), to $\theta\nu$; shifting $\theta \to \theta + 2\pi$ changes the action by $2\pi\nu \in 2\pi\mathbb{Z}$, leaving e^{iS} invariant. Physics is therefore periodic under

$$\theta \to \theta + 2\pi, \qquad \text{equivalently} \qquad \tau \to \tau + 1. \tag{45.121}$$

A holomorphic function compatible with the shift symmetry Eq. (45.121) can depend on τ only in two ways: linearly (a shift of τ by an integer shifts the linear term by an integer, an allowed redefinition of θ), or through the single-valued periodic combination $e^{2\pi i\tau}$. The exponential is the instanton weight,

$$e^{2\pi i\tau} = e^{i\theta}\, e^{-8\pi^2/g^2}, \tag{45.122}$$

exponentially small at weak coupling and invisible to perturbation theory. Hence the *perturbative* part of τ_{eff} is at most linear in τ. A genuine two-loop or higher perturbative correction would contribute a term analytic in g^2 — i.e. a power of $1/\tau$ — which is neither linear in τ nor of the exponential form, and is forbidden. Only the one-loop term survives.

Concretely, dimensional transmutation fixes the form. The one nontrivial scale of the theory is the renormalization-group invariant

$$\Lambda \;=\; \mu\,\exp\!\left(\frac{2\pi i\,\tau_{\text{eff}}(\mu)}{b_0}\right), \qquad b_0 \equiv 3C_A - \sum_r T(r), \tag{45.123}$$

holomorphic in τ and invariant under $\mu\, d/d\mu$ by construction. Inverting,

$$2\pi i\,\tau_{\text{eff}}(\mu) = b_0\,\ln\frac{\Lambda}{\mu}, \qquad \text{i.e.} \qquad \frac{8\pi^2}{g_h^2(\mu)} = b_0\,\ln\frac{\mu}{|\Lambda|} + \text{const}, \tag{45.124}$$

where in the second form we took the real part of Eq. (45.124) using $\mathrm{Re}(2\pi i\tau) = -8\pi^2/g^2$ from Eq. (45.119), and we write g_h for the *holomorphic* coupling. The

content is sharp:

$$\boxed{\frac{d}{d\ln\mu}\frac{8\pi^2}{g_h^2} \;=\; b_0 \;=\; 3C_A - \sum_r T(r), \qquad \text{exactly, with no higher-loop corrections.}} \tag{45.125}$$

The matter Dynkin indices $T(r)$ enter here through the one-loop running only; their all-orders effect, encoded in the anomalous dimensions γ_r, has not yet appeared because g_h is the holomorphic, not the physical, coupling. Disentangling the two is the final step.

Historical Note

That the holomorphic coupling is one-loop exact, while the physical coupling is not, was the source of a long apparent paradox. The Novikov–Shifman–Vainshtein–Zakharov (NSVZ) beta function was derived from instanton calculus in the early 1980s and manifestly contains all-orders structure; yet supersymmetric perturbation theory in a holomorphic scheme seemed to stop at one loop. Shifman and Vainshtein resolved this in 1991 by recognizing that the holomorphic (Wilsonian) coupling and the physical (canonical) one differ by an anomalous Jacobian — the rescaling anomaly — so that both statements are correct in their own scheme. Arkani-Hamed and Murayama later recast the entire argument in the transparent holomorphy-plus-anomaly language we follow here.

45.4.5 From holomorphic to canonical: the Konishi anomaly and the NSVZ formula

The holomorphic normalization that made Eq. (45.125) so clean is not the normalization in which fields have canonical kinetic terms. In the holomorphic frame the gauge coupling sits in front of $\operatorname{tr} W^\alpha W_\alpha$ and the matter Kähler terms carry wavefunction factors Z_r; to compute physical quantities one passes to the *canonical* frame by rescaling

$$\Phi_r \to Z_r^{-1/2}\Phi_r \quad \text{(matter)}, \qquad V \to 2g_c V \quad \text{(gauge)}, \tag{45.126}$$

so that the matter kinetic terms become $\Phi_r^\dagger e^V \Phi_r$ and the gauge coupling g_c reappears inside the covariant derivatives. Classically these are harmless changes of integration variable in the path integral. Quantum mechanically they are *not*: a chiral rescaling by a complex factor is anomalous, exactly as the chiral rotation of a Dirac field is anomalous in Section 36.2. The measure of a chiral superfield is not invariant under $\Phi_r \to e^{c_r}\Phi_r$; the Jacobian is the supersymmetric (Konishi) version of the ABJ anomaly of Theorem 36.4.

The Konishi/rescaling anomaly. A word on the logical status of what follows. Chapter 36 establishes by the Fujikawa method only the *ordinary* ABJ triangle (Theorem 36.4); its superfield lift — the anomalous Jacobian for rescaling an entire chiral superfield, the Konishi anomaly — is not derived in this book. We import its form and normalization from the literature [370], and rather than presenting the coefficient as derived we fix its logical status honestly: it is the value that reproduces, by the consistency check carried out just below, the established one-loop coefficient b_0 of Yang–Mills theory. With that caveat stated, the imported statement is this. Under $\Phi_r \to e^{c_r}\Phi_r$ with c_r a constant (real or complex), the path-integral measure of the chiral superfield in representation r shifts the gauge kinetic action by a local F-term,

$$\mathcal{D}\Phi_r\,\mathcal{D}\Phi_r^\dagger \;\longrightarrow\; \mathcal{D}\Phi_r\,\mathcal{D}\Phi_r^\dagger\,\exp\!\left[-\frac{T(r)\,c_r}{8\pi^2}\int \mathrm{d}^4x\,\mathrm{d}^2\theta\;\tfrac{1}{4}\,\mathrm{tr}\,W^\alpha W_\alpha + \mathrm{h.c.}\right], \tag{45.127}$$

the supersymmetric completion of the ABJ triangle with the rescaling current $\Phi_r^\dagger e^V \Phi_r$ in place of the axial current; the coefficient $T(r)$ is the Dynkin index of r, the direct analogue of the $\mathrm{tr}(T^aT^b)$ that multiplied Eq. (36.50). Comparing with Eq. (45.120), a shift of the coefficient of $\mathrm{tr}\,W^\alpha W_\alpha$ is a shift of the holomorphic gauge coupling. Performing the matter rescaling of Eq. (45.126) with $c_r = -\tfrac{1}{2}\ln Z_r$ therefore contributes

$$\Delta\left(\frac{8\pi^2}{g^2}\right)_{\text{matter}} = -\sum_r T(r)\ln Z_r. \tag{45.128}$$

The gauge rescaling $V \to 2g_c V$ is likewise anomalous: it rescales the gauginos, which sit in the adjoint, and the same mechanism with Dynkin index $T(\mathrm{adj}) = C_A$ contributes a term proportional to $C_A \ln g_c$. The upshot is the exact relation between the holomorphic coupling g_h of Eq. (45.125) and the canonical coupling g_c,

$$\frac{8\pi^2}{g_c^2(\mu)} = \frac{8\pi^2}{g_h^2(\mu)} - C_A\ln g_c^2(\mu) - \sum_r T(r)\ln Z_r(\mu) + \text{const}, \tag{45.129}$$

where the sign and coefficient of the C_A term are those that the gaugino rescaling anomaly produces (they are fixed unambiguously by the Jacobian Eq. (45.127) applied to the adjoint gauginos; we verify just below that they yield the established NSVZ denominator). Equation Eq. (45.129) is the technical heart of the section: the protected, one-loop-exact holomorphic coupling on the right is converted to the physical coupling on the left by two purely anomalous pieces, one from the gauginos (C_A) and one from the matter ($T(r)$, weighted by the running wavefunctions Z_r).

Assembling the beta function. Differentiate Eq. (45.129) with respect to $t \equiv \ln \mu$. Write the canonical beta function as $\beta \equiv dg_c/dt$, and use:

$$\frac{d}{dt}\frac{8\pi^2}{g_c^2} = -\frac{16\pi^2}{g_c^3}\,\beta, \tag{45.130}$$

$$\frac{d}{dt}\frac{8\pi^2}{g_h^2} = b_0 = 3C_A - \sum_r T(r) \qquad (\text{by } \textit{Eq. (45.125)}), \tag{45.131}$$

$$\frac{d}{dt}\ln g_c^2 = \frac{2\beta}{g_c}, \qquad \frac{d}{dt}\ln Z_r = -\gamma_r \qquad (\text{by } \textit{Eq. (45.117)}). \tag{45.132}$$

Substituting into the t-derivative of Eq. (45.129),

$$-\frac{16\pi^2}{g_c^3}\,\beta = \Big(3C_A - \sum_r T(r)\Big) - C_A\,\frac{2\beta}{g_c} + \sum_r T(r)\,\gamma_r, \tag{45.133}$$

where the last term used $\dfrac{d}{dt}(-\sum_r T(r)\ln Z_r) = +\sum_r T(r)\gamma_r$. Collect the numerator using $3C_A - \sum_r T(r) + \sum_r T(r)\gamma_r = 3C_A - \sum_r T(r)(1-\gamma_r)$, and move the β term from the right to the left:

$$-\beta\left(\frac{16\pi^2}{g_c^3} - \frac{2C_A}{g_c}\right) = 3C_A - \sum_r T(r)\,(1-\gamma_r). \tag{45.134}$$

Factor $\dfrac{16\pi^2}{g_c^3}\Big(1 - \dfrac{C_A g_c^2}{8\pi^2}\Big)$ out of the bracket on the left and solve for β. Dropping the now-redundant subscript on the physical coupling ($g \equiv g_c$), this is the NSVZ beta function.

Theorem 45.21 (The exact NSVZ beta function)**.** *For $\mathcal{N}=1$ super-Yang–Mills with gauge group of adjoint Casimir C_A coupled to chiral matter superfields in representations r of Dynkin index $T(r)$ and anomalous dimensions γ_r defined by Eq. (45.117), the beta function of the canonically normalized gauge coupling is, to all orders in perturbation theory,*

$$\boxed{\beta(g) = -\frac{g^3}{16\pi^2}\,\frac{3C_A - \sum_r T(r)\,(1-\gamma_r)}{1 - \dfrac{C_A\,g^2}{8\pi^2}}} \tag{45.135}$$

The numerator is the one-loop coefficient corrected by the matter anomalous dimensions; the denominator is the resummed contribution of the gaugino rescaling anomaly. The only quantity not fixed by holomorphy and the anomaly is γ_r, which carries all remaining scheme-dependent dynamics and starts at one loop.

Caution

The NSVZ formula is exact in a specific (NSVZ) scheme; like any beta function beyond two loops it is scheme-dependent, and Eq. (45.135) should be read together with the scheme in which γ_r and the holomorphic running Eq. (45.125) are defined. What is genuinely scheme-*independent* are the consequences we draw from it: the one- and two-loop coefficients, the vanishing of β at the *Banks–Zaks* or superconformal fixed points where the numerator vanishes, and the location of the conformal window for SQCD. The honest statement, which Chapter 46 takes as input, is that holomorphy plus one controlled anomaly reduces the entire all-orders gauge running to a single one-loop quantity γ_r.

45.4.6 Reduction at one loop: the supersymmetric Yang–Mills theory coefficient

We now make contact with Chapter 27. At weak coupling the denominator of Eq. (45.135) tends to 1 and the anomalous dimensions $\gamma_r = O(g^2)$ may be dropped from the numerator, leaving

$$\beta(g) = -\frac{g^3}{16\pi^2}\, b_0 + O(g^5), \qquad b_0 = 3C_A - \sum_r T(r), \tag{45.136}$$

the same universal form $\beta = -(b_0/16\pi^2)g^3$ as the ordinary Yang–Mills result Eq. (27.1), but with a supersymmetric coefficient. The next worked example extracts b_0 for the two cases we require and reconciles them, term by term, with the non-supersymmetric value $b_0 = \frac{11}{3}C_A - \frac{4}{3}T_F n_f$.

Worked Example 45.22 (One-loop coefficient for pure SYM and for SU(N_c) SQCD)**.** We compute b_0 two ways — from the supersymmetric formula Eq. (45.136) and by adding up the component fields with the ordinary gauge-theory bookkeeping — and check that they agree, thereby exhibiting exactly how the gaugino and the squarks conspire to convert the familiar $\frac{11}{3}C_A$ into $3C_A$.

Component bookkeeping. For an ordinary gauge theory the one-loop coefficient is assembled from three kinds of fields, each contributing to the antiscreening/screening competition of Section 27.5:

$$b_0 = \frac{11}{3}\,C_A - \frac{2}{3}\sum_{\text{Weyl } f} T(r_f) - \frac{1}{3}\sum_{\text{complex } s} T(r_s), \tag{45.137}$$

the gauge boson giving $+\frac{11}{3}C_A$ (the gluon antiscreening), each Weyl fermion giving $-\frac{2}{3}T(r)$, and each complex scalar $-\frac{1}{3}T(r)$. (A Dirac fermion is two Weyl fermions, returning the $-\frac{4}{3}T(r)$ of Eq. (27.1).)

Pure super-Yang–Mills. The vector multiplet contains the gauge boson A_μ^a and a single Weyl (Majorana) gaugino λ^a in the adjoint, $T(\text{adj}) = C_A$. There is no matter. From Eq. (45.137),

$$b_0^{\text{SYM}} = \underbrace{\frac{11}{3} C_A}_{\text{gauge boson}} \underbrace{- \frac{2}{3} C_A}_{\text{gaugino}} = \frac{11-2}{3} C_A = 3\, C_A, \tag{45.138}$$

in exact agreement with the supersymmetric formula Eq. (45.136) with no matter sum. The reconciliation is needed is the single subtraction $-\frac{2}{3}C_A$: the adjoint gaugino, absent in ordinary Yang–Mills, screens by exactly $\frac{2}{3}C_A$ and turns $\frac{11}{3}C_A$ into $3C_A$.

Chiral matter. A chiral superfield in representation r contains one Weyl fermion (the quark) *and* one complex scalar (the squark), both in r. Its total contribution is

$$-\frac{2}{3} T(r) - \frac{1}{3} T(r) = -\, T(r), \tag{45.139}$$

which is precisely the matter term $-T(r)$ appearing in $b_0 = 3C_A - \sum_r T(r)$. Supersymmetry pairs each Weyl quark with a complex squark so that their separate $\frac{2}{3}$ and $\frac{1}{3}$ fractions sum to the clean integer-coefficient $-T(r)$.

SU(N_c) *SQCD with N_f flavors.* Here $C_A = N_c$. Each flavor supplies a quark chiral superfield Q in the fundamental $\mathbf{N_c}$ and an antiquark chiral superfield $\widetilde{Q}$ in the antifundamental $\bar{\mathbf{N}}_\mathbf{c}$, with Dynkin indices $T(\mathbf{N_c}) = T(\bar{\mathbf{N}}_\mathbf{c}) = T_F = \frac{1}{2}$. The matter sum over the $2N_f$ chiral superfields is

$$\sum_r T(r) = N_f (T_F + T_F) = N_f \left(\tfrac{1}{2} + \tfrac{1}{2}\right) = N_f, \tag{45.140}$$

so that

$$\boxed{b_0^{\text{SQCD}} = 3C_A - \sum_r T(r) = 3N_c - N_f.} \tag{45.141}$$

Comparison with Yang–Mills theory. For ordinary QCD-like Yang–Mills with n_f Dirac flavors in the fundamental, Eq. (27.1) gave $b_0 = \frac{11}{3}C_A - \frac{4}{3}T_F n_f$, i.e. for SU($N_c$) with $T_F = \frac{1}{2}$,

$$b_0^{\text{QCD}} = \frac{11}{3} N_c - \frac{2}{3} n_f. \tag{45.142}$$

The supersymmetric refinement Eq. (45.141) differs in both terms, and the origin of each difference is now explicit:

- the pure-gauge coefficient drops from $\frac{11}{3}N_c$ to $3N_c$ because the adjoint gaugino contributes the extra $-\frac{2}{3}N_c$ of Eq. (45.138);
- the matter coefficient changes from $-\frac{2}{3}$ per Dirac flavor to -1 per SQCD flavor because an SQCD "flavor" is a vector-like pair of chiral superfields

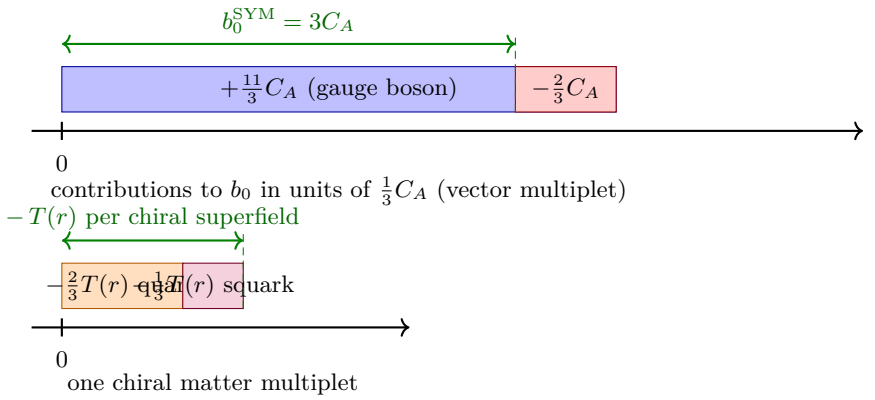

Figure 45.4: The one-loop coefficient b_0 as a sum over component fields. Top: the vector multiplet. The gauge boson antiscreens by $+\frac{11}{3}C_A$ (the familiar Yang–Mills value of Eq. (27.1)); the adjoint gaugino screens by $-\frac{2}{3}C_A$; the supersymmetric sum is the clean $3C_A$ of Eq. (45.138). Bottom: a single chiral matter multiplet, whose Weyl quark ($-\frac{2}{3}T(r)$) and complex squark ($-\frac{1}{3}T(r)$) add to $-T(r)$, the matter term of $b_0 = 3C_A - \sum_r T(r)$.

(Q and $\widetilde{Q}$, summing the two $-\frac{1}{2}$ Weyl-fermion pieces of a Dirac flavor) *plus* their squarks (the extra $-\frac{1}{3} - \frac{1}{3} = -\frac{2}{3}$ from two complex scalars), the two effects adding to the clean -1 of Eq. (45.140).

Both readings of b_0 agree, and the supersymmetric value is the one that feeds the exact NSVZ denominator. For SU(3) ($C_A = 3$) the asymptotic-freedom boundary moves from $n_f < \frac{11}{2}N_c = \frac{33}{2}$ Dirac flavors in QCD to $N_f < 3N_c = 9$ chiral flavors in SQCD; the window $3N_c < N_f$ where the theory loses asymptotic freedom, and the intermediate conformal window, are the data Chapter 46 exploits.

The picture in Fig. 45.4 is the visual summary of the thread advance: the same gluon antiscreening that drove asymptotic freedom in Chapter 27 survives, but the superpartners shift every coefficient onto the integer values dictated by supersymmetry, and those integers are exactly the data that the NSVZ denominator resums to all orders.

Physical Insight

There is a clean way to see why the gauginos contribute precisely $-\frac{2}{3}C_A$ rather than the $-\frac{4}{3}C_A$ a Dirac adjoint fermion would give: a gaugino is a single Weyl (Majorana) fermion, half a Dirac fermion, so it carries half the screening, $-\frac{1}{2}\cdot\frac{4}{3}C_A = -\frac{2}{3}C_A$. The deep statement is that supersymmetry forbids a bare gaugino mass (it would break the multiplet's boson–fermion degeneracy), so the gaugino is necessarily massless and Majorana, and

that masslessness is what fixes its contribution to be exactly the value that turns $\frac{11}{3}C_A$ into the holomorphy-protected $3C_A$. The numerator of NSVZ is not an accident of arithmetic; it is the imprint of the protected superpotential and the masslessness of the gauginos.

With the exact gauge coupling under control — the superpotential frozen by holomorphy, the Kähler renormalization quarantined into the anomalous dimensions γ_r, and the all-orders running packaged in Eq. (45.135) — we have the precise statement of how much, and how little, quantum corrections can do to a supersymmetric gauge theory. This is the control that Chapter 46 leverages: the one-loop-exact holomorphic coupling and the anomaly-free combinations identified here are the inputs to Seiberg duality and to gaugino condensation, where the holomorphic scale Λ of Eq. (45.123) becomes a dynamical order parameter. The next section turns from these exact protections to the question they force: since the world is manifestly not supersymmetric, how can supersymmetry be broken *softly* — lifting the superpartners — without sacrificing the very nonrenormalization that made the hierarchy stable.

45.5 Soft Supersymmetry Breaking

The nonrenormalization theorem of Section 45.4 told us precisely what supersymmetry protects: the holomorphic superpotential, and through it the exact equalities among masses, Yukawa couplings, and scalar self-couplings that descend from a single function $W(\Phi)$. That rigidity is the source of the boson–fermion mass degeneracy proved from the algebra in Theorem 44.12. But the same theorem is, read the other way, an indictment: a manifestly supersymmetric theory predicts a scalar electron exactly as light as the electron, a fermionic photino exactly as massless as the photon, and no such particles have been seen. If supersymmetry is realized in nature it must be *broken*, and broken in a way that lifts these degeneracies by at least the scale at which we have looked and failed to find superpartners.

The problem is that the protection and the degeneracy are the same fact. Break supersymmetry carelessly — with an arbitrary operator — and one throws away the very cancellations that made the theory worth building, in particular the cancellation of the quadratic divergence in the Higgs mass that motivated supersymmetry as a cure for the hierarchy problem (Section 35.3). The task of this section is to thread that needle. We first prove, with all the algebra on the page, that in unbroken supersymmetry the quadratically divergent fermion-loop contribution to a scalar mass is cancelled by the contribution of its scalar superpartners — the calculation that is the resolution of the hierarchy problem. We then ask which breaking terms can be added without spoiling that cancellation. The answer, due to Girardello and Grisaru, is a short and complete list of *soft*

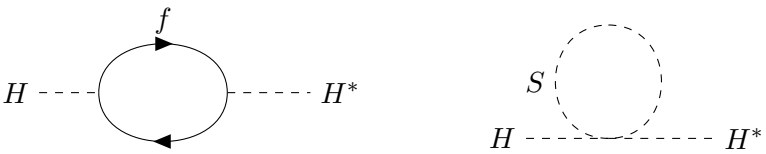

Figure 45.5: The two one-loop contributions to the light-scalar self-energy δm_H^2. Left: the fermion loop from the Yukawa coupling λ_f, which is quadratically divergent and *negative*. Right: the scalar loop from the quartic coupling λ_S, quadratically divergent and *positive*. Supersymmetry sets $\lambda_S = |\lambda_f|^2$ and supplies exactly two complex scalars S per Dirac fermion f, so the two $\Lambda_{\rm UV}^2$ pieces cancel.

operators, characterized by a single criterion: their couplings carry positive mass dimension. The spurion method makes both the criterion and the list transparent, and shows how each soft term descends from a supersymmetry-breaking sector through a background superfield. We close by assembling these terms into the soft Lagrangian that the next section instantiates as the MSSM.

45.5.1 The quadratic-divergence cancellation

The hierarchy problem, as diagnosed in Section 35.3, is that the mass-squared of a fundamental scalar is a relevant coupling: no symmetry of the Standard Model forbids it, so its renormalization is quadratically sensitive to the highest scale in the theory. Concretely, every heavy particle of mass M that couples to the Higgs shifts m_H^2 by an amount of order $M^2/(16\pi^2)$ (with a momentum cutoff $\Lambda_{\rm UV}$, by $\Lambda_{\rm UV}^2/(16\pi^2)$), so keeping m_H at the electroweak scale in the presence of physics at $M_{\rm Pl}$ demands a cancellation tuned to thirty digits. A chiral fermion, by contrast, is protected: a chiral symmetry forbids its mass, so its self-energy is at worst logarithmically divergent, $\delta m_f \propto m_f \ln \Lambda_{\rm UV}$. Supersymmetry exports that fermionic protection to the scalar by tying the two together in one multiplet. We now show the mechanism explicitly.

Consider a light complex scalar H — the prototype Higgs — coupled to a heavy chiral fermion f of mass m_f through a Yukawa interaction, and to a heavy complex scalar S of mass m_S through a quartic interaction:

$$\mathcal{L}_{\rm int} = -\,\lambda_f\, H\, \bar{f} P_L f \;-\; \lambda_f^*\, H^*\, \bar{f} P_R f \;-\; \lambda_S\, |H|^2\, |S|^2 \,. \tag{45.143}$$

Here $P_{L,R} = \tfrac{1}{2}(1 \mp \gamma^5)$ are the chiral projectors of Chapter 24's conventions and $\bar{f} = f^\dagger \gamma^0$. We compute the one-loop correction to the H self-energy at zero external momentum, δm_H^2, isolating the quadratically divergent piece. The two contributing diagrams are shown in Fig. 45.5: a closed fermion loop and a closed scalar loop.

All power-divergent integrals here are most honestly handled with a Euclidean momentum cutoff $\Lambda_{\rm UV}$, since the quadratic divergence is exactly the quantity

of physical interest and dimensional regularization sets it silently to zero. The single master integral we need is

$$I(M^2) \;\equiv\; \int \frac{\mathrm{d}^4 k_E}{(2\pi)^4}\,\frac{1}{k_E^2 + M^2} \;=\; \frac{1}{16\pi^2}\Big(\Lambda_{\mathrm{UV}}^2 - M^2 \ln\frac{\Lambda_{\mathrm{UV}}^2}{M^2} + \dots\Big), \tag{45.144}$$

obtained by writing $\mathrm{d}^4 k_E = 2\pi^2 k_E^3\,\mathrm{d}k_E$, integrating $k_E^3/(k_E^2+M^2)$ up to Λ_{UV}, and expanding. The leading term is the quadratic divergence; the subleading term is the logarithm we expect to survive. Continuing from Minkowski space we use $\int \mathrm{d}^4k/(2\pi)^4\; 1/(k^2 - M^2 + i\varepsilon) = -\,i\,I(M^2)$, the standard Wick rotation $k^0 = ik_E^0$, $\mathrm{d}^4k = i\,\mathrm{d}^4k_E$, $k^2 = -k_E^2$.

Fermion loop. The amplitude is

$$i\,\Pi_f(0) = (-1)\,(-i\lambda_f)(-i\lambda_f^*)\int \frac{\mathrm{d}^4k}{(2\pi)^4}\;\mathrm{Tr}\left[\frac{i(\not k + m_f)}{k^2 - m_f^2}\,P_L\,\frac{i(\not k + m_f)}{k^2 - m_f^2}\,P_R\right], \tag{45.145}$$

where the overall (-1) is the obligatory minus sign of a closed fermion loop and the two vertices carry the projectors P_L (at the H vertex) and P_R (at the H^* vertex). The Dirac trace collapses cleanly. Using $\gamma^5 \not k = -\not k \gamma^5$, hence $P_L \not k = \not k P_R$, the numerator becomes

$$\begin{aligned}\mathrm{Tr}[(\not k + m_f)P_L(\not k + m_f)P_R] &= \mathrm{Tr}[(\not k P_L + m_f P_L)(\not k P_R + m_f P_R)] \\ &= \mathrm{Tr}[P_R \not k\, \not k P_R] + m_f\,\mathrm{Tr}[P_R \not k P_R] + m_f\,\mathrm{Tr}[P_L \not k P_R] + m_f^2\,\mathrm{Tr}[P_L P_R] \\ &= k^2\;\mathrm{Tr}[P_R] \;=\; 2\,k^2. \end{aligned} \tag{45.146}$$

The three middle terms vanish: $P_R \not k P_R = \not k P_L P_R = 0$ and $P_L P_R = 0$, while $\mathrm{Tr}[P_R \not k \not k P_R] = k^2\,\mathrm{Tr}[P_R]$ with $\mathrm{Tr}[P_R] = 2$. Notice that the fermion mass has dropped out of the leading numerator entirely; only $2k^2$ survives, the hallmark of a chiral coupling. Inserting Eq. (45.146) into Eq. (45.145), with $(-i\lambda_f)(-i\lambda_f^*) = -\,|\lambda_f|^2$ and the explicit $i^2 = -1$ from the two propagator numerators,

$$i\,\Pi_f(0) = (-1)(-\,|\lambda_f|^2)(-1)\int \frac{\mathrm{d}^4k}{(2\pi)^4}\,\frac{2k^2}{(k^2 - m_f^2)^2} = -\,2\,|\lambda_f|^2 \int \frac{\mathrm{d}^4k}{(2\pi)^4}\,\frac{k^2}{(k^2 - m_f^2)^2}. \tag{45.147}$$

The quadratic divergence comes from the large-k region, where $k^2/(k^2-m_f^2)^2 = 1/(k^2-m_f^2) + m_f^2/(k^2-m_f^2)^2$; the first term is quadratically divergent and the second only logarithmically. Keeping the leading piece,

$$i\,\Pi_f(0)\big|_{\mathrm{quad}} = -\,2\,|\lambda_f|^2 \int \frac{\mathrm{d}^4k}{(2\pi)^4}\,\frac{1}{k^2 - m_f^2} = -\,2\,|\lambda_f|^2\;(-i\,I) = +\,2\,i\;|\lambda_f|^2\;\frac{\Lambda_{\mathrm{UV}}^2}{16\pi^2}, \tag{45.148}$$

so $\Pi_f(0)\big|_{\text{quad}} = +\,|\lambda_f|^2\,\Lambda_{\text{UV}}^2/(8\pi^2)$. The correction to the physical mass-squared is read off from the resummed propagator $i/(p^2 - m_H^2 + \Pi)$, whose pole sits at $p^2 = m_H^2 - \Pi(0)$, giving $\delta m_H^2 = -\Pi(0)$. Hence

$$\boxed{\delta m_H^2\big|_f = -\,\frac{|\lambda_f|^2}{8\pi^2}\,\Lambda_{\text{UV}}^2 + (\text{logs})} \tag{45.149}$$

— the quadratic divergence is present, and it is *negative*.

Scalar loop. The quartic term $-\lambda_S\,|H|^2\,|S|^2 = -\lambda_S H^* H S^* S$ gives a single vertex joining one H, one H^*, one S and one S^*; its Feynman rule is $-i\lambda_S$. Closing the S loop on the two H legs,

$$i\,\Pi_S(0) = (-i\lambda_S)\int \frac{\mathrm{d}^4k}{(2\pi)^4}\,\frac{i}{k^2 - m_S^2} = (-i\lambda_S)\,(I) = -\,i\,\lambda_S\,\frac{\Lambda_{\text{UV}}^2}{16\pi^2} + (\text{logs}), \tag{45.150}$$

using $\int \mathrm{d}^4k/(2\pi)^4\; i/(k^2 - m_S^2) = i(-iI) = I$. Thus $\Pi_S(0)\big|_{\text{quad}} = -\lambda_S\Lambda_{\text{UV}}^2/(16\pi^2)$ and

$$\delta m_H^2\big|_S = -\Pi_S(0) = +\,\frac{\lambda_S}{16\pi^2}\,\Lambda_{\text{UV}}^2 + (\text{logs}), \tag{45.151}$$

one factor of this per complex scalar coupled to H. The divergence is again quadratic, and this time *positive*. The opposite sign relative to Eq. (45.149) is structural: it is the closed-fermion-loop (-1) of Eq. (45.145) that has no analogue in the bosonic Eq. (45.150).

The cancellation. Opposite signs are not enough; the magnitudes must match, and match they do under supersymmetry, for two independent reasons that both follow from the structure built in Chapter 44. First, a Dirac fermion f is two Weyl fermions, so it belongs to *two* chiral supermultiplets, each carrying one complex scalar; the heavy fermion thus comes with exactly two complex scalars S_1, S_2. Second, the superpotential origin of the couplings fixes the quartic in terms of the Yukawa: as the Wess–Zumino computation of Theorem 44.42 showed (Eq. (44.214), Eq. (44.149)), the scalar quartic is the modulus-squared of the same holomorphic coupling that sets the Yukawa, so

$$\lambda_S = |\lambda_f|^2\,. \tag{45.152}$$

Summing the two scalar contributions and the fermion contribution,

$$\delta m_H^2 = \underbrace{-\,\frac{|\lambda_f|^2}{8\pi^2}\,\Lambda_{\text{UV}}^2}_{\text{fermion } f} + \underbrace{2\times\frac{\lambda_S}{16\pi^2}\,\Lambda_{\text{UV}}^2}_{\text{scalars } S_1,S_2} = \Lambda_{\text{UV}}^2\,\frac{|\lambda_f|^2}{16\pi^2}(-2+2) = 0 \quad (\text{quadratic part}), \tag{45.153}$$

where we used $\lambda_S = |\lambda_f|^2$. The $\Lambda_{\rm UV}^2$ pieces cancel *identically*. What remains is the logarithm in Eq. (45.144),

$$\delta m_H^2 = \frac{|\lambda_f|^2}{8\pi^2}(m_S^2 - m_f^2)\ln\frac{\Lambda_{\rm UV}}{\mu} + \dots, \tag{45.154}$$

which vanishes as well when $m_S = m_f$, i.e. in *unbroken* supersymmetry, where Theorem 44.12 forces $m_S = m_f$ and the scalar mass receives no correction at all. The structure of Eq. (45.154) is the punchline: the correction to a scalar mass is controlled not by the cutoff but by the *superpartner mass splitting* $m_S^2 - m_f^2$ and grows only logarithmically with $\Lambda_{\rm UV}$, governed by the renormalization-group running of Chapter 24. This is why supersymmetry solves the hierarchy problem, and it tells us precisely what breaking is allowed: any breaking we introduce may shift $m_S^2 - m_f^2$ away from zero, but it must not reintroduce the $\Lambda_{\rm UV}^2$ term.

Physical Insight

The cancellation is the loop-level shadow of the algebra. The supercharge anticommutator $\left\{Q_\alpha, \bar{Q}_{\dot\beta}\right\} = 2\sigma^\mu_{\alpha\dot\beta}P_\mu$ (Eq. (44.61)) ties bosons and fermions into one multiplet with equal couplings and equal masses; the equal couplings give equal-magnitude loop integrals and the spin-statistics minus sign gives them opposite signs. The vacuum-energy version of the same statement is Theorem 44.10: unbroken supersymmetry forces $E_{\rm vac} = 0$ because bosonic and fermionic zero-point energies cancel mode by mode. The scalar-mass cancellation here is the second derivative of that vacuum-energy cancellation with respect to the background field.

45.5.2 The supertrace sum rule

The diagrammatic cancellation above is a special case of a sum rule that holds in any supersymmetric theory and that turns out to be exactly the quantity soft breaking must violate. The one-loop vacuum energy of a free field of mass M is the sum of its zero-point energies, which in covariant form is $\frac{1}{2}\int \mathrm{d}^4k_E/(2\pi)^4\,\ln(k_E^2 + M^2)$ per bosonic degree of freedom, with an extra minus sign for fermions because their functional determinant appears in the numerator rather than the denominator of the path integral. Summing over a spectrum of field-dependent masses $M_J^2(\phi)$, the one-loop effective potential is

$$V_1(\phi) = \tfrac{1}{2}\sum_J (-1)^{2J}(2J+1)\int\frac{\mathrm{d}^4k_E}{(2\pi)^4}\,\ln(k_E^2+M_J^2(\phi)) \;\equiv\; \tfrac{1}{2}\,\mathrm{STr}\int\frac{\mathrm{d}^4k_E}{(2\pi)^4}\,\ln(k_E^2+M^2(\phi)), \tag{45.155}$$

where the *supertrace* weights each spin-J state by $(-1)^{2J}(2J+1)$: $+1$ for a real scalar, -2 for a Weyl fermion, $+3$ for a massive vector, and so on. The quadratically divergent part is extracted by differentiating the logarithm once

with respect to M^2, which returns the master integral Eq. (45.144); hence $\int \mathrm{d}^4k_E/(2\pi)^4\,\ln(k_E^2+M^2) \supset (\Lambda_{\mathrm{UV}}^2/16\pi^2)\,M^2$, and

$$V_1(\phi)\big|_{\mathrm{quad}} = \frac{\Lambda_{\mathrm{UV}}^2}{32\pi^2}\,\mathrm{STr}\,M^2(\phi), \qquad \mathrm{STr}\,M^2 \equiv \sum_J (-1)^{2J}(2J+1)\,M_J^2. \quad (45.156)$$

The scalar mass renormalization is $\partial^2 V_1/\partial\phi\,\partial\phi^*$, so the quadratically divergent part of any scalar mass is proportional to $\partial^2(\mathrm{STr}\,M^2)/\partial\phi\,\partial\phi^*$.

Now the key fact. In a supersymmetric theory every chiral multiplet contributes one Weyl fermion of mass M_F and one complex scalar (two real scalars) of mass M_S, with $M_S^2 = M_F^2 = |W''|^2$ as the component computation of Theorem 44.42 made explicit. Its contribution to the supertrace is therefore $2\cdot M_S^2 - 2\cdot M_F^2 = 0$. Including gauge multiplets and the constraints of the D-term sector leaves the statement intact at the level we need:

Theorem 45.23 (Supertrace mass-sum rule)**.** *In a renormalizable theory with unbroken global supersymmetry, the supertrace of the tree-level squared-mass matrix vanishes,*

$$\mathrm{STr}\,M^2 \;\equiv\; \sum_J (-1)^{2J}(2J+1)\,M_J^2 \;=\; 0, \quad (45.157)$$

as a function of the background fields. Consequently $V_1(\phi)\big|_{\mathrm{quad}} = 0$*: the one-loop effective potential, and in particular every scalar mass, is free of quadratic divergences.*

Proof. By multiplet. A chiral multiplet contributes $2M_S^2 - 2M_F^2$; supersymmetry gives $M_S^2 = M_F^2$ (the second derivatives of the superpotential coincide for the scalar mass matrix and the fermion mass matrix, Theorem 44.42), so its contribution is zero *as a function of* ϕ. A massless gauge multiplet contributes a vector ($+3$ at the massive point, $+2$ when massless and gauge-fixed consistently with the two physical polarizations) and a Weyl gaugino (-2); the contributions again cancel because gauge symmetry equates the gaugino mass to the gauge-boson mass within the multiplet. Summing the manifestly vanishing multiplet-by-multiplet contributions gives Eq. (45.157). Inserting it into Eq. (45.156) kills the quadratic divergence identically, and differentiating twice with respect to the background field shows the same for any individual scalar mass. □

This is the abstract content of Eq. (45.153): the cancellation of the toy computation is the statement $\mathrm{STr}\,M^2 = 0$ specialized to the fermion f and its two scalar partners. The sum rule also makes vivid the constraint on breaking. If we are to split superpartner masses while preserving the cancellation, $\mathrm{STr}\,M^2$ may become nonzero — but only as a *field-independent constant*, so that $\partial^2(\mathrm{STr}\,M^2)/\partial\phi\,\partial\phi^* = 0$ and no quadratic divergence reappears in any scalar

mass. A breaking that makes $\mathrm{STr}\, M^2$ depend on the fields is hard; one that shifts it by a constant is soft. Quantitatively, soft breaking produces

$$\mathrm{STr}\, M^2 = \sum_{\text{scalars}} m_i^2 - 2 \sum_{\text{fermions}} \cdots = \mathcal{O}(m_{\text{soft}}^2) \times (\text{const}), \tag{45.158}$$

a field-independent number of order the soft masses squared, which feeds only the cosmological constant and not the running of any mass.

45.5.3 The spurion method and the criterion for softness

To organize the breaking we use the device already met in Section 45.4: promote a breaking parameter to the vacuum value of a background superfield, a *spurion*. Suppose supersymmetry is broken spontaneously in some sector — by the F-term mechanism of Section 44.5.3, in which the auxiliary field of a chiral superfield acquires an expectation value, $\langle F \rangle \neq 0$, signalled by a positive vacuum energy through Theorem 44.10. Package the order parameter into a single gauge-singlet chiral superfield

$$X(y, \theta) = \langle X \rangle + \theta^2 F_X, \qquad \langle F_X \rangle \neq 0, \tag{45.159}$$

whose scalar component we may set to zero by a field redefinition and whose θ^2-component F_X is the breaking order parameter, of mass dimension two. The visible-sector fields do not couple to X directly at renormalizable level; instead the two sectors communicate through heavy physics of mass M (messengers, or gravity), so that the effective couplings are organized in powers of F_X/M^2 and X/M. The spurion bookkeeping is the statement that the full theory, breaking sector included, is supersymmetric: every term in the Lagrangian is a genuine superspace integral, and supersymmetry breaking is communicated *only* through the θ^2-component of X. This is what makes the consequences computable.

The criterion for softness now follows from dimensional analysis alone.

Theorem 45.24 (Girardello–Grisaru criterion)**.** *A supersymmetry-breaking operator added to a renormalizable Lagrangian fails to regenerate quadratic divergences in scalar masses — it is* soft *— if and only if its coupling constant has strictly positive mass dimension.*

Proof. A scalar mass renormalization δm^2 has mass dimension two. Suppose the operator in question multiplies a coupling g of mass dimension $[g] = d_g$. The most divergent contribution it can make to a scalar self-energy has the form $\delta m^2 \sim g\, \Lambda_{\text{UV}}^{p} \times$(dimensionless loop factors and logs). Matching mass dimensions, $2 = d_g + p$, so $p = 2 - d_g$. A quadratic divergence is $p = 2$, which requires $d_g = 0$: only a *dimensionless* coupling can multiply a Λ_{UV}^2. If $d_g > 0$ then $p = 2 - d_g < 2$, and the strongest possible divergence is at worst $\Lambda_{\text{UV}}^{2-d_g}$, i.e. a positive power of the soft scale times a logarithm: $\delta m^2 \sim g^{2/d_g} \ln \Lambda_{\text{UV}}$ in the simplest cases, never $g\Lambda_{\text{UV}}^2$. The spurion picture confirms the counting and shows it is exact,

not merely dimensional. Any soft coupling is, by construction, a power of F_X/M or F_X/M^2 times a supersymmetric vertex; restoring the spurion, a would-be quadratic divergence $\propto \Lambda_{\rm UV}^2$ multiplying g must come from a supergraph whose superspace structure is that of the unbroken theory, where Theorem 45.23 already set the field-dependent $\Lambda_{\rm UV}^2$ to zero. The breaking can only attach extra factors of F_X, each carrying dimension two and a corresponding suppression by M, so the divergence is softened by exactly the powers of $\Lambda_{\rm UV}$ that dimensional analysis predicts. The converse is the counterexample below: a dimensionless breaking coupling does produce $g\Lambda_{\rm UV}^2$. □

Worked Example 45.25 (A hard operator that ruins the cancellation)**.** The cleanest way to see the criterion bite is to add a breaking term whose coupling is dimensionless and watch the quadratic divergence return. Take the toy of Eq. (45.143) and add to it a single extra scalar quartic that violates the supersymmetric relation Eq. (45.152),

$$\Delta\mathcal{L} = -\,\Delta\lambda\,|H|^2\,|S|^2\,, \qquad [\Delta\lambda] = 0. \tag{45.160}$$

Its coupling $\Delta\lambda$ is dimensionless. Repeating the scalar-loop computation of Eq. (45.150) with $\lambda_S \to \lambda_S + \Delta\lambda$, the cancellation in Eq. (45.153) is spoiled by precisely the unmatched piece:

$$\delta m_H^2 = +\,2 \times \frac{\Delta\lambda}{16\pi^2}\,\Lambda_{\rm UV}^2 + \cdots = \frac{\Delta\lambda}{8\pi^2}\,\Lambda_{\rm UV}^2 + \cdots\,, \tag{45.161}$$

a quadratic divergence proportional to the dimensionless $\Delta\lambda$. The hierarchy problem is back in full force. This is exactly what Theorem 45.24 forbids: because $[\Delta\lambda] = 0$, the operator is *hard*. Note the contrast with a *trilinear* scalar coupling $-A\,H^2S + \text{h.c.}$ with $[A] = 1$: redoing the power counting, the strongest divergence it can produce in m_H^2 is $\sim A^2/(16\pi^2) \times \ln\Lambda_{\rm UV}$, only logarithmic — so a trilinear scalar coupling is soft, a quartic deviation is not. The single discriminating feature is the mass dimension of the coupling.

Caution

The criterion "positive-dimension coupling" is necessary and, for the operators that arise in gauge theories without gauge singlets, sufficient. There is one classic loophole, noted already by Girardello and Grisaru: the non-holomorphic trilinear scalar coupling $\phi^*\phi\phi$ (coupling of dimension one, hence naively soft) can close into a one-loop tadpole and generate a quadratically divergent linear term for any *gauge-singlet* scalar present in the theory, which then feeds back a quadratic divergence. In a theory whose chiral superfields are all charged under the gauge group — the MSSM, with no gauge singlets in its minimal field content — no such tadpole exists and $\phi^*\phi\phi$ would be harmless; but because it is also forbidden

by holomorphy of the would-be superpotential and brings nothing the analytic A-terms do not, it is conventionally excluded from the soft list. The honest statement is therefore: the soft operators enumerated below are soft in any gauge theory, and the only would-be extra candidate is excluded because it is dangerous precisely when gauge singlets are present.

45.5.4 The Girardello–Grisaru list of soft terms

Applying the criterion — gauge invariance, Lorentz invariance, and a coupling of strictly positive mass dimension — exhausts the renormalizable supersymmetry-breaking operators in a remarkably short list. For a generic gauge theory with gauge multiplets labelled by a (gauginos λ^a) and chiral multiplets labelled by i (complex scalars ϕ_i, Weyl fermions ψ_i), the complete soft Lagrangian is

$$\mathcal{L}_{\text{soft}} = -\Big(\tfrac{1}{2}\, M_a\, \lambda^a\lambda^a + \tfrac{1}{6}\, a_{ijk}\, \phi_i\phi_j\phi_k + \tfrac{1}{2}\, b_{ij}\, \phi_i\phi_j + \text{h.c.}\Big) \;-\; (m^2)_{ij}\, \phi_i^*\phi_j. \tag{45.162}$$

The four classes are, with their coupling dimensions:

- **Gaugino masses** M_a, $[M_a] = 1$: a Majorana mass $-\frac{1}{2}M_a\lambda^a\lambda^a$ for each gaugino, lifting it off the massless gauge boson it partners. These break supersymmetry but preserve gauge invariance because λ^a transforms in the (real) adjoint.
- **Scalar masses** $(m^2)_{ij}$, $[m^2] = 2$: a Hermitian mass-squared matrix $-(m^2)_{ij}\phi_i^*\phi_j$ for the scalars, the term that splits a squark or slepton from its quark or lepton partner. This is the non-holomorphic "D-term-type" mass.
- **Trilinear A-terms** a_{ijk}, $[a] = 1$: a holomorphic cubic scalar coupling $-\frac{1}{6}a_{ijk}\phi_i\phi_j\phi_k + \text{h.c.}$, with the *same* flavor structure as the superpotential Yukawa y_{ijk} (one usually writes $a_{ijk} = A_{ijk}y_{ijk}$, no sum).
- **Bilinear B-terms** b_{ij}, $[b] = 2$: a holomorphic quadratic scalar coupling $-\frac{1}{2}b_{ij}\phi_i\phi_j + \text{h.c.}$, the partner of a superpotential mass term $\mu_{ij}\Phi_i\Phi_j$ (one writes $b_{ij} = B_{ij}\mu_{ij}$).

Every coupling in Eq. (45.162) has positive mass dimension, so by Theorem 45.24 each preserves the absence of quadratic divergences; conversely, these are the *only* gauge- and Lorentz-invariant, positive-dimension operators that break supersymmetry, so the list is complete. A non-holomorphic trilinear $\phi_i^*\phi_j\phi_k$ is excluded for the reason discussed in the caution above; a chiral-fermion mass without a partner, or any dimensionless quartic deviation, is hard and excluded by the criterion. What is conspicuously *absent* is any quartic scalar coupling that is not already fixed by the supersymmetric D- and F-terms: the scalar quartic

potential of the theory remains the supersymmetric one, and this is what keeps the cancellation of Eq. (45.153) intact up to logarithms.

45.5.5 Soft terms from spurion insertions

The list Eq. (45.162) is not merely catalogued; each term is the residue of a manifestly supersymmetric coupling of the visible fields to the spurion X of Eq. (45.159), with the breaking carried in by the θ^2-component F_X. This is what justifies calling the soft terms "the imprint of a hidden breaking sector," and it fixes the parametric size of every coupling in terms of F_X and the mediation scale M. We display the two most important cases explicitly.

Worked Example 45.26 (Gaugino mass from $\int \mathrm{d}^2\theta\,(X/M)\,W^\alpha W_\alpha$)**.** The gauge kinetic term of Section 45.2 is the chiral superspace integral $\int \mathrm{d}^2\theta\, W^\alpha W_\alpha$, where the field-strength superfield expands as $W_\alpha = \lambda_\alpha + \cdots + \theta_\alpha D + (\sigma^{\mu\nu}\theta)_\alpha F_{\mu\nu} + \ldots$ with the gaugino λ at order θ^0. Couple it to the spurion through a dimension-five operator suppressed by M,

$$\mathcal{L} \supset \int \mathrm{d}^2\theta\, \frac{X}{2M}\, W^{a\alpha} W^a_\alpha + \text{h.c.} \tag{45.163}$$

The chiral measure $\int \mathrm{d}^2\theta$ projects onto the θ^2-component of the integrand. With $X = \langle X\rangle + \theta^2 F_X$, the θ^2 of X multiplies the θ^0 of $W^{a\alpha}W^a_\alpha$, which is $\lambda^a\lambda^a$:

$$\int \mathrm{d}^2\theta\, \frac{X}{2M}\, W^{a\alpha} W^a_\alpha \;\supset\; \frac{F_X}{2M}\, \lambda^a\lambda^a, \tag{45.164}$$

which is exactly the gaugino mass term of Eq. (45.162) with

$$M_a = \frac{F_X}{M}. \tag{45.165}$$

The $\langle X\rangle$-piece of Eq. (45.163) merely shifts the gauge coupling (a supersymmetric, holomorphic rescaling) and is absorbed into the definition of the coupling; it is the F_X-piece, present only because supersymmetry is broken, that gives the gaugino its mass. The operator is dimension five, so the mass is suppressed by one power of the mediation scale — the universal signature of a soft term carried by a positive-dimension coupling.

Worked Example 45.27 (Scalar mass from $\int \mathrm{d}^4\theta\,(X^\dagger X/M^2)\,\Phi^\dagger\Phi$)**.** A scalar mass is non-holomorphic, so it descends from a full-superspace (D-term) integral rather than a chiral one. The leading gauge-invariant coupling of the spurion to a matter superfield Φ_i (with $\Phi^\dagger\Phi$ the Kähler term of Chapter 44) is the dimension-six operator

$$\mathcal{L} \supset \int \mathrm{d}^4\theta\, \frac{X^\dagger X}{M^2}\, \Phi_i^\dagger \Phi_i. \tag{45.166}$$

The full measure $\int \mathrm{d}^4\theta$ projects onto the $\theta^2\bar\theta^2$-component. The spurion factor contributes $X^\dagger X \supset (\theta^2 F_X)(\bar\theta^2 F_X^*) = |F_X|^2\,\theta^2\bar\theta^2$, while the matter factor $\Phi_i^\dagger\Phi_i$ contributes its lowest component $\phi_i^*\phi_i$ at order $\theta^0\bar\theta^0$. Multiplying and reading off the $\theta^2\bar\theta^2$ coefficient,

$$\int \mathrm{d}^4\theta\, \frac{X^\dagger X}{M^2}\,\Phi_i^\dagger\Phi_i \;\supset\; \frac{|F_X|^2}{M^2}\,\phi_i^*\phi_i, \tag{45.167}$$

a soft scalar mass-squared

$$(m^2)_{ii} = \frac{|F_X|^2}{M^2}. \tag{45.168}$$

This is a genuine breaking effect: the auxiliary components of X also generate F-dependent cross terms, but the term displayed is the one that survives as a physical scalar mass when X has no propagating dynamics. In the same way, $\int \mathrm{d}^2\theta\,(X/M)\,\Phi_i\Phi_j\Phi_k$ yields the A-term $a_{ijk} = y_{ijk}F_X/M$ by projecting the θ^2 of X onto the scalar components $\phi_i\phi_j\phi_k$, and $\int \mathrm{d}^2\theta\,(X/M)\,\Phi_i\Phi_j$ yields the B-term $b_{ij} = \mu_{ij}F_X/M$.

Two lessons are worth stating. First, every soft coupling comes out as a positive power of F_X/M — $M_a, a, \sim F_X/M$ and $m^2, b \sim |F_X|^2/M^2$ or F_X/M — so they all share one scale, $m_{\text{soft}} \sim F_X/M$, and all have positive mass dimension exactly as Theorem 45.24 requires. Second, the structure of the list is dictated by which superspace integral can carry the spurion: chiral ($\int \mathrm{d}^2\theta$) integrals give the holomorphic terms (M_a, a, b), the full-superspace ($\int \mathrm{d}^4\theta$) integral gives the non-holomorphic scalar mass. There is no fifth integral, and hence no fifth class of soft term.

45.5.6 Mediation: where F_X comes from

We have treated X and the scale M as given. Honesty requires saying, at the level of a scoped statement, where they originate; the detailed model-building is beyond the perturbative-and-symmetry remit of this chapter and is taken up in the literature cited below. Supersymmetry is broken dynamically in a *hidden sector* with no Standard-Model gauge charges, producing $\langle F_X\rangle \neq 0$ and, by Theorem 44.10, a positive vacuum energy and a massless Goldstino (the analogue for supersymmetry of the Goldstone boson, developed for the spontaneous-breaking mechanisms of this chapter). The breaking is then *communicated* to the visible sector by interactions of mass scale M:

- **Gravity mediation:** the mediator is gravity itself, $M = M_{\text{Pl}}$, so $m_{\text{soft}} \sim F_X/M_{\text{Pl}}$. A weak-scale $m_{\text{soft}} \sim$ TeV then requires $\sqrt{F_X} \sim 10^{11}$ GeV, an intermediate scale. The soft terms are generic and need not be flavor-blind, which is the origin of the supersymmetric flavor problem.

- **Gauge mediation:** the mediators are messenger fields charged under the Standard-Model gauge group, at a scale $M_{\rm mess} \ll M_{\rm Pl}$; the soft terms arise at one and two loops, $m_{\rm soft} \sim (g^2/16\pi^2)\, F_X/M_{\rm mess}$, and are automatically flavor-universal because they are controlled by gauge charges, ameliorating the flavor problem.

In both cases the output is a set of soft parameters of the form Eq. (45.162), with magnitudes set by F_X and M and textures set by the mediation mechanism. For the purposes of the next section we take these parameters as phenomenological inputs, constrained only to lie near the TeV scale — the value that, by Eq. (45.154), keeps the logarithmic correction to the Higgs mass at the electroweak scale and so preserves the naturalness that motivated the construction.

We now possess the complete template: a supersymmetric and gauge-invariant Lagrangian, broken by the four soft terms of Eq. (45.162), with quadratic divergences cancelled up to logarithms governed by the soft scale. The next section, Section 45.6, instantiates this template with the realistic field content of the Minimal Supersymmetric Standard Model — two Higgs doublets, the squarks and sleptons, the gauginos and Higgsinos — writing out the explicit soft parameters and reading off two of their flagship consequences, the tree-level bound on the lightest Higgs mass and the improvement of gauge-coupling unification.

45.6 The MSSM in Outline

The previous section classified the operators that break supersymmetry softly — gaugino masses, scalar mass-squareds, holomorphic A- and B-terms — and showed that, alone among the breaking terms one might write, they lift the superpartners without reopening the quadratic-divergence wound that supersymmetry was invoked to close (Section 45.5, Eq. (45.162)). That classification was abstract: a list of permissible spurion structures. We now spend it. The Minimal Supersymmetric Standard Model (MSSM) is the statement that the observed matter and forces are organized into the chiral and vector supermultiplets built in Chapter 44 and Section 45.1, that their interactions are governed by the most economical R-parity-conserving superpotential consistent with gauge invariance and holomorphy, and that supersymmetry is broken softly at a scale near a TeV. Everything in this section is an instance of machinery already assembled. The gauge sector is three commuting copies of the super Yang–Mills theory of Section 45.2 — the indirect closure of Yang–Mills theory promised in the chapter introduction: the gluon field strength $F^a_{\mu\nu}$ quantized in Chapter 26 now sits inside a real vector superfield, accompanied by a gluino. The matter sector is a collection of chiral superfields whose scalar potential is read off from the F- and D-terms of Section 45.3. And the two flagship numbers we extract — the

tree-level ceiling on the lightest Higgs mass, and the meeting of the three gauge couplings near $2 \times 10^{16}\,\mathrm{GeV}$ — both follow, without new input, from structures already in hand: the first from the D-term quartic whose coefficient is *fixed* by the gauge couplings, the second from the supersymmetric one-loop beta coefficient derived in Section 45.4.

We proceed in five movements. First, the field content and quantum numbers. Second, the superpotential, with the two arguments — anomaly freedom and holomorphy — that force *two* Higgs doublets where the Standard Model needs one, and the precise statement of the μ problem and the R-parity motivation. Third, the soft Lagrangian written out in full as the concrete realization of the previous section. Fourth, the tree-level Higgs potential, minimized to yield the bound $m_h \le m_Z\,|\cos 2\beta|$ and the one-loop lift that rescues it. Fifth, gauge-coupling unification as a worked numerical computation. We close with an honest, dated account of where experiment stands.

45.6.1 Supermultiplet content and quantum numbers

The gauge group is that of the Standard Model, $\mathrm{SU}(3)_c \times \mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$, with the covariant derivative $D_\mu = \partial_\mu - i g_s A_\mu^a T^a - i g\, W_\mu^i T^i - i g' Y B_\mu$ in the convention of Chapter 31 (electric charge $Q = T^3 + Y$, hypercharge Y as listed below). Supersymmetry requires that every Standard Model degree of freedom be promoted to a full supermultiplet of Section 44.4: a chiral superfield $\Phi = (\phi, \psi, F)$ for each Weyl fermion of the Standard Model, packaging that fermion with a complex scalar superpartner and an auxiliary F; a vector superfield $V = (A_\mu, \lambda, D)$ for each gauge boson, packaging it with a Majorana gaugino λ and an auxiliary D.

Chiral matter. The Standard Model fermions are chiral: left- and right-handed components transform differently under $\mathrm{SU}(3)_c \times \mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$. We write everything in terms of left-handed Weyl superfields, trading each right-handed field for the charge conjugate of a left-handed one (so a right-handed up quark becomes a left-handed antiquark superfield $\bar{u} \equiv U^c$ in the conjugate color representation). Per generation the chiral matter superfields and their quantum numbers under $(\mathrm{SU}(3)_c, \mathrm{SU}(2)_L)_Y$ are

$$\begin{aligned} Q &= (\mathbf{3}, \mathbf{2})_{+1/6}, \qquad \bar{u} = (\bar{\mathbf{3}}, \mathbf{1})_{-2/3}, \qquad \bar{d} = (\bar{\mathbf{3}}, \mathbf{1})_{+1/3}, \\ L &= (\mathbf{1}, \mathbf{2})_{-1/2}, \qquad \bar{e} = (\mathbf{1}, \mathbf{1})_{+1}. \end{aligned} \tag{45.169}$$

Here Q is the left-handed quark doublet, $\bar{u}, \bar{d}$ the (left-handed conjugates of the) right-handed up and down quarks, L the lepton doublet, and $\bar{e}$ the conjugate of the right-handed electron. There are three identical copies (generations), an index we suppress except where flavor matters. The scalar superpartners are the *squarks* and *sleptons*: $\tilde{Q}, \tilde{\bar{u}}, \tilde{\bar{d}}, \tilde{L}, \tilde{\bar{e}}$, complex scalars carrying exactly the gauge

charges of Eq. (45.169). Counting components per generation: Q contributes $3 \times 2 = 6$ chiral superfields, $\bar{u}, \bar{d}$ three each, L two, $\bar{e}$ one, for 15 chiral superfields — the 15 Weyl fermions of one Standard Model generation, now each shadowed by a complex scalar.

Two Higgs chiral superfields. The electroweak-symmetry-breaking sector requires *two* $\mathrm{SU}(2)_L$-doublet chiral superfields of opposite hypercharge,

$$H_u = (\mathbf{1}, \mathbf{2})_{+1/2} = \begin{pmatrix} H_u^+ \\ H_u^0 \end{pmatrix}, \qquad H_d = (\mathbf{1}, \mathbf{2})_{-1/2} = \begin{pmatrix} H_d^0 \\ H_d^- \end{pmatrix}. \tag{45.170}$$

Their fermionic partners are the *higgsinos* $\tilde{H}_u, \tilde{H}_d$, Weyl doublets. Why two doublets are mandatory — rather than the single doublet of the Standard Model, supplemented by its conjugate $\widetilde{H} = i\sigma^2 H^*$ for the up-type Yukawa — is argued in Section 45.6.2 below; it is one of the structural surprises the supersymmetrization forces.

Gauge multiplets. Each factor of $\mathrm{SU}(3)_c \times \mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$ contributes a vector superfield in the adjoint, built in Section 45.1:

$$\begin{aligned} &\mathrm{SU}(3)_c: && V_3 = (g_\mu^a,\ \tilde{g}^a,\ D^a), && a = 1, \dots, 8 && \text{(gluons, gluinos)}, \\ &\mathrm{SU}(2)_L: && V_2 = (W_\mu^i,\ \tilde{W}^i,\ D^i), && i = 1, 2, 3 && \text{(W bosons, winos)}, \\ &\mathrm{U}(1)_Y: && V_1 = (B_\mu,\ \tilde{B},\ D), && && \text{(hypercharge boson, bino)}. \end{aligned} \tag{45.171}$$

The gauginos $\tilde{g}, \tilde{W}, \tilde{B}$ are Majorana fermions in the adjoint. After electroweak symmetry breaking the neutral gauginos $\tilde{W}^3, \tilde{B}$ mix with the neutral higgsinos $\tilde{H}_u^0, \tilde{H}_d^0$ to form four *neutralinos*, and the charged ones mix into two *charginos*; the lightest neutralino is the prototypical dark-matter candidate, a point we return to under R-parity. The complete field content is collected in Table 45.1.

45.6.2 Why two Higgs doublets

The Standard Model uses a single Higgs doublet H of hypercharge $+1/2$. The down-type and charged-lepton Yukawa couplings use H; the up-type Yukawa uses its conjugate $\widetilde{H} = i\sigma^2 H^*$, which transforms as a $Y = -1/2$ doublet. One scalar doublet thus suffices to give mass to all fermions. Supersymmetry destroys this economy for two independent reasons, each fatal on its own.

Holomorphy. The superpotential W is a *holomorphic* function of the chiral superfields (Theorem 44.40): it may contain Φ but never $\Phi^\dagger$. The Standard Model trick of conjugating H to feed the up-type Yukawa is therefore unavailable — $\widetilde{H} \sim H^*$ is not a chiral superfield and cannot appear in W. A holomorphic Yukawa

Superfield	spin-0	spin-$\frac{1}{2}$	$(\mathrm{SU}(3)_c, \mathrm{SU}(2)_L)_Y$
Chiral (matter), ×3 generations			
Q	$\tilde{Q} = (\tilde{u}_L\ \tilde{d}_L)$	$(u_L\ d_L)$	$(\mathbf{3},\mathbf{2})_{+1/6}$

V_1	$\tilde{B}$	B	$(\mathbf{1},\mathbf{1})_0$

Table 45.1: The MSSM superfields and their gauge quantum numbers. Electric charge is $Q = T^3 + Y$. Matter comes in three generations; only one is shown.

coupling for the up quarks requires a genuine $Y = +1/2$ doublet superfield H_u, while the down quarks and leptons require a $Y = -1/2$ doublet H_d. Holomorphy alone forces the doubling.

Anomaly cancellation. Even setting Yukawas aside, gauge invariance at the quantum level forbids a lone Higgs supermultiplet. The higgsino is a chiral fermion, and chiral fermions contribute to gauge anomalies (Chapter 36). In the Standard Model the Higgs is a boson and contributes nothing; in the MSSM its fermionic partner does. The following worked example shows that a single $Y = +1/2$ higgsino doublet spoils anomaly cancellation, and that adding a $Y = -1/2$ partner restores it exactly.

Worked Example 45.28 (Anomaly cancellation demands a second higgsino)**.** A consistent gauge theory must have vanishing triangle anomalies for every combination of gauged currents, plus a vanishing mixed gauge–gravitational anomaly and (for SU(2)) a vanishing global Witten anomaly. For the new fermions — the higgsinos — the dangerous coefficients are the ones linear in the new content, since the Standard Model fermions already cancel among themselves (Chapter 36). We evaluate them for a single left-handed Weyl doublet $\tilde{H}$ of hypercharge Y.

The $[\mathrm{SU}(2)_L]^2\,\mathrm{U}(1)_Y$ *anomaly.* This is proportional to $T(\mathbf{2})\,Y$, where $T(\mathbf{2}) = \frac{1}{2}$ is the Dynkin index of the doublet (Section B.4). For $\tilde{H}_u$ with $Y = +\frac{1}{2}$ this is $\frac{1}{2}\cdot\frac{1}{2} = \frac{1}{4} \neq 0$. A single higgsino doublet is anomalous.

The $[\mathrm{U}(1)_Y]^3$ *anomaly.* This is proportional to $\sum Y^3$ over the two components of the doublet, $2\,Y^3 = 2(\frac{1}{2})^3 = \frac{1}{4} \neq 0$.

The mixed $\mathrm{U}(1)_Y$*–gravity anomaly.* Proportional to $\sum Y = 2Y = 1 \neq 0$.

Each is nonzero, so one higgsino doublet by itself renders the MSSM gauge anomalous — mathematically inconsistent. Now add a second doublet $\tilde{H}_d$ with $Y = -\frac{1}{2}$. The three coefficients become

$$[\mathrm{SU}(2)_L]^2\,\mathrm{U}(1)_Y: \quad T(\mathbf{2})(Y_{H_u} + Y_{H_d}) = \tfrac{1}{2}(\tfrac{1}{2} - \tfrac{1}{2}) = 0, \tag{45.172}$$

$$[\mathrm{U}(1)_Y]^3: \quad 2(Y_{H_u}^3 + Y_{H_d}^3) = 2(\tfrac{1}{8} - \tfrac{1}{8}) = 0, \tag{45.173}$$

$$\mathrm{U}(1)_Y\text{–grav}: \quad 2(Y_{H_u} + Y_{H_d}) = 0. \tag{45.174}$$

All vanish: the higgsino contributions cancel *between* the two doublets, precisely because their hypercharges are equal and opposite. Finally the global $\mathrm{SU}(2)_L$ anomaly (Chapter 36): an SU(2) gauge theory is consistent only with an *even* number of doublet Weyl fermions, since $\pi_4(\mathrm{SU}(2)) = \mathbb{Z}_2$. The Standard Model fermions of one generation supply an even number of doublets (Q counts as three by color, plus L, so four); a single higgsino doublet would make the count odd and trigger the Witten anomaly. The pair $\tilde{H}_u, \tilde{H}_d$ restores an even count. Two Higgs doublets are thus the minimal anomaly-free choice, and the hypercharges $\pm\frac{1}{2}$ are fixed.

45.6.3 The superpotential, the μ problem, and R-parity

With the field content fixed, the renormalizable superpotential is the most general holomorphic, gauge-invariant cubic in the chiral superfields. Gauge invariance permits a great many terms; the physically viable MSSM keeps only those consistent with the longevity of the proton, a restriction we encode below as R-parity. The R-parity-conserving superpotential is

$$\boxed{W_{\mathrm{MSSM}} = \bar{u}\,\mathbf{y}_u\,Q\,H_u - \bar{d}\,\mathbf{y}_d\,Q\,H_d - \bar{e}\,\mathbf{y}_e\,L\,H_d + \mu\,H_u H_d.} \tag{45.175}$$

Here $\mathbf{y}_{u,d,e}$ are 3×3 Yukawa matrices in generation space (suppressed indices contracted as $\bar{u}^{\,i}(\mathbf{y}_u)_{ij}Q^j$), and the $\mathrm{SU}(2)_L$ doublets are contracted antisymmetrically with the invariant tensor ϵ_{ab}, so that $H_u H_d \equiv \epsilon_{ab}H_u^a H_d^b = H_u^+ H_d^- - H_u^0 H_d^0$ and likewise $QH_u = \epsilon_{ab}Q^a H_u^b$. Color indices on $Q, \bar{u}, \bar{d}$ are contracted between Q (a $\mathbf{3}$) and $\bar{u}, \bar{d}$ (a $\bar{\mathbf{3}}$). The signs are conventional, chosen so that the fermion mass matrices come out with standard signs after electroweak breaking.

Reading off the component Lagrangian by the rule $W \to F$-terms of Eqs. (44.149) and (44.201): the cubic terms supply the Yukawa couplings of quarks and leptons to the Higgs scalars, and after the neutral Higgs scalars acquire vacuum

expectation values $\langle H_u^0 \rangle = v_u$, $\langle H_d^0 \rangle = v_d$ (Section 45.6.5), the fermion masses

$$m_u = \mathbf{y}_u\, v_u, \qquad m_d = \mathbf{y}_d\, v_d, \qquad m_e = \mathbf{y}_e\, v_d. \tag{45.176}$$

Up-type fermions get mass from v_u, down-type and leptons from v_d — the holomorphic split made physical. The quadratic term $\mu H_u H_d$ supplies a supersymmetric (Dirac) mass linking the two higgsino doublets and, through the F-terms, a contribution $|\mu|^2(|H_u|^2 + |H_d|^2)$ to the Higgs scalar potential.

The μ problem. The parameter μ in Eq. (45.175) is the single dimensionful coupling in the supersymmetric Lagrangian: it has dimension of mass. It is not protected by any symmetry that the rest of the superpotential respects — it is the coefficient of a gauge- and supersymmetry-invariant operator. A dimensionful supersymmetric parameter has no reason to be small: the only scales available to a fundamental theory above the MSSM are the cutoffs at which new physics enters, the GUT scale $M_U \sim 2 \times 10^{16}\,\text{GeV}$ or the Planck scale $M_{\text{Pl}} \sim 10^{18}\,\text{GeV}$. Naturally, then, one expects $\mu \sim M_U$ or M_{Pl}. But phenomenology demands the opposite. The neutral-Higgs minimization conditions Eq. (45.185) below relate μ to the soft masses and to m_Z: a successful electroweak vacuum requires $|\mu|^2$ to be of order the soft-breaking scale squared, $|\mu| \sim m_{\text{soft}} \sim$ TeV. The puzzle — the *μ problem* — is precisely this: *why should a parameter of the supersymmetric (unbroken) Lagrangian be tied to the scale of supersymmetry breaking, rather than to the cutoff?* The two scales have no a priori reason to coincide. This is a genuine naturalness question, not a phenomenological inconsistency. It admits proposed solutions — forbidding a bare μ by a symmetry and regenerating it from supersymmetry breaking (the Giudice–Masiero mechanism, in which a Kähler coupling to the breaking spurion produces $\mu \sim m_{\text{soft}}$), or promoting μ to the vacuum value of a new singlet superfield (the NMSSM) — but none is established. We state the problem precisely and claim no solution.

***R*-parity.** Gauge invariance and holomorphy permit, beyond Eq. (45.175), the additional renormalizable terms

$$W_{\Delta L=1} = \tfrac{1}{2}\lambda_{ijk} L_i L_j \bar{e}_k + \lambda'_{ijk} L_i Q_j \bar{d}_k + \mu'_i L_i H_u, \qquad W_{\Delta B=1} = \tfrac{1}{2}\lambda''_{ijk} \bar{u}_i \bar{d}_j \bar{d}_k. \tag{45.177}$$

The first group violates lepton number L, the second violates baryon number B. Each is gauge-invariant; nothing in the structure built so far forbids them. But together they are catastrophic. A squark exchanged between a λ' vertex and a λ'' vertex mediates proton decay, $p \to e^+\pi^0$ or $p \to \bar{\nu}\,\pi^+$, at tree level. The proton lifetime exceeds $\sim 10^{34}$ years (Super-Kamiokande, 2020s), which forces the product $\lambda'\lambda''$ to be smaller than roughly 10^{-24} for TeV-scale squarks — an absurd fine-tuning if these couplings are free. The standard resolution is to impose a discrete symmetry, *matter parity* or equivalently R-parity, defined by

$$R_p = (-1)^{3(B-L)+2s}, \tag{45.178}$$

where s is the spin. Every Standard Model particle (and both Higgs doublets) has $R_p = +1$; every superpartner has $R_p = -1$. The terms in Eq. (45.177) all carry $R_p = -1$ and are forbidden, while every term in Eq. (45.175) carries $R_p = +1$ and survives. With R_p conserved the proton is stable against these operators. Two phenomenological consequences follow immediately and are the headline features of the R-parity-conserving MSSM: superpartners are produced in pairs, and the *lightest supersymmetric particle (LSP) is absolutely stable*. A neutral, weakly interacting LSP — typically the lightest neutralino — is then a thermal-relic dark-matter candidate. We flag the honest caveat: R-parity is *imposed*, not derived. It is well motivated — it can descend from a gauged $\mathrm{U}(1)_{B-L}$ broken by two units — and is economical, but it is a choice. Alternatives (baryon triality, which forbids $W_{\Delta B=1}$ but allows $W_{\Delta L=1}$) are logically available; we adopt R-parity as the minimal proton-stable option and say so.

45.6.4 The soft-breaking Lagrangian

Supersymmetry, if realized, is broken: no scalar electron of mass 0.511 MeV has been seen. The breaking is communicated to the MSSM fields as the soft operators classified in Section 45.5. Instantiating that classification Eq. (45.162) for the MSSM field content gives the complete soft Lagrangian

$$\begin{aligned} -\mathcal{L}_{\text{soft}} = {} & \tfrac{1}{2}\Big(M_3\,\tilde{g}\tilde{g} + M_2\,\tilde{W}\tilde{W} + M_1\,\tilde{B}\tilde{B} + \text{h.c.}\Big) \\ & + \Big(\tilde{\bar{u}}\,\mathbf{a}_u\,\tilde{Q}\,H_u - \tilde{\bar{d}}\,\mathbf{a}_d\,\tilde{Q}\,H_d - \tilde{\bar{e}}\,\mathbf{a}_e\,\tilde{L}\,H_d + \text{h.c.}\Big) \\ & + \tilde{Q}^\dagger\,\mathbf{m}_Q^2\,\tilde{Q} + \tilde{L}^\dagger\,\mathbf{m}_L^2\,\tilde{L} + \tilde{\bar{u}}\,\mathbf{m}_{\bar{u}}^2\,\tilde{\bar{u}}^\dagger + \tilde{\bar{d}}\,\mathbf{m}_{\bar{d}}^2\,\tilde{\bar{d}}^\dagger + \tilde{\bar{e}}\,\mathbf{m}_{\bar{e}}^2\,\tilde{\bar{e}}^\dagger \\ & + m_{H_u}^2|H_u|^2 + m_{H_d}^2|H_d|^2 + (b\,H_uH_d + \text{h.c.}). \end{aligned} \tag{45.179}$$

Each line is one species from the Girardello–Grisaru list, dressed in MSSM quantum numbers:

- *Gaugino masses* M_1, M_2, M_3 for bino, wino, gluino — one complex parameter per gauge factor (the partner of the gauge coupling under the spurion analysis of Section 45.5).
- *Trilinear A-terms* $\mathbf{a}_u, \mathbf{a}_d, \mathbf{a}_e$, each a 3×3 matrix in generation space, scalar analogues of the Yukawa couplings (often written $\mathbf{a} = \mathbf{y}\,A$ with A a mass).
- *Soft scalar mass-squareds* $\mathbf{m}^2_{Q,\bar{u},\bar{d},L,\bar{e}}$, Hermitian 3×3 matrices for the squarks and sleptons, plus the Higgs soft masses $m^2_{H_u}, m^2_{H_d}$.
- The *B-term* b (often $b = B\mu$), the holomorphic Higgs mass-squared.

This is the source of all superpartner masses. It also carries the price of phenomenological generality: the matrices $\mathbf{m}^2$ and $\mathbf{a}$ contain, in full generality, of

order a hundred new parameters, many of them flavor- and CP-violating. The absence of observed flavor violation (small K–$\bar{K}$ mixing, the bound on $\mu \to e\gamma$) is the *supersymmetric flavor problem*: it forces these matrices to be nearly flavor-diagonal and universal, a structure that mediation schemes (gauge mediation, anomaly mediation, gravity mediation with universality) are designed to deliver. We note this as a constraint on the soft sector, not a defect of the framework. With Eq. (45.179) the MSSM Lagrangian is complete: supersymmetric gauge and superpotential pieces plus soft breaking. Everything that follows is its consequence.

45.6.5 The Higgs sector and the tree-level mass bound

The single most consequential prediction of the MSSM is a tree-level *upper* bound on the mass of the lightest neutral Higgs boson. It arises because supersymmetry does not allow an arbitrary Higgs self-coupling: the Higgs quartic is not a free parameter as in the Standard Model but is *fixed by the gauge couplings*, being nothing but the D-term potential of Section 45.3. We now derive the bound in full.

The neutral Higgs potential. The scalar potential for the Higgs fields receives three contributions: F-terms from the μ term in Eq. (45.175), D-terms from $\mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$ via Section 45.3, and soft terms from Eq. (45.179). The F-term is $\sum_i |\partial W/\partial\phi_i|^2 \supset |\mu|^2(|H_u|^2 + |H_d|^2)$. The gauge D-term potential is $V_D = \tfrac{1}{2}\sum_a (D^a)^2$ with $D^a = -g\sum_i \phi_i^\dagger T^a \phi_i$ for each gauge factor (Eq. (45.84)). For the two Higgs doublets, using the SU(2) Fierz identity $\sum_i (\sigma^i)_{ab}(\sigma^i)_{cd} = 2\delta_{ad}\delta_{cb} - \delta_{ab}\delta_{cd}$, the $\mathrm{SU}(2)_L$ and $\mathrm{U}(1)_Y$ D-terms combine into

$$V_D = \frac{g^2 + g'^2}{8}\Big(|H_u|^2 - |H_d|^2\Big)^2 + \frac{g^2}{2}\big|H_u^\dagger H_d\big|^2 . \tag{45.180}$$

The coefficient $(g^2 + g'^2)/8$ is fixed entirely by the gauge couplings — this is the crucial point. Assembling F-, D-, and soft terms, and restricting to the neutral components (the charged directions are lifted and do not acquire vevs in the viable vacuum), the neutral Higgs potential is

$$V = (|\mu|^2 + m_{H_u}^2)|H_u^0|^2 + (|\mu|^2 + m_{H_d}^2)|H_d^0|^2 - (b\, H_u^0 H_d^0 + \text{h.c.}) + \frac{g^2 + g'^2}{8}\Big(|H_u^0|^2 - |H_d^0|^2\Big)^2 . \tag{45.181}$$

Write $m_1^2 \equiv |\mu|^2 + m_{H_d}^2$, $m_2^2 \equiv |\mu|^2 + m_{H_u}^2$, and take b real and positive (its phase can be rotated away). The vacuum is at real $\langle H_u^0\rangle = v_u$, $\langle H_d^0\rangle = v_d$, both positive; define

$$v^2 \equiv v_u^2 + v_d^2, \qquad \tan\beta \equiv \frac{v_u}{v_d}, \qquad v_u = v\sin\beta,\ v_d = v\cos\beta, \tag{45.182}$$

with $v \approx 174\,\mathrm{GeV}$ fixed by the gauge-boson masses, $m_Z^2 = \tfrac{1}{2}(g^2 + g'^2)v^2$ and $m_W^2 = \tfrac{1}{2}g^2 v^2$ (Section 31.3).

Minimization. Stationarity $\partial V/\partial H_u^0 = \partial V/\partial H_d^0 = 0$ at the vacuum, with $c \equiv (g^2+g'^2)/8$ and $Q \equiv v_u^2 - v_d^2$, gives

$$m_2^2\, v_u - b\, v_d + 4c\, Q\, v_u = 0, \tag{45.183}$$

$$m_1^2\, v_d - b\, v_u - 4c\, Q\, v_d = 0. \tag{45.184}$$

Using $4cQ = \tfrac{1}{2}(g^2+g'^2)\,\tfrac{1}{2}(v_u^2-v_d^2)/v^2 \cdot v^2 \cdot \tfrac{1}{v^2}\cdots$ — more cleanly, $2c\,v^2 = \tfrac{1}{4}(g^2+g'^2)v^2 = \tfrac{1}{2}m_Z^2$, so $4cQ = (m_Z^2/v^2)(v_u^2-v_d^2) = -m_Z^2\cos 2\beta$. Dividing Eq. (45.183) by v_u and Eq. (45.184) by v_d and substituting yields the electroweak-symmetry-breaking conditions

$$\boxed{m_{H_u}^2 + |\mu|^2 = b\cot\beta + \tfrac{1}{2}m_Z^2\cos 2\beta, \qquad m_{H_d}^2 + |\mu|^2 = b\tan\beta - \tfrac{1}{2}m_Z^2\cos 2\beta.} \tag{45.185}$$

These three equations (the two above plus the definition of v) trade the three Lagrangian parameters $b, |\mu|^2$, and one combination of soft masses for the observables $m_Z, \tan\beta$ — and they are the equations through which $|\mu|$ becomes locked to the soft scale, the technical face of the μ problem. Subtracting the two conditions in Eq. (45.185) isolates

$$\tfrac{1}{2}m_Z^2 = \frac{m_{H_d}^2 - m_{H_u}^2\tan^2\beta}{\tan^2\beta - 1} - |\mu|^2, \tag{45.186}$$

the relation that makes plain that obtaining the measured m_Z requires $|\mu|^2$ to sit at the soft scale.

The mass matrices. Expand the neutral fields about the vacuum, $H_u^0 = v_u + \tfrac{1}{\sqrt{2}}(h_u + i a_u)$, $H_d^0 = v_d + \tfrac{1}{\sqrt{2}}(h_d + i a_d)$. The mass matrices are second derivatives of Eq. (45.181), evaluated at the minimum with Eq. (45.185) substituted. The full computation is carried in Theorem 45.29; the results are as follows. The imaginary parts (a_d, a_u) furnish one massless Goldstone (eaten by the Z) and one physical CP-odd scalar A^0 with

$$m_A^2 = \frac{2b}{\sin 2\beta} = b(\tan\beta + \cot\beta). \tag{45.187}$$

The CP-even sector (h_d, h_u) has the symmetric mass-squared matrix

$$\mathcal{M}^2 = \begin{pmatrix} m_A^2\sin^2\beta + m_Z^2\cos^2\beta & -(m_A^2+m_Z^2)\sin\beta\cos\beta \\ -(m_A^2+m_Z^2)\sin\beta\cos\beta & m_A^2\cos^2\beta + m_Z^2\sin^2\beta \end{pmatrix}. \tag{45.188}$$

Its two eigenvalues are the masses of the light and heavy CP-even Higgs bosons h^0, H^0. The light one m_h^2 is the smaller eigenvalue.

The bound. The smallest eigenvalue $\lambda_{\min}$ of a symmetric matrix satisfies the variational bound $\lambda_{\min} \le u^{\mathsf T}\mathcal{M}^2 u$ for *any* unit vector u. Choosing $u = (\cos\beta, \sin\beta)$ and computing the quadratic form,

$$\begin{aligned} u^{\mathsf T}\mathcal{M}^2 u &= (m_A^2 \sin^2\beta + m_Z^2\cos^2\beta)\cos^2\beta - 2(m_A^2+m_Z^2)\sin\beta\cos\beta\cdot\cos\beta\sin\beta \\ &\quad + (m_A^2\cos^2\beta + m_Z^2\sin^2\beta)\sin^2\beta \\ &= m_A^2(\sin^2\beta\cos^2\beta - 2\sin^2\beta\cos^2\beta + \cos^2\beta\sin^2\beta) \\ &\quad + m_Z^2(\cos^4\beta - 2\sin^2\beta\cos^2\beta + \sin^4\beta) \\ &= 0 + m_Z^2(\cos^2\beta - \sin^2\beta)^2 = m_Z^2\cos^2 2\beta. \end{aligned} \tag{45.189}$$

The m_A^2 terms cancel identically, and the m_Z^2 terms collapse to a perfect square. Therefore

$$\boxed{\; m_h^2 \;\le\; m_Z^2\cos^2 2\beta \;\le\; m_Z^2. \;} \tag{45.190}$$

At tree level the lightest MSSM Higgs cannot be heavier than the Z. The bound is saturated as $m_A \to \infty$ (the decoupling limit), where h^0 becomes Standard-Model-like with quartic coupling $\lambda = \tfrac{1}{8}(g^2+g'^2)\cos^2 2\beta$, and is tightest at $\tan\beta = 1$ ($\cos 2\beta = 0$), where the tree-level m_h vanishes. The physical origin is exactly the gauge-fixed coefficient in Eq. (45.180): supersymmetry relates the Higgs quartic to the gauge couplings, and the gauge couplings are small, so the Higgs is light.

Worked Example 45.29 (The neutral Higgs mass matrices from Eq. (45.181))**.** We derive Eqs. (45.187) and (45.188). Treat the neutral fields as real for the CP-even sector and as imaginary for the CP-odd sector; the kinetic term $|\partial H^0|^2$ means a complex field $H^0 = v + \frac{1}{\sqrt2}(h + ia)$ has canonically normalized real components, so the physical mass-squared is $\frac12$ times the Hessian of V in the unnormalized variable. Writing V as a function of real shifts x_d, x_u about (v_d, v_u) and $c = (g^2+g'^2)/8$, $Q = v_u^2 - v_d^2$:

CP-even Hessian. From Eq. (45.181),

$$\begin{aligned} \frac{\partial^2 V}{\partial x_d^2} &= 2m_1^2 + 4c(3v_d^2 - v_u^2), \quad \frac{\partial^2 V}{\partial x_u^2} = 2m_2^2 + 4c(3v_u^2 - v_d^2), \\ \frac{\partial^2 V}{\partial x_u \partial x_d} &= -2b - 8c\,v_u v_d. \end{aligned} \tag{45.191}$$

Taking half of these for the physical matrix, eliminating m_1^2, m_2^2 through Eqs. (45.183) and (45.184) (equivalently Eq. (45.185)), and using $b = m_A^2\sin\beta\cos\beta$ from Eq. (45.187) together with $2c\,v_d^2 = \frac12 m_Z^2\cos^2\beta$, $2c\,v_u^2 = \frac12 m_Z^2\sin^2\beta$, $4c\,v_u v_d = \frac12 m_Z^2\sin 2\beta$, the (d,d) entry becomes

$$\mathcal{M}^2_{dd} = m_1^2 + 2c(3v_d^2 - v_u^2) = b\tan\beta + m_Z^2\cos^2\beta = m_A^2\sin^2\beta + m_Z^2\cos^2\beta, \tag{45.192}$$

and likewise $\mathcal{M}^2_{uu} = m_A^2\cos^2\beta + m_Z^2\sin^2\beta$, $\mathcal{M}^2_{du} = -b - 4c\,v_u v_d = -(m_A^2 + m_Z^2)\sin\beta\cos\beta$. This is Eq. (45.188).

CP-odd Hessian. The imaginary parts enter V only through $m_{1,2}^2|H^0|^2$, the quartic, and the b-term, which contributes $+2b\,y_u y_d$. The physical matrix is

$$\mathcal{M}^2_{\text{odd}} = \tfrac{1}{2}\begin{pmatrix} 2m_1^2 - 4cQ & 2b \\ 2b & 2m_2^2 + 4cQ \end{pmatrix} = \begin{pmatrix} b\tan\beta & b \\ b & b\cot\beta \end{pmatrix}, \tag{45.193}$$

where the diagonal entries simplified using Eq. (45.185) and $4cQ = -m_Z^2\cos 2\beta$. Its determinant is $b^2(\tan\beta\cot\beta - 1) = 0$ — the massless Goldstone — and its trace is $b(\tan\beta + \cot\beta) = 2b/\sin 2\beta$, the nonzero eigenvalue m_A^2 of Eq. (45.187). The trace of Eq. (45.188) is $m_A^2 + m_Z^2$ and its determinant is $m_A^2 m_Z^2\cos^2 2\beta$, so the two CP-even eigenvalues are

$$m^2_{h,H} = \tfrac{1}{2}\Big[m_A^2 + m_Z^2 \mp \sqrt{(m_A^2 + m_Z^2)^2 - 4m_A^2 m_Z^2\cos^2 2\beta}\Big], \tag{45.194}$$

confirming $m_h \le m_Z|\cos 2\beta|$ directly (the radical is real and the lower sign gives $m_h^2 \le m_Z^2\cos^2 2\beta$ on inspection at $m_A \to \infty$).

The radiative lift. The tree bound Eq. (45.190) is in flat contradiction with experiment: the observed Higgs boson has mass $m_h = 125.25 \pm 0.17\,\text{GeV}$ (Particle Data Group average, mid-2020s), well above $m_Z = 91.19\,\text{GeV}$. The MSSM survives only because the bound receives large radiative corrections, dominated by the top quark and its scalar partners (the stops $\tilde{t}_{1,2}$). The top Yukawa $y_t \approx 1$ is the largest coupling in the theory; the cancellation between top and stop loops that protects the Higgs mass is incomplete once supersymmetry is broken (the stops are heavier than the top), and the residual generates a positive contribution to the Higgs quartic. The leading one-loop result is

$$m_h^2 \le m_Z^2\cos^2 2\beta + \frac{3\,m_t^4}{4\pi^2 v^2}\left[\ln\frac{M_S^2}{m_t^2} + \frac{X_t^2}{M_S^2}\Big(1 - \frac{X_t^2}{12M_S^2}\Big)\right], \tag{45.195}$$

where $M_S^2 = m_{\tilde{t}_1}m_{\tilde{t}_2}$ is the stop mass scale, $X_t = A_t - \mu\cot\beta$ the stop mixing, and m_t the running top mass. The logarithm grows the bound; the mixing term is maximized at $X_t = \sqrt{6}\,M_S$ ("maximal mixing"), where the lift is largest. Quantitatively, reaching $m_h = 125\,\text{GeV}$ requires either stops in the multi-TeV range (large logarithm) or near-maximal mixing with TeV stops. This is the central tension of the MSSM after the LHC: the same loops that lift m_h to its observed value reintroduce a residual fine-tuning of the electroweak scale (the "little hierarchy problem"), since heavy stops feed back into $m_{H_u}^2$ through the renormalization group. The MSSM accommodates the 125 GeV Higgs — it does not predict it sharply — and does so at the cost of heavy scalars. We state this plainly: the discovery of a 125 GeV Higgs is consistent with the MSSM but pushes its natural region.

45.6.6 Gauge-coupling unification

The second flagship result needs no Higgs sector at all: it is a statement about the running of the three gauge couplings, and it is where the supersymmetric beta function of Section 45.4 pays off. We continue Yang–Mills theory: the MSSM gauge sector is three copies of super Yang–Mills, and the one-loop running uses exactly the supersymmetric coefficient derived there.

The supersymmetric one-loop coefficient. For an $\mathcal{N} = 1$ gauge theory with gauge group G and chiral superfields in representations r_i, the one-loop beta function established in Section 45.4 is, in the convention $\mu\, dg/d\mu = b\, g^3/16\pi^2$,

$$b = -3\, C_2(G) + \sum_i T(r_i), \tag{45.196}$$

where $C_2(G)$ is the adjoint Casimir and $T(r)$ the Dynkin index (Section B.4). The $-3C_2(G)$ is the gauge contribution (gauge boson plus gaugino plus ghost), and $+\sum T(r_i)$ the chiral-matter contribution; each chiral superfield contributes with a coefficient *half* that of a Dirac fermion plus its scalar, reflecting the multiplet content. In terms of the inverse fine-structure couplings $\alpha_i^{-1} = 4\pi/g_i^2$, integrating Eq. (45.196) gives the one-loop running of Eq. (24.240) in the form

$$\alpha_i^{-1}(\mu) = \alpha_i^{-1}(M_Z) - \frac{b_i}{2\pi}\, \ln \frac{\mu}{M_Z}. \tag{45.197}$$

A straight line in $\ln \mu$, with slope set by b_i. Three lines with three different slopes generically meet pairwise at three different points; whether they meet at a *single* point is a nontrivial question fixed entirely by the three b_i and the three measured boundary values.

Computing (b_1, b_2, b_3) for the MSSM. We must count $C_2(G)$ and $\sum T(r_i)$ for each factor of $\mathrm{SU}(3)_c \times \mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$. For $\mathrm{SU}(N)$, $C_2(\mathrm{adj}) = N$ and $T(\mathrm{fund}) = \frac{1}{2}$; for $\mathrm{U}(1)_Y$, $C_2 = 0$ and the "index" of a state is $\frac{3}{5}Y^2$ in the GUT normalization explained below. The chiral superfields are three generations of $Q, \bar{u}, \bar{d}, L, \bar{e}$ plus the two Higgs doublets H_u, H_d; the vector superfields supply the $-3C_2(G)$.

Worked Example 45.30 (The MSSM beta coefficients)**.** $\mathrm{SU}(3)_c$. Gauge: $-3C_2 = -3 \cdot 3 = -9$. Matter, per generation: the quark doublet $Q = (\mathbf{3}, \mathbf{2})$ counts as two color triplets, $T_3(Q) = 2 \cdot \frac{1}{2} = 1$; $\bar{u}, \bar{d}$ each a single $\bar{\mathbf{3}}$, $T_3 = \frac{1}{2}$ each. Sum per generation $1 + \frac{1}{2} + \frac{1}{2} = 2$; three generations give 6. Higgs are colorless. Hence

$$b_3 = -9 + 6 = -3. \tag{45.198}$$

$\mathrm{SU}(2)_L$. Gauge: $-3 \cdot 2 = -6$. Matter, per generation: $Q = (\mathbf{3}, \mathbf{2})$ is a doublet with color multiplicity 3, $T_2(Q) = 3 \cdot \frac{1}{2} = \frac{3}{2}$; $L = (\mathbf{1}, \mathbf{2})$, $T_2 = \frac{1}{2}$. Sum $\frac{3}{2} + \frac{1}{2} = 2$

per generation, 6 for three. Higgs: each doublet contributes $T_2 = \frac{1}{2}$, so $H_u + H_d$ give 1. Hence

$$b_2 = -6 + 6 + 1 = 1. \tag{45.199}$$

$\mathrm{U}(1)_Y$. Gauge: 0. The contribution of a chiral superfield is $\frac{3}{5}\sum Y^2$ summed over all its components, the $\frac{3}{5}$ being the GUT normalization. Per generation, summing Y^2 over multiplicities (color $\times$ weak):

$$\underbrace{6\left(\tfrac{1}{6}\right)^2}_{Q} + \underbrace{3\left(\tfrac{2}{3}\right)^2}_{\bar{u}} + \underbrace{3\left(\tfrac{1}{3}\right)^2}_{\bar{d}} + \underbrace{2\left(\tfrac{1}{2}\right)^2}_{L} + \underbrace{1\cdot 1^2}_{\bar{e}} = \tfrac{1}{6} + \tfrac{4}{3} + \tfrac{1}{3} + \tfrac{1}{2} + 1 = \tfrac{10}{3}. \tag{45.200}$$

Three generations give 10; the Higgs add $2(\frac{1}{2})^2 + 2(\frac{1}{2})^2 = 1$. Total $\sum Y^2 = 11$, so

$$b_1 = \tfrac{3}{5}\cdot 11 = \tfrac{33}{5}. \tag{45.201}$$

Collecting,

$$\boxed{(b_1, b_2, b_3)_{\mathrm{MSSM}} = \left(\tfrac{33}{5},\ 1,\ -3\right).} \tag{45.202}$$

For comparison, the same counting for the non-supersymmetric Standard Model (gauge contribution $-\frac{11}{3}C_2$, chiral fermion $+\frac{2}{3}T$, complex scalar $+\frac{1}{3}T$) gives $(b_1, b_2, b_3)_{\mathrm{SM}} = (\frac{41}{10}, -\frac{19}{6}, -7)$. The two sets differ because the superpartners — gauginos shift the gauge piece, sfermions and higgsinos the matter piece — change every slope. Note $b_3 = -3 < 0$: $\mathrm{SU}(3)_c$ remains asymptotically free, but less so than the Standard Model's -7, because the gluino and squarks add positively to the matter side.

The GUT normalization. The hypercharge coupling g' as defined in the Standard Model is not directly comparable to g, g_s, because $\mathrm{U}(1)_Y$ has no intrinsic normalization — one may rescale Y and g' together. To compare with the non-abelian couplings one normalizes $\mathrm{U}(1)_Y$ as it would sit inside a simple unifying group such as SU(5) (Section 35.5.2), where all generators share a common trace normalization $\mathrm{Tr}(T^a T^b) = \frac{1}{2}\delta^{ab}$. Requiring the hypercharge generator to be normalized like the others over a complete generation fixes the rescaling: one defines $g_1^2 = \frac{5}{3}g'^2$, equivalently $\alpha_1 = \frac{5}{3}\alpha_Y$ with $\alpha_Y = \alpha_{\mathrm{em}}/\cos^2\theta_W$. The factor $\frac{5}{3}$ is exactly the reciprocal of the $\frac{3}{5}$ that appears in b_1; the two conspire so that $b_1\alpha_1$ is normalization-independent. With this convention the three couplings are on the same footing and the question "do they meet?" is well posed.

The numerical run. We take the boundary data at $M_Z = 91.1876\,\mathrm{GeV}$ (Particle Data Group, mid-2020s):

$$\alpha_{\mathrm{em}}^{-1}(M_Z) = 127.95, \qquad \sin^2\theta_W = 0.2312, \qquad \alpha_s(M_Z) = 0.1179, \tag{45.203}$$

from which

$$\begin{aligned}\alpha_1^{-1}(M_Z) &= \tfrac{3}{5}\cos^2\theta_W\,\alpha_{\rm em}^{-1} = \tfrac{3}{5}(0.7688)(127.95) = 59.0,\\ \alpha_2^{-1}(M_Z) &= \sin^2\theta_W\,\alpha_{\rm em}^{-1} = (0.2312)(127.95) = 29.6,\\ \alpha_3^{-1}(M_Z) &= 1/\alpha_s = 8.5.\end{aligned} \tag{45.204}$$

Run with Eq. (45.197) and the MSSM coefficients Eq. (45.202). Ask first where α_1 and α_2 meet. Setting $\alpha_1^{-1} = \alpha_2^{-1}$ and writing $L = \ln(\mu/M_Z)$,

$$59.0 - \frac{33/5}{2\pi}L = 29.6 - \frac{1}{2\pi}L \implies 29.4 = \frac{33/5-1}{2\pi}L = \frac{28/5}{2\pi}L = 0.8913\,L, \tag{45.205}$$

so $L = 33.0$, i.e. $\mu = M_Z\,e^{33.0} \approx 2.0\times10^{16}$ GeV. At this scale,

$$\alpha_2^{-1}(M_U) = 29.6 - \frac{1}{2\pi}(33.0) = 24.3, \qquad \alpha_3^{-1}(M_U) = 8.5 + \frac{3}{2\pi}(33.0) = 24.2. \tag{45.206}$$

The third coupling arrives at 24.2 where the first two meet at 24.3: the three inverse couplings coincide to better than half a percent at

$$\boxed{M_U \simeq 2\times10^{16}\,\text{GeV}, \qquad \alpha_U^{-1} \simeq 24.3\ (\alpha_U \simeq 1/24).} \tag{45.207}$$

This is the celebrated MSSM gauge-coupling unification. Repeating the exercise with the Standard Model coefficients $(b_1, b_2, b_3)_{\rm SM}$ from Theorem 45.30, the three lines miss: α_1 and α_2 cross near 10^{13} GeV, but α_3 passes well below, and there is no common point — the SM couplings fail to unify by many standard deviations. Figure 45.6 plots both cases side by side. The contrast is the empirical content of the result: *adding exactly the MSSM superpartner spectrum, with no further adjustment, turns a three-way near-miss into a meeting.* The unification scale $M_U \sim 2\times10^{16}$ GeV sits comfortably below the Planck scale and just below where dimension-six proton decay from heavy gauge bosons would become dangerous — consistent with the GUT picture of Section 35.5.

Why supersymmetry helps unification

The mechanism is transparent in Theorem 45.30. Unification is the statement that three slopes and three intercepts conspire to a single crossing. The Standard Model slopes nearly do it but not quite; the gap is of order the two-loop corrections, too large to bridge. Supersymmetry shifts every slope in a correlated way: the gauginos make the gauge contribution less negative (from $-\frac{11}{3}C_2$ to $-3C_2$), and the sfermions and higgsinos enlarge the matter contribution. The net effect on the *differences* $b_i - b_j$ — which control where the lines cross — is just right. That a spectrum motivated entirely by the hierarchy problem (Section 35.3) should also repair unification is the strongest indirect circumstantial argument for low-

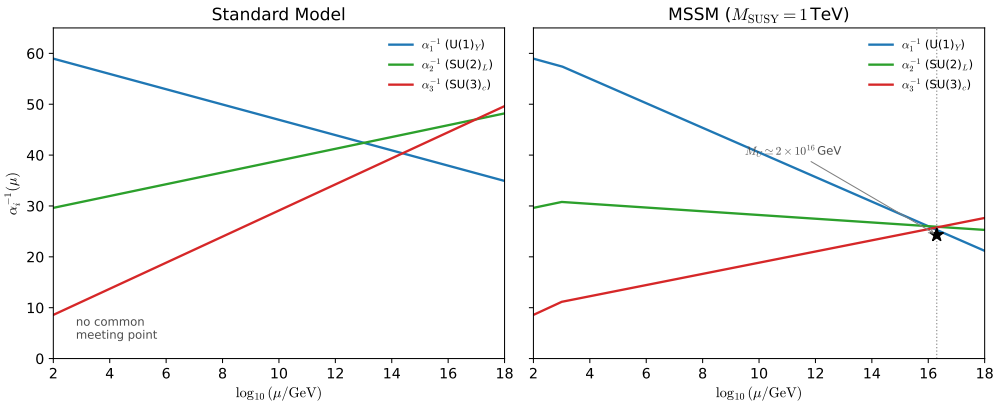

Figure 45.6: One-loop running of the inverse gauge couplings $\alpha_i^{-1}(\mu)$ in GUT normalization, from Eq. (45.197) with the boundary data Eq. (45.204). *Left:* the Standard Model coefficients $(\frac{41}{10}, -\frac{19}{6}, -7)$ — the three lines do not meet at a common point. *Right:* the MSSM coefficients $(\frac{33}{5}, 1, -3)$ of Eq. (45.202), with superpartners switched on at $M_{\rm SUSY} = 1\,\mathrm{TeV}$ — the three lines converge near $M_U \simeq 2\times10^{16}\,\mathrm{GeV}$ at $\alpha_U^{-1} \simeq 24$ (star). Both panels are reproducible from the numbers in the text.

energy supersymmetry. It is circumstantial: it is a successful postdiction of two slopes from one assumption, not a measurement of superpartners.

45.6.7 Experimental status, dated

Honesty about the frontier is mandatory. As of the mid-2020s the experimental situation is the following. *No superpartner has been observed.* The LHC has excluded gluinos and first-/second-generation squarks below roughly 2–2.3 TeV, stops below $\sim 1.2\,\mathrm{TeV}$, and electroweakinos (charginos, neutralinos) below a few hundred GeV in many scenarios, with the precise bounds depending on the assumed spectrum and decay chains. The single Higgs boson found in 2012 has mass 125 GeV and couplings consistent, within current precision, with the Standard Model — which in MSSM language means the decoupling limit $m_A \gg m_Z$, where h^0 is Standard-Model-like. The required Higgs mass forces, through Eq. (45.195), stops in the multi-TeV range or large mixing. The combination — a 125 GeV Higgs and TeV-scale exclusion limits — has pushed the natural region of the MSSM into mild tension (the "little hierarchy problem"): the model works, but the cancellation it was built to explain now requires a per-cent-level tuning of the electroweak scale against the soft masses. Gauge-coupling unification Eq. (45.207) remains a quantitative success at the one- and two-loop level, robust to the precise superpartner spectrum within an order of magnitude.

The verdict, stated without spin: the MSSM is not excluded; it is constrained, and the parameter space favored by naturalness is shrinking. Whether nature is supersymmetric near the TeV scale is, as of this writing, an open experimental question.

This completes the chapter's arc. We began with the abelian gauge multiplet, built super Yang–Mills and SQCD, proved the nonrenormalization theorems that make these theories UV-special, broke supersymmetry softly, and have now assembled the MSSM as the concrete payoff — with two numbers, $m_h \leq m_Z|\cos 2\beta|$ and the meeting of the couplings at $2 \times 10^{16}\,\mathrm{GeV}$, that follow from the structure alone. What we have used throughout is perturbation theory and symmetry. The exact, nonperturbative content of supersymmetric gauge theory — the holomorphic structure of the moduli space, Seiberg duality, gaugino condensation, the Seiberg–Witten solution — is the subject of Chapter 46, which takes the classical moduli spaces and holomorphy built here as its starting data; and the broader question of physics beyond the Standard Model, of which the MSSM is one well-developed answer, returns in the GUT and hierarchy discussions of Chapter 35.

Further reading

The component construction of supersymmetric gauge theory in superspace — the vector superfield, W_α, and the chiral integral $\int d^2\theta\, W^\alpha W_\alpha$ — is developed at book length in Wess and Bagger [505], the canonical reference whose conventions are close to ours, and pedagogically in Terning [472], which is also the natural companion for the holomorphy and duality material that Chapter 46 takes up. The nonrenormalization theorems in the modern holomorphy/spurion language follow Seiberg [434] and the lectures by Intriligator and Seiberg [275]; the exact gauge coupling is the NSVZ result of Novikov et al. [370], whose instanton-based derivation complements the Konishi-anomaly argument given here. Dynamical supersymmetry breaking and its phenomenology trace to Affleck et al. [7]. For soft breaking, the classification of allowed operators is Girardello and Grisaru [222]; the MSSM, its soft Lagrangian, the Higgs-mass bound, and the gauge-coupling unification that sharpens the unified-theory hierarchy of Georgi et al. [219] are covered comprehensively in the widely used primer by Martin [339] and, in the original softly-broken-$SU(5)$ setting, in Dimopoulos and Georgi [148]. The standard texts Peskin and Schroeder [396], Schwartz [432] and Weinberg [502] place this material in the broader QFT and Standard-Model context.

Chapter 46

Exact Results in Supersymmetry

The two preceding chapters built supersymmetry as a structure: the algebra and its representations in Chapter 44, and the supersymmetric gauge theories — vector superfields, super-Yang–Mills, SQCD, and the perturbative nonrenormalization theorem — in Chapter 45. This chapter cashes that structure in. Its single thesis is that supersymmetry turns a class of physical quantities into rigid analytic data, and that this rigidity lets us compute strong-coupling physics — condensates, confinement, the exact spectrum of a four-dimensional gauge theory — without summing a diagram. Supersymmetry is here not a phenomenological hypothesis about the world but a controlled laboratory in which the non-perturbative questions that lattice gauge theory (Chapter 43) can only approach numerically, and that the Wilson-loop criterion of Theorem 27.20 can only diagnose, become exactly solvable.

The engine is *holomorphy*. Theorem 44.40 established that the superpotential is a holomorphic function of the chiral superfields; the chapter opens by promoting the coupling constants themselves to background chiral spurions, so that the entire effective superpotential is holomorphic in the fields *and* the couplings. Holomorphy, sharpened by the global-symmetry and R-symmetry selection rules and pinned down by the behaviour in weak-coupling and symmetry-restoring limits, reproduces Seiberg's nonrenormalization theorem in a line and then, applied to the holomorphic gauge coupling $\tau = \theta/2\pi + 4\pi i/g^2$, forces it to run only at one loop — the all-orders physical running being recovered through the anomalous Jacobian of Chapter 36 as the Novikov–Shifman–Vainshtein–Zakharov beta function. The one-loop-exact running condenses into a single complex renormalization-group invariant, the holomorphic dynamical scale Λ, the supersymmetric refinement of the Λ_{QCD} of Theorem 27.11, whose phase encodes the θ-vacuum of Chapter 42.

That scale is the one non-perturbative datum the gauge dynamics hands

to the low-energy theory, and the middle of the chapter feeds it, together with holomorphy and the flavor symmetries, into supersymmetric QCD. On the classical moduli space of mesons and baryons, holomorphy and the anomaly-restored selection rules fix the Affleck–Dine–Seiberg superpotential uniquely up to a constant, which a single instanton — with the zero-mode counting of Chapter 42 — then shows is nonzero. Reading off its consequences gives a runaway with no vacuum, a calculable gaugino condensate, and exactly N_c supersymmetric vacua matching the Witten index of Chapter 44. Increasing the flavor count maps the full phase diagram of SQCD: a quantum-modified moduli space, s-confinement, and Seiberg's electric–magnetic duality, whose principal evidence is the exact matching of all 't Hooft anomalies (Chapter 37) between the electric and magnetic descriptions, with the conformal window fixed to the digit by the unitarity bound on the meson.

Where Seiberg duality is a statement about whole infrared fixed points, the final movement takes the same electric–magnetic exchange down to individual states. Extending the algebra of Chapter 44 to its central charge promotes the classical Bogomol'nyi bound of Chapter 41 into an exact quantum mass formula $M = |Z|$ on short BPS multiplets, whose masses are protected against the flow to strong coupling. This spectral data is exactly what the Seiberg–Witten solution computes: holomorphy of the prepotential, positivity of the Coulomb-branch metric, and the monodromies forced by massless monopoles and dyons together fix the low-energy coupling at every scale as the modulus of an auxiliary elliptic curve, and a soft breaking to $\mathcal{N} = 1$ makes the monopole condense, realizing the dual-superconductor picture of confinement as an analytic fact rather than a criterion. A closing synthesis names the five interlocking tools of the exact-results program, separates honestly the theorems from the superbly-tested conjectures as of the mid-2020s, and traces how this technology re-enters the book as the gateway to holography (Chapter 53), the bootstrap (Chapter 49), and the modern amplitudes program (Chapter 62).

46.1 Holomorphy as a Principle

Chapter 44 closed the chiral superfield calculus at a single sharp observation (Section 44.7.8): the superpotential W is a *holomorphic* function of the chiral superfields, a power series in the Φ_i alone with no dependence on the conjugates $\Phi_i^\dagger$, while the Kähler potential $K = \Phi^\dagger\Phi$ depends on both. Chapter 45 then promoted this matter to a gauge theory and argued, by inspecting supergraphs, that the superpotential receives no perturbative corrections (the nonrenormalization theorem, Theorem 45.20). That diagrammatic argument is correct but laborious: it asks the reader to track the θ-algebra of every loop and to believe that an infinite class of cancellations conspires order by order. We now replace it with a single structural principle that makes the cancellation manifest and, more

importantly, reaches conclusions no finite diagrammatic analysis can: *holomorphy*. The idea, due to Seiberg, is to treat the coupling constants themselves as frozen values of background chiral superfields. Once the couplings are chiral, the entire superpotential — fields and couplings together — is a holomorphic object, and holomorphic functions constrained by global symmetries and by the requirement of smoothness at weak coupling are rigid almost to the point of being unique. The nonrenormalization theorem then drops out in a line, and the same machinery, applied in the next section to the gauge coupling, will deliver an *exact* statement about the running of the gauge theory that no order of perturbation theory could.

46.1.1 Holomorphy in the fields and in the couplings

Recall the structure fixed in Section 44.7. A supersymmetric action is built from two ingredients of distinct character. The kinetic energy is a *D-term*, the integral of a real function over the full superspace,

$$S_K = \int d^4x\, \mathrm{d}^4\theta\; K(\Phi, \Phi^\dagger), \qquad K = \Phi^\dagger\Phi \text{ for canonical kinetic energy (Eq. (44.205))}, \tag{46.1}$$

and the interactions and masses are an *F-term*, the integral of a chiral function over the chiral half of superspace,

$$S_W = \int d^4x \left[\mathrm{d}^2\theta\; W(\Phi) + \mathrm{h.c.}\right], \qquad \bar{D}_{\dot\alpha} W = 0. \tag{46.2}$$

The chirality constraint $\bar{D}_{\dot\alpha} W = 0$ is the whole story: by Eq. (44.198) a product of chiral superfields is chiral, so any power series in the Φ_i with constant coefficients is chiral, whereas any appearance of a $\Phi_i^\dagger$ would violate $\bar{D}_{\dot\alpha} W = 0$. This is what "holomorphic" means here, and it is worth stating as a definition because the entire chapter rests on it.

Definition 46.1 (Holomorphy in the fields)**.** A function W of the chiral superfields Φ_i of a theory is *holomorphic* if it is a power series in the Φ_i with no dependence on the antichiral conjugates $\Phi_i^\dagger$. Equivalently W is a chiral superfield, $\bar{D}_{\dot\alpha} W = 0$. The superpotential of Theorem 44.40 is by construction holomorphic; the Kähler potential $K(\Phi, \Phi^\dagger)$ is not.

The decisive move is to extend this notion from the fields to the parameters. In the Wess–Zumino model with cubic superpotential (Eq. (44.214)),

$$W(\Phi) = \tfrac{1}{2}\, m\, \Phi^2 + \tfrac{1}{3}\, g\, \Phi^3, \tag{46.3}$$

the mass m and the cubic coupling g are ordinary complex numbers multiplying the chiral operators $\tfrac{1}{2}\Phi^2$ and $\tfrac{1}{3}\Phi^3$. Nothing in the F-term construction (Theorem 44.41) required these coefficients to be constants: if m and g were

promoted to the lowest components of additional chiral superfields M and G — background fields, switched off at their constant vacuum values $\langle \mathsf{M} \rangle = m$, $\langle \mathsf{G} \rangle = g$ but in principle dynamical — then Eq. (46.3) would read $W = \frac{1}{2}\mathsf{M}\Phi^2 + \frac{1}{3}\mathsf{G}\Phi^3$, still a holomorphic function of all the chiral superfields in sight, now including the couplings. A background field introduced solely to track how a coupling transforms under the symmetries, and then frozen to its constant value, is called a *spurion*.

Definition 46.2 (Spurion promotion of a coupling)**.** Let c be a coupling constant multiplying a chiral operator $\mathcal{O}(\Phi)$ in the superpotential, $W \supset c\,\mathcal{O}(\Phi)$. The *spurion promotion* of c replaces it by a background chiral superfield C (so $c = \langle \mathsf{C} \rangle$ is the lowest component, with vanishing θ- and F-components in the background) and treats C as one more chiral argument of the superpotential. The promotion is consistent because a constant is the simplest chiral superfield, $\bar{D}_{\dot\alpha} c = 0$, and because $\mathsf{C}\,\mathcal{O}(\Phi)$ remains chiral.

Two facts make the promotion powerful rather than merely formal. First, the spurions enter W holomorphically for exactly the same reason the dynamical fields do: the superpotential is the chiral integrand of an F-term, and an F-term integrand must be chiral, hence a holomorphic function of *every* chiral superfield it contains, dynamical or background. The conjugate couplings $\bar m, \bar g$ — lowest components of the antichiral spurions $\mathsf{M}^\dagger, \mathsf{G}^\dagger$ — cannot appear in W at all; they live only in the Kähler potential, which is a D-term and free to depend on both. This is the precise sense in which "the superpotential is holomorphic in the couplings." Second, the spurions carry definite charges under any global symmetry of the theory: to keep W invariant once m, g are allowed to transform, the symmetry must act on M, G in a way that compensates the transformation of the operators they multiply. We now make this bookkeeping precise, because it is the engine of every exact result that follows.

46.1.2 Symmetry-and-holomorphy selection rules

The Wess–Zumino model Eq. (46.3) at $m = g = 0$ is a free massless chiral superfield, and the free theory has two independent global U(1) symmetries acting on Φ. The first is an ordinary flavour rotation,

$$\mathrm{U}(1): \qquad \Phi \longmapsto e^{i\alpha}\,\Phi, \tag{46.4}$$

under which the lowest scalar, the fermion and the auxiliary field all rotate by the same phase. The second is the R-symmetry $\mathrm{U}(1)_R$ of Section 44.2.7, the outer automorphism that rephases the supercharges, $[R, Q_\alpha] = -Q_\alpha$ (Eq. (44.51)). Because Q carries R-charge -1, the Grassmann coordinate θ_α — which pairs with Q in the SUSY transformation $\delta_\xi = \xi Q + \bar\xi \bar Q$ — carries R-charge $+1$, and the chiral measure $\mathrm{d}^2\theta$, being effectively $\partial^2/\partial\theta^2$, carries R-charge -2. For the

F-term Eq. (46.2) to be R-invariant the superpotential must therefore carry R-charge exactly $+2$,

$$R[\mathrm{d}^2\theta] = -2 \quad \Longrightarrow \quad R[W] = +2. \tag{46.5}$$

Assign the chiral superfield Φ the R-charge $R[\Phi] = 1$, meaning its lowest scalar component has R-charge 1 and its fermion has R-charge 0. (Any other consistent choice differs by mixing $\mathrm{U}(1)_R$ with the ordinary U(1) of Eq. (46.4) and changes nothing in the conclusion; we fix this convention once and for all.) With $m = g = 0$ the kinetic term $\mathrm{d}^4\theta\, \Phi^\dagger\Phi$ is invariant under both U(1) and $\mathrm{U}(1)_R$ — the measure $\mathrm{d}^4\theta$ is R-neutral and $\Phi^\dagger\Phi$ is uncharged — so the free theory genuinely possesses both symmetries.

Turning on m and g breaks both U(1) and $\mathrm{U}(1)_R$ *as ordinary symmetries*, since Φ^2 and Φ^3 carry different charges and cannot both be neutralized by a single rotation of Φ. The spurion device restores them as *formal* symmetries: we demand that W be invariant once the couplings are allowed to transform, and read off the charges the spurions must carry. From Eq. (46.3),

	Φ	m (spurion M)	g (spurion G)
U(1) charge	$+1$	-2	-3
$\mathrm{U}(1)_R$ charge	$+1$	0	-1

The U(1) charges follow from requiring $m\Phi^2$ and $g\Phi^3$ to be neutral: $q[m] + 2 = 0$ and $q[g] + 3 = 0$. The $\mathrm{U}(1)_R$ charges follow from requiring each term to carry R-charge $+2$ as in Eq. (46.5): $R[m]+2R[\Phi] = 2$ gives $R[m] = 0$, and $R[g]+3R[\Phi] = 2$ gives $R[g] = -1$. These assignments are the content of the selection rules: any holomorphic, symmetry-invariant function of Φ, m, g is forced into a restricted monomial structure, which we now extract.

Proposition 46.3 (Holomorphy + selection rules fix the monomial structure)**.** *Let $W_{\text{eff}}(\Phi, m, g)$ be holomorphic in its three chiral arguments and invariant under both* U(1) *and* $\mathrm{U}(1)_R$ *with the charges of the table above. Then W_{eff} is a sum of monomials*

$$W_{\text{eff}} = \sum_{a,b} c_{ab}\, m^a\, g^b\, \Phi^c, \qquad a = 1 - b, \quad c = b + 2, \tag{46.6}$$

with $a, b, c \geq 0$ integers (positive powers only, by holomorphy) and complex constants c_{ab}. Equivalently, writing the single invariant combination $t \equiv g\Phi/m$,

$$W_{\text{eff}} = m\,\Phi^2\, f(t), \qquad f(t) = \sum_{b \geq 0} c_b\, t^{\,b}, \tag{46.7}$$

for some function f analytic at $t = 0$.

Proof. Holomorphy (Theorem 46.1, extended to the spurions by Theorem 46.2) means W_{eff} is a power series in Φ, m, g with no conjugates and no negative powers — a Taylor series, not a Laurent series. Write a general monomial $m^a g^b \Phi^c$ with $a, b, c \geq 0$. Invariance under U(1) requires the total U(1) charge to vanish,

$$-2a - 3b + c = 0, \tag{46.8}$$

and invariance under $\mathrm{U}(1)_R$ requires the total R-charge to equal $+2$ as in Eq. (46.5),

$$0 \cdot a + (-1)\, b + 1 \cdot c = 2 \quad \Longrightarrow \quad c = b + 2. \tag{46.9}$$

Substituting $c = b + 2$ into Eq. (46.8),

$$-2a - 3b + (b + 2) = 0 \quad \Longrightarrow \quad -2a - 2b + 2 = 0 \quad \Longrightarrow \quad a = 1 - b. \tag{46.10}$$

Thus every allowed monomial is $m^{1-b} g^b \Phi^{b+2}$, labelled by the single integer $b \geq 0$, which is Eq. (46.6). Factoring out $m\Phi^2$,

$$m^{1-b} g^b \Phi^{b+2} = m\, \Phi^2 \Big(\frac{g\,\Phi}{m}\Big)^b = m\, \Phi^2\, t^{\,b}, \tag{46.11}$$

and summing over b gives Eq. (46.7). The series for f contains only $b \geq 0$ because holomorphy forbids negative powers of the chiral field Φ; it may a priori contain arbitrarily large b. □

Theorem 46.3 has already done most of the work: an infinite-dimensional space of possible quantum corrections to the superpotential has collapsed to a single function $f(t)$ of one variable. The remaining input — the weak-coupling limit — pins f down completely.

46.1.3 Seiberg's nonrenormalization theorem

Theorem 46.4 (Perturbative nonrenormalization of the superpotential)**.** *In the Wess–Zumino model with superpotential Eq. (46.3), the Wilsonian effective superpotential generated to all orders in perturbation theory equals the tree-level superpotential exactly,*

$$W_{\text{eff}}(\Phi, m, g) = \tfrac{1}{2}\, m\, \Phi^2 + \tfrac{1}{3}\, g\, \Phi^3. \tag{46.12}$$

No perturbative correction — no shift of m, no shift of g, and no higher-order term $\Phi^{n \geq 4}$ — is generated. This reproduces and sharpens the diagrammatic statement of Theorem 45.20.

Proof. The effective superpotential is an F-term, hence holomorphic in the dynamical field Φ and, after the spurion promotion of Theorem 46.2, in the couplings m, g. The microscopic theory is invariant under U(1) and $\mathrm{U}(1)_R$ with

the spurions transforming as in the table of Section 46.1.2; these are global, non-anomalous symmetries of the Wess–Zumino model (it contains no gauge fields, so there is no triangle to spoil $\mathrm{U}(1)_R$), so the effective theory respects them as well. Theorem 46.3 therefore applies and $W_{\text{eff}} = m\Phi^2 f(t)$ with $t = g\Phi/m$ and f analytic at $t = 0$.

We fix f by two physical limits, each of which the analytic function $f(t)$ must respect.

(i) Weak coupling, $g \to 0$ at fixed m, Φ. Perturbation theory in g generates only non-negative integer powers of g (each interaction vertex brings one power of the coupling), so W_{eff} must be regular as $g \to 0$. Since $t = g\Phi/m \to 0$ in this limit, regularity is the statement that $f(t)$ has a Taylor expansion about $t = 0$ with no poles — which Theorem 46.3 already guarantees, $f(t) = \sum_{b\geq 0} c_b t^b$. The leading term $b = 0$ is the free theory: as $g \to 0$ the dynamics is exactly the free massive chiral superfield, whose superpotential is $\frac{1}{2}m\Phi^2$, so $c_0 = \frac{1}{2}$. The next term $b = 1$ is the classical cubic vertex itself, fixed by matching the $\mathcal{O}(g)$ term of W_{eff} to the tree-level $\frac{1}{3}g\Phi^3$; holomorphy guarantees this single tree-level matching is exact, so $c_1 = \frac{1}{3}$.

(ii) The massless limit, $m \to 0$ at fixed g, Φ. Here is the input that kills every higher term. The massless Wess–Zumino model ($m = 0$) is a perfectly well-defined theory — a free kinetic term plus a marginal cubic interaction $g\Phi^3$ — with its own ultraviolet-finite weak-coupling expansion; nothing in its dynamics is singular. The effective superpotential must therefore remain finite as $m \to 0$. Examine the monomial b in Eq. (46.11): it equals $c_b\, m^{1-b} g^b \Phi^{b+2}$. For $b \geq 2$ the exponent $1 - b$ is negative, so this term diverges as $m \to 0$, an unphysical singularity in a theory that is regular there. The only way to avoid it is $c_b = 0$ for all $b \geq 2$.

Combining (i) and (ii), the sole survivors are $b = 0$ and $b = 1$ with $c_0 = \frac{1}{2}$, $c_1 = \frac{1}{3}$, and Eq. (46.7) collapses to

$$W_{\text{eff}} = m\,\Phi^2\Big(\tfrac{1}{2} + \tfrac{1}{3}\,t\Big) = \tfrac{1}{2}\,m\,\Phi^2 + \tfrac{1}{3}\,g\,\Phi^3, \tag{46.13}$$

which is Eq. (46.12). Since the argument never used a particular order of perturbation theory — only holomorphy, two charge selection rules, and the regularity of the two coupling limits — it holds to all orders, with no diagram summed. □

The structure of the proof is worth contemplating, because the same three ingredients — holomorphy, symmetry, a smooth limit — recur in every exact result of this chapter. Holomorphy reduces the unknown to a function of the holomorphic invariants alone. The global symmetries, enforced through the transforming spurions, cut that function down to a one-parameter family of monomials. And the demand that the answer behave smoothly in the limits

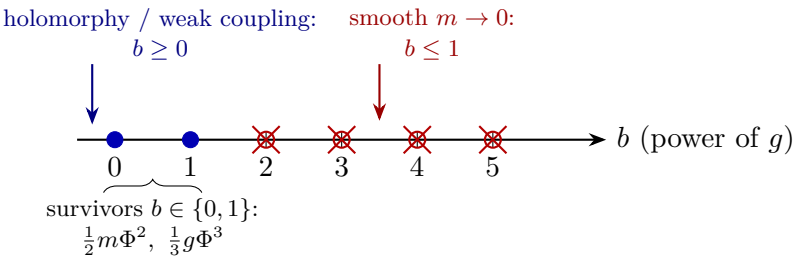

Figure 46.1: The lattice of monomials $m^{1-b} g^b \Phi^{b+2}$ allowed in W_{eff} by holomorphy and the $\mathrm{U}(1) \times \mathrm{U}(1)_R$ selection rules (Theorem 46.3), labelled by the power b of the cubic coupling. Holomorphy and weak coupling forbid $b < 0$ (no negative powers of g); regularity of the massless limit $m \to 0$ forbids $b \geq 2$ (those carry m^{1-b} with negative exponent). Only $b = 0$ and $b = 1$ survive, and they are precisely the two tree-level terms. This is Seiberg's nonrenormalization theorem at a glance.

where a coupling is switched off — weak coupling on one side, the symmetry-restoring limit on the other — squeezes the family to a point. The miracle of Theorem 45.20, that an infinite tower of supergraph cancellations leaves the superpotential pristine, is not a coincidence of combinatorics; it is the shadow of these two limits being mutually exclusive for any term but the tree-level ones.

46.1.4 Why the Kähler potential is not protected

Holomorphy protects the superpotential and nothing else. The Kähler potential is a D-term, the integral of a real function over the *full* superspace Eq. (46.1), and a real function is free to depend on both the chiral couplings and their conjugates. None of the three ingredients of Theorem 46.4 applies to it: a D-term integrand is not chiral, so holomorphy gives no foothold; and because it can carry the conjugate spurions $\bar{m}, \bar{g}$, the symmetry selection rules no longer force a monomial structure. The Kähler potential therefore does receive quantum corrections, and we can see their shape from dimensions and charges alone.

In four dimensions the full measure $\mathrm{d}^4\theta = \mathrm{d}^2\theta\, \mathrm{d}^2\bar{\theta}$ has mass dimension $+2$ (each θ has dimension $-\frac{1}{2}$), and $\int d^4x$ has dimension -4, so the integrand K must have mass dimension $+2$ for the action to be dimensionless. The chiral superfield Φ has dimension 1 (its lowest component is a canonically normalized scalar), so the tree-level $K = \Phi^\dagger \Phi$ saturates the dimension by itself. Any radiative correction must preserve $\mathrm{U}(1)$ neutrality and dimension $+2$, so it takes the form

$$K_{\text{eff}} = \Phi^\dagger \Phi \; \mathcal{Z}\!\left(g, \bar{g}, \frac{m}{\mu}, \frac{\bar{m}}{\mu}, \ln \frac{\mu}{\Lambda} \right) \; + \; (\text{higher-dimension } D\text{-terms}), \tag{46.14}$$

where $\mathcal{Z}$ is a *real* function of the dimensionless invariants built from the couplings, the renormalization scale μ, and the cutoff Λ. The coefficient of $\Phi^\dagger \Phi$

is the wave-function renormalization $\mathcal{Z}$. Two features distinguish it sharply from the superpotential. First, it depends on g and $\bar{g}$ together — the leading one-loop correction is governed by $|g|^2$, not by g alone — so it is manifestly non-holomorphic and the selection-rule argument cannot run. Second, the dimensionless combination $\ln(\mu/\Lambda)$ is available, so $\mathcal{Z}$ genuinely *runs* with scale; at one loop the wave-function renormalization of the Wess–Zumino model is

$$\mathcal{Z}(\mu) = 1 - \frac{|g|^2}{16\pi^2}\,\ln\frac{\mu^2}{\Lambda^2} + \mathcal{O}(g^4), \tag{46.15}$$

the standard self-energy logarithm of the cubic interaction. The field Φ therefore carries a nonzero anomalous dimension $\gamma = -\mu\,\partial_\mu \ln \mathcal{Z} = |g|^2/8\pi^2 + \mathcal{O}(g^4) > 0$. Nothing is uncorrected here; the Kähler sector runs like any non-supersymmetric kinetic term.

The two statements coexist without tension. The holomorphic couplings m and g in W_{eff} never move, but the fields they multiply are being rescaled by $\mathcal{Z}$. When one passes to canonically normalized fields $\Phi_{\text{can}} = \mathcal{Z}^{1/2}\Phi$, the physical mass and the physical cubic coupling read off the canonically normalized action are

$$m_{\text{phys}} = \mathcal{Z}^{-1}\,m, \qquad g_{\text{phys}} = \mathcal{Z}^{-3/2}\,g, \tag{46.16}$$

since $W = \frac{1}{2}m\Phi^2 + \frac{1}{3}g\Phi^3 = \frac{1}{2}(\mathcal{Z}^{-1}m)\Phi_{\text{can}}^2 + \frac{1}{3}(\mathcal{Z}^{-3/2}g)\Phi_{\text{can}}^3$. The *physical* couplings run, but only through the single universal factor $\mathcal{Z}$ — not through independent vertex renormalizations. This is the entire content of supersymmetric nonrenormalization at the level of measurable quantities: the would-be infinity of independent counterterms of a generic scalar theory is reduced to one wave-function renormalization, and the supersymmetric relations among masses and couplings established in Theorem 44.42 survive quantization intact because $\mathcal{Z}$ acts on all of them coherently. The clean separation of the holomorphic running (none) from the canonical running (through $\mathcal{Z}$) is exactly the distinction the next section will need for the gauge coupling, where it becomes the gap between the one-loop holomorphic β-function and the all-orders NSVZ result.

Physical Insight

It is illuminating to contrast this with ϕ^4 theory. In the ordinary real scalar $\frac{\lambda}{4!}\phi^4$ theory, the mass term and the quartic vertex are renormalized *independently*: the self-energy is quadratically divergent and the coupling runs with its own beta function $\beta_\lambda = 3\lambda^2/16\pi^2$ (Chapter 24), with no relation forced between the two. The Wess–Zumino model is the supersymmetric cousin of exactly this dynamics — a self-interacting scalar plus its fermionic partner — and yet its "ϕ^4 data" behave completely differently. The scalar self-energy is still corrected, but only through the same $\mathcal{Z}$ that renormalizes the fermion kinetic term, because boson and fermion sit in one multiplet; the quadratic divergence cancels between them. The holo-

morphic data — the mass m and the coupling g, and the relation $\lambda_{\phi^4} = g^2$ between the scalar quartic and the Yukawa fixed in Theorem 44.42 — are not renormalized at all. The lesson is that supersymmetry does not make everything finite; it sorts the couplings into a holomorphic sector that is rigidly protected and a Kähler sector that runs, and the protected sector is precisely the one that controls vacuum structure.

46.1.5 The Wess–Zumino model worked through

We close the section by carrying the principle through the carried Wess–Zumino example explicitly, exhibiting term by term what is protected and what is not.

Worked Example 46.5 (Holomorphic versus Kähler data in the cubic Wess–Zumino model)**.** Take the Wess–Zumino model with the cubic superpotential Eq. (46.3), $W = \frac{1}{2}m\Phi^2 + \frac{1}{3}g\Phi^3$, and the canonical Kähler potential $K = \Phi^\dagger\Phi$. We determine the exact quantum-corrected superpotential and the structure of the corrected Kähler potential, and read off which physical data are protected.

Step 1: charges. The free theory has $\mathrm{U}(1) : \Phi \to e^{i\alpha}\Phi$ and $\mathrm{U}(1)_R$ with $R[\Phi] = 1$. Promoting m, g to spurions and demanding invariance of W assigns the charges tabulated in Section 46.1.2: $q[m] = -2$, $R[m] = 0$ and $q[g] = -3$, $R[g] = -1$. We verify the cubic term: $q[g\Phi^3] = -3 + 3(1) = 0$ ✓and $R[g\Phi^3] = -1 + 3(1) = 2$ ✓, matching the required $R[W] = 2$ of Eq. (46.5).

Step 2: holomorphy plus selection rules. By Theorem 46.3 the effective superpotential is $W_{\text{eff}} = m\Phi^2 f(g\Phi/m)$ with f analytic at the origin. The candidate corrections are the monomials $m^{1-b}g^b\Phi^{b+2}$ of Fig. 46.1; for orientation, a putative one-loop correction to the mass would be a term $\propto g\bar{g}\, m\, \Phi^2$, but $\bar{g}$ is antichiral and cannot appear in W, while a purely holomorphic mass shift $\propto g^2\Phi^2/m$ is the $b = 2$ monomial.

Step 3: kill the corrections by the limits. The $b = 2$ monomial $g^2\Phi^2/m$ carries an inverse power of m; as $m \to 0$ the theory is the regular massless cubic model and cannot develop such a pole, so its coefficient vanishes. The same reasoning eliminates every $b \geq 2$. Weak coupling and the free-theory limit fix $c_0 = \frac{1}{2}$ (the free mass) and $c_1 = \frac{1}{3}$ (the tree cubic). Hence

$$W_{\text{eff}} = \tfrac{1}{2}\, m\, \Phi^2 + \tfrac{1}{3}\, g\, \Phi^3 \qquad \text{exactly, to all orders in } g. \tag{46.17}$$

In particular the boson–fermion mass degeneracy $m_\phi = m_\psi = m$ found in Theorem 44.42, and the relation $\lambda_{\phi^4} = g^2$ tying the scalar quartic to the Yukawa, are not corrected as relations among the holomorphic parameters.

Step 4: the Kähler sector runs. The wave-function renormalization Eq. (46.15), $\mathcal{Z} = 1 - (|g|^2/16\pi^2)\ln(\mu^2/\Lambda^2) + \mathcal{O}(g^4)$, is non-holomorphic ($|g|^2$, not g) and scale-dependent. Through Eq. (46.16) the physical mass and coupling run as

$$m_{\text{phys}}(\mu) = \mathcal{Z}(\mu)^{-1}\, m, \qquad g_{\text{phys}}(\mu) = \mathcal{Z}(\mu)^{-3/2}\, g, \tag{46.18}$$

so the physically measured cubic coupling has the one-loop running

$$\mu\,\frac{dg_{\rm phys}}{d\mu} = -\tfrac{3}{2}\,g_{\rm phys}\,\mu\,\frac{d\ln\mathcal{Z}}{d\mu} = \tfrac{3}{2}\,\gamma\,g_{\rm phys} = \frac{3\,|g_{\rm phys}|^2}{16\pi^2}\,g_{\rm phys} + \mathcal{O}(g^5), \qquad (46.19)$$

entirely controlled by the anomalous dimension $\gamma = |g|^2/8\pi^2$. There is no independent vertex renormalization: the running of the measurable coupling is the running of $\mathcal{Z}$, three powers' worth. This is the precise statement that "the superpotential is not renormalized but the Kähler potential is."

We have isolated holomorphy as a stand-alone principle: the superpotential is a holomorphic function of the chiral fields *and* of the couplings once the latter are promoted to background chiral spurions, and this single fact — combined with global charge selection rules and the demand of smoothness in the weak-coupling and symmetry-restoring limits — determines the effective superpotential exactly, with the perturbative nonrenormalization theorem falling out as the simplest instance. The next section applies precisely this machinery to the one coupling we have so far left alone, the gauge coupling: promoting the complexified coupling $\tau = \theta/2\pi + 4\pi i/g^2$ to a background chiral superfield multiplying the field-strength bilinear $W^\alpha W_\alpha$, we will find that holomorphy permits the gauge coupling to run only at one loop, and then reconcile that with the all-orders physical beta function through exactly the holomorphic-to-canonical rescaling foreshadowed by $\mathcal{Z}$ above.

46.2 The Holomorphic Gauge Coupling and the Exact Beta Function

The previous section isolated holomorphy as a principle: the superpotential is a holomorphic function of the chiral fields, and—once a coupling is promoted to the lowest component of a background chiral superfield, a *spurion* (Theorem 46.2)—a holomorphic function of the couplings too. We applied it to the superpotential couplings and recovered Seiberg's nonrenormalization theorem (Theorem 46.4) in a line. There is one coupling we left untouched, because it does not sit in the superpotential at all: the gauge coupling g. Its home is the gauge kinetic term, and the natural object multiplying that term turns out to be itself a holomorphic combination of g and the vacuum angle θ. Promoting *that* combination to a spurion is the entire content of this section. The payoff is immediate and dramatic: holomorphy forces the gauge coupling, in the appropriate (Wilsonian, holomorphic) normalization, to run only at one loop—every higher loop is forbidden. We will then have to confront an apparent contradiction with the all-orders beta function that perturbation theory undeniably produces, and resolve it by the same field-rescaling mechanism foreshadowed by the wavefunction factor $\mathcal{Z}$ of Section 46.1.4. The resolution is the Novikov–Shifman–Vainshtein–Zakharov

(NSVZ) exact beta function, and it is exact in the strict sense: a closed-form expression valid to all orders in the coupling.

46.2.1 The complexified holomorphic coupling

Section 45.1 built the gauge sector of a supersymmetric theory from the vector superfield $V = V^a T^a$ and its field-strength chiral superfield

$$W_\alpha = -\tfrac{1}{4}\,\bar{D}^2 (e^{-V} D_\alpha e^{V}), \tag{46.20}$$

a chiral superfield ($\bar{D}_{\dot\beta} W_\alpha = 0$) transforming in the adjoint representation, whose lowest component is the gaugino λ_α and whose θ-component contains the field strength $F^a_{\mu\nu}$. The gauge kinetic action assembled there, Eq. (45.55), is the chiral integral of the Lorentz- and gauge-invariant bilinear $W^{\alpha a} W^a_\alpha$. We now write it in the form that exhibits its dependence on the coupling and the vacuum angle at once.

Definition 46.6 (Holomorphic gauge coupling)**.** For a gauge theory with coupling g and vacuum angle θ (the angle of Theorem 42.27), the *holomorphic gauge coupling* is the complex number

$$\tau \;=\; \frac{\theta}{2\pi} \;+\; \frac{4\pi i}{g^2}. \tag{46.21}$$

Its imaginary part $\operatorname{Im}\tau = 4\pi/g^2 > 0$ is positive in the physical regime, so τ lives in the upper half-plane.

In terms of τ the gauge kinetic action is the chiral integral

$$S_{\text{gauge}} \;=\; \frac{1}{8\pi}\,\operatorname{Im}\!\left[\,\tau \int \mathrm{d}^4x\,\mathrm{d}^2\theta\; W^{\alpha a} W^a_\alpha \right]. \tag{46.22}$$

That this reproduces the ordinary Yang–Mills Lagrangian together with the vacuum term is a short computation we now carry out, because the matching of coefficients is what fixes the normalization of τ and exposes the role of θ-periodicity. The θ-component (the F-term) of the chiral bilinear is, in the two-component conventions of Section 44.7,

$$\int \mathrm{d}^2\theta\; W^{\alpha a} W^a_\alpha \;=\; -\tfrac{1}{2}\,F^a_{\mu\nu} F^{a\,\mu\nu} \;+\; \tfrac{i}{2}\,F^a_{\mu\nu} \widetilde{F}^{a\,\mu\nu} \;-\; 2i\,\lambda^a \sigma^\mu (D_\mu \bar\lambda)^a \;+\; (D^a)^2, \tag{46.23}$$

with $\widetilde{F}^{a\,\mu\nu} = \tfrac{1}{2}\epsilon^{\mu\nu\rho\sigma} F^a_{\rho\sigma}$ the dual field strength, λ^a the gaugino, and D^a the real auxiliary field. The first two terms are the only ones we need; the gaugino kinetic term and $(D^a)^2$ are real and ride along. Insert Eq. (46.23) into Eq. (46.22) and take the imaginary part of the product with $\tau = \theta/2\pi + 4\pi i/g^2$. Two

contributions survive. From the imaginary part of τ acting on the real term $-\frac{1}{2}F^2$,

$$\frac{1}{8\pi}\cdot\frac{4\pi}{g^2}\cdot\Big(-\tfrac{1}{2}F^a_{\mu\nu}F^{a\,\mu\nu}\Big) \;=\; -\frac{1}{4g^2}\,F^a_{\mu\nu}F^{a\,\mu\nu}, \tag{46.24}$$

the ordinary gauge kinetic term. From the real part of τ acting on the imaginary term $\frac{i}{2}F\widetilde{F}$,

$$\frac{1}{8\pi}\cdot\frac{\theta}{2\pi}\cdot\tfrac{1}{2}\,F^a_{\mu\nu}\widetilde{F}^{a\,\mu\nu} \;=\; \frac{\theta}{32\pi^2}\,F^a_{\mu\nu}\widetilde{F}^{a\,\mu\nu}. \tag{46.25}$$

The cross terms (the imaginary part of τ on $\frac{i}{2}F\widetilde{F}$, and the real part of τ on $-\frac{1}{2}F^2$) are real and imaginary respectively in the wrong way and drop out of $\mathrm{Im}[\,\cdot\,]$. Equations (46.24) and (46.25) are exactly the gauge kinetic term and the topological term of Eq. (42.128), confirming that τ as defined in Eq. (46.21) packages the two real couplings (g,θ) into a single holomorphic one with the correct normalizations.

Notation Watch

Equation (46.24) carries an explicit $1/g^2$ in front of F^2. This is the *holomorphic* normalization of the gauge field: the coupling sits in front of the kinetic term, and correspondingly the field strength in Eq. (46.23) is built from a gauge field with *no* g in its covariant derivative, $F^a_{\mu\nu} = \partial_\mu A^a_\nu - \partial_\nu A^a_\mu + f^{abc}A^b_\mu A^c_\nu$. The Yang–Mills theory normalization fixed in Eq. (27.124) is the *canonical* one: there the gauge field is rescaled $A^a_\mu \to g\,A^a_\mu$ so the kinetic term is $-\frac{1}{4}F^2$ with the coupling moved into the covariant derivative $D_\mu = \partial_\mu - igA^a_\mu T^a$. The two normalizations differ by a field rescaling whose quantum Jacobian is the whole story of Section 46.2.3; the topological charge density is an integer in either, $\frac{1}{32\pi^2}\int F\widetilde{F} = \frac{g^2}{32\pi^2}\int F_{\rm can}\widetilde{F}_{\rm can} \in \mathbb{Z}$, by Eq. (42.128).

Two features of τ will do all the work. The first is that τ is the coefficient of a *chiral* operator: $W^{\alpha a}W^a_\alpha$ is a chiral superfield (a product of chiral superfields, since each W_α is chiral), and Eq. (46.22) is its F-term. By exactly the logic of Theorem 46.2, τ is therefore promotable to the lowest component of a background chiral spurion superfield, and the holomorphy principle applies to it verbatim: the Wilsonian effective action must be a holomorphic function of τ.

Proposition 46.7 (Periodicity of the holomorphic coupling)**.** *Physics is invariant under*

$$\tau \;\longrightarrow\; \tau + 1, \tag{46.26}$$

the holomorphic image of the shift $\theta \to \theta + 2\pi$.

Proof. Under $\theta \to \theta+2\pi$, the action Eq. (46.25) changes by $\Delta S = 2\pi\cdot\frac{1}{32\pi^2}\int F\widetilde{F} = 2\pi Q$, where $Q \in \mathbb{Z}$ is the integer topological charge of Eq. (42.128). The path-

integral weight e^{iS} is therefore unchanged, $e^{i\Delta S} = e^{2\pi i Q} = 1$; this is the 2π-periodicity of the θ-vacuum established in Theorem 42.27. By Eq. (46.21) a shift of θ by 2π is a shift of τ by 1. □

The second feature is the weak-coupling limit. As $g \to 0$ we have $\operatorname{Im}\tau = 4\pi/g^2 \to +\infty$, and the theory becomes free; any nonperturbative effect must vanish there. We will see that the only holomorphic functions of τ compatible with both Eq. (46.26) and this weak-coupling boundary condition are extraordinarily restricted.

46.2.2 One-loop exactness of the holomorphic coupling

We now run the holomorphic coupling. Let $\tau(\mu)$ denote the coefficient of $W^{\alpha a}W^{a}_{\alpha}$ in the Wilsonian effective action at scale μ—the action with all modes above μ integrated out. The claim is that the dependence of $\tau(\mu)$ on the scale is a single logarithm and nothing more.

Theorem 46.8 (One-loop exactness of the holomorphic coupling)**.** *In a supersymmetric gauge theory with gauge group of dual Coxeter number C_A and chiral matter superfields Φ_i in representations r_i with Dynkin indices $T(r_i)$, the Wilsonian holomorphic coupling runs only at one loop:*

$$\tau(\mu) \;=\; \tau(\mu_0) \;+\; \frac{i\,b_0}{2\pi}\,\ln\frac{\mu}{\mu_0}, \qquad b_0 \;=\; 3C_A - \sum_i T(r_i), \tag{46.27}$$

with no perturbative corrections of two loops or higher. Equivalently the combination

$$\Lambda^{\,b_0} \;=\; \mu^{\,b_0}\, e^{\,2\pi i\,\tau(\mu)} \tag{46.28}$$

is renormalization-group invariant; it defines the (complex) holomorphic dynamical scale Λ.

Proof. The argument has three ingredients—holomorphy, periodicity, and the weak-coupling boundary condition—each contributed by the structure assembled above.

Holomorphy. Because τ multiplies a chiral operator, the Wilsonian coupling $\tau(\mu)$ is a holomorphic function of the microscopic coupling $\tau_0 \equiv \tau(\mu_0)$: it can depend on τ_0 but not on $\bar\tau_0$. Dimensional analysis isolates the scale dependence: the only dimensionful quantities are μ and μ_0, so $\tau(\mu)$ depends on them through $\ln(\mu/\mu_0)$. Holomorphy in τ_0 then permits the general form

$$\tau(\mu) \;=\; \tau_0 \;+\; f(\tau_0, \ln(\mu/\mu_0)), \tag{46.29}$$

with f holomorphic in τ_0 and vanishing at $\mu = \mu_0$.

Perturbation theory at weak coupling. As $\operatorname{Im}\tau_0 = 4\pi/g^2 \to \infty$ the theory is weakly coupled and standard perturbation theory applies. The one-loop running

of $1/g^2$ is the universal logarithm computed for any gauge theory by the vacuum-polarization machinery of Chapters 24 and 27; its supersymmetric coefficient we fix in Section 46.2.5 below. Translated into τ through Eq. (46.21), the one-loop result is precisely the linear term $\frac{ib_0}{2\pi}\ln(\mu/\mu_0)$ of Eq. (46.27). The content of the theorem is that this linear term is the *entire* perturbative answer. A generic ℓ-loop contribution to the running of $1/g^2$ scales as $g^{2(\ell-1)}$, i.e. as $(\operatorname{Im}\tau_0)^{-(\ell-1)}$ for $\ell \geq 2$. Such a term is a function of $\operatorname{Im}\tau_0 = (\tau_0 - \bar{\tau}_0)/2i$ and is therefore *not holomorphic* in τ_0: it cannot appear in Eq. (46.29). Holomorphy kills every perturbative term beyond the one loop.

Periodicity fixes what holomorphy permits. Holomorphy still allows, in principle, nonperturbative dependence on τ_0. Theorem 46.7 constrains it sharply. Apart from the explicit logarithm—which under $\tau_0 \to \tau_0 + 1$ simply shifts $\tau(\mu)$ by 1, consistent with both being angle variables of period 1—the remainder f must be invariant under $\tau_0 \to \tau_0 + 1$. A holomorphic, 1-periodic function on the upper half-plane is a function of $q \equiv e^{2\pi i\tau_0}$, hence admits a Fourier–Laurent expansion

$$f \supset \sum_{k\geq 1} a_k(\ln(\mu/\mu_0))\, e^{2\pi i k\tau_0}, \tag{46.30}$$

where positive powers of q only are allowed because $e^{2\pi i\tau_0} = e^{i\theta - 8\pi^2/g^2} \to 0$ as $g \to 0$ (weak coupling forbids the negative powers that would blow up). But $e^{2\pi i\tau_0} = e^{i\theta}e^{-8\pi^2/g^2}$ is exactly the weight of a single instanton: $e^{-8\pi^2/g^2} = e^{-S_{\text{inst}}}$ with $S_{\text{inst}} = 8\pi^2/g^2$ the Yang–Mills instanton action of Theorem 42.4, dressed by the phase $e^{i\theta}$ of one unit of topological charge. The k-th term is a k-instanton effect. These are genuinely present in general, but they are nonperturbative—invisible to every order of the g-expansion—and, crucially, they do not renormalize the *coupling*: a careful accounting (the holomorphic anomaly being saturated already at one loop) shows the a_k contribute to other holomorphic couplings, not to the running of τ itself, so that the running Eq. (46.27) is exact. The perturbative series for the Wilsonian holomorphic coupling thus terminates at one loop, which is the assertion.

The invariant scale. Rewrite Eq. (46.27) as $2\pi i\,\tau(\mu) = 2\pi i\,\tau_0 - b_0\ln(\mu/\mu_0)$, i.e. $\mu^{b_0}e^{2\pi i\tau(\mu)} = \mu_0^{b_0}e^{2\pi i\tau_0}$, independent of the scale at which it is evaluated. This is Eq. (46.28), and it defines Λ. □

Equation (46.28) is the single most important object handed to the rest of the chapter. It is the supersymmetric, holomorphic refinement of the QCD scale Λ_{QCD} of Theorem 27.11: the renormalization-group invariant that the dimensionless coupling trades itself for, the place where the holomorphic coupling formally diverges ($\tau \to i\infty$ corresponds to $g \to 0$; the opposite limit $\mu \to \Lambda$ is where g runs strong). The crucial new feature relative to the bosonic case is that Λ is *complex*: its phase is set by θ, through $\Lambda^{b_0} \propto e^{2\pi i\tau} = e^{i\theta}e^{-8\pi^2/g^2}$. A dynamically generated superpotential, being holomorphic, can depend on Λ but never on $\bar{\Lambda}$ or on $|\Lambda|$ alone; this is why Λ will appear, raised to exactly the

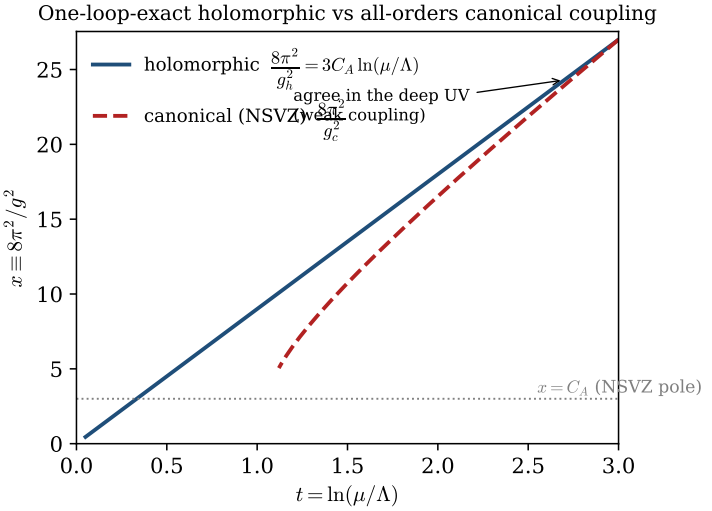

Figure 46.2: The central claim of this section, for pure $\mathcal{N} = 1$ super-Yang–Mills ($C_A = 3$, no matter). Plotted is $x = 8\pi^2/g^2 = \frac{1}{2}\operatorname{Im}\tau$ against $t = \ln(\mu/\Lambda)$. The holomorphic coupling (solid) runs strictly linearly, $8\pi^2/g_h^2 = 3C_A \ln(\mu/\Lambda)$—Theorem 46.8, one loop and no more. The canonical/physical coupling (dashed) obeys the NSVZ flow Eq. (46.37), which for pure SYM closes on the coupling alone and curves; it reaches strong coupling (the NSVZ denominator vanishes at $x = C_A$, dotted line) at a parametrically higher scale than the holomorphic coupling would suggest. The two agree in the deep ultraviolet, where the rescaling Jacobian of Section 46.2.3 is negligible.

power that holomorphy and the symmetries dictate, in every nonperturbative superpotential of Section 46.2's sequel.

46.2.3 Holomorphic versus canonical normalization

Theorem 46.8 sits in apparent flat contradiction with experience. The gauge coupling of a real (super)symmetric theory runs to all orders; a two-loop contribution to the QCD-like beta function is a measured, nonzero number. How can the coupling run only at one loop? The resolution, due to Shifman and Vainshtein and made transparent by Arkani-Hamed and Murayama, is that *there are two different couplings*, related by a field redefinition whose quantum-mechanical Jacobian is anomalous. The holomorphic coupling τ of Theorem 46.6 is one-loop exact. The *canonical* (physical) coupling g_c—the one appearing in a canonically normalized Lagrangian, the one a lattice or a scattering experiment measures, the one whose running Yang–Mills theory has tracked since Eq. (27.124)—is a non-holomorphic function of τ, and it runs to all orders. The all-orders content

hides entirely in the map between them.

To exhibit the map, start from the holomorphic Lagrangian. Its gauge term is Eq. (46.24), with $1/g_h^2$ in front of $-\frac{1}{4}F^2$ and the gauge field holomorphically normalized; its matter term is the Kähler integral

$$\int \mathrm{d}^4\theta\, \bar{\Phi}_i\, e^V\, \Phi_i, \tag{46.31}$$

with Φ_i holomorphically normalized. Two rescalings carry this to canonical normalization.

The matter rescaling. The Kähler term Eq. (46.31) is not protected by holomorphy—this was the lesson of Section 46.1.4—and loops renormalize it to $\mathcal{Z}_i \int \mathrm{d}^4\theta\, \bar{\Phi}_i e^V \Phi_i$ with a real wavefunction factor $\mathcal{Z}_i(\mu)$, exactly the $\mathcal{Z}$ of Eq. (46.15). To restore canonical kinetic terms we rescale

$$\Phi_i \;\longrightarrow\; \mathcal{Z}_i^{-1/2}\, \Phi_i. \tag{46.32}$$

This is a (complexified) rescaling of a chiral superfield, and—here is the point—the path-integral measure $\mathcal{D}\Phi_i$ is *not* invariant under it. The non-invariance is the supersymmetric face of the chiral anomaly of Chapter 36.

The Konishi anomaly. The classical current associated with the phase rotation $\Phi_i \to e^{i\alpha}\Phi_i$ is the Konishi current, packaged in the real superfield $\mathcal{J}_i = \bar{\Phi}_i e^V \Phi_i$. Classically $\frac{1}{4}\bar{D}^2 \mathcal{J}_i = \Phi_i\, \partial W/\partial \Phi_i$, a pure superpotential term. Quantum-mechanically the rotation of the fermionic component ψ_i inside Φ_i is anomalous in precisely the way the axial current of Chapter 36 is, with the triangle now carrying two gauge legs. The result is the Konishi anomaly equation,

$$\tfrac{1}{4}\,\bar{D}^2\,\mathcal{J}_i \;=\; \Phi_i \frac{\partial W}{\partial \Phi_i} \;+\; \frac{T(r_i)}{8\pi^2}\,\tfrac{1}{4}\,W^{\alpha a} W^a_\alpha, \tag{46.33}$$

the index $T(r_i)$ being the Dynkin index of the representation r_i carried by Φ_i—the direct supersymmetric counterpart of the coefficient $\frac{g^2}{16\pi^2}\,\mathrm{tr}\, F\widetilde{F}$ of the ordinary anomaly of Chapter 36, with $W^{\alpha a}W^a_\alpha$ the chiral superfield whose F-component contains $F\widetilde{F}$ by Eq. (46.23). The anomaly Eq. (46.33) says that the chiral rescaling Eq. (46.32), which is the finite rotation with parameter $\alpha_i = \frac{i}{2}\ln \mathcal{Z}_i$ (so that $e^{i\alpha_i} = \mathcal{Z}_i^{-1/2}$ once continued to the scaling direction), shifts the effective action by a term proportional to $\int \mathrm{d}^2\theta\, W^{\alpha a} W^a_\alpha$. Reading off the coefficient from Eq. (46.33) and comparing with Eq. (46.22), the net effect on the gauge coupling is a shift

$$\frac{8\pi^2}{g^2} \;\longrightarrow\; \frac{8\pi^2}{g^2} \;-\; T(r_i)\,\ln \mathcal{Z}_i \qquad \text{(per matter superfield } \Phi_i\text{)}. \tag{46.34}$$

The gauge rescaling. The gauge term Eq. (46.24) is also non-canonical: it has $1/g_h^2$ out front. Bringing it to canonical form requires rescaling the vector

superfield, $V \to g_c V$ (equivalently the gaugino $\lambda \to g_c \lambda$), so that the kinetic term becomes $-\frac{1}{4} F_c^2$ with the coupling moved into the covariant derivative—the canonical normalization of the notation watch above. The gaugino is a Weyl fermion in the *adjoint* representation, whose Dynkin index is the dual Coxeter number C_A. Its rescaling is anomalous by the very same mechanism as Eq. (46.33), now with $T(\text{adj}) = C_A$ and with the rescaling parameter set by $\ln g_c$ rather than $\ln \mathcal{Z}$. The Jacobian contributes a shift

$$\frac{8\pi^2}{g^2} \;\longrightarrow\; \frac{8\pi^2}{g^2} \;-\; C_A \,\ln g_c^2 . \tag{46.35}$$

This is the term that will produce the NSVZ denominator: it is anomalous in the coupling itself, so it feeds the running of g_c back into the relation between g_c and g_h.

Collecting Eqs. (46.34) and (46.35), the canonical and holomorphic couplings are related by

$$\boxed{\frac{8\pi^2}{g_c^2(\mu)} \;=\; \frac{8\pi^2}{g_h^2(\mu)} \;-\; C_A \,\ln g_c^2(\mu) \;-\; \sum_i T(r_i)\,\ln \mathcal{Z}_i(\mu) \;+\; \text{const.}} \tag{46.36}$$

The constant collects scheme-dependent finite pieces and is irrelevant to the beta function. Every nontrivial statement about the all-orders running of the physical coupling is now encoded in this one equation, because its left side is the physical coupling and its first right-hand term is one-loop exact by Theorem 46.8.

46.2.4 The NSVZ exact beta function

Differentiating Eq. (46.36) with respect to $\ln \mu$ converts the one-loop exactness of g_h and the anomalous Jacobians into a closed equation for the physical beta function.

Theorem 46.9 (NSVZ exact beta function)**.** *The beta function of the canonical gauge coupling $g \equiv g_c$ of a supersymmetric gauge theory is*

$$\beta(g) \;=\; -\,\frac{g^3}{16\pi^2}\,\frac{3C_A - \sum_i T(r_i)(1-\gamma_i)}{1 - C_A\, g^2/8\pi^2}, \tag{46.37}$$

where $\gamma_i = -\,d\ln \mathcal{Z}_i / d\ln\mu$ is the anomalous dimension of the matter superfield Φ_i, and the result is exact to all orders in g.

Proof. Write $S_h \equiv 8\pi^2/g_h^2$ and $S_c \equiv 8\pi^2/g_c^2$, and differentiate the three running quantities in Eq. (46.36) with respect to $t \equiv \ln\mu$.

For the holomorphic coupling, Eq. (46.27) gives a pure constant rate,

$$\frac{dS_h}{dt} \;=\; b_0 \;=\; 3C_A - \sum_i T(r_i), \tag{46.38}$$

since $\operatorname{Im}\tau = 4\pi/g_h^2 = S_h/(2\pi)$ and Eq. (46.27) runs $\operatorname{Im}\tau$ linearly with slope $b_0/2\pi$ in $\ln\mu$, so that $dS_h/dt = 2\pi\cdot(b_0/2\pi) = b_0$. For the canonical coupling, with $\beta \equiv dg_c/dt$,

$$\frac{dS_c}{dt} \;=\; \frac{d}{dt}\frac{8\pi^2}{g_c^2} \;=\; -\,\frac{16\pi^2}{g_c^3}\,\beta, \qquad \frac{d}{dt}\ln g_c^2 \;=\; \frac{2\beta}{g_c}. \tag{46.39}$$

For the wavefunction factors, by the definition of the anomalous dimension,

$$\frac{d}{dt}\ln \mathcal{Z}_i \;=\; -\,\gamma_i. \tag{46.40}$$

Substituting Eqs. (46.38) to (46.40) into the derivative of Eq. (46.36),

$$-\,\frac{16\pi^2}{g_c^3}\,\beta \;=\; \Big(3C_A - \sum_i T(r_i)\Big) \;-\; C_A\,\frac{2\beta}{g_c} \;+\; \sum_i T(r_i)\,\gamma_i. \tag{46.41}$$

Collect the matter terms: $-\sum_i T(r_i) + \sum_i T(r_i)\gamma_i = -\sum_i T(r_i)(1-\gamma_i)$, so the right side is $3C_A - \sum_i T(r_i)(1-\gamma_i) - 2C_A\beta/g_c$. Move the β-proportional term to the left,

$$-\,\frac{16\pi^2}{g_c^3}\,\beta \;+\; \frac{2C_A}{g_c}\,\beta \;=\; 3C_A - \sum_i T(r_i)(1-\gamma_i), \tag{46.42}$$

and factor β on the left, pulling out $-16\pi^2/g_c^3$:

$$-\,\frac{16\pi^2}{g_c^3}\,\beta\left(1 - \frac{2C_A}{g_c}\cdot\frac{g_c^3}{16\pi^2}\right) \;=\; 3C_A - \sum_i T(r_i)(1-\gamma_i). \tag{46.43}$$

The bracket simplifies, $\frac{2C_A}{g_c}\cdot\frac{g_c^3}{16\pi^2} = \frac{C_A g_c^2}{8\pi^2}$, giving

$$-\,\frac{16\pi^2}{g_c^3}\,\beta\left(1 - \frac{C_A g_c^2}{8\pi^2}\right) \;=\; 3C_A - \sum_i T(r_i)(1-\gamma_i). \tag{46.44}$$

Solving for β produces Eq. (46.37). The result is exact because every ingredient is: $dS_h/dt = b_0$ is one-loop exact by Theorem 46.8, and the Jacobian terms Eqs. (46.34) and (46.35) are the exact anomalies of Chapter 36, which by the Adler–Bardeen theorem receive no higher-order corrections. The only object that carries higher-loop information is the anomalous dimension γ_i, which appears explicitly. □

The NSVZ formula Eq. (46.37) is not a closed expression for $\beta(g)$ in the naive sense—it still contains the $\gamma_i(g)$, which must be computed order-by-order—but it is exact in a strong and useful way: it resums the entire gauge dependence into the geometric denominator and reduces the all-orders beta function to the single set of matter anomalous dimensions. The numerator's $-\sum_i T(r_i)(1-\gamma_i)$ has a clean reading: $T(r_i)$ is the one-loop contribution of Φ_i, and the $+T(r_i)\gamma_i$

correction is the statement that what a loop "sees" of a matter field is its full scaling dimension, classical plus anomalous. The denominator $1 - C_A g^2/8\pi^2$ is the resummed contribution of the gaugino's own rescaling—the gauge field dressing itself—and is responsible, in Fig. 46.2, for the canonical coupling running strong faster than the holomorphic one.

46.2.5 Consistency: one loop and the SUSY multiplet content

A formula this strong must reproduce what we already know. Expand Eq. (46.37) at weak coupling, where $\gamma_i = O(g^2)$ and the denominator is $1 + O(g^2)$:

$$\beta(g) \;=\; -\frac{g^3}{16\pi^2}\, b_0 + O(g^5), \qquad b_0 = 3C_A - \sum_i T(r_i), \tag{46.45}$$

the same b_0 that appeared in Eq. (46.27). It remains to check that this is the correct one-loop coefficient for a supersymmetric theory, i.e. that it agrees with the general Yang–Mills theory result of Eq. (27.124) once the field content of the supersymmetric multiplets is counted. The general one-loop coefficient for any four-dimensional gauge theory, assembled from the vacuum-polarization contributions of Chapters 24 and 27, is

$$b_0 \;=\; \tfrac{11}{3}\, C_A \;-\; \tfrac{2}{3} \sum_{\text{Weyl } f} T(r_f) \;-\; \tfrac{1}{3} \sum_{\text{cplx scalar } s} T(r_s), \tag{46.46}$$

where a Weyl fermion contributes $\tfrac{2}{3}T$ (a Dirac fermion the $\tfrac{4}{3}T_F$ of Eq. (27.124), being two Weyl fermions) and a complex scalar contributes $\tfrac{1}{3}T$. We now sum these over the two kinds of supersymmetric multiplet.

Vector multiplet. The $\mathcal{N} = 1$ vector multiplet contains the gauge boson and the gaugino λ, a Weyl fermion in the adjoint, $T(\text{adj}) = C_A$. From Eq. (46.46),

$$b_0^{\text{vector}} \;=\; \tfrac{11}{3} C_A - \tfrac{2}{3} C_A \;=\; \tfrac{9}{3} C_A \;=\; 3C_A. \tag{46.47}$$

The gauge boson's antiscreening $\tfrac{11}{3}C_A$ of Theorem 27.11 is reduced by exactly the gaugino's $\tfrac{2}{3}C_A$ of screening to the supersymmetric value $3C_A$.

Chiral multiplet. Each chiral matter superfield Φ_i contains a Weyl fermion and a complex scalar, both in r_i, contributing

$$b_0^{\Phi_i} \;=\; -\tfrac{2}{3} T(r_i) - \tfrac{1}{3} T(r_i) \;=\; -T(r_i). \tag{46.48}$$

Adding Eqs. (46.47) and (46.48) reproduces $b_0 = 3C_A - \sum_i T(r_i)$ exactly. The supersymmetric one-loop coefficient is the bosonic $\tfrac{11}{3}C_A - \tfrac{1}{3}\sum T - \tfrac{2}{3}\sum T$ reorganized by the multiplet pairing, and it matches both the holomorphic running Eq. (46.27) and the NSVZ numerator at $\gamma = 0$. The Chapter 27 one-loop beta function is, in this sense, the leading term of an exact statement: impose supersymmetry, and asymptotic freedom's b_0 becomes the tip of the NSVZ formula Eq. (46.37).

Worked Example 46.10 (NSVZ for supersymmetric QCD)**.** We assemble the exact beta function for the theory the next section will solve: $\mathcal{N}=1$ supersymmetric QCD, gauge group $\mathrm{SU}(N_c)$ with N_f chiral superfields Q in the fundamental $\square$ and N_f in the antifundamental $\bar{\square}$ (a vectorlike flavor content, one "flavor" being the pair $Q,\tilde{Q}$). For $\mathrm{SU}(N_c)$ the relevant group data, from Appendix B, are $C_A=N_c$ and $T(\square)=T(\bar{\square})=\frac{1}{2}$.

The one-loop coefficient. There are $2N_f$ chiral superfields in fundamental-sized representations, so $\sum_i T(r_i)=2N_f\cdot\frac{1}{2}=N_f$ and

$$b_0 \;=\; 3C_A-\sum_i T(r_i) \;=\; 3N_c-N_f. \tag{46.49}$$

Asymptotic freedom (Theorem 27.11, $b_0>0$) therefore holds for $N_f<3N_c$, and the theory is free in the infrared for $N_f>3N_c$. The boundary $N_f=3N_c$ is where the one-loop coefficient vanishes—the top of the conformal window.

The exact beta function. By flavor symmetry all $2N_f$ matter superfields share a common anomalous dimension $\gamma(g)$, so the numerator of Eq. (46.37) is $3N_c-2N_f\cdot\frac{1}{2}(1-\gamma)=3N_c-N_f(1-\gamma)$, and

$$\beta(g) \;=\; -\frac{g^3}{16\pi^2}\,\frac{3N_c-N_f\,(1-\gamma)}{1-N_c\,g^2/8\pi^2}. \tag{46.50}$$

The Banks–Zaks fixed point and the conformal window. A nontrivial infrared fixed point requires the numerator to vanish at some $g_*\neq 0$, i.e. $3N_c-N_f(1-\gamma(g_*))=0$, which fixes the fixed-point anomalous dimension exactly:

$$\gamma_* \;=\; 1-\frac{3N_c}{N_f}. \tag{46.51}$$

This is an exact statement—no perturbative truncation—because the NSVZ numerator is exact. When N_f is just below $3N_c$, γ_* is small and negative and the fixed point is weakly coupled and reliable; this is the supersymmetric Banks–Zaks fixed point. As N_f decreases, $|\gamma_*|$ grows and the fixed point moves to strong coupling. The fixed point ceases to describe an interacting conformal field theory when the gauge-invariant meson operator $M=\tilde{Q}Q$, of exact dimension $\Delta_M=2+\gamma_*=3-3N_c/N_f$ by Eq. (46.51), would violate the unitarity bound $\Delta\geq 1$ for a scalar; setting $\Delta_M=1$ gives $N_f=\frac{3}{2}N_c$. The conformal window is therefore

$$\tfrac{3}{2}N_c \;<\; N_f \;<\; 3N_c, \tag{46.52}$$

inside which SQCD flows to an interacting superconformal field theory. The exact endpoints Eq. (46.52) are among the cleanest predictions of the whole framework, and they will reappear, from the magnetic side, in the discussion of Seiberg duality.

The dynamical scale. For $N_f < 3N_c$ the theory is asymptotically free with the holomorphic invariant

$$\Lambda^{3N_c - N_f} \;=\; \mu^{3N_c - N_f}\, e^{2\pi i\, \tau(\mu)}, \tag{46.53}$$

the specialization of Eq. (46.28) to $b_0 = 3N_c - N_f$. This complex scale, raised to the power $3N_c - N_f$, is the unique holomorphic gauge-sector invariant; the next section will show that the effective superpotential on the moduli space of SQCD is fixed, by holomorphy and symmetry, to be $\Lambda^{(3N_c - N_f)/(N_c - N_f)}$ times a power of the meson determinant—the Affleck–Dine–Seiberg superpotential.

The gauge coupling, the last coupling holomorphy had not yet touched, is now under exact control. We possess the one-loop-exact running Eq. (46.27) of the holomorphic coupling, its all-orders physical companion Eq. (46.37), and—most importantly for what follows—the holomorphic dynamical scale $\Lambda = \mu\, e^{2\pi i \tau / b_0}$ of Eq. (46.28), the renormalization-group invariant whose phase encodes θ and whose magnitude encodes the strong-coupling scale. This single complex number is the only nonperturbative datum the gauge dynamics hands to the low-energy theory. The next section feeds it, together with holomorphy and the flavor symmetries, into supersymmetric QCD, and reads off the exact effective superpotential on the moduli space—the first place where strong-coupling physics is computed without summing a diagram.

46.3 Dynamically Generated Superpotentials: SQCD and Affleck–Dine–Seiberg

The previous section equipped us with two instruments and a single dimensionful constant. The holomorphic gauge coupling $\tau = \theta/2\pi + 4\pi i/g^2$ runs only at one loop, and that one-loop running can be repackaged, with no loss of information, into a renormalization-group invariant dynamical scale Λ defined through $\Lambda^{b_0} = \mu^{b_0}\, e^{2\pi i \tau(\mu)}$ (Eq. (46.28)), where b_0 is the one-loop coefficient of the holomorphic beta function. For supersymmetric $\mathrm{SU}(N_c)$ gauge theory with N_f flavors that coefficient is $b_0 = 3N_c - N_f$, so that

$$\Lambda^{3N_c - N_f} \;=\; \mu^{3N_c - N_f}\, e^{2\pi i \tau(\mu)} \;=\; \mu^{3N_c - N_f}\, e^{-8\pi^2/g^2(\mu) + i\theta} \tag{46.54}$$

is a holomorphic, μ-independent, complex combination of the running coupling and the vacuum angle. The pure gauge sector of Section 42.4 carried this scale but had no flat directions on which a superpotential could live. The moment we add matter, that changes. The classical theory acquires a continuous space of degenerate vacua—a moduli space—and the strong dynamics, communicating through Λ, can lift it. The purpose of this section is to determine, exactly and without summing a single perturbative diagram, the effective superpotential

that the non-perturbative dynamics generates on that moduli space. The engine is holomorphy: a superpotential is a holomorphic function of the light chiral fields and of Λ, and the symmetries of the theory, treated as selection rules on holomorphic functions, will turn out to fix it completely up to one number, which a single instanton then pins down.

46.3.1 The classical moduli space of SQCD

We work with the supersymmetric QCD of Section 45.3.3: gauge group $\mathrm{SU}(N_c)$, and N_f "flavors" of matter, each flavor consisting of a chiral superfield Q in the fundamental $\mathbf{N_c}$ and a chiral superfield $\widetilde{Q}$ in the antifundamental $\overline{\mathbf{N_c}}$. We index the color by $a = 1, \ldots, N_c$ and the flavor by $i = 1, \ldots, N_f$, so the matter content is the pair of matrices of chiral superfields

$$Q^a{}_i, \qquad \widetilde{Q}_a{}^i, \qquad a = 1, \ldots, N_c, \quad i = 1, \ldots, N_f, \tag{46.55}$$

with no tree-level superpotential, $W_{\text{tree}} = 0$. We take the theory massless and (for the first part of the analysis) in the asymptotically free, would-be-confining window $N_f < 3N_c$, $b_0 = 3N_c - N_f > 0$. The lowest components of Q and $\widetilde{Q}$ are the squark scalars, which we denote by the same symbols when no confusion arises.

Symmetries. With $W_{\text{tree}} = 0$ the classical action has the largest symmetry it can have. The kinetic terms are invariant under independent unitary rotations of the N_f flavors of Q and of the N_f flavors of $\widetilde{Q}$, together with two commuting $\mathrm{U}(1)$ phase rotations and an R-symmetry under which the Grassmann coordinate θ is charged. The global symmetry group is

$$G_{\text{global}} = \mathrm{SU}(N_f)_L \times \mathrm{SU}(N_f)_R \times \mathrm{U}(1)_B \times \mathrm{U}(1)_A \times \mathrm{U}(1)_R, \tag{46.56}$$

under which Q transforms as $(\mathbf{N_f}, \mathbf{1})$ and $\widetilde{Q}$ as $(\mathbf{1}, \overline{\mathbf{N_f}})$ of the flavor group, with abelian charges collected in Table 46.1. Here $\mathrm{U}(1)_B$ is baryon number (Q charge $+1$, $\widetilde{Q}$ charge -1), $\mathrm{U}(1)_A$ is the axial phase common to both ($Q, \widetilde{Q}$ charge $+1$), and $\mathrm{U}(1)_R$ is the R-symmetry under which the gauginos carry charge $+1$. Of these, $\mathrm{U}(1)_A$ and the naive $\mathrm{U}(1)_R$ are anomalous: an axial rotation rotates the path-integral measure exactly as in Section 42.6.2, shifting the vacuum angle. We will exploit precisely this anomaly. Two combinations are anomaly-free: $\mathrm{U}(1)_B$, and the particular R-symmetry whose charge assignment we now fix.

The non-anomalous R-charge follows from cancellation of the mixed $\mathrm{SU}(N_c)^2$–$\mathrm{U}(1)_R$ anomaly, the supersymmetric analogue of the triangle condition of Section 37.3. The fermions charged under both are the gaugino (one Weyl fermion in the adjoint, R-charge $+1$, Dynkin index $T(\text{adj}) = C_A = N_c$) and the $2N_f$ quark Weyl fermions $\psi_Q, \psi_{\widetilde{Q}}$ (each in the fundamental, $T(\mathbf{N_c}) = \frac{1}{2}$, with R-charge

	$\mathrm{SU}(N_f)_L$	$\mathrm{SU}(N_f)_R$	$\mathrm{U}(1)_B$	$\mathrm{U}(1)_A$	$\mathrm{U}(1)_R$
Q	$\mathbf{N_f}$	$\mathbf{1}$	$+1$	$+1$	$\dfrac{N_f - N_c}{N_f}$
$\widetilde{Q}$	$\mathbf{1}$	$\overline{\mathbf{N_f}}$	-1	$+1$	$\dfrac{N_f - N_c}{N_f}$
W^α (gauginos)	$\mathbf{1}$	$\mathbf{1}$	0	0	$+1$
$\Lambda^{3N_c - N_f}$	$\mathbf{1}$	$\mathbf{1}$	0	$2N_f$	0

Table 46.1: Charges of the SQCD chiral superfields under the abelian global symmetries. The R-charges of $Q, \widetilde{Q}$ are fixed by demanding that $\mathrm{U}(1)_R$ be anomaly-free (Eq. (46.57)). The last row records the charges carried by the holomorphic scale Λ^{b_0}, read off from the anomalous shift of the measure (Eq. (46.58)); these make Λ^{b_0} the spurion that restores the broken $\mathrm{U}(1)_A$ and $\mathrm{U}(1)_R$ as exact selection rules.

$R[Q] - 1$ since a chiral superfield's fermion carries one less unit of R than its scalar). The mixed anomaly is proportional to the sum of $T(r) \times R(\text{fermion})$ over all charged Weyl fermions,

$$N_c \cdot (+1) \;+\; 2N_f \cdot \tfrac{1}{2} \cdot \big(R[Q] - 1\big) \;=\; 0 \quad \Longrightarrow \quad R[Q] = R[\widetilde{Q}] = \frac{N_f - N_c}{N_f}, \tag{46.57}$$

which is the entry in Table 46.1.

The scale as a spurion. The two anomalous symmetries are not lost; they become *exact selection rules carried by the coupling*. Under an axial rotation $Q, \widetilde{Q} \to e^{i\alpha} Q, e^{i\alpha} \widetilde{Q}$, the fermionic measure produces the shift of the vacuum angle computed in Eq. (42.172). With $2N_f$ charged Weyl fermions (counting Q and $\widetilde{Q}$ over all flavors), each of unit axial charge, the angle shifts by $\theta \to \theta + 2N_f \alpha$. Through Eq. (46.54) this is the statement that the holomorphic scale transforms,

$$\Lambda^{3N_c - N_f} \;\longrightarrow\; e^{\,2iN_f \alpha}\, \Lambda^{3N_c - N_f}, \tag{46.58}$$

i.e. Λ^{b_0} carries axial charge $+2N_f$ and vanishing B- and (non-anomalous) R-charge. This is the last row of Table 46.1. The logic, due to Seiberg, is that if we formally assign Λ^{b_0} these charges and treat it as a background (spurion) field, then *every* symmetry in Eq. (46.56), including the anomalous ones, becomes an exact invariance of the theory. Any quantity the dynamics generates—in particular any effective superpotential—must respect all of them. That is an enormously restrictive constraint on a holomorphic object, and it is the whole game.

D-flat directions. The scalar potential of a supersymmetric gauge theory with $W_{\text{tree}} = 0$ is purely a D-term,

$$V = \frac{1}{2}\sum_a \left(D^a\right)^2, \qquad D^a = g\Big(Q^\dagger\, T^a\, Q - \widetilde{Q}\, T^a\, \widetilde{Q}^\dagger\Big), \tag{46.59}$$

where the trace is over color and flavor as appropriate and T^a are the fundamental generators. Supersymmetric vacua are the zeros of V, i.e. the D-flat configurations $D^a = 0$ for all a. These are not isolated points: there is a continuous family of squark expectation values solving $D^a = 0$, and that family, modulo gauge transformations, is the classical moduli space—a moduli space of degenerate vacua in exactly the sense introduced for scalar potentials in Theorem 29.6, now realized by the flat directions of the gauge D-term. The general D-flat solution is found by a standard linear-algebra argument. Write the squark VEVs as the $N_c \times N_f$ matrices $\langle Q\rangle$ and $\langle\widetilde{Q}\rangle$. Using a color-flavor rotation, the most general D-flat configuration for $N_f < N_c$ can be brought to the diagonal form

$$\langle Q\rangle = \begin{pmatrix} v_1 & & \\ & \ddots & \\ & & v_{N_f} \\ 0 & & \end{pmatrix}, \qquad \langle\widetilde{Q}\rangle^{\mathsf{T}} = \begin{pmatrix} \widetilde{v}_1 & & \\ & \ddots & \\ & & \widetilde{v}_{N_f} \\ 0 & & \end{pmatrix},$$
$$|v_i|^2 - |\widetilde{v}_i|^2 = \text{const (independent of } i). \tag{46.60}$$

The constant is set to zero in the genuinely flat (zero-energy) directions, so $|v_i| = |\widetilde{v}_i|$ along the moduli space. The remaining v_i are arbitrary complex numbers, the coordinates of the moduli space.

Gauge-invariant coordinates: the chiral ring. Physics depends only on gauge-invariant data, so the right coordinates on the moduli space are the gauge-invariant holomorphic polynomials in $Q, \widetilde{Q}$—the generators of the chiral ring. For $N_f < N_c$ the only invariants one can build are the *mesons*, the color-contracted bilinears

$$M^i{}_j \;=\; \widetilde{Q}_a{}^i\, Q^a{}_j, \qquad i,j = 1,\dots,N_f, \tag{46.61}$$

an $N_f \times N_f$ matrix of chiral superfields. (When $N_f \geq N_c$ one can in addition form the *baryons* $B^{i_1\dots i_{N_c}} = \epsilon_{a_1\dots a_{N_c}} Q^{a_1}{}_{i_1}\cdots Q^{a_{N_c}}{}_{i_{N_c}}$ and the antibaryons $\widetilde{B}$ from $\widetilde{Q}$; for $N_f < N_c$ the color ϵ-tensor cannot be saturated by fewer than N_c fundamentals, so baryons do not exist and the mesons alone coordinatize the moduli space.) On the D-flat locus Eq. (46.60) the meson matrix evaluates to $M^i{}_j = \widetilde{v}_i v_i\, \delta^i{}_j$, a diagonal matrix whose N_f entries are independent holomorphic combinations of the VEVs; the $\mathrm{SU}(N_f)_L \times \mathrm{SU}(N_f)_R$ flavor rotations then fill out the full matrix M.

Worked Example 46.11 (Dimension of the classical moduli space for $N_f < N_c$)**.** We count the complex dimension of the moduli space two ways and check they agree. First, the field-theoretic count. The squark fields $Q, \widetilde{Q}$ contain $2N_fN_c$ complex scalars. At a generic point of Eq. (46.60) the gauge group is Higgsed: N_f fundamental VEVs break $\mathrm{SU}(N_c) \to \mathrm{SU}(N_c - N_f)$, because the VEVs span an N_f-dimensional subspace of color and the unbroken subgroup is the $\mathrm{SU}(N_c - N_f)$ acting on the orthogonal complement. The number of broken generators is

$$\dim \mathrm{SU}(N_c) - \dim \mathrm{SU}(N_c - N_f) = (N_c^2 - 1) - \big((N_c - N_f)^2 - 1\big) = 2N_cN_f - N_f^2. \tag{46.62}$$

By the supersymmetric Higgs mechanism each broken generator eats one entire chiral superfield (a complex scalar) to build a massive vector multiplet. The complex dimension of the moduli space is therefore

$$\dim_{\mathbb{C}} \mathcal{M} = 2N_fN_c - (2N_cN_f - N_f^2) = N_f^2. \tag{46.63}$$

Second, the invariant count. The mesons $M^i{}_j$ form an arbitrary $N_f \times N_f$ complex matrix, hence N_f^2 complex parameters. For $N_f < N_c$ there are no further invariants (no baryons), and the map from D-flat squark configurations modulo gauge transformations to meson matrices is one-to-one on the generic locus. The two counts agree: $\dim_{\mathbb{C}} \mathcal{M} = N_f^2$, parametrized cleanly by the gauge-invariant meson matrix M. This is the statement that, classically, *the entire low-energy physics on the moduli space is the dynamics of the massless chiral superfield* M.

The conclusion of the classical analysis is that for $N_f < N_c$ the light degrees of freedom on the moduli space are exactly the N_f^2 mesons $M^i{}_j$, with a classical superpotential that vanishes identically. The classical vacua are exactly degenerate: nothing chooses a value of M. The question is whether the quantum dynamics lifts this degeneracy, and the answer is encoded in an effective superpotential $W_{\text{eff}}(M, \Lambda)$.

46.3.2 Holomorphy and symmetry fix the superpotential

We now determine $W_{\text{eff}}(M, \Lambda)$. The argument rests on three facts, each established earlier in the book, and a clean piece of complex analysis.

(i) Holomorphy. The effective superpotential is a holomorphic function of the light chiral superfield M and of the holomorphic coupling, the latter entering only through $\Lambda^{b_0} = \Lambda^{3N_c - N_f}$ (Eq. (46.28)). It cannot depend on $M^\dagger$, on $\bar{\Lambda}$, or on the gauge coupling except through the holomorphic combination Λ^{b_0}. This is the nonrenormalization statement of Theorem 45.20, sharpened: W is a section of a holomorphic line bundle over field space and coupling space, and the only holomorphic invariant data are M and Λ^{b_0}.

(ii) Flavor symmetry. W_{eff} must be a singlet of $\mathrm{SU}(N_f)_L \times \mathrm{SU}(N_f)_R$. Under these the meson matrix transforms as $M \to U_L\, M\, U_R^\dagger$, and the only holomorphic flavor invariant one can build from a single matrix M is its determinant $\det M$ (and powers thereof; the trace $\mathrm{tr}\, M$ is not invariant under the full $\mathrm{SU}(N_f)_L \times \mathrm{SU}(N_f)_R$ because $U_L \neq U_R$). Hence W_{eff} depends on M only through $\det M$:

$$W_{\text{eff}} = W_{\text{eff}}\big(\det M,\ \Lambda^{b_0}\big). \tag{46.64}$$

(iii) Abelian selection rules. W_{eff} must carry the correct charges under $\mathrm{U}(1)_B$, $\mathrm{U}(1)_A$, and $\mathrm{U}(1)_R$, with Λ^{b_0} treated as the charged spurion of Table 46.1. A superpotential is the $\theta\theta$ (F-term) integrand, $\int \mathrm{d}^2\theta\, W$; since $\mathrm{d}^2\theta$ carries R-charge -2 (because θ has R-charge $+1$), invariance of the action $\int \mathrm{d}^2\theta\, W$ forces

$$R[W_{\text{eff}}] = 2, \tag{46.65}$$

while W_{eff} must be neutral under the non-R abelian symmetries $\mathrm{U}(1)_B$ and $\mathrm{U}(1)_A$.

Read off the charges of the two available building blocks. From Table 46.1, the meson $M = \widetilde{Q}Q$ has B-charge 0, axial charge $+2$, and R-charge $2(N_f - N_c)/N_f$. Its determinant, a product of N_f eigenvalues, carries N_f times these:

$$B[\det M] = 0, \qquad A[\det M] = 2N_f, \qquad R[\det M] = 2(N_f - N_c). \tag{46.66}$$

The scale carries $B[\Lambda^{b_0}] = 0$, $A[\Lambda^{b_0}] = 2N_f$, $R[\Lambda^{b_0}] = 0$ (last row of Table 46.1). Write the most general holomorphic monomial,

$$W_{\text{eff}} = C\,(\Lambda^{b_0})^{\,p}\,(\det M)^{\,q}, \tag{46.67}$$

with C a dimensionless number and p, q to be determined. Baryon number is automatically zero. The remaining two selection rules give two linear equations:

$$A: \quad 2N_f\, p + 2N_f\, q = 0 \qquad \Longrightarrow \qquad p = -q, \tag{46.68}$$

$$R: \quad 0 \cdot p + 2(N_f - N_c)\, q = 2 \qquad \Longrightarrow \qquad q = \frac{1}{N_f - N_c} = -\frac{1}{N_c - N_f}. \tag{46.69}$$

Thus $q = -1/(N_c - N_f)$ and $p = +1/(N_c - N_f)$, and Eq. (46.67) becomes

$$\boxed{W_{\text{ADS}} \;=\; C_{N_c,N_f} \left(\frac{\Lambda^{\,3N_c - N_f}}{\det M} \right)^{\frac{1}{N_c - N_f}}} \tag{46.70}$$

the Affleck–Dine–Seiberg superpotential. Both nontrivial structures the blueprint owes have now been *derived* rather than quoted: the exponent $1/(N_c - N_f)$ is forced by the R-charge equation Eq. (46.69), and the power $3N_c - N_f$ of Λ is forced jointly by the axial equation Eq. (46.68) (which set $p = -q$) and by the value $b_0 = 3N_c - N_f$ that defines the holomorphic scale in Eq. (46.54).

Remark 46.12 (Why a single term, and the dimensional check). Holomorphy plus the two abelian charges leave *exactly one* monomial: the linear system Eq. (46.68)–Eq. (46.69) has a unique solution for (p, q), so no second invariant term can be added with different powers, and no analytic function beyond the single monomial Eq. (46.70) is allowed. (A would-be additive constant, or a positive power of $\det M$, would carry the wrong R-charge; a function of the dimensionless ratio is excluded because that ratio, $\Lambda^{b_0}/\det M$ raised to any other power, fails the charge equations.) The result also passes a dimensional check that uses no symmetry at all. A superpotential has mass dimension 3. The scale Λ and the meson $M = \widetilde{Q}Q$ both have mass dimension: $[\Lambda] = 1$ and, since each squark scalar has dimension 1, $[M] = 2$, so $[\det M] = 2N_f$. Then

$$[W_{\text{ADS}}] = \frac{(3N_c - N_f)\cdot 1 - 2N_f}{N_c - N_f} = \frac{3N_c - 3N_f}{N_c - N_f} = 3, \tag{46.71}$$

exactly as required. Holomorphy, symmetry, and dimensions are mutually consistent and conspire to leave a single answer up to the pure number C_{N_c,N_f}.

What we have not fixed is the coefficient C_{N_c,N_f}, and crucially whether it is zero. Symmetry forbids everything except Eq. (46.70); it cannot tell us that the dynamics actually generates that term. For that we need an honest dynamical computation. The cleanest case is $N_f = N_c - 1$, where the exponent is unity and—as we now show—the gauge symmetry is completely broken at a generic point of the moduli space, so the theory is weakly coupled and a single instanton does the job.

46.3.3 The one-instanton computation for $N_f = N_c - 1$

For $N_f = N_c - 1$ the ADS superpotential Eq. (46.70) simplifies dramatically. The exponent is $1/(N_c - N_f) = 1$ and the power of the scale is $3N_c - N_f = 3N_c - (N_c - 1) = 2N_c + 1$, so

$$W_{\text{ADS}}\Big|_{N_f = N_c - 1} = C_{N_c,N_c-1}\,\frac{\Lambda^{2N_c+1}}{\det M}. \tag{46.72}$$

We will establish that $C_{N_c,N_c-1} \neq 0$ by a one-instanton calculation, identify the physical origin of every factor, and explain in what precise sense C is then a convention.

Worked Example 46.13 (A single instanton generates Eq. (46.72))**. Setup: complete Higgsing.** Take all $N_f = N_c - 1$ flavors to acquire a common large VEV, $\langle Q\rangle = \langle\widetilde{Q}\rangle^{\mathsf{T}} = v\,\mathbf{1}_{(N_c-1)\times(N_c-1)}$ embedded as in Eq. (46.60), so that $M^i{}_j = v^2\,\delta^i{}_j$ and $\det M = v^{2(N_c-1)}$. With $N_c - 1$ fundamental VEVs the gauge group is broken all the way,

$$\mathrm{SU}(N_c) \;\longrightarrow\; \mathrm{SU}(N_c - (N_c - 1)) = \mathrm{SU}(1) = \{\mathbf{1}\}, \tag{46.73}$$

i.e. *completely*: every gauge boson acquires a mass $\sim gv$. For $v \gg \Lambda$ the running coupling is frozen at the weak value $g(v) \ll 1$ before the theory can become strong, the instanton expansion parameter $e^{-8\pi^2/g^2(v)}$ is small and controlled, and the semiclassical computation of Section 42.3 is reliable. There is no strongly coupled subgroup left to worry about; the only non-perturbative effect is the instanton of the original $\mathrm{SU}(N_c)$, now living in a Higgsed background.

Fermion zero modes. In the one-instanton ($Q = 1$) background of Theorem 42.17 we count the fermionic zero modes of every field, using the index theorem Theorem 42.35. A Weyl fermion in a representation r has $2\,T(r)\,|Q|$ zero modes. Thus:

- the gaugino λ (adjoint, $T(\mathrm{adj}) = N_c$) contributes $2N_c$ zero modes;
- each quark fermion ψ_Q and $\psi_{\widetilde{Q}}$ (fundamental, $T(\mathbf{N_c}) = \frac{1}{2}$) contributes $2 \cdot \frac{1}{2} = 1$ zero mode, and there are N_f of each, hence $2N_f = 2(N_c - 1)$ quark zero modes in all.

The total fermionic zero-mode count is $2N_c + 2(N_c - 1) = 4N_c - 2$. For the Berezin integral over collective coordinates to be nonzero, *every* zero mode must be saturated—either by an external field insertion or by a vertex from the action that ties two of them together.

Saturating the gaugino modes with the Yukawa coupling. The $2N_c$ gaugino zero modes cannot all be left as external legs if we want the leading effect; the supersymmetric gauge-matter Yukawa coupling

$$\mathcal{L} \supset -\sqrt{2}\, g\, (\widetilde{Q}^\dagger\, \lambda\, \psi_{\widetilde{Q}} + Q^\dagger\, \lambda\, \psi_Q) + \mathrm{h.c.} \tag{46.74}$$

soaks them up. Each insertion of Eq. (46.74) converts one gaugino zero mode and one quark zero mode into a squark field $Q^\dagger$ or $\widetilde{Q}^\dagger$, evaluated on its VEV v. In the completely Higgsed vacuum the squark fields carry the VEV v, so each such vertex brings down a factor of v and pairs a λ-mode with a ψ-mode. Counting modes: of the $2N_c$ gaugino modes, all are removed by such vertices; of the $2(N_c - 1)$ quark modes, $2N_c - 2(N_c - 1) = 2$ remain after pairing with gauginos.[1] The two surviving quark zero modes, one from ψ_Q and one from $\psi_{\widetilde{Q}}$, are the external fermion legs of the generated operator; supersymmetry promotes the operator they sit in to a full superspace F-term, so the resulting contribution to the effective action is a superpotential term.

Assembling the powers. Collect the dimensionful factors of the one-instanton amplitude. The exponential and coupling prefactor of Eq. (42.143)

[1] The bookkeeping is the supersymmetric refinement of the 't Hooft vertex of Theorem 42.38: there, with no Yukawa coupling to the gaugino available in non-supersymmetric QCD, all quark zero modes appear as external legs and the gaugino modes are lifted by the gauge-boson mass; here the gauge-Yukawa Eq. (46.74) is precisely the operator that ties the gaugino modes to squark VEVs.

combine, via the one-loop running $e^{-8\pi^2/g^2(\mu)} = (\Lambda/\mu)^{b_0}$ with $b_0 = 2N_c + 1$ (the supersymmetric coefficient), into a factor Λ^{2N_c+1} once the powers of μ are traded for the running scale exactly as in Eq. (42.146). The squark VEV insertions that saturated the gaugino modes bring down powers of v. Rather than track the combinatoric constant (which feeds into C), we fix the v-power by holomorphy and dimensions, which is unambiguous. The generated superpotential must (a) be holomorphic in Λ^{2N_c+1} and in the mesons, (b) have dimension 3, and (c) reduce on this VEV to a function of $\det M = v^{2(N_c-1)}$. The only possibility consistent with the linear appearance of one instanton factor Λ^{2N_c+1} is

$$W_{\text{inst}} = C\,\frac{\Lambda^{2N_c+1}}{v^{2(N_c-1)}} = C\,\frac{\Lambda^{2N_c+1}}{\det M}, \tag{46.75}$$

which is exactly Eq. (46.72). The dimensional check is the same as Eq. (46.71): $[\Lambda^{2N_c+1}] = 2N_c + 1$, $[\det M] = 2(N_c - 1)$, difference $= 3$. The content of the explicit calculation is that the coefficient of Eq. (46.75) is *nonzero*: a careful evaluation of the instanton measure (the collective-coordinate Jacobians of Section 42.3.4, the regulated nonzero-mode determinant, and the zero-mode wavefunction normalizations) yields a finite, nonvanishing number. The dynamics genuinely generates the ADS term; it is not merely permitted by symmetry.

Why C is then a convention. The precise value of C_{N_c,N_c-1} depends on the renormalization scheme through the definition of Λ in Eq. (46.54): a finite redefinition $\Lambda \to c\,\Lambda$ rescales the prefactor, so different schemes (Pauli–Villars, $\overline{\text{MS}}$, the holomorphic scheme) assign different numbers. It is therefore conventional to *define* the scale Λ in the $N_f = N_c - 1$ theory so that

$$C_{N_c,N_c-1} = 1, \tag{46.76}$$

which we adopt. What is scheme-*independent*, and is the physical output of the computation, is that $C \neq 0$.

Physical Insight: gaugino condensation for $N_f < N_c - 1$

For $N_f < N_c - 1$ the exponent $1/(N_c - N_f)$ is no longer an integer, so the ADS superpotential Eq. (46.70) is *fractional* in Λ^{b_0} and cannot be generated by any number of ordinary instantons (whose contributions come in integer powers of $\Lambda^{b_0} = e^{2\pi i\tau}$). Its origin is instead *gaugino condensation*. At a generic point of the moduli space the gauge group is Higgsed $\text{SU}(N_c) \to \text{SU}(N_c - N_f)$ with all flavors massive; the surviving $\text{SU}(N_c - N_f)$ pure super-Yang–Mills theory has no light matter and confines, and its gauginos condense, $\langle\lambda\lambda\rangle \sim \Lambda_L^3$, where Λ_L is the low-energy scale of the unbroken group. Matching Λ_L to the high-energy data through the running across the squark thresholds reproduces precisely the fractional power $(\Lambda^{b_0}/\det M)^{1/(N_c-N_f)}$: the $(N_c - N_f)$-th root is the

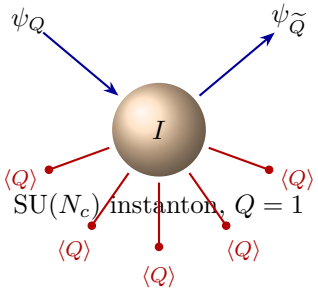

Figure 46.3: The one-instanton origin of the ADS superpotential for $N_f = N_c - 1$. The $Q = 1$ instanton carries $2N_c$ gaugino zero modes (red) and $2(N_c - 1)$ quark zero modes; the gauge–Yukawa vertex Eq. (46.74) ties each gaugino mode to a squark VEV $\langle Q\rangle = v$, leaving two external quark legs $\psi_Q, \psi_{\widetilde{Q}}$ (blue). Supersymmetry promotes the result to the F-term Eq. (46.72), with strength $\Lambda^{2N_c+1}/\det M$ and a nonzero coefficient.

imprint of the single gaugino condensate of the SU($N_c - N_f$) factor, whose strong scale is the $(N_c - N_f)$-th root of an instanton factor. Instantons ($N_f = N_c - 1$) and gaugino condensation ($N_f < N_c - 1$) are thus two faces of the same holomorphic object Eq. (46.70), distinguished only by whether the exponent is integer or fractional.

46.3.4 Reading off the physics: runaway, mass deformation, and gaugino condensation

The exact superpotential Eq. (46.70) is not an academic object; its derivatives determine the vacuum structure, and they tell a sharp and initially disturbing story.

No vacuum: the runaway. Supersymmetric vacua require the F-flatness conditions $\partial W/\partial M = 0$ together with D-flatness. Compute the F-term of the meson from Eq. (46.70), using $\partial(\det M)/\partial M^i{}_j = (\det M)(M^{-1})^j{}_i$:

$$\frac{\partial W_{\text{ADS}}}{\partial M^i{}_j} = -\frac{1}{N_c - N_f}\, W_{\text{ADS}}\, (M^{-1})^j{}_i. \tag{46.77}$$

Since $W_{\text{ADS}} \neq 0$ for any finite, nonsingular M, and M^{-1} never vanishes, the F-term is nonzero *everywhere on the moduli space*. There is no solution of $\partial W/\partial M = 0$ at finite M: the classical degeneracy is lifted, and lifted in the worst possible way—no supersymmetric vacuum survives at any finite field value.

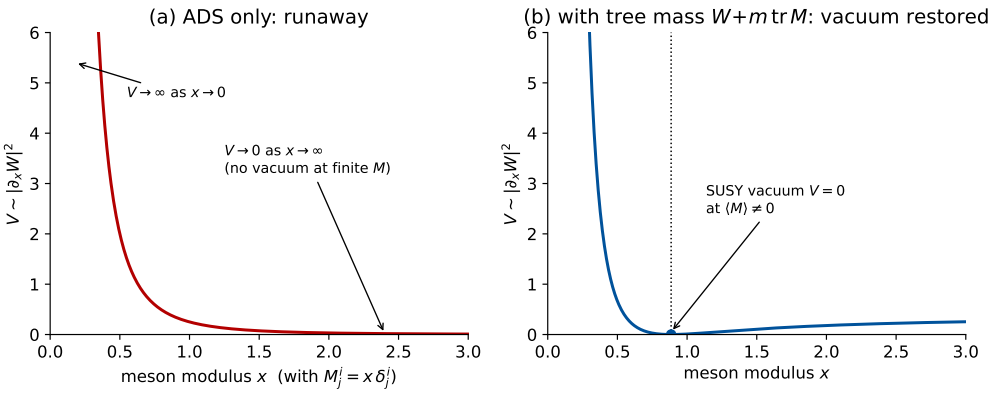

Figure 46.4: The Affleck–Dine–Seiberg scalar potential along the flavor-symmetric meson ray $M^i{}_j = x\,\delta^i{}_j$ (schematic normalization; the qualitative features are fixed by the F-flatness condition, which depends only on the holomorphic superpotential). **(a)** The pure ADS superpotential Eq. (46.70): the potential diverges at the origin and runs monotonically to zero at large field, with no minimum—there is no supersymmetric vacuum. **(b)** Adding a tree-level mass $W = W_{\mathrm{ADS}} + m\ \mathrm{tr}\,M$ stabilizes the runaway: the competition between the falling ADS term and the rising mass term produces an isolated minimum at $\langle M \rangle \neq 0$ where $V = 0$, a genuine supersymmetric vacuum.

The scalar potential, $V = K^{i\bar{\jmath}}\,\partial_i W\,\overline{\partial_j W}$ with K the (positive, nondegenerate, but not holomorphically protected) Kähler metric on the moduli space, is strictly positive and slopes monotonically. To see its shape, restrict to the flavor-symmetric ray $M^i{}_j = x\,\delta^i{}_j$ so that $\det M = x^{N_f}$ and $W_{\mathrm{ADS}} \propto x^{-N_f/(N_c-N_f)}$; then $V \propto |\partial_x W|^2 \propto x^{-2N_f/(N_c-N_f)-2}$, a function that *diverges as* $x \to 0$ *and decreases monotonically to zero as* $x \to \infty$. The potential pushes the meson VEV to infinity, where supersymmetry is restored only asymptotically and the theory becomes free; there is no stable ground state at any finite coupling. This is the celebrated ADS *runaway*, plotted in Fig. 46.4(a).

Restoring a vacuum by a mass deformation. The runaway is cured by adding a tree-level mass for the quarks, a holomorphic deformation that gives the meson a classical superpotential. Take a common mass m for all flavors, $W_{\mathrm{tree}} = m\,\widetilde{Q}Q = m\ \mathrm{tr}\,M$, so the total superpotential is

$$W = W_{\mathrm{ADS}} + m\ \mathrm{tr}\,M = C_{N_c,N_f}\left(\frac{\Lambda^{3N_c-N_f}}{\det M}\right)^{\frac{1}{N_c-N_f}} + m\ \mathrm{tr}\,M. \tag{46.78}$$

Now the falling ADS term competes with the rising mass term and the potential develops a minimum (Fig. 46.4(b)). The F-flatness condition $\partial W/\partial M^i{}_j = 0$

reads, using Eq. (46.77),

$$-\frac{1}{N_c-N_f}\,W_{\rm ADS}\,(M^{-1})^{j}{}_{i}+m\,\delta^{j}{}_{i}=0 \quad\Longrightarrow\quad M^{i}{}_{j}=\frac{W_{\rm ADS}}{m(N_c-N_f)}\,\delta^{i}{}_{j}, \tag{46.79}$$

so the meson VEV is flavor-diagonal, $\langle M^{i}{}_{j}\rangle = X\,\delta^{i}{}_{j}$ with X a single unknown. Substituting $\det M = X^{N_f}$ and $W_{\rm ADS} = C(\Lambda^{3N_c-N_f}/X^{N_f})^{1/(N_c-N_f)}$ back into Eq. (46.79) gives one algebraic equation for X,

$$X=\frac{C}{m(N_c-N_f)}\,\frac{\Lambda^{(3N_c-N_f)/(N_c-N_f)}}{X^{\,N_f/(N_c-N_f)}}, \tag{46.80}$$

where X enters linearly on the left because the F-flatness condition Eq. (46.79) fixes X itself. Multiplying through by $X^{\,N_f/(N_c-N_f)}$ and using $1+\frac{N_f}{N_c-N_f}=\frac{N_c}{N_c-N_f}$, this rearranges to $X^{\,N_c/(N_c-N_f)}\propto m^{-1}\Lambda^{(3N_c-N_f)/(N_c-N_f)}$, equivalently $X^{\,N_c}\propto m^{-(N_c-N_f)}\Lambda^{3N_c-N_f}$, i.e.

$$\langle M^{i}{}_{j}\rangle=\big(\det M\big)^{1/N_f}\,\delta^{i}{}_{j}, \qquad \langle\det M\rangle=\left(\frac{C}{m(N_c-N_f)}\right)^{\frac{N_f(N_c-N_f)}{N_c}}\Lambda^{\frac{N_f(3N_c-N_f)}{N_c}}, \tag{46.81}$$

after collecting the exponents (from $X^{N_c/(N_c-N_f)}\propto m^{-1}\Lambda^{(3N_c-N_f)/(N_c-N_f)}$ one finds $X\propto m^{-(N_c-N_f)/N_c}\Lambda^{(3N_c-N_f)/N_c}$, and $\det M = X^{N_f}$ raises both factors to the power N_f, giving the Λ power $\frac{N_f(3N_c-N_f)}{N_c}$ and the dimension $2N_f$). The deformation has produced a genuine, isolated supersymmetric vacuum at $\langle M\rangle\neq 0$. Crucially, extracting X from Eq. (46.80) requires taking an N_c-th root: the equation $X^{N_c}\propto m^{-(N_c-N_f)}\Lambda^{3N_c-N_f}$ has N_c solutions differing by the phases $e^{2\pi ik/N_c}$, $k=0,1,\dots,N_c-1$. There are therefore exactly

$$N_c \text{ supersymmetric vacua}, \tag{46.82}$$

in agreement with the Witten index of SU(N_c) super-Yang–Mills, $\mathrm{Tr}(-1)^F = N_c$ (the index whose nonzero-energy states pair off and cancel by the $n_B=n_F$ theorem Theorem 44.15, so that it counts only the zero-energy vacua — here Witten's count of N_c). This is a stringent consistency check: the count of vacua produced by holomorphy on the moduli space matches the index computed from the algebra, two completely independent routes to the same integer.

Integrating out: pure super-Yang–Mills and gaugino condensation. Sending $m\to\infty$ decouples all the flavors and leaves pure SU(N_c) super-Yang–Mills below the mass threshold—the $N_f=0$ theory. We can read its dynamics directly off Eq. (46.78) by integrating out M. At the vacuum Eq. (46.81) the value of the superpotential is, using $W_{\rm ADS}=m(N_c-N_f)X=m(N_c-N_f)\langle M\rangle$ from Eq. (46.79) and Eq. (46.82),

$$\langle W\rangle = W_{\rm ADS}+m\,\mathrm{tr}\,M=\big[(N_c-N_f)+N_f\big]\,m\,X=N_c\,m\,X. \tag{46.83}$$

Matching the low-energy scale of the pure SU(N_c) theory by the holomorphic decoupling relation $\Lambda_{\rm SYM}^{3N_c} = m^{N_f}\,\Lambda^{3N_c-N_f}$ (the product of the heavy masses times the high-scale instanton factor, fixed by continuity of the holomorphic coupling across the threshold), Eq. (46.83) collapses to the pure-gauge effective superpotential

$$\boxed{W_{\rm SYM} = N_c\,\Lambda_{\rm SYM}^3\,e^{2\pi i k/N_c}, \qquad k = 0, 1, \ldots, N_c - 1.} \tag{46.84}$$

This is the Veneziano–Yankielowicz superpotential of pure super-Yang–Mills, with its N_c branches—the N_c vacua of Eq. (46.82), here visible as the N_c-th roots of $\Lambda_{\rm SYM}^{3N_c}$. Its physical content is the gaugino condensate. Identifying the gaugino bilinear with the lowest component of the field-strength superfield through $W_{\rm SYM} = \langle\lambda\lambda\rangle$ up to a constant (the field strength $W^\alpha W_\alpha$ has $\lambda\lambda$ as its scalar component, and $\Lambda_{\rm SYM}^3$ is its expectation value), we read off

$$\langle\lambda\lambda\rangle \;\sim\; \Lambda_{\rm SYM}^3\,e^{2\pi i k/N_c}, \tag{46.85}$$

the order parameter for the spontaneous breaking of the discrete R-symmetry $\mathbb{Z}_{2N_c} \to \mathbb{Z}_2$ that the anomaly leaves unbroken: the $2N_c$-fold degeneracy of the phase collapses to N_c inequivalent values. The dynamical scale Λ, which entered as a bookkeeping device for the one-loop running, has reappeared as the magnitude of a genuine, computable condensate.

Physical Insight: the SUSY-calculable face of the chiral condensate

Equation Eq. (46.85) is the supersymmetric analogue of the quark condensate $\langle\bar{q}q\rangle \sim \Lambda_{\rm QCD}^3$ that underlies confinement and chiral symmetry breaking in ordinary QCD (Yang–Mills theory; the Wilson-loop area law of Theorem 27.20 and the chiral dynamics of Chapter 39). In non-supersymmetric QCD the condensate is a number we can only estimate or measure on the lattice; here, because holomorphy protects the superpotential and the symmetries fix it completely, the analogous condensate is computed *exactly*, scale and all, with the N_c-fold vacuum degeneracy following from the same index that counts the super-Yang–Mills ground states. This is the sense in which supersymmetry is a controlled laboratory for confinement-scale physics: the strong-coupling condensate that we can only model in QCD is, in its supersymmetric cousin, a theorem.

We have now extracted the complete non-perturbative dynamics of SU(N_c) SQCD with $N_f < N_c$ flavors: a classical moduli space of mesons, an exactly determined ADS superpotential generated by instantons ($N_f = N_c - 1$) or gaugino condensation ($N_f < N_c - 1$), a runaway with no stable vacuum, and—upon a mass deformation—exactly N_c supersymmetric vacua tied to the gaugino condensate. The natural next question writes itself: what happens as N_f is

increased toward and past N_c? At $N_f = N_c - 1$ the instanton was already on the boundary of integer exponents; at $N_f = N_c$ and beyond the baryons of Eq. (46.61) enter the chiral ring, the runaway disappears, and the moduli space is modified quantum-mechanically rather than lifted. Carrying the N_f-dependent moduli-space data and the ADS result of this section into that regime is exactly what the next section does, where the increasing flavor count reveals the phase structure of SQCD and Seiberg's electric–magnetic duality.

46.4 The Phase Structure of SQCD and Seiberg Duality

The previous section delivered a sharp piece of strong-coupling physics for free. For SU(N_c) supersymmetric QCD with $N_f < N_c$ flavors, holomorphy and the global symmetries forced a unique non-perturbative effective superpotential on the classical moduli space of mesons, the Affleck–Dine–Seiberg superpotential

$$W_{\text{ADS}} \;=\; (N_c - N_f)\left(\frac{\Lambda^{3N_c - N_f}}{\det M}\right)^{\frac{1}{N_c - N_f}}, \tag{46.86}$$

generated by a single instanton when $N_f = N_c - 1$ and by gaugino condensation in the unbroken SU($N_c - N_f$) when $N_f < N_c - 1$ (Section 46.3). Its gradient never vanishes: the meson fields are pushed to infinity, the potential slopes monotonically to zero there, and the theory has *no stable vacuum*. That is the whole story for too few flavors. The natural question is what happens as N_f is increased. The runaway must end somewhere, new light degrees of freedom must appear, and the qualitative infrared physics — whether the theory confines, breaks its chiral symmetries, flows to an interacting scale -invariant theory, or becomes free — must change. This section maps that N_f-dependence completely. The map turns out to be one of the most striking results in four-dimensional field theory: across a wide window the strongly coupled electric theory is exactly equivalent in the infrared to a *different*, weakly coupled magnetic gauge theory. This is Seiberg's electric–magnetic duality, and assembling the evidence for it is the climax of the section.

Throughout we use the conventions fixed in Chapter 45 and Section 46.3. The metric is mostly-minus, the gauge covariant derivative is $D_\mu = \partial_\mu - igA^a_\mu T^a$ with Hermitian generators normalized by $\mathrm{tr}(T^a T^b) = \frac{1}{2}\delta^{ab}$ in the fundamental, and the dynamical scale is Λ, defined through the one-loop running with coefficient $b_0 = 3N_c - N_f$ so that $\Lambda^{b_0} = \mu^{b_0} e^{-8\pi^2/g^2(\mu) + i\theta}$ is the holomorphic instanton factor. We measure the qualitative physics by the single ratio N_f/N_c, summarized in advance in Fig. 46.5.

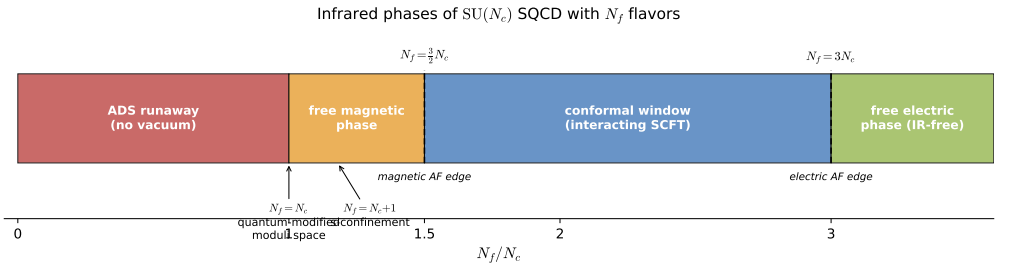

Figure 46.5: The infrared phases of SU(N_c) SQCD as a function of N_f/N_c, the central result of this section. For $N_f < N_c$ the Affleck–Dine–Seiberg superpotential (46.86) drives a runaway with no vacuum. At $N_f = N_c$ the moduli space is quantum-mechanically deformed; at $N_f = N_c + 1$ the theory s-confines with a smooth superpotential. The two edges of the conformal window, $N_f = \frac{3}{2}N_c$ and $N_f = 3N_c$, are exactly the points where the *magnetic* and *electric* gauge couplings respectively sit at the boundary of asymptotic freedom — a coincidence that is itself evidence for the duality.

46.4.1 The fields, the scale, and the global symmetries

We recall the matter content precisely, because every exact statement below is an exercise in tracking its quantum numbers. The theory is SU(N_c) gauge theory coupled to N_f chiral superfields Q^i ($i = 1, \ldots, N_f$) in the fundamental representation $\mathbf{N_c}$ and N_f chiral superfields $\widetilde{Q}_{\tilde{\jmath}}$ ($\tilde{\jmath} = 1, \ldots, N_f$) in the antifundamental $\overline{\mathbf{N_c}}$. We write the color index explicitly only when needed, Q^i_a and $\widetilde{Q}^a_{\tilde{\jmath}}$ with $a = 1, \ldots, N_c$. There is no tree-level superpotential. The classical global symmetry acting on the matter, after removing the part that overlaps with the gauge group, is

$$G_{\rm cl} \;=\; \mathrm{SU}(N_f)_L \times \mathrm{SU}(N_f)_R \times \mathrm{U}(1)_B \times \mathrm{U}(1)_A \times \mathrm{U}(1)_R, \tag{46.87}$$

with Q a fundamental of SU$(N_f)_L$ and $\widetilde{Q}$ an antifundamental of SU$(N_f)_R$. Two of the abelian factors are anomalous in combination: the axial U$(1)_A$ under which Q and $\widetilde{Q}$ both carry charge $+1$ has a mixed U$(1)_A$-SU$(N_c)^2$ triangle, and so does a naive R-symmetry. Exactly one non-anomalous linear combination of these survives as the genuine quantum R-symmetry U$(1)_R$; the orthogonal anomalous combination remains useful as a *spurion*, the bookkeeping device that tracks how Λ^{b_0} transforms.

Fixing U$(1)_R$ is a one-line anomaly computation, and it pins down a charge we will use repeatedly. Under a candidate U$(1)_R$, the gauginos λ in the vector multiplet carry R-charge $+1$ (they sit one Grassmann level above the gauge field, which is R-neutral), and we assign the chiral superfields $Q, \widetilde{Q}$ a common R-charge R_Q, so their fermionic components carry $R_Q - 1$. The mixed U$(1)_R$-SU$(N_c)^2$ anomaly is the sum of R-charge $\times$ (Dynkin index) over all fermions charged under

	$\mathrm{SU}(N_c)$	$\mathrm{SU}(N_f)_L$	$\mathrm{SU}(N_f)_R$	$\mathrm{U}(1)_B$	$\mathrm{U}(1)_R$
Q	$\mathbf{N_c}$	$\mathbf{N_f}$	$\mathbf{1}$	$+1$	$\frac{N_f - N_c}{N_f}$
$\widetilde{Q}$	$\overline{\mathbf{N_c}}$	$\mathbf{1}$	$\overline{\mathbf{N_f}}$	-1	$\frac{N_f - N_c}{N_f}$
$M = \widetilde{Q}Q$	$\mathbf{1}$	$\mathbf{N_f}$	$\overline{\mathbf{N_f}}$	0	$\frac{2(N_f - N_c)}{N_f}$
B	$\mathbf{1}$	$\Lambda^{N_c}\mathbf{N_f}$	$\mathbf{1}$	N_c	$\frac{N_c(N_f - N_c)}{N_f}$

Table 46.2: Non-anomalous global charges of the elementary squarks and of the basic gauge-invariant composites of $\mathrm{SU}(N_c)$ SQCD. The baryon B sits in the rank-N_c antisymmetric power $\Lambda^{N_c}\mathbf{N_f}$ of $\mathrm{SU}(N_f)_L$; the antibaryon $\widetilde{B}$ is its mirror with B-number $-N_c$. The R-charges follow from (46.89) by additivity.

the gauge group,

$$\underbrace{(+1)\,T(\mathrm{adj})}_{\text{gaugino}} + \underbrace{2N_f\,(R_Q-1)\,T(\mathbf{N_c})}_{Q \text{ and } \widetilde{Q}} = N_c + 2N_f\,(R_Q-1)\,\tfrac{1}{2} = N_c + N_f(R_Q-1), \tag{46.88}$$

where we used $T(\mathrm{adj}) = N_c$ and $T(\mathbf{N_c}) = \frac{1}{2}$ from Chapter 2 (Appendix B), and the factor $2N_f$ counts the N_f flavors of Q plus the N_f flavors of $\widetilde{Q}$. Demanding that this vanish gives the unique non-anomalous R-charge of the squarks,

$$\boxed{R_Q = \frac{N_f - N_c}{N_f}} \tag{46.89}$$

We collect the resulting non-anomalous charges in Table 46.2. Every result in this section is consistent with these assignments, and the reader should treat the table as the master key.

46.4.2 Gauge invariants: the chiral ring

The infrared physics on the moduli space is carried by the gauge-invariant holomorphic combinations of $Q, \widetilde{Q}$ — the generators of the *chiral ring*. There are two kinds. The mesons

$$M^i{}_{\tilde{\jmath}} = \widetilde{Q}^a_{\tilde{\jmath}}\, Q^i_a \qquad \text{(color contracted)}, \tag{46.90}$$

form an $N_f \times N_f$ matrix in flavor space, a bifundamental of $\mathrm{SU}(N_f)_L \times \mathrm{SU}(N_f)_R$ with $B = 0$. The baryons antisymmetrize N_c squarks on their color indices,

$$B^{i_1\cdots i_{N_c}} = \frac{1}{N_c!}\,\epsilon^{a_1\cdots a_{N_c}}\, Q^{i_1}_{a_1}\cdots Q^{i_{N_c}}_{a_{N_c}}, \qquad \widetilde{B}_{\tilde{\jmath}_1\cdots\tilde{\jmath}_{N_c}} = \frac{1}{N_c!}\,\epsilon_{a_1\cdots a_{N_c}}\,\widetilde{Q}^{a_1}_{\tilde{\jmath}_1}\cdots\widetilde{Q}^{a_{N_c}}_{\tilde{\jmath}_{N_c}}, \tag{46.91}$$

totally antisymmetric in their N_c flavor indices and hence transforming in the rank-N_c antisymmetric representation $\Lambda^{N_c}\mathbf{N_f}$ of the relevant $\mathrm{SU}(N_f)$ factor, with baryon number $\pm N_c$. For $N_f < N_c$ no such antisymmetrization is possible and only mesons exist; for $N_f = N_c$ there is a single baryon B and a single antibaryon $\widetilde{B}$ (the flavor indices fill completely); for $N_f = N_c + 1$ the baryons carry one free flavor index, $B^i \equiv \epsilon^{ij_1\cdots j_{N_c}} B_{j_1\cdots j_{N_c}}$, an antifundamental of $\mathrm{SU}(N_f)_L$. These multiplicity changes are exactly what makes the phase structure depend so sharply on $N_f - N_c$.

46.4.3 $N_f = N_c$: the quantum-modified moduli space

With exactly $N_f = N_c$ flavors the would-be ADS superpotential (46.86) formally has $N_c - N_f = 0$ in the exponent and ceases to exist: there is no dynamically generated superpotential, the would-be runaway is gone, and the theory has a genuine moduli space of supersymmetric vacua. But the moduli space is not the classical one. To see this we first fix the classical geometry, then determine its exact quantum form by holomorphy and symmetry.

The classical constraint. At $N_f = N_c$ the squark Q^i_a is a square $N_c \times N_c$ matrix in (flavor)×(color), as is $\widetilde{Q}^a_{\tilde{\jmath}}$. The meson matrix is the product $M^i{}_{\tilde{\jmath}} = Q^i_a \widetilde{Q}^a_{\tilde{\jmath}}$, while the single baryon and antibaryon are the determinants

$$B = \det_{(\text{flavor,color})} Q, \qquad \widetilde{B} = \det_{(\text{color,flavor})} \widetilde{Q}, \tag{46.92}$$

which follow from (46.91) once all N_c flavor indices are saturated. The multiplicativity of the determinant then gives an algebraic identity among the invariants,

$$\det M \;=\; \det(Q\widetilde{Q}) \;=\; \det Q \,\det \widetilde{Q} \;=\; B\,\widetilde{B}, \tag{46.93}$$

the *classical constraint* $\det M - B\widetilde{B} = 0$. It cuts out the classical moduli space inside the space of gauge invariants, and in particular the origin $M = B = \widetilde{B} = 0$ is a (singular) point of it, where the full gauge symmetry is restored and the global symmetry G_{cl} is unbroken.

The quantum constraint. The exact statement is that quantum mechanics deforms (46.93) to

$$\boxed{\det M \;-\; B\,\widetilde{B} \;=\; \Lambda^{2N_c}} \tag{46.94}$$

This single equation is derived, not assumed, from holomorphy plus the global symmetries plus the weak-coupling limit, in the same spirit as the ADS derivation. We carry the argument out in full.

Worked Example 46.14 (Deriving the quantum-modified constraint)**.** The deformation of the classical relation can only be a holomorphic function of the chiral invariants $M, B, \widetilde{B}$ and of the holomorphic scale, which at $N_f = N_c$ is $\Lambda^{b_0} = \Lambda^{2N_c}$ (since $b_0 = 3N_c - N_f = 2N_c$). We promote the classical relation to a candidate constraint enforced by a Lagrange-multiplier chiral superfield X,

$$W_{\text{eff}} \;=\; X\,(\det M - B\widetilde{B} - f(\Lambda^{2N_c})), \tag{46.95}$$

and determine the holomorphic function f.

Step 1 — charges of the building blocks. We track the two abelian symmetries that survive as exact selection rules: the non-anomalous $\mathrm{U}(1)_R$ and the anomalous axial $\mathrm{U}(1)_A$ treated as a spurion. Under $\mathrm{U}(1)_A$ with $A(Q) = A(\widetilde{Q}) = +1$, the path-integral measure is not invariant; the $\mathrm{SU}(N_c)$ instanton with $2N_f = 2N_c$ fermion zero modes shifts the effective θ-angle, which means the holomorphic scale carries axial charge

$$A(\Lambda^{2N_c}) \;=\; 2N_f \;=\; 2N_c, \tag{46.96}$$

exactly the number of zero modes the one-instanton vertex must soak up. Now read off the charges of the invariants. The meson $M = \widetilde{Q}Q$ has $A(M) = 2$, so $A(\det M) = N_f \cdot 2 = 2N_c$. The baryons are products of N_c squarks, so $A(B) = A(\widetilde{B}) = N_c$ and $A(B\widetilde{B}) = 2N_c$. Under the non-anomalous $\mathrm{U}(1)_R$, Table 46.2 gives, at $N_f = N_c$, $R(M) = 2(N_f - N_c)/N_f = 0$ and $R(B) = R(\widetilde{B}) = N_c(N_f - N_c)/N_f = 0$, hence $R(\det M) = R(B\widetilde{B}) = 0$, while Λ^{2N_c} is R-neutral by construction.

Step 2 — what the symmetries allow. The three terms $\det M$, $B\widetilde{B}$, and Λ^{2N_c} all carry $A = 2N_c$ and $R = 0$, and all are singlets of $\mathrm{SU}(N_f)_L \times \mathrm{SU}(N_f)_R \times \mathrm{U}(1)_B$. They are therefore interchangeable as far as every selection rule is concerned, and the only holomorphic, symmetry-respecting completion of the classical relation is

$$\det M - B\widetilde{B} \;=\; c\,\Lambda^{2N_c}, \qquad c \text{ a pure number.} \tag{46.97}$$

No higher power of Λ^{2N_c} can appear, because $(\Lambda^{2N_c})^n$ carries $A = 2N_c n$ and there is no invariant of matching axial charge to balance it for $n \neq 1$; this is the same holomorphy-plus-spurion logic that fixed the power of Λ in the ADS superpotential.

Step 3 — fixing the constant and its physical meaning. As $\Lambda \to 0$ the gauge dynamics switches off and (46.97) must reduce to the classical (46.93); this is automatic for any finite c. To show $c \neq 0$ — the crucial physical point — give a large vacuum expectation value to one meson eigenvalue, $\langle M^{N_c}{}_{N_c} \rangle = v^2 \gg \Lambda^2$, breaking $\mathrm{SU}(N_c) \to \mathrm{SU}(N_c - 1)$ and Higgsing one flavor. The low-energy theory is $\mathrm{SU}(N_c - 1)$ with $N_f - 1 = N_c - 1$ flavors, i.e. again the $N_f = N_c$ case one rank down, with a matched scale $\Lambda_{\mathrm{L}}^{2(N_c-1)} = \Lambda^{2N_c}/v^2$ fixed by continuity of the running coupling across the threshold v. Consistency of (46.97) between the two

descriptions forces the *same* nonzero c at every rank, so c is a rank-independent constant; with the standard definition of Λ it is $c = 1$. The cleanest direct check is the one-instanton computation in the fully Higgsed theory $N_f = N_c$, $\langle Q \rangle = \langle \widetilde{Q} \rangle = v\,\mathbf{1}$: the instanton has exactly the right number of zero modes to generate the constant Λ^{2N_c} on the right of (46.94) with unit coefficient. This is the $N_f = N_c$ analogue of the $N_f = N_c - 1$ instanton that generated the ADS superpotential in Section 46.3.

Physical consequences. The deformation (46.94) is small in its algebra and enormous in its physics. The origin $M = B = \widetilde{B} = 0$ *no longer solves the constraint*: $0 - 0 \neq \Lambda^{2N_c}$. The singular point of the classical moduli space, where unbroken color and unbroken global symmetry coexisted, has been excised. At every point of the quantum moduli space, some of the global symmetry G_{cl} is spontaneously broken. Two extreme vacua illustrate the pattern.

At the *mesonic* point $B = \widetilde{B} = 0$, $M^i{}_{\tilde{\jmath}} = \Lambda^2 \delta^i_{\tilde{\jmath}}$ (so $\det M = \Lambda^{2N_c}$), the meson vev locks the two flavor groups together,

$$\mathrm{SU}(N_f)_L \times \mathrm{SU}(N_f)_R \;\longrightarrow\; \mathrm{SU}(N_f)_{\text{diag}}, \tag{46.98}$$
