The orientation is enforced by a vanishing theorem. The other time-ordered pairings, ϕ with ϕ and $\phi^\dagger$ with $\phi^\dagger$, are identically zero:

$$\langle 0|\mathcal{T}\,\phi(x)\phi(y)|0\rangle = 0, \qquad \Big\langle 0|\mathcal{T}\,\phi^\dagger(x)\phi^\dagger(y)|0\Big\rangle = 0. \tag{9.247}$$

The proof is immediate from the mode content. Expanding $\langle 0|\phi(x)\phi(y)|0\rangle$, the surviving vacuum expectation values would have to be of the form $\big\langle 0|(\text{annih. or } b^\dagger)(\text{annih. or}$ but ϕ contains only $a_{\mathbf{p}}$ and $b^\dagger_{\mathbf{p}}$, so every term is one of $\langle 0|aa|0\rangle$, $\big\langle 0|ab^\dagger|0\big\rangle$, $\big\langle 0|b^\dagger a|0\big\rangle$, $\big\langle 0|b^\dagger b^\dagger|0\big\rangle$, each of which annihilates a vacuum on one side (the a's kill $|0\rangle$ on the right; the $b^\dagger$'s kill $\langle 0|$ on the left, since a and b commute one may always order an a to the right or a $b^\dagger$ to the left). Hence the equal-ordering Wightman functions vanish for either time order, and so does their time-ordered combination. The same holds for $\phi^\dagger\phi^\dagger$. Charge conservation gives the structural reason: $\phi\phi$ would carry total charge -2 and cannot connect to the neutral vacuum. In the diagrammatic language of Chapters 14 and 15, Eq. (9.247) is the statement that charge must *flow through* a propagator – a line always has a ϕ end and a $\phi^\dagger$ end – never source or sink at it.

9.7.5 The neutral scalar as its own antiparticle

The real scalar carried through the rest of this chapter is the special case in which the two ladder sets coincide. Imposing the reality condition $\phi = \phi^\dagger$ on Eqs. (9.218) and (9.219) forces, mode by mode,

$$b_{\mathbf{p}} = a_{\mathbf{p}}, \tag{9.248}$$

collapsing the two families into one and recovering exactly the real-field mode expansion used earlier in the chapter. There is then only one species of quantum, and the charge Eq. (9.229) becomes

$$Q = \int \widetilde{dp}\,(a^\dagger_{\mathbf{p}} a_{\mathbf{p}} - a^\dagger_{\mathbf{p}} a_{\mathbf{p}}) = 0. \tag{9.249}$$

The neutral field carries no conserved U(1) charge – consistent with the fact that a real Lagrangian has no phase symmetry to begin with – and its single quantum is its own antiparticle: applying $\phi = \phi^\dagger$ to the propagator collapses Eq. (9.245) and the would-be $\langle \mathcal{T}\phi\phi\rangle$ into the single real-scalar Feynman function, and the oriented line of Fig. 9.7 loses its arrow. This is the precise sense, promised in the earlier sections, in which the real scalar of ϕ^4 theory is the uncharged member of a family whose charged members we have now built. The interacting $\lambda\phi^4$ dynamics taken up in Chapters 14 and 15 lives entirely in this neutral sector; the charged construction of this section is the scaffolding the book will mount when it gauges a scalar or, more importantly, when it builds the charged Dirac field.

With the free scalar theory now complete in both its neutral and charged forms, the chapter has delivered the two ideas the rest of the book most depends on from a charged field: a conserved charge realized as a self-adjoint operator whose spectrum is integral, and the particle/antiparticle doubling that any such charge entails. These hand directly to Chapter 11, where the same logic – mode

expansion, a Noether charge, particle and antiparticle towers – is repeated for the Dirac field with anticommutators in place of commutators, and to Chapter 13 and QED, where the global U(1) of this section is promoted to a local gauge symmetry and Q becomes the electric charge that couples matter to the photon.

Further reading

The canonical quantization of the scalar field is presented in Peskin and Schroeder [396] ch. 2 and Schwartz [432] chs. 2–3; Weinberg [500] ch. 5 builds the free field starting instead from Wigner's particle classification, the complementary route to the same object. Srednicki [454] chs. 1–3 emphasize the same Lorentz-invariant normalization adopted here, and Zee [532] ch. I gives the quickest physical motivation for the propagator as a particle worldline. Coleman [129] and Klauber [296] are unusually careful pedagogically about Fock space, normal ordering, and the particle interpretation. For the structural results only sketched here, the axiomatic treatment of microcausality and the spin-statistics connection is Streater and Wightman [458], and Haag's theorem and the algebraic view of free fields are developed in Haag [246].

Chapter 10

The Path Integral for Scalar Fields

Canonical quantization, built in Chapter 9, is one of the two pillars on which quantum field theory rests. This chapter erects the other. Where the operator approach promotes the field $\phi(x)$ to an operator and reads dynamics off commutators, the path integral keeps $\phi(x)$ a number-valued configuration and sums over *all* of them, each weighted by the phase $e^{iS[\phi]}$. The two formulations describe the same physics — we will prove their equivalence on the central object, the Feynman propagator — but they make different things easy. The path integral makes symmetries, the classical limit, non-perturbative configurations, and above all the bookkeeping of perturbation theory transparent in a way the operator formalism does not, and it is the language in which the rest of the book is most naturally written. We develop it for the real scalar of ϕ^4 theory, beginning with the free sector quantized in Chapter 9 and ending with the apparatus that turns the interaction back on.

The chapter is deliberate about its imports because Part I built its tools for exactly this moment. The functional calculus — functional differentiation (Theorem 4.4), the finite- and infinite-dimensional Gaussian integral (Theorems 4.14 and 4.15), the generating-functional idea (Section 4.4), and the Legendre transform that will produce the effective action (Theorem 4.31) — is taken wholesale from Chapter 4, where its rigorous status was fixed. The analytic machinery that makes the oscillatory integral converge — the $i\varepsilon$ prescription, the residue calculus, and the Wick rotation $t \to -i\tau$ (Theorem 5.30) — is imported from Chapter 5. From Chapter 9 we take the Fock vacuum (Theorem 9.17) and the canonically-derived Feynman propagator (Theorem 9.24 and Eq. (9.154)) as the fixed target every path-integral computation must reproduce, and we take the classical ϕ^4 Lagrangian and its $\mathbb{Z}_2$ symmetry from Chapters 6 and 7. The one place where the formal manipulations of the main text outrun what can be made rigorous — the existence of the functional measure and the meaning of the functional determinants it produces — is discharged in Chapter E, whose results we use by reference rather than reprove.

The development follows a single arc from one degree of freedom to infinitely many. We first derive the path integral honestly in ordinary quantum mechanics (Section 10.1), slicing time with the Trotter formula so that the continuum measure appears as a controlled limit of finite-dimensional integrals rather than an axiom; the same slicing shows that path-integral insertions compute *time-ordered* products and that an $i\varepsilon$ tilt projects onto the ground state, giving the quantum-mechanical generating functional $Z[J]$ (Section 10.2). Promoting the single coordinate to a field on a spacetime lattice and taking the continuum limit converts $Z[J]$ into the field-theory generating functional and identifies its functional derivatives with the time-ordered vacuum correlators of Chapter 9 (Section 10.3). For the free theory the integral is Gaussian and is done in closed form: completing the square yields $Z_0[J]$ and delivers the Feynman propagator as the inverse Klein–Gordon operator, in exact agreement with the canonical result (Section 10.4). From $Z_0[J]$ alone, by repeated functional differentiation, Wick's theorem emerges as pure Gaussian combinatorics — correlators are sums over pairings — reproducing the operator theorem of Chapter 9 without ever mentioning an operator (Section 10.5). Wick-rotating the whole construction (Section 10.6) trades the oscillatory weight e^{iS} for a positive, convergent Boltzmann weight e^{-S_E}, exposes the exact dictionary between Euclidean field theory and classical statistical mechanics, and gives, in reflection positivity, the criterion under which a Euclidean theory reconstructs a unitary Lorentzian one. The final section (Section 10.7) switches on the ϕ^4 interaction: a master formula expresses the full $Z[J]$ as a differential operator acting on $Z_0[J]$, perturbative expansion generates the contractions, vacuum bubbles cancel, and the connected and effective generating functionals $W[J]$ and $\Gamma[\phi_{\text{cl}}]$ organize the output for everything that follows.

Conventions are those in force book-wide and stated once here: the mostly-minus metric $\eta_{\mu\nu} = \text{diag}(+,-,-,-)$, natural units $\hbar = c = 1$, the Fourier convention of Appendix A, and the Feynman $i\varepsilon$ prescription, which in the path integral arises not as a rule imposed by hand but as the residue of the ground-state projection. One honesty is owed at the outset, in the spirit of Chapter 9: the Minkowski functional measure $\mathcal{D}\phi$ is, taken literally, a formal object — there is no Lebesgue measure on an infinite-dimensional space — and it is rigorous, as a genuine Gaussian measure, only after Wick rotation and only for the free theory. The construction of the *interacting* four-dimensional scalar measure as a true continuum object remains a famous open problem, and the accumulated evidence that ϕ^4_4 is trivial means the perturbation series we set up is best read as an asymptotic expansion about the free theory. None of this weakens the chapter's results: a measure understood as a controlled lattice limit, a closed-form free generating functional, Wick's theorem, and the master perturbative formula are exactly the objects that the S-matrix and LSZ reduction of Chapter 14, the Feynman rules of Chapter 15, the renormalization and effective-action machinery of Chapter 22, the Wilsonian RG of Chapter 23, and the fermionic Grassmann

integral of Chapter 12 all build upon.

10.1 The Path Integral in Quantum Mechanics

The previous chapter built the first pillar of quantum field theory by the route the reader already trusts: it took a classical field, imposed equal-time canonical commutators (Section 9.1), and let the Heisenberg equations grind out the dynamics, with operators ordered by hand whenever two of them met at the same point. That construction is complete and correct, but it has a feature one eventually wants to escape. It singles out a time direction at every step — the commutators live on a time slice, the time-ordering symbol in the propagator is an instruction about which operator stands to the left — and so it hides the Lorentz invariance that the classical Lagrangian wore openly. There is a second, logically independent road to the very same quantum mechanics, due to Dirac and Feynman, on which time and space re-enter on a more even footing: the transition amplitude between two configurations is written as a single integral over *all* histories connecting them, each history weighted by the phase e^{iS} built from the classical action. This section builds that road from the ground up, and it does so where every reader is on solid ground — in ordinary one-particle quantum mechanics — before Section 10.2 and the rest of the chapter lift the entire apparatus to fields. The promise to be redeemed across the chapter is that the two pillars agree: the free scalar propagator obtained by time-ordering operators in Eq. (9.154) will re-emerge, in Section 10.4, from a Gaussian integral over field histories.

Everything here is built on quantum mechanics the reader already owns at the Sakurai level: a Hilbert space, position and momentum eigenstates, the resolution of the identity, and the Hamiltonian as the generator of time translation. We add nothing to that postulate set. What we add is a way of *re-expressing* the matrix elements of the time-evolution operator, and the entire content of the section is that this re-expression is an identity, not a new physical assumption.

Notation Watch

Throughout this section a hat denotes an operator on the Hilbert space ($\hat{x}$, $\hat{p}$, $\hat{H}$), to be carefully distinguished from the c-number integration variables (x, p) that label its eigenstates and over which the path integral runs. Chapter 9 could write the field ϕ without a hat because no eigenvalue of ϕ ever appeared alongside it; here the distinction between the operator $\hat{x}$ and the number x in $\hat{x}\,|x\rangle = x\,|x\rangle$ is the whole point, so the hats are kept. We work in one spatial dimension with a single particle of mass m; the generalization to many degrees of freedom, and then to a field, is notational and is made in Section 10.3. Natural units $\hbar = 1$ are in force,

so that the action S in e^{iS} is dimensionless.

10.1.1 The transition amplitude as the central object

The quantity we set out to compute is the amplitude for a particle prepared at position x_i at time $t = 0$ to be found at position x_f at a later time $t = T$. In the Schrödinger picture, states evolve by the unitary operator $e^{-i\hat{H}T}$ generated by the Hamiltonian

$$\hat{H} = \frac{\hat{p}^2}{2m} + V(\hat{x}) \equiv \hat{T} + \hat{V}, \tag{10.1}$$

where we have named the kinetic and potential operators $\hat{T} = \hat{p}^2/2m$ and $\hat{V} = V(\hat{x})$ for later use. The object of interest is the matrix element of the evolution operator between position eigenstates, called the *propagator* or *transition amplitude*,

$$K(x_f, T; x_i, 0) \;\equiv\; \left\langle x_f \middle| e^{-i\hat{H}T} \middle| x_i \right\rangle . \tag{10.2}$$

Definition 10.1 (Transition amplitude)**.** For a quantum system with Hamiltonian $\hat{H}$, the transition amplitude $K(x_f, T; x_i, 0)$ is the matrix element (10.2) of the time-evolution operator between the initial and final position eigenstates. Equivalently, if the particle is in the state $|\psi(0)\rangle$ at $t = 0$, its wavefunction at time T is reconstructed from K by

$$\psi(x_f, T) = \langle x_f | \psi(T) \rangle = \int \mathrm{d}x_i \; K(x_f, T; x_i, 0)\, \psi(x_i, 0), \tag{10.3}$$

so that K is the integral kernel that propagates the wavefunction forward in time.

Two facts make K the right object to attack. First, it contains the entire dynamics: by (10.3) it solves the initial-value problem for the Schrödinger equation for an arbitrary initial state, so anything computable in the canonical formalism is encoded in it. Second, it is built from the single operator $e^{-i\hat{H}T}$, and that operator has a structural weakness we can exploit. The difficulty in evaluating (10.2) directly is that $\hat{T}$ and $\hat{V}$ do not commute, so the exponential of their sum does not factor, $e^{-i(\hat{T}+\hat{V})T} \neq e^{-i\hat{T}T} e^{-i\hat{V}T}$. The strategy of the path integral is to chop the evolution into many infinitesimal steps, over each of which the non-commutativity is a negligible higher-order effect, and then to take the limit. We record the two tools from elementary quantum mechanics on which the chopping relies. Position and momentum eigenstates are complete and are paired by the plane-wave overlap,

$$\int_{-\infty}^{\infty} \mathrm{d}x \;\; |x\rangle \langle x| = \mathbf{1}, \qquad \int_{-\infty}^{\infty} \frac{\mathrm{d}p}{2\pi} \;\; |p\rangle \langle p| = \mathbf{1}, \qquad \langle x|p\rangle = e^{ipx}, \tag{10.4}$$

with $\langle x|x'\rangle = \delta(x-x')$ and $\langle p|p'\rangle = 2\pi\,\delta(p-p')$, the factors of 2π fixed by the Fourier conventions of Chapter 5 and consistent with the normalization $\langle x|p\rangle = e^{ipx}$. These are the only inputs; the rest is computation.

10.1.2 Slicing time: the Trotter product formula

The first move is to write the evolution over the finite interval T as a product of N identical evolutions over the short interval

$$\epsilon \equiv \frac{T}{N}, \tag{10.5}$$

which is exact and trivial because the exponents simply add,

$$e^{-i\hat{H}T} = \left(e^{-i\hat{H}\epsilon}\right)^N. \tag{10.6}$$

The non-trivial step is to factor each short-time evolution into a kinetic and a potential piece, which is legitimate only up to a correction we must now control. Because $\hat{T}$ and $\hat{V}$ do not commute, the Baker–Campbell–Hausdorff expansion gives

$$e^{-i\hat{H}\epsilon} = e^{-i\hat{T}\epsilon}\, e^{-i\hat{V}\epsilon}\, \exp\!\Big[+\tfrac{1}{2}\,\epsilon^2\,\big[\hat{T},\hat{V}\big] + O(\epsilon^3)\Big], \tag{10.7}$$

so the splitting error in a single slice is of order ϵ^2. The content of the Trotter (Lie–Trotter) product formula is that an error of order ϵ^2 per slice, accumulated over $N = T/\epsilon$ slices, washes out in the limit $N\to\infty$, leaving the factored product equal to the true evolution.

Theorem 10.2 (Lie–Trotter product formula)**.** *Let $\hat{A}$ and $\hat{B}$ be bounded operators on a Hilbert space. Then*

$$e^{\hat{A}+\hat{B}} = \lim_{N\to\infty}\left(e^{\hat{A}/N}\, e^{\hat{B}/N}\right)^N. \tag{10.8}$$

Applied to $\hat{A} = -i\hat{T}\,T$ and $\hat{B} = -i\hat{V}\,T$, this gives the time-sliced evolution

$$e^{-i\hat{H}T} = \lim_{N\to\infty}\left(e^{-i\hat{T}\epsilon}\, e^{-i\hat{V}\epsilon}\right)^N, \qquad \epsilon = T/N. \tag{10.9}$$

Proof. Write $S_N \equiv e^{(\hat{A}+\hat{B})/N}$ for the true single-slice evolution and $P_N \equiv e^{\hat{A}/N}e^{\hat{B}/N}$ for the factored one, so that the assertion is $\lim_N P_N^N = e^{\hat{A}+\hat{B}} = S_N^N$. Taylor-expanding each exponential to second order in $1/N$,

$$S_N = \mathbf{1} + \frac{\hat{A}+\hat{B}}{N} + \frac{(\hat{A}+\hat{B})^2}{2N^2} + O(N^{-3}), \tag{10.10}$$

$$P_N = \left(\mathbf{1} + \frac{\hat{A}}{N} + \frac{\hat{A}^2}{2N^2} + \cdots\right)\left(\mathbf{1} + \frac{\hat{B}}{N} + \frac{\hat{B}^2}{2N^2} + \cdots\right) = \mathbf{1} + \frac{\hat{A}+\hat{B}}{N} + \frac{\hat{A}^2 + 2\hat{A}\hat{B} + \hat{B}^2}{2N^2} + O(1 \tag{10.11}$$

the two agree through order $1/N$ and differ at order $1/N^2$ only through the ordering of the cross term,

$$S_N - P_N = \frac{1}{2N^2}\left[(\hat{A}+\hat{B})^2 - \hat{A}^2 - 2\hat{A}\hat{B} - \hat{B}^2\right] + O(N^{-3}) = -\frac{1}{2N^2}\left[\hat{A},\hat{B}\right] + O(N^{-3}), \tag{10.12}$$

so $\|S_N - P_N\| \le C/N^2$ for some constant C and all large N. It remains to show that an $O(N^{-2})$ discrepancy per factor produces an $O(N^{-1})$ discrepancy in the N-fold product. This is the standard telescoping estimate: for any two operators X, Y,

$$X^N - Y^N = \sum_{k=0}^{N-1} X^{\,N-1-k}\,(X-Y)\,Y^{\,k}, \tag{10.13}$$

which collapses because consecutive terms cancel in pairs. Taking norms with $X = S_N$, $Y = P_N$ and using submultiplicativity,

$$\left\|S_N^N - P_N^N\right\| \le \sum_{k=0}^{N-1} \|S_N\|^{\,N-1-k}\,\|S_N - P_N\|\,\|P_N\|^{\,k} \le N\left(\max\{\|S_N\|, \|P_N\|\}\right)^{N-1}\|S_N - P_N\| \tag{10.14}$$

Both $\|S_N\|$ and $\|P_N\|$ are bounded by $e^{(\|\hat{A}\|+\|\hat{B}\|)/N}$, so their $(N-1)$-th power is bounded by the N-independent constant $e^{\|\hat{A}\|+\|\hat{B}\|}$. Hence

$$\left\|S_N^N - P_N^N\right\| \le N \cdot e^{\|\hat{A}\|+\|\hat{B}\|}\cdot\frac{C}{N^2} = \frac{C\,e^{\|\hat{A}\|+\|\hat{B}\|}}{N} \xrightarrow[N\to\infty]{} 0, \tag{10.15}$$

which establishes (10.8). Specializing to $\hat{A} = -i\hat{T}\,T$, $\hat{B} = -i\hat{V}\,T$ gives (10.9). □

Caution

The clean proof above assumes $\hat{A}$ and $\hat{B}$ bounded, whereas the physical kinetic and potential operators are unbounded (the spectrum of $\hat{p}^2/2m$ is all of $[0,\infty)$, and most potentials are unbounded too). The formula nonetheless survives in the form actually needed here: Trotter's theorem, sharpened by Kato, guarantees that (10.9) holds in the strong operator topology — that is, when both sides act on a fixed state vector — for self-adjoint $\hat{T}, \hat{V}$ whose sum $\hat{H}$ is essentially self-adjoint, which covers every Hamiltonian in this book. The strong-topology statement is exactly what (10.2) requires, since we only ever sandwich the operators between fixed states. We use the bounded-operator proof for its transparency and flag the functional-analytic upgrade; the rigorous continuum construction of the resulting measure is collected in Chapter E.

10.1.3 The short-time kernel

With (10.9) in hand we insert a resolution of the identity in the position basis between every pair of adjacent factors. Labelling the intermediate positions $x_1, \dots, x_{N-1}$ and writing $x_0 \equiv x_i$, $x_N \equiv x_f$ for the fixed endpoints,

$$K(x_f, T; x_i, 0) = \int\Big(\prod_{j=1}^{N-1} \mathrm{d}x_j\Big) \prod_{j=0}^{N-1} \Big\langle x_{j+1}\Big| e^{-i\hat{T}\epsilon}\, e^{-i\hat{V}\epsilon}\Big| x_j\Big\rangle , \tag{10.16}$$

where each of the N factors is a *short-time kernel* carrying the evolution from x_j to x_{j+1} across one slice. The integral runs over the values of the position at every intermediate time; this is the discrete skeleton of the sum over histories, sketched in Fig. 10.1. Everything now hinges on evaluating one short-time kernel, and here the factorization pays off. The potential operator $\hat{V} = V(\hat{x})$ is diagonal in the position basis, so acting to the right on $|x_j\rangle$ it is just a number,

$$e^{-i\hat{V}\epsilon}\,|x_j\rangle = e^{-i\epsilon V(x_j)}\,|x_j\rangle\,. \tag{10.17}$$

The kinetic operator $\hat{T} = \hat{p}^{\,2}/2m$ is diagonal in the *momentum* basis, so we evaluate its matrix element by inserting a complete set of momentum states from (10.4):

$$\Big\langle x_{j+1}\Big| e^{-i\hat{T}\epsilon}\Big| x_j\Big\rangle = \int \frac{\mathrm{d}p_j}{2\pi}\, \Big\langle x_{j+1}\Big| e^{-i\hat{p}^{\,2}\epsilon/2m}\Big| p_j\Big\rangle\, \langle p_j|x_j\rangle = \int \frac{\mathrm{d}p_j}{2\pi}\, e^{-ip_j^2\epsilon/2m}\, e^{ip_j(x_{j+1}-x_j)}. \tag{10.18}$$

This is a Gaussian integral over the slice momentum p_j, of exactly the oscillatory (Fresnel) type catalogued in Chapter 5. We isolate the evaluation as a lemma, since the same integral recurs at every step of the chapter.

Lemma 10.3 (Fresnel integral)**.** *For real $a > 0$ and complex b, defining the oscillatory integral by the convergence-generating tilt $a \to a - i0^+$ (the Feynman $i\epsilon$ prescription of Section 5.1, applied here to the slice),*

$$\int_{-\infty}^{\infty} \mathrm{d}p\; e^{-iap^2+ibp} = \sqrt{\frac{\pi}{ia}}\; e^{\,ib^2/4a}, \qquad \int_{-\infty}^{\infty} \mathrm{d}x\; e^{+iAx^2+iBx} = \sqrt{\frac{i\pi}{A}}\; e^{-iB^2/4A}, \tag{10.19}$$

where the branch is fixed by $\sqrt{i} = e^{i\pi/4}$, equivalently by analytic continuation from the convergent Gaussian.

Proof. Complete the square in the first integral, $-iap^2 + ibp = -ia\big(p - \frac{b}{2a}\big)^2 + \frac{ib^2}{4a}$, and shift p. The shifted integral is $\int \mathrm{d}u\, e^{-iau^2}$, which converges absolutely once a carries the negative imaginary part $a - i0^+$ and equals $\sqrt{\pi/(ia)}$ — this is the purely oscillatory case of the Gaussian computed in Theorem 5.16, where the contour is rotated by $\pi/4$ onto the line of steepest descent. The second identity is the same statement with $a \to -A$, completing the square as $iAx^2 + iBx = iA\big(x + \frac{B}{2A}\big)^2 - \frac{iB^2}{4A}$ and using $\int \mathrm{d}u\, e^{iAu^2} = \sqrt{i\pi/A}$. □

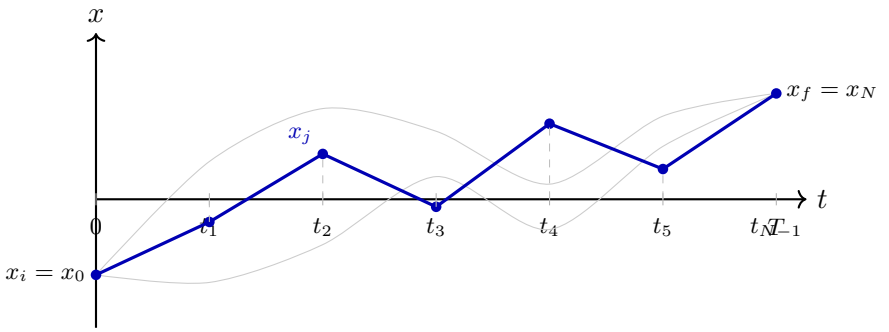

Figure 10.1: The discrete skeleton of the path integral. Time is sliced into N steps of width $\epsilon = T/N$; a single history is the broken line through the intermediate positions $x_1, \dots, x_{N-1}$ (blue), with endpoints $x_0 = x_i$ and $x_N = x_f$ held fixed. The amplitude (10.16) integrates each short-time kernel (10.21) over all values of every intermediate x_j, i.e. over all broken-line histories (two further ones shown faint). As $N \to \infty$ the broken lines fill out the space of continuous paths and the exponent of the product becomes i times the classical action.

Applying the first identity of (10.19) to (10.18) with $a = \epsilon/2m$ and $b = x_{j+1} - x_j$,

$$\Big\langle x_{j+1}\Big|e^{-i\hat{T}\epsilon}\Big|x_j\Big\rangle = \frac{1}{2\pi}\sqrt{\frac{2\pi m}{i\epsilon}}\,\exp\Big[\frac{im(x_{j+1}-x_j)^2}{2\epsilon}\Big] = \sqrt{\frac{m}{2\pi i\epsilon}}\,\exp\Big[\frac{im(x_{j+1}-x_j)^2}{2\epsilon}\Big]. \tag{10.20}$$

Combining this with the potential factor (10.17), the full short-time kernel is

$$\Big\langle x_{j+1}\Big|e^{-i\hat{T}\epsilon}e^{-i\hat{V}\epsilon}\Big|x_j\Big\rangle = \sqrt{\frac{m}{2\pi i\epsilon}}\,\exp\Big[\,i\epsilon\Big(\frac{m}{2}\Big(\frac{x_{j+1}-x_j}{\epsilon}\Big)^2 - V(x_j)\Big)\Big], \tag{10.21}$$

valid up to the $O(\epsilon^2)$ correction tracked in (10.7), which is subleading once summed over slices. The exponent is the discrete version of $i\epsilon\, L$, where $L = \frac{m}{2}\dot{x}^2 - V(x)$ is the classical Lagrangian: the kinetic term is built from the discrete velocity $(x_{j+1} - x_j)/\epsilon$ and the potential is read off at the slice. This is the moment at which the Lagrangian, an object the canonical formalism discarded after the Legendre transform, walks back onto the stage.

10.1.4 The phase-space path integral

It is worth pausing one step earlier in the calculation, before the momentum integrals (10.18) are done, because the intermediate expression is itself a fundamental object — the path integral in phase space — and it is the form best suited to constrained and gauge systems later in the book. Keep the momentum integral in each slice undone. Then each factor of (10.16) reads

$$\Big\langle x_{j+1}\Big|e^{-i\hat{T}\epsilon}e^{-i\hat{V}\epsilon}\Big|x_j\Big\rangle = \int\frac{\mathrm{d}p_j}{2\pi}\,\exp\Big[\,ip_j(x_{j+1}-x_j) - i\epsilon\,H(p_j,x_j)\Big], \tag{10.22}$$

where $H(p,x) = p^2/2m + V(x)$ is now the classical Hamiltonian *function* (the operator's symbol), and the ordering chosen — kinetic momentum to the left of potential position — has fixed it unambiguously. Assembling the N factors, the amplitude becomes an integral over N momenta and $N-1$ positions,

$$K(x_f,T;x_i,0) = \lim_{N\to\infty} \int \Big(\prod_{j=1}^{N-1} \mathrm{d}x_j\Big)\Big(\prod_{j=0}^{N-1} \frac{\mathrm{d}p_j}{2\pi}\Big) \exp\Big[\, i \sum_{j=0}^{N-1} \Big(p_j\,(x_{j+1}-x_j) - \epsilon\, H(p_j,x_j)\Big)\Big]. \tag{10.23}$$

In the continuum limit the discrete sum in the exponent becomes the phase-space action, $p_j(x_{j+1}-x_j) \to p\,\dot{x}\,\mathrm{d}t$ and $\epsilon H \to H\,\mathrm{d}t$, and we write the result as

$$\boxed{K(x_f,T;x_i,0) = \int \mathcal{D}x\,\mathcal{D}p\ \exp\Big[\, i\int_0^T \mathrm{d}t\,\big(p\,\dot{x} - H(p,x)\big)\Big]} \tag{10.24}$$

with the boundary conditions $x(0)=x_i$, $x(T)=x_f$ on the position path and no boundary condition on the momentum path. The asymmetry — one more momentum integral than position integral, the momenta unconstrained at the ends — is not an accident of bookkeeping; it reflects that the path integral knows phase space, where x and p are independent coordinates, and that the amplitude is diagonal in x at the endpoints by construction. Equation (10.24) is the most primitive form of the path integral and the one from which all others descend.

10.1.5 Gaussian momentum integration and the configuration-space measure

For the Hamiltonians of this book the momentum enters H only quadratically, so the momentum integrals in (10.23) are Gaussian and can be done once and for all. This is the step that produces the Lagrangian form together with the precise normalization of the measure — the result the next section depends on. Performing the integral over p_j in (10.22) is exactly the computation (10.18)–(10.20) run in reverse: each momentum integral contributes the factor $\sqrt{m/2\pi i\epsilon}$ and converts $p_j\dot{x} - \frac{p_j^2}{2m}$ into $\frac{m}{2}\dot{x}^2$. Carrying this out in every slice turns (10.23) into

$$K(x_f,T;x_i,0) = \lim_{N\to\infty} \Big(\frac{m}{2\pi i\epsilon}\Big)^{N/2} \int \Big(\prod_{j=1}^{N-1} \mathrm{d}x_j\Big)\, \exp\Big[\, i\epsilon \sum_{j=0}^{N-1} \Big(\frac{m}{2}\Big(\frac{x_{j+1}-x_j}{\epsilon}\Big)^2 - V(x_j)\Big)\Big]. \tag{10.25}$$

Here is the bookkeeping that fixes the measure, and it must be stated exactly because it is the single most error-prone point in the whole construction. There are N slices, hence N momentum integrals, hence N factors of $\sqrt{m/2\pi i\epsilon}$; but there are only $N-1$ intermediate positions to integrate over, the two endpoints being fixed. The measure therefore carries one more power of the normalization

than it has integration variables:

$$\mathcal{D}x \;\equiv\; \lim_{N\to\infty}\Big(\frac{m}{2\pi i\epsilon}\Big)^{N/2}\prod_{j=1}^{N-1}\mathrm{d}x_j, \qquad \epsilon=\frac{T}{N}. \tag{10.26}$$

The exponent of (10.25) is a Riemann sum: as $\epsilon\to 0$ the discrete velocity $(x_{j+1}-x_j)/\epsilon$ becomes $\dot{x}(t)$ and the sum $\epsilon\sum_j(\cdots)$ becomes the time integral of the Lagrangian, that is, the classical action

$$S[x]=\int_0^T \mathrm{d}t\; L(x,\dot{x})=\int_0^T \mathrm{d}t\,\Big(\frac{m}{2}\dot{x}^2-V(x)\Big). \tag{10.27}$$

We have arrived at Feynman's formula.

Theorem 10.4 (Configuration-space path integral)**.** *The transition amplitude* (10.2) *of a one-dimensional quantum particle with Hamiltonian* $\hat{H}=\hat{p}^{\,2}/2m+V(\hat{x})$ *equals the sum over histories*

$$\boxed{K(x_f,T;x_i,0)=\int_{x(0)=x_i}^{x(T)=x_f}\mathcal{D}x\; e^{\,iS[x]}} \tag{10.28}$$

with the classical action $S[x]$ *of* (10.27) *and the measure* $\mathcal{D}x$ *defined by the discretization* (10.26)*. The integral runs over all continuous paths* $x(t)$ *obeying the boundary conditions* $x(0)=x_i$ *and* $x(T)=x_f$*, and is to be understood as the* $N\to\infty$ *limit of the finite-dimensional integral* (10.25)*.*

This is the central identity of the section, and three remarks make its meaning precise.

It is an *equality*, derived from (10.2) by inserting completeness relations and doing Gaussian integrals; no new postulate has entered. Each weight $e^{iS[x]}$ is a pure phase of unit modulus, so the path integral is not a probability average over histories but a coherent sum of amplitudes: histories interfere. The classical trajectory is distinguished only because it is the stationary point of S, near which neighbouring phases add constructively while elsewhere they cancel — the principle of stationary action recovered as a stationary-phase statement, made quantitative for the oscillator in Theorem 10.7.

The symbol $\mathcal{D}x$ has been *defined*, not merely written: it is the limit (10.26), prefactor and all. Taken in isolation that limit does not converge — the prefactor $(m/2\pi i\epsilon)^{N/2}$ diverges as $\epsilon\to 0$ and the typical path is nowhere differentiable, so $\dot{x}$ in (10.27) is formal. What is well defined is the *combination* in (10.25): the prefactor's divergence is exactly compensated by the integrals, as the free-particle and oscillator computations below verify by producing finite, correct answers. For Gaussian (free) actions the manipulations are exact at finite N and the limit is clean; for interacting actions the limit defines the theory perturbatively, and

its rigorous construction — the genuine measure-theoretic content, the role of the Wiener measure after Wick rotation, and the functional determinants — is deferred to Chapter E. We will be candid wherever a step is formal.

Finally, the continuum notation $\int \mathrm{d}t\,(\frac{m}{2}\dot{x}^2 - V)$ should always be read as shorthand for the well-defined discrete sum in (10.25). Whenever an ambiguity threatens — an ordering question, a measure factor, a would-be total derivative — the discretization is the arbiter, and we return to it.

Physical Insight

The path integral trades the operator non-commutativity of canonical quantization for an integral over ordinary numbers. Everything quantum — interference, the uncertainty principle, the spreading of wave packets — is repackaged into the instruction to sum the phase e^{iS} over *all* histories rather than to follow the single classical one. The non-commutativity has not disappeared; it survives as the $O(\epsilon^2)$ ordering correction (10.7) and, equivalently, as the fact that the typical contributing path is non-differentiable, so that $(\Delta x)^2 \sim \epsilon$ rather than ϵ^2 — the discrete fingerprint of $[\hat{x}, \hat{p}] = i$. This last fact is exactly the moment $M_2 = i\epsilon/m$ that drives the recovery of the Schrödinger equation in Theorem 10.6.

10.1.6 The free particle

The first test of the machine is the free particle, $V \equiv 0$, for which the path integral can be evaluated in closed form and compared against the elementary result. It also exhibits, in the cleanest possible setting, why the measure normalization (10.26) is exactly right.

Worked Example 10.5 (The free-particle propagator)**.** Set $V = 0$. The fastest evaluation bypasses the discretization: since $\hat{H} = \hat{p}^2/2m$ is diagonal in momentum, insert one momentum completeness relation into (10.2),

$$K_0(x_f, T; x_i, 0) = \int \frac{\mathrm{d}p}{2\pi}\, e^{-ip^2T/2m}\, \langle x_f|p\rangle\, \langle p|x_i\rangle = \int \frac{\mathrm{d}p}{2\pi}\, e^{-ip^2T/2m}\, e^{ip(x_f - x_i)}. \tag{10.29}$$

This is the Fresnel integral (10.19) with $a = T/2m$ and $b = x_f - x_i$, giving

$$\boxed{K_0(x_f, T; x_i, 0) = \sqrt{\frac{m}{2\pi i T}}\, \exp\Big[\frac{im(x_f - x_i)^2}{2T}\Big].} \tag{10.30}$$

The exponent is precisely iS_{cl}: the classical free path is the straight line $x(t) = x_i + (x_f - x_i)t/T$ with constant velocity $(x_f - x_i)/T$, whose action is $S_{\mathrm{cl}} = \frac{m}{2}\big((x_f - x_i)/T\big)^2 T = m(x_f - x_i)^2/2T$. So already here the amplitude has the semiclassical shape $K_0 = (\text{prefactor}) \times e^{iS_{\mathrm{cl}}}$, with the prefactor independent of the endpoints.

It remains to check that the *discretized* definition (10.25)–(10.26) reproduces (10.30), for this is the consistency test of the measure. The key is the composition (semigroup) property of the free kernel under convolution. Take two free short-time kernels of durations ϵ_1 and ϵ_2 and integrate over the shared intermediate point x_1:

$$\int_{-\infty}^{\infty} \mathrm{d}x_1 \sqrt{\frac{m}{2\pi i\epsilon_1}}\, e^{\,im(x_2-x_1)^2/2\epsilon_1} \sqrt{\frac{m}{2\pi i\epsilon_2}}\, e^{\,im(x_1-x_0)^2/2\epsilon_2}. \tag{10.31}$$

The exponent is quadratic in x_1: writing it as $iA\,x_1^2 + iB\,x_1 + iC$ with

$$A = \frac{m}{2}\Big(\frac{1}{\epsilon_1}+\frac{1}{\epsilon_2}\Big), \quad B = -m\Big(\frac{x_2}{\epsilon_1}+\frac{x_0}{\epsilon_2}\Big), \quad C = \frac{m}{2}\Big(\frac{x_2^2}{\epsilon_1}+\frac{x_0^2}{\epsilon_2}\Big), \tag{10.32}$$

the second Fresnel identity in (10.19) integrates x_1 out and leaves the exponent $i(C - B^2/4A)$. A short computation with $u = 1/\epsilon_1$, $v = 1/\epsilon_2$ collapses the bracket,

$$C - \frac{B^2}{4A} = \frac{m}{2}\,\frac{(ux_2^2+vx_0^2)(u+v)-(ux_2+vx_0)^2}{u+v} = \frac{m}{2}\,\frac{uv\,(x_2-x_0)^2}{u+v} = \frac{m\,(x_2-x_0)^2}{2(\epsilon_1+\epsilon_2)}, \tag{10.33}$$

while the prefactors combine, using $\sqrt{i\pi/A} = \sqrt{2\pi i\epsilon_1\epsilon_2/m(\epsilon_1+\epsilon_2)}$, into

$$\sqrt{\frac{m}{2\pi i\epsilon_1}}\sqrt{\frac{m}{2\pi i\epsilon_2}}\sqrt{\frac{i\pi}{A}} = \sqrt{\frac{m}{2\pi i(\epsilon_1+\epsilon_2)}}. \tag{10.34}$$

Hence (10.31) equals the single free kernel of duration $\epsilon_1+\epsilon_2$,

$$K_0(\epsilon_1+\epsilon_2) = \int \mathrm{d}x_1\; K_0(\epsilon_2)\,K_0(\epsilon_1), \tag{10.35}$$

which is the composition law $e^{-i\hat{H}(\epsilon_1+\epsilon_2)} = e^{-i\hat{H}\epsilon_2}e^{-i\hat{H}\epsilon_1}$ realized on kernels. By induction the chained integral over $N-1$ intermediate points of N kernels of duration $\epsilon = T/N$ gives one kernel of duration T, namely (10.30), *for every* N. The discretized path integral is thus not merely correct in the limit; for the free particle it is exact at every finite N, and the measure factor in (10.26) is precisely what makes the chain close onto itself with no leftover constant. This is the cleanest possible evidence that the normalization is right.

10.1.7 Consistency: recovery of the Schrödinger equation

The path integral was derived *from* the Schrödinger evolution, so it must reproduce it; verifying this directly from the short-time kernel both closes the logical loop and shows in microscopic detail how the differential equation is encoded in one infinitesimal slice. The argument is Feynman's original one.

Theorem 10.6 (The short-time kernel generates the Schrödinger equation)**.** *Let $\psi(x,t)$ evolve by one slice through the short-time kernel* (10.21)*, i.e.*

$$\psi(x,t+\epsilon)=\int_{-\infty}^{\infty}\mathrm{d}y\,\sqrt{\frac{m}{2\pi i\epsilon}}\,\exp\!\Big[\frac{im(x-y)^2}{2\epsilon}\Big]\,e^{-i\epsilon V(y)}\,\psi(y,t). \tag{10.36}$$

Then, to first order in ϵ, ψ satisfies the Schrödinger equation

$$i\,\partial_t\psi(x,t)=-\frac{1}{2m}\,\partial_x^2\psi(x,t)+V(x)\,\psi(x,t). \tag{10.37}$$

Proof. Substitute $y=x+\xi$, so that the Gaussian weight is $\exp[im\xi^2/2\epsilon]$. This weight oscillates ever faster as $\epsilon\to 0$ and concentrates the integral on $\xi^2\sim\epsilon$, i.e. on displacements of order $\xi\sim\sqrt{\epsilon}$; this scaling — $\xi\sim\sqrt{\epsilon}$, not $\xi\sim\epsilon$ — is the quantum fingerprint noted above, and it dictates how far to Taylor-expand. We need the answer through $O(\epsilon)$, so we keep ψ to second order in ξ and the potential to first order in ϵ:

$$e^{-i\epsilon V(x+\xi)}=1-i\epsilon V(x)+O(\epsilon^{3/2}),\qquad \psi(x+\xi,t)=\psi+\xi\,\partial_x\psi+\tfrac{1}{2}\xi^2\,\partial_x^2\psi+O(\xi^3), \tag{10.38}$$

where the $O(\epsilon^{3/2})$ in the first expansion comes from $\epsilon\,\xi\sim\epsilon^{3/2}$. The integral then requires the first three Gaussian moments, all instances of the Fresnel lemma (10.19):

$$\sqrt{\frac{m}{2\pi i\epsilon}}\int\mathrm{d}\xi\,e^{im\xi^2/2\epsilon}=1,\qquad \sqrt{\frac{m}{2\pi i\epsilon}}\int\mathrm{d}\xi\,\xi\,e^{im\xi^2/2\epsilon}=0,\qquad \sqrt{\frac{m}{2\pi i\epsilon}}\int\mathrm{d}\xi\,\xi^2\,e^{im\xi^2/2\epsilon}=\frac{i\epsilon}{m}. \tag{10.39}$$

The first is the normalization (10.20) at $x_{j+1}=x_j$; the second vanishes by oddness; the third follows from differentiating the first under the integral sign with respect to the parameter, $\langle\xi^2\rangle=(-i\,\partial/\partial(m/2\epsilon))\,\ln\sqrt{\cdots}=i\epsilon/m$. Inserting the expansions and the moments into (10.36),

$$\psi(x,t+\epsilon)=\big(1-i\epsilon V(x)\big)\Big[\psi+\tfrac{1}{2}\,\frac{i\epsilon}{m}\,\partial_x^2\psi\Big]+O(\epsilon^{3/2})=\psi+\frac{i\epsilon}{2m}\,\partial_x^2\psi-i\epsilon V(x)\,\psi+O(\epsilon^{3/2}). \tag{10.40}$$

The left side is $\psi(x,t)+\epsilon\,\partial_t\psi+O(\epsilon^2)$. Matching the terms of order ϵ and cancelling the common $\psi(x,t)$,

$$\partial_t\psi=\frac{i}{2m}\,\partial_x^2\psi-iV(x)\,\psi, \tag{10.41}$$

which is (10.37) after multiplication by i. The path integral and the Schrödinger equation are therefore the same dynamics; the $O(\epsilon)$ matching is exactly the place where the kinetic term of the action becomes the Laplacian and the potential term becomes multiplication by V. □

10.1.8 The harmonic oscillator

The free particle was Gaussian because its action was quadratic with no potential; the harmonic oscillator is the next solvable case, quadratic *with* a restoring force, and it is the single most important worked example in the chapter. It is the quantum-mechanical template for the free field — a field is a continuum of oscillators (Section 9.1.2), so its generating functional in Section 10.3 is an infinite product of the result computed here — and it exhibits, exactly, the semiclassical structure "$e^{iS_{\rm cl}}$ times a fluctuation determinant" that organizes every Gaussian path integral in the book.

Worked Example 10.7 (The harmonic-oscillator propagator and its fluctuation determinant)**.** Take the oscillator action, in the conventions of the oscillator template Section 9.1.2 and the free Hamiltonian Eq. (9.3) from which it descends,

$$S[x] = \int_0^T \mathrm{d}t\, \Big(\frac{m}{2}\dot{x}^2 - \frac{m\omega^2}{2}x^2\Big), \tag{10.42}$$

and compute $K_{\rm HO} = \int \mathcal{D}x\, e^{iS[x]}$ with $x(0) = x_i$, $x(T) = x_f$.

Step 1: exact split into classical path and fluctuation. Let $x_{\rm cl}(t)$ be the solution of the classical equation of motion $\ddot{x}_{\rm cl} + \omega^2 x_{\rm cl} = 0$ obeying the boundary conditions, and write a general path as $x(t) = x_{\rm cl}(t) + \eta(t)$ with the fluctuation η vanishing at both ends, $\eta(0) = \eta(T) = 0$. Because S is quadratic, its Taylor expansion in η terminates exactly at second order,

$$S[x_{\rm cl}+\eta] = S[x_{\rm cl}] + \underbrace{\int_0^T \mathrm{d}t\, \Big(m\dot{x}_{\rm cl}\dot{\eta} - m\omega^2 x_{\rm cl}\eta\Big)}_{\text{linear}} + \int_0^T \mathrm{d}t\, \Big(\frac{m}{2}\dot{\eta}^2 - \frac{m\omega^2}{2}\eta^2\Big). \tag{10.43}$$

The linear term vanishes identically: integrating its first piece by parts and using $\eta(0) = \eta(T) = 0$ to kill the boundary term gives $-\int m\eta(\ddot{x}_{\rm cl} + \omega^2 x_{\rm cl})\,\mathrm{d}t = 0$ by the classical equation of motion. The split is therefore exact and the measure is translation-invariant under $x \to x_{\rm cl} + \eta$ (a constant shift of the integration variables in (10.26)), so

$$K_{\rm HO} = e^{\,iS_{\rm cl}} \underbrace{\int_{\eta(0)=\eta(T)=0} \mathcal{D}\eta\, \exp\Big[\, i\int_0^T \mathrm{d}t\, \Big(\tfrac{m}{2}\dot{\eta}^2 - \tfrac{m\omega^2}{2}\eta^2\Big)\Big]}_{F(T)}, \qquad S_{\rm cl} \equiv S[x_{\rm cl}]. \tag{10.44}$$

The fluctuation factor $F(T)$ no longer depends on the endpoints x_i, x_f — they have been absorbed entirely into $x_{\rm cl}$ — so it is a pure function of T. This is the promised semiclassical structure, here exact rather than approximate because the action is Gaussian.

Step 2: the classical action. Solve $\ddot{x}_{\rm cl} + \omega^2 x_{\rm cl} = 0$ with $x_{\rm cl}(0) = x_i$, $x_{\rm cl}(T) = x_f$:

$$x_{\rm cl}(t) = \frac{x_f \sin\omega t + x_i \sin\omega(T-t)}{\sin\omega T}. \tag{10.45}$$

On shell the action reduces to a boundary term: integrating (10.42) by parts,

$$S_{\rm cl} = \frac{m}{2}\big[x_{\rm cl}\dot{x}_{\rm cl}\big]_0^T - \frac{m}{2}\int_0^T \mathrm{d}t\, x_{\rm cl}(\ddot{x}_{\rm cl}+\omega^2 x_{\rm cl}) = \frac{m}{2}\big[x_f\,\dot{x}_{\rm cl}(T) - x_i\,\dot{x}_{\rm cl}(0)\big], \tag{10.46}$$

the bulk integral vanishing by the equation of motion. From $\dot{x}_{\rm cl}(t) = \omega(x_f\cos\omega t - x_i\cos\omega(T-t))/\sin\omega T$ we read off $\dot{x}_{\rm cl}(T) = \omega(x_f\cos\omega T - x_i)/\sin\omega T$ and $\dot{x}_{\rm cl}(0) = \omega(x_f - x_i\cos\omega T)/\sin\omega T$, whence

$$\boxed{S_{\rm cl} = \frac{m\omega}{2\sin\omega T}\Big[(x_f^2+x_i^2)\cos\omega T - 2x_f x_i\Big].} \tag{10.47}$$

As $\omega\to 0$ this reduces to $m(x_f-x_i)^2/2T$, the free classical action, as it must.

Step 3: the fluctuation determinant by mode expansion. Integrate the quadratic action in (10.44) by parts once more (boundary term again killed by $\eta(0)=\eta(T)=0$) to write it as a quadratic form in the operator $\hat{O} = -\partial_t^2 - \omega^2$,

$$\int_0^T \mathrm{d}t\,\Big(\tfrac{m}{2}\dot{\eta}^2 - \tfrac{m\omega^2}{2}\eta^2\Big) = \frac{m}{2}\int_0^T \mathrm{d}t\,\eta\,(-\partial_t^2-\omega^2)\,\eta. \tag{10.48}$$

The eigenfunctions of $-\partial_t^2$ on $[0,T]$ obeying Dirichlet conditions $\eta(0)=\eta(T)=0$ are the sine modes

$$\eta_n(t) = \sin\frac{n\pi t}{T}, \qquad -\partial_t^2\,\eta_n = \Big(\frac{n\pi}{T}\Big)^2\eta_n, \qquad n = 1,2,3,\ldots, \tag{10.49}$$

a complete orthogonal basis for fluctuations with these boundary conditions. Expand $\eta(t) = \sum_{n=1}^{\infty} a_n \sin(n\pi t/T)$. Using $\int_0^T \sin(n\pi t/T)\sin(n'\pi t/T)\,\mathrm{d}t = \frac{T}{2}\delta_{nn'}$, the action becomes a sum of decoupled quadratics in the mode amplitudes,

$$\int_0^T \mathrm{d}t\,\Big(\tfrac{m}{2}\dot{\eta}^2 - \tfrac{m\omega^2}{2}\eta^2\Big) = \frac{mT}{4}\sum_{n=1}^{\infty} a_n^2\Big[\Big(\frac{n\pi}{T}\Big)^2 - \omega^2\Big]. \tag{10.50}$$

Changing integration variables in the measure from the discretized values $\{\eta_j\}$ to the mode amplitudes $\{a_n\}$ introduces a Jacobian $\mathcal{J}$; crucially, $\mathcal{J}$ depends on the basis and the discretization but *not* on ω, since the modes and the change of variables are the same for any quadratic action. Hence the fluctuation factor is

$$F(T) = \mathcal{J}\prod_{n=1}^{\infty}\int_{-\infty}^{\infty}\mathrm{d}a_n\;\exp\Big[\,i\,\frac{mT}{4}a_n^2\Big(\Big(\tfrac{n\pi}{T}\Big)^2-\omega^2\Big)\Big] = \mathcal{J}\prod_{n=1}^{\infty}\sqrt{\frac{4\pi i/(mT)}{(n\pi/T)^2-\omega^2}}\,, \tag{10.51}$$

each integral being a Fresnel integral (10.19).

Step 4: fixing $\mathcal{J}$ by the free ratio. Both $\mathcal{J}$ and the individual mode integrals are separately ill-defined (the infinite product of $\sqrt{4\pi i/mT}$ diverges), but their ω-dependence is finite and clean, and that is all we need: the unknown $\mathcal{J}$ cancels

in the ratio of the oscillator factor to the free-particle factor, which is the same object at $\omega = 0$. Dividing (10.51) by itself with $\omega = 0$,

$$\frac{F_{\mathrm{HO}}(T)}{F_{\mathrm{free}}(T)} = \prod_{n=1}^{\infty} \sqrt{\frac{(n\pi/T)^2}{(n\pi/T)^2 - \omega^2}} = \prod_{n=1}^{\infty} \Big(1 - \frac{\omega^2 T^2}{n^2\pi^2}\Big)^{-1/2}. \tag{10.52}$$

This infinite product is evaluated by Euler's product formula for the sine, a classical result of complex analysis: $\sin z = z\prod_{n=1}^{\infty}(1 - z^2/n^2\pi^2)$, which encodes the zeros of $\sin z$ at $z = n\pi$. With $z = \omega T$ this gives $\prod_n(1 - \omega^2T^2/n^2\pi^2) = \sin(\omega T)/(\omega T)$, so the ratio (10.52) is $(\sin\omega T/\omega T)^{-1/2} = (\omega T/\sin\omega T)^{1/2}$. The free factor was computed in Theorem 10.5: matching (10.28) to (10.30) identifies $F_{\mathrm{free}}(T) = \sqrt{m/2\pi i T}$. Therefore

$$F_{\mathrm{HO}}(T) = \sqrt{\frac{m}{2\pi i T}}\Big(\frac{\omega T}{\sin\omega T}\Big)^{1/2} = \sqrt{\frac{m\omega}{2\pi i \sin\omega T}}\,, \tag{10.53}$$

and assembling (10.44), (10.47), (10.53),

$$\boxed{K_{\mathrm{HO}}(x_f, T; x_i, 0) = \sqrt{\frac{m\omega}{2\pi i \sin\omega T}}\,\exp\Big[\frac{im\omega}{2\sin\omega T}\Big((x_f^2 + x_i^2)\cos\omega T - 2x_f x_i\Big)\Big].} \tag{10.54}$$

Three checks confirm the result. As $\omega \to 0$, $\sin\omega T \to \omega T$ and the bracket $\to (x_f - x_i)^2$, so (10.54) collapses to the free propagator (10.30). As $T \to 0$ at fixed ω, $\sin\omega T \to \omega T$ likewise and $K_{\mathrm{HO}} \to \delta(x_f - x_i)$ in the distributional sense, as any propagator must at coincident times. Finally, the periodic singularities at $\omega T = n\pi$, where $\sin\omega T$ vanishes and the prefactor diverges, are the oscillator's classical focusing times — every trajectory launched from x_i returns to a single point after a half-period — and the extra phase the amplitude acquires on passing each focus is the Maslov index of the semiclassical expansion.

Remark 10.8 (The same determinant via Gelfand–Yaglom). The mode sum above *is* a regularized functional determinant: $F_{\mathrm{HO}}/F_{\mathrm{free}} = (\det(-\partial_t^2 - \omega^2)/\det(-\partial_t^2))^{-1/2}$ with Dirichlet conditions, and (10.52) is the statement $\det(-\partial_t^2 - \omega^2)/\det(-\partial_t^2) = \sin\omega T/\omega T$. The same ratio can be obtained without ever listing eigenvalues, by the Gelfand–Yaglom theorem: the determinant of $-\partial_t^2 + W(t)$ on $[0, T]$ with Dirichlet conditions is proportional to $D(T)$, where $D(t)$ solves the homogeneous equation $(-\partial_t^2 + W)D = 0$ with initial data $D(0) = 0$, $\dot D(0) = 1$, the proportionality constant cancelling in any ratio. For the oscillator $W = -\omega^2$ gives $D(t) = \sin(\omega t)/\omega$, and for the free case $W = 0$ gives $D_0(t) = t$; their ratio at $t = T$ is $\sin(\omega T)/\omega T$, reproducing (10.52) with no infinite product. We will not need the general theorem here — the mode sum delivered the answer in full — but the Gelfand–Yaglom recursion is the practical tool for fluctuation determinants in less symmetric backgrounds, and Chapter E develops it and the ζ-function regularization that makes the individual determinants, not merely their ratio, well defined.

Physical Insight

Equation (10.54) is the entire quantum oscillator in one line, and it is built from purely classical data: the classical action $S_{\rm cl}$ in the phase, and the classical *spread* of trajectories — the fluctuation determinant — in the amplitude. This is the general anatomy of a Gaussian path integral, and it is why free quantum field theory will turn out to be exactly solvable: a free field is Gaussian, so its generating functional is, mode by mode, an instance of (10.53), a classical action times a determinant. Interactions are the non-Gaussian corrections to this skeleton, organized as a perturbation series around it — the subject from Chapter 14 onward.

The section has delivered exactly the toolkit the rest of the chapter runs on. We have the short-time kernel (10.21); the configuration-space path integral (10.28) with its measure normalization $(m/2\pi i\epsilon)^{N/2}$ pinned down in (10.26); the phase-space form (10.24) for later constrained systems; and the two exactly evaluated propagators, free (10.30) and harmonic (10.54), together with the semiclassical structure $e^{iS_{\rm cl}}$ times a fluctuation determinant that they share. The next section, Section 10.2, puts this amplitude to work as a *generator*: by coupling the path to an external source $J(t)$ and projecting onto the ground state with the $i\epsilon$ tilt of Section 5.4, it promotes K into the vacuum generating functional $Z[J]$, from which time-ordered correlation functions drop out as functional derivatives — the bridge from this quantum-mechanical warm-up to the field-theoretic ϕ^4 theory.

10.2 Correlation Functions and the Generating Functional

The previous section turned the transition amplitude of a single quantum-mechanical degree of freedom into a sum over histories, $\langle x_f, t_f | x_i, t_i\rangle = \int \mathcal{D}x\, e^{iS[x]}$, and fixed the configuration-space measure by exact computation for the harmonic oscillator, where the integral could be done in closed form. That amplitude, however, is not yet the object a field theorist wants. What the perturbative expansion of Chapter 14 will be built from — and what Section 9.5.2 already identified as the basic correlator of the canonical theory — is the vacuum expectation value of a *time-ordered product* of operators. The task of this section is to promote the bare amplitude into a machine that manufactures exactly these objects: we couple the system to an external source $J(t)$, assemble the *generating functional* $Z[J]$, and show that every time-ordered correlation function is a functional derivative of $Z[J]$ with respect to J. Along the way two things that look like technical fine print turn out to carry the physics: the path integral produces the *time-ordered* product and no other (the ordering is not imposed by

hand but emerges from the time-slicing), and a small tilt of the time contour into the complex plane is precisely what projects the dangling endpoint states onto the interacting ground state. Everything here is done for one degree of freedom $x(t)$, the quantum-mechanical template; the next section lifts the entire apparatus, symbol for symbol, to the scalar field of ϕ^4 theory.

Throughout, H is the system Hamiltonian, $|n\rangle$ its orthonormal energy eigenstates with $H|n\rangle = E_n|n\rangle$ and $E_0 < E_1 \le E_2 \le \cdots$, and $|\Omega\rangle \equiv |0\rangle$ is the (assumed non-degenerate) ground state. Heisenberg-picture operators are $\hat{x}(t) = e^{iHt}\hat{x}\,e^{-iHt}$. We use the mostly-minus conventions of Chapter 9; for a single particle of unit mass the action is $S[x] = \int dt\, L$ with $L = \frac{1}{2}\dot{x}^2 - V(x)$.

10.2.1 Path-integral insertions are time-ordered products

We begin with the cleanest statement and then prove it: inserting the c-number $x(t_1)\cdots x(t_n)$ into the path-integral integrand computes the matrix element of the *time-ordered* operator product $\mathcal{T}\,\hat{x}(t_1)\cdots\hat{x}(t_n)$, with later operators standing to the left. The ordering is not an extra rule. It is forced on us by the only consistent way to cut the evolution into pieces.

Recall first the single-slice identity behind the path integral. The amplitude $\langle x_f, t_f | x_i, t_i\rangle = \left\langle x_f \middle| e^{-iH(t_f - t_i)} \middle| x_i \right\rangle$ is built by chopping $[t_i, t_f]$ into many short steps and inserting a resolution of the identity $\int dx\ |x\rangle\langle x| = \mathbf{1}$ between each pair of adjacent factors $e^{-iH\,\Delta t}$. The integration variables are the values $x(t)$ of the path at the intermediate times, and the product of short-time kernels assembles into $e^{iS[x]}$ in the continuum limit. Suppose now we wish to compute not the bare amplitude but the matrix element with one Heisenberg operator inserted at an intermediate time $t_1 \in (t_i, t_f)$,

$$\langle x_f | \hat{x}(t_1) | x_i\rangle = \left\langle x_f \middle| e^{-iH(t_f - t_1)}\, \hat{x}\, e^{-iH(t_1 - t_i)} \middle| x_i \right\rangle, \tag{10.55}$$

where we used $\left\langle x_f \middle| e^{iHt_f}\hat{x}e^{-iHt_1}\cdots \right\rangle$ and cancelled the outer phases against the definitions of $|x_f, t_f\rangle$, $|x_i, t_i\rangle$. Insert a position resolution of the identity immediately to the right of $\hat{x}$, at the instant t_1, and use $\hat{x}\,|x_1\rangle = x_1\,|x_1\rangle$:

$$\begin{aligned} \langle x_f | \hat{x}(t_1) | x_i\rangle &= \int dx_1\ \left\langle x_f \middle| e^{-iH(t_f - t_1)} \middle| x_1 \right\rangle\ x_1\ \left\langle x_1 \middle| e^{-iH(t_1 - t_i)} \middle| x_i \right\rangle \\ &= \int dx_1\ x_1 \left(\int_{x_1, t_1}^{x_f, t_f} \mathcal{D}x\, e^{iS} \right) \left(\int_{x_i, t_i}^{x_1, t_1} \mathcal{D}x\, e^{iS} \right). \end{aligned} \tag{10.56}$$

Each factor is itself a path integral over its subinterval, and gluing two path integrals that share the common endpoint x_1 at the common time t_1 — then integrating over that shared value x_1 — is nothing but the single unrestricted path integral over $[t_i, t_f]$, now carrying the extra factor equal to the path's value at t_1. Hence

$$\langle x_f | \hat{x}(t_1) | x_i\rangle = \int \mathcal{D}x\ x(t_1)\, e^{iS[x]}. \tag{10.57}$$

The lone operator went in cleanly because there was only one of it; ordering became an issue only when two or more insertions compete for the same slot.

Theorem 10.9 (Insertions generate the time-ordered product)**.** *For any times* $t_1, \dots, t_n \in (t_i, t_f)$*,*

$$\langle x_f | \mathcal{T}\, \hat{x}(t_1)\hat{x}(t_2)\cdots\hat{x}(t_n)|x_i\rangle = \int \mathcal{D}x\; x(t_1)x(t_2)\cdots x(t_n)\, e^{iS[x]}, \tag{10.58}$$

where $\mathcal{T}$ *orders the operators with later times to the left, as in Eq. (9.151).*

Proof. Take $n = 2$ first; the general case is identical with more labels. Consider the right-hand side of Eq. (10.58), $\int \mathcal{D}x\, x(t_1)x(t_2)e^{iS}$. The integrand contains the two ordinary numbers $x(t_1)$ and $x(t_2)$, evaluated on the same path, so the integrand is manifestly *symmetric* under $t_1 \leftrightarrow t_2$: relabelling the two insertion times does nothing to it. Now reconstruct the operator content by the slicing of Eq. (10.56). To cut the evolution operators into pieces with strictly forward time steps — the only way the short-time expansion $e^{-iH\Delta t}$ and the intervening completeness insertions make sense — we must list the cut times in *increasing* order. Suppose first $t_1 > t_2$. Then cutting at t_2 and at t_1 and inserting position eigenstates at both,

$$\begin{aligned}\int \mathcal{D}x\, x(t_1)x(t_2)e^{iS} &= \int dx_1\, dx_2\; x_1\, x_2 \left\langle x_f\middle|e^{-iH(t_f-t_1)}\middle|x_1\right\rangle \left\langle x_1\middle|e^{-iH(t_1-t_2)}\middle|x_2\right\rangle \left\langle x_2\middle|e^{-iH(t_2-t_i}\right. \\ &= \left\langle x_f\middle|e^{-iH(t_f-t_1)}\,\hat{x}\,e^{-iH(t_1-t_2)}\,\hat{x}\,e^{-iH(t_2-t_i)}\middle|x_i\right\rangle \\ &= \langle x_f|\hat{x}(t_1)\,\hat{x}(t_2)|x_i\rangle \qquad (t_1 > t_2), \end{aligned} \tag{10.59}$$

where the last line restores the Heisenberg operators by reattaching the phases $e^{\pm iHt}$. The operator with the *later* argument, $\hat{x}(t_1)$, came out on the *left*, because the leftmost intermediate evolution operator carries the latest time. If instead $t_2 > t_1$, the same c-number integral — unchanged, by the symmetry just noted — is reconstructed by cutting first at t_1 and then at t_2, and the identical manipulation delivers $\langle x_f|\hat{x}(t_2)\hat{x}(t_1)|x_i\rangle$, again with the later operator on the left. The two cases are summarized by a single formula precisely when the right-hand side carries the step functions of the time-ordering symbol,

$$\int \mathcal{D}x\, x(t_1)x(t_2)e^{iS} = \theta(t_1{-}t_2)\,\langle x_f|\hat{x}(t_1)\hat{x}(t_2)|x_i\rangle + \theta(t_2{-}t_1)\,\langle x_f|\hat{x}(t_2)\hat{x}(t_1)|x_i\rangle = \langle x_f|\mathcal{T}\hat{x}(t_1)\hat{x}$$

For general n, let π be the permutation that sorts the times into decreasing order $t_{\pi(1)} > t_{\pi(2)} > \cdots > t_{\pi(n)}$. Cutting at all n instants in increasing order and inserting position eigenstates at each yields the product of $n{+}1$ kernels with $x_{\pi(1)}\cdots x_{\pi(n)}$ inserted; reattaching phases gives $\left\langle x_f\middle|\hat{x}(t_{\pi(1)})\cdots\hat{x}(t_{\pi(n)})\middle|x_i\right\rangle$, the operators in decreasing-time (i.e. time-ordered) sequence. Because the c-number integrand $x(t_1)\cdots x(t_n)$ is totally symmetric, this holds for every choice of the t_k, which is the content of Eq. (10.58). □

Physical Insight

The lesson is worth stating plainly because it recurs everywhere in the path-integral formalism. Inside the functional integral the field values are ordinary commuting numbers, so the integrand never remembers an ordering; ordering is a property of *operators*, and it is reintroduced only when one re-expresses the integral as a sliced product of non-commuting evolution operators. The slicing can only run forward in time, so the operator product it produces is automatically the time-ordered one. This is why the path integral computes time-ordered Green's functions for free, and it is the deep reason the formalism makes Lorentz invariance manifest: there is no preferred time-slicing of a c-number product, hence no privileged frame hidden in the construction.

10.2.2 Projecting onto the vacuum: the $i\varepsilon$ tilt

Equation Eq. (10.58) still carries the arbitrary boundary data $|x_i, t_i\rangle$ and $\langle x_f, t_f|$. The correlators of quantum field theory are taken not between position eigenstates but in the *ground state*, $\langle \mathcal{T}\hat{x}(t_1)\cdots\hat{x}(t_n)\rangle \equiv \langle\Omega|\mathcal{T}\hat{x}(t_1)\cdots\hat{x}(t_n)|\Omega\rangle$. We must therefore replace the endpoint states by $|\Omega\rangle$. Doing so by hand would require knowing the ground-state wavefunction; the elegant alternative, which generalizes intact to the field theory, is to let an infinitesimal rotation of the time contour into the lower-half complex plane do the projection automatically.

Consider sandwiching the evolution operator between fixed but otherwise arbitrary states $|\chi_i\rangle$ and $\langle\chi_f|$ that have nonzero overlap with the vacuum, $\langle\Omega|\chi_i\rangle \neq 0 \neq \langle\chi_f|\Omega\rangle$. Insert the spectral resolution $\mathbf{1} = \sum_n |n\rangle\langle n|$:

$$\Big\langle \chi_f \Big| e^{-iHT} \Big| \chi_i \Big\rangle = \sum_n \langle\chi_f|n\rangle\, \langle n|\chi_i\rangle\, e^{-iE_nT}, \qquad T \equiv t_f - t_i. \tag{10.60}$$

Each term oscillates with its own frequency E_n, and no single term dominates as $T \to \infty$ along the real axis. Now tilt the time axis by an infinitesimal angle into the complex plane, replacing the elapsed time by $T \to T(1 - i\varepsilon)$ with $\varepsilon > 0$, equivalently rotating each instant $t \to t(1 - i\varepsilon)$. The phase becomes

$$e^{-iE_nT(1-i\varepsilon)} = e^{-iE_nT}\, e^{-\varepsilon E_nT}, \tag{10.61}$$

so that high-energy states are exponentially damped relative to low-energy ones as $T \to \infty$. Because the ground state has the lowest energy E_0, in the limit $T \to \infty(1 - i\varepsilon)$ the sum Eq. (10.60) is dominated by the $n = 0$ term:

$$\Big\langle \chi_f \Big| e^{-iHT} \Big| \chi_i \Big\rangle \xrightarrow{T\to\infty(1-i\varepsilon)} \langle\chi_f|\Omega\rangle\, \langle\Omega|\chi_i\rangle\, e^{-iE_0T}\, [1 + O(e^{-\varepsilon(E_1-E_0)T})]. \tag{10.62}$$

The tilt has converted the oscillating evolution operator into a (complex) projector onto the ground state, up to the c-number prefactor $\langle\chi_f|\Omega\rangle\,\langle\Omega|\chi_i\rangle\,e^{-iE_0T}$. This prefactor is universal: it knows nothing about the operator insertions, only about the endpoints and the total elapsed time. It will therefore cancel in any ratio in which it appears identically in numerator and denominator.

Physical Insight

The tilt $t \to t(1-i\varepsilon)$ is an *infinitesimal Wick rotation*. The full rotation $t \to -i\tau$ defined in Theorem 5.30 and Section 5.4.2 turns e^{-iHT} into the positive heat kernel $e^{-H\tau}$, which projects onto the ground state at $\tau \to +\infty$ with no oscillation at all and no need to take a limit through complex angles: $e^{-H\tau} \to |\Omega\rangle\, e^{-E_0\tau}\,\langle\Omega|$ manifestly. The $i\varepsilon$ prescription is the minimal amount of that Euclidean damping required to make the Minkowski limit well-defined; it is the same $i\varepsilon$ that we will see decorate every propagator. Tilting the contour and Wick-rotating fully are two ends of one continuous deformation, and the vacuum projection is what both accomplish.

We can now state the vacuum correlator as a normalized ratio of path integrals.

Theorem 10.10 (Ground-state correlators from the path integral)**.** *Let the system have a non-degenerate ground state $|\Omega\rangle$ and let the endpoints $|\chi_i\rangle, |\chi_f\rangle$ have nonzero vacuum overlap. With the time contour tilted as $t \to t(1-i\varepsilon)$ and the endpoints sent to $t_i \to -\infty$, $t_f \to +\infty$, the time-ordered vacuum correlators are*

$$\langle \mathcal{T}\,\hat{x}(t_1)\cdots\hat{x}(t_n)\rangle \;\equiv\; \langle\Omega|\mathcal{T}\,\hat{x}(t_1)\cdots\hat{x}(t_n)|\Omega\rangle = \frac{\displaystyle\int \mathcal{D}x\; x(t_1)\cdots x(t_n)\, e^{iS[x]}}{\displaystyle\int \mathcal{D}x\; e^{iS[x]}}, \tag{10.63}$$

where on both sides the action carries the $i\varepsilon$ tilt and the paths run over the whole (tilted) time axis with the fixed endpoint data, whose dependence cancels in the ratio.

Proof. Apply Theorem 10.9 but now contract the endpoints against $|\chi_i\rangle, \langle\chi_f|$ rather than position eigenstates. Split the evolution at the earliest insertion time $t_{\min} = \min_k t_k$ and the latest $t_{\max} = \max_k t_k$, writing the full evolution as $e^{-iH(t_f - t_{\max})}$, then the ordered block of operators and intervening evolutions confined to $[t_{\min}, t_{\max}]$, then $e^{-iH(t_{\min}-t_i)}$. As $t_f \to +\infty(1-i\varepsilon)$, the leading factor projects the left endpoint: $\langle\chi_f|\, e^{-iH(t_f-t_{\max})} \to \langle\chi_f|\Omega\rangle\, e^{-iE_0(t_f-t_{\max})}\,\langle\Omega|$ by the argument leading to Eq. (10.62), applied with the intervening operators held fixed at finite times. Likewise $t_i \to -\infty(1-i\varepsilon)$ projects the right endpoint,

$e^{-iH(t_{\min}-t_i)}\,|\chi_i\rangle \to |\Omega\rangle\,\langle\Omega|\chi_i\rangle\,e^{-iE_0(t_{\min}-t_i)}$. What survives between the two projectors is exactly $\langle\Omega|\mathcal{T}\hat{x}(t_1)\cdots\hat{x}(t_n)|\Omega\rangle$, multiplied by the endpoint-and-energy prefactor

$$P = \langle\chi_f|\Omega\rangle\,\langle\Omega|\chi_i\rangle\;e^{-iE_0(t_f-t_i)}.$$

This same P is produced with *no* insertions, since the denominator $\int\mathcal{D}x\,e^{iS} = \left\langle\chi_f\middle|e^{-iHT}\middle|\chi_i\right\rangle \to P$ by Eq. (10.62) directly. Dividing numerator by denominator cancels P and the wavefunction data along with it, leaving Eq. (10.63). □

Caution

The normalization by $\int\mathcal{D}x\,e^{iS}$ is not cosmetic. The unnormalized numerator carries the divergent (in the $T\to\infty$ limit) and endpoint-dependent prefactor P, which has no physical meaning; only the ratio is finite and independent of the arbitrary boundary states. In the field theory this same denominator is the sum of vacuum bubbles, and dividing by it is precisely what removes disconnected vacuum diagrams. The structure "correlator = insertions over no-insertions" established here is permanent.

10.2.3 The source and the generating functional

Computing $\langle\mathcal{T}\hat{x}(t_1)\cdots\hat{x}(t_n)\rangle$ one n at a time through Eq. (10.63) is correct but clumsy. The decisive simplification, due to Schwinger, is to introduce a classical external source $J(t)$ coupled linearly to the dynamical variable, so that a *single* functional packages all the correlators at once and individual ones are extracted by differentiation. We add to the Lagrangian a source term $L \to L + J(t)\,x(t)$, which shifts the action by $\int dt\,J(t)x(t)$, and integrate.

Definition 10.11 (Generating functional)**.** The *vacuum generating functional* of the quantum-mechanical system in the presence of the source J is

$$Z[J] \;\equiv\; \int\mathcal{D}x\;\exp\!\left\{i\int_{-\infty}^{\infty}dt\,\big[L(x,\dot{x}) + J(t)\,x(t)\big]\right\}, \tag{10.64}$$

the path integral taken over the $i\varepsilon$-tilted contour with vacuum-overlapping endpoints, as in Theorem 10.10. It is a functional of the source: a number assigned to each function J. We write $Z[0]$ for its value at $J\equiv 0$, the source-free path integral.

The point of the definition is that differentiating $Z[J]$ with respect to the source at a time t_1 pulls a factor $x(t_1)$ down from the exponent. Concretely, applying the functional derivative of Theorem 4.4 and Eq. (4.5) — here in its one-dimensional "index" form, where $\delta J(t)/\delta J(t') = \delta(t-t')$ — to Eq. (10.64) gives

$$\frac{\delta Z[J]}{\delta J(t_1)} = \int\mathcal{D}x\;\big[\,i\,x(t_1)\,\big]\;\exp\!\left\{i\int dt\,(L + Jx)\right\}, \tag{10.65}$$

because the only J-dependence is in the exponent, and $\frac{\delta}{\delta J(t_1)}\, i\int dt\, J(t)x(t) = i\,x(t_1)$. Each further derivative brings down another factor $i\,x(t_k)$. The factors of i are the only bookkeeping needed.

Theorem 10.12 (Correlators as functional derivatives of Z)**.** *The time-ordered vacuum correlation functions are the normalized functional derivatives of the generating functional at vanishing source:*

$$\langle \mathcal{T}\, \hat{x}(t_1)\cdots\hat{x}(t_n)\rangle = \frac{1}{i^{\,n}}\,\frac{1}{Z[0]}\,\frac{\delta^{\,n} Z[J]}{\delta J(t_1)\,\delta J(t_2)\cdots\delta J(t_n)}\bigg|_{J=0}. \tag{10.66}$$

Equivalently, with $W[J]\equiv \ln Z[J]$ and Z normalized so that $Z[0]=1$, $Z[J]$ is the moment-generating functional of the $x(t_k)$ and its Taylor coefficients in J are the correlators.

Proof. Differentiate Eq. (10.64) n times, each time using Eq. (10.65); since the integrand depends on J only through the smooth exponential, the derivatives pass under the path integral and act successively:

$$\frac{\delta^{\,n} Z[J]}{\delta J(t_1)\cdots\delta J(t_n)} = \int \mathcal{D}x\, \big[\,i\,x(t_1)\big]\cdots\big[\,i\,x(t_n)\big]\, \exp\!\Big\{ i\int dt\,(L + Jx)\Big\} = i^{\,n}\int \mathcal{D}x\; x(t_1)\cdots x(t$$

Setting $J=0$ removes the source from the exponent, leaving $i^{\,n}\int \mathcal{D}x\, x(t_1)\cdots x(t_n)\, e^{iS}$. Dividing by $Z[0]=\int \mathcal{D}x\, e^{iS}$ and the explicit $i^{\,n}$ reproduces exactly the ratio of Eq. (10.63), which Theorem 10.10 identified as $\langle \mathcal{T}\hat{x}(t_1)\cdots\hat{x}(t_n)\rangle$. This is Eq. (10.66). The Taylor statement follows by expanding the exponential of the source term inside Eq. (10.64) in powers of J: the coefficient of $\frac{i^n}{n!}\int J(t_1)\cdots J(t_n)$ is the symmetric kernel $\int \mathcal{D}x\, x(t_1)\cdots x(t_n) e^{iS}/Z[0]$, i.e. the n-point correlator, so

$$\frac{Z[J]}{Z[0]} = \sum_{n=0}^{\infty} \frac{i^{\,n}}{n!}\int dt_1\cdots dt_n\; \langle \mathcal{T}\,\hat{x}(t_1)\cdots\hat{x}(t_n)\rangle\; J(t_1)\cdots J(t_n), \tag{10.67}$$

the generating series of the correlators. □

This is the master identity the section was built to reach. It says that all the dynamical information of the quantum theory — every time-ordered correlator, hence (via the reduction formula of Chapter 14) every scattering amplitude — is encoded in the single functional $Z[J]$. The strategy from here is uniform: find $Z[J]$, then differentiate. For an interacting system $Z[J]$ cannot be computed exactly, and the differentiation is organized into Feynman diagrams; but for a quadratic action it can be done in closed form, and that solvable case is the foundation of all of perturbation theory. We turn to it now.

10.2.4 The oscillator generating functional

Specialize to the harmonic oscillator, the free theory of one degree of freedom and the $0+1$-dimensional avatar of the free scalar field. With unit mass and frequency ω,

$$S_0[x] = \int_{-\infty}^{\infty} dt \left[\tfrac{1}{2}\dot{x}^2 - \tfrac{1}{2}\omega^2 x^2\right] = \frac{1}{2}\int_{-\infty}^{\infty} dt\; x(t)\big(-\partial_t^2 - \omega^2\big)x(t), \tag{10.68}$$

where the second form follows from integrating $\frac{1}{2}\dot{x}^2$ by parts and discarding the boundary term, legitimate because the tilted contour forces $x(t) \to 0$ at the (complex) infinite endpoints. Define the kinetic operator

$$\mathcal{K} \equiv -\partial_t^2 - \omega^2, \tag{10.69}$$

so that $S_0 = \frac{1}{2}\int x\,\mathcal{K}x$. The $i\varepsilon$ tilt of Section 10.2.2 amounts, at the level of the action, to the replacement $\omega^2 \to \omega^2 - i\varepsilon$, as we verify below; this is the convergence factor that makes the oscillatory Gaussian well-defined. The source-coupled free generating functional is then

$$Z_0[J] = \int \mathcal{D}x\; \exp\!\left\{\frac{i}{2}\int dt\, x\,\mathcal{K}x + i\int dt\, Jx\right\}. \tag{10.70}$$

This is a (functional) Gaussian integral with a linear source. We evaluate it by completing the square, the continuum version of Theorem 4.15.

Theorem 10.13 (Free generating functional)**.** *The harmonic-oscillator generating functional is*

$$Z_0[J] = Z_0[0]\,\exp\!\left\{-\frac{1}{2}\int_{-\infty}^{\infty} dt\, dt'\; J(t)\,G(t-t')\,J(t')\right\}, \tag{10.71}$$

where the kernel G is the Feynman Green's function *of the kinetic operator $\mathcal{K}$, defined by*

$$\big(-\partial_t^2 - \omega^2\big)\,G(t-t') = i\,\delta(t-t'), \tag{10.72}$$

together with the boundary condition fixed by the $i\varepsilon$ tilt, namely the Fourier representation

$$G(t-t') = \int_{-\infty}^{\infty} \frac{d\nu}{2\pi}\,\frac{i\,e^{-i\nu(t-t')}}{\nu^2 - \omega^2 + i\varepsilon}. \tag{10.73}$$

Proof. The integral Eq. (10.70) is Gaussian, so it is evaluated exactly by shifting the integration variable to the classical trajectory in the presence of the source and isolating the source-dependent constant. Seek the stationary point of the exponent: with $f[x] \equiv \frac{i}{2}\int x\mathcal{K}x + i\int Jx$, the first variation Eq. (4.4) is

$$\frac{\delta f}{\delta x(t)} = i\,\mathcal{K}x(t) + iJ(t) = 0 \quad\Longrightarrow\quad \mathcal{K}\,x_c = -J, \tag{10.74}$$

the classical equation of motion driven by the source; we used $\mathcal{K}^{\mathsf{T}} = \mathcal{K}$ (the operator $-\partial_t^2 - \omega^2$ is formally self-adjoint) so that the variation of $\frac{1}{2}\int x\mathcal{K}x$ is $\mathcal{K}x$. Its solution, with the boundary condition supplied by the tilt, is $x_c = -\mathcal{K}^{-1}J$, where $\mathcal{K}^{-1}$ is the appropriate Green's function. Substitute $x = x_c + y$. Because the exponent is exactly quadratic, it splits with no cross term between the constant piece and the fluctuation y:

$$\frac{i}{2}\int x\mathcal{K}x + i\int Jx = \underbrace{\Big[\tfrac{i}{2}\int x_c\mathcal{K}x_c + i\int Jx_c\Big]}_{\text{stationary value}} + \underbrace{\tfrac{i}{2}\int y\,\mathcal{K}\,y}_{\text{fluctuation}}, \tag{10.75}$$

the linear-in-y terms cancelling by the stationarity condition Eq. (10.74) exactly as in the finite-dimensional computation Eqs. (4.55) and (4.56). Evaluate the stationary value using $\mathcal{K}x_c = -J$ and the symmetry of $\mathcal{K}$:

$$\frac{i}{2}\int x_c\mathcal{K}x_c + i\int Jx_c = \frac{i}{2}\int x_c(-J) + i\int Jx_c = \frac{i}{2}\int Jx_c = \frac{i}{2}\int J\,(-\mathcal{K}^{-1}J) = -\frac{i}{2}\int J\,\mathcal{K}^{-1}J. \tag{10.76}$$

The fluctuation integral $\int \mathcal{D}y\,\exp\{\frac{i}{2}\int y\mathcal{K}y\}$ is precisely the source-free path integral $Z_0[0]$, since shifting an integration variable leaves the measure invariant. Hence

$$Z_0[J] = Z_0[0]\,\exp\Big\{-\tfrac{i}{2}\int J\,\mathcal{K}^{-1}J\Big\}. \tag{10.77}$$

It remains to identify $\mathcal{K}^{-1}$ and recast the result. Define $G \equiv i\,\mathcal{K}^{-1}$, so that $\mathcal{K}G = i$ as operators, which spelled out is the differential equation Eq. (10.72). Then $\mathcal{K}^{-1} = -iG$ and the exponent becomes

$$-\tfrac{i}{2}\int J\,\mathcal{K}^{-1}J = -\tfrac{i}{2}\int J(-iG)J = -\tfrac{i\cdot(-i)}{2}\int JGJ = -\tfrac{1}{2}\int JGJ,$$

which is Eq. (10.71). Finally we fix the boundary condition — which Green's function $\mathcal{K}^{-1}$ is — from the $i\varepsilon$ tilt. Pass to frequency space, $G(t) = \int \frac{d\nu}{2\pi}\tilde{G}(\nu)e^{-i\nu t}$ and $\delta(t) = \int \frac{d\nu}{2\pi}e^{-i\nu t}$. Acting with $\mathcal{K} = -\partial_t^2 - \omega^2$ multiplies $\tilde{G}$ by $(\nu^2 - \omega^2)$, so Eq. (10.72) reads $(\nu^2 - \omega^2)\tilde{G}(\nu) = i$, i.e. $\tilde{G}(\nu) = i/(\nu^2 - \omega^2)$. The operator $\mathcal{K}$ has zero modes at $\nu = \pm\omega$, so its inverse is ambiguous until a contour prescription is supplied; the tilt $\omega^2 \to \omega^2 - i\varepsilon$ inherited from Eq. (10.61) is exactly that prescription, displacing the poles and yielding Eq. (10.73). This $+i\varepsilon$ is the same prescription that selects the Feynman (time-ordered) boundary conditions, as the explicit evaluation below confirms. □

It remains to perform the frequency integral and read off the boundary conditions G obeys. The computation is the $0+1$-dimensional rehearsal of the contour manipulation that produced the covariant scalar propagator in Section 9.5.3, and it teaches the same lesson: the $+i\varepsilon$ in the denominator routes positive frequencies forward in time.

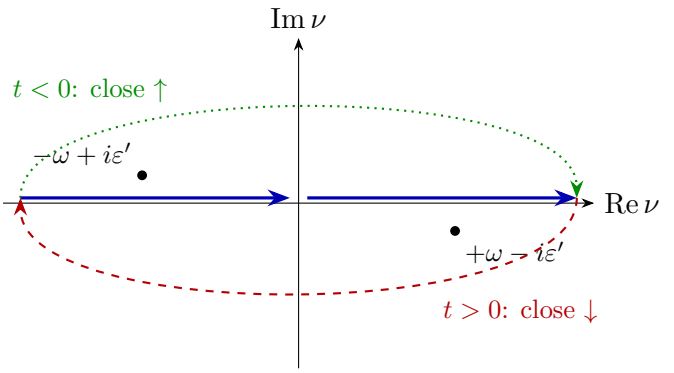

Figure 10.2: The complex frequency plane for the Feynman Green's function Eq. (10.73). The $+i\varepsilon$ prescription pushes the pole at $\nu = +\omega$ below the real axis and the pole at $\nu = -\omega$ above it. For $t - t' > 0$ the factor $e^{-i\nu(t-t')}$ forces the contour closed in the lower half-plane, enclosing $+\omega$; for $t - t' < 0$ it closes above, enclosing $-\omega$. Either way a single positive-frequency exponential results, giving $G(t) = \frac{1}{2\omega} e^{-i\omega|t|}$.

Worked Example 10.14 (The Feynman Green's function by contour integration)**.** We evaluate Eq. (10.73) explicitly. Factor the denominator. With the $+i\varepsilon$ in place, $\nu^2 - \omega^2 + i\varepsilon = (\nu - \nu_+)(\nu - \nu_-)$ where the roots are displaced off the real axis,

$$\nu_\pm = \pm\sqrt{\omega^2 - i\varepsilon} = \pm(\omega - i\varepsilon'), \qquad \varepsilon' \equiv \frac{\varepsilon}{2\omega} > 0,$$

so the pole near $+\omega$ sits just *below* the real axis and the pole near $-\omega$ just *above* it; see Fig. 10.2. Write $\tau \equiv t - t'$ and

$$G(\tau) = \int_{-\infty}^{\infty} \frac{d\nu}{2\pi} \, \frac{i\, e^{-i\nu\tau}}{(\nu - \nu_+)(\nu - \nu_-)}.$$

The exponential $e^{-i\nu\tau} = e^{-i(\mathrm{Re}\,\nu)\tau}\, e^{(\mathrm{Im}\,\nu)\tau}$ decays in the lower half-plane ($\mathrm{Im}\,\nu < 0$) when $\tau > 0$, and in the upper half-plane when $\tau < 0$; closing the contour with the vanishing semicircle in the appropriate half-plane lets us apply the residue theorem.

Case $\tau > 0$. Close downward, enclosing only $\nu_+ = \omega - i\varepsilon'$ and traversing the closed contour clockwise (an extra minus sign). The residue is

$$\mathrm{Res}_{\nu=\nu_+} \frac{i\, e^{-i\nu\tau}}{(\nu - \nu_+)(\nu - \nu_-)} = \frac{i\, e^{-i\omega\tau}}{\nu_+ - \nu_-}\bigg|_{\varepsilon\to 0} = \frac{i\, e^{-i\omega\tau}}{2\omega}.$$

Hence

$$G(\tau > 0) = \frac{1}{2\pi}\,(-2\pi i)\,\frac{i\, e^{-i\omega\tau}}{2\omega} = \frac{e^{-i\omega\tau}}{2\omega},$$

using $(-2\pi i)(i) = 2\pi$.

Case $\tau < 0$. Close upward, enclosing only $\nu_- = -\omega + i\varepsilon'$ and traversing counterclockwise ($+2\pi i$). The residue is $i\,e^{+i\omega\tau}/(\nu_- - \nu_+) = i\,e^{i\omega\tau}/(-2\omega)$, so

$$G(\tau<0) = \frac{1}{2\pi}\,(2\pi i)\,\frac{i\,e^{i\omega\tau}}{-2\omega} = \frac{e^{+i\omega\tau}}{2\omega}.$$

The two cases combine into the manifestly even, positive-frequency-forward result

$$G(\tau) = \frac{1}{2\omega}\,e^{-i\omega|\tau|}. \tag{10.78}$$

For $\tau > 0$ the Green's function propagates the phase $e^{-i\omega\tau}$ of the positive-energy state forward; for $\tau < 0$ it is the complex conjugate. This is precisely the time-ordered structure: the $+i\varepsilon$ in Eq. (10.73) is the Feynman prescription, and Eq. (10.78) is the quantum-mechanical Feynman propagator. It is the $0+1$-dimensional shadow of the covariant momentum-space propagator $i/(p^2 - m^2 + i\varepsilon)$ obtained for the field in Section 9.5.3: the frequency ν plays the role of p^0, the gap ω the role of the on-shell energy $E_{\boldsymbol{p}}$, and the contour logic is identical.

Worked Example 10.15 (The two-point function, two ways)**.** We confirm that the generating-functional machinery reproduces the canonical result, closing the loop with Chapter 9. Apply the master identity Eq. (10.66) with $n = 2$ to the free $Z_0[J]$ of Eq. (10.71). Writing $Z_0[J]/Z_0[0] = \exp\{-\frac{1}{2}\int JGJ\}$, the first derivative is

$$\frac{1}{Z_0[0]}\frac{\delta Z_0}{\delta J(t_1)} = \Big(-\int dt'\,G(t_1 - t')J(t')\Big)\,\frac{Z_0[J]}{Z_0[0]},$$

using $G(t-t') = G(t'-t)$ from Eq. (10.78) so that the two ways of hitting the symmetric kernel agree. Differentiating again,

$$\frac{1}{Z_0[0]}\frac{\delta^2 Z_0}{\delta J(t_1)\delta J(t_2)} = \Big[-G(t_1-t_2) + \Big(\int G(t_1-t')J\Big)\Big(\int G(t_2-t')J\Big)\Big]\frac{Z_0[J]}{Z_0[0]}.$$

Set $J = 0$: the second term vanishes and $Z_0[J]/Z_0[0] \to 1$, leaving $-G(t_1 - t_2)$. Divide by $i^2 = -1$:

$$\langle \mathcal{T}\,\hat{x}(t_1)\hat{x}(t_2)\rangle = \frac{1}{i^2}\big(-G(t_1-t_2)\big) = G(t_1-t_2) = \frac{1}{2\omega}\,e^{-i\omega|t_1-t_2|}. \tag{10.79}$$

Now the canonical computation, for comparison. In the Heisenberg picture the oscillator coordinate is $\hat{x}(t) = \frac{1}{\sqrt{2\omega}}(\hat{a}\,e^{-i\omega t} + \hat{a}^\dagger e^{i\omega t})$, with $[\hat{a}, \hat{a}^\dagger] = 1$ and $\hat{a}\,|\Omega\rangle = 0$. For $t_1 > t_2$,

$$\langle\Omega|\hat{x}(t_1)\hat{x}(t_2)|\Omega\rangle = \frac{1}{2\omega}\,\Big\langle\Omega\Big|\hat{a}\,\hat{a}^\dagger\Big|\Omega\Big\rangle\; e^{-i\omega t_1}e^{+i\omega t_2} = \frac{1}{2\omega}\,e^{-i\omega(t_1-t_2)},$$

only the $\hat{a}\hat{a}^\dagger$ term surviving because $\hat{a}\,|\Omega\rangle = 0 = \langle\Omega|\,\hat{a}^\dagger$ and $\Big\langle\Omega\Big|\hat{a}\hat{a}^\dagger\Big|\Omega\Big\rangle = 1$. Time-ordering supplies the same expression with $t_1 \leftrightarrow t_2$ for $t_2 > t_1$, i.e. $\frac{1}{2\omega}e^{-i\omega|t_1-t_2|}$, in exact agreement with Eq. (10.79). The two pillars — canonical quantization and the path integral — give the identical correlator, as they must.

The agreement in Theorem 10.15 is the simplest instance of the central claim of the chapter: the sum over histories and the operator formalism are two computations of the same physics. We obtained the Feynman propagator a second, independent way, as the kernel of a Gaussian integral rather than as a vacuum matrix element of ordered operators, and the $i\varepsilon$ that was a contour choice in Chapter 9 is here the contour tilt that projects onto the ground state. Higher correlators follow by further differentiation of Eq. (10.71); because $Z_0[J]$ is the exponential of a quadratic, those derivatives organize into all pairings of the insertion times, which is Wick's theorem — the topic to which the next chapter material returns once the field has been installed.

With the quantum-mechanical template complete, the structure that hands forward to the field theory is fixed and will be lifted verbatim: the generating functional $Z[J] = \int \mathcal{D}x\, \exp\{i \int dt\, (L + Jx)\}$ of Eq. (10.64), the rule that time-ordered correlators are normalized functional derivatives $\frac{1}{i^n}\delta^n Z/\delta J^n$ at $J = 0$ of Eq. (10.66), the $i\varepsilon$ contour tilt that selects the vacuum, and the complete-the-square template $Z_0[J] = \exp\{-\frac{1}{2}\int\int JGJ\}$ of Eq. (10.71) with G the Feynman Green's function. In the next section the single coordinate $x(t)$ is replaced by the field value $\phi(\mathbf{x}, t)$ at every spatial point, the source $J(t)$ becomes $J(x)$, and the operator $-\partial_t^2 - \omega^2$ becomes the Klein–Gordon operator $-\Box - m^2$ of ϕ^4 theory — whereupon the same Gaussian integral returns the covariant Feynman propagator $i/(p^2 - m^2 + i\varepsilon)$ a second time.

10.3 The Generating Functional for a Scalar Field

The previous section built the entire path-integral apparatus in its smallest nontrivial laboratory: a quantum system with a single degree of freedom. We learned there to package every time-ordered correlator of a coordinate $q(t)$ into one object, the generating functional $Z[J] = \int \mathcal{D}q\, \exp\left[i \int dt\, (L + Jq)\right]$; we saw that differentiating $Z[J]$ with respect to the source $J(t)$ pulls down insertions of q, so that correlators are functional derivatives of Z; we saw that the ground state is selected automatically by an infinitesimal clockwise tilt of the time contour, the $i\varepsilon$ prescription, which damps every excited state in the spectral sum; and we saw that the resulting Gaussian is evaluated by completing the square. None of that machinery cared that there was only one coordinate. The business of this section is to let the number of coordinates grow without bound until it becomes a continuum — to turn $q(t)$ into the field $\phi(t, \mathbf{x})$ — and to read off what each piece of the one-dimensional template becomes in the limit. The payoff is the central object of the path-integral formulation of scalar field theory: the generating functional $Z[J]$ for the frozen ϕ^4 Lagrangian, the definition of its n-point Green's functions, and an honest account of the one genuinely new ingredient, the functional measure $\mathcal{D}\phi$.

We continue ϕ^4 theory from its free canonical quantization in Chapter 9. The

target Lagrangian density is the one frozen for the thread in Eq. (6.56),

$$\mathcal{L} \;=\; \tfrac{1}{2}\,(\partial_\mu\phi)(\partial^\mu\phi) \;-\; \tfrac{1}{2}m^2\phi^2 \;-\; \frac{\lambda}{4!}\,\phi^4, \qquad \phi \text{ real},\ \lambda > 0, \tag{10.80}$$

in the conventions fixed for the whole book: mostly-minus metric $\eta_{\mu\nu} = \mathrm{diag}(+,-,-,-)$, natural units $\hbar = c = 1$. We call this Lagrangian *frozen* because in this section the coupling λ is carried along untouched: every manipulation below is exact as a formal statement for any λ, and the actual evaluation of the integral — which is possible in closed form only for the free, $\lambda = 0$, Gaussian piece — is the work of Section 10.4. The role of the present section is purely to *construct* the object $Z[J]$ and to say precisely what it means.

10.3.1 From a lattice of oscillators to a spacetime lattice

In Section 9.1.2 we replaced the continuous spatial argument $\mathbf{x}$ of the field by a cubic lattice of sites $\mathbf{x}_\mathbf{n} = a\mathbf{n}$, $\mathbf{n} \in \mathbb{Z}^3$, of spacing a, and discovered that the free scalar is nothing but a lattice of coupled harmonic oscillators: at each site sits a coordinate $q_\mathbf{n}(t) = \phi(t, \mathbf{x}_\mathbf{n})$, the neighbours are joined by springs that encode the gradient energy $\frac{1}{2}(\nabla\phi)^2$, and the mass term $\frac{1}{2}m^2\phi^2$ supplies an on-site restoring force (Fig. 9.1). That mechanical picture is exactly the bridge we need. The path integral of the previous section was derived for a system with finitely many coordinates $q_a(t)$, $a = 1, \ldots, N$, and is insensitive to whether those coordinates are genuinely different particles or, as here, the values of one field at different points of space. We therefore take the coupled-oscillator system of Chapter 9 and feed it straight into the path-integral construction.

Discretize space into a large cubic box of side $L = N_s a$ with periodic boundary conditions, so the spatial label $\mathbf{n}$ runs over the finitely many sites $\mathbf{n} \in \{0, \ldots, N_s - 1\}^3$. The field at fixed time is then the finite collection of numbers $\{\phi_\mathbf{n}(t)\}$. Writing the gradient as a nearest-neighbour difference, the discretized Lagrangian of the frozen theory Eq. (10.80) is the sum over sites

$$L(\{\phi_\mathbf{n}\}, \{\dot\phi_\mathbf{n}\}) = \sum_\mathbf{n} a^3 \left[\, \tfrac{1}{2}\,\dot\phi_\mathbf{n}^2 - \tfrac{1}{2}\sum_{i=1}^{3}\Big(\frac{\phi_{\mathbf{n}+\hat\imath} - \phi_\mathbf{n}}{a}\Big)^2 - \tfrac{1}{2}m^2\phi_\mathbf{n}^2 - \frac{\lambda}{4!}\,\phi_\mathbf{n}^4 \right], \tag{10.81}$$

where $\hat\imath$ is the unit lattice vector in the i-th direction and the cell volume a^3 converts each site density into an energy, exactly as in Chapter 9. This is a perfectly ordinary mechanical system of $N = N_s^3$ coupled anharmonic oscillators, and the previous section tells us, verbatim, how to write its generating functional.

Recall the one-dimensional template in its multi-coordinate form. For a system with coordinates q_a and Lagrangian $L(q, \dot q)$, the vacuum generating functional with sources $J_a(t)$ coupled to each coordinate is the time-sliced path integral

$$Z[\{J_a\}] \;=\; \int \prod_a \mathcal{D}q_a \;\exp\Big[\, i\int_{-\infty}^{\infty} dt\,\Big(L(q,\dot q) + \sum_a J_a(t)\,q_a(t)\Big)\Big], \tag{10.82}$$

the integral running over all trajectories with the $i\varepsilon$ vacuum boundary conditions established in Section 10.2. Each $\mathcal{D}q_a$ is itself the limit of a product of ordinary integrals over the value of q_a at each of a fine mesh of time slices $t_j = j\,\Delta t$, with the standard kinetic-term normalization. Inserting the lattice Lagrangian Eq. (10.81) for L and renaming the coordinate at site $\mathbf{n}$ back to $\phi_{\mathbf{n}}$, with the source $J_a \to a^3 J_{\mathbf{n}}$ (the cell volume again, so that $\sum_{\mathbf{n}} a^3 J_{\mathbf{n}}\phi_{\mathbf{n}} \to \int d^3x\, J\phi$ in the limit), the generating functional of the discretized scalar field is

$$Z[J] = \int \prod_{\mathbf{n}} \mathcal{D}\phi_{\mathbf{n}}\ \exp\Big[\, i \int dt\, \Big(L(\{\phi_{\mathbf{n}}\}) + \sum_{\mathbf{n}} a^3 J_{\mathbf{n}}(t)\, \phi_{\mathbf{n}}(t) \Big)\Big]. \tag{10.83}$$

Now perform the same time-slicing inside each $\mathcal{D}\phi_{\mathbf{n}}$. The combined effect of slicing time into steps Δt and slicing space into the cubic lattice is to replace the field $\phi(t, \mathbf{x})$ by its values $\phi_{j,\mathbf{n}} \equiv \phi(t_j, \mathbf{x}_{\mathbf{n}})$ on a four-dimensional spacetime lattice (Fig. 10.3), and the integral becomes an ordinary (very high-dimensional) multiple integral over one real variable $\phi_{j,\mathbf{n}}$ per spacetime point:

$$Z[J] \;=\; \lim_{\substack{a,\Delta t\to 0\\ L,T\to\infty}} \mathcal{N} \prod_{j,\mathbf{n}} \int_{-\infty}^{\infty} d\phi_{j,\mathbf{n}}\ \exp\Big[\, i\, a^3\, \Delta t \sum_{j,\mathbf{n}} \big(\mathcal{L}_{\text{disc}} + J_{j,\mathbf{n}}\phi_{j,\mathbf{n}}\big)\Big], \tag{10.84}$$

where $\mathcal{L}_{\text{disc}}$ is the fully discretized Lagrangian density — Eq. (10.81) with $\dot\phi_{\mathbf{n}} \to (\phi_{j+1,\mathbf{n}} - \phi_{j,\mathbf{n}})/\Delta t$ — and $\mathcal{N}$ collects the kinetic-term normalization factors (one power of $\sqrt{a^3/2\pi i\,\Delta t}$ per time step per site) inherited from the one-dimensional measure. The quantity $a^3\Delta t$ is the four-volume of one lattice cell, so the exponent is a Riemann sum for the spacetime integral of $\mathcal{L} + J\phi$. This is the construction we wanted: the field path integral has been *derived* from the canonical theory of Chapter 9 by discretization, not postulated.

10.3.2 The functional measure

The continuum limit of Eq. (10.84) demands a name for the limiting integration. We adopt the standard notation and define the functional measure as exactly that limit.

Definition 10.16 (Functional measure as a lattice limit)**.** The *functional integration measure* over scalar field configurations is the symbol

$$\int \mathcal{D}\phi\ (\cdots) \;\equiv\; \lim_{\substack{a,\Delta t\to 0\\ L,T\to\infty}} \mathcal{N} \prod_{\text{cells } (j,\mathbf{n})} \int_{-\infty}^{\infty} d\phi_{j,\mathbf{n}}\ (\cdots), \tag{10.85}$$

the product running over the cells of a four-dimensional spacetime lattice and $\mathcal{N}$ the normalization inherited from the time-sliced kinetic term. The symbol $\mathcal{D}\phi = \prod_x d\phi(x)$, "one ordinary integral for every spacetime point," is shorthand for the right-hand side.

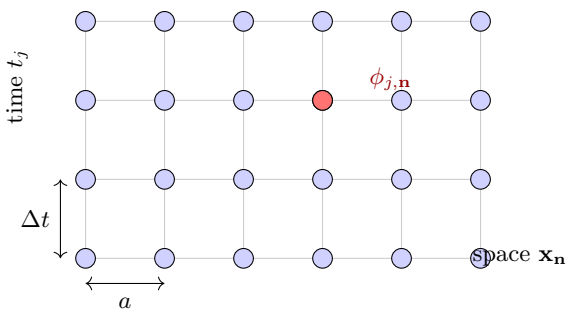

Figure 10.3: The spacetime lattice underlying Eq. (10.84). Slicing time (as in the quantum-mechanical path integral of the previous section) and slicing space (as in the coupled-oscillator picture of Fig. 9.1) together replace the field $\phi(t, \mathbf{x})$ by one real integration variable $\phi_{j,\mathbf{n}}$ per cell. The generating functional is the limit of an ordinary multiple integral over all of these variables; the functional measure $\mathcal{D}\phi$ is the name of that limit (Section 10.3.2). Each cell carries four-volume $a^3\,\Delta t$, and the exponent of Eq. (10.84) is the corresponding Riemann sum for $\int d^4x\,(\mathcal{L} + J\phi)$.

Three honest remarks fix what this definition does and does not deliver, in the spirit of the book's rigor doctrine. They matter because the measure is the one ingredient of the path integral that has no finite-dimensional precedent and is the source of every genuine subtlety in the formalism.

First, what the lattice definition *is good for*. Equation Eq. (10.85) is a completely explicit prescription: for any finite lattice the right-hand side is an ordinary, finite-dimensional multiple integral, and every formal manipulation we perform on $\int\mathcal{D}\phi$ in this chapter — shifting the integration variable, completing the square, differentiating under the integral sign with respect to a source — is first to be read as that operation on the finite-dimensional integral, after which the continuum limit is taken. For the *free*, Gaussian, theory the limit exists and all these operations are exact; the next section carries the Gaussian integration out and recovers the Feynman propagator, providing an a-posteriori certificate that the manipulations were legitimate.

Second, the normalization $\mathcal{N}$ is divergent as $a, \Delta t \to 0$, but *it cancels in every physical quantity*. The constant $\mathcal{N}$ multiplies both numerator and denominator of every correlator, because correlators are always normalized by $Z[0]$ (Section 10.3.5); it never appears in a Green's function. We therefore never need to compute $\mathcal{N}$, and it is standard — and harmless — to absorb it into the definition of the symbol $\mathcal{D}\phi$ and not write it again. What survives the limit is the ratio of integrals, and that ratio is finite for the free theory.

Third, the rigorous status. The claim that the lattice family Eq. (10.85) converges to a genuine measure on a space of field configurations is a statement of functional analysis, not of physics, and it is delicate: a naive "Lebesgue measure

on an infinite-dimensional space" does not exist. What can be made fully rigorous is the *Euclidean* version obtained by Wick rotation (Theorem 5.30), in which the oscillatory e^{iS} becomes a positive, exponentially damped weight e^{-S_E} and Eq. (10.85) converges, for the free theory, to a bona fide Gaussian measure on the space of distributions. The functional determinants that the Gaussian integral produces, and the precise sense in which the lattice limit defines the measure, are developed in Chapter E; we will use the results there by reference rather than reproving them in the main text. The honest summary is that the formal Minkowski measure is a well-controlled abbreviation for a finite-dimensional limit, rigorous for the Gaussian theory, and that the construction of the *interacting* four-dimensional scalar measure as a genuine continuum object remains a famous open problem.

Caution

The notation $\mathcal{D}\phi = \prod_x d\phi(x)$ is suggestive but must not be taken to assert that an infinite-dimensional Lebesgue measure exists. It is defined *only* as the lattice limit Eq. (10.85), and only ratios in which the normalization $\mathcal{N}$ cancels are guaranteed to be finite. Treating $\mathcal{D}\phi$ as an ordinary measure — e.g. asserting translation invariance or a change-of-variables Jacobian — is legitimate exactly when the corresponding statement holds at finite lattice size and survives the limit, and not otherwise. Every such step in this book is one that does survive; Chapter E is where that is checked.

10.3.3 The generating functional $Z[J]$

With the measure named, the continuum limit of Eq. (10.84) is immediate: the Riemann sum in the exponent becomes the spacetime integral of $\mathcal{L} + J\phi$, and the product of integrals becomes $\int \mathcal{D}\phi$. We elevate the result to a definition, the central object of the chapter.

Definition 10.17 (Generating functional of the scalar field)**.** For the frozen ϕ^4 Lagrangian Eq. (10.80), the *vacuum generating functional* in the presence of a classical source $J(x)$ is

$$\boxed{Z[J] \;=\; \int \mathcal{D}\phi \;\exp\Big[\, i \int d^4x \,\big(\mathcal{L}[\phi] + J(x)\,\phi(x)\big)\Big] \;=\; \int \mathcal{D}\phi \; e^{\,i\,(S[\phi] + \int J\phi)}\,,} \tag{10.86}$$

where $S[\phi] = \int d^4x\, \mathcal{L}[\phi]$ is the action and the measure is Theorem 10.16. The source $J(x)$ is an ordinary real function on spacetime, an external "handle" with no dynamics of its own; physical answers are read off at $J = 0$ after differentiation.

This is the field-theory analogue, term for term, of the one-dimensional $Z[J]$ of the previous section, and of the Euclidean functional generating object whose

formal structure was set up in Eq. (4.205). The exponent is real-times-i, so the integrand is a pure phase; the integral is defined by the lattice limit and made convergent by the $i\varepsilon$ prescription we now make precise.

10.3.4 Vacuum projection and the $i\varepsilon$ prescription

There is one ingredient of Eq. (10.86) that the bare symbol e^{iS} does not display: the boundary conditions on the field integration at $t \to \pm\infty$. In the quantum mechanics of the previous section, the statement that $Z[J]$ generates *vacuum* expectation values — correlators in the ground state $|0\rangle$ rather than in some arbitrary state fixed by the endpoints of the trajectory — was enforced by an infinitesimal tilt of the time contour into the lower half-plane, $t \to t\,(1 - i\varepsilon)$, equivalently a small negative imaginary part added to every energy. We now lift that prescription to the field and show it does two things at once: it projects onto the Fock vacuum of Chapter 9, and it produces precisely the Feynman pole structure of Theorem 9.25.

Consider the mechanism first in spectral terms, where it is transparent. Diagonalizing the free part of the lattice Hamiltonian into normal modes (the relativistic plane waves of Chapter 9) turns the field into a collection of independent oscillators, one for each spatial momentum $\mathbf{p}$, with frequency the on-shell energy $E_{\mathbf{p}} = \sqrt{\mathbf{p}^2 + m^2}$. The path integral over a time interval $(-T, T)$ computes a matrix element of e^{-2iHT} between boundary configurations. Inserting a complete set of energy eigenstates,

$$\langle \phi_f |\, e^{-2iHT}\, | \phi_i \rangle \;=\; \sum_n e^{-2iE_nT}\, \langle \phi_f | n \rangle \langle n | \phi_i \rangle, \tag{10.87}$$

and tilting $T \to T(1 - i\varepsilon)$ multiplies the n-th term by $e^{-2E_nT\varepsilon}$. Since $E_0 < E_1 \le E_2 \le \cdots$, in the limit $T \to \infty$ every excited contribution is exponentially suppressed relative to the ground state, and the lattice integral is dominated by $|0\rangle\,\langle 0|$: the boundary conditions are forgotten and the integral computes vacuum-to-vacuum amplitudes. This is identical, mode by mode, to the single-oscillator argument of Section 10.2; the field merely has one oscillator per momentum, and the tilt damps the excited states of all of them simultaneously. The state it projects onto is exactly the Fock vacuum $|0\rangle$ of Theorem 9.17, the no-particle state annihilated by every $a_{\mathbf{p}}$.

The same prescription has a clean and equivalent expression directly in the action, which is the form we carry forward. The tilt $t \to t(1 - i\varepsilon)$ acts on the action by giving the quadratic potential a small negative imaginary part; tracked through the normal-mode frequencies it is precisely equivalent to the replacement

$$m^2 \;\longrightarrow\; m^2 - i\varepsilon \tag{10.88}$$

in the Lagrangian Eq. (10.80), with $\varepsilon \to 0^+$ at the end. To see why this is the

right amount, write out the resulting mass term in the exponent of $Z[J]$:

$$\exp\Big[i\int d^4x\,\big(-\tfrac{1}{2}(m^2-i\varepsilon)\phi^2\big)\Big] \;=\; \exp\Big[-\tfrac{\varepsilon}{2}\int d^4x\,\phi^2\Big]\times\exp\Big[-\tfrac{i}{2}\int d^4x\,m^2\phi^2\Big]. \tag{10.89}$$

The first factor is a real, positive-definite *Gaussian damping* of the field amplitude: it suppresses configurations of large $\int\phi^2$ and renders the otherwise purely oscillatory integral Eq. (10.86) absolutely convergent on each finite lattice. The $i\varepsilon$ is thus not an optional decoration but the very thing that makes the Minkowski functional integral well-defined — it is the analytic continuation, infinitesimally performed, that connects the oscillatory e^{iS} to the convergent Euclidean weight e^{-S_E} of Theorem 5.30. The same calculation done in full Wick rotation, with the contour turned all the way to the Euclidean axis, is the subject of the Euclidean section of this chapter; here we keep only the infinitesimal tilt.

That the tilt Eq. (10.88) reproduces the Feynman boundary condition is now a one-line check against Chapter 9, and it is the consistency statement the chapter is built around. The free quadratic action, after an integration by parts that throws away the boundary term, is $S_0=\frac{1}{2}\int d^4x\,\phi(-\Box-m^2)\phi$, so the kinetic operator carried into the exponent of $Z[J]$ is $-\Box-m^2$. In momentum space, with the Fourier convention $\phi(x)=\int\frac{d^4p}{(2\pi)^4}e^{-ip\cdot x}\tilde\phi(p)$ fixed for the book, $-\Box\to p^2$ and the prescription Eq. (10.88) sends the operator to

$$-\Box-m^2 \;\longrightarrow\; p^2-m^2+i\varepsilon, \tag{10.90}$$

where the sign of the imaginary part flips because the operator carries $-m^2$, turning $-(-i\varepsilon)=+i\varepsilon$. The inverse of this operator — the object the Gaussian integration of Section 10.4 will produce as the propagator — is therefore proportional to $1/(p^2-m^2+i\varepsilon)$, which is exactly the denominator of the canonical Feynman propagator $D_F(p)=i/(p^2-m^2+i\varepsilon)$ established in Eq. (9.154). The staggered placement of the two poles in the complex p^0 plane, $p^0=\pm(E_{\mathbf p}-i\varepsilon')$, that the contour proof of Theorem 9.25 identified with "create forward, propagate forward in time," is here seen to descend from a single infinitesimal tilt of the time integration. The two pillars agree at the level of the boundary condition before a single Gaussian integral is done.

Physical Insight

The $i\varepsilon$ wears three faces, and they are the same face. In the operator formalism (Chapter 9) it is the rule "time-order the fields," the staggered poles that send positive-energy quanta forward in time. In the path integral it is the convergence factor Eq. (10.89) that makes an oscillatory integral well-defined. And spectrally it is the projector Eq. (10.87) onto the ground state. That one infinitesimal does all three jobs is not a coincidence: time-ordering, vacuum selection, and Gaussian convergence are three

descriptions of the single analytic continuation that ties Minkowski field theory to its Euclidean shadow.

10.3.5 The n-point Green's functions

We now harvest from $Z[J]$ the quantities it was built to generate. The construction repeats the one-dimensional master identity of Eq. (10.66) with the source promoted to a function of all four spacetime coordinates, so that ordinary derivatives $\partial/\partial J_a$ become functional derivatives $\delta/\delta J(x)$ in the sense of Theorem 4.4.

The basic move is to differentiate Eq. (10.86) with respect to the source. Only the factor $e^{i\int J\phi}$ depends on J, and $\frac{\delta}{\delta J(x)}\int d^4y\, J(y)\phi(y) = \phi(x)$, so each functional derivative pulls down one factor of $i\,\phi(x)$ from the exponent:

$$\frac{1}{i}\frac{\delta Z[J]}{\delta J(x)} \;=\; \int \mathcal{D}\phi\; \phi(x)\, e^{\,i(S[\phi]+\int J\phi)}. \tag{10.91}$$

Iterating n times, the $1/i$ compensating each i brought down by the exponent,

$$\frac{1}{i^n}\frac{\delta^n Z[J]}{\delta J(x_1)\cdots\delta J(x_n)} \;=\; \int \mathcal{D}\phi\; \phi(x_1)\cdots\phi(x_n)\, e^{\,i(S[\phi]+\int J\phi)}. \tag{10.92}$$

Setting the source to zero leaves the unsourced field average of the product of fields, and dividing by $Z[0] = \int\mathcal{D}\phi\, e^{iS}$ removes the (divergent, J-independent) overall normalization, including the constant $\mathcal{N}$ of Theorem 10.16. This defines the central correlators of the theory.

Definition 10.18 (n-point Green's functions)**.** The *n-point Green's functions* (or full n-point correlation functions) of the scalar field are

$$G^{(n)}(x_1,\dots,x_n) \;\equiv\; \frac{1}{Z[0]}\,\frac{1}{i^n}\,\frac{\delta^n Z[J]}{\delta J(x_1)\cdots\delta J(x_n)}\bigg|_{J=0} \;=\; \frac{\displaystyle\int \mathcal{D}\phi\; \phi(x_1)\cdots\phi(x_n)\, e^{\,iS[\phi]}}{\displaystyle\int \mathcal{D}\phi\; e^{\,iS[\phi]}}\,. \tag{10.93}$$

Two pieces of bookkeeping are worth stating once. First, $Z[J]/Z[0]$ is the natural normalized generating functional — the field-theory instance of $\widehat{Z}[J]$ from Theorem 4.26 — and its functional Taylor coefficients are exactly the $G^{(n)}$, so that $Z[J]/Z[0] = \sum_n \frac{i^n}{n!}\int d^4x_1\cdots d^4x_n\, G^{(n)}(x_1,\dots,x_n)\, J(x_1)\cdots J(x_n)$, with the factors of i now visible because the Minkowski exponent carries them. Second, the division by $Z[0]$ is not cosmetic: $Z[0]$ is the sum of all vacuum-to-vacuum amplitudes ("vacuum bubbles"), and dividing it out is what makes $G^{(n)}$ finite and equal to a physical correlator. We return to this when the diagrammatic

content is unpacked in Chapter 15; here it is simply the normalization that the canonical correlators also carry.

It remains to prove that the object Eq. (10.93), manufactured entirely inside the path integral, is the canonical time-ordered correlator of Chapter 9. This equivalence is the whole point of having two pillars, and we now establish it.

Theorem 10.19 (Path-integral correlators are time-ordered vacuum correlators)**.** *Let $\phi(x)$ be the Heisenberg-picture field operator of Chapter 9 and $|0\rangle$ the vacuum of Theorem 9.17. Then the path-integral Green's function Eq. (10.93) equals the vacuum expectation value of the time-ordered product of the corresponding operators,*

$$G^{(n)}(x_1,\dots,x_n) \;=\; \langle 0|\, \mathcal{T}\,\phi(x_1)\cdots\phi(x_n)\,|0\rangle\,. \tag{10.94}$$

For the free theory ($\lambda = 0$) this holds as an exact identity of tempered distributions; for the interacting theory it holds order by order in the coupling, with the same proof.

Proof. The mechanism is the time-slicing that defined the measure, and the key fact is that time-ordering is produced *automatically* by the slicing, not imposed by hand. We carry the argument in full for two insertions, $n = 2$; the general case is identical with more factors, and the structure makes plain that it never used $\lambda = 0$.

Work on the spacetime lattice of Section 10.3.1 and reinstate the canonical interpretation of each time slice. The time-sliced construction of the path integral — carried out for a general Hamiltonian system in Section 10.2 and applied here to the coupled-oscillator Hamiltonian of Chapter 9 — represents the amplitude between an initial configuration at t_i and a final one at t_f as a product of short-time evolution kernels, one per slice. At each slice the integration variable $\phi_{j,\mathbf{n}}$ is the eigenvalue of the Schrödinger-picture field operator $\hat\phi(\mathbf{x_n})$ on that slice. Consequently, inserting a c-number factor $\phi_{j,\mathbf{n}}$ into the integrand is the same as inserting the operator $\hat\phi$ at the corresponding time *at that position in the chain of kernels*, i.e. sandwiched between the evolution from t_i up to t_j on its right and from t_j to t_f on its left.

Take two insertions at $x_1 = (t_1, \mathbf{x}_1)$ and $x_2 = (t_2, \mathbf{x}_2)$, and suppose without loss of generality that $t_1 > t_2$. In the sliced integral the factor ϕ at the later time t_1 sits to the left of the factor at the earlier time t_2 in the product of kernels, because the kernels are ordered by increasing time from right to left. Reassembling the kernels into evolution operators and passing to the Heisenberg picture via $\hat\phi_H(t,\mathbf{x}) = e^{iHt}\hat\phi(\mathbf{x})e^{-iHt}$, the field integral with the two insertions becomes

$$\int\!\mathcal{D}\phi\;\phi(x_1)\phi(x_2)\,e^{iS} \;\xrightarrow[t_1>t_2]{}\; \mathcal{N}'\,\langle\phi_f,t_f|\;\phi_H(x_1)\,\phi_H(x_2)\;|\phi_i,t_i\rangle\,, \tag{10.95}$$

with $\phi_H(x_1)$ standing to the left precisely because t_1 is the later time. Had we assumed $t_2 > t_1$ instead, the identical manipulation would have produced

$\phi_H(x_2)\phi_H(x_1)$, the later field again on the left. The two cases combine into a single statement: whatever the time order of x_1 and x_2, the slicing delivers the operators arranged with the later one to the left — which is the definition of the time-ordered product,

$$\mathcal{T}\,\phi(x_1)\phi(x_2) = \theta(t_1 - t_2)\,\phi(x_1)\phi(x_2) + \theta(t_2 - t_1)\,\phi(x_2)\phi(x_1), \tag{10.96}$$

in the convention of Eq. (9.151). The c-number commutativity of the integration variables, $\phi(x_1)\phi(x_2) = \phi(x_2)\phi(x_1)$ under the integral, is exactly what is needed for this to be consistent: the path integral cannot tell the two orderings apart, and the only operator object with that symmetry is the time-ordered product, in which the operators have been reordered into a canonical (time) order. The path integral thus computes the time-ordered correlator and nothing else — it has no way to represent a fixed, untime-ordered operator order.

Finally, attach the boundary data. The $i\varepsilon$ tilt of Section 10.3.4 sends $t_i \to -\infty(1 - i\varepsilon)$ and $t_f \to +\infty(1 - i\varepsilon)$, which by the spectral argument Eq. (10.87) replaces the endpoint states $|\phi_i, t_i\rangle$ and $\langle\phi_f, t_f|$ by the vacuum, up to a constant overlap factor $\langle\phi_f|0\rangle\langle 0|\phi_i\rangle$ that is independent of the insertions. That same constant, together with $\mathcal{N}'$, appears in the denominator $Z[0]$ and cancels in the ratio Eq. (10.93). What survives is exactly

$$G^{(2)}(x_1, x_2) = \langle 0|\,\mathcal{T}\,\phi(x_1)\phi(x_2)\,|0\rangle\,, \tag{10.97}$$

which is Eq. (10.94) for $n = 2$. The two-point case is the Feynman propagator $D_F(x_1 - x_2)$ of Theorem 9.24; that the Gaussian evaluation of the right-hand side of Eq. (10.93) reproduces the explicit form Eq. (9.154) is the computation of Section 10.4.

For general n the slicing inserts n c-number factors, each at its own time, and the same reasoning sorts them into the unique operator ordering compatible with their commutativity under the integral — the full time-ordered product $\mathcal{T}\,\phi(x_1)\cdots\phi(x_n)$. Nothing in the argument used the value of λ: the slicing represents the evolution generated by the *full* Hamiltonian, free or interacting, and the only place the free theory is special is that there the integrals can actually be done in closed form. For the interacting theory the identity Eq. (10.94) is therefore exact as a formal statement and is realized order by order in λ by expanding $e^{iS} = e^{iS_0}e^{-i\frac{\lambda}{4!}\int\phi^4}$ in powers of the coupling, each term being a free correlator of the type just established — the perturbative expansion taken up in Chapters 14 and 15. □

Caution

The path integral computes *time-ordered* correlators and only those. It is structurally incapable of representing a product of Heisenberg operators in a fixed, non-time-ordered sequence, because the integration variables

commute and carry no operator order of their own (Eq. (10.95)). This is a feature, not a limitation: time-ordered correlators are exactly the objects perturbation theory and the LSZ reduction of Chapter 14 require. Unordered (Wightman) correlators and equal-time commutators must be reconstructed from the time-ordered ones by analytic continuation, as in Chapter 9; the path integral does not give them directly.

We close the section's formal development with a worked computation that exercises the master identity Eq. (10.93) and exhibits the role of the normalization, before the next section evaluates the integrals themselves.

Worked Example 10.20 (Functional derivatives and the cancellation of vacuum bubbles)**.** We extract $G^{(1)}$ and $G^{(2)}$ from $Z[J]$ explicitly, tracking every factor and confirming that the division by $Z[0]$ in Theorem 10.18 is what removes the disconnected vacuum contributions.

The one-point function. Apply Eq. (10.91) and set $J = 0$:

$$G^{(1)}(x) = \frac{1}{Z[0]}\,\frac{1}{i}\,\frac{\delta Z[J]}{\delta J(x)}\bigg|_{J=0} = \frac{1}{Z[0]}\int \mathcal{D}\phi\;\phi(x)\,e^{iS} = \langle 0|\,\phi(x)\,|0\rangle\,. \tag{10.98}$$

For the frozen ϕ^4 theory theory this vanishes. The cleanest argument is the unbroken $\mathbb{Z}_2$ symmetry $\phi \to -\phi$ of the Lagrangian Eq. (10.80), the symmetry catalogued for the thread in Section 7.3.6: the action $S[\phi] = S[-\phi]$ is even and the measure $\mathcal{D}\phi$ is invariant under the sign flip of every integration variable (a finite-lattice statement that survives the limit), while the insertion $\phi(x)$ is odd. The integrand of $\int\mathcal{D}\phi\,\phi(x)e^{iS}$ is therefore odd under $\phi \to -\phi$ and integrates to zero, so $G^{(1)}(x) = 0$. The field has no vacuum expectation value, consistent with the canonical statement that ϕ acting on the vacuum creates one-particle states orthogonal to $|0\rangle$.

The two-point function and the bubbles. The second derivative requires the quotient rule, because what is physical is $G^{(2)} = Z[0]^{-1}i^{-2}\,\delta^2 Z/\delta J\,\delta J|_0$, and it is instructive to see why only $Z[0]^{-1}$, and not a more complicated combination, appears. Write $Z[J] = Z[0]\,\widehat{Z}[J]$ with $\widehat{Z}[0] = 1$. Differentiating twice and using $\delta\widehat{Z}/\delta J|_0 = i\,G^{(1)} = 0$ from the previous part,

$$G^{(2)}(x_1,x_2) = \frac{1}{i^2}\,\frac{\delta^2\widehat{Z}[J]}{\delta J(x_1)\,\delta J(x_2)}\bigg|_{J=0} = \frac{1}{i^2}\,\frac{1}{Z[0]}\,\frac{\delta^2 Z[J]}{\delta J(x_1)\,\delta J(x_2)}\bigg|_{J=0}, \tag{10.99}$$

where the cross-terms from differentiating $Z[0]^{-1}$ vanish because they are proportional to $G^{(1)} = 0$. Had we instead computed the *unnormalized* object $i^{-2}\delta^2 Z/\delta J\,\delta J|_0 = \int\mathcal{D}\phi\,\phi(x_1)\phi(x_2)e^{iS}$, it would equal $Z[0]\times G^{(2)}$: the field average of $\phi(x_1)\phi(x_2)$ *times* the sum of all vacuum-to-vacuum amplitudes. Diagrammatically (anticipating Chapter 15) the factor $Z[0]$ is the exponential of all

disconnected vacuum bubbles; the explicit $1/Z[0]$ in Theorem 10.18 divides them out, leaving the genuine two-point correlator. This is the field-theory realization of the finite-dimensional statement Theorem 4.26 that full correlators are normalized derivatives of Z, and it is why the normalization $\mathcal{N}$ of the measure never matters: it is part of $Z[0]$ and cancels here. By Theorem 10.19, the surviving $G^{(2)}(x_1, x_2) = \langle 0| \mathcal{T}\phi(x_1)\phi(x_2) |0\rangle = D_F(x_1 - x_2)$ is the Feynman propagator, whose closed form the Gaussian integration of the next section delivers.

We have now constructed, from the coupled oscillators of Chapter 9 rather than by decree, the generating functional $Z[J] = \int \mathcal{D}\phi \, \exp\left[i \int d^4x \, (\mathcal{L} + J\phi)\right]$ for the frozen ϕ^4 Lagrangian; we have said honestly what the measure $\mathcal{D}\phi$ is (a lattice limit, rigorous for the Gaussian theory, with the rest deferred to Chapter E); we have fixed the vacuum boundary conditions through the $m^2 \to m^2 - i\varepsilon$ tilt and checked that it reproduces the Feynman pole structure of Theorem 9.25; and we have proved that the functional derivatives of $Z[J]$, normalized by $Z[0]$, are exactly the time-ordered vacuum correlators $G^{(n)}$. The only thing still owed is the integral itself. In the next section we set $\lambda = 0$, complete the square in the now-quadratic exponent, and carry out the Gaussian functional integration in closed form — recovering the Feynman propagator a second, independent way and confirming, number for number, that Feynman's sum over histories and the canonical quantization of Chapter 9 describe one and the same physics.

10.4 The Free Generating Functional and the Feynman Propagator

The previous section delivered the generating functional $Z[J] = \int \mathcal{D}\phi \, \exp\left[i \int d^4x \, (\mathcal{L} + J\phi)\right]$ for the frozen ϕ^4 Lagrangian, fixed its vacuum boundary conditions through the $m^2 \to m^2 - i\varepsilon$ tilt, and proved that its normalized functional derivatives are the time-ordered correlators $G^{(n)}$ of Theorem 10.18. Everything there was structural: not a single integral was evaluated, because the integral cannot be done in closed form once $\lambda \neq 0$. We now make the one move that *can* be carried through exactly. Setting $\lambda = 0$ leaves a purely quadratic exponent — a Gaussian, the infinite-dimensional cousin of the sourced integral Eq. (4.54) we already control — and a Gaussian integral is evaluated by completing the square. The reward is twofold. First, $Z_0[J]$ collapses to a closed form, $Z_0[0]$ times the exponential of a quadratic in the source whose kernel is a single two-point function. Second, that kernel turns out to be, on the nose, the Feynman propagator D_F that Chapter 9 built by time-ordering operators. This is the central consistency check of the two-pillar programme: the same object, $D_F(p) = i/(p^2 - m^2 + i\varepsilon)$, emerges from a sum over field histories and from a vacuum matrix element of ordered operators. We carry the computation out in full, with every shift, every Jacobian, and every contour exhibited.

10.4.1 The free action and its kinetic operator

Set $\lambda = 0$ in Eq. (10.80). The action is then quadratic,

$$S_0[\phi] \;=\; \int d^4x \,\Big[\tfrac{1}{2}\,(\partial_\mu\phi)(\partial^\mu\phi) - \tfrac{1}{2}m^2\phi^2\Big], \tag{10.100}$$

and we write $Z_0[J]$ for the generating functional Eq. (10.86) evaluated on this free action — the $\lambda = 0$ instance of $Z[J]$, the only one we can integrate exactly. To expose the Gaussian structure we must rewrite the kinetic term with both derivatives acting on a single field, which is achieved by integrating by parts:

$$\int d^4x\,\tfrac{1}{2}(\partial_\mu\phi)(\partial^\mu\phi) \;=\; \int d^4x\,\Big[\tfrac{1}{2}\,\partial_\mu(\phi\,\partial^\mu\phi) - \tfrac{1}{2}\,\phi\,\partial_\mu\partial^\mu\phi\Big] \;=\; -\tfrac{1}{2}\int d^4x\,\phi\,\Box\phi, \tag{10.101}$$

where $\Box \equiv \partial_\mu\partial^\mu = \partial_t^2 - \nabla^2$ and the total-derivative term has been dropped. That the boundary term vanishes is not an act of faith. On the finite spacetime lattice of Section 10.3.1, which is what Eq. (10.101) abbreviates, the integration by parts is a summation by parts on a periodic box, and a periodic lattice has no boundary at all: the boundary term is identically absent before any limit is taken. In the continuum limit the same conclusion is enforced by the convergence factor of the $i\varepsilon$ prescription, Eq. (10.89), which exponentially suppresses field configurations that fail to decay at infinity, so that $\phi\,\partial^\mu\phi$ has no support on the surface at infinity. Either way the surface term is legitimately zero, and we may use Eq. (10.101) inside the path integral.

Assembling Eq. (10.101) with the mass term, and installing the vacuum tilt $m^2 \to m^2 - i\varepsilon$ established in Eq. (10.88), the free action becomes a single quadratic form,

$$S_0[\phi] \;=\; \tfrac{1}{2}\int d^4x\;\phi(x)\,\mathcal{O}_x\,\phi(x), \qquad \mathcal{O}_x \;\equiv\; -\Box - m^2 + i\varepsilon, \tag{10.102}$$

where $\mathcal{O}$ is the *kinetic operator* of the free scalar — the (negative, $i\varepsilon$-deformed) Klein–Gordon operator. It is the field-theory analogue of the symmetric matrix A in the finite-dimensional Gaussian Eq. (4.54), and it is a symmetric operator in the sense that $\int \phi\,\mathcal{O}\,\chi = \int \chi\,\mathcal{O}\,\phi$ for fields decaying at infinity (again, just the integration by parts of Eq. (10.101), applied to two fields). The whole computation of the section is the inversion of this one operator, weighted by a source.

10.4.2 Gaussian functional integration: completing the square

With Eq. (10.102) the free generating functional reads

$$Z_0[J] \;=\; \int \mathcal{D}\phi\;\exp\Big[\,i\int d^4x\,\big(\tfrac{1}{2}\,\phi\,\mathcal{O}\,\phi + J\phi\big)\Big]. \tag{10.103}$$

The exponent is quadratic plus linear in ϕ; this is exactly the structure that the finite-dimensional theorem Theorem 4.15 dispatches by completing the square, and the manipulation lifts verbatim to the functional integral because, on each finite lattice, Eq. (10.103) *is* an ordinary multidimensional Gaussian. We perform the completion directly in the continuum notation and justify each step by its finite-lattice meaning.

Introduce the *classical field in the presence of the source*, ϕ_J, defined as the solution of the sourced free equation of motion

$$(\Box + m^2)\,\phi_J(x) \;=\; J(x), \tag{10.104}$$

which is precisely the stationarity condition $\delta(S_0 + \int J\phi)/\delta\phi = 0$ of the exponent (the Euler–Lagrange equation of Eq. (10.100) with the source, in the convention fixed for the thread in Eq. (6.60)). In terms of the kinetic operator, $(\Box + m^2) = -\mathcal{O}$ up to the infinitesimal $i\varepsilon$, so Eq. (10.104) is $\mathcal{O}\,\phi_J = -J$, with solution $\phi_J = -\mathcal{O}^{-1}J$. Now shift the integration variable to fluctuations about this classical configuration,

$$\phi(x) \;=\; \phi_J(x) + \eta(x), \tag{10.105}$$

exactly as the proof of Theorem 4.15 shifted $x = y + A^{-1}J$. The shift is by a fixed (source-dependent but field-independent) function ϕ_J, so it is a pure translation of every integration variable, and the measure is invariant:

$$\mathcal{D}\phi \;=\; \prod_x d\phi(x) \;=\; \prod_x d\eta(x) \;=\; \mathcal{D}\eta. \tag{10.106}$$

This is the one place the nature of the measure must be checked rather than assumed. On the finite lattice the shift $\phi_{j,\mathbf{n}} \to \phi_{j,\mathbf{n}} + (\phi_J)_{j,\mathbf{n}}$ is a translation of each of the finitely many real integration variables by a constant, whose Jacobian is the determinant of the identity, namely 1; and a unit Jacobian survives the lattice limit untouched. The translation invariance flagged with appropriate caution in Section 10.3.2 is therefore genuinely available here, because it holds at finite lattice size, which is the criterion the caution box set. No anomaly in the Jacobian can arise for a constant shift; the subtle Jacobians of the path integral (Chapter 36, the chiral anomaly) come only from *field-dependent* changes of variable, never from a translation.

Insert Eq. (10.105) into the exponent of Eq. (10.103) and expand, using the symmetry of $\mathcal{O}$ to combine the two cross terms:

$$\begin{aligned}
\tfrac{1}{2}\int \phi\,\mathcal{O}\,\phi + \int J\phi &= \tfrac{1}{2}\int (\phi_J+\eta)\,\mathcal{O}\,(\phi_J+\eta) + \int J(\phi_J+\eta) \\
&= \underbrace{\tfrac{1}{2}\int \eta\,\mathcal{O}\,\eta}_{\text{fluctuation}} \;+\; \underbrace{\int \eta\,(\mathcal{O}\,\phi_J + J)}_{\text{linear in } \eta} \;+\; \underbrace{\tfrac{1}{2}\int \phi_J\,\mathcal{O}\,\phi_J + \int J\phi_J}_{\text{classical, } \eta\text{-independent}}\,.
\end{aligned} \tag{10.107}$$

The middle term vanishes identically: by construction $\mathcal{O}\,\phi_J = -J$, so $\mathcal{O}\,\phi_J + J = 0$. This is the whole point of shifting to the classical solution — it annihilates the term linear in the fluctuation, which is what "completing the square" means. The classical remainder simplifies using $\mathcal{O}\,\phi_J = -J$ once more:

$$\tfrac{1}{2}\int \phi_J\,\mathcal{O}\,\phi_J + \int J\phi_J \;=\; \tfrac{1}{2}\int \phi_J(-J) + \int J\phi_J \;=\; \tfrac{1}{2}\int J\,\phi_J \;=\; -\tfrac{1}{2}\int J\,\mathcal{O}^{-1}J, \tag{10.108}$$

where the last equality used $\phi_J = -\mathcal{O}^{-1}J$. The exponent has separated cleanly into an η-dependent Gaussian and a source-dependent constant. Therefore

$$Z_0[J] \;=\; \exp\Big[-\tfrac{i}{2}\int d^4x\, J\,\mathcal{O}^{-1}J\Big] \times \underbrace{\int \mathcal{D}\eta\; \exp\Big[\tfrac{i}{2}\int d^4x\,\eta\,\mathcal{O}\,\eta\Big]}_{=\,Z_0[0]}, \tag{10.109}$$

the remaining fluctuation integral being precisely $Z_0[J]$ at $J = 0$ (the classical piece is then absent), so it equals $Z_0[0]$. The source dependence is now entirely explicit and resides in the prefactor; the divergent functional integral has been quarantined into the constant $Z_0[0]$, which will cancel in every correlator.

It remains to name the kernel $\mathcal{O}^{-1}$. Define the *Feynman propagator* of the path integral as

$$D_F(x-y) \;\equiv\; i\,\mathcal{O}^{-1}(x,y), \qquad \text{equivalently} \qquad \mathcal{O}_x\,D_F(x-y) = i\,\delta^4(x-y), \tag{10.110}$$

the factor of i chosen to match the canonical normalization of Chapter 9; we verify in Section 10.4.4 that this choice makes the two definitions coincide. With $\mathcal{O}^{-1} = -iD_F$, the exponent of Eq. (10.109) becomes $-\frac{i}{2}\int J(-iD_F)J = -\frac{1}{2}\int JD_FJ$, and we arrive at the closed form that organizes the entire free theory:

$$\boxed{Z_0[J] \;=\; Z_0[0]\,\exp\Big[-\tfrac{1}{2}\int d^4x\,d^4y\; J(x)\,D_F(x-y)\,J(y)\Big].} \tag{10.111}$$

This is the field-theory image, term for term, of the finite-dimensional master formula $Z(J) = Z(0)\,e^{\frac{1}{2}J^{\mathsf{T}}A^{-1}J}$ of Eq. (4.54), with the kernel A^{-1} replaced by the operator inverse $\mathcal{O}^{-1}$ and the overall i's tracked through. The kernel that appears is, as promised by the finite-dimensional lesson recorded after Eq. (4.54), the *inverse* of the operator in the action — never the operator itself — and it is a single two-point function D_F. Every correlator of the free theory will be a sum of products of this one object.

Mathematical Detail

The completion of the square is exact, not formal, in the following precise sense. Discretize Eq. (10.103) on the lattice of Theorem 10.16: $\phi \to (\phi_a)$ a finite vector, $\int d^4x \to \sum_a (\Delta V)$ with $\Delta V = a^3\Delta t$ the cell

four-volume, and $\mathcal{O} \to \mathcal{O}_{ab}$ a finite symmetric matrix. The exponent is $-\frac{1}{2}\phi^{\mathsf{T}}(-i\mathcal{O}\,\Delta V)\phi + (iJ\Delta V)^{\mathsf{T}}\phi$, which is Eq. (4.54) with $A = -i\mathcal{O}\,\Delta V$ and source $iJ\Delta V$. The $i\varepsilon$ in $\mathcal{O}$ gives A a positive-definite real part (in momentum space $A \propto \varepsilon - i(p^2 - m^2)$, with $\mathrm{Re}\,A = \varepsilon > 0$), which is exactly the condition under which the Gaussian formula Eq. (4.54) converges and its analytic continuation in A is valid. Applying it gives $Z_0[J] = Z_0[0]\exp\!\left[\frac{1}{2}(iJ\Delta V)^{\mathsf{T}}A^{-1}(iJ\Delta V)\right]$; with $A^{-1} = (-i\mathcal{O}\,\Delta V)^{-1} = i\,\mathcal{O}^{-1}/\Delta V$ the exponent is $-\frac{1}{2}\sum_{ab} J_a\,\mathcal{O}^{-1}_{ab}\,J_b\,(\Delta V)^2/\Delta V \cdot (\dots)$, which is the Riemann sum for $-\frac{1}{2}\int J\,\mathcal{O}^{-1}J$ (after the i) and reproduces Eq. (10.111) in the limit. The continuum manipulation is shorthand for this convergent finite-dimensional computation; the $i\varepsilon$ is what makes it converge.

10.4.3 Inverting the kinetic operator: the propagator in momentum space

Equation Eq. (10.111) is only as explicit as our knowledge of $D_F = i\mathcal{O}^{-1}$, and inverting a differential operator is most cleanly done in momentum space, where it becomes division. Use the book's Fourier convention $\phi(x) = \int \frac{d^4p}{(2\pi)^4} e^{-ip\cdot x}\tilde{\phi}(p)$, fixed for the whole book and used already in Section 10.3.4. The kinetic operator acts on a plane wave by

$$\mathcal{O}_x\, e^{-ip\cdot x} = (-\Box - m^2 + i\varepsilon)\, e^{-ip\cdot x} = (p^2 - m^2 + i\varepsilon)\, e^{-ip\cdot x}, \tag{10.112}$$

since $\partial_\mu e^{-ip\cdot x} = -ip_\mu e^{-ip\cdot x}$ gives $\Box e^{-ip\cdot x} = (-ip)\cdot(-ip)\, e^{-ip\cdot x} = -p^2 e^{-ip\cdot x}$, hence $-\Box \to p^2$, and the tilt $m^2 \to m^2 - i\varepsilon$ supplies $+i\varepsilon$ because the operator carries $-m^2$. The defining equation $\mathcal{O}_x D_F(x-y) = i\delta^4(x-y)$ from Eq. (10.110), written with $D_F(x-y) = \int \frac{d^4p}{(2\pi)^4} e^{-ip\cdot(x-y)}\widetilde{D_F}(p)$ and $\delta^4(x-y) = \int \frac{d^4p}{(2\pi)^4} e^{-ip\cdot(x-y)}$, becomes the algebraic equation $(p^2 - m^2 + i\varepsilon)\,\widetilde{D_F}(p) = i$. Solving,

$$\boxed{\widetilde{D_F}(p) \;=\; \frac{i}{p^2 - m^2 + i\varepsilon}\,,} \tag{10.113}$$

and transforming back,

$$D_F(x-y) \;=\; \int \frac{d^4p}{(2\pi)^4}\, \frac{i\, e^{-ip\cdot(x-y)}}{p^2 - m^2 + i\varepsilon}. \tag{10.114}$$

The $i\varepsilon$ is not optional and is not a separate postulate: it descended, through the chain $m^2 \to m^2 - i\varepsilon$ in Eq. (10.88), from the single infinitesimal tilt of the time contour that selected the vacuum. Its role here is to displace the two poles of the integrand off the real p^0 axis. The denominator factors as $p^2 - m^2 + i\varepsilon = (p^0)^2 - E_{\mathbf{p}}^2 + i\varepsilon$ with $E_{\mathbf{p}} = \sqrt{\mathbf{p}^2 + m^2}$, whose zeros sit at $p^0 = \pm\sqrt{E_{\mathbf{p}}^2 - i\varepsilon} = \pm(E_{\mathbf{p}} - i\varepsilon')$ to first order in the infinitesimal (with $\varepsilon' = \varepsilon/2E_{\mathbf{p}} > 0$):

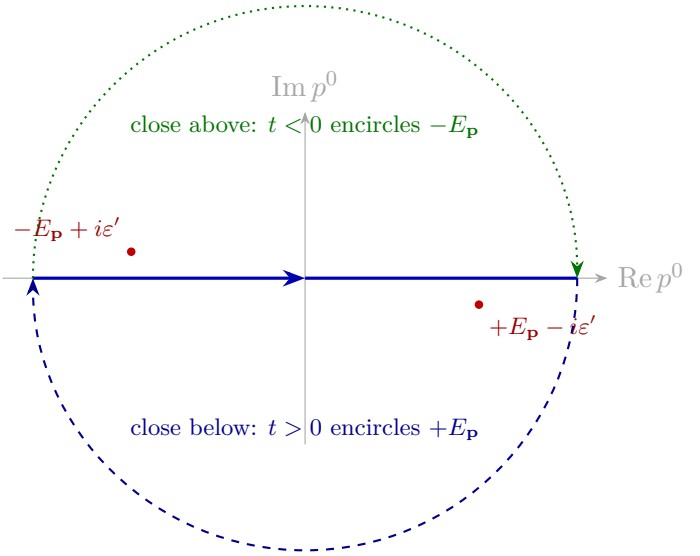

Figure 10.4: The Feynman contour for the p^0 integral in Eq. (10.114), the path-integral image of Theorem 9.25. The $i\varepsilon$ pushes the positive-energy pole to $p^0 = +E_{\mathbf{p}} - i\varepsilon'$ (lower half-plane) and the negative-energy pole to $-E_{\mathbf{p}} + i\varepsilon'$ (upper half-plane). For $t = x^0 - y^0 > 0$ the exponential $e^{-ip^0 t}$ forces closure in the lower half-plane (dashed), enclosing only $+E_{\mathbf{p}}$ and selecting the positive-energy quantum propagating forward in time; for $t < 0$ one closes above (dotted), enclosing $-E_{\mathbf{p}}$. This is the contour analogue of the time-ordering built into the slicing of Theorem 10.19.

the positive-energy pole is pushed *below* the real axis and the negative-energy pole *above* it (Fig. 10.4). This staggered placement is the Feynman prescription, and it is what makes Eq. (10.114) a well-defined tempered distribution rather than an ambiguous integral over a singular denominator (Section 5.1).

10.4.4 The two-pillar agreement

We have now produced, from a Gaussian integral over field histories, a definite two-point object D_F. The canonical quantization of Chapter 9 produced another object also called the Feynman propagator, defined there as the time-ordered vacuum two-point function $\langle 0|\mathcal{T}\phi(x)\phi(y)|0\rangle$ of operators (Theorem 9.24). The promise of the chapter is that these are the same. We now prove it, and the proof is gratifyingly short precisely because all the hard analysis was done once already, in Chapter 9.

Theorem 10.21 (Path-integral and canonical propagators agree)**.** *The propagator D_F obtained from the free generating functional, Eq. (10.113) and Eq. (10.114), is identical as a tempered distribution to the canonical Feynman propagator of*

Chapter 9: its momentum-space form equals Eq. (9.154), and its position-space form equals Eq. (9.153),

$$D_F(x-y) = \int \frac{d^4p}{(2\pi)^4} \frac{i\, e^{-ip\cdot(x-y)}}{p^2 - m^2 + i\varepsilon} = \theta(x^0-y^0)\, D(x-y)+\theta(y^0-x^0)\, D(y-x) = \langle 0|\mathcal{T}\phi(x)\phi(y)| \tag{10.115}$$

Proof. The first equality is the momentum-space result Eq. (10.113)–Eq. (10.114) just derived. Comparing it with the canonical momentum-space propagator Eq. (9.154), established in Chapter 9 as the covariant integral representation of the time-ordered correlator, the two integrands are *character for character identical*: the same numerator i, the same denominator $p^2 - m^2 + i\varepsilon$, the same Fourier kernel $e^{-ip\cdot(x-y)}$, the same measure $d^4p/(2\pi)^4$. There is nothing left to compute for the momentum-space statement; the path integral has reproduced Eq. (9.154) exactly.

The second equality — that this covariant integral equals the time-ordered position-space form Eq. (9.153) — is precisely the content of the contour theorem Theorem 9.25, which evaluated this same integral by the p^0 contour of Fig. 10.4. We do not reprove it; we recall its mechanism to make the agreement concrete. Hold $\mathbf{p}$ fixed and do the p^0 integral. The factor $e^{-ip^0(x^0-y^0)} = e^{-ip^0 t}$ with $t \equiv x^0 - y^0$ decays in the lower half p^0-plane when $t > 0$, forcing the contour to close below, where it encircles only the pole at $p^0 = +E_{\mathbf{p}} - i\varepsilon'$; the residue theorem (Theorem 5.23) then returns $D(x-y) = \int \frac{d^3p}{(2\pi)^3 2E_{\mathbf{p}}} e^{-ip\cdot(x-y)}\big|_{p^0=E_{\mathbf{p}}}$, the positive-energy Wightman function. When $t < 0$ the contour closes above, encircling $-E_{\mathbf{p}} + i\varepsilon'$ and yielding $D(y-x)$. Reassembled with the step functions that record which closure applied, this is exactly the middle expression of Eq. (10.115), namely Eq. (9.153).

The third equality is the definition Theorem 9.24 of the canonical propagator as the time-ordered vacuum correlator. Independently, Theorem 10.19 of the previous section already established that the path-integral two-point function $G^{(2)}(x,y)$ *is* $\langle 0|\mathcal{T}\phi(x)\phi(y)|0\rangle$, by the time-slicing argument that needed no Gaussian integration; the present theorem supplies its closed form. The two derivations therefore close a logical loop: the slicing argument shows the path integral computes the time-ordered correlator, and the Gaussian evaluation shows that correlator is Eq. (9.154). Both pillars stand on the same propagator. □

The agreement is worth pausing on, because it is the first hard quantitative confrontation of the two formalisms and it is exact, not approximate. In Chapter 9 the $i\varepsilon$ was a choice of contour around poles, justified after the fact by demanding that positive-energy quanta propagate forward in time. In the path integral the *same* $i\varepsilon$ was forced on us as the convergence factor Eq. (10.89) that makes the oscillatory functional integral define a number at all, and as the tilt that projects onto the vacuum. Two prescriptions adopted for entirely different reasons —

causality in the operator formalism, convergence in the functional one — produce the identical analytic structure. That coincidence is the signature that the two are descriptions of one physics.

Physical Insight

Read Eq. (10.111) backwards and it says something striking: the entire free quantum field theory — every vacuum correlator of every order — is encoded in the single classical Green's function D_F. The quantum content of the free theory is exhausted by knowing how a disturbance at one spacetime point propagates to another with Feynman boundary conditions. Interactions, when λ is switched back on in Chapter 14, do not change this propagator; they only stitch copies of it together at vertices. The propagator is thus the atom of perturbation theory, and the path integral has just handed it to us as the inverse of the kinetic operator — the most direct route to it in the entire book.

We now exercise Eq. (10.111) by extracting the two-point function from it directly, both to confirm Theorem 10.21 a third way and to rehearse the differentiation technique that the next section will turn into Wick's theorem.

Worked Example 10.22 (The two-point function from $Z_0[J]$)**.** We compute $G^{(2)}$ by applying the master identity Eq. (10.93) to the closed form Eq. (10.111), tracking every factor. Write the normalized functional $\widehat{Z}_0[J] \equiv Z_0[J]/Z_0[0] = \exp\big[-\tfrac{1}{2}\int J D_F J\big]$, so that $G^{(2)}(x_1,x_2) = i^{-2}\,\delta^2 \widehat{Z}_0/\delta J(x_1)\delta J(x_2)\big|_{J=0}$.

First derivative. Only the exponent depends on J, and the quadratic form is symmetric in its two slots, so

$$\frac{\delta}{\delta J(x_1)}\Big[-\tfrac{1}{2}\int d^4y\, d^4z\, J(y) D_F(y-z) J(z)\Big] = -\int d^4z\, D_F(x_1-z)\, J(z), \tag{10.116}$$

where the factor of 2 from differentiating either J in the symmetric product cancelled the $\tfrac{1}{2}$. Hence

$$\frac{\delta \widehat{Z}_0[J]}{\delta J(x_1)} = \Big[-\int d^4z\, D_F(x_1-z) J(z)\Big]\, \widehat{Z}_0[J]. \tag{10.117}$$

Second derivative. Differentiate Eq. (10.117) with respect to $J(x_2)$. The product rule gives two terms — one from differentiating the bracket, one from differentiating $\widehat{Z}_0$:

$$\frac{\delta^2 \widehat{Z}_0[J]}{\delta J(x_2)\delta J(x_1)} = \Big[-D_F(x_1-x_2)\Big]\widehat{Z}_0[J] + \Big[-\int D_F(x_1-z)J(z)\Big]\Big[-\int D_F(x_2-w)J(w)\Big]\widehat{Z}_0[J]. \tag{10.118}$$

Now set $J = 0$. The second term is quadratic in J and vanishes; $\widehat{Z}_0[0] = 1$ remains. Thus

$$G^{(2)}(x_1, x_2) = \frac{1}{i^2} \left. \frac{\delta^2 \widehat{Z}_0[J]}{\delta J(x_1)\delta J(x_2)} \right|_{J=0} = \frac{-D_F(x_1 - x_2)}{i^2} = D_F(x_1 - x_2), \quad (10.119)$$

using $i^2 = -1$. The two-point Green's function is the Feynman propagator, in exact agreement with Theorem 10.21 and with the canonical result $G^{(2)} = \langle 0|\mathcal{T}\phi(x_1)\phi(x_2)|0\rangle$ of Eq. (10.97). Three independent routes — the time-slicing argument of Theorem 10.19, the Gaussian inversion of Section 10.4.3, and this direct differentiation of the closed form — all land on the same D_F. The structure of Eq. (10.118) also previews the next section: each functional derivative either "pulls down" a propagator joining the new point to an existing one, or acts on the surviving exponential to leave a leftover J; at $J = 0$ only the fully paired terms survive, which is Wick's theorem in embryo.

10.4.5 The prefactor as a functional determinant

One object in Eq. (10.111) we have used but not evaluated: the source-independent normalization $Z_0[0]$, the fluctuation integral in Eq. (10.109). From the finite-dimensional master formula Eq. (4.54), a Gaussian $\int d^n x\, e^{-\frac{1}{2}x^{\mathsf{T}}Ax} = (2\pi)^{n/2}(\det A)^{-1/2}$ evaluates to the inverse square root of the determinant of the quadratic form. Applying this to the lattice version of the fluctuation integral, with $A = -i\mathcal{O}\,\Delta V$ as in the boxed dictionary above, gives

$$Z_0[0] \;=\; \mathcal{N}' \left[\det(-i\mathcal{O})\right]^{-1/2} \;\propto\; \left[\det(-\Box - m^2 + i\varepsilon)\right]^{-1/2}, \qquad (10.120)$$

where $\mathcal{N}'$ collects the divergent (2π)-powers, cell-volume factors, and the phase $(-i)^{n/2}$, all field-independent, and the final proportionality records that, up to that constant, $Z_0[0]$ is the inverse square root of the *functional determinant* of the Klein–Gordon operator. The $-1/2$ power is the hallmark of a bosonic Gaussian; for the fermionic Gaussians of Chapter 12 the same calculation will produce det to the $+1$ power instead, the sign of the exponent flipping with the statistics.

Three honest words on this object, in the spirit of Section 10.3.2. First, $Z_0[0]$ is badly divergent as the lattice is refined — det of a differential operator is an infinite product of growing eigenvalues — but, as established in Section 10.3.5, it cancels identically in every Green's function, because $G^{(n)}$ is defined with $Z[0]$ in the denominator; Theorem 10.20 traced exactly this cancellation. We therefore never need its value for any correlator in this chapter. Second, the determinant is nonetheless physical when ratios of two such determinants are taken — a free energy, a one-loop effective action, a Casimir energy — and giving it a finite meaning (zeta-function or heat-kernel regularization) is a genuine computation, not bookkeeping. Third, that computation, the precise definition

of det for an unbounded operator and the proof that the lattice limit Eq. (10.120) converges to it, belongs to the technical appendix on the path integral and is carried out there in full; we state Eq. (10.120) here and defer its evaluation to Chapter E (the Gaussian master formula of Theorem E.1 and the functional determinants developed in the sections that follow it), using those results by reference rather than reproving them in the main line of the chapter. The rigorous construction of the limiting Gaussian *measure* itself — legitimate, as anticipated in Section 10.3.2, only after Wick rotation to the Euclidean weight e^{-S_E} of Theorem 5.30 — is likewise an Appendix E matter; that the corresponding interacting four-dimensional measure exists at all remains the open problem of constructive field theory.

We have evaluated the free generating functional exactly. Completing the square by the source-shift Eq. (10.105), whose measure invariance is the unit Jacobian of a translation, collapsed $Z_0[J]$ to the closed form Eq. (10.111), $Z_0[J] = Z_0[0]\exp\big[-\frac{1}{2}\int\!\int J D_F J\big]$; inverting the kinetic operator delivered the propagator $D_F(p) = i/(p^2 - m^2 + i\varepsilon)$ of Eq. (10.113); and Theorem 10.21 verified, number for number, that this is the very Feynman propagator that canonical quantization built in Chapter 9 — the central two-pillar consistency check now discharged. The prefactor $Z_0[0]$ has been identified as a functional determinant and set aside, harmless because it cancels in correlators. What we hand to the next section is exactly Eq. (10.111): a single Gaussian generating functional whose only ingredient is the propagator D_F. Every correlator of the free theory is obtained by differentiating it, and because it is the exponential of a quadratic, those derivatives organize themselves into all possible pairings of the field insertions — the combinatorial statement we make precise, and identify with the operator Wick's theorem of Chapter 9, in the section that follows.

10.5 Wick's Theorem from Functional Derivatives

The previous section reduced the entire free scalar theory to a single closed-form object. Setting $\lambda = 0$ in the generating functional Eq. (10.86) left a Gaussian functional integral, and completing the square in the now-quadratic exponent — exactly as for the one-dimensional oscillator of Section 10.2.4, only with the Klein–Gordon operator $-\Box - m^2$ in place of $-\partial_t^2 - \omega^2$ — collapsed it to

$$\frac{Z_0[J]}{Z_0[0]} \;=\; \exp\!\left\{-\frac{1}{2}\int d^4x\, d^4y\; J(x)\, D_F(x-y)\, J(y)\right\}, \tag{10.121}$$

where $D_F(x-y)$ is the Feynman propagator, recovered there a second, independent way as the inverse of the kinetic operator and shown to coincide, number for number, with the canonical propagator $D_F(p) = i/(p^2 - m^2 + i\varepsilon)$ of Eq. (9.154) and Theorem 9.24. We use the symmetry $D_F(x-y) = D_F(y-x)$ throughout,

which holds because the Feynman propagator depends only on $x - y$ through the Lorentz invariant $(x - y)^2$ and is even in its argument.

The result Eq. (10.121) is more than a tidy formula: it is the entire free theory, because every correlation function of the free field is, by Theorem 10.18, a functional derivative of $Z_0[J]$ at $J = 0$. The whole content of the present section is to differentiate Eq. (10.121) and watch what comes out. Because the right-hand side is the exponential of a quadratic in J, those derivatives organize themselves into a single combinatorial pattern: a sum over all ways of pairing up the insertion points, each pair contributing one propagator. That pattern is *Wick's theorem*, the statement that promised in Section 9.4.3 and seeded in the two-particle pairings of Chapter 9 but never yet proved in full. Here we prove it directly from $Z_0[J]$, recover the operator-formalism version of Chapter 9 from it as a cross-check, and extract the explicit four-point structure — three pairings of propagators — that is the combinatorial seed of every Feynman diagram in Chapter 15.

10.5.1 The free n-point functions as derivatives of a Gaussian

We continue ϕ^4 theory in its free sector. The objects we want are the *free* n-point Green's functions, the $\lambda = 0$ specialization of Theorem 10.18,

$$G_0^{(n)}(x_1, \dots, x_n) \;=\; \frac{1}{i^n}\,\frac{\delta^n}{\delta J(x_1)\cdots\delta J(x_n)}\,\frac{Z_0[J]}{Z_0[0]}\bigg|_{J=0}, \tag{10.122}$$

where the functional derivative is the one defined in Theorem 4.4, with the elementary rule

$$\frac{\delta J(y)}{\delta J(x)} = \delta^{(4)}(x - y) \tag{10.123}$$

and the product/chain rules it inherits from ordinary differentiation. The normalization by $Z_0[0]$ has already been carried out in Eq. (10.121), so we differentiate the right-hand side of that equation directly; the factor $1/i^n$ is the one prescribed by Theorem 10.18, compensating the i that each source insertion carried in the Minkowski exponent.

It is convenient to give the quadratic form in the exponent a name. Write

$$W[J] \;\equiv\; -\frac{1}{2}\int d^4x\, d^4y\; J(x)\, D_F(x - y)\, J(y), \qquad \frac{Z_0[J]}{Z_0[0]} = e^{W[J]}. \tag{10.124}$$

Two functional derivatives of W exhaust its content, because W is exactly quadratic. The first derivative, using Eq. (10.123) and the symmetry of D_F to combine the two terms in which J is hit, is the *linear* functional

$$\frac{\delta W[J]}{\delta J(x)} \;=\; -\int d^4y\; D_F(x - y)\, J(y) \;\equiv\; L(x; J), \tag{10.125}$$

and the second derivative is the *constant* (i.e. J-independent) kernel

$$\frac{\delta^2 W[J]}{\delta J(x)\,\delta J(x')} \;=\; -\,D_F(x-x'), \tag{10.126}$$

while all third and higher derivatives of W vanish identically. Equations Eqs. (10.125) and (10.126) are the only two facts about W we shall use; everything below is bookkeeping of how the chain rule distributes them across the exponential.

The structure of that bookkeeping is already visible after one and two derivatives. Acting on e^W once,

$$\frac{\delta}{\delta J(x_1)}\,e^W \;=\; L(x_1;J)\,e^W, \tag{10.127}$$

and acting again, by the product rule and Eq. (10.126),

$$\frac{\delta^2}{\delta J(x_1)\,\delta J(x_2)}\,e^W \;=\; \Big[L(x_1;J)\,L(x_2;J) \;-\; D_F(x_1-x_2)\Big]\,e^W. \tag{10.128}$$

Each further derivative does one of exactly two things to the polynomial-in-L prefactor that has accumulated: by Eqs. (10.125) and (10.126) it either differentiates an existing factor $L(x_a;J)$, turning it into $-D_F(x_a-x_b)$ where x_b is the new derivative point, or it produces a new factor $L(x_b;J)$ from acting on e^W. At the end we set $J=0$, where every surviving $L(x;0)=0$ by Eq. (10.125). Therefore *only those terms in which every derivative point has been used up to manufacture a propagator survive*: the terms with any leftover factor of L die at $J=0$. This single observation is the whole of Wick's theorem, and we now make it precise and count.

10.5.2 The combinatorics: derivatives of e^W are sums over pairings

The cleanest way to carry out the count, with no induction left implicit, is to expand the exponential as a power series and read off the term that survives n derivatives at $J=0$. Write the quadratic form as

$$W[J]=\frac{1}{2}\int d^4u\,d^4v\;J(u)\,A(u,v)\,J(v), \qquad A(u,v)\equiv -\,D_F(u-v)=A(v,u), \tag{10.129}$$

so that A is a symmetric kernel, and expand

$$e^{W[J]}=\sum_{m=0}^{\infty}\frac{1}{m!}\,W[J]^m=\sum_{m=0}^{\infty}\frac{1}{m!\,2^m}\int\Big(\textstyle\prod_{a=1}^{m}d^4u_a\,d^4v_a\Big)\;\prod_{a=1}^{m}J(u_a)\,A(u_a,v_a)\,J(v_a). \tag{10.130}$$

The m-th term is a homogeneous polynomial of degree $2m$ in the source J. Applying n functional derivatives and then setting $J = 0$ annihilates every term of the wrong degree: a polynomial of degree $2m$ differentiated n times and evaluated at $J = 0$ gives zero if $2m < n$ (too few sources to absorb the derivatives) and zero if $2m > n$ (a surviving power of J vanishes at $J = 0$). Only $2m = n$ contributes. Two consequences are immediate.

Odd n vanish. If n is odd there is no integer m with $2m = n$, so

$$G_0^{(2k+1)}(x_1, \ldots, x_{2k+1}) = 0 \qquad \text{for all } k \geq 0. \tag{10.131}$$

This is the path-integral face of the elementary fact that the free vacuum overlaps only with states containing an even number of quanta; in operator language it is the statement that a product of an odd number of free fields has no fully-contracted piece and so vanishes between the vacuum, and it is enforced here, even before any explicit contraction, by the $\mathbb{Z}_2$ parity $J \to -J$ of the Gaussian Eq. (10.121).

Even $n = 2k$. Only the $m = k$ term of Eq. (10.130) survives, and with the prefactor $1/(k!\,2^k)$ it reads

$$\frac{1}{k!\,2^k} \int \Big(\textstyle\prod_{a=1}^{k} d^4u_a\, d^4v_a \Big)\, J(u_1)A(u_1, v_1)J(v_1) \cdots J(u_k)A(u_k, v_k)J(v_k). \tag{10.132}$$

We must differentiate this with respect to $J(x_1), \ldots, J(x_{2k})$ and set $J = 0$. There are exactly $2k$ source factors and $2k$ derivatives, so the result is the sum over all ways of matching the $2k$ derivatives to the $2k$ source factors, one to each. Each such matching is a bijection σ from the set of derivative labels $\{x_1, \ldots, x_{2k}\}$ onto the set of source slots $\{u_1, v_1, \ldots, u_k, v_k\}$; differentiating the slot $J(u_a)$ by $\delta/\delta J(x_i)$ produces $\delta^{(4)}(x_i - u_a)$, which the integral over u_a then collapses, replacing the dummy variable u_a by x_i. After all $2k$ collapses, each kernel factor $A(u_a, v_a)$ has become $A(x_i, x_j)$ for the two derivative labels x_i, x_j assigned to that factor's two slots. The contribution of the bijection σ is therefore the product of k kernels,

$$\prod_{a=1}^{k} A\big(x_{\sigma^{-1}(u_a)},\, x_{\sigma^{-1}(v_a)}\big), \tag{10.133}$$

and the full derivative is the sum of Eq. (10.133) over all $(2k)!$ bijections σ, all divided by $k!\,2^k$.

Now we remove the overcounting hidden in the $(2k)!$ bijections, and this is exactly what the prefactor $1/(k!\,2^k)$ was built to do. Two distinct bijections give the *same* product Eq. (10.133) whenever they differ only by (i) a permutation of which kernel factor is called the first, second, …, k-th — there are $k!$ such relabelings, and they leave the product of kernels unchanged because multiplication is commutative — or (ii) a swap of the two slots $u_a \leftrightarrow v_a$ within any factor — there are 2 choices per factor, hence 2^k in all, and they leave each

kernel unchanged because A is symmetric, $A(u,v) = A(v,u)$. The group of these trivial reshufflings has order $k!\,2^k$, and it acts freely, so the $(2k)!$ bijections fall into $(2k)!/(k!\,2^k)$ orbits, each orbit contributing one distinct product of kernels with multiplicity $k!\,2^k$. That multiplicity cancels the prefactor exactly. What is left is a sum with unit coefficient over the orbits, and an orbit is precisely an unordered partition of the $2k$ labels $\{x_1,\dots,x_{2k}\}$ into k unordered pairs — a *pairing*. Therefore

$$\frac{\delta^{2k}}{\delta J(x_1)\cdots\delta J(x_{2k})}\,e^{W}\Big|_{J=0} \;=\; \sum_{\text{pairings } P}\;\prod_{\{i,j\}\in P} A(x_i,x_j) \;=\; \sum_{\text{pairings } P}\;\prod_{\{i,j\}\in P}\bigl(-D_F(x_i-x_j)\bigr). \tag{10.134}$$

The number of pairings of $2k$ objects is the double factorial

$$(2k-1)!! \;=\; (2k-1)(2k-3)\cdots 3\cdot 1 \;=\; \frac{(2k)!}{k!\,2^k}, \tag{10.135}$$

counted directly as follows: pick the partner of x_1 in $2k-1$ ways, then the partner of the lowest remaining label in $2k-3$ ways, and so on down to the last pair, with one way; this is the same integer that emerged as the orbit count above, a satisfying internal consistency check. For $k = 1, 2, 3$ it gives 1, 3, 15 pairings respectively.

Finally restore the prefactor $1/i^n$ of Eq. (10.122). With $n = 2k$ each of the k factors $-D_F$ supplies a sign (-1), contributing $(-1)^k$, while $1/i^{2k} = 1/(-1)^k = (-1)^k$; the two signs multiply to $(-1)^{2k} = +1$. The minus signs cancel completely and we arrive at the clean statement.

Theorem 10.23 (Wick's theorem for the free scalar field)**.** *The free n-point Green's functions of the scalar field, defined by Eq. (10.122), vanish for odd n and, for even $n = 2k$, equal the sum over all pairings of the n points of the product of Feynman propagators over the pairs:*

$$\boxed{G_0^{(2k)}(x_1,\dots,x_{2k}) \;=\; \sum_{\text{pairings } P}\;\prod_{\{i,j\}\in P} D_F(x_i-x_j)\,, \qquad G_0^{(2k+1)} = 0.} \tag{10.136}$$

There are $(2k-1)!!$ terms in the sum, each a product of k propagators that joins the $2k$ points in pairs.

This is the same combinatorial law that the single-oscillator template anticipated at the close of Section 10.2.4: differentiating the exponential of a quadratic generates all pairings of the insertion points. The field theory has merely promoted the discrete insertion times to spacetime points x_i and the oscillator Green's function to the covariant propagator D_F. Nothing in the derivation used anything but the Gaussian form Eq. (10.121) of $Z_0[J]$ and the two derivative rules Eqs. (10.125) and (10.126); the theorem is therefore an identity of tempered distributions, exact for the free theory.

Physical Insight

Wick's theorem is the assertion that a free field is, statistically, a Gaussian random field, and Theorem 10.23 is exactly the statement that a Gaussian's higher moments are fixed by its covariance. Replace "field" by "random variable," "propagator" by "covariance," and "$G_0^{(n)}$" by "n-th moment," and Eq. (10.136) is the probabilist's Isserlis (Wick) formula for the moments of a multivariate Gaussian. The path integral makes the analogy literal: in the Euclidean version of the next section, $e^{-S_{E,0}}\,\mathcal{D}\phi$ *is* a Gaussian measure, D_F *is* its covariance, and the n-point functions *are* its moments. Free quantum field theory contains no information beyond its two-point function; all higher correlators are bookkeeping of how the two-point function can be wired up.

10.5.3 The two-point function and the four-point function

The smallest cases of Theorem 10.23 are the ones the rest of the book uses constantly, and it is worth seeing them land explicitly.

For $n = 2$ there is a single pairing, $\{1, 2\}$, so

$$G_0^{(2)}(x_1, x_2) \;=\; D_F(x_1 - x_2). \tag{10.137}$$

The free two-point function is the Feynman propagator, with no decoration. This is consistent at one stroke with three earlier results: with the general identification $G^{(2)} = \langle 0|\,\mathcal{T}\phi(x_1)\phi(x_2)\,|0\rangle$ of Theorem 10.19, with the direct second-derivative computation Eq. (10.128) (set $J = 0$, where the LL term dies, leaving $-D_F$, then divide by $i^2 = -1$), and with the canonical definition of D_F in Theorem 9.24. The single internal line of every Feynman diagram is this object.

For $n = 4$ there are $(4-1)!! = 3$ pairings of the labels $\{1, 2, 3, 4\}$ — namely $\{12\}\{34\}$, $\{13\}\{24\}$, $\{14\}\{23\}$ — and Eq. (10.136) gives

$$G_0^{(4)}(x_1, x_2, x_3, x_4) = D_F(x_1 - x_2)D_F(x_3 - x_4) + D_F(x_1 - x_3)D_F(x_2 - x_4) + D_F(x_1 - x_4) \tag{10.138}$$

These three terms are the three distinct ways to join four points pairwise with propagators; pictorially they are the three ways of drawing two non-intersecting (or intersecting) chords among four points on a circle, shown in Fig. 10.5. They are not yet a scattering process — there is no interaction vertex in the free theory — but they are precisely the contractions that, in Chapter 15, will be tied off against the first $\lambda\phi^4$ vertex to build the $O(\lambda)$ four-point amplitude of ϕ^4 theory. The combinatorial seed of the Feynman expansion is exactly Eq. (10.138).

Worked Example 10.24 (The free four-point function, derived in full from $Z_0[J]$)**.** We carry out the four functional differentiations of Eq. (10.122) by hand,

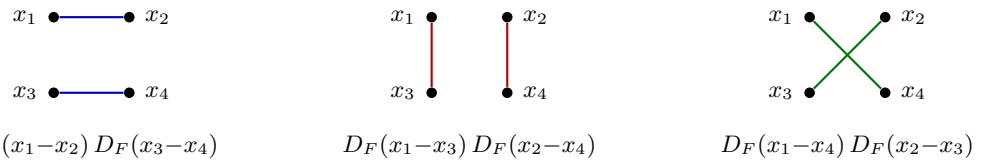

Figure 10.5: The three pairings of the free four-point function Eq. (10.138). Each panel joins the four points $x_1, \ldots, x_4$ into two pairs by Feynman-propagator lines; the sum of the three is $G_0^{(4)}$. These are the $(4-1)!! = 3$ terms of Wick's theorem at $n = 4$ and the combinatorial seed of the ϕ^4 Feynman rules of Chapter 15: tying the four loose ends to a single four-point vertex turns these disconnected pairings into the first interacting amplitude of ϕ^4 theory.

with every intermediate term written, to verify Eq. (10.138) and to display the mechanism — "differentiate an L into a propagator, or pull down a fresh L" — in action. Throughout we abbreviate $L_i \equiv L(x_i; J)$ for the linear functional Eq. (10.125) and $D_{ij} \equiv D_F(x_i - x_j)$ for the propagator, and we record the two rules we will use repeatedly:

$$\frac{\delta}{\delta J(x_b)}\, L_a = -D_{ab}, \qquad \frac{\delta}{\delta J(x_b)}\, e^{W} = L_b\, e^{W}. \tag{10.139}$$

The first is Eq. (10.126) written for the linear functional; the second is Eq. (10.127). Note D_{ab} is a J-independent constant, so it is killed by any further derivative.

First derivative. From the second rule,

$$\frac{\delta}{\delta J(x_1)} e^{W} = L_1\, e^{W}. \tag{10.140}$$

Second derivative. Apply $\delta/\delta J(x_2)$ by the product rule, using both rules in Eq. (10.139):

$$\frac{\delta^2}{\delta J(x_2)\delta J(x_1)} e^{W} = (-D_{12}) e^{W} + L_1\, L_2\, e^{W} = (L_1 L_2 - D_{12}) e^{W}, \tag{10.141}$$

reproducing Eq. (10.128).

Third derivative. Apply $\delta/\delta J(x_3)$ to Eq. (10.141). The constant $-D_{12}$ contributes only through the e^W it multiplies; the product $L_1 L_2$ is differentiated term by term:

$$\begin{aligned} \frac{\delta^3}{\delta J(x_3)\delta J(x_2)\delta J(x_1)} e^{W} &= \Big[(-D_{13})L_2 + L_1(-D_{23})\Big] e^{W} + (L_1 L_2 - D_{12}) L_3\, e^{W} \\ &= \Big[L_1 L_2 L_3 - D_{12} L_3 - D_{13} L_2 - D_{23} L_1\Big] e^{W}. \end{aligned} \tag{10.142}$$

Every term contains at least one factor of L, so this vanishes at $J = 0$ — the explicit confirmation of Eq. (10.131) for $n = 3$: there is no way to use up an odd number of derivatives in propagators alone, so a stray L always remains.

Fourth derivative. Apply $\delta/\delta J(x_4)$ to the bracket in Eq. (10.142), again differentiating each term and adding the term from differentiating the trailing e^W. Differentiating the bracket $B_3 \equiv L_1L_2L_3 - D_{12}L_3 - D_{13}L_2 - D_{23}L_1$:

$$\begin{aligned}\frac{\delta B_3}{\delta J(x_4)} &= (-D_{14})L_2L_3 + L_1(-D_{24})L_3 + L_1L_2(-D_{34}) \\ &\quad - D_{12}(-D_{34}) - D_{13}(-D_{24}) - D_{23}(-D_{14}) \\ &= -D_{14}L_2L_3 - D_{24}L_1L_3 - D_{34}L_1L_2 + (D_{12}D_{34} + D_{13}D_{24} + D_{14}D_{23}),\end{aligned} \tag{10.143}$$

where the second line is the only place fresh propagator–propagator products are born: each surviving single propagator $-D_{ij}$ from the third derivative meets the derivative $\delta/\delta J(x_4)$ acting on its lone L partner, and the two minus signs make a plus. The full fourth derivative is $(\delta B_3/\delta J(x_4) + B_3\, L_4)e^W$. Setting $J = 0$ now annihilates every term that still carries an L: in $\delta B_3/\delta J(x_4)$ the three LL terms die, and in B_3L_4 all four terms die (each has at least one L). What remains is the propagator–propagator block of Eq. (10.143):

$$\frac{\delta^4}{\delta J(x_1)\delta J(x_2)\delta J(x_3)\delta J(x_4)} e^W \bigg|_{J=0} = D_{12}D_{34} + D_{13}D_{24} + D_{14}D_{23}. \tag{10.144}$$

Divide by $i^4 = 1$ as prescribed in Eq. (10.122): the free four-point function is exactly the three-term sum,

$$G_0^{(4)}(x_1, x_2, x_3, x_4) = D_{12}D_{34} + D_{13}D_{24} + D_{14}D_{23}, \tag{10.145}$$

which is Eq. (10.138). The three terms are the three pairings $\{12\}\{34\}$, $\{13\}\{24\}$, $\{14\}\{23\}$, with no surplus factors and no missing ones; the $(4-1)!! = 3$ of Eq. (10.135) is verified by direct computation, and the mechanism by which the Gaussian generates exactly the pairings is laid bare.

10.5.4 Cross-check: recovering the operator Wick's theorem of Chapter 9

The result Theorem 10.23 was derived entirely inside the path integral, with no operators in sight. It must agree with the operator formalism of Chapter 9, since by Theorem 10.19 the free Green's function $G_0^{(n)}$ *is* the time-ordered vacuum expectation value $\langle 0|\,\mathcal{T}\,\phi(x_1)\cdots\phi(x_n)\,|0\rangle$. The operator statement that reduces this VEV to the same sum over pairings is the classical Wick's theorem, the result foreshadowed in the two-particle pairings of Section 9.5.2 and the charged-field bookkeeping of Theorem 9.37; it was not proved in Chapter 9, which deferred

it precisely to this generating-functional derivation. We now state and prove it in the operator language and confirm the two routes coincide, completing the cross-check.

Decompose the free Heisenberg field into its positive- and negative-frequency parts as in Chapter 9, $\phi(x) = \phi^+(x) + \phi^-(x)$, where ϕ^+ contains the annihilation operators $a_{\mathbf{p}}$ (it annihilates the vacuum on the right, $\phi^+ |0\rangle = 0$) and ϕ^- the creation operators $a^\dagger_{\mathbf{p}}$ (so $\langle 0| \phi^- = 0$), obeying the mode algebra of Theorem 9.37. The *contraction* of two fields is the c-number

$$\overbracket{\phi(x)\,\phi(y)} \;\equiv\; \mathcal{T}\,\phi(x)\phi(y) - :\phi(x)\phi(y): \,, \tag{10.146}$$

with $: \cdots :$ the normal ordering of Theorem 9.19. For $x^0 > y^0$, $\mathcal{T}\phi(x)\phi(y) = \phi(x)\phi(y)$, and moving the annihilation part $\phi^+(x)$ to the right of the creation part $\phi^-(y)$ to reach normal order costs exactly the commutator $[\phi^+(x), \phi^-(y)]$, a c-number; for $y^0 > x^0$ one gets $[\phi^+(y), \phi^-(x)]$. In either order the contraction is a c-number, and since it is a c-number it equals its own vacuum expectation value,

$$\overbracket{\phi(x)\,\phi(y)} = \langle 0| \overbracket{\phi(x)\,\phi(y)} |0\rangle = \langle 0| \mathcal{T}\,\phi(x)\phi(y) |0\rangle = D_F(x-y), \tag{10.147}$$

because $\langle 0| :\phi\phi: |0\rangle = 0$ by Theorem 9.19. The contraction of two free fields is the Feynman propagator — the operator counterpart of Eq. (10.126).

Theorem 10.25 (Operator Wick's theorem for free fields)**.** *A time-ordered product of free scalar field operators equals the sum of all its normal-ordered terms with every possible set of contractions:*

$$\mathcal{T}\,\phi(x_1)\cdots\phi(x_n) = :\phi(x_1)\cdots\phi(x_n): \;+ \sum_{\substack{\text{single}\\ \text{contractions}}} :(\cdots): \;+\cdots+ \sum_{\substack{\text{full}\\ \text{contractions}}} (\cdots), \tag{10.148}$$

where each contraction replaces a pair of fields by the c-number Eq. (10.147) and the remaining uncontracted fields are normal-ordered; the last group, present only for even n, consists of fully-contracted (pure c-number) terms.

Proof. By induction on n. For $n = 1$ the statement is $\phi(x_1) = :\phi(x_1):$, true since a single field is already normal-ordered. For $n = 2$ it is the rearrangement of Eq. (10.146): $\mathcal{T}\phi(x_1)\phi(x_2) = :\phi(x_1)\phi(x_2): + \overbracket{\phi(x_1)\phi(x_2)}$. Assume Eq. (10.148) holds for n fields. Order the labels so that x_{n+1} has the earliest time, $x^0_{n+1} \le x^0_i$ for all $i \le n$ (always possible, since both sides of Eq. (10.148) are totally symmetric under relabeling — the left side because $\mathcal{T}$ symmetrizes, the right because the sum is over all contraction patterns); then

$$\mathcal{T}\,\phi(x_1)\cdots\phi(x_{n+1}) = \Big(\mathcal{T}\,\phi(x_1)\cdots\phi(x_n)\Big)\,\phi(x_{n+1}), \tag{10.149}$$

because $\phi(x_{n+1})$ sits to the right of all the others in time and the time-ordering symbol places it there. Substitute the inductive hypothesis for the bracket and multiply each normal-ordered term on the right by $\phi(x_{n+1}) = \phi^+(x_{n+1}) + \phi^-(x_{n+1})$. The creation piece $\phi^-(x_{n+1})$ is already to the right of nothing it needs to pass and may be absorbed into the normal ordering directly (creation operators stand left, and ϕ^- being rightmost we may write it inside the colons by moving it left past nothing it fails to commute with as a c-number—more precisely, $:X:\,\phi^- = :X\phi^-:$ since ϕ^- is a creation operator and normal ordering puts it to the left at no commutator cost). The annihilation piece $\phi^+(x_{n+1})$ must instead be moved leftward through each normal-ordered factor to bring it inside the colons; passing it across the negative-frequency (creation) content of a field $\phi(x_i)$ generates the c-number commutator $[\phi^+(x_{n+1}), \phi^-(x_i)] = \overbrace{\phi(x_{n+1})\phi(x_i)} = D_F(x_{n+1} - x_i)$ by Eq. (10.147) (valid as the contraction since x_{n+1} is the earliest time), each such commutator being precisely one new contraction of x_{n+1} with x_i. Collecting the term in which $\phi(x_{n+1})$ is absorbed uncontracted, and all the terms in which it is contracted once with each available partner, regenerates Eq. (10.148) for $n+1$ fields: the patterns are the old patterns with x_{n+1} either left uncontracted or contracted with one previously-uncontracted field, which is exactly the enumeration of all contraction patterns of $n+1$ fields. This closes the induction. □

Taking the vacuum expectation value of Eq. (10.148) now reproduces Theorem 10.23 term for term. Every term that still contains a normal-ordered product of one or more uncontracted fields has vanishing vacuum expectation value, $\langle 0|\,:(\cdots):\,|0\rangle = 0$ (Theorem 9.19); only the *fully*-contracted terms, which are pure c-numbers, survive. For odd n no full contraction exists (one field is always left over), so the VEV vanishes, matching Eq. (10.131). For even $n = 2k$ the surviving terms are exactly the pairings, each a product of k contractions $= k$ propagators:

$$\langle 0|\,\mathcal{T}\,\phi(x_1)\cdots\phi(x_{2k})\,|0\rangle = \sum_{\text{full contractions}} \prod_{\{i,j\}} D_F(x_i - x_j) = \sum_{\text{pairings } P} \prod_{\{i,j\}\in P} D_F(x_i - x_j). \tag{10.150}$$

A full contraction of $2k$ fields is the same combinatorial object as a pairing of $2k$ points, so Eq. (10.150) is identical to Eq. (10.136). The path integral and the operator formalism produce not merely the same answer but the same intermediate structure — a sum over pairings, one propagator per pair, $(2k-1)!!$ terms — arrived at by completely different mechanisms: the path integral by the chain rule on a Gaussian, the operator formalism by commuting annihilation operators to the right. For $n = 4$ this is the explicit statement

$$\langle 0|\,\mathcal{T}\,\phi_1\phi_2\phi_3\phi_4\,|0\rangle = D_F(x_1 - x_2)D_F(x_3 - x_4) + D_F(x_1 - x_3)D_F(x_2 - x_4) + D_F(x_1 - x_4)D_F(x_2 - \tag{10.151}$$

which is Eq. (10.138) again, now read off the operator side. The two pillars agree on the free four-point function, completing the consistency check this section was charged with.

Caution

The contraction Eq. (10.147) is the *time-ordered* two-point function D_F, not the Wightman function or the commutator. This matters when one is tempted to "contract" fields inside an already-fixed (non-time-ordered) operator order: Theorem 10.25 is a statement about the *time-ordered* product on the left, and it is the time-ordered product that the path integral computes (Theorem 10.19). Wick's theorem in the form Eq. (10.148) for ordinary (non-time-ordered) products also exists, but with the Wightman two-point function as the contraction; the two versions must not be mixed. Throughout the perturbation theory of Chapters 14 and 15 it is the time-ordered version with D_F, the one derived here, that is used.

10.5.5 What Wick's theorem hands forward

We have now derived Wick's theorem for the free scalar field twice over and shown the two derivations coincide. From the path integral, the free n-point function is a single functional derivative of the Gaussian $Z_0[J] = Z_0[0]\, e^{W[J]}$ of Eq. (10.121), and the chain rule turns each such derivative into the sum over pairings Eq. (10.136): odd correlators vanish, the even ones are sums of $(2k-1)!!$ products of propagators, the two-point function is D_F alone, and the four-point function is the three pairings of Eq. (10.138). From the operator side, the same sum emerges as the vacuum expectation value of the Wick-expanded time-ordered product Eq. (10.148), with the contraction equal to D_F. The free theory is thereby completely solved: *every* correlation function is an explicit, finite sum of propagators, with no integration left to do.

These pairings are the combinatorial seed of the entire diagrammatic expansion. In Section 10.7 (Theorem 10.33) the interacting generating functional is written as $Z[J] = \exp\!\big[-i\tfrac{\lambda}{4!}\int d^4z\,(\tfrac{1}{i}\tfrac{\delta}{\delta J(z)})^4\big]\, Z_0[J]$, so that each power of λ inserts four extra functional derivatives at a common point z; Theorem 10.23 then dictates that the resulting correlators are again sums over pairings, now of the external points *and* the four legs of each vertex. The three pairings of Eq. (10.138), tied off against a single $\lambda\phi^4$ vertex, are exactly the contractions that dress the first ϕ^4 interaction and produce the $O(\lambda)$ four-point amplitude $-i\lambda$ of ϕ^4 theory; the symmetry factors that count how many pairings give the same diagram are bookkeeping of the $(2k-1)!!$ of Eq. (10.135). The Feynman rules of Chapter 15 are nothing more than a graphical shorthand for the contraction sum proved here. Before turning the crank on the interaction, however, we change the contour: the next section rotates time to the imaginary axis, trading the

oscillatory weight e^{iS} for the convergent, positive Euclidean measure e^{-S_E} in which the Gaussian of this section becomes a genuine probability measure and the propagator its covariance — the form that powers the renormalization group, the lattice, and the bridge to statistical mechanics.

10.6 The Euclidean Path Integral

Everything we have built so far in this chapter lives on a real time axis. The free generating functional assembled in Section 10.4,

$$Z_0[J] \;=\; Z_0[0]\,\exp\Big[-\tfrac{1}{2}\int d^4x\,d^4y\;J(x)\,D_F(x-y)\,J(y)\Big], \tag{10.152}$$

with the Feynman propagator $D_F(x-y)$ of Theorem 9.24 as its kernel, is a Gaussian whose exponent is *imaginary*: the unsourced weight is the pure phase e^{iS}, and the integral converges only conditionally, kept alive by the infinitesimal tilt $m^2 \to m^2 - i\varepsilon$ of Section 10.3.4. That tilt was an infinitesimal rotation of the time contour into the lower half-plane. The business of this section is to complete the rotation: to turn the contour all the way to the imaginary time axis, $t \to -i\tau$, and watch the oscillatory weight e^{iS} become a real, positive, exponentially damped weight e^{-S_E}. The resulting object, the *Euclidean* path integral, is not a mere computational convenience. It is a genuinely convergent integral against a positive measure; it is, formally, the partition function of a classical statistical-mechanical system in four dimensions; and it is the form in which the path integral powers the renormalization group (Chapter 23), the lattice (Chapter 43), and conformal field theory (Chapter 52). We continue ϕ^4 theory, and the Euclidean action S_E we fix here is the object those later chapters will flow, discretize, and sit inside.

The analytic machinery we need was assembled in Section 5.4: the Wick rotation as a change of variables (Theorem 5.30), and the theorem (Theorem 5.31) that the rotation is a legal contour deformation precisely because the Feynman $i\varepsilon$ places the propagator poles out of its path. We import those results rather than reprove them, and spend our effort on what is owed here: carrying the rotation through the path integral itself, deriving the all-plus Euclidean action of ϕ^4 theory sign by sign, exhibiting the convergent positive Gaussian measure, constructing the Euclidean propagator and continuing it back to D_F, and laying out the dictionary that makes a quantum field theory and a statistical-mechanical system two readings of one integral.

10.6.1 Wick rotation as the completion of the $i\varepsilon$ tilt

The starting point is the observation, already made in Section 10.3.4, that the $i\varepsilon$ prescription is not an independent decoration of the Minkowski path

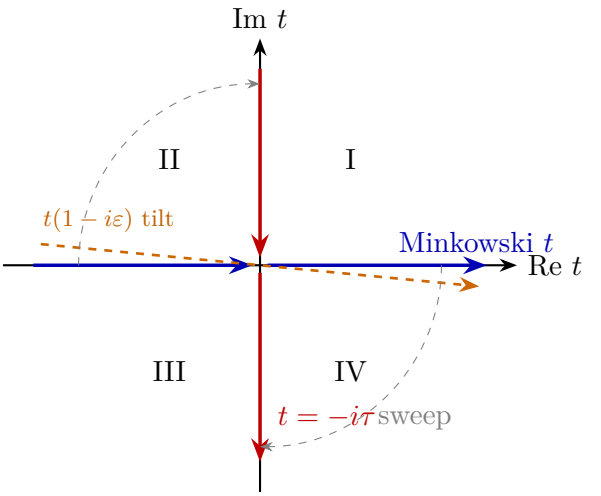

Figure 10.6: The Wick rotation in the complex-t plane. The vacuum $i\varepsilon$ prescription of Section 10.3.4 tilts the real-time contour (blue) infinitesimally clockwise (orange dashed). The Wick rotation completes that tilt to a quarter turn, bringing the contour to the imaginary axis $t = -i\tau$ (red), with τ increasing as t runs $-i\infty \to +i\infty$ traversed downward. The dual rotation of the energy contour in the complex p^0 plane sweeps the pole-free quadrants of Fig. 5.4; the tilt directions are conjugate, t clockwise as p^0 counterclockwise, because t and p^0 are Fourier-conjugate.

integral but the first infinitesimal step of a finite rotation. Recall the mechanism. The vacuum generating functional is computed on a time interval $(-T, T)$, and the prescription that selects the ground state tilts the endpoints into the complex plane, $t \to t(1 - i\varepsilon)$, so that the evolution operator e^{-iHt} acquires a real damping factor $e^{-Ht\varepsilon}$ that suppresses every excited state relative to $|0\rangle$ (the spectral argument of Eq. (10.87)). Geometrically the tilt rotates the time contour infinitesimally clockwise, into the fourth quadrant of the complex-t plane. The Wick rotation is the statement that we may continue this rotation all the way to a quarter turn, until the contour lies along the negative imaginary axis,

$$t \;=\; -i\,\tau, \qquad \tau \in \mathbb{R}, \quad \tau\colon\; -\infty \to +\infty, \tag{10.153}$$

the substitution of Theorem 5.30 with τ the Euclidean time. The infinitesimal tilt and the finite rotation are the same operation carried to different angles; the only question is whether nothing goes wrong along the way, and "nothing goes wrong" means precisely that the rotating contour sweeps across no singularity of the integrand.

The cleanest place to certify pole avoidance is the Fourier-conjugate variable, the energy p^0, where the singularities are explicit. Every correlator the path integral produces is built, by the Gaussian evaluation of Section 10.4, from the

Feynman propagator, whose momentum-space form is

$$D_F(p) \;=\; \frac{i}{p^2 - m^2 + i\varepsilon} \;=\; \frac{i}{(p^0)^2 - E_{\mathbf{p}}^2 + i\varepsilon}, \qquad E_{\mathbf{p}} = \sqrt{\mathbf{p}^2 + m^2}, \tag{10.154}$$

the object established in Eq. (9.154), with $E_{\mathbf{p}}$ the on-shell energy of the dispersion relation Eq. (9.108). Its poles in the complex p^0 plane were located exactly in Eq. (9.157): one at $p^0 = +E_{\mathbf{p}} - i\varepsilon'$, just below the positive real axis (fourth quadrant), and one at $p^0 = -E_{\mathbf{p}} + i\varepsilon'$, just above the negative real axis (second quadrant). The dual of the time rotation Eq. (10.153) is the energy rotation $p^0 \to ip_E^4$ of Eq. (5.93), which swings the p^0 contour *counterclockwise* from the real axis to the imaginary axis (the conjugacy of the two tilt directions is exactly the statement that t and p^0 are Fourier conjugate: a clockwise turn of t is a counterclockwise turn of p^0). That counterclockwise sweep passes through the first and third quadrants of the p^0 plane — and those are precisely the quadrants left empty by the Feynman pole placement. This is the geometry drawn in Fig. 5.4, and it is the content of the legality theorem.

Proposition 10.26 (The rotation crosses no propagator pole)**.** *For the free scalar with the Feynman prescription, the rotation of the energy contour $p^0 \to ip_E^4$ dual to the time rotation Eq. (10.153) sweeps only the pole-free first and third quadrants of the complex p^0 plane. Consequently, for each fixed real spatial momentum $\mathbf{p}$ the Minkowski energy integral equals the rotated Euclidean one,*

$$\int_{-\infty}^{\infty} dp^0 \, \frac{i\,F(p^0)}{(p^0)^2 - E_{\mathbf{p}}^2 + i\varepsilon} \;=\; i\int_{-\infty}^{\infty} dp_E^4 \, \frac{i\,F(ip_E^4)}{-\big[(p_E^4)^2 + E_{\mathbf{p}}^2\big]}, \tag{10.155}$$

for any F analytic and suitably decaying in the swept quadrants.

Proof. The poles of the integrand are those of Eq. (10.154) at $p^0 = \pm(E_{\mathbf{p}} - i\varepsilon')$ together with whatever singularities F may carry; by hypothesis F is analytic in the first and third quadrants, and the propagator poles sit in the second and fourth, as recorded in Eq. (9.157). The closed contour built from the real segment, the quarter-circle arc at infinity, and the imaginary segment therefore encloses no singularity in the first quadrant, and likewise in the third; Cauchy's theorem (Theorem 5.23) makes the closed integral vanish, and the decay hypothesis kills the arcs by the ML-estimate. The two straight segments are then equal and opposite, which is the equality Eq. (10.155); the prefactor i on the right is the Jacobian $dp^0 = i\,dp_E^4$ of $p^0 = ip_E^4$. This is the special case of the legality theorem Theorem 5.31 for the Feynman denominator, and we invoke that theorem for the analytic estimates rather than repeating them. □

The point worth dwelling on is that the rotation is legal *because of* the $i\varepsilon$, not in spite of it. Had we chosen the retarded prescription, both poles would lie below the real axis and the fourth-quadrant sweep would drag the contour across

one of them, picking up a residue and spoiling the equality; the advanced choice fails symmetrically in the second quadrant. Only the Feynman placement — the same staggering that the operator formalism produced from time-ordering — leaves the rotation unobstructed. The three faces of the $i\varepsilon$ noted in Section 10.3.4 (time-ordering, vacuum projection, Gaussian damping) here acquire a fourth, which is in fact their unification: the $i\varepsilon$ is the infinitesimal germ of the Wick rotation, and the rotation is exactly the analytic continuation that the $i\varepsilon$ certifies as legal.

10.6.2 The Euclidean action of Scalar ϕ^4 theory

We now carry the rotation Eq. (10.153) through the action of the frozen ϕ^4 theory theory, tracking every sign so that the all-plus Euclidean form emerges with nothing assumed. The Minkowski action is $S = \int d^4x\,\mathcal{L}$ with the Lagrangian density Eq. (10.80),

$$S[\phi] \;=\; \int dt\,d^3x\,\Big[\tfrac{1}{2}(\partial_t\phi)^2 - \tfrac{1}{2}(\nabla\phi)^2 - \tfrac{1}{2}m^2\phi^2 - \frac{\lambda}{4!}\phi^4\Big], \tag{10.156}$$

where we have split the kinetic term $\frac{1}{2}(\partial_\mu\phi)(\partial^\mu\phi) = \frac{1}{2}(\partial_t\phi)^2 - \frac{1}{2}(\nabla\phi)^2$ into its temporal and spatial parts using the mostly-minus metric $\eta_{\mu\nu} = \mathrm{diag}(+,-,-,-)$ fixed for the book. The rotation acts on three things at once — the time derivative, the integration measure, and the overall factor of i in the weight e^{iS} — and the all-plus action is the residue of those three changes conspiring.

Take them in turn. First the time derivative: from $t = -i\tau$ we have $dt = -i\,d\tau$, hence

$$\partial_t \;=\; \frac{\partial\tau}{\partial t}\,\partial_\tau \;=\; \frac{1}{-i}\,\partial_\tau \;=\; i\,\partial_\tau, \qquad \text{so} \qquad (\partial_t\phi)^2 \;=\; (i\,\partial_\tau\phi)^2 \;=\; -(\partial_\tau\phi)^2. \tag{10.157}$$

The temporal kinetic term flips sign. Second the measure: the four-volume element becomes

$$dt\,d^3x \;=\; -i\,d\tau\,d^3x \;=\; -i\,d^4x_E, \qquad d^4x_E \equiv d\tau\,d^3x, \tag{10.158}$$

with $x_E = (\tau, \mathbf{x})$ the Euclidean coordinate. The spatial pieces $(\nabla\phi)^2$, $m^2\phi^2$, ϕ^4 are untouched by the rotation, since the spatial coordinates are unchanged. Substituting Eqs. (10.157) and (10.158) into Eq. (10.156),

$$\begin{aligned} S &= \int(-i\,d^4x_E)\,\Big[\tfrac{1}{2}\big(-(\partial_\tau\phi)^2\big) - \tfrac{1}{2}(\nabla\phi)^2 - \tfrac{1}{2}m^2\phi^2 - \frac{\lambda}{4!}\phi^4\Big] \\ &= -i\int d^4x_E\,\Big[-\tfrac{1}{2}(\partial_\tau\phi)^2 - \tfrac{1}{2}(\nabla\phi)^2 - \tfrac{1}{2}m^2\phi^2 - \frac{\lambda}{4!}\phi^4\Big] \\ &= +i\int d^4x_E\,\Big[\tfrac{1}{2}(\partial_\tau\phi)^2 + \tfrac{1}{2}(\nabla\phi)^2 + \tfrac{1}{2}m^2\phi^2 + \frac{\lambda}{4!}\phi^4\Big]. \end{aligned} \tag{10.159}$$

The two sign flips — one from the squared time derivative, one from pulling the overall minus out of the bracket — have turned every term positive. Defining the Euclidean action as the all-plus integral in the last line, $S = iS_E$, the weight transforms as

$$e^{iS} \longrightarrow e^{i(iS_E)} = e^{-S_E}, \tag{10.160}$$

the central exchange: the oscillatory phase becomes a real, decaying exponential. This is the mechanism announced generically in Eq. (5.95); here it is carried out for the specific quartic theory of the thread.

Definition 10.27 (Euclidean action of ϕ^4 theory)**.** The *Euclidean action* obtained from Eq. (10.156) by the Wick rotation Eq. (10.153) is

$$\boxed{S_E[\phi] = \int d^4x_E \left[\tfrac{1}{2}(\partial_\mu\phi)(\partial_\mu\phi) + \tfrac{1}{2}m^2\phi^2 + \frac{\lambda}{4!}\phi^4\right],} \tag{10.161}$$

where the index μ now runs over the four Euclidean directions (τ, x^1, x^2, x^3) and is summed with the positive-definite metric $\delta_{\mu\nu} = \mathrm{diag}(+,+,+,+)$, so $(\partial_\mu\phi)(\partial_\mu\phi) = (\partial_\tau\phi)^2 + (\nabla\phi)^2 \geq 0$. The Euclidean Lagrangian density is $\mathcal{L}_E = \frac{1}{2}(\partial_\mu\phi)^2 + \frac{1}{2}m^2\phi^2 + \frac{\lambda}{4!}\phi^4$.

This is exactly the Euclidean ϕ^4 action frozen for ϕ^4 theory and quoted at the chapter level in Eq. (5.96): all signs plus, the relative signs of kinetic, mass, and quartic terms now identical rather than alternating. It is the object the Wilsonian renormalization group of Chapter 23 integrates shells of momentum out of, the lattice of Chapter 43 discretizes cell by cell, and the conformal field theory of Chapter 52 flows to at its fixed point. The sign structure matters: because every term in Eq. (10.161) is non-negative (for $\lambda > 0$), the Euclidean action is bounded below by zero, and e^{-S_E} is bounded above by one. There is no longer any cancellation among phases to engineer; large field configurations are simply rare.

Notation Watch

In the Minkowski Lagrangian the relative sign between the kinetic and potential terms is negative, $\frac{1}{2}(\partial\phi)^2 - V$, an artifact of the indefinite metric. In the Euclidean action it is positive, $\frac{1}{2}(\partial\phi)^2 + V$, because the metric is now Euclidean and the time-derivative term has flipped. A reader translating a formula between the two conventions must flip exactly the temporal-kinetic relative sign; the spatial-gradient, mass, and interaction terms keep their Euclidean-positive signs. Failing to track this is the most common error in passing between S and S_E, and it produces a theory that is unbounded below.

10.6.3 The Euclidean generating functional and the convergence of its measure

With the action rotated, the generating functional follows. Applying the replacements Eqs. (10.158) and (10.160) to the Minkowski definition Eq. (10.86) — and continuing the source term, $i\int d^4x\, J\phi \to i(-i)\int d^4x_E\, J\phi = \int d^4x_E\, J\phi$, so that the source coupling also loses its i — gives the Euclidean object.

Definition 10.28 (Euclidean generating functional)**.** The *Euclidean generating functional* of the scalar field is

$$\boxed{Z_E[J] \;=\; \int \mathcal{D}\phi\, \exp\Big[-S_E[\phi] + \int d^4x_E\, J(x)\,\phi(x)\Big]\,,} \tag{10.162}$$

with S_E the action Eq. (10.161) and the functional measure $\mathcal{D}\phi$ the lattice limit of Theorem 10.16, now built on a four-dimensional *Euclidean* lattice. Its normalized functional derivatives generate the *Euclidean* (Schwinger) correlation functions,

$$G_E^{(n)}(x_1,\dots,x_n) \;=\; \frac{1}{Z_E[0]}\,\frac{\delta^n Z_E[J]}{\delta J(x_1)\cdots\delta J(x_n)}\Big|_{J=0} \;=\; \frac{\displaystyle\int \mathcal{D}\phi\;\phi(x_1)\cdots\phi(x_n)\,e^{-S_E}}{\displaystyle\int \mathcal{D}\phi\; e^{-S_E}}, \tag{10.163}$$

the analytic continuations to imaginary time of the Minkowski Green's functions $G^{(n)}$ of Theorem 10.18.

Note the structural simplification relative to the Minkowski case Eq. (10.93): the factors of $1/i^n$ that decorated the Minkowski correlators are gone, because the Euclidean exponent carries no i to bring down. Each functional derivative $\delta/\delta J(x)$ acting on $e^{\int J\phi}$ pulls down a bare $\phi(x)$, with no compensating $1/i$. Euclidean correlators are real, as befits expectation values against a real positive weight.

That last phrase is the heart of the matter, and we now make it precise. The single most important property of Eq. (10.162), the property that the Minkowski integral did not possess, is that the weight e^{-S_E} is a *convergent, positive* integrand: at finite lattice size the integral Eq. (10.162) is an ordinary, absolutely convergent multiple integral against a genuine probability density, with none of the conditional-convergence delicacy that forced the $i\varepsilon$ crutch in Minkowski signature. The reason is the positive-definiteness of the free quadratic form.

Proposition 10.29 (The free Euclidean weight is a convergent positive Gaussian)**.** *Let $S_E^{(0)}$ be the free ($\lambda = 0$) part of Eq. (10.161). After an integration by parts that discards the boundary term, it is the manifestly real quadratic form*

$$S_E^{(0)}[\phi] \;=\; \int d^4x_E\,\Big[\tfrac{1}{2}(\partial_\mu\phi)^2 + \tfrac{1}{2}m^2\phi^2\Big] \;=\; \tfrac{1}{2}\int d^4x_E\;\phi\,(-\partial_E^2 + m^2)\,\phi, \tag{10.164}$$

where $\partial_E^2 = \partial_\tau^2 + \nabla^2$ is the four-dimensional Euclidean Laplacian. The operator $K_E \equiv -\partial_E^2 + m^2$ is symmetric and strictly positive: its momentum-space eigenvalues are

$$K_E(p_E) \;=\; p_E^2 + m^2 \;\geq\; m^2 \;>\; 0, \qquad p_E^2 = (p_E^4)^2 + \mathbf{p}^2, \tag{10.165}$$

bounded below by the mass gap m^2. Hence $S_E^{(0)}[\phi] \geq \frac{1}{2}m^2 \int d^4x_E\, \phi^2 \geq 0$, vanishing only at $\phi \equiv 0$, and $e^{-S_E^{(0)}}$ is a bona fide Gaussian probability weight. The full weight $e^{-S_E} = e^{-S_E^{(0)}}\, e^{-\frac{\lambda}{4!}\int \phi^4}$ is the product of this Gaussian with a factor ≤ 1 for $\lambda \geq 0$, hence also bounded and integrable on each finite lattice.

Proof. The integration by parts rewriting $\int (\partial_\mu \phi)^2 = \int \phi(-\partial_E^2)\phi$ uses the vanishing of ϕ at the boundary of the (large, periodic) Euclidean box, the same finite-lattice statement that justified the corresponding Minkowski manipulation in Section 10.3.4. Passing to momentum space with the (now real-exponent) Euclidean Fourier transform $\phi(x) = \int \frac{d^4p_E}{(2\pi)^4} e^{ip_E\cdot x}\tilde{\phi}(p_E)$, the operator $-\partial_E^2$ acts as multiplication by $p_E^2 = (p_E^4)^2 + \mathbf{p}^2 \geq 0$, giving the eigenvalues Eq. (10.165); the smallest is m^2, attained at $p_E = 0$. Therefore the quadratic form is positive-definite, $S_E^{(0)}[\phi] = \frac{1}{2}\int \frac{d^4p_E}{(2\pi)^4}(p_E^2 + m^2)|\tilde{\phi}(p_E)|^2 \geq \frac{1}{2}m^2\|\phi\|_2^2$. On a finite lattice the field is a finite vector $\{\phi_{j,\mathbf{n}}\}$ and $e^{-S_E^{(0)}}$ is $\exp(-\frac{1}{2}\phi^{\mathsf{T}} M \phi)$ with M a real symmetric positive-definite matrix (the lattice discretization of K_E, whose eigenvalues are positive for the same reason), so the integral $\int \prod d\phi_{j,\mathbf{n}}\, e^{-\frac{1}{2}\phi^{\mathsf{T}} M\phi} = (2\pi)^{N/2}(\det M)^{-1/2}$ is finite and positive by the multidimensional Gaussian formula Theorem 4.14. For $\lambda \geq 0$ the quartic factor $e^{-\frac{\lambda}{4!}\int \phi^4} \in (0, 1]$ only improves convergence. The continuum limit of the ratio defining correlators is then the limit of well-defined finite integrals. □

This is the decisive structural gain. In Minkowski signature the operator $K = -\Box - m^2$ in the exponent of $Z[J]$ has eigenvalues $p^2 - m^2$ that *change sign and vanish on the mass shell* (Eq. (10.90)); the integral is oscillatory, the operator is not invertible without a prescription, and the $i\varepsilon$ was the prescription. In Euclidean signature the operator $K_E = -\partial_E^2 + m^2$ has eigenvalues $p_E^2 + m^2$ that are *strictly positive and never vanish*; the integral is convergent, the operator is invertible outright, and no prescription is needed. The Euclidean theory is the place where the path integral is, for the free theory, a completely rigorous object — a Gaussian measure on the space of (tempered-distribution) field configurations, the construction of which is carried out in Chapter E. It is precisely this convergence that the lattice of Chapter 43 exploits to give a non-perturbative *definition* of the theory, and that statistical mechanics borrows wholesale.

Physical Insight

The Minkowski path integral and the Euclidean path integral are the same Gaussian read in two metrics, and the metric decides everything about convergence. With an indefinite metric the quadratic form $\phi K \phi$ is indefinite, the weight is a phase, and the integral survives only by the conditional cancellation of oscillations. With a definite metric the quadratic form is positive, the weight is a Boltzmann factor, and the integral converges absolutely. Wick rotation is the bridge between the two, and the mass gap $m^2 > 0$ is the spectral reason the Euclidean side is so much better behaved: it is the gap between the smallest eigenvalue of K_E and zero.

10.6.4 The Euclidean propagator and its continuation to D_F

Because the free Euclidean weight is a convergent Gaussian, its generating functional is evaluated by completing the square exactly as in the Minkowski case (Section 10.4), but now with no $i\varepsilon$ to carry and the inverse of K_E unambiguous. Shifting $\phi \to \phi + K_E^{-1} J$ in Eq. (10.162) with $\lambda = 0$ and using Eq. (10.164) gives

$$Z_E^{(0)}[J] \;=\; Z_E^{(0)}[0]\, \exp\Big[\tfrac{1}{2}\int d^4x_E\, d^4y_E\; J(x)\, G_E(x-y)\, J(y)\Big], \tag{10.166}$$

where G_E is the inverse of the Euclidean kinetic operator, the unique solution of

$$(-\partial_E^2 + m^2)\, G_E(x_E) \;=\; \delta^4(x_E). \tag{10.167}$$

The sign of the exponent in Eq. (10.166) is positive, in contrast to the negative sign of the Minkowski Eq. (10.152), because the Euclidean source coupling carries no i and the completed square produces $+\frac{1}{2} J K_E^{-1} J$. Inverting Eq. (10.167) in momentum space — multiplication by $p_E^2 + m^2$ becomes division — and Fourier transforming back yields the Euclidean propagator in closed form.

Definition 10.30 (Euclidean propagator)**.** The *Euclidean (Schwinger) propagator* of the free scalar is

$$\boxed{G_E(x_E) \;=\; \int \frac{d^4p_E}{(2\pi)^4}\, \frac{e^{\,ip_E\cdot x_E}}{p_E^2 + m^2}\,,} \qquad p_E \cdot x_E = p_E^4 \tau + \mathbf{p}\cdot\mathbf{x}, \tag{10.168}$$

the two-point Schwinger function $G_E^{(2)}(x, 0)$ of Eq. (10.163). Its denominator $p_E^2 + m^2 \geq m^2 > 0$ never vanishes for real Euclidean momentum, so the integral requires no $i\varepsilon$ prescription and defines a real, smooth function of x_E away from the origin.

The contrast with the Feynman propagator Eq. (10.154) is the whole story of this section in one line. The Minkowski denominator $p^2 - m^2$ vanishes on the mass shell and needed the $i\varepsilon$ to be defined; the Euclidean denominator $p_E^2 + m^2$ is bounded away from zero and needs nothing. The two are connected by the rotation, as we now verify directly, both in momentum and in position space.

Momentum-space continuation. Start from the position-space Feynman propagator and substitute the rotation. The Feynman propagator is

$$D_F(x) \;=\; \int \frac{d^4p}{(2\pi)^4}\,\frac{i\,e^{-ip\cdot x}}{p^2 - m^2 + i\varepsilon}, \qquad p\cdot x = p^0x^0 - \mathbf{p}\cdot\mathbf{x}, \tag{10.169}$$

with the book's Fourier convention. Rotate both the external time and the energy integration, $x^0 = -i\tau$ and $p^0 = ip_E^4$ (Eq. (5.93)), the latter legitimate by Theorem 10.26. Three things continue. The measure: $dp^0 = i\,dp_E^4$, so $d^4p = i\,d^4p_E$. The denominator: by Eq. (5.94), $p^2 = (p^0)^2 - \mathbf{p}^2 \to -(p_E^2)$, so $p^2 - m^2 + i\varepsilon \to -(p_E^2 + m^2)$, the $i\varepsilon$ now redundant since the rotated denominator is strictly negative. The phase: with $p^0 = ip_E^4$ and $x^0 = -i\tau$,

$$p\cdot x \;=\; p^0x^0 - \mathbf{p}\cdot\mathbf{x} \;=\; (ip_E^4)(-i\tau) - \mathbf{p}\cdot\mathbf{x} \;=\; p_E^4\tau - \mathbf{p}\cdot\mathbf{x}, \qquad \text{so} \qquad e^{-ip\cdot x} = e^{-ip_E^4\tau}\,e^{\,i\mathbf{p}\cdot\mathbf{x}}. \tag{10.170}$$

Assembling the three,

$$D_F(x)\big|_{x^0=-i\tau} \;=\; \int \frac{i\,d^4p_E}{(2\pi)^4}\,\frac{i\,e^{-ip_E^4\tau}\,e^{i\mathbf{p}\cdot\mathbf{x}}}{-(p_E^2+m^2)} \;=\; \int \frac{d^4p_E}{(2\pi)^4}\,\frac{e^{-ip_E^4\tau}\,e^{i\mathbf{p}\cdot\mathbf{x}}}{p_E^2+m^2}, \tag{10.171}$$

where the two factors of i in the numerator combine with the -1 in the denominator, $i\cdot i/(-1) = (-1)/(-1) = +1$, to leave a clean real-weighted integral. Finally, since the integrand denominator is even in p_E^4 and the measure is symmetric, relabel the dummy variable $p_E^4 \to -p_E^4$ to convert $e^{-ip_E^4\tau}$ into $e^{+ip_E^4\tau}$, whereupon the phase becomes $e^{i(p_E^4\tau + \mathbf{p}\cdot\mathbf{x})} = e^{ip_E\cdot x_E}$ and

$$\boxed{D_F(x)\big|_{x^0=-i\tau} \;=\; \int \frac{d^4p_E}{(2\pi)^4}\,\frac{e^{\,ip_E\cdot x_E}}{p_E^2+m^2} \;=\; G_E(x_E)\,.} \tag{10.172}$$

The Feynman propagator, analytically continued to imaginary time $t = -i\tau$, *is* the Euclidean propagator. The relation runs both ways: G_E continued back along $\tau = it$ recovers D_F, and the $i\varepsilon$ of the Minkowski denominator is the instruction for *which* continuation — which side of the mass-shell singularity to approach — when the rotation is undone. The Euclidean object, free of singularities, is in this sense the more fundamental one; the Feynman propagator is its boundary value as the contour returns to real time, and the $i\varepsilon$ records the direction of approach.

Worked Example 10.31 (The Euclidean propagator in position space: convergence made manifest)**.** We evaluate Eq. (10.168) in closed form, both to exhibit

a genuinely convergent four-dimensional integral and to display the propagator's exponential decay — the Euclidean shadow of the mass gap. Introduce the Schwinger proper-time representation of the denominator, valid because $p_E^2 + m^2 > 0$,

$$\frac{1}{p_E^2 + m^2} \;=\; \int_0^\infty ds\, e^{-s(p_E^2+m^2)}, \tag{10.173}$$

an ordinary convergent integral with no prescription needed; this is itself a benefit of the positive denominator. Substituting into Eq. (10.168) and exchanging orders,

$$G_E(x_E) \;=\; \int_0^\infty ds\, e^{-sm^2} \int \frac{d^4p_E}{(2\pi)^4}\, e^{-sp_E^2 + ip_E\cdot x_E}. \tag{10.174}$$

The momentum integral is a product of four ordinary Gaussians (one per Euclidean direction), each evaluated by completing the square, $\int \frac{dp}{2\pi} e^{-sp^2+ipx} = \frac{1}{\sqrt{4\pi s}}\, e^{-x^2/4s}$; the four-dimensional version is

$$\int \frac{d^4p_E}{(2\pi)^4}\, e^{-sp_E^2 + ip_E\cdot x_E} \;=\; \frac{1}{(4\pi s)^2}\, e^{-x_E^2/4s}, \qquad x_E^2 = \tau^2 + \mathbf{x}^2 \equiv r^2, \tag{10.175}$$

manifestly finite for every $s > 0$ because the Euclidean exponent $-sp_E^2$ is real and negative. Hence

$$G_E(x_E) \;=\; \frac{1}{16\pi^2} \int_0^\infty \frac{ds}{s^2}\, \exp\Big[- sm^2 - \frac{r^2}{4s}\Big], \tag{10.176}$$

a positive integrand integrated over positive s: the result is positive and finite for $r > 0$, with the convergence at large s guaranteed by the mass term and at small s by the $r^2/4s$ term. The remaining integral is the standard integral representation of the modified Bessel function K_ν, namely $\int_0^\infty ds\, s^{-\nu-1} e^{-as-b/s} = 2(a/b)^{\nu/2} K_\nu(2\sqrt{ab})$; with $\nu = 1$, $a = m^2$, $b = r^2/4$, so that $2\sqrt{ab} = mr$ and $(a/b)^{1/2} = 2m/r$,

$$G_E(x_E) \;=\; \frac{1}{16\pi^2} \cdot 2 \cdot \frac{2m}{r}\, K_1(mr) \;=\; \frac{m}{4\pi^2\, r}\, K_1(mr), \qquad r = \sqrt{\tau^2 + \mathbf{x}^2}. \tag{10.177}$$

This is a real, positive, smooth function of the Euclidean radius r, exactly as a convergent Gaussian integral against a positive weight must produce. Its long-distance behavior, from the asymptotics $K_1(z) \sim \sqrt{\pi/2z}\, e^{-z}$ for $z \to \infty$, is

$$G_E(x_E) \;\xrightarrow{mr \gg 1}\; \frac{m}{4\pi^2 r} \sqrt{\frac{\pi}{2mr}}\, e^{-mr} \;=\; \frac{\sqrt{m}}{4\sqrt{2}\,\pi^{3/2}}\, \frac{e^{-mr}}{r^{3/2}}, \tag{10.178}$$

an exponential decay with correlation length $\xi = 1/m$. The mass gap of the quantum field theory has reappeared as the inverse correlation length of the Euclidean two-point function — the first entry of the dictionary developed next. Its short-distance behavior, from $K_1(z) \sim 1/z$ as $z \to 0$, is $G_E \to 1/(4\pi^2 r^2)$, the massless Euclidean Coulomb-like singularity of the four-dimensional Laplacian, recovering the $\lambda = m = 0$ free-field result and confirming that Eq. (10.177) solves Eq. (10.167) with the correct unit-strength point source.

Euclidean quantum field theory	**Classical statistical mechanics**
Field configuration $\phi(x_E)$	Microstate / configuration $\{\sigma_i\}$
Euclidean action $S_E[\phi]$	Reduced energy $\beta H[\sigma]$
Functional measure $\mathcal{D}\phi$	Sum over configurations $\prod_i d\sigma_i$
Partition function $Z_E[0] = \int \mathcal{D}\phi\, e^{-S_E}$	Partition function $Z = \sum e^{-\beta H}$
Source $J(x)$	External field (e.g. magnetic h)
Schwinger functions $G_E^{(n)}$	Thermal correlators $\langle \sigma \cdots \sigma \rangle$
Mass gap m	Inverse correlation length $1/\xi$
Massless / critical theory	Critical point ($\xi \to \infty$)
Wilsonian RG flow (Chapter 23)	Kadanoff block-spin / RG
Lattice regularization (Chapter 43)	Lattice model (Ising, etc.)

Table 10.1: The quantum-field-theory / statistical-mechanics dictionary, read off from the identity of the Euclidean generating functional Eq. (10.162) with a classical partition function. Each line is an exact correspondence between objects, not an analogy; it is the reason the renormalization group, born in statistical physics, governs quantum field theory, and the reason the lattice computes both.

10.6.5 The dictionary: quantum field theory as statistical mechanics

The form of the Euclidean generating functional Eq. (10.162) invites a reading that has organized half of modern theoretical physics. Written out,

$$Z_E[0] \;=\; \int \mathcal{D}\phi\; e^{-S_E[\phi]}, \tag{10.179}$$

it is structurally identical to the partition function of classical statistical mechanics, $Z = \int \prod_i d\sigma_i\, e^{-\beta H[\sigma]}$, the sum over configurations $\{\sigma_i\}$ of a system with energy functional H at inverse temperature β, weighted by the Boltzmann factor. The dictionary is exact and term-by-term: the field configuration $\phi(x_E)$ is the configuration of a classical statistical system in four spatial dimensions; the Euclidean action $S_E[\phi]$ plays the role of the dimensionless energy $\beta H[\phi]$; the functional integral $\int \mathcal{D}\phi$ is the sum over configurations; $Z_E[0]$ is the partition function; and the Schwinger correlation functions Eq. (10.163) are the thermal correlation functions of the statistical system. Quantum fluctuations of the $(3+1)$-dimensional quantum field theory are thermal fluctuations of the four-dimensional classical statistical system, with $\hbar$ in the role of temperature.

The dictionary, collected in Table 10.1, is more than a formal curiosity; it is a two-way street that the rest of the book travels repeatedly. The entry that

anchors the others is the identification of the mass gap with the inverse correlation length, which the worked example above has already demonstrated: the Euclidean two-point function $G_E \sim e^{-mr}/r^{3/2}$ decays with correlation length $\xi = 1/m$, exactly the statement that the connected correlations of a statistical system fall off over the length ξ. A massless quantum field theory is therefore a statistical system at a *critical point*, where $\xi \to \infty$ and correlations become scale-free — the regime where conformal symmetry emerges and the bootstrap of Chapter 52 operates. The renormalization group, which we introduce as a Wilsonian flow in Chapter 23, was born in this statistical setting as Kadanoff's block-spin transformation and Wilson's integration over short-distance fluctuations; the dictionary is what licenses importing it wholesale into quantum field theory. And the lattice of Chapter 43 is the dictionary read in reverse: a quantum field theory is *defined* non-perturbatively by writing down the corresponding lattice statistical model and taking the continuum limit at its critical point, with the convergent positive measure of Theorem 10.29 making the integral amenable to the same Monte-Carlo sampling that statistical mechanics uses.

Physical Insight

There is a sharper version of the dictionary that fixes the role of temperature. If, instead of taking the Euclidean time τ to run over all of $\mathbb{R}$, one compactifies it onto a circle of circumference β with periodic boundary conditions on the field, $\phi(\tau + \beta, \mathbf{x}) = \phi(\tau, \mathbf{x})$, the Euclidean path integral computes the quantum-statistical trace $Z(\beta) = \mathrm{Tr}\, e^{-\beta H}$ — the thermal partition function of the quantum field theory at physical temperature $T = 1/\beta$. The infinite-τ vacuum theory of this section is the zero-temperature limit $\beta \to \infty$. Thus the same rotated integral describes both vacuum correlators (line $\tau \in \mathbb{R}$) and thermal equilibrium (circle of circumference β); the imaginary-time formalism of finite-temperature field theory is nothing but the Euclidean path integral on a cylinder. We will not develop thermal field theory here, but the reader should register that the Wick rotation has, for free, delivered the bridge to it.

10.6.6 Reflection positivity and the return to Lorentzian operators

The Wick rotation as we have used it runs in one direction: from a Lorentzian quantum theory, defined by canonical quantization in Chapter 9 and reproduced by the Minkowski path integral, we passed to a convergent Euclidean integral. For the Euclidean formulation to stand on its own — to be, as the lattice and constructive programs intend, a *definition* of quantum field theory rather than a derived shadow of a pre-existing Lorentzian one — we need the converse: a criterion guaranteeing that a given Euclidean theory, specified by its Schwinger

functions $G_E^{(n)}$, continues back to a sensible Lorentzian theory with a Hilbert space of positive norm and a self-adjoint Hamiltonian bounded below. That criterion is reflection (Osterwalder–Schrader) positivity. We state it precisely and explain its content; its proof in full generality belongs to the constructive program and is beyond the scope of this chapter, but the statement is exactly what the lattice (Chapter 43) and conformal (Chapter 52) chapters invoke.

Let Θ denote reflection of the Euclidean time about the hyperplane $\tau = 0$, acting on configurations by $(\Theta\phi)(\tau, \mathbf{x}) = \phi(-\tau, \mathbf{x})$ and on functionals of the field accordingly. Call a functional $F[\phi]$ *supported at positive time* if it depends on the field only through its values at $\tau > 0$.

Theorem 10.32 (Reflection positivity and reconstruction; stated)**.** *A set of Euclidean Schwinger functions arising from a measure $e^{-S_E}\mathcal{D}\phi$ that is reflection positive — meaning that for every functional F supported at positive Euclidean time*

$$\big\langle\, (\Theta F)^{*}\, F \,\big\rangle_E \;=\; \frac{1}{Z_E[0]} \int \mathcal{D}\phi\; (\Theta F[\phi])^{*}\, F[\phi]\, e^{-S_E[\phi]} \;\geq\; 0 \tag{10.180}$$

holds — together with Euclidean invariance and the appropriate regularity (the Osterwalder–Schrader axioms), determines a unique Lorentzian quantum field theory. Its Hilbert space $\mathcal{H}$ is built from positive-time functionals with inner product Eq. (10.180), its vacuum is the constant functional, and its Hamiltonian $H \geq 0$ is the generator of Euclidean time translations continued to real time; the Lorentzian Wightman functions are the analytic continuations of the $G_E^{(n)}$ back to real time, $\tau \to it$.

The structural meaning of Eq. (10.180) is worth unpacking, because it is exactly the property that the indefinite-metric Minkowski integral cannot guarantee on its own. The combination $(\Theta F)^{*}F$ pairs a positive-time functional with its time-reflected conjugate; the Euclidean expectation of this combination is, after reconstruction, the squared norm of the state F creates from the vacuum. Demanding it be non-negative for *every* positive-time F is demanding that the reconstructed Hilbert space have a positive-definite inner product — that there be no negative-norm "ghost" states. The reflection Θ is the Euclidean avatar of Hermitian conjugation: under the continuation $\tau \to it$, reflecting Euclidean time about $\tau = 0$ becomes complex-conjugating a Lorentzian amplitude, so Eq. (10.180) is the Euclidean transcription of the statement $\langle\psi|\psi\rangle \geq 0$. A Euclidean measure that satisfies it is one whose statistical correlations encode a unitary quantum theory; one that violates it (and there are perfectly sensible-looking Euclidean actions that do) corresponds to no Lorentzian quantum mechanics at all.

Caution

Not every positive Euclidean weight e^{-S_E} defines a Lorentzian quantum field theory. Positivity of the *measure* — guaranteed here by Theorem 10.29 — makes Z_E a convergent statistical partition function, but reflection positivity Eq. (10.180) is the strictly stronger, separate requirement that the reconstructed Hilbert space have no negative-norm states. The free scalar and the lattice ϕ^4 theory satisfy it; higher-derivative actions with improved ultraviolet behavior typically do not, which is why they fail to define unitary theories despite having perfectly convergent Euclidean integrals. The two notions of positivity must not be conflated.

Theorem Theorem 10.32 closes the logical circle of the chapter. Canonical quantization (Chapter 9) gave a Lorentzian operator theory; the Minkowski path integral reproduced its time-ordered correlators (Theorem 10.19); the Wick rotation carried those to convergent Euclidean Schwinger functions; and reflection positivity is the guarantee that the Euclidean data can be carried *back* to Lorentzian operators with a positive-norm Hilbert space and a stable Hamiltonian. The Euclidean theory is thus not a poor relation of the Lorentzian one but a complete and self-standing formulation, equivalent to it precisely when Eq. (10.180) holds.

With the Euclidean action S_E of Eq. (10.161) fixed for ϕ^4 theory, the convergent positive measure $e^{-S_E}\mathcal{D}\phi$ established, the Euclidean propagator G_E constructed and tied to D_F by analytic continuation, and the statistical-mechanics dictionary and reflection-positivity criterion in hand, we have assembled the form of the path integral that the renormalization group will flow, the lattice will discretize, and conformal field theory will inhabit. It remains to put the machinery of this chapter to work on the interacting theory: in the final section we expand $e^{-\frac{\lambda}{4!}\int \phi^4}$ perturbatively inside the generating functional, organize the resulting correlators into connected and effective generating functionals, and hand the assembled apparatus forward to the S-matrix and the Feynman rules.

10.7 The Interacting Generating Functional and the Road Ahead

The free machinery is now complete and exact. We have the free generating functional $Z_0[J]$ in closed form (Section 10.4), its single nontrivial datum the Feynman propagator D_F recovered a second way from a Gaussian integral, and Wick's theorem (Theorem 10.23) telling us that every free correlator is a sum over pairings into propagators. All of this lived at $\lambda = 0$: the exponent of Eq. (10.86) was quadratic and the integral was Gaussian. The frozen ϕ^4 Lagrangian, however, carries a quartic term, and the moment we restore it the integral is no longer

one we can do. What we *can* do — and what organizes the entire remainder of perturbative field theory — is express the full $Z[J]$ as a differential operator built from the interaction acting on the free $Z_0[J]$ we already possess. That single formula turns every interacting correlator into a finite collection of free correlators, i.e. into propagators and combinatorics; it is the algebraic seed of the Feynman diagram. This closing section plants that seed: it sets up the interacting $Z[J]$ perturbatively, isolates the connected part through the functional $W[J]$, and points to the effective action Γ, handing the assembled apparatus to the chapters that will grow it into the S-matrix, the Feynman rules, and the renormalization group — without doing their work here.

10.7.1 Splitting the action: the master formula

The starting point is the trivial observation that the action of the frozen theory splits into a free quadratic piece and an interaction,

$$S[\phi] \;=\; S_0[\phi]+S_{\rm int}[\phi], \qquad S_0[\phi]=\int d^4x\,\Big[\tfrac{1}{2}(\partial_\mu\phi)(\partial^\mu\phi)-\tfrac{1}{2}m^2\phi^2\Big], \quad S_{\rm int}[\phi]=-\int d^4x\,\frac{\lambda}{4!}\,\phi(\tag{10.181}$$

We write $\mathcal{L}_{\rm int}[\phi]=-\frac{\lambda}{4!}\phi^4$ for the interaction density, so $S_{\rm int}=\int d^4x\,\mathcal{L}_{\rm int}$. Inserting Eq. (10.181) into the generating functional Eq. (10.86) factorizes the exponential,

$$Z[J] \;=\; \int\!\mathcal{D}\phi\; e^{\,iS_{\rm int}[\phi]}\; e^{\,i\left(S_0[\phi]+\int J\phi\right)}. \tag{10.182}$$

The second factor is exactly the free integrand whose integral is $Z_0[J]$; the first factor, $e^{iS_{\rm int}}$, is the obstruction. The trick that removes the obstruction is to notice that inside the integral every power of the field can be manufactured by differentiating the free integrand with respect to the source. From the elementary identity $\frac{1}{i}\frac{\delta}{\delta J(x)}\,e^{\,i\int J\phi}=\phi(x)\,e^{\,i\int J\phi}$, established in Eq. (10.91), it follows that for *any* point x,

$$\frac{1}{i}\frac{\delta}{\delta J(x)}\,\Big[\;\cdots\;e^{\,i(S_0+\int J\phi)}\Big] \;=\; \Big[\;\cdots\;\phi(x)\;e^{\,i(S_0+\int J\phi)}\Big] \tag{10.183}$$

whenever the omitted factors $\cdots$ do not depend on J — in particular when they are themselves powers of ϕ, which are J-independent c-number functions under the integral sign. Because the functional derivatives $\delta/\delta J(x)$ at distinct points commute, and because they act on ϕ-factors as the identity (those factors carry no J), *any* functional $F[\phi]$ that is a power series in the field satisfies the operator replacement rule

$$F\Big[\tfrac{1}{i}\tfrac{\delta}{\delta J}\Big]\;e^{\,i\int J\phi} \;=\; F[\phi]\,e^{\,i\int J\phi}, \tag{10.184}$$

read as: replace each field in $F[\phi]$ by the source-derivative $\frac{1}{i}\frac{\delta}{\delta J}$, let the resulting differential operator act on $e^{\,i\int J\phi}$, and recover $F[\phi]$ times the same exponential.

Applying this with $F[\phi] = e^{iS_{\text{int}}[\phi]}$ converts the troublesome factor in Eq. (10.182) into a differential operator that no longer references ϕ at all,

$$e^{\,iS_{\text{int}}[\phi]}\, e^{\,i(S_0+\int J\phi)} \;=\; \exp\Big(iS_{\text{int}}\big[\tfrac{1}{i}\tfrac{\delta}{\delta J}\big]\Big)\, e^{\,i(S_0+\int J\phi)}. \tag{10.185}$$

The operator $\exp(iS_{\text{int}}[\frac{1}{i}\frac{\delta}{\delta J}])$ depends only on J, not on ϕ, so it commutes with the field integration $\int\mathcal{D}\phi$ and may be pulled out in front of it. The integral that remains is precisely $Z_0[J]$. This proves the central structural identity of perturbative field theory.

Theorem 10.33 (The interacting generating functional as a differential operator)**.** *For the split Eq. (10.181), the full generating functional is obtained from the free one by acting with the interaction, the fields in the interaction replaced by source-derivatives:*

$$\boxed{Z[J] \;=\; \exp\Big(i\int d^4x\; \mathcal{L}_{\text{int}}\big[\tfrac{1}{i}\tfrac{\delta}{\delta J(x)}\big]\Big)\, Z_0[J] \;=\; \exp\Big(-\,\frac{i\lambda}{4!}\int d^4z\,\frac{\delta^4}{\delta J(z)^4}\Big)\, Z_0[J]\,,} \tag{10.186}$$

where in the second form we used $\mathcal{L}_{\text{int}} = -\frac{\lambda}{4!}\phi^4$ *and* $\big(\frac{1}{i}\big)^4 = 1$*, and*

$$Z_0[J] \;=\; Z_0[0]\,\exp\Big[-\tfrac{1}{2}\int d^4x\, d^4y\; J(x)\, D_F(x-y)\, J(y)\Big] \tag{10.187}$$

is the free generating functional of Eq. (10.111), with D_F *the Feynman propagator of Eq. (9.154).*

Proof. Combine Eq. (10.182), Eq. (10.185), and the commutation of the J-only operator with $\int\mathcal{D}\phi$:

$$\begin{aligned} Z[J] &= \int\mathcal{D}\phi\;\exp\Big(iS_{\text{int}}\big[\tfrac{1}{i}\tfrac{\delta}{\delta J}\big]\Big)\, e^{\,i(S_0+\int J\phi)} \\ &= \exp\Big(iS_{\text{int}}\big[\tfrac{1}{i}\tfrac{\delta}{\delta J}\big]\Big)\int\mathcal{D}\phi\; e^{\,i(S_0+\int J\phi)} = \exp\Big(iS_{\text{int}}\big[\tfrac{1}{i}\tfrac{\delta}{\delta J}\big]\Big)\, Z_0[J]. \end{aligned} \tag{10.188}$$

The only non-elementary step is the second equality, the interchange of the differential operator with the field integral. On any finite spacetime lattice (Theorem 10.16) this is rigorous: $Z[J]$ is then an ordinary finite-dimensional integral, $J(z)$ is a finite collection of integration-independent parameters, and differentiating under the integral sign with respect to a parameter is legitimate because the integrand and its J-derivatives are absolutely integrable thanks to the $i\varepsilon$ Gaussian damping Eq. (10.89). The exponential of the differential operator is then read as its power series, applied term by term; the continuum limit is taken at the end. The expression is therefore exact as a formal power series in λ: expanding the exponential generates, at each order, finitely many source-derivatives of the explicitly known $Z_0[J]$. □

The formula Eq. (10.186) is the whole of perturbation theory in embryo. The free generating functional $Z_0[J]$ is known in closed form; the interaction has been demoted from an obstruction inside the integral to a differential operator outside it; and every interacting Green's function of Theorem 10.18 is now computable, to any finite order in λ, by differentiating $Z_0[J]$ a finite number of times. No integral remains to be done that we cannot do. The price is that "any finite order in λ" is the best the formula offers: the series it generates is, for ϕ^4, only asymptotic, a point we revisit when its Borel structure is analyzed in Chapter 23.

Notation Watch

The replacement rule Eq. (10.184) carries one factor of $1/i$ per field because the source couples as $e^{+i\int J\phi}$ in the Minkowski generating functional Eq. (10.86). For the quartic vertex the four factors combine to $(1/i)^4 = 1$, so the operator in Eq. (10.186) is simply $-\frac{i\lambda}{4!}\int_z \delta^4/\delta J^4$; for an odd vertex (e.g. a ϕ^3 interaction) the surviving factor of $1/i$ would not cancel and must be tracked. The Euclidean version replaces e^{iS} by e^{-S_E} (Section 10.6) and the rule becomes $\frac{\delta}{\delta J} e^{\int J\phi} = \phi\, e^{\int J\phi}$ with no factors of i at all.

10.7.2 Perturbation theory and the birth of contractions

To see the diagrammatic content emerge, expand the operator exponential in Eq. (10.186) in powers of the coupling,

$$Z[J] \;=\; \Big[\,1 \;-\; \frac{i\lambda}{4!}\int d^4z\,\frac{\delta^4}{\delta J(z)^4} \;+\; O(\lambda^2)\,\Big]\,Z_0[J]. \tag{10.189}$$

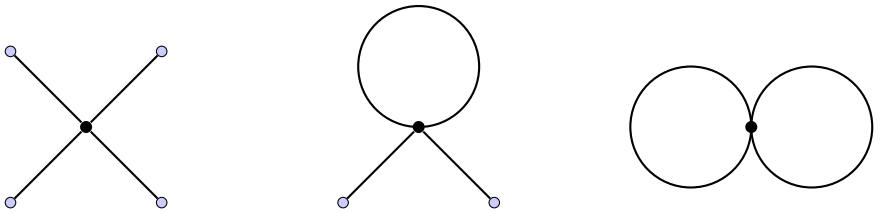
Each order is a definite number of source-derivatives acting on the Gaussian $Z_0[J]$, and the act of differentiating an exponential of a quadratic is exactly what produces propagators. Write $Z_0[J] = Z_0[0]\,e^{W_0[J]}$ with the quadratic exponent

$$W_0[J] \;=\; -\tfrac{1}{2}\int d^4x\,d^4y\;J(x)\,D_F(x-y)\,J(y), \qquad \frac{\delta W_0}{\delta J(z)} \;=\; -\,\phi_J(z), \qquad \frac{\delta^2 W_0}{\delta J(z)^2} \;=\; -\,D_F(0), \tag{10.190}$$

where we have introduced the *source-induced field*

$$\phi_J(z) \;\equiv\; \int d^4y\;D_F(z-y)\,J(y), \tag{10.191}$$

the propagator smeared against the source (this $\phi_J = D_F * J$ is the source-smeared object and differs by a factor i from the classical field of Eq. (10.104), $\phi_J^{\rm cl} = -\mathcal{O}^{-1}J = i\,D_F * J$, since $(\Box + m^2)^{-1} = i\,D_F$), and where $D_F(0)$ denotes the propagator at coincident points (a single closed loop, formally divergent — its taming is the business of Chapters 21 and 22, not here). Because W_0 is quadratic, all derivatives beyond the second vanish, and the fourth source-derivative of e^{W_0}



(a) $\phi_J(z)^4$
four legs to J

(b) $\phi_J(z)^2\, D_F(0)$
two legs, one loop

(c) $D_F(0)^2$
vacuum bubble

Figure 10.7: The three $O(\lambda)$ topologies generated by the four source-derivatives in Eq. (10.193). A single quartic vertex (black dot) at z has four legs; each leg either runs to a source (open circle, a factor $\phi_J(z) = \int D_F(z-y)J(y)$) or closes back on the vertex (a loop, a factor $D_F(0)$). Diagram (a) is the seed of the four-point amplitude; (b) is the one-loop correction to the propagator (a "tadpole"); (c) is a disconnected vacuum bubble. The combinatorial weights $1, 6, 3$ count the pairings; their reduction to symmetry factors is carried out in Chapter 15.

is given by the standard exponential-of-a-function expansion, in which only the first and second derivatives of W_0 appear:

$$\frac{\delta^4}{\delta J(z)^4}\, e^{W_0} \;=\; e^{W_0}\Big[(W_0')^4 + 6\,(W_0')^2\, W_0'' + 3\,(W_0'')^2\Big], \tag{10.192}$$

all derivatives evaluated at the single point z. Substituting Eq. (10.190), the bracket becomes a sum of three terms,

$$\frac{\delta^4}{\delta J(z)^4}\, Z_0[J] \;=\; Z_0[J]\Big[\underbrace{\phi_J(z)^4}_{\text{four legs to sources}} - 6\,\underbrace{\phi_J(z)^2\, D_F(0)}_{\text{two legs, one loop}} + 3\,\underbrace{D_F(0)^2}_{\text{vacuum loop}}\Big], \tag{10.193}$$

and the $O(\lambda)$ contribution to $Z[J]$ is $-\frac{i\lambda}{4!}\int d^4z$ of this. The three terms are the three ways of distributing the four legs of a single vertex: all four attached to sources, two attached and two contracted with each other into a loop, or all four contracted in pairs into two loops with no source at all. *This is the origin of Feynman diagrams.* Each $\phi_J(z)$ is a propagator running from the vertex at z out to a source; each factor of $D_F(0)$ is a propagator that begins and ends at the vertex, a loop; and the integer coefficients $1, 6, 3$ are the numbers of distinct pairings of the four identical derivatives, the seeds of the symmetry factors developed systematically in Chapter 15. Figure 10.7 draws the three topologies.

The piece that advances ϕ^4 theory to the threshold of its first amplitude is diagram (a), the term $\phi_J(z)^4$ with all four legs attached to sources. Stripping the four sources by functional differentiation exposes the bare vertex.

Worked Example 10.34 (The $O(\lambda)$ four-point function and the vertex $-i\lambda$)**.** We extract the connected four-point Green's function $G_c^{(4)}$ at first order in λ and read off the vertex factor that Chapter 14 will turn into a scattering amplitude.

The connected part of $G^{(4)}$ comes entirely from the all-legs-to-sources term $\phi_J(z)^4$ in Eq. (10.193): the other two terms either carry too few sources (the vacuum bubble has none) or factorize off a disconnected loop (the tadpole). Using Theorem 10.18, $G^{(4)} = i^{-4}\,\delta^4(Z[J]/Z[0])/\delta J^4|_{J=0}$ with $i^{-4}=1$, and keeping only the term in which all four derivatives land on the four induced fields (this is what "connected" selects — any derivative landing on the residual e^{W_0} would attach an extra propagator between external points, a disconnected piece),

$$G_c^{(4)}\big|_{O(\lambda)}(x_1,x_2,x_3,x_4) \;=\; -\frac{i\lambda}{4!}\int d^4z\;\frac{\delta^4}{\delta J(x_1)\,\delta J(x_2)\,\delta J(x_3)\,\delta J(x_4)}\,\phi_J(z)^4\Big|_{J=0}. \tag{10.194}$$

Now $\phi_J(z)^4 = \big[\int d^4y\, D_F(z-y)J(y)\big]^4$, and each $\delta/\delta J(x_i)$ removes one factor of J, leaving a propagator $D_F(z-x_i)$; there are exactly 4! ways to assign the four distinct derivatives to the four identical factors, so

$$\frac{\delta^4}{\delta J(x_1)\cdots\delta J(x_4)}\,\phi_J(z)^4\Big|_{J=0} \;=\; 4!\,\prod_{i=1}^{4} D_F(x_i-z). \tag{10.195}$$

The combinatorial 4! cancels the symmetry factor $1/4!$ of the vertex exactly, and we obtain the clean position-space result

$$G_c^{(4)}\big|_{O(\lambda)}(x_1,x_2,x_3,x_4) \;=\; -i\lambda\int d^4z\; D_F(x_1-z)\,D_F(x_2-z)\,D_F(x_3-z)\,D_F(x_4-z). \tag{10.196}$$

Each external point is joined to a common vertex z by one Feynman propagator, and the vertex carries the factor $-i\lambda$. To expose the amplitude, pass to momentum space with the book's convention $\phi(x)=\int \frac{d^4p}{(2\pi)^4}e^{-ip\cdot x}\tilde\phi(p)$. The z-integral produces overall momentum conservation, $\int d^4z\, e^{-i(p_1+p_2+p_3+p_4)\cdot z} = (2\pi)^4\delta^{(4)}(p_1+p_2+p_3+p_4)$, and each leg contributes a momentum-space propagator $D_F(p_i) = i/(p_i^2-m^2+i\varepsilon)$, so

$$\widetilde{G}_c^{(4)}\big|_{O(\lambda)} \;=\; (2\pi)^4\delta^{(4)}\Big(\textstyle\sum_i p_i\Big)\,(-i\lambda)\,\prod_{i=1}^4 \frac{i}{p_i^2-m^2+i\varepsilon}. \tag{10.197}$$

Removing the four external propagators — the *amputation* that the LSZ reduction of Chapter 14 will justify physically — and stripping the momentum-conserving delta leaves the amputated four-point vertex function

$$\boxed{\,i\mathcal{M}\big|_{O(\lambda)} \;=\; -i\lambda\,.\,} \tag{10.198}$$

This is the carried number of ϕ^4 theory: the lowest-order $\phi\phi\to\phi\phi$ amplitude is $\mathcal{M}=-\lambda$, the Feynman rule "a four-point vertex contributes $-i\lambda$." The path

integral has delivered it as nothing more than four functional derivatives acting on a Gaussian. What Chapter 14 adds is the physical interpretation through the S-matrix and LSZ; what Chapter 15 adds is the systematic bookkeeping — the Feynman rules and symmetry factors — that makes Eq. (10.193) routine at every order.

10.7.3 The cancellation of vacuum bubbles

The third term of Eq. (10.193), the source-free $D_F(0)^2$, deserves a closer look, because it is the first instance of a general phenomenon that the normalization $1/Z[0]$ in Theorem 10.18 was built to handle. Setting $J = 0$ in $Z[J]$ kills ϕ_J and leaves only this term, so to first order

$$Z[0] \;=\; Z_0[0]\Big[1 - \frac{i\lambda}{4!}\int d^4z\, 3\, D_F(0)^2 + O(\lambda^2)\Big] \;=\; Z_0[0]\Big[1 - \frac{i\lambda}{8}\int d^4z\, D_F(0)^2 + O(\lambda^2)\Big]. \tag{10.199}$$

The quantity $\frac{1}{8}\int d^4z\, D_F(0)^2$ is the value of the disconnected figure-eight diagram of Fig. 10.7(c), with its symmetry factor $\frac{1}{8}$ already correct; it is a pure number times the spacetime volume, carrying no external legs and hence no physical information. It is precisely the kind of vacuum-to-vacuum amplitude that the worked example of Theorem 10.20 warned must be divided out. We now see it cancel explicitly.

Proposition 10.35 (Vacuum bubbles cancel in normalized correlators)**.** *In the normalized generating functional $Z[J]/Z[0]$, every diagram with a disconnected vacuum component is removed. At first order in λ this is the statement that the source-free term $3\,D_F(0)^2$ of Eq. (10.193) does not appear in $Z[J]/Z[0]$.*

Proof. Assemble the numerator from Eq. (10.189) and Eq. (10.193), and the denominator from Eq. (10.199). Writing $\mathcal{V} \equiv \frac{1}{8}\int d^4z\, D_F(0)^2$ for the bubble and keeping terms through $O(\lambda)$,

$$\begin{aligned}\frac{Z[J]}{Z[0]} &= \frac{Z_0[0]\, e^{W_0}\Big[1 - \frac{i\lambda}{4!}\int d^4z(\phi_J^4 - 6\phi_J^2 D_F(0) + 3D_F(0)^2)\Big]}{Z_0[0]\,[\,1 - i\lambda\,\mathcal{V}\,]} \\ &= e^{W_0}\Big[1 - \tfrac{i\lambda}{4!}\int d^4z(\phi_J^4 - 6\phi_J^2 D_F(0)) - i\lambda\,\mathcal{V}\Big]\,[\,1 + i\lambda\,\mathcal{V} + O(\lambda^2)] \\ &= e^{W_0}\Big[1 - \tfrac{i\lambda}{4!}\int d^4z(\phi_J^4 - 6\phi_J^2 D_F(0))\Big] + O(\lambda^2),\end{aligned} \tag{10.200}$$

where in the second line we isolated the source-free piece of the numerator, $-\frac{i\lambda}{4!}\int 3D_F(0)^2 = -i\lambda\mathcal{V}$, and expanded the denominator; in the third line the $-i\lambda\mathcal{V}$ from the numerator cancels exactly against the $+i\lambda\mathcal{V}$ produced by the denominator multiplying the leading 1. The figure-eight is gone. What survives carries at least one source and hence connects to the external points. □

This is the diagrammatic content of the seemingly innocuous division by $Z[0]$ in the definition of the Green's functions. The general statement, proved in Chapter 15, is that $Z[0]$ exponentiates the sum of all connected vacuum diagrams, so that $Z[J]/Z[0]$ retains only those diagrams every part of which is tied, through some chain of propagators and vertices, to an external source. The infinite, volume-proportional vacuum energy that $Z[0]$ encodes is thereby quarantined and discarded before any correlator is computed — which is why no physical quantity ever depends on it, and why the divergent measure normalization $\mathcal{N}$ of Theorem 10.16, itself part of $Z[0]$, never appears in an answer.

10.7.4 Connected correlators: the functional $W[J]$

Cancelling the vacuum bubbles removed the *wholly* disconnected diagrams, but the surviving correlators still contain pieces that are disconnected among the external points: at four points, for instance, $G^{(4)}$ includes the product of two independent propagators, two pairs of particles that never meet. For scattering we want only the genuinely connected processes, in which all external legs communicate. The object that isolates them is the logarithm of the generating functional, exactly as the logarithm of a partition function isolates cumulants from moments. We define it with the factor of i appropriate to the Minkowski exponent.

Definition 10.36 (Connected generating functional)**.** The *connected generating functional* of the scalar field is

$$W[J] \;\equiv\; -\,i\,\ln Z[J], \tag{10.201}$$

the branch fixed by $W[0] = -i \ln Z[0]$. Its connected n-point Green's functions are the functional Taylor coefficients

$$G_c^{(n)}(x_1,\dots,x_n) \;\equiv\; \frac{1}{i^{\,n-1}}\;\frac{\delta^n W[J]}{\delta J(x_1)\cdots\delta J(x_n)}\bigg|_{J=0}. \tag{10.202}$$

The single derivative has a transparent meaning. Using $\delta Z/\delta J(x) = i\,\langle\phi(x)\rangle_J\, Z$, where $\langle\,\cdot\,\rangle_J \equiv Z^{-1}\int\!\mathcal{D}\phi\,(\cdot)\,e^{i(S+\int J\phi)}$ denotes the source-dependent field average,

$$\frac{\delta W}{\delta J(x)} \;=\; -\,i\,\frac{1}{Z}\frac{\delta Z}{\delta J(x)} \;=\; \langle\phi(x)\rangle_J \;\equiv\; \phi_{\rm cl}(x), \tag{10.203}$$

the expectation value of the field in the presence of the source — the *classical field*, the object we will Legendre-transform on in a moment. It is the field-theory instance of "the first derivative of the free energy is the magnetization," the dictionary of Section 10.6 made functional. That $W[J]$ generates *connected* correlators, with the disconnected products subtracted, is the linked-cluster theorem. Its full combinatorial proof is the work of Chapter 15; here we establish it explicitly at the two- and four-point level, which already exhibits the mechanism and supplies the relations the later chapters use.

Proposition 10.37 (W generates connected correlators at two and four points)**.** *With $G^{(1)} = \langle\phi\rangle_0 = 0$ for the frozen $\mathbb{Z}_2$-symmetric theory (Section 7.3.6), the connected correlators Eq. (10.202) satisfy*

$$G_c^{(2)}(x_1,x_2) = G^{(2)}(x_1,x_2), \tag{10.204}$$

$$\begin{aligned} G_c^{(4)}(x_1,x_2,x_3,x_4) = {} & G^{(4)}(x_1,x_2,x_3,x_4) \;-\; G^{(2)}(x_1,x_2)\,G^{(2)}(x_3,x_4) \\ & -\; G^{(2)}(x_1,x_3)\,G^{(2)}(x_2,x_4) -\; G^{(2)}(x_1,x_4)\,G^{(2)}(x_2,x_3). \end{aligned} \tag{10.205}$$

That is, W reproduces the full two-point function and the full four-point function with its three disconnected "$2+2$" channels subtracted off.

Proof. The engine is the elementary rule that differentiating a source-dependent average attaches one connected field:

$$\frac{\delta}{\delta J(y)}\,\langle A\rangle_J \;=\; \frac{\delta}{\delta J(y)}\,\frac{1}{Z}\int\mathcal{D}\phi\, A\, e^{i(S+\int J\phi)} \;=\; i\big[\,\langle A\,\phi(y)\rangle_J - \langle A\rangle_J\,\langle\phi(y)\rangle_J\,\big], \tag{10.206}$$

where the subtracted term comes from differentiating the $1/Z$ prefactor, $\delta(1/Z)/\delta J(y) = -i\langle\phi(y)\rangle_J/Z$. Apply this once to Eq. (10.203):

$$\frac{\delta^2 W}{\delta J(x_1)\delta J(x_2)} = \frac{\delta\,\langle\phi(x_1)\rangle_J}{\delta J(x_2)} = i\big[\langle\phi(x_1)\phi(x_2)\rangle_J - \langle\phi(x_1)\rangle_J\langle\phi(x_2)\rangle_J\big]. \tag{10.207}$$

At $J=0$ the second term vanishes ($\langle\phi\rangle_0 = 0$), so $\delta^2 W/\delta J^2|_0 = i\,G^{(2)}$, and Eq. (10.202) with $n=2$ gives $G_c^{(2)} = i^{-1}\cdot iG^{(2)} = G^{(2)}$, which is Eq. (10.204).

For the four-point relation, differentiate Eq. (10.207) twice more using Eq. (10.206) on each average, and evaluate at $J=0$, where every odd correlator vanishes by $\mathbb{Z}_2$. Writing the third derivative first,

$$\frac{\delta^3 W}{\delta J(x_1)\delta J(x_2)\delta J(x_3)} = i^2\Big[\langle\phi_1\phi_2\phi_3\rangle_J - \langle\phi_1\phi_2\rangle_J\langle\phi_3\rangle_J - \langle\phi_1\phi_3\rangle_J\langle\phi_2\rangle_J - \langle\phi_2\phi_3\rangle_J\langle\phi_1\rangle_J + 2\langle\phi_1\rangle_J\langle\phi_2\rangle_J$$

(10.208)

abbreviating $\phi_i \equiv \phi(x_i)$. Differentiating once more with respect to $J(x_4)$ via Eq. (10.206) and then setting $J=0$, every term containing a surviving single average $\langle\phi\rangle_0$ drops out, and only two kinds of contribution remain: from the leading triple average, $\langle\phi_1\phi_2\phi_3\rangle \to i[\langle\phi_1\phi_2\phi_3\phi_4\rangle - 0]$; and from each double average paired with the $\langle\phi\rangle$ that $\delta/\delta J(x_4)$ promotes to a double average, $-\langle\phi_i\phi_j\rangle\langle\phi_k\rangle \to -\langle\phi_i\phi_j\rangle\, i\langle\phi_k\phi_4\rangle$. Collecting,

$$\frac{\delta^4 W}{\delta J(x_1)\cdots\delta J(x_4)}\bigg|_{J=0} = i^3\Big[G^{(4)} - G^{(2)}_{12}G^{(2)}_{34} - G^{(2)}_{13}G^{(2)}_{24} - G^{(2)}_{14}G^{(2)}_{23}\Big], \tag{10.209}$$

with $G^{(2)}_{ij} \equiv G^{(2)}(x_i,x_j)$. Dividing by i^3 as in Eq. (10.202) yields Eq. (10.205). □

The subtraction in Eq. (10.205) is exactly the removal of the three disconnected channels: a ϕ^4 four-point function in which particles $1,2$ propagate to $3,4$ as two non-interacting pairs contributes $G^{(2)}_{13}G^{(2)}_{24}+\cdots$ to $G^{(4)}$, and W discards precisely these, retaining only the part where all four legs meet — at lowest order, the vertex diagram Eq. (10.196) of Theorem 10.34, which is connected and therefore survives untouched. The pattern continues to all orders: $G_c^{(n)}$ is the sum of connected diagrams alone, and the full correlator is recovered by summing over all ways of partitioning the external points into connected clusters. That linked-cluster expansion, and the proof that $\ln Z$ generates exactly the connected pieces at every n, is taken up in Chapter 15; what Theorem 10.36 contributes here is the precise object and the verified low-order relations on which that development rests.

10.7.5 The effective action and the road ahead

There is one more functional in the hierarchy, and it is the one the renormalization and symmetry-breaking chapters will lean on hardest. Having traded $Z[J]$ for its logarithm $W[J]$ to isolate connected diagrams, we now trade the source J for the classical field ϕ_{cl} it induces, by a Legendre transform. The construction is the field-theory instance of the Legendre duality between thermodynamic potentials developed abstractly in Section 4.5.1, with $W[J]$ playing the role of the free energy and ϕ_{cl} the conjugate "magnetization" Eq. (10.203).

Definition 10.38 (Effective action)**.** Let $\phi_{\mathrm{cl}}(x)=\delta W/\delta J(x)$ as in Eq. (10.203), and let $J=J_{\phi_{\mathrm{cl}}}$ denote the source that produces a given classical field, obtained by inverting this relation. The *effective action* is the Legendre transform of W,

$$\boxed{\Gamma[\phi_{\mathrm{cl}}] \;\equiv\; W[J] \;-\; \int d^4x\, J(x)\,\phi_{\mathrm{cl}}(x)\,\Big|_{J=J_{\phi_{\mathrm{cl}}}}} \,. \tag{10.210}$$

The transform is well-posed under the same convexity hypothesis that governed the abstract case (Theorem 4.31): the map $J\mapsto\phi_{\mathrm{cl}}$ is invertible precisely when $\delta^2W/\delta J^2$ — the full propagator, by Eq. (10.207) — is nondegenerate, which holds order by order in perturbation theory. The defining virtue of Γ is that it returns the source as its own gradient. Differentiating Eq. (10.210),

$$\frac{\delta\Gamma}{\delta\phi_{\mathrm{cl}}(x)} = \int d^4y\,\frac{\delta W}{\delta J(y)}\frac{\delta J(y)}{\delta\phi_{\mathrm{cl}}(x)} - J(x) - \int d^4y\,\frac{\delta J(y)}{\delta\phi_{\mathrm{cl}}(x)}\phi_{\mathrm{cl}}(y), \tag{10.211}$$

and since $\delta W/\delta J(y)=\phi_{\mathrm{cl}}(y)$ the first and third terms cancel identically, leaving the *quantum equation of motion*

$$\boxed{\frac{\delta\Gamma[\phi_{\mathrm{cl}}]}{\delta\phi_{\mathrm{cl}}(x)} \;=\; -\,J(x)\,.} \tag{10.212}$$

In the absence of an external source, the physical configuration of the theory is therefore a stationary point of Γ, $\delta\Gamma/\delta\phi_{\rm cl} = 0$ — the exact, quantum-corrected analogue of the classical principle of stationary action $\delta S/\delta\phi = 0$. At leading (tree) order one finds $\Gamma[\phi_{\rm cl}] = S[\phi_{\rm cl}]$, so Γ is the action dressed by all quantum fluctuations; the systematic loop expansion that computes the dressing is the subject of Chapter 22.

The second derivatives of W and Γ are functional inverses, and this is the precise sense in which Γ is the generator of one-particle-irreducible (1PI) vertices. Differentiate the relation $\delta W/\delta J(x) = \phi_{\rm cl}(x)$ with respect to $\phi_{\rm cl}(y)$ and use Eq. (10.212) in the form $\delta J(z)/\delta\phi_{\rm cl}(y) = -\delta^2\Gamma/\delta\phi_{\rm cl}(z)\delta\phi_{\rm cl}(y)$:

$$\delta^{(4)}(x-y) = \frac{\delta\phi_{\rm cl}(x)}{\delta\phi_{\rm cl}(y)} = \int d^4z\, \frac{\delta^2 W}{\delta J(x)\delta J(z)}\, \frac{\delta J(z)}{\delta\phi_{\rm cl}(y)} = -\int d^4z\, \frac{\delta^2 W}{\delta J(x)\delta J(z)}\, \frac{\delta^2\Gamma}{\delta\phi_{\rm cl}(z)\delta\phi_{\rm cl}(y)}. \tag{10.213}$$

Thus $W^{(2)}$ and $-\Gamma^{(2)}$ are reciprocal kernels. Since $W^{(2)}|_0 = i\,G_c^{(2)} = i\,D_F$ is (i times) the full propagator, $\Gamma^{(2)}$ is minus the inverse of $W^{(2)}$, that is $\Gamma^{(2)} = -(i\,D_F)^{-1} = i\,D_F^{-1}$; in momentum space, at tree level where $D_F(p) = i/(p^2 - m^2 + i\varepsilon)$, this gives

$$\widetilde{\Gamma}^{(2)}(p) \;=\; p^2 - m^2, \tag{10.214}$$

the Klein–Gordon operator itself — exactly $\delta^2 S/\delta\phi^2$ in momentum space, confirming $\Gamma = S$ at tree level. The interactions correct this: $\widetilde{\Gamma}^{(2)}(p) = p^2 - m^2 - \Sigma(p^2)$, with Σ the self-energy, the sum of 1PI two-point diagrams whose first contribution is the tadpole of Fig. 10.7(b). That every $\Gamma^{(n)}$ is the sum of amputated 1PI diagrams, and that this is what makes Γ the natural object on which to impose renormalization conditions and to read off spontaneous symmetry breaking from the shape of the effective potential, is the content of Chapter 22; we have established here only the defining transform Eq. (10.210), the equation of motion Eq. (10.212), and the propagator-inverse relation Eq. (10.214) that pin down what Γ is.

With this the path-integral apparatus is complete and self-contained: a measure (Theorem 10.16), a free generating functional in closed form (Eq. (10.111)), Wick's theorem (Theorem 10.23), the master perturbative formula Eq. (10.186), and the three nested generators $Z \to W \to \Gamma$ for full, connected, and 1PI correlators respectively. These objects are handed forward intact: the vertex $-i\lambda$ of Eq. (10.198) and the time-ordered correlators of Theorem 10.19 become physical amplitudes through the S-matrix and LSZ reduction of Chapter 14; the contraction structure of Eq. (10.193) becomes the Feynman rules and symmetry factors of Chapter 15; the effective action Γ becomes the carrier of renormalization and the RG in Chapters 22 and 23; and the entire construction is repeated, with the anticommuting Grassmann measure replacing $\mathcal{D}\phi$, for the fermionic fields of Chapter 12.

Further reading

The space-time, sum-over-histories formulation originates with Feynman [192] and is developed pedagogically in Feynman and Hibbs [193]; Kleinert [297] is an encyclopedic modern treatment of the quantum-mechanical path integral and its measure. The field-theory generating functional, $Z_0[J]$, Wick's theorem from functional derivatives, and the connected and effective functionals are presented in Peskin and Schroeder [396] ch. 9, Schwartz [432] chs. 14–16, Srednicki [454] chs. 6–9, and — with the quickest physical motivation — Zee [532] ch. I. Weinberg [500] ch. 9 gives the careful operator-to-path-integral correspondence. For the Euclidean formulation, the statistical-mechanics dictionary, and the renormalization group born from it, Zinn-Justin [534] is the standard reference. The rigorous status of the measure, reflection positivity, and the reconstruction of a Lorentzian theory from Euclidean data are the subject of constructive field theory: the axioms are those of Osterwalder and Schrader [372], and the program is developed in full in Glimm and Jaffe [225].

Chapter 11

The Dirac Field

With the scalar field quantized in Chapter 9, the book has one relativistic quantum field in hand — and exactly the wrong one for matter. The particles of nature that carry charge and build atoms are spin-$\frac{1}{2}$ fermions, and a spin-0 field cannot describe them. This chapter constructs the field that can. We begin from the representation theory of Chapter 3, where the Lorentz group was found to act on a four-component object, the Dirac spinor, sitting in the reducible $(\frac{1}{2},0)\oplus(0,\frac{1}{2})$ representation; and we take from Chapter 6 the classical Dirac Lagrangian $\bar{\psi}(i\partial\!\!\!/ - m)\psi$ as one of the recurring cast of classical field theories. The gamma-matrix algebra $\{\gamma^\mu,\gamma^\nu\} = 2\eta^{\mu\nu}$, the chiral basis, the trace and spinor identities, and the symmetry properties of the charge-conjugation matrix are the book-wide canon of Appendix C (Chapter C); we invoke them where they are used rather than re-listing them. Throughout we keep the mostly-minus metric $\eta_{\mu\nu} = \mathrm{diag}(+,-,-,-)$ and natural units of the book, so that $p^2 = m^2$ on shell. The thread carried here is QED: the electron, which entered as a classical $U(1)$ matter field in Chapter 8, is promoted in this chapter to a quantum field whose quanta are the electrons and positrons that the rest of the thread will scatter.

The chapter follows a single arc, from classical kinematics to a fully solved, demonstrably consistent quantum theory. The first section shows that Lorentz covariance *forces* the four-component spinor and that the demand for a first-order equation reproducing the mass shell *forces* the Dirac equation $(i\partial\!\!\!/ - m)\psi = 0$; it establishes form-invariance through the intertwining identity, derives the conserved vector current $j^\mu = \bar{\psi}\gamma^\mu\psi$ from the Lagrangian, and catalogues the sixteen bilinear covariants. The second section solves the equation: it constructs the positive- and negative-frequency plane-wave amplitudes $u^s(p), v^s(p)$, fixes their normalization and orthogonality, and proves the completeness (spin-sum) identities $\sum_s u^s\bar{u}^s = p\!\!\!/ + m$, $\sum_s v^s\bar{v}^s = p\!\!\!/ - m$ together with the energy, chirality, and helicity projectors — the raw material both for the canonical mode expansion and for every QED trace.

The quantization itself is the dramatic centre of the chapter. The third section

carries out canonical quantization and discovers that the naive commutator postulate fails catastrophically: it produces a Hamiltonian unbounded below and negative-norm states. The cure — imposing *anticommutators* — is forced by the demand for a stable vacuum, and it carries the fermionic ladder algebra in its wake. On that algebra the fourth section builds the antisymmetric Fock space: a unique vacuum, the Pauli exclusion principle as an operator identity, normal-ordered energy, momentum, and charge, and the identification of the excitations as spin-$\frac{1}{2}$ electrons and positrons carrying opposite charge. The fifth section constructs the central dynamical object, the Dirac–Feynman propagator S_F, exhibiting it simultaneously as the time-ordered two-point function, the Dirac operator applied to the scalar propagator of Chapter 9, the $i\epsilon$-contour momentum-space object, and the Green's function of $i\not{\partial} - m$ — the internal electron line of every diagram from Chapter 17 onward.

The final two sections close the consistency loop. The sixth proves microcausality of the Dirac field and the causality of its bilinear observables, and with it the spin–statistics connection for spin $\frac{1}{2}$: relativity together with positivity of the energy does not merely permit but *requires* the anticommutator quantization used throughout, completing the fermionic half of the theorem whose scalar half Chapter 9 established and whose general form (Theorem 9.33) is quoted without full proof. The seventh assembles the discrete symmetries C, P, T and the CPT combination, tabulates the transformation of every bilinear, and closes with the Majorana condition and the dated open question of the neutrino's nature. By the end the free electron is a complete relativistic quantum theory — bounded energy, causal observables, exclusion principle, and the propagator — and QED is ready for interactions.

11.1 Spinor Representations and the Dirac Equation

The quantization of the scalar field in Chapter 9 followed a fixed recipe: start from a classical field with a known Lagrangian, Hamiltonian, equation of motion, and conserved current; promote the field to an operator; expand it in the normal modes of its free equation of motion; and impose the algebra on the mode coefficients that the canonical structure demands. We are about to run that same recipe for the spin-$\frac{1}{2}$ field, and Chapter 9 is the template we will be modifying at every step — most dramatically when the canonical algebra turns out to be an *anti*commutator. But the recipe has a non-negotiable first ingredient: the classical field, with its equation, its Lagrangian, its adjoint, and its current all in hand. For the scalar that ingredient was almost free, because a single real function of spacetime is the most primitive field one can write. For spin $\frac{1}{2}$ it is not free at all. The very object the field is valued in — a four-component spinor — and the first-order equation it must satisfy are forced on us by Lorentz covariance, and unpacking that "forced on us" is the work of this section. We

assemble the classical Dirac field as the unique Lorentz-covariant first-order field equation living on the reducible four-component spinor representation, drawing the representation theory from Chapter 3 and the Clifford-algebra technology from Chapter C, and we record the adjoint, the conserved current, and the complete catalogue of bilinear covariants that the quantum theory of the following sections — and all of QED downstream — will lean on.

11.1.1 The Dirac representation, recalled

We begin by collecting, in the conventions fixed in Chapter A and used throughout this chapter, the representation-theoretic facts established in Section 3.4.4 and Chapter C. The reader who has those chapters fresh may skim to Eq. (11.9); we restate rather than re-derive, flagging each result by the label of its proof.

A spin-$\frac{1}{2}$ field that respects parity — and electromagnetism, the force that binds the electron of QED, does respect parity — cannot be a single Weyl spinor. Theorem 3.28 showed that parity exchanges the two irreducible spinor representations $(\frac{1}{2},0) \leftrightarrow (0,\frac{1}{2})$ of the Lorentz group, so the smallest parity-invariant carrier of spin $\frac{1}{2}$ is the *reducible* sum

$$(\tfrac{1}{2},0) \oplus (0,\tfrac{1}{2}), \tag{11.1}$$

realized on the four-component *Dirac spinor* $\psi = (\psi_L, \psi_R)^{\mathsf{T}} \in \mathbb{C}^4$ of Theorem 3.26. The arena natural to this representation is the Clifford algebra. There exist four 4×4 matrices γ^μ, $\mu = 0,1,2,3$, satisfying the *Clifford (Dirac) algebra*

$$\{\gamma^\mu, \gamma^\nu\} = 2\eta^{\mu\nu}\, \mathbf{1}_4, \tag{11.2}$$

with $\eta_{\mu\nu} = \mathrm{diag}(+,-,-,-)$; their existence and their uniqueness up to similarity are Theorems C.10 and C.16. We work in the *chiral (Weyl) basis* of Eq. (3.111),

$$\gamma^\mu = \begin{pmatrix} 0 & \sigma^\mu \\ \bar{\sigma}^\mu & 0 \end{pmatrix}, \qquad \sigma^\mu = (\mathbf{1}, \vec{\sigma}), \quad \bar{\sigma}^\mu = (\mathbf{1}, -\vec{\sigma}), \tag{11.3}$$

in which the chirality matrix $\gamma^5 \equiv i\gamma^0\gamma^1\gamma^2\gamma^3$ is diagonal,

$$\gamma^5 = \begin{pmatrix} -\mathbf{1} & 0 \\ 0 & +\mathbf{1} \end{pmatrix}, \qquad \left\{\gamma^5, \gamma^\mu\right\} = 0, \qquad (\gamma^5)^2 = \mathbf{1}_4, \tag{11.4}$$

the algebraic properties being Theorem C.26. The Dirac adjoint is $\bar{\psi} \equiv \psi^\dagger \gamma^0$, the insertion of γ^0 being dictated by the *Hermiticity relation* (Theorem C.30)

$$\gamma^{\mu\dagger} = \gamma^0 \gamma^\mu \gamma^0, \tag{11.5}$$

as we will see explicitly in Section 11.1.4.

The Lorentz group acts on ψ through the generators built from the gammas. With

$$S^{\mu\nu} \equiv \frac{i}{4}\,[\gamma^\mu, \gamma^\nu] = \frac{i}{2}(\gamma^\mu\gamma^\nu - \eta^{\mu\nu}), \tag{11.6}$$

(the second form following from $\gamma^\mu\gamma^\nu = \eta^{\mu\nu} + \frac{1}{2}\,[\gamma^\mu, \gamma^\nu]$ and Eq. (11.2)), one has the central structural fact, proved in full in Theorem 3.27 from the Clifford relation alone: the $S^{\mu\nu}$ satisfy the Lorentz Lie algebra of Section 3.2,

$$[S^{\mu\nu}, S^{\rho\sigma}] = i(\eta^{\nu\rho}S^{\mu\sigma} - \eta^{\mu\rho}S^{\nu\sigma} - \eta^{\nu\sigma}S^{\mu\rho} + \eta^{\mu\sigma}S^{\nu\rho}). \tag{11.7}$$

A finite Lorentz transformation $\Lambda = \exp\omega$, parametrized by an antisymmetric $\omega_{\mu\nu}$, is therefore represented on the spinor by

$$\psi(x) \;\longmapsto\; \psi'(x') = S(\Lambda)\,\psi(x), \qquad S(\Lambda) = \exp\!\Big(-\tfrac{i}{2}\,\omega_{\mu\nu}S^{\mu\nu}\Big), \qquad x' = \Lambda x. \tag{11.8}$$

The engine that drives every covariance statement below is the infinitesimal action of $S^{\mu\nu}$ on a single gamma matrix. From Eq. (11.6) one computes (this is Eq. (3.117); we reproduce the one-line core because it is used repeatedly)

$$[S^{\mu\nu}, \gamma^\rho] = i(\eta^{\nu\rho}\gamma^\mu - \eta^{\mu\rho}\gamma^\nu), \tag{11.9}$$

the statement that γ^ρ *transforms as a four-vector index* under the generators. Indeed, only the $\gamma^\mu\gamma^\nu$ piece of Eq. (11.6) contributes, and $[\gamma^\mu\gamma^\nu, \gamma^\rho] = 2\eta^{\nu\rho}\gamma^\mu - 2\eta^{\mu\rho}\gamma^\nu$ by two applications of Eq. (11.2), whence Eq. (11.9). Exponentiating Eq. (11.9) promotes the infinitesimal four-vector law to the finite *intertwining identity* proved in Theorem C.6,

$$S(\Lambda)^{-1}\,\gamma^\mu\,S(\Lambda) = \Lambda^\mu{}_\nu\,\gamma^\nu, \tag{11.10}$$

the single relation on which the Lorentz covariance of the Dirac equation rests. This is exactly the physical consequence that Chapter C derived the identity in order to feed; we now collect the dividend.

Notation Watch

Two antisymmetric tensors of gammas appear in this book and must not be confused. The *Lorentz generators* are $S^{\mu\nu} = \frac{i}{4}\,[\gamma^\mu, \gamma^\nu]$ of Eq. (11.6), satisfying the algebra Eq. (11.7); the *tensor bilinear* is

$$\sigma^{\mu\nu} \equiv \frac{i}{2}\,[\gamma^\mu, \gamma^\nu] = 2\,S^{\mu\nu}, \tag{11.11}$$

the object whose bilinear $\bar\psi\sigma^{\mu\nu}\psi$ enters the covariant catalogue of Section 11.1.5 and the magnetic-moment coupling of QED. The factor of two between them, $\sigma^{\mu\nu} = 2S^{\mu\nu}$, follows the convention of Eqs. (C.72) and (C.73); it is the standard particle-physics normalization (Peskin–

Schroeder). We use $S^{\mu\nu}$ exclusively for transformations and $\sigma^{\mu\nu}$ exclusively as a bilinear insertion.

11.1.2 The Dirac equation as the forced first-order equation

With the representation in hand we can answer the question that organizes the whole chapter: what is the equation of motion of a free spin-$\frac{1}{2}$ field? Two requirements pin it down uniquely, and seeing them do so is more instructive than postulating the answer.

The first requirement is physical and is shared with every free relativistic field: each component of ψ describes a particle of mass m, so each component must satisfy the mass-shell condition $p^2 = m^2$, i.e. the Klein–Gordon equation $(\Box + m^2)\psi = 0$. The scalar of Chapter 9 satisfied exactly this, and nothing about adding spin can relax the relativistic dispersion relation. The second requirement is the one that distinguishes the fermion. We demand a *first-order* equation — linear in ∂_μ — rather than the second-order Klein–Gordon equation directly. The motivation is the same one that drove the representation theory: a first-order equation needs an initial condition only on ψ itself, not on ψ and $\dot{\psi}$ independently, which is the field-theoretic shadow of the fact that the spinor already carries, in its multiple components, the data a second-order scalar equation would have to supply through a time derivative. (Historically this was Dirac's own demand, made in the hope of a positive-definite probability density; the demand survives even though that original interpretation does not.) The most general Lorentz-covariant first-order linear equation with constant coefficients is

$$(i\beta^\mu \partial_\mu - m)\psi = 0, \tag{11.12}$$

with β^μ four constant 4×4 matrices to be determined and the mass m a scalar. We now show that the Klein–Gordon requirement *forces* β^μ to be a set of gamma matrices.

Theorem 11.1 (The Dirac equation is forced)**.** *A constant-coefficient first-order equation Eq. (11.12) implies the Klein–Gordon equation $(\Box + m^2)\psi = 0$ for every component of ψ if and only if the matrices β^μ obey the Clifford algebra $\{\beta^\mu, \beta^\nu\} = 2\eta^{\mu\nu}\mathbf{1}$. By the uniqueness theorem Theorem C.16, β^μ is then similar to the gamma matrices γ^μ, and Eq. (11.12) becomes the* Dirac equation

$$\boxed{(i\not{\partial} - m)\psi = 0}, \qquad \not{\partial} \equiv \gamma^\mu \partial_\mu. \tag{11.13}$$

Proof. Apply the conjugate first-order operator $(i\beta^\nu \partial_\nu + m)$ to Eq. (11.12):

$$(i\beta^\nu \partial_\nu + m)(i\beta^\mu \partial_\mu - m)\psi = (-\beta^\nu \beta^\mu \partial_\nu \partial_\mu - m^2)\psi = 0. \tag{11.14}$$

The cross terms $\pm im\,\beta^\mu\partial_\mu$ cancel because m is a scalar that commutes with the constant β^μ. The double derivative $\partial_\nu\partial_\mu$ is symmetric in (μ,ν), so only the symmetric part of $\beta^\nu\beta^\mu$ survives the contraction:

$$\beta^\nu\beta^\mu\partial_\nu\partial_\mu = \tfrac{1}{2}\{\beta^\mu,\beta^\nu\}\,\partial_\mu\partial_\nu. \tag{11.15}$$

Therefore Eq. (11.14) reads $(\frac{1}{2}\{\beta^\mu,\beta^\nu\}\,\partial_\mu\partial_\nu + m^2)\psi = 0$. This coincides with the Klein–Gordon equation $(\eta^{\mu\nu}\partial_\mu\partial_\nu + m^2)\psi = (\Box + m^2)\psi = 0$ for arbitrary ψ precisely when

$$\tfrac{1}{2}\{\beta^\mu,\beta^\nu\} = \eta^{\mu\nu}\mathbf{1} \quad\Longleftrightarrow\quad \{\beta^\mu,\beta^\nu\} = 2\eta^{\mu\nu}\mathbf{1}, \tag{11.16}$$

which is the Clifford algebra Eq. (11.2). (That the condition is necessary as well as sufficient follows by reading the calculation backward: if some $\{\beta^\mu,\beta^\nu\} \neq 2\eta^{\mu\nu}\mathbf{1}$, then the symmetric tensor $\frac{1}{2}\{\beta^\mu,\beta^\nu\} - \eta^{\mu\nu}\mathbf{1}$ is nonzero, and contracting it with a plane wave $\psi \propto e^{-ip\cdot x}$ of generic p gives a nonzero residual, so Klein–Gordon fails for that mode.) By Theorem C.16 any two solutions of the Clifford algebra in four dimensions are related by a similarity transformation $\beta^\mu = A\gamma^\mu A^{-1}$; redefining $\psi \to A^{-1}\psi$ absorbs A and brings Eq. (11.12) to the canonical form Eq. (11.13). □

Physical Insight

The Dirac equation is not a clever guess that happened to work; it is the unique first-order avatar of the relativistic dispersion relation. The operator $i\partial\!\!\!/ - m$ is a "square root" of the Klein–Gordon operator $-(\Box + m^2)$ in the precise sense of Eq. (11.14): $(i\partial\!\!\!/ + m)(i\partial\!\!\!/ - m) = -(\Box + m^2)$. Taking a matrix square root of a scalar differential operator is possible only at the cost of letting the matrices fail to commute — and the failure-to-commute they are forced into is exactly the Clifford algebra, whose smallest faithful representation in four dimensions is four-dimensional. The four components of the Dirac spinor are the unavoidable price of the square root; spin $\frac{1}{2}$ and antiparticles (two components each for particle and antiparticle, as the next section's plane waves will show) are what is hiding inside that price.

The proof of Theorem 11.1 already contains the converse statement promised in the chapter's opening, that each component of a Dirac field independently solves the Klein–Gordon equation. It is worth isolating, because the algebraic identity behind it — the factorization of the Klein–Gordon operator — recurs constantly (it is, for instance, how the Dirac propagator will be obtained from the scalar one in Section 11.2 and beyond).

Worked Example 11.2 (Squaring the Dirac operator)**.** Let ψ solve the Dirac equation Eq. (11.13). We show $(\Box + m^2)\psi = 0$ directly. Multiply Eq. (11.13) on

the left by the conjugate operator $(i\partial\!\!\!/ + m)$:

$$(i\partial\!\!\!/ + m)(i\partial\!\!\!/ - m)\psi = (-\partial\!\!\!/\,\partial\!\!\!/ - m^2)\psi = 0. \tag{11.17}$$

The slashed-derivative square is evaluated with the Clifford algebra:

$$\partial\!\!\!/\,\partial\!\!\!/ = \gamma^\mu\gamma^\nu\partial_\mu\partial_\nu = \tfrac{1}{2}\{\gamma^\mu,\gamma^\nu\}\,\partial_\mu\partial_\nu = \eta^{\mu\nu}\partial_\mu\partial_\nu = \Box, \tag{11.18}$$

where in the second equality we used that $\partial_\mu\partial_\nu$ is symmetric to replace $\gamma^\mu\gamma^\nu$ by its symmetric part $\frac{1}{2}\{\gamma^\mu,\gamma^\nu\}$, and in the third we used Eq. (11.2). Substituting into Eq. (11.17) gives $-(\Box + m^2)\psi = 0$, i.e. $(\Box + m^2)\psi = 0$: every component of the Dirac field is a Klein–Gordon field of mass m, as required for a relativistic particle of that mass. The identity Eq. (11.18), $a\!\!\!/\,a\!\!\!/ = a^2$ for any commuting four-vector a_μ, is the workhorse contraction; we record its general form $a\!\!\!/\,b\!\!\!/ = a\cdot b + \sigma_{ab}$ with $\sigma_{ab} = -\frac{i}{2}\sigma^{\mu\nu}(a_\mu b_\nu - a_\nu b_\mu)$ for later trace work, where $\sigma^{\mu\nu}$ is Eq. (11.11).

In momentum space, writing $\psi(x) = u(p)\,e^{-ip\cdot x}$ for a positive-frequency mode, Eq. (11.13) becomes the purely algebraic condition

$$(p\!\!\!/ - m)\,u(p) = 0, \qquad p\!\!\!/ \equiv \gamma^\mu p_\mu, \tag{11.19}$$

and Theorem 11.2 guarantees that this has nontrivial solutions only on the mass shell $p^2 = m^2$, since acting with $(p\!\!\!/ + m)$ gives $(p^2 - m^2)u = 0$. Solving Eq. (11.19) explicitly, normalizing its solutions, and assembling them into a complete basis is the business of Section 11.2; here we have established only that the equation is the right one and that its solutions live on the mass shell.

11.1.3 Lorentz covariance: form-invariance of the Dirac equation

An equation built to be "the unique Lorentz-covariant first-order equation" must actually be Lorentz covariant, and we have not yet checked it. Covariance means *form-invariance*: an observer in a boosted or rotated frame, applying the same equation Eq. (11.13) to the transformed field, must get a true statement whenever the original observer did. The intertwining identity Eq. (11.10) is exactly the tool that makes this work, and the proof is short and clean.

Theorem 11.3 (Form-invariance of the Dirac equation)**.** *Let $\psi(x)$ satisfy $(i\partial\!\!\!/ - m)\psi = 0$, and define the transformed field under the Lorentz transformation $x' = \Lambda x$ by $\psi'(x') = S(\Lambda)\psi(x)$ as in Eq. (11.8). Then ψ' satisfies the Dirac equation in the primed coordinates,*

$$(i\gamma^\mu\partial'_\mu - m)\psi'(x') = 0, \qquad \partial'_\mu \equiv \frac{\partial}{\partial x'^\mu}. \tag{11.20}$$

The gamma matrices are the same *numerical matrices in both frames; covariance is carried entirely by the spinor rotation $S(\Lambda)$ and the index rotation Λ.*

Proof. The coordinate derivative transforms as $\partial'_\mu = (\Lambda^{-1})^\nu{}_\mu\,\partial_\nu$, by the chain rule applied to $x^\nu = (\Lambda^{-1})^\nu{}_\mu x'^\mu$. Substitute this and $\psi'(x') = S(\Lambda)\psi(x)$ into the kinetic term:

$$\begin{aligned} i\gamma^\mu \partial'_\mu\, \psi'(x') &= i\,\gamma^\mu (\Lambda^{-1})^\nu{}_\mu\, \partial_\nu \big(S(\Lambda)\psi(x)\big) \\ &= i\, S(\Lambda)\, \big[S(\Lambda)^{-1}\gamma^\mu S(\Lambda)\big](\Lambda^{-1})^\nu{}_\mu\, \partial_\nu \psi(x), \end{aligned} \tag{11.21}$$

where in the second line we inserted $S(\Lambda)S(\Lambda)^{-1} = \mathbf{1}$ to the left of γ^μ and pulled the constant matrix $S(\Lambda)$ out front (it does not act on the coordinate x). Now apply the intertwining identity Eq. (11.10), $S(\Lambda)^{-1}\gamma^\mu S(\Lambda) = \Lambda^\mu{}_\rho \gamma^\rho$:

$$i\gamma^\mu \partial'_\mu\, \psi'(x') = i\, S(\Lambda)\, \Lambda^\mu{}_\rho\, (\Lambda^{-1})^\nu{}_\mu\, \gamma^\rho\, \partial_\nu \psi(x). \tag{11.22}$$

The two Lorentz matrices contract to the identity, $\Lambda^\mu{}_\rho (\Lambda^{-1})^\nu{}_\mu = (\Lambda^{-1})^\nu{}_\mu \Lambda^\mu{}_\rho = \delta^\nu{}_\rho$, leaving

$$i\gamma^\mu \partial'_\mu\, \psi'(x') = i\, S(\Lambda)\, \gamma^\rho \partial_\rho \psi(x) = S(\Lambda)\, i\partial\!\!\!/\, \psi(x). \tag{11.23}$$

The mass term transforms trivially, $m\psi'(x') = S(\Lambda)\, m\psi(x)$, since m is a scalar. Subtracting,

$$(i\gamma^\mu \partial'_\mu - m)\psi'(x') = S(\Lambda)\, (i\partial\!\!\!/ - m)\psi(x) = 0, \tag{11.24}$$

the last equality because ψ solves the Dirac equation and $S(\Lambda)$ is invertible. The transformed field solves the transformed equation, which is form-invariance. □

The proof exhibits exactly why the representation theory of Chapter 3 had to come first. Form-invariance is not an algebraic accident; it is the statement that the spinor index of ψ and the vector index of γ^μ rotate in a coordinated way, the coordination being the intertwining identity. A first-order equation written with matrices that did *not* obey Eq. (11.10) would single out a preferred frame and violate relativity. The Dirac equation is the unique first-order equation whose matrices do.

11.1.4 Lagrangian, adjoint, canonical momentum, and the conserved current

The classical action principle for the Dirac field was constructed in Chapter 6; we import it and use it, rather than rebuild it. The *Dirac Lagrangian* (Eq. (6.68)) is

$$\mathcal{L} = \bar\psi (i\partial\!\!\!/ - m)\psi, \tag{11.25}$$

whose Euler–Lagrange equations, obtained in Theorem 6.11 by varying $\bar\psi$ and ψ as independent fields, are the Dirac equation Eq. (11.13) and its Dirac-adjoint partner (Eq. (6.74))

$$i\,\partial_\mu \bar\psi\, \gamma^\mu + m\,\bar\psi = 0 \quad\Longleftrightarrow\quad \bar\psi (i\overleftarrow{\partial\!\!\!/} + m) = 0, \tag{11.26}$$

the arrow indicating that the derivative acts to the left. The Lagrangian is first order in derivatives, so its Legendre transform is degenerate: the momentum conjugate to ψ is (Eq. (6.78))

$$\pi_\psi = \frac{\partial \mathcal{L}}{\partial \dot{\psi}} = i\,\psi^\dagger, \tag{11.27}$$

not an independent velocity but the field $\psi^\dagger$ itself. This is the classical constraint that Chapter 6 flagged as the origin of the anticommutator structure; the canonical quantization of Section 11.3 will turn $\pi_\psi = i\psi^\dagger$ into the equal-time relation $\left\{\psi_a(\mathbf{x}), \psi_b^\dagger(\mathbf{y})\right\} = \delta_{ab}\delta^{(3)}(\mathbf{x}-\mathbf{y})$. For the present classical section we need only the Lagrangian, its symmetries, and their currents.

That the action $S = \int d^4x\,\mathcal{L}$ is Lorentz invariant, and that $\mathcal{L}$ itself is a Lorentz scalar, hinges on a single fact: under Eq. (11.8) the Dirac adjoint transforms not with $S(\Lambda)$ but with its inverse. We prove this now, because everything about the covariance of bilinears follows from it.

Theorem 11.4 (Transformation of the adjoint)**.** *Under $\psi \to S(\Lambda)\psi$, the Dirac adjoint transforms as*

$$\bar{\psi} \;\longmapsto\; \bar{\psi}\, S(\Lambda)^{-1}, \tag{11.28}$$

which is the statement

$$\gamma^0\, S(\Lambda)^\dagger\, \gamma^0 = S(\Lambda)^{-1}. \tag{11.29}$$

Proof. We first establish the infinitesimal version, that $\gamma^0 S^{\mu\nu\dagger}\gamma^0 = S^{\mu\nu}$. Conjugate the generator Eq. (11.6). Since $[\gamma^\mu,\gamma^\nu]^\dagger = \gamma^{\nu\dagger}\gamma^{\mu\dagger} - \gamma^{\mu\dagger}\gamma^{\nu\dagger} = -\left[\gamma^{\mu\dagger},\gamma^{\nu\dagger}\right]$,

$$S^{\mu\nu\dagger} = \left(\tfrac{i}{4}\left[\gamma^\mu,\gamma^\nu\right]\right)^\dagger = -\tfrac{i}{4}\left[\gamma^\mu,\gamma^\nu\right]^\dagger = \tfrac{i}{4}\left[\gamma^{\mu\dagger},\gamma^{\nu\dagger}\right]. \tag{11.30}$$

Insert the Hermiticity relation Eq. (11.5), $\gamma^{\mu\dagger} = \gamma^0\gamma^\mu\gamma^0$, and use $(\gamma^0)^2 = \mathbf{1}$ to cancel the inner pair of γ^0's:

$$\left[\gamma^{\mu\dagger},\gamma^{\nu\dagger}\right] = \left[\gamma^0\gamma^\mu\gamma^0,\gamma^0\gamma^\nu\gamma^0\right] = \gamma^0\gamma^\mu\gamma^\nu\gamma^0 - \gamma^0\gamma^\nu\gamma^\mu\gamma^0 = \gamma^0\left[\gamma^\mu,\gamma^\nu\right]\gamma^0, \tag{11.31}$$

so that $S^{\mu\nu\dagger} = \frac{i}{4}\gamma^0\left[\gamma^\mu,\gamma^\nu\right]\gamma^0 = \gamma^0 S^{\mu\nu}\gamma^0$. Multiplying on both sides by γ^0 and using $(\gamma^0)^2 = \mathbf{1}$ gives the infinitesimal statement

$$\gamma^0\, S^{\mu\nu\dagger}\,\gamma^0 = S^{\mu\nu}. \tag{11.32}$$

Now exponentiate. From Eq. (11.8), $S(\Lambda)^\dagger = \exp\!\left(+\frac{i}{2}\omega_{\mu\nu}S^{\mu\nu\dagger}\right)$ (the $-i$ becomes $+i$ and each $S^{\mu\nu} \to S^{\mu\nu\dagger}$, the real parameters $\omega_{\mu\nu}$ unchanged). Conjugating by γ^0 commutes with the exponential because $\gamma^0(\cdots)^n\gamma^0 = (\gamma^0(\cdots)\gamma^0)^n$, so

$$\gamma^0\, S(\Lambda)^\dagger\,\gamma^0 = \exp\!\Big(+\tfrac{i}{2}\omega_{\mu\nu}\,\gamma^0 S^{\mu\nu\dagger}\gamma^0\Big) = \exp\!\Big(+\tfrac{i}{2}\omega_{\mu\nu}\,S^{\mu\nu}\Big) = S(\Lambda)^{-1}, \tag{11.33}$$

using Eq. (11.32) in the middle step and recognizing the result as the inverse of Eq. (11.8). This is Eq. (11.29). Finally, $\bar{\psi} = \psi^\dagger\gamma^0 \to (S\psi)^\dagger\gamma^0 = \psi^\dagger S^\dagger\gamma^0 = \psi^\dagger\gamma^0\,(\gamma^0 S^\dagger\gamma^0) = \bar{\psi}\,S(\Lambda)^{-1}$, which is Eq. (11.28). □

The payoff is immediate. The scalar bilinear is genuinely a scalar:

$$\bar{\psi}\psi \;\longmapsto\; \bar{\psi}\, S(\Lambda)^{-1} S(\Lambda)\, \psi = \bar{\psi}\psi, \tag{11.34}$$

which confirms that the mass term $-m\bar{\psi}\psi$ in Eq. (11.25) is Lorentz invariant; and the kinetic term is invariant by the same cancellation combined with the intertwining Eq. (11.10), since $\bar{\psi}\gamma^\mu\partial_\mu\psi \to \bar{\psi}S^{-1}\gamma^\mu S\,\Lambda_\mu{}^\nu\partial_\nu\psi = \bar{\psi}\,\Lambda^\mu{}_\rho\Lambda_\mu{}^\nu\gamma^\rho\partial_\nu\psi = \bar{\psi}\partial\!\!\!/\psi$. The Dirac Lagrangian is a Lorentz scalar, as a Lagrangian must be.

The vector bilinear transforms as a four-vector,

$$\bar{\psi}\gamma^\mu\psi \;\longmapsto\; \bar{\psi}\, S(\Lambda)^{-1}\gamma^\mu S(\Lambda)\, \psi = \Lambda^\mu{}_\nu\, \bar{\psi}\gamma^\nu\psi, \tag{11.35}$$

again by Eq. (11.10). This is exactly the object the chapter's quantum theory will need as a conserved current. The Dirac Lagrangian Eq. (11.25) is invariant under the global U(1) phase rotation

$$\psi \to e^{-i\alpha}\psi, \qquad \bar{\psi} \to e^{+i\alpha}\bar{\psi}, \qquad \alpha \text{ constant}, \tag{11.36}$$

since the phases cancel in every term ($\bar{\psi}\psi$ and $\bar{\psi}\partial\!\!\!/\psi$ each pair one ψ with one $\bar{\psi}$). By Noether's first theorem (Theorem 7.10), applied exactly as for the complex scalar of Section 7.3.2 but now with the field-space generator acting as multiplication by $\mp i$ on $(\psi, \bar{\psi})$, the associated conserved current is read off from Eq. (7.32) as

$$\boxed{j^\mu = \bar{\psi}\gamma^\mu\psi}, \qquad \partial_\mu j^\mu = 0 \;\text{ on shell.} \tag{11.37}$$

We verify the conservation directly, since the check is short and exhibits the interplay of the two equations of motion.

Theorem 11.5 (Conservation of the vector current)**.** *On any solution of the Dirac equation, $\partial_\mu j^\mu = 0$ with $j^\mu = \bar{\psi}\gamma^\mu\psi$.*

Proof. Differentiate and apply the Leibniz rule:

$$\partial_\mu j^\mu = (\partial_\mu\bar{\psi})\gamma^\mu\psi + \bar{\psi}\gamma^\mu(\partial_\mu\psi). \tag{11.38}$$

The Dirac equation Eq. (11.13) gives $i\gamma^\mu\partial_\mu\psi = m\psi$, hence $\bar{\psi}\gamma^\mu\partial_\mu\psi = -im\,\bar{\psi}\psi$. The adjoint equation Eq. (11.26) gives $i(\partial_\mu\bar{\psi})\gamma^\mu = -m\bar{\psi}$, hence $(\partial_\mu\bar{\psi})\gamma^\mu\psi = +im\,\bar{\psi}\psi$. Adding,

$$\partial_\mu j^\mu = +im\,\bar{\psi}\psi - im\,\bar{\psi}\psi = 0. \tag{11.39}$$

The two equal-and-opposite mass terms cancel, exactly the mechanism by which the complex-scalar current was conserved in Section 7.3.2. □

Physical Insight — QED: identifying the electron field

The conserved charge $Q = \int d^3x\, j^0 = \int d^3x\, \bar\psi\gamma^0\psi = \int d^3x\, \psi^\dagger\psi$ is the U(1) charge whose phase symmetry Eq. (11.36) is the global precursor of the gauge symmetry of electromagnetism. This is the point at which QED acquires its matter content: the field ψ built in this section *is* the electron field, continuing the classical U(1) logic of Chapter 8, and the current Eq. (11.37) is the electromagnetic current that the photon of Chapter 13 will couple to. The coupling is installed by the minimal substitution $\partial_\mu \to D_\mu = \partial_\mu + ieA_\mu$ acting on ψ (electron charge $-e$, with $e > 0$), the convention the interaction chapters will use; consistent with $D_\mu = \partial_\mu - iqA_\mu$ at charge $q = -e$. We flag the sign here and switch on no gauge coupling yet: this chapter quantizes the *free* electron field, and the photon and the vertex are the business of Chapter 13 and Part V.

11.1.5 The sixteen bilinear covariants

The scalar $\bar\psi\psi$ and vector $\bar\psi\gamma^\mu\psi$ are two members of a complete family of fermion bilinears, one for each element of a basis of the 4×4 matrices. There are sixteen linearly independent 4×4 matrices, and Theorem C.2 organizes them into five Lorentz-covariant sets,

$$\Gamma \in \{\, \mathbf{1},\ \gamma^\mu,\ \sigma^{\mu\nu},\ \gamma^\mu\gamma^5,\ \gamma^5 \,\}, \qquad 1+4+6+4+1 = 16, \tag{11.40}$$

where $\sigma^{\mu\nu} = \frac{i}{2}[\gamma^\mu, \gamma^\nu]$ from Eq. (11.11) contributes its six independent antisymmetric components. The corresponding bilinears $\bar\psi\,\Gamma\,\psi$ are the *bilinear covariants*; the entire local content of a Dirac field — mass terms, currents, dipole couplings, the weak interaction's $V-A$ structure — is assembled from them, which is why the QED chapters (Chapters 17 and 19) and the electroweak chapters will draw on the classification below as a standing reference.

The transformation of each bilinear under a proper orthochronous Lorentz transformation follows from Theorem 11.4 and the intertwining identity, exactly as for the scalar and vector above. The new ingredient needed to complete the table is the behavior of γ^5 under both proper transformations and parity, which sorts the five sets into scalar/pseudoscalar and vector/axial pairs.

Theorem 11.6 (Lorentz classification of the bilinears)**.** *Under a proper orthochronous Lorentz transformation $\Lambda \in \mathrm{SO}^+(1,3)$ acting by $\psi \to S(\Lambda)\psi$, and under parity P acting by $\psi(t,\mathbf{x}) \to \gamma^0\psi(t,-\mathbf{x})$, the bilinears transform as catalogued in Table 11.1: $\bar\psi\psi$ is a scalar, $\bar\psi\gamma^5\psi$ a pseudoscalar, $\bar\psi\gamma^\mu\psi$ a vector, $\bar\psi\gamma^\mu\gamma^5\psi$ an axial vector, and $\bar\psi\sigma^{\mu\nu}\psi$ an antisymmetric rank-two tensor.*

Proof. Proper transformations. The key auxiliary fact is that γ^5 commutes with

every generator,

$$\left[\gamma^5, S^{\mu\nu}\right] = 0, \tag{11.41}$$

because γ^5 anticommutes with each γ^μ (Eq. (11.4)), so it commutes with the product of any two of them, hence with $S^{\mu\nu} = \frac{i}{4}[\gamma^\mu, \gamma^\nu]$. Therefore γ^5 commutes with $S(\Lambda) = \exp(-\frac{i}{2}\omega_{\mu\nu}S^{\mu\nu})$, giving $S(\Lambda)^{-1}\gamma^5 S(\Lambda) = \gamma^5$. With Eq. (11.28) the five proper transformations follow by sandwiching $S^{-1}\Gamma S$:

$$\begin{aligned}
\bar\psi\psi &\to \bar\psi S^{-1}S\psi = \bar\psi\psi,\\
\bar\psi\gamma^5\psi &\to \bar\psi S^{-1}\gamma^5 S\psi = \bar\psi\gamma^5\psi,\\
\bar\psi\gamma^\mu\psi &\to \bar\psi S^{-1}\gamma^\mu S\psi = \Lambda^\mu{}_\nu\,\bar\psi\gamma^\nu\psi,\\
\bar\psi\gamma^\mu\gamma^5\psi &\to \bar\psi S^{-1}\gamma^\mu\gamma^5 S\psi = \Lambda^\mu{}_\nu\,\bar\psi\gamma^\nu\gamma^5\psi,\\
\bar\psi\sigma^{\mu\nu}\psi &\to \bar\psi S^{-1}\sigma^{\mu\nu}S\psi = \Lambda^\mu{}_\rho\Lambda^\nu{}_\sigma\,\bar\psi\sigma^{\rho\sigma}\psi,
\end{aligned} \tag{11.42}$$

where the vector and axial cases use $S^{-1}\gamma^\mu S = \Lambda^\mu{}_\nu\gamma^\nu$ from Eq. (11.10) (with γ^5 slipped through unchanged by Eq. (11.41)), and the tensor case uses it twice, $S^{-1}\sigma^{\mu\nu}S = \frac{i}{2}S^{-1}[\gamma^\mu,\gamma^\nu]S = \frac{i}{2}[\Lambda^\mu{}_\rho\gamma^\rho, \Lambda^\nu{}_\sigma\gamma^\sigma] = \Lambda^\mu{}_\rho\Lambda^\nu{}_\sigma\sigma^{\rho\sigma}$. Under proper transformations $\bar\psi\psi$ and $\bar\psi\gamma^5\psi$ are indistinguishable — both invariant — and likewise $\bar\psi\gamma^\mu\psi$ and $\bar\psi\gamma^\mu\gamma^5\psi$ both transform as vectors. Parity breaks the degeneracy.

Parity. Under P the field becomes $\psi(t,\mathbf{x}) \to \psi_P(t,\mathbf{x}) = \gamma^0\psi(t,-\mathbf{x})$, and the adjoint $\bar\psi = \psi^\dagger\gamma^0 \to (\gamma^0\psi)^\dagger\gamma^0 = \psi^\dagger\gamma^0\gamma^0 = \psi^\dagger$, i.e. $\bar\psi_P = \bar\psi\gamma^0$ (all fields evaluated at the parity-reflected point, suppressed below). The two relations we need are $\gamma^0\gamma^0\gamma^0 = \gamma^0$ and, for spatial i, $\gamma^0\gamma^i\gamma^0 = -\gamma^i$, both consequences of the Clifford algebra; together they read $\gamma^0\gamma^\mu\gamma^0 = \gamma^\mu{}_P$, where $\gamma^\mu{}_P \equiv (\gamma^0, -\gamma^i)$ has its spatial part reversed. Also $\gamma^0\gamma^5\gamma^0 = -\gamma^5$, since γ^5 anticommutes with γ^0. Then

$$\begin{aligned}
\bar\psi\psi &\to \bar\psi\gamma^0\gamma^0\psi = +\bar\psi\psi && \text{(scalar: parity-even)},\\
\bar\psi\gamma^5\psi &\to \bar\psi\gamma^0\gamma^5\gamma^0\psi = -\bar\psi\gamma^5\psi && \text{(pseudoscalar: parity-odd)},\\
\bar\psi\gamma^\mu\psi &\to \bar\psi\gamma^0\gamma^\mu\gamma^0\psi = \bar\psi\gamma^\mu{}_P\psi && \text{(vector: spatial part flips)},\\
\bar\psi\gamma^\mu\gamma^5\psi &\to \bar\psi\gamma^0\gamma^\mu\gamma^5\gamma^0\psi = -\bar\psi\gamma^\mu{}_P\gamma^5\psi && \text{(axial: spatial part } \textit{does not} \text{ flip)},
\end{aligned} \tag{11.43}$$

the extra sign in the axial case coming from $\gamma^0\gamma^5\gamma^0 = -\gamma^5$, which combines with the spatial flip of γ^μ to leave the spatial components unchanged and reverse the time component — the defining signature of an axial (pseudo-)vector. Thus parity is exactly the operation that distinguishes the scalar from the pseudoscalar and the polar vector from the axial vector. This completes the classification. □

Table 11.1 records the result. The "Parity" column for the vector lists the signs $(+,-,-,-)$ acquired by the components ($\mu = 0,1,2,3$): the timelike component (charge density $\bar\psi\gamma^0\psi = \psi^\dagger\psi$) is parity-even and the spacelike components (the current $\bar\psi\gamma^i\psi$) are parity-odd, exactly as a polar vector like the electric

Table 11.1: The sixteen bilinear covariants $\bar{\psi}\,\Gamma\,\psi$ of a Dirac field, classified by their behavior under proper orthochronous Lorentz transformations $\Lambda \in \mathrm{SO}^+(1,3)$ and under parity P. The number of independent components sums to $16 = \dim(4\times 4 \text{ matrices})$, the basis being complete by Theorem C.2. This table is the standing reference drawn on by the QED chapters (Chapters 17 and 19) and the weak-interaction chapters.

Γ	Bilinear	Lorentz type	# comp.	Parity P
$\mathbf{1}$	$\bar{\psi}\psi$	scalar (S)	1	$+$
γ^5	$\bar{\psi}\gamma^5\psi$	pseudoscalar (P)	1	$-$
γ^μ	$\bar{\psi}\gamma^\mu\psi$	vector (V)	4	$(+,-,-,-)$
$\gamma^\mu\gamma^5$	$\bar{\psi}\gamma^\mu\gamma^5\psi$	axial vector (A)	4	$(-,+,+,+)$
$\sigma^{\mu\nu}$	$\bar{\psi}\sigma^{\mu\nu}\psi$	antisymmetric tensor (T)	6	(as $F_{\mu\nu}$)

current should behave. The axial vector carries the opposite pattern $(-,+,+,+)$, the hallmark of a quantity like spin or magnetic field that does not reverse under spatial reflection. The pseudoscalar's single sign flip is what makes $\bar{\psi}\gamma^5\psi$ the natural coupling for a parity-odd scalar particle (the pion, in the strong interactions developed much later). The worked computation below carries the pseudoscalar and axial cases explicitly, since the sign that distinguishes them from their parity-even partners is the single most error-prone step in the whole catalogue.

Worked Example 11.7 (The pseudoscalar and axial vector under parity)**.** We trace the parity signs of $\bar{\psi}\gamma^5\psi$ and $\bar{\psi}\gamma^\mu\gamma^5\psi$ in full, using only $\gamma^0\gamma^0 = \mathbf{1}$, $\{\gamma^5,\gamma^\mu\} = 0$, and the parity action $\psi \to \gamma^0\psi$, $\bar{\psi} \to \bar{\psi}\gamma^0$ (the spatial argument flip $\mathbf{x} \to -\mathbf{x}$ is understood throughout and does not affect the matrix algebra at a point).

Pseudoscalar. Sandwiching γ^5 between the transformed adjoint and field,

$$\bar{\psi}\gamma^5\psi \;\longmapsto\; (\bar{\psi}\gamma^0)\,\gamma^5\,(\gamma^0\psi) = \bar{\psi}\,(\gamma^0\gamma^5\gamma^0)\,\psi. \tag{11.44}$$

Move the first γ^0 through γ^5 using $\gamma^0\gamma^5 = -\gamma^5\gamma^0$ (from $\{\gamma^5,\gamma^0\} = 0$):

$$\gamma^0\gamma^5\gamma^0 = -\gamma^5\gamma^0\gamma^0 = -\gamma^5\,\mathbf{1} = -\gamma^5. \tag{11.45}$$

Hence $\bar{\psi}\gamma^5\psi \to -\bar{\psi}\gamma^5\psi$: a scalar under proper rotations (by Eq. (11.42)) but odd under parity — a pseudoscalar.

Axial vector. Now sandwich $\gamma^\mu\gamma^5$:

$$\bar{\psi}\gamma^\mu\gamma^5\psi \;\longmapsto\; \bar{\psi}\,(\gamma^0\gamma^\mu\gamma^5\gamma^0)\,\psi = \bar{\psi}\,(\gamma^0\gamma^\mu\gamma^0)(\gamma^0\gamma^5\gamma^0)\,\psi, \tag{11.46}$$

where we inserted $\gamma^0\gamma^0 = \mathbf{1}$ between γ^μ and γ^5 to split the product into two already-computed factors. We have $\gamma^0\gamma^5\gamma^0 = -\gamma^5$ from above, and $\gamma^0\gamma^\mu\gamma^0 = \gamma^\mu{}_P$,

i.e. $+\gamma^0$ for $\mu = 0$ and $-\gamma^i$ for $\mu = i$. Combining,

$$\bar{\psi}\gamma^\mu\gamma^5\psi \;\longmapsto\; -\bar{\psi}\,\gamma^\mu{}_P\gamma^5\,\psi = \begin{cases} -\bar{\psi}\gamma^0\gamma^5\psi, & \mu = 0, \\ +\bar{\psi}\gamma^i\gamma^5\psi, & \mu = i. \end{cases} \tag{11.47}$$

The time component flips sign and the spatial components are preserved — precisely the reverse of the polar vector $\bar{\psi}\gamma^\mu\psi$, whose time component is preserved and space components flipped. The product of the two extra signs (one from $\gamma^0\gamma^5\gamma^0 = -\gamma^5$, one from the γ^μ reflection) is what converts a polar vector into an axial vector. Quantum-mechanically this is why the spin operator, built from $\bar{\psi}\gamma^i\gamma^5\psi$-type bilinears, is parity-even while the momentum, a polar vector, is parity-odd.

The catalogue is now complete, and with it the classical kinematics of the Dirac field. We have shown that Lorentz covariance forces the four-component spinor, that the demand of a first-order equation reproducing the mass shell forces the Dirac equation $(i\partial\!\!\!/ - m)\psi = 0$, that the equation is form-invariant by virtue of the intertwining identity, and that the Dirac Lagrangian $\bar{\psi}(i\partial\!\!\!/ - m)\psi$ delivers a conserved vector current $j^\mu = \bar{\psi}\gamma^\mu\psi$ together with the sixteen bilinear covariants of Table 11.1. Every object the quantum theory will manipulate — the field, its adjoint, its canonical momentum $\pi_\psi = i\psi^\dagger$, its current, and the spin and dipole bilinears — is now specified classically. What remains before quantization is to solve the equation: to construct the explicit positive- and negative-frequency plane-wave solutions of $(p\!\!\!/ - m)u(p) = 0$ and $(p\!\!\!/ + m)v(p) = 0$, fix their normalizations, and prove the spin-sum and projector identities that will serve both as the mode basis for the canonical expansion and as the raw material for every QED trace. That construction is the work of Section 11.2.

11.2 Plane-Wave Solutions, Spin Sums, and Projectors

The previous section assembled the classical Dirac field: the unique Lorentz-covariant first-order equation $(i\partial\!\!\!/ - m)\psi = 0$ living on the reducible $(\tfrac{1}{2}, 0) \oplus (0, \tfrac{1}{2})$ representation, together with the gamma algebra, the chiral basis, and the bilinear covariants the quantum theory will need. Having the equation is not yet having its *solutions*. Before we can promote ψ to an operator we must know the complete set of classical wave packets it will be built from, exactly as the scalar field of Chapter 9 was assembled out of the plane waves $e^{\mp ip\cdot x}$. For a four-component spinor field the plane waves carry, in addition to their frequency, a polarization: a constant spinor amplitude that the Dirac operator constrains. The whole of this section is the determination of those amplitudes. We will find precisely two independent positive-frequency amplitudes $u^s(p)$ and

two negative-frequency amplitudes $v^s(p)$ at each on-shell momentum, build them explicitly in the chiral basis by boosting their rest-frame form, and then prove the algebra they satisfy: the normalization and orthogonality relations that will let us *invert* the mode expansion of the next section, the completeness (spin-sum) identities $\sum_s u^s\bar{u}^s = \not{p} + m$ and $\sum_s v^s\bar{v}^s = \not{p} - m$, and the projector technology—energy projectors $\Lambda_\pm$, chirality and helicity—that organizes every later spinor computation. The spin sums in particular are not a local convenience: they are the exact identities that Chapter 17 will trace over to obtain the unpolarized cross section for $e^+e^- \to \mu^+\mu^-$, the computational core of QED. This section proves them once, in full.

Throughout we use the chiral (Weyl) representation fixed in Section C.3.2,

$$\gamma^0 = \begin{pmatrix} \mathbf{0} & I \\ I & \mathbf{0} \end{pmatrix}, \qquad \gamma^i = \begin{pmatrix} \mathbf{0} & \sigma^i \\ -\sigma^i & \mathbf{0} \end{pmatrix}, \qquad \gamma^\mu = \begin{pmatrix} \mathbf{0} & \sigma^\mu \\ \bar{\sigma}^\mu & \mathbf{0} \end{pmatrix}, \tag{11.48}$$

with the two-component packaging $\sigma^\mu = (I, \sigma^i)$, $\bar{\sigma}^\mu = (I, -\sigma^i)$ of Eq. (C.58) and the Pauli matrices of Eq. (C.54). Every statement we prove is, by Pauli's theorem (Section C.2), basis independent in its invariant content—the normalizations, the spin sums, and the projector identities are scalars or covariant matrices—so the reader may translate any result to the Dirac or Majorana basis by the explicit unitaries of Section C.3 without changing a single number. The on-shell energy is $E_{\mathbf{p}} = +\sqrt{\mathbf{p}^2 + m^2}$ and the Lorentz-invariant measure is $\widetilde{dp} = d^3p/[(2\pi)^3 2E_{\mathbf{p}}]$, both imported verbatim from Eq. (9.211); the relativistic normalization $u^\dagger u = 2E_{\mathbf{p}}$ we are about to derive is the one paired with that measure.

11.2.1 The momentum-space Dirac equation

A free Dirac field, like a free scalar, is a superposition of plane waves. The novelty is that the amplitude multiplying each plane wave is a four-component constant spinor, and that the two signs of frequency carry independent amplitudes. We therefore posit the two families of elementary solutions

$$\psi^{(+)}(x) = u(p)\, e^{-ip\cdot x}, \qquad \psi^{(-)}(x) = v(p)\, e^{+ip\cdot x}, \qquad p^0 = E_{\mathbf{p}} > 0, \tag{11.49}$$

where $u(p)$ and $v(p)$ are x-independent spinors to be determined and, in both cases, $p^\mu = (E_{\mathbf{p}}, \mathbf{p})$ is a genuine future-pointing on-shell momentum. The label "positive frequency" refers to the sign in the exponent $e^{-iE_{\mathbf{p}}x^0}$ of $\psi^{(+)}$; the "negative-frequency" wave $\psi^{(-)}$ oscillates as $e^{+iE_{\mathbf{p}}x^0}$. Writing both with a manifestly positive p^0 and carrying the sign in the exponent—rather than allowing $p^0 < 0$—is the bookkeeping that will let Section 11.3 reinterpret the negative-frequency half as antiparticles, exactly as the scalar did in Section 9.7.

Insert the ansätze (11.49) into the position-space Dirac equation $(i\not{\partial} - m)\psi = 0$ of Eq. (11.13). Differentiation brings down a momentum factor: $\partial_\mu e^{\mp ip\cdot x} =$

$\mp i p_\mu e^{\mp ip\cdot x}$, so that $i\partial\!\!\!/$ acts on $\psi^{(\pm)}$ as multiplication by $\pm p\!\!\!/$. The exponentials cancel, leaving two purely algebraic conditions on the constant spinors,

$$(p\!\!\!/ - m)\, u(p) = 0, \tag{11.50}$$

$$(p\!\!\!/ + m)\, v(p) = 0, \tag{11.51}$$

with $p\!\!\!/ = \gamma^\mu p_\mu$. These are the *momentum-space Dirac equations*. Equation (11.50) is a homogeneous linear system; it has nontrivial solutions only where $\det(p\!\!\!/ - m) = 0$. We can read off that determinant without effort using the Clifford algebra. Multiply (11.50) on the left by $(p\!\!\!/ + m)$:

$$(p\!\!\!/+m)(p\!\!\!/-m)\, u = (p\!\!\!/^2 - m^2)\, u = 0, \qquad p\!\!\!/^2 = p_\mu p_\nu\, \gamma^\mu\gamma^\nu = p_\mu p_\nu\, \tfrac{1}{2}\{\gamma^\mu,\gamma^\nu\} = p_\mu p_\nu\, \eta^{\mu\nu}\, \mathbf{1} = p^2\, \mathbf{1}, \tag{11.52}$$

where the symmetrization is legitimate because $p_\mu p_\nu$ is symmetric and we used the Clifford relation (C.184). Thus a nonzero u requires $p^2 = m^2$, i.e. $p^0 = \pm E_{\mathbf{p}}$; the same computation applied to (11.51) gives the identical mass-shell condition. The constant spinor amplitude exists only on shell, and (11.52) is the spinorial echo of the fact—already visible in (11.49)—that each Dirac plane wave is a Klein–Gordon plane wave wearing a polarization.

It will be convenient to have $p\!\!\!/$ in 2×2 block form. From (11.48),

$$p\!\!\!/ = p_\mu\gamma^\mu = \begin{pmatrix} \mathbf{0} & p_\mu\sigma^\mu \\ p_\mu\bar\sigma^\mu & \mathbf{0} \end{pmatrix} \equiv \begin{pmatrix} \mathbf{0} & p\cdot\sigma \\ p\cdot\bar\sigma & \mathbf{0} \end{pmatrix}, \qquad \begin{aligned} p\cdot\sigma &\equiv p_\mu\sigma^\mu = E_{\mathbf{p}}\, I - \mathbf{p}\cdot\boldsymbol{\sigma}, \\ p\cdot\bar\sigma &\equiv p_\mu\bar\sigma^\mu = E_{\mathbf{p}}\, I + \mathbf{p}\cdot\boldsymbol{\sigma}, \end{aligned} \tag{11.53}$$

where $\mathbf{p}\cdot\boldsymbol{\sigma} = p^i\sigma^i$ and we used $p_i = -p^i$. The two Hermitian 2×2 matrices $p\cdot\sigma$ and $p\cdot\bar\sigma$ are the workhorses of everything below. Two of their properties we will use constantly. First, they are positive definite for a massive on-shell momentum: their eigenvalues are $E_{\mathbf{p}} \mp |\mathbf{p}|$, both strictly positive since $E_{\mathbf{p}} = \sqrt{\mathbf{p}^2 + m^2} > |\mathbf{p}|$. Second, their product is a multiple of the identity,

$$(p\cdot\sigma)(p\cdot\bar\sigma) = (E_{\mathbf{p}} - \mathbf{p}\cdot\boldsymbol{\sigma})(E_{\mathbf{p}} + \mathbf{p}\cdot\boldsymbol{\sigma}) = E_{\mathbf{p}}^2 - (\mathbf{p}\cdot\boldsymbol{\sigma})^2 = E_{\mathbf{p}}^2 - \mathbf{p}^2\, I = m^2\, I, \tag{11.54}$$

using $(\mathbf{p}\cdot\boldsymbol{\sigma})^2 = p^i p^j \sigma^i\sigma^j = p^i p^j \delta^{ij} I = \mathbf{p}^2 I$ from the Pauli algebra (C.38); the same holds with the factors reversed. Because each is positive definite it has a unique positive-definite Hermitian square root, written $\sqrt{p\cdot\sigma}$ and $\sqrt{p\cdot\bar\sigma}$; both are functions of the single Hermitian matrix $\mathbf{p}\cdot\boldsymbol{\sigma}$, hence commute with each other and with $\mathbf{p}\cdot\boldsymbol{\sigma}$. Equation (11.54) then gives the relation we will invoke at almost every step,

$$\sqrt{p\cdot\sigma}\,\sqrt{p\cdot\bar\sigma} = \sqrt{p\cdot\bar\sigma}\,\sqrt{p\cdot\sigma} = m\, I. \tag{11.55}$$

11.2.2 Rest-frame solutions and the boost

The cleanest way to solve (11.50) and (11.51) is to solve them once in the particle's rest frame, where the answer is transparent, and then carry the solution

to a general frame. In the rest frame $\mathbf{p}=0$, $p^\mu=(m,\mathbf{0})$, so $p\cdot\sigma=p\cdot\bar\sigma=mI$ and $\not p=m\gamma^0$. Equation (11.50) becomes $m(\gamma^0-1)u=0$, i.e. $\gamma^0u=u$: the rest-frame positive-frequency spinor is an eigenvector of γ^0 with eigenvalue $+1$. Writing a four-spinor in the chiral basis as a pair of two-component blocks, $u=(u_L,u_R)^{\mathsf T}$, and using $\gamma^0=\left(\begin{smallmatrix}0&I\\I&0\end{smallmatrix}\right)$, the condition $\gamma^0u=u$ reads $u_R=u_L$. Thus the positive-frequency rest-frame solutions are the spinors with equal upper and lower blocks. There are exactly two linearly independent such spinors, one for each choice of the common two-component block, and we label them by an orthonormal basis ξ^s $(s=1,2)$ of $\mathbb{C}^2$,

$$\xi^1=\begin{pmatrix}1\\0\end{pmatrix},\qquad \xi^2=\begin{pmatrix}0\\1\end{pmatrix},\qquad \xi^{r\dagger}\xi^s=\delta^{rs},\qquad \sum_{s=1,2}\xi^s\xi^{s\dagger}=I. \tag{11.56}$$

Likewise, in the rest frame (11.51) becomes $m(\gamma^0+1)v=0$, i.e. $\gamma^0v=-v$: the negative-frequency rest-frame spinor is the -1 eigenvector of γ^0, which in block form means $v_R=-v_L$. Again there are two, labelled by a basis η^s of $\mathbb{C}^2$ with $\eta^{r\dagger}\eta^s=\delta^{rs}$ and $\sum_s\eta^s\eta^{s\dagger}=I$. The reducible four-component representation has split, in the rest frame, into a two-dimensional space of positive-frequency amplitudes and a two-dimensional space of negative-frequency ones; the factor of two in each is the spin degeneracy of a massive spin-$\frac12$ particle, and the choice of basis ξ^s, η^s is a choice of spin quantization axis (the z-axis for the standard (11.56)).

To reach a general momentum we could apply the explicit spinor boost $S(\Lambda)$ of Eq. (11.8), but it is faster, and self-contained, to write down the boosted spinor and verify it solves the momentum-space equation directly. We claim that

$$\boxed{u^s(p)=\begin{pmatrix}\sqrt{p\cdot\sigma}\,\xi^s\\ \sqrt{p\cdot\bar\sigma}\,\xi^s\end{pmatrix},\qquad v^s(p)=\begin{pmatrix}\sqrt{p\cdot\sigma}\,\eta^s\\ -\sqrt{p\cdot\bar\sigma}\,\eta^s\end{pmatrix},\qquad s=1,2,} \tag{11.57}$$

are the four independent on-shell solutions. These reduce correctly in the rest frame: there $\sqrt{p\cdot\sigma}=\sqrt{p\cdot\bar\sigma}=\sqrt{m}\,I$, so $u^s=\sqrt{m}\,(\xi^s,\xi^s)^{\mathsf T}$ has equal blocks and $v^s=\sqrt{m}\,(\eta^s,-\eta^s)^{\mathsf T}$ has opposite blocks, matching the rest-frame analysis. We record this as a definition and then prove it solves the equations.

Definition 11.8 (Plane-wave spinor basis)**.** For each on-shell momentum $p^\mu=(E_{\mathbf p},\mathbf p)$ and each $s=1,2$, the *positive-* and *negative-frequency spinor amplitudes* are the four-component spinors (11.57), built from the rest-frame two-spinors (11.56) and the positive square roots of the Hermitian matrices (11.53). The associated elementary solutions of the Dirac equation are $u^s(p)e^{-ip\cdot x}$ and $v^s(p)e^{+ip\cdot x}$.

Proposition 11.9 (The amplitudes solve the momentum-space equations)**.** *The spinors* (11.57) *satisfy* $(\not p-m)u^s(p)=0$ *and* $(\not p+m)v^s(p)=0$.

Proof. Write $\not{p} - m = \left(\begin{smallmatrix} -m\,I & p\cdot\sigma \\ p\cdot\bar\sigma & -m\,I \end{smallmatrix}\right)$ from (11.53). Acting on u^s,

$$(\not{p} - m)u^s = \begin{pmatrix} -m\sqrt{p\cdot\sigma}\,\xi^s + (p\cdot\sigma)\sqrt{p\cdot\bar\sigma}\,\xi^s \\ (p\cdot\bar\sigma)\sqrt{p\cdot\sigma}\,\xi^s - m\sqrt{p\cdot\bar\sigma}\,\xi^s \end{pmatrix}. \tag{11.58}$$

In the upper block, $(p\cdot\sigma)\sqrt{p\cdot\bar\sigma} = \sqrt{p\cdot\sigma}\,(\sqrt{p\cdot\sigma}\,\sqrt{p\cdot\bar\sigma}) = \sqrt{p\cdot\sigma}\,(mI) = m\sqrt{p\cdot\sigma}$ by (11.55), so the two terms cancel. In the lower block, $(p\cdot\bar\sigma)\sqrt{p\cdot\sigma} = \sqrt{p\cdot\bar\sigma}\,(\sqrt{p\cdot\bar\sigma}\,\sqrt{p\cdot\sigma}) = m\sqrt{p\cdot\bar\sigma}$, and again the terms cancel. Hence $(\not{p}-m)u^s = 0$. For v^s, with $\not{p}+m = \left(\begin{smallmatrix} m\,I & p\cdot\sigma \\ p\cdot\bar\sigma & m\,I \end{smallmatrix}\right)$,

$$(\not{p}+m)v^s = \begin{pmatrix} m\sqrt{p\cdot\sigma}\,\eta^s - (p\cdot\sigma)\sqrt{p\cdot\bar\sigma}\,\eta^s \\ (p\cdot\bar\sigma)\sqrt{p\cdot\sigma}\,\eta^s - m\sqrt{p\cdot\bar\sigma}\,\eta^s \end{pmatrix} = \begin{pmatrix} m\sqrt{p\cdot\sigma}\,\eta^s - m\sqrt{p\cdot\sigma}\,\eta^s \\ m\sqrt{p\cdot\bar\sigma}\,\eta^s - m\sqrt{p\cdot\bar\sigma}\,\eta^s \end{pmatrix} = 0, \tag{11.59}$$

using (11.55) in both blocks. □

The four spinors u^1, u^2, v^1, v^2 are linearly independent: in the rest frame they are visibly so (two have equal blocks, two opposite, and the ξ^s, η^s are bases), and linear independence is preserved by the invertible boost that carries the rest frame to p. Since the momentum-space equations (11.50)–(11.51) each have a two-dimensional solution space—the projectors of Section 11.2.5 will make this count manifest, $\Lambda_\pm$ having trace 2—these four exhaust the solutions. The basis is complete.

To make (11.57) fully explicit one needs the square roots as concrete matrices. For any Hermitian 2×2 matrix of the form $A = aI + \mathbf{b}\cdot\boldsymbol{\sigma}$ with $a > |\mathbf{b}|$, the positive square root has the closed form $\sqrt{A} = (A + \sqrt{\det A}\,I)/\sqrt{\operatorname{tr}A + 2\sqrt{\det A}}$, as one checks by squaring. Applied to $p\cdot\sigma$ (for which $\operatorname{tr} = 2E_{\mathbf{p}}$, $\det = m^2$, so $\sqrt{\det} = m$) this gives

$$\sqrt{p\cdot\sigma} = \frac{p\cdot\sigma + m\,I}{\sqrt{2(E_{\mathbf{p}}+m)}} = \frac{(E_{\mathbf{p}}+m)I - \mathbf{p}\cdot\boldsymbol{\sigma}}{\sqrt{2(E_{\mathbf{p}}+m)}}, \qquad \sqrt{p\cdot\bar\sigma} = \frac{(E_{\mathbf{p}}+m)I + \mathbf{p}\cdot\boldsymbol{\sigma}}{\sqrt{2(E_{\mathbf{p}}+m)}}, \tag{11.60}$$

the second following from the first by $\mathbf{p}\to-\mathbf{p}$. These are the formulae one actually substitutes into a numerical computation.

Worked Example 11.10 (Explicit spinors for momentum along $\hat{\mathbf{z}}$)**.** Take $\mathbf{p} = p\,\hat{\mathbf{z}}$ with $p \equiv |\mathbf{p}| > 0$, so $\mathbf{p}\cdot\boldsymbol{\sigma} = p\,\sigma^3 = \operatorname{diag}(p, -p)$. Then $p\cdot\sigma = \operatorname{diag}(E-p,\, E+p)$ and $p\cdot\bar\sigma = \operatorname{diag}(E+p,\, E-p)$, writing $E \equiv E_{\mathbf{p}}$, and the square roots are taken entrywise on these diagonal matrices,

$$\sqrt{p\cdot\sigma} = \begin{pmatrix} \sqrt{E-p} & 0 \\ 0 & \sqrt{E+p} \end{pmatrix}, \qquad \sqrt{p\cdot\bar\sigma} = \begin{pmatrix} \sqrt{E+p} & 0 \\ 0 & \sqrt{E-p} \end{pmatrix}. \tag{11.61}$$

With $\xi^1 = (1,0)^{\mathsf{T}}$, $\xi^2 = (0,1)^{\mathsf{T}}$ the positive-frequency amplitudes (11.57) are the four-component column vectors

$$u^1(p) = \begin{pmatrix} \sqrt{E-p} \\ 0 \\ \sqrt{E+p} \\ 0 \end{pmatrix}, \qquad u^2(p) = \begin{pmatrix} 0 \\ \sqrt{E+p} \\ 0 \\ \sqrt{E-p} \end{pmatrix}. \tag{11.62}$$

As a check of the relativistic normalization derived below, $u^{1\dagger}u^1 = (E-p) + (E+p) = 2E$, and indeed $u^{1\dagger}u^2 = 0$ since the nonzero entries sit in disjoint rows. The Lorentz-invariant normalization is $\bar{u}^1 u^1 = u^{1\dagger}\gamma^0 u^1$; with γ^0 swapping the upper and lower two-blocks, $\bar{u}^1 u^1 = 2\sqrt{(E-p)(E+p)} = 2\sqrt{E^2-p^2} = 2m$, again as it must. In the ultrarelativistic limit $p \to E$ (i.e. $m \to 0$) the entry $\sqrt{E-p} \to 0$, so $u^1 \to (0,0,\sqrt{2E},0)^{\mathsf{T}}$ collapses onto its lower (right-handed) block and $u^2 \to (0,\sqrt{2E},0,0)^{\mathsf{T}}$ onto its upper (left-handed) block: chirality and helicity coincide in the massless limit, the fact that powers the $V-A$ bookkeeping of Section 11.2.5.

11.2.3 Normalization and orthogonality

We can now compute every inner product of the basis spinors directly from (11.57). Two natural bilinears appear. The Lorentz *scalar* $\bar{\psi}\chi = \psi^\dagger\gamma^0\chi$ is the invariant pairing; the *Dirac inner product* $\psi^\dagger\chi$ is the time component of the conserved current $\bar{\psi}\gamma^\mu\chi$ and so transforms as a density, which is why it carries the energy factor that pairs with the invariant measure (9.211). We need both, and we need the cross terms between u and v. The one repeated tool is (11.55); the one repeated fact about γ^0 is that, acting on a block spinor, it exchanges the upper and lower two-blocks. In particular for $u^s = (\sqrt{p\cdot\sigma}\,\xi^s,\ \sqrt{p\cdot\bar{\sigma}}\,\xi^s)^{\mathsf{T}}$, using that the square roots are Hermitian,

$$u^{s\dagger} = (\xi^{s\dagger}\sqrt{p\cdot\sigma}\ ,\ \xi^{s\dagger}\sqrt{p\cdot\bar{\sigma}}), \qquad \bar{u}^s = u^{s\dagger}\gamma^0 = (\xi^{s\dagger}\sqrt{p\cdot\bar{\sigma}}\ ,\ \xi^{s\dagger}\sqrt{p\cdot\sigma}), \tag{11.63}$$

the row vector being a 1×4 object split into two 1×2 blocks; γ^0 has swapped them. Likewise $v^{s\dagger} = (\eta^{s\dagger}\sqrt{p\cdot\sigma},\ -\eta^{s\dagger}\sqrt{p\cdot\bar{\sigma}})$ and $\bar{v}^s = (-\eta^{s\dagger}\sqrt{p\cdot\bar{\sigma}},\ \eta^{s\dagger}\sqrt{p\cdot\sigma})$.

Proposition 11.11 (Normalizations and orthogonality)**.** *For all on-shell p and all $r,s \in \{1,2\}$,*

$$\bar{u}^r(p)\,u^s(p) = 2m\,\delta^{rs}, \qquad \bar{v}^r(p)\,v^s(p) = -2m\,\delta^{rs}, \tag{11.64}$$

$$u^{r\dagger}(\mathbf{p})\,u^s(\mathbf{p}) = 2E_{\mathbf{p}}\,\delta^{rs}, \qquad v^{r\dagger}(\mathbf{p})\,v^s(\mathbf{p}) = 2E_{\mathbf{p}}\,\delta^{rs}, \tag{11.65}$$

$$\bar{u}^r(p)\,v^s(p) = 0, \qquad \bar{v}^r(p)\,u^s(p) = 0, \tag{11.66}$$

and, with $\tilde{p}^\mu \equiv (E_{\mathbf{p}},-\mathbf{p})$ the spatially reflected momentum,

$$u^{r\dagger}(\mathbf{p})\,v^s(-\mathbf{p}) = 0, \qquad v^{r\dagger}(\mathbf{p})\,u^s(-\mathbf{p}) = 0. \tag{11.67}$$

Proof. Scalar normalizations (11.64). Contract the row $\bar{u}^r$ of (11.63) with the column u^s of (11.57):

$$\bar{u}^r u^s = \xi^{r\dagger}\sqrt{p\cdot\bar{\sigma}}\,\sqrt{p\cdot\sigma}\,\xi^s + \xi^{r\dagger}\sqrt{p\cdot\sigma}\,\sqrt{p\cdot\bar{\sigma}}\,\xi^s = \xi^{r\dagger}(mI)\xi^s + \xi^{r\dagger}(mI)\xi^s = 2m\,\xi^{r\dagger}\xi^s = 2m\,\delta^{rs}, \tag{11.68}$$

using (11.55) twice and the orthonormality (11.56). For the v's,

$$\bar{v}^r v^s = (-\eta^{r\dagger}\sqrt{p\cdot\bar{\sigma}})(\sqrt{p\cdot\sigma}\,\eta^s) + (\eta^{r\dagger}\sqrt{p\cdot\sigma})(-\sqrt{p\cdot\bar{\sigma}}\,\eta^s) = -m\,\eta^{r\dagger}\eta^s - m\,\eta^{r\dagger}\eta^s = -2m\,\delta^{rs}. \tag{11.69}$$

The opposite sign is forced by the relative minus in the lower block of v^s; it is the spinor-level origin of the negative-norm danger that the next section's anticommutators resolve.

Dirac-product normalizations (11.65). Contract $u^{r\dagger}$ of (11.63) with u^s, now without the γ^0 swap:

$$u^{r\dagger}u^s = \xi^{r\dagger}\sqrt{p\cdot\sigma}\,\sqrt{p\cdot\sigma}\,\xi^s + \xi^{r\dagger}\sqrt{p\cdot\bar{\sigma}}\,\sqrt{p\cdot\bar{\sigma}}\,\xi^s = \xi^{r\dagger}(p\cdot\sigma + p\cdot\bar{\sigma})\xi^s = \xi^{r\dagger}(2E_{\mathbf{p}}I)\xi^s = 2E_{\mathbf{p}}\,\delta^{rs}, \tag{11.70}$$

where $p\cdot\sigma + p\cdot\bar{\sigma} = 2E_{\mathbf{p}}I$ from (11.53). The same computation with η's gives $v^{r\dagger}v^s = \eta^{r\dagger}(p\cdot\sigma + p\cdot\bar{\sigma})\eta^s = 2E_{\mathbf{p}}\delta^{rs}$; the relative minus in v squares away and does not flip this sign.

Scalar orthogonality (11.66). Contract $\bar{u}^r$ with v^s:

$$\bar{u}^r v^s = \xi^{r\dagger}\sqrt{p\cdot\bar{\sigma}}\,\sqrt{p\cdot\sigma}\,\eta^s + \xi^{r\dagger}\sqrt{p\cdot\sigma}\,(-\sqrt{p\cdot\bar{\sigma}})\eta^s = m\,\xi^{r\dagger}\eta^s - m\,\xi^{r\dagger}\eta^s = 0, \tag{11.71}$$

identically in the choice of ξ^r, η^s; the two terms cancel by (11.55). The relation $\bar{v}^r u^s = 0$ follows by the same cancellation.

Mixed Dirac orthogonality (11.67). This is the relation needed to invert the mode expansion, where u and v appear at *opposite* spatial momenta. Reflecting $\mathbf{p} \to -\mathbf{p}$ sends $\mathbf{p}\cdot\boldsymbol{\sigma} \to -\mathbf{p}\cdot\boldsymbol{\sigma}$, hence $\tilde{p}\cdot\sigma = p\cdot\bar{\sigma}$ and $\tilde{p}\cdot\bar{\sigma} = p\cdot\sigma$ with $\tilde{p} = (E_{\mathbf{p}}, -\mathbf{p})$. Therefore $v^s(-\mathbf{p}) = (\sqrt{p\cdot\bar{\sigma}}\,\eta^s,\, -\sqrt{p\cdot\sigma}\,\eta^s)^{\mathsf{T}}$, and contracting with $u^{r\dagger}(\mathbf{p}) = (\xi^{r\dagger}\sqrt{p\cdot\sigma},\, \xi^{r\dagger}\sqrt{p\cdot\bar{\sigma}})$,

$$u^{r\dagger}(\mathbf{p})\,v^s(-\mathbf{p}) = \xi^{r\dagger}\sqrt{p\cdot\sigma}\,\sqrt{p\cdot\bar{\sigma}}\,\eta^s + \xi^{r\dagger}\sqrt{p\cdot\bar{\sigma}}\,(-\sqrt{p\cdot\sigma})\eta^s = m\,\xi^{r\dagger}\eta^s - m\,\xi^{r\dagger}\eta^s = 0, \tag{11.72}$$

again term-by-term. The companion $v^{r\dagger}(\mathbf{p})u^s(-\mathbf{p}) = 0$ is identical with $\xi \leftrightarrow \eta$. □

Three features of Theorem 11.11 deserve emphasis before we use them. First, the invariant pairing $\bar{u}u = 2m$ *vanishes in the massless limit*—a chiral fermion has no Lorentz-scalar bilinear with itself—whereas the density $u^\dagger u = 2E_{\mathbf{p}}$ survives, which is precisely why the latter is the right normalization to carry through to the quantum field, where it pairs with $\widetilde{dp}$ to make $u^\dagger u\,\widetilde{dp}$ a Lorentz scalar. Second, the relative sign between $\bar{u}u > 0$ and $\bar{v}v < 0$ is not a defect of convention but a structural fact: it is the seed of the indefiniteness that, in the

next section, makes the naive (commutator) quantization of the Dirac field fail and selects anticommutators. Third, the orthogonality relations (11.66)–(11.67) are exactly what is needed to project a given field configuration onto a definite mode: in Section 11.2 we built the modes; relations (11.65) and (11.67) are the orthogonality that will let Section 11.3 read off each ladder operator by a Fourier-type inversion.

11.2.4 Completeness: the spin sums

The single most reused output of this chapter is the pair of *spin-sum* (completeness) identities. They express the fact that the two u's span the positive-energy subspace and the two v's the negative-energy subspace, packaged as 4×4 matrices. They are what makes the unpolarized cross section computable: when an experiment neither prepares nor measures spin, the matrix element is averaged over initial and summed over final spins, and these sums collapse the spin labels into the Lorentz-covariant matrices $\not{p}\pm m$, leaving a trace over gamma matrices. This is the mechanism by which Chapter 17 reduces $|\mathcal{M}|^2$ for $e^+e^-\to\mu^+\mu^-$ to traces; we prove the identities here, once.

Theorem 11.12 (Spin sums)**.** *The plane-wave amplitudes of Theorem 11.8 satisfy the outer-product completeness relations*

$$\sum_{s=1,2} u^s(p)\,\bar u^s(p) = \not{p} + m, \qquad \sum_{s=1,2} v^s(p)\,\bar v^s(p) = \not{p} - m, \tag{11.73}$$

as 4×4 matrix identities for every on-shell p.

Proof. Each term $u^s\bar u^s$ is the outer product of the column (11.57) with the row (11.63), a 4×4 matrix written in 2×2 blocks. For the u sum,

$$u^s\bar u^s = \begin{pmatrix} \sqrt{p\cdot\sigma}\,\xi^s \\ \sqrt{p\cdot\bar\sigma}\,\xi^s \end{pmatrix}\left(\xi^{s\dagger}\sqrt{p\cdot\bar\sigma}\,,\ \xi^{s\dagger}\sqrt{p\cdot\sigma}\right) = \begin{pmatrix} \sqrt{p\cdot\sigma}\,\xi^s\xi^{s\dagger}\sqrt{p\cdot\bar\sigma} & \sqrt{p\cdot\sigma}\,\xi^s\xi^{s\dagger}\sqrt{p\cdot\sigma} \\ \sqrt{p\cdot\bar\sigma}\,\xi^s\xi^{s\dagger}\sqrt{p\cdot\bar\sigma} & \sqrt{p\cdot\bar\sigma}\,\xi^s\xi^{s\dagger}\sqrt{p\cdot\sigma} \end{pmatrix}. \tag{11.74}$$

Summing over s and using the two-component completeness $\sum_s \xi^s\xi^{s\dagger} = I$ from (11.56), every $\xi^s\xi^{s\dagger}$ becomes the identity, and the square roots collapse via (11.55) and (11.54):

$$\sum_s u^s\bar u^s = \begin{pmatrix} \sqrt{p\cdot\sigma}\,\sqrt{p\cdot\bar\sigma} & p\cdot\sigma \\ p\cdot\bar\sigma & \sqrt{p\cdot\bar\sigma}\,\sqrt{p\cdot\sigma} \end{pmatrix} = \begin{pmatrix} m\,I & p\cdot\sigma \\ p\cdot\bar\sigma & m\,I \end{pmatrix} = m\,\mathbf{1} + \begin{pmatrix} \mathbf{0} & p\cdot\sigma \\ p\cdot\bar\sigma & \mathbf{0} \end{pmatrix} = \not{p} + m, \tag{11.75}$$

where the off-diagonal blocks used $\sqrt{p\cdot\sigma}\,\sqrt{p\cdot\sigma} = p\cdot\sigma$ and similarly for $\bar\sigma$, the diagonal blocks used (11.55), and the last step is the block form (11.53) of $\not{p}$. For the v sum, with $v^s = (\sqrt{p\cdot\sigma}\,\eta^s,\ -\sqrt{p\cdot\bar\sigma}\,\eta^s)^{\mathsf T}$ and $\bar v^s = (-\eta^{s\dagger}\sqrt{p\cdot\bar\sigma},\ \eta^{s\dagger}\sqrt{p\cdot\sigma})$,

$$v^s\bar v^s = \begin{pmatrix} -\sqrt{p\cdot\sigma}\,\eta^s\eta^{s\dagger}\sqrt{p\cdot\bar\sigma} & \sqrt{p\cdot\sigma}\,\eta^s\eta^{s\dagger}\sqrt{p\cdot\sigma} \\ \sqrt{p\cdot\bar\sigma}\,\eta^s\eta^{s\dagger}\sqrt{p\cdot\bar\sigma} & -\sqrt{p\cdot\bar\sigma}\,\eta^s\eta^{s\dagger}\sqrt{p\cdot\sigma} \end{pmatrix}, \tag{11.76}$$

where the two minus signs come from the lower block of v^s paired against the components of $\bar{v}^s$ (the upper-left and lower-right entries carry exactly one factor of the relative minus, the off-diagonal entries carry zero or two). Summing over s with $\sum_s \eta^s \eta^{s\dagger} = I$,

$$\sum_s v^s \bar{v}^s = \begin{pmatrix} -m\,I & p\cdot\sigma \\ p\cdot\bar{\sigma} & -m\,I \end{pmatrix} = -m\,\mathbf{1} + \begin{pmatrix} \mathbf{0} & p\cdot\sigma \\ p\cdot\bar{\sigma} & \mathbf{0} \end{pmatrix} = \not{p} - m. \tag{11.77}$$

□

The result is independent of the rest-frame bases ξ^s, η^s, as it must be: the only property of those bases that entered is their completeness $\sum \xi\xi^\dagger = \sum \eta\eta^\dagger = I$, not the particular axis chosen. One may also read Theorem 11.12 as the boosted form of the rest-frame projectors. In the rest frame $\sum_s u^s \bar{u}^s = m(\mathbf{1} + \gamma^0)$, which is m times the projector $\frac{1}{2}(1+\gamma^0)$ onto the $\gamma^0 = +1$ subspace, doubled; boosting $\gamma^0 \to \not{p}/m$ turns it into $\not{p} + m$. This is the viewpoint that makes the energy projectors of the next subsection inevitable.

11.2.5 Energy, chirality, and helicity projectors

The spin sums are completeness relations for two complementary subspaces of the four-dimensional spinor space at fixed p; the operators that isolate those subspaces are the *energy projectors*. They, together with the chirality projectors imported from Section C.3.5 and the helicity operator built below, are the standard kit for decomposing a spinor by its physical quantum numbers. Figure 11.1 summarizes how the three decompositions sit on the one four-dimensional space.

Definition 11.13 (Energy projectors)**.** For an on-shell momentum p ($p^2 = m^2$, $m > 0$) define

$$\Lambda_+(p) \equiv \frac{\not{p} + m}{2m}, \qquad \Lambda_-(p) \equiv \frac{-\not{p} + m}{2m} = \frac{m - \not{p}}{2m}. \tag{11.78}$$

By Theorem 11.12 these are exactly the (suitably normalized) spin-sum matrices: $\Lambda_+ = \frac{1}{2m}\sum_s u^s \bar{u}^s$ and $\Lambda_- = -\frac{1}{2m}\sum_s v^s \bar{v}^s$. Their projector properties follow from the single on-shell identity $\not{p}^2 = p^2\mathbf{1} = m^2\mathbf{1}$ established in (11.52).

Proposition 11.14 (Projector algebra of $\Lambda_\pm$)**.** *The energy projectors satisfy*

$$\Lambda_+ + \Lambda_- = \mathbf{1}, \qquad \Lambda_\pm^2 = \Lambda_\pm, \qquad \Lambda_+\Lambda_- = \Lambda_-\Lambda_+ = \mathbf{0}, \qquad \operatorname{tr}\Lambda_\pm = 2. \tag{11.79}$$

Proof. Completeness is immediate from (11.78): $\Lambda_+ + \Lambda_- = \big[(\not{p} + m) + (m - \not{p})\big]/2m = 2m/2m = \mathbf{1}$. For idempotency, expand using $\not{p}^2 = m^2\mathbf{1}$:

$$(\not{p} + m)^2 = \not{p}^2 + 2m\not{p} + m^2\mathbf{1} = 2m^2\mathbf{1} + 2m\not{p} = 2m(\not{p} + m), \tag{11.80}$$

so $\Lambda_+^2 = (\not{p}+m)^2/4m^2 = 2m(\not{p}+m)/4m^2 = (\not{p}+m)/2m = \Lambda_+$; the identical computation with $\not{p} \to -\not{p}$ gives $(m-\not{p})^2 = 2m(m-\not{p})$ and $\Lambda_-^2 = \Lambda_-$. Orthogonality is the difference of squares,

$$\Lambda_+\Lambda_- = \frac{(\not{p}+m)(m-\not{p})}{4m^2} = \frac{m\not{p} - \not{p}^2 + m^2 - m\not{p}}{4m^2} = \frac{m^2-\not{p}^2}{4m^2} = \frac{m^2-m^2}{4m^2}\,\mathbf{1} = \mathbf{0}, \tag{11.81}$$

and $\Lambda_-\Lambda_+ = \mathbf{0}$ since $\not{p}$ commutes with itself. Finally, $\operatorname{tr}\Lambda_+ = \frac{1}{2m}(\operatorname{tr}\not{p} + m\operatorname{tr}\mathbf{1}) = \frac{1}{2m}(0+4m) = 2$, using $\operatorname{tr}\gamma^\mu = 0$ from Section C.7.3 and $\operatorname{tr}\mathbf{1} = 4$; likewise $\operatorname{tr}\Lambda_- = 2$. □

The trace count $\operatorname{tr}\Lambda_\pm = 2$ is the promised confirmation that each frequency sector is exactly two-dimensional, so the four amplitudes u^1, u^2, v^1, v^2 of Theorem 11.8 are a complete basis with no solutions missed and none double-counted. Moreover Λ_+ acts as the identity on the u's and annihilates the v's, and vice versa for Λ_-: from $(\not{p}-m)u^s = 0$ we get $\not{p}\,u^s = mu^s$, hence $\Lambda_+u^s = (\not{p}+m)u^s/2m = 2mu^s/2m = u^s$ and $\Lambda_-u^s = (m-\not{p})u^s/2m = 0$; from $(\not{p}+m)v^s = 0$, $\not{p}\,v^s = -mv^s$, so $\Lambda_-v^s = v^s$ and $\Lambda_+v^s = 0$. The energy projectors literally project onto the particle and antiparticle solution spaces.

Chirality. The second decomposition of the spinor space is by *chirality*, the eigenvalue of $\gamma^5 = i\gamma^0\gamma^1\gamma^2\gamma^3$, which in the chiral basis is $\gamma^5 = \operatorname{diag}(-I, I)$. We do not re-derive its properties—they are established once and for all in Section C.3.5—but recall them for use here. The chirality projectors are

$$P_L = \tfrac{1}{2}(1-\gamma^5), \qquad P_R = \tfrac{1}{2}(1+\gamma^5), \tag{11.82}$$

(Theorem C.27), and by Theorem C.28 they are a complete orthogonal system, $P_L + P_R = \mathbf{1}$, $P_{L,R}^2 = P_{L,R}$, $P_LP_R = P_RP_L = \mathbf{0}$, satisfying the intertwining $\gamma^\mu P_L = P_R\gamma^\mu$. In the chiral basis P_L keeps the upper two-block and P_R the lower, so a spinor's handedness is the statement of which Weyl block it occupies. Chirality is Lorentz invariant (because γ^5 commutes with the generators $\sigma^{\mu\nu}$, Eq. (11.11)) but it is *not* conserved by the massive Dirac equation: acting with P_L on $(\not{p}-m)u = 0$ and using the intertwining gives $\not{p}\,(P_Ru) = m\,(P_Lu)$, so the mass term couples the two chiralities and a chirality eigenstate is not a solution unless $m = 0$. This is the precise sense in which mass mixes left and right, and it is why chirality, though geometrically fundamental, is not the conserved label that organizes a massive particle's spin states. That role falls to helicity.

Helicity. The conserved spin label for a massive free particle is the projection of spin along the direction of motion. The four-dimensional spin operator in the chiral basis is block-diagonal, $\boldsymbol{\Sigma} = \operatorname{diag}(\boldsymbol{\sigma}, \boldsymbol{\sigma})$ with components $\Sigma^k = \varepsilon^{kij}\sigma^{ij} = \operatorname{diag}(\sigma^k, \sigma^k)$ (it is block-diagonal precisely because rotations act identically on

the two Weyl components), and the spin vector is $\mathbf{S} = \frac{1}{2}\boldsymbol{\Sigma}$. The *helicity operator* is its projection on the unit momentum $\hat{\mathbf{p}} = \mathbf{p}/|\mathbf{p}|$,

$$h(\mathbf{p}) \equiv \hat{\mathbf{p}} \cdot \mathbf{S} = \tfrac{1}{2}\,\hat{\mathbf{p}} \cdot \boldsymbol{\Sigma} = \tfrac{1}{2}\begin{pmatrix} \hat{\mathbf{p}}\cdot\boldsymbol{\sigma} & \mathbf{0} \\ \mathbf{0} & \hat{\mathbf{p}}\cdot\boldsymbol{\sigma} \end{pmatrix}. \tag{11.83}$$

To build helicity eigenspinors, choose the rest-frame two-spinors to be eigenstates of $\hat{\mathbf{p}}\cdot\boldsymbol{\sigma}$: let $\xi_\pm$ solve $(\hat{\mathbf{p}}\cdot\boldsymbol{\sigma})\,\xi_\pm = \pm\xi_\pm$ (these exist and are orthonormal since $\hat{\mathbf{p}}\cdot\boldsymbol{\sigma}$ is Hermitian with eigenvalues ± 1), and build $u_\pm(p)$ from $\xi_\pm$ by (11.57). Because $p\cdot\sigma = E_{\mathbf{p}} I - |\mathbf{p}|\,\hat{\mathbf{p}}\cdot\boldsymbol{\sigma}$ is a function of $\hat{\mathbf{p}}\cdot\boldsymbol{\sigma}$ alone, both $\sqrt{p\cdot\sigma}$ and $\sqrt{p\cdot\bar\sigma}$ commute with $\hat{\mathbf{p}}\cdot\boldsymbol{\sigma}$ and preserve its eigenspaces. Hence

$$h(\mathbf{p})\,u_\pm(p) = \tfrac{1}{2}\begin{pmatrix} \sqrt{p\cdot\sigma}\,(\hat{\mathbf{p}}\cdot\boldsymbol{\sigma})\xi_\pm \\ \sqrt{p\cdot\bar\sigma}\,(\hat{\mathbf{p}}\cdot\boldsymbol{\sigma})\xi_\pm \end{pmatrix} = \pm\tfrac{1}{2}\,u_\pm(p), \tag{11.84}$$

so u_+ and u_- are helicity eigenspinors with eigenvalues $+\frac{1}{2}$ (right-handed helicity) and $-\frac{1}{2}$. The same construction with $\eta_\pm$ gives helicity eigenspinors $v_\pm$; the standard convention assigns the antiparticle described by v the *opposite* physical helicity to its spinor label, a point we will fix operationally when these become creation operators in Section 11.3. Theorem 11.10 already exhibited the eigenstates concretely: for $\mathbf{p} = p\hat{\mathbf{z}}$, $\hat{\mathbf{p}}\cdot\boldsymbol{\sigma} = \sigma^3$, so $\xi_+ = \xi^1$ and $\xi_- = \xi^2$, and the spinors (11.62) are already helicity eigenstates. Unlike chirality, helicity *is* conserved by the free Dirac equation—it commutes with the free Hamiltonian because both $\hat{\mathbf{p}}\cdot\boldsymbol{\sigma}$ and the dynamics are diagonal in $\mathbf{p}$—but it is not Lorentz invariant for $m > 0$, since a boost faster than the particle reverses $\hat{\mathbf{p}}$ and flips the sign. In the massless limit the two notions coincide, as Theorem 11.10 showed and as the next chapters on the weak interaction will exploit.

11.2.6 The Gordon decomposition

A last identity belongs here because it is pure on-shell spinor algebra and because QED will lean on it heavily: the *Gordon decomposition* of the vector current $\bar u(p')\gamma^\mu u(p)$. It rewrites the Dirac current as the sum of a convective piece, proportional to the total momentum $(p+p')^\mu$ and structurally identical to the Schrödinger probability current, and a spin piece, proportional to the momentum transfer $q^\mu = (p'-p)^\mu$ contracted into the antisymmetric tensor $\sigma^{\mu\nu}$. The spin piece is the magnetic-moment coupling: when these currents are sandwiched between the electron and the photon in Chapters 17 and 20, that term is precisely what produces the tree-level gyromagnetic ratio $g = 2$, and its loop correction is the anomalous moment $a_e = \alpha/2\pi$. We isolate it now.

Theorem 11.15 (Gordon decomposition)**.** *Let $u(p), u(p')$ be positive-frequency amplitudes (Theorem 11.8) of equal mass m, and $q^\mu \equiv (p'-p)^\mu$. With $\sigma^{\mu\nu} = \frac{i}{2}[\gamma^\mu,\gamma^\nu]$ (Eq. (11.11)),*

$$\bar u(p')\,\gamma^\mu\,u(p) = \bar u(p')\left[\frac{(p+p')^\mu}{2m} + \frac{i\,\sigma^{\mu\nu}q_\nu}{2m}\right]u(p). \tag{11.85}$$

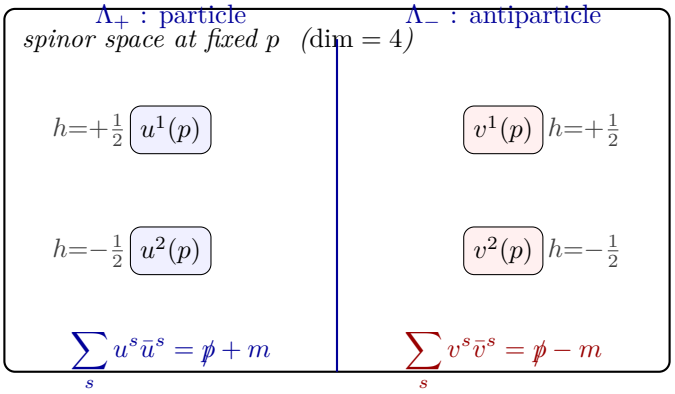


Figure 11.1: The three decompositions of the four-dimensional spinor space at a fixed on-shell momentum p. The energy projectors $\Lambda_\pm$ of (11.78) split it into the two-dimensional particle (u) and antiparticle (v) sectors, each of trace 2; within each sector the helicity operator (11.83) resolves the two spin states; the chirality projectors $P_{L,R}$ (not shown) give a third, rotated splitting that aligns with helicity only as $m \to 0$. The completeness of each sector is the content of the spin sums (11.73).

Proof. The amplitudes obey the Dirac equations in both their forms: $\not{p}\,u(p) = m\,u(p)$ from (11.50), and, taking the Dirac adjoint of $(\not{p}' - m)u(p') = 0$, also $\bar{u}(p')\not{p}' = m\,\bar{u}(p')$. (The adjoint step uses $\gamma^{\mu\dagger} = \gamma^0\gamma^\mu\gamma^0$: from $(\not{p}' - m)u(p') = 0$ take $\dagger$ to get $u(p')^\dagger(\not{p}'^\dagger - m) = 0$, then multiply by γ^0 on the right and insert $\gamma^0\gamma^0 = 1$, giving $\bar{u}(p')(\not{p}' - m) = 0$.) Use these to write $2m\,\bar{u}'\gamma^\mu u$ symmetrically, replacing one factor of m on each side:

$$2m\,\bar{u}'\gamma^\mu u = \bar{u}'\,\gamma^\mu(\not{p}\,u) + (\bar{u}'\not{p}')\,\gamma^\mu u = \bar{u}'(\gamma^\mu\gamma^\nu p_\nu + \gamma^\nu\gamma^\mu p'_\nu)u, \tag{11.86}$$

where in the first term $\not{p} = \gamma^\nu p_\nu$ stands to the right of γ^μ and in the second $\not{p}' = \gamma^\nu p'_\nu$ to the left. Now split each gamma product into its symmetric and antisymmetric parts using the Clifford relation (C.184) together with the definition (11.11), $\gamma^\mu\gamma^\nu = \eta^{\mu\nu}\mathbf{1} - i\sigma^{\mu\nu}$, and its transpose $\gamma^\nu\gamma^\mu = \eta^{\mu\nu}\mathbf{1} + i\sigma^{\mu\nu}$ (from $\sigma^{\nu\mu} = -\sigma^{\mu\nu}$):

$$\begin{aligned} 2m\,\bar{u}'\gamma^\mu u &= \bar{u}'\Big[(\eta^{\mu\nu}\mathbf{1} - i\sigma^{\mu\nu})p_\nu + (\eta^{\mu\nu}\mathbf{1} + i\sigma^{\mu\nu})p'_\nu\Big]u \\ &= \bar{u}'\Big[(p+p')^\mu\,\mathbf{1} + i\,\sigma^{\mu\nu}(p'_\nu - p_\nu)\Big]u = \bar{u}'\Big[(p+p')^\mu + i\,\sigma^{\mu\nu}q_\nu\Big]u. \end{aligned} \tag{11.87}$$

Dividing by $2m$ gives (11.85). □

The decomposition is exact and rests on nothing but the Dirac equation and the Clifford algebra. Two consequences are worth flagging for later use.

Setting $p' = p$ (forward matrix element, $q = 0$) collapses (11.85) to $\bar{u}(p)\gamma^\mu u(p) = \bar{u}(p)\, p^\mu/m\, u(p) = 2p^\mu$ on using $\bar{u}u = 2m$ from (11.64): the forward charge current is just $2p^\mu$, the relativistic flux, with no spin contribution—the magnetic moment shows up only at nonzero momentum transfer. And the antisymmetry $\sigma^{\mu\nu}q_\nu$ guarantees that contracting (11.85) with q_μ kills the spin term identically, leaving $q_\mu \bar{u}'\gamma^\mu u = \bar{u}'(q\cdot(p+p'))/2m\, u = \bar{u}'(p'^2 - p^2)/2m\, u = 0$; this is the spinor-level current conservation that will reappear as the Ward identity in Chapter 19.

We now hold the complete, normalized basis the rest of the chapter requires: two positive-frequency amplitudes $u^s(p)$ and two negative-frequency amplitudes $v^s(p)$ at every on-shell momentum, their full table of inner products (11.64)–(11.67), the completeness relations (11.73), and the projector toolkit (11.78)–(11.84) that resolves a spinor into particle/antiparticle, chirality, and helicity. The orthogonality relations (11.65) and (11.67) are exactly the inversion formulae the next section needs: expanding the field operator $\psi(x)$ over $\{u^s(p)e^{-ip\cdot x},\, v^s(p)e^{+ip\cdot x}\}$ with ladder operators, they let us solve for each ladder operator individually—and the relative sign $\bar{u}u = +2m$ versus $\bar{v}v = -2m$ already glimpsed here is the thread we will pull in Section 11.3 to discover that the Dirac field admits a sensible Hamiltonian only if its quanta are fermions.

Before closing, we record the worked computation that makes the thread obligation explicit: the spin sums of Theorem 11.12 are not merely tidy—they are the engine of every unpolarized rate.

Worked Example 11.16 (The master trace formula—why the spin sums matter for QED)**.** Consider any process whose amplitude has the spinor structure $\mathcal{M} = \bar{u}^{s'}(p')\,\Gamma\, u^s(p)$, where Γ is some product of gamma matrices (a current, a propagator numerator, a vertex string). This is the generic shape of every QED tree amplitude with one incoming and one outgoing fermion line; in $e^+e^- \to \mu^+\mu^-$ of Chapter 17 the muon line is exactly of this form. An unpolarized cross section requires $\sum_{s,s'} |\mathcal{M}|^2$ (averaging factors aside). We show this collapses to a single gamma trace, with no reference to the explicit spinors.

First write the complex conjugate of a bilinear as a bilinear with the conjugated insertion. Since $\mathcal{M}$ is a number, $\mathcal{M}^* = \mathcal{M}^\dagger = \left(\bar{u}^{s'}(p')\Gamma u^s(p)\right)^\dagger = u^s(p)^\dagger \Gamma^\dagger \gamma^{0\dagger} u^{s'}(p')$. Using $\gamma^{0\dagger} = \gamma^0$ and inserting $\gamma^0\gamma^0 = \mathbf{1}$,

$$\mathcal{M}^* = u^s(p)^\dagger \gamma^0 \left(\gamma^0\Gamma^\dagger\gamma^0\right) u^{s'}(p') = \bar{u}^s(p)\,\bar{\Gamma}\, u^{s'}(p'), \qquad \bar{\Gamma} \equiv \gamma^0\Gamma^\dagger\gamma^0, \tag{11.88}$$

where $\bar{\Gamma}$ is the "Dirac conjugate" of the insertion (for a single γ^μ one has $\bar{\gamma^\mu} = \gamma^0\gamma^{\mu\dagger}\gamma^0 = \gamma^\mu$, so a vector current conjugates to itself). Therefore

$$|\mathcal{M}|^2 = \mathcal{M}\,\mathcal{M}^* = \left[\bar{u}^{s'}(p')\Gamma u^s(p)\right]\left[\bar{u}^s(p)\bar{\Gamma} u^{s'}(p')\right]. \tag{11.89}$$

Now sum over both spins. Group the factors so that each spin label closes a loop. The s sum acts on $u^s(p)\bar{u}^s(p)$, and the s' sum on $u^{s'}(p')\bar{u}^{s'}(p')$; by Theorem 11.12

these become $\not{p}+m$ and $\not{p}'+m'$ respectively (allowing distinct masses m, m' on the two lines):

$$\sum_{s,s'} |\mathcal{M}|^2 = \sum_{s,s'} \bar{u}_a^{s'}(p')\,\Gamma_{ab}\,u_b^{s}(p)\,\bar{u}_c^{s}(p)\,\bar{\Gamma}_{cd}\,u_d^{s'}(p') = \left[\not{p}'+m'\right]_{da}\Gamma_{ab}\left[\not{p}+m\right]_{bc}\bar{\Gamma}_{cd}, \tag{11.90}$$

writing spinor indices a, b, c, d explicitly and reassembling the chain that begins and ends on index $d = a'$. The right-hand side is a closed matrix product traced over the single remaining index, i.e. a trace:

$$\boxed{\sum_{s,s'} \left|\bar{u}^{s'}(p')\,\Gamma\,u^{s}(p)\right|^2 = \mathrm{tr}\Big[\left(\not{p}'+m'\right)\Gamma\left(\not{p}+m\right)\bar{\Gamma}\Big].} \tag{11.91}$$

The explicit spinor components have vanished entirely; what remains is a trace of gamma matrices, evaluated by the contraction and trace identities of Section C.7.3. This is the single most-used computational identity of perturbative QED, and Eq. (11.91) is exactly the formula Chapter 17 feeds into the trace technology to obtain the unpolarized $|\mathcal{M}|^2$ for $e^+e^- \to \mu^+\mu^-$. (For an antiparticle line one repeats the steps with $\sum_s v^s\bar{v}^s = \not{p} - m$ in place of the u sum, which is why both spin sums were needed.) The lesson is structural: the work of this section—constructing the basis and proving its completeness—is precisely what lets the later computation forget the basis and reduce to algebra.

11.3 Canonical Quantization and the Necessity of Anticommutators

The previous section handed us a complete basis. For each spatial momentum $\mathbf{p}$ and each of two spin labels $s \in \{1, 2\}$ we have a positive-frequency solution $u^s(p)\,e^{-ip\cdot x}$ and a negative-frequency solution $v^s(p)\,e^{+ip\cdot x}$ of the Dirac equation, with $p^0 = E_{\mathbf{p}} = \sqrt{\mathbf{p}^2+m^2}$ throughout, normalized so that the Dirac inner products $\bar{u}^r u^s = 2m\,\delta^{rs}$, $\bar{v}^r v^s = -2m\,\delta^{rs}$ hold, the row–vector products satisfy

$$u^{r\dagger}(\mathbf{p})\,u^s(\mathbf{p}) = 2E_{\mathbf{p}}\,\delta^{rs}, \qquad v^{r\dagger}(\mathbf{p})\,v^s(\mathbf{p}) = 2E_{\mathbf{p}}\,\delta^{rs}, \tag{11.92}$$

the cross terms at opposite spatial momentum vanish,

$$u^{r\dagger}(\mathbf{p})\,v^s(-\mathbf{p}) = 0, \qquad v^{r\dagger}(\mathbf{p})\,u^s(-\mathbf{p}) = 0, \tag{11.93}$$

and the completeness (spin-sum) identities read

$$\sum_s u^s(p)\,\bar{u}^s(p) = \not{p} + m, \qquad \sum_s v^s(p)\,\bar{v}^s(p) = \not{p} - m \tag{11.94}$$

(recall Eqs. (11.64), (11.65), (11.67) and (11.73); here $v^s(-\mathbf{p})$ denotes the negative-frequency spinor carrying spatial momentum $-\mathbf{p}$, i.e. four-momentum $(E_{\mathbf{p}}, -\mathbf{p})$).

These relations are the entire raw material of this section: every operator identity below is obtained by folding the field against one of these spinors and using Eqs. (11.92) to (11.94).

The task is now exactly the one Chapter 9 carried out for the scalar: promote the classical field to an operator, expand it in this basis with operator-valued coefficients, and *fix the algebra of those coefficients by a canonical postulate*. For the scalar that postulate was the equal-time commutator, and it produced Bose statistics, a positive Hamiltonian, and a Fock space of identical bosons (Sections 9.1 and 9.3). We will follow the same structural template here — mode expansion, inversion, evaluation of H — but we will find that the commutator postulate, applied verbatim to the Dirac field, produces a catastrophe: a Hamiltonian with no ground state and a state space with negative-norm vectors. The repair is forced and unique. The equal-time *anti*commutator cures both diseases simultaneously, and in doing so it deduces, rather than assumes, that the spin-$\frac{1}{2}$ field must be quantized as fermions. This is the first genuinely fermionic fact of QED, and the classical foreshadowing was already explicit: in Section 6.5.4 the Dirac field's first-order kinetic term made its momentum a *second-class* constraint, whose Dirac bracket $\{\psi_a(\mathbf{x}), \psi_b^\dagger(\mathbf{y})\}_{\mathrm{D}} = -i\,\delta_{ab}\,\delta^3(\mathbf{x}-\mathbf{y})$ is symmetric under exchange and therefore quantizes to an anticommutator. The present section is where that promissory note is paid in full, and where the spectrum itself is shown to demand it.

11.3.1 The Heisenberg mode expansion

The classical free Dirac field obeys $(i\partial\!\!\!/ - m)\psi = 0$ (Eq. (6.70)), and the general classical solution is a superposition of the plane-wave basis built in the previous section. We promote ψ to a Heisenberg-picture operator by attaching an operator coefficient to each basis wave.

Definition 11.17 (Dirac mode expansion)**.** The quantized Dirac field is

$$\psi(x) = \sum_{s=1,2} \int \frac{d^3p}{(2\pi)^3\, 2E_{\mathbf{p}}} \Big[\, b^s_{\mathbf{p}}\, u^s(p)\, e^{-ip\cdot x} + d^{s\dagger}_{\mathbf{p}}\, v^s(p)\, e^{+ip\cdot x} \,\Big], \tag{11.95}$$

with the Lorentz-invariant measure $\int d^3p/[(2\pi)^3 2E_{\mathbf{p}}]$ of Theorem 9.4, and the four-component adjoint

$$\psi^\dagger(x) = \sum_{s=1,2} \int \frac{d^3p}{(2\pi)^3\, 2E_{\mathbf{p}}} \Big[\, b^{s\dagger}_{\mathbf{p}}\, u^{s\dagger}(p)\, e^{+ip\cdot x} + d^{s}_{\mathbf{p}}\, v^{s\dagger}(p)\, e^{-ip\cdot x} \,\Big]. \tag{11.96}$$

Here $b^s_{\mathbf{p}}, b^{s\dagger}_{\mathbf{p}}$ and $d^s_{\mathbf{p}}, d^{s\dagger}_{\mathbf{p}}$ are operators on a Hilbert space yet to be built, and $p\cdot x = E_{\mathbf{p}}x^0 - \mathbf{p}\cdot\mathbf{x}$ with $p^0 = E_{\mathbf{p}}$ on shell.

Two features of Eq. (11.95) are choices that deserve their motivation spelled out, because the entire success of the construction turns on them.

First, the expansion uses *two* independent families of operators, b and d, where the real scalar used only one. The real scalar field is Hermitian, $\phi = \phi^\dagger$, so its positive- and negative-frequency coefficients were related by conjugation, a and $a^\dagger$ (Eq. (9.42)). The Dirac field is intrinsically complex — its Lagrangian $\bar\psi(i\partial\!\!\!/ - m)\psi$ is invariant under the global phase rotation $\psi \to e^{-i\alpha}\psi$ whose Noether charge is the electric charge of QED — so $\psi \neq \psi^\dagger$ and the negative-frequency coefficient is an *independent* operator. We have written it as $d^{s\dagger}$ rather than d^s: the negative-frequency part of the field is built from a creation operator. This is the deliberate move that Chapter 9 also made for the complex scalar (Section 9.7). Its payoff, deferred to the next section, is that ψ then *annihilates* a particle of charge $-e$ (an electron) and *creates* a particle of charge $+e$ (a positron) in a single local operator, which is exactly what a charge-lowering field must do. For now it is simply the parametrization that will make the charge operator come out diagonal and positive.

Second, the spinor $u^s(p)$ rides with $b^s_{\mathbf{p}}$ and $v^s(p)$ rides with $d^{s\dagger}_{\mathbf{p}}$, each at its own four-momentum $p = (E_{\mathbf{p}}, \mathbf{p})$, so that every term in Eq. (11.95) is by construction a solution of the Dirac equation. Indeed, acting with the Dirac operator and using $(\not{p} - m)u^s(p) = 0$ and $(\not{p} + m)v^s(p) = 0$,

$$(i\partial\!\!\!/ - m)\, u^s(p) e^{-ip\cdot x} = (\not{p} - m)u^s(p)\, e^{-ip\cdot x} = 0, \qquad (i\partial\!\!\!/ - m)\, v^s(p) e^{+ip\cdot x} = -(\not{p} + m)v^s(p)\, e^{+ip\cdot x} \tag{11.97}$$

so $\psi(x)$ of Eq. (11.95) satisfies the Dirac equation Eq. (6.70) for *any* choice of the operator coefficients. The Dirac equation alone therefore does not fix the algebra of b and d; that is the job of the canonical postulate, to which we now turn.

11.3.2 The conjugate momentum and the two candidate postulates

From Eq. (6.78) the momentum conjugate to ψ is

$$\pi_\psi = \frac{\partial \mathcal{L}_{\mathrm{D}}}{\partial \dot\psi} = i\,\psi^\dagger, \tag{11.98}$$

a relation that is itself a (second-class) constraint, not a definition of a velocity: the Dirac Lagrangian is first order in time, so π_ψ is algebraically tied to the field rather than to $\dot\psi$. In an unconstrained theory canonical quantization would read off $[\psi_a(\mathbf{x}, t), \pi_b(\mathbf{y}, t)] = i\,\delta_{ab}\,\delta^3(\mathbf{x} - \mathbf{y})$, i.e. with Eq. (11.98), $\left[\psi_a(\mathbf{x}, t), \psi^\dagger_b(\mathbf{y}, t)\right] = \delta_{ab}\,\delta^3(\mathbf{x} - \mathbf{y})$. The constraint structure of Section 6.5.4 warns that this naive reading is not the final word — the proper bracket is the Dirac bracket — but it is exactly the naive bosonic reading whose failure we want to exhibit. We therefore

set up the two candidate postulates side by side and test each by computing its consequences.

Definition 11.18 (The two equal-time postulates)**.** We compare, at equal times $x^0 = y^0$:

$$\text{(B) commutators:} \quad \Big[\psi_a(\mathbf{x}), \psi_b^\dagger(\mathbf{y})\Big] = \delta_{ab}\,\delta^3(\mathbf{x}-\mathbf{y}), \qquad [\psi_a(\mathbf{x}), \psi_b(\mathbf{y})] = 0, \tag{11.99}$$

$$\text{(F) anticommutators:} \quad \Big\{\psi_a(\mathbf{x}), \psi_b^\dagger(\mathbf{y})\Big\} = \delta_{ab}\,\delta^3(\mathbf{x}-\mathbf{y}), \quad \{\psi_a(\mathbf{x}), \psi_b(\mathbf{y})\} = 0, \tag{11.100}$$

where a, b are Dirac (spinor) indices. Postulate (B) is the rule that worked for the scalar; postulate (F) is the rule we will be forced into. We will find that (B) is fatal and (F) is consistent.

11.3.3 Inverting the expansion

Both postulates are statements about the field; to test them we must translate them into statements about b and d. The translation is the inversion of Eq. (11.95), performed exactly as in Theorem 9.7 but now using the spinor orthonormality Eqs. (11.92) to (11.93) to project out a single mode. The result is the following.

Proposition 11.19 (Inversion of the Dirac mode expansion)**.** *At any fixed time $x^0 = t$, the ladder operators are recovered from the field by*

$$b_{\mathbf{p}}^r = \int d^3x\, e^{+ip\cdot x}\, u^{r\dagger}(p)\, \psi(x), \qquad d_{\mathbf{p}}^r = \int d^3x\, e^{+ip\cdot x}\, \psi^\dagger(x)\, v^r(p), \tag{11.101}$$

with Hermitian conjugates

$$b_{\mathbf{p}}^{r\dagger} = \int d^3x\, e^{-ip\cdot x}\, \psi^\dagger(x)\, u^r(p), \qquad d_{\mathbf{p}}^{r\dagger} = \int d^3x\, e^{-ip\cdot x}\, v^{r\dagger}(p)\, \psi(x). \tag{11.102}$$

Proof. Work at fixed t and abbreviate $u^s(p)e^{-ip\cdot x} = u^s(\mathbf{p})e^{-iE_{\mathbf{p}}t}e^{i\mathbf{p}\cdot\mathbf{x}}$ and $v^s(p)e^{+ip\cdot x} = v^s(\mathbf{p})e^{+iE_{\mathbf{p}}t}e^{-i\mathbf{p}\cdot\mathbf{x}}$. Multiply Eq. (11.95) by $e^{-i\mathbf{q}\cdot\mathbf{x}}$ and integrate over $\mathbf{x}$. The spatial integral produces $\int d^3x\, e^{i(\mathbf{p}-\mathbf{q})\cdot\mathbf{x}} = (2\pi)^3\delta^3(\mathbf{p}-\mathbf{q})$ on the b term and $\int d^3x\, e^{-i(\mathbf{p}+\mathbf{q})\cdot\mathbf{x}} = (2\pi)^3\delta^3(\mathbf{p}+\mathbf{q})$ on the $d^\dagger$ term, collapsing each momentum integral against its measure $1/2E$:

$$\int d^3x\, e^{-i\mathbf{q}\cdot\mathbf{x}}\,\psi(\mathbf{x},t) = \sum_s \frac{1}{2E_{\mathbf{q}}}\Big[b_{\mathbf{q}}^s\, u^s(\mathbf{q})\, e^{-iE_{\mathbf{q}}t} + d_{-\mathbf{q}}^{s\dagger}\, v^s(-\mathbf{q})\, e^{+iE_{\mathbf{q}}t}\Big]. \tag{11.103}$$

Now contract from the left with $u^{r\dagger}(\mathbf{q})$. The first term gives $u^{r\dagger}(\mathbf{q})u^s(\mathbf{q}) = 2E_{\mathbf{q}}\delta^{rs}$ by Eq. (11.92); the second term gives $u^{r\dagger}(\mathbf{q})v^s(-\mathbf{q}) = 0$ by Eq. (11.93). Hence

$$u^{r\dagger}(\mathbf{q}) \int d^3x\, e^{-i\mathbf{q}\cdot\mathbf{x}}\,\psi(\mathbf{x},t) = b_{\mathbf{q}}^r\, e^{-iE_{\mathbf{q}}t}, \tag{11.104}$$

and multiplying through by $e^{+iE_{\mathbf{q}}t}$ and using $e^{+iE_{\mathbf{q}}t}e^{-i\mathbf{q}\cdot\mathbf{x}} = e^{+iq\cdot x}$ gives the first formula in Eq. (11.101). The cross orthogonality Eq. (11.93) is precisely what makes the antiparticle ($d^\dagger$) contribution drop out, isolating b cleanly. To obtain $d^r_{\mathbf{p}}$, multiply instead by $e^{+i\mathbf{q}\cdot\mathbf{x}}$, integrate, and contract from the left with $v^{r\dagger}(\mathbf{q})$ acting on ψ; the analogous projection ($v^{r\dagger}v^s = 2E\delta^{rs}$ surviving, $v^{r\dagger}(\mathbf{q})u^s(-\mathbf{q}) = 0$ dropping) yields $d^{r\dagger}_{\mathbf{q}}$ from ψ, whose adjoint is the second formula in Eq. (11.101). The conjugate formulas Eq. (11.102) follow by Hermitian conjugation, noting that $u^{r\dagger}(p)\psi$ is a scalar (a contracted spinor index) so its conjugate is $\psi^\dagger u^r(p)$. □

The inversion is the engine of the whole section: it converts any postulated equal-time bracket of the fields into a bracket of the ladder operators by sandwiching the field bracket between two spinor projections. We use it twice — once for each postulate of Theorem 11.18 — and the two computations differ only by where a single sign lands.

11.3.4 The Hamiltonian, and why commutators fail

Before testing the postulates on the brackets directly, it is most illuminating to compute the Hamiltonian, because it is the Hamiltonian that exhibits the disease in physical terms.

Worked Example 11.20 (The Dirac Hamiltonian in the mode basis)**.** The Dirac Hamiltonian density established classically in Eq. (6.138) is

$$\mathcal{H}_{\mathrm{D}} = \psi^\dagger(\boldsymbol{\alpha}\cdot\hat{\mathbf{p}} + \beta m)\psi, \qquad \hat{\mathbf{p}} = -i\nabla, \quad \alpha^i = \gamma^0\gamma^i, \quad \beta = \gamma^0, \tag{11.105}$$

and the Hamiltonian is $H = \int d^3x\, \mathcal{H}_{\mathrm{D}}$. We evaluate it on Eq. (11.95), carrying every step.

Step 1: the momentum-space Dirac operator on the modes. Write $h(\mathbf{p}) \equiv \boldsymbol{\alpha}\cdot\mathbf{p} + \beta m$. From $(\not{p} - m)u^s(p) = 0$ with $\not{p} = \gamma^0 E_{\mathbf{p}} - \boldsymbol{\gamma}\cdot\mathbf{p}$, multiply on the left by γ^0 and use $\gamma^0\gamma^0 = 1$, $\gamma^0\boldsymbol{\gamma} = \boldsymbol{\alpha}$, $\gamma^0 m = \beta m$:

$$(E_{\mathbf{p}} - \boldsymbol{\alpha}\cdot\mathbf{p} - \beta m)u^s(\mathbf{p}) = 0 \implies h(\mathbf{p})\,u^s(\mathbf{p}) = E_{\mathbf{p}}\,u^s(\mathbf{p}). \tag{11.106}$$

Likewise from $(\not{p} + m)v^s(p) = 0$,

$$(E_{\mathbf{p}} - \boldsymbol{\alpha}\cdot\mathbf{p} + \beta m)v^s(\mathbf{p}) = 0 \implies h(-\mathbf{p})\,v^s(\mathbf{p}) = -E_{\mathbf{p}}\,v^s(\mathbf{p}). \tag{11.107}$$

The single-particle Dirac Hamiltonian has a positive-energy spectrum on the u-spinors and a negative-energy spectrum on the v-spinors — the negative-energy sea of the old hole theory. In the field theory this sign is benign on its own; it becomes lethal only in combination with the wrong statistics.

Step 2: act on ψ. The spatial derivative in $\hat{\mathbf{p}} = -i\nabla$ brings down $+\mathbf{p}$ on $e^{-ip\cdot x} = e^{-iEt}e^{i\mathbf{p}\cdot\mathbf{x}}$ and $-\mathbf{p}$ on $e^{+ip\cdot x} = e^{+iEt}e^{-i\mathbf{p}\cdot\mathbf{x}}$. Hence, using Eqs. (11.106)

and (11.107),

$$(\boldsymbol{\alpha}\cdot\hat{\mathbf{p}}+\beta m)\psi = \sum_s \int \frac{d^3p}{(2\pi)^3 2E_{\mathbf{p}}} \Big[E_{\mathbf{p}}\, b^s_{\mathbf{p}} u^s(p) e^{-ip\cdot x} - E_{\mathbf{p}}\, d^{s\dagger}_{\mathbf{p}} v^s(p) e^{+ip\cdot x}\Big]. \quad (11.108)$$

The crucial minus sign on the antiparticle term is the negative eigenvalue Eq. (11.107).

Step 3: contract with $\psi^\dagger$ and integrate over $\mathbf{x}$. Multiplying Eq. (11.108) on the left by $\psi^\dagger$ of Eq. (11.96) and integrating $\int d^3x$ produces four terms with momentum-conserving deltas. The $b^\dagger b$ and $d\,d^\dagger$ terms carry $\int d^3x\, e^{i(\mathbf{p}-\mathbf{q})\cdot\mathbf{x}} = (2\pi)^3\delta^3(\mathbf{p}-\mathbf{q})$; the $b^\dagger d^\dagger$ and $d\,b$ terms carry $(2\pi)^3\delta^3(\mathbf{p}+\mathbf{q})$. The two off-diagonal terms vanish: each is proportional to a cross overlap at opposite spatial momentum, $u^{r\dagger}(-\mathbf{p})v^s(\mathbf{p}) = 0$ or $v^{r\dagger}(-\mathbf{p})u^s(\mathbf{p}) = 0$, by Eq. (11.93). Concretely, the $b^\dagger d^\dagger$ term comes with the time factor $e^{+2iE_{\mathbf{p}}t}$ and the spinor factor $u^{r\dagger}(-\mathbf{p})v^s(\mathbf{p})$, which is zero; were it not zero, the Hamiltonian would fail to be time independent. Only the two diagonal terms survive. Doing the $\mathbf{q}$ integral against $\delta^3(\mathbf{p}-\mathbf{q})$,

$$\begin{aligned} H &= \sum_s \int \frac{d^3p}{(2\pi)^3 2E_{\mathbf{p}}} \frac{1}{2E_{\mathbf{p}}} \Big[E_{\mathbf{p}}\, u^{s\dagger}(\mathbf{p})u^s(\mathbf{p})\, b^{s\dagger}_{\mathbf{p}} b^s_{\mathbf{p}} - E_{\mathbf{p}}\, v^{s\dagger}(\mathbf{p})v^s(\mathbf{p})\, d^s_{\mathbf{p}} d^{s\dagger}_{\mathbf{p}}\Big] \\ &= \sum_s \int \frac{d^3p}{(2\pi)^3 2E_{\mathbf{p}}} E_{\mathbf{p}} \Big[b^{s\dagger}_{\mathbf{p}} b^s_{\mathbf{p}} - d^s_{\mathbf{p}} d^{s\dagger}_{\mathbf{p}}\Big], \end{aligned} \quad (11.109)$$

where the second line used $u^{s\dagger}u^s = v^{s\dagger}v^s = 2E_{\mathbf{p}}$ from Eq. (11.92), so that $\frac{1}{2E_{\mathbf{p}}} E_{\mathbf{p}}(2E_{\mathbf{p}}) = E_{\mathbf{p}}$.

The result Eq. (11.109),

$$\boxed{H = \sum_s \int \frac{d^3p}{(2\pi)^3 2E_{\mathbf{p}}} E_{\mathbf{p}} \Big(b^{s\dagger}_{\mathbf{p}} b^s_{\mathbf{p}} - d^s_{\mathbf{p}} d^{s\dagger}_{\mathbf{p}}\Big)} \quad (11.110)$$

is the pivot of the chapter. The particle sector enters with the manifestly nonnegative combination $b^\dagger b$; the antiparticle sector enters with $-d\,d^\dagger$ — the operators in the *wrong order* and with the *wrong sign*. Everything now depends on what we are allowed to do with $d\,d^\dagger$, and that is fixed by the postulate.

Postulate (B): commutators give negative norms. Apply the inversion Theorem 11.19 to the commutator postulate Eq. (11.99). For the particle operators,

$$\begin{aligned} \Big[b^r_{\mathbf{p}}, b^{s\dagger}_{\mathbf{q}}\Big] &= \int d^3x\, d^3y\, e^{ip\cdot x} e^{-iq\cdot y}\, u^{r\dagger}_a(p)\, u^s_b(q)\, \Big[\psi_a(x), \psi^\dagger_b(y)\Big] \\ &= \int d^3x\, e^{i(p-q)\cdot x}\, u^{r\dagger}(p)u^s(q) = (2\pi)^3\delta^3(\mathbf{p}-\mathbf{q})\, u^{r\dagger}(\mathbf{p})u^s(\mathbf{p}) = (2\pi)^3 2E_{\mathbf{p}}\, \delta^{rs}\delta^3(\mathbf{p}-\mathbf{q}), \end{aligned} \quad (11.111)$$

positive, as for a healthy oscillator. But the antiparticle operators are extracted from $\psi^\dagger$, not ψ, so they sample the bracket in the opposite order. Using $\left[\psi_a^\dagger(\mathbf{x}), \psi_b(\mathbf{y})\right] = -\left[\psi_b(\mathbf{y}), \psi_a^\dagger(\mathbf{x})\right] = -\delta_{ab}\delta^3(\mathbf{x}-\mathbf{y})$,

$$\begin{aligned}\left[d^r_{\mathbf{p}}, d^{s\dagger}_{\mathbf{q}}\right] &= \int d^3x\, d^3y\; e^{ip\cdot x} e^{-iq\cdot y}\, v^r_a(p)\, v^{s\dagger}_b(q)\; \left[\psi_a^\dagger(x), \psi_b(y)\right] \\ &= -\int d^3x\; e^{i(p-q)\cdot x}\, v^{s\dagger}(q) v^r(p) = -(2\pi)^3 2E_{\mathbf{p}}\, \delta^{rs}\delta^3(\mathbf{p}-\mathbf{q}). \quad (11.112)\end{aligned}$$

The minus sign in Eq. (11.112) is not a convention — it is forced by the antisymmetry of the commutator together with the fact that d lives in $\psi^\dagger$. Its consequence is immediate and fatal. The state $d^{s\dagger}_{\mathbf{p}}|0\rangle$, the would-be one-antiparticle state, has squared norm

$$\left\| d^{s\dagger}_{\mathbf{p}}|0\rangle \right\|^2 = \langle 0| d^s_{\mathbf{p}} d^{s\dagger}_{\mathbf{p}}|0\rangle = \langle 0|\left[d^s_{\mathbf{p}}, d^{s\dagger}_{\mathbf{p}}\right]|0\rangle = -(2\pi)^3 2E_{\mathbf{p}}\, \delta^3(\mathbf{0})\, \langle 0|0\rangle < 0, \quad (11.113)$$

where we used $d^s_{\mathbf{p}}|0\rangle = 0$ for the annihilation operator d. A negative-norm state has no probability interpretation: the inner product is not positive definite, so the space built on the commutator postulate is not a Hilbert space at all. This is the first disease.

The Hamiltonian shows the same disease as unboundedness. One might try to dodge the negative norm by reinterpreting which operator creates and which annihilates. Suppose we declare $\hat{d} \equiv d^\dagger$ to be the annihilator (so $\hat{d}|0\rangle = 0$), making $\left[\hat{d}_{\mathbf{p}}, \hat{d}^\dagger_{\mathbf{q}}\right] = \left[d^\dagger_{\mathbf{p}}, d_{\mathbf{q}}\right] = +(2\pi)^3 2E_{\mathbf{p}}\delta^{rs}\delta^3(\mathbf{p}-\mathbf{q}) > 0$, which restores positive norms. Then the Hamiltonian Eq. (11.110) becomes, using $d\, d^\dagger = \hat{d}^\dagger \hat{d}$,

$$H = \sum_s \int \frac{d^3p}{(2\pi)^3 2E_{\mathbf{p}}}\, E_{\mathbf{p}} \left(b^{s\dagger}_{\mathbf{p}} b^s_{\mathbf{p}} - \hat{d}^{s\dagger}_{\mathbf{p}} \hat{d}^s_{\mathbf{p}} \right). \quad (11.114)$$

Now every $\hat{d}^\dagger$ quantum *lowers* the energy by $E_{\mathbf{p}} > 0$. Applying $\hat{d}^\dagger_{\mathbf{p}}$ repeatedly drives the energy to $-\infty$: the spectrum has no ground state, the vacuum is unstable against producing antiparticles, and the theory has no sensible lowest-energy state to call a vacuum. This is the second disease. The two diseases are the same obstruction seen from two sides: the commutator forces a fixed relative sign between the b and d sectors, and that sign cannot be both positive-norm *and* positive-energy.

Worked Example 11.21 (No choice of c-number normalizations rescues the commutator)**.** One might hope that the disaster is an artifact of our spinor normalization and could be tuned away by rescaling. We show it cannot. Allow arbitrary real, positive c-number normalizations: rescale the spinors $u^s \to N_u u^s$,

$v^s \to N_v v^s$ and the operators $b \to \beta_b\, b$, $d \to \beta_d\, d$ with $N_u, N_v, \beta_b, \beta_d$ nonzero constants, and keep the commutator postulate Eq. (11.99). The inversion is linear, so the brackets simply pick up positive factors:

$$\left[b^r_{\mathbf{p}}, b^{s\dagger}_{\mathbf{q}}\right] = +C_b\, \delta^{rs}\delta^3(\mathbf{p}-\mathbf{q}), \qquad \left[d^r_{\mathbf{p}}, d^{s\dagger}_{\mathbf{q}}\right] = -C_d\, \delta^{rs}\delta^3(\mathbf{p}-\mathbf{q}), \tag{11.115}$$

with $C_b = (2\pi)^3 2E_{\mathbf{p}} N_u^2\, \beta_b^{-2} > 0$ and $C_d = (2\pi)^3 2E_{\mathbf{p}} N_v^2\, \beta_d^{-2} > 0$. The relative minus sign between the two brackets is untouched, because it came from the antisymmetry $\left[\psi^\dagger, \psi\right] = -\left[\psi, \psi^\dagger\right]$ in Eq. (11.112), a structural fact independent of any normalization. The energy, recomputed with the same rescalings, is $H = \int E_{\mathbf{p}}(\,\#\, b^\dagger b - \#'\, d\, d^\dagger\,)$ with the same relative minus sign on $d\, d^\dagger$, because that sign came from the negative eigenvalue Eq. (11.107), again normalization independent. Thus for *any* positive constants: if d is the annihilator, the norm $\propto -C_d < 0$ is negative; if $d^\dagger$ is the annihilator, the energy $\propto -\#' < 0$ is unbounded below. No positive c-number can flip a structural sign, so no rescaling rescues postulate (B). The obstruction is intrinsic to bosonic quantization of a first-order, charged, half-integer-spin field.

Physical Insight

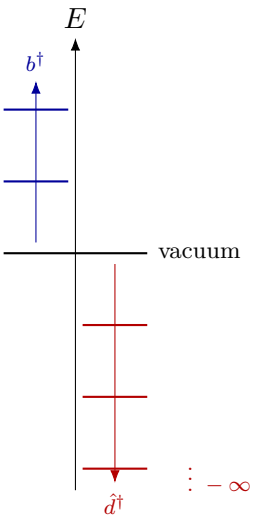
The deep reason both signs are immovable is that they have a common origin: the spin-$\frac{1}{2}$ field is a square root of the scalar. Its energy density $\psi^\dagger h \psi$ is *linear* in h, whose spectrum $\pm E_{\mathbf{p}}$ is sign-indefinite, whereas the scalar's energy density was built from $\dot\phi^2 + (\nabla\phi)^2 + m^2\phi^2$, manifestly a sum of squares. A field linear in a sign-indefinite operator can only have a stable vacuum if the filling of its negative-energy modes is *saturated* — if each mode can hold at most one quantum, so that lowering the energy by exciting antiparticles terminates. That is exactly the Pauli exclusion principle, and exclusion is exactly what anticommutators enforce. The spectrum is telling us, before we impose anything, that this field must be fermionic.

11.3.5 The cure: anticommutators and the ladder algebra

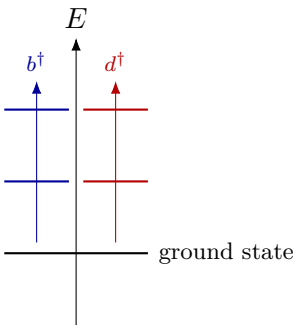
We now impose postulate (F), Eq. (11.100), and show that both diseases vanish. The inversion Theorem 11.19 is unchanged — it is a kinematic identity independent of the bracket — so we simply repeat the two computations Eqs. (11.111) and (11.112) with anticommutators.

Theorem 11.22 (The fermionic ladder algebra)**.** *The equal-time anticommutators Eq.* (11.100) *are equivalent to the ladder algebra*

$$\left\{b^r_{\mathbf{p}}, b^{s\dagger}_{\mathbf{q}}\right\} = \left\{d^r_{\mathbf{p}}, d^{s\dagger}_{\mathbf{q}}\right\} = (2\pi)^3\, 2E_{\mathbf{p}}\, \delta^{rs}\, \delta^3(\mathbf{p}-\mathbf{q}), \tag{11.116}$$



(a) commutators: no ground state



(b) anticommutators: bounded below

Figure 11.2: The spectrum of $H = \int E_{\mathbf{p}}(b^\dagger b - d\,d^\dagger)$ under the two postulates. (a) With commutators, restoring positive norms forces $d^\dagger$ (relabelled $\hat{d}^\dagger$) to *lower* the energy without bound: there is no ground state. (b) With anticommutators, $-d\,d^\dagger = +d^\dagger d - \text{const}$, both towers raise the energy, and the spectrum is bounded below by a unique vacuum.

with all other anticommutators among $b, b^\dagger, d, d^\dagger$ *vanishing:*

$$\left\{b^r_{\mathbf{p}}, b^s_{\mathbf{q}}\right\} = \left\{d^r_{\mathbf{p}}, d^s_{\mathbf{q}}\right\} = \left\{b^r_{\mathbf{p}}, d^s_{\mathbf{q}}\right\} = \left\{b^r_{\mathbf{p}}, d^{s\dagger}_{\mathbf{q}}\right\} = 0. \tag{11.117}$$

Proof. ($\Rightarrow$) Substitute the inversions into the anticommutator. For b,

$$\left\{b^r_{\mathbf{p}}, b^{s\dagger}_{\mathbf{q}}\right\} = \int d^3x\, d^3y\; e^{ip\cdot x} e^{-iq\cdot y}\, u^{r\dagger}_a(p) u^s_b(q)\, \left\{\psi_a(x), \psi^\dagger_b(y)\right\} = \int d^3x\; e^{i(p-q)\cdot x}\, u^{r\dagger}(p) u^s(q), \tag{11.118}$$

using Eq. (11.100). The $\mathbf{x}$ integral gives $(2\pi)^3\delta^3(\mathbf{p}-\mathbf{q})$, after which $u^{r\dagger}(\mathbf{p})u^s(\mathbf{p}) = 2E_{\mathbf{p}}\delta^{rs}$ by Eq. (11.92), yielding Eq. (11.116) for b. For d, now the anticommutator is symmetric, $\left\{\psi^\dagger_a(\mathbf{x}), \psi_b(\mathbf{y})\right\} = \left\{\psi_b(\mathbf{y}), \psi^\dagger_a(\mathbf{x})\right\} = \delta_{ab}\delta^3(\mathbf{x}-\mathbf{y})$, so the would-be minus sign of Eq. (11.112) is now a plus:

$$\left\{d^r_{\mathbf{p}}, d^{s\dagger}_{\mathbf{q}}\right\} = \int d^3x\, d^3y\; e^{ip\cdot x} e^{-iq\cdot y}\, v^r_a(p) v^{s\dagger}_b(q)\, \left\{\psi^\dagger_a(x), \psi_b(y)\right\} = +(2\pi)^3 2E_{\mathbf{p}}\, \delta^{rs}\delta^3(\mathbf{p}-\mathbf{q}). \tag{11.119}$$

The vanishing anticommutators Eq. (11.117) follow from $\{\psi_a, \psi_b\} = 0$ (which gives $\{b, b\} = \left\{b, d^\dagger\right\} = 0$ and $\{d, d\} = 0$ on projecting) and its conjugate. For example $\left\{b^r_{\mathbf{p}}, d^s_{\mathbf{q}}\right\} = \int e^{ip\cdot x} e^{iq\cdot y} u^{r\dagger}_a(p) v^s_b(q)\, \left\{\psi_a(x), \psi^\dagger_b(y)\right\}$ collapses to $u^{r\dagger}(\mathbf{p})v^s(-\mathbf{p}) = 0$ by the cross orthogonality Eq. (11.93).

($\Leftarrow$) Conversely, substituting Eqs. (11.95) and (11.96) into $\{\psi_a(\mathbf{x}), \psi_b^\dagger(\mathbf{y})\}$ and using Eqs. (11.116) and (11.117),

$$\begin{aligned}\{\psi_a(\mathbf{x}), \psi_b^\dagger(\mathbf{y})\} &= \sum_{r,s}\int \frac{d^3p}{(2\pi)^3 2E_{\mathbf{p}}}\frac{d^3q}{(2\pi)^3 2E_{\mathbf{q}}}\Big[u_a^r(p)u_b^{s\dagger}(q)\,e^{-ip\cdot x+iq\cdot y}\,\{b_{\mathbf{p}}^r, b_{\mathbf{q}}^{s\dagger}\} \\ &\qquad + v_a^r(p)v_b^{s\dagger}(q)\,e^{+ip\cdot x-iq\cdot y}\,\{d_{\mathbf{p}}^{r\dagger}, d_{\mathbf{q}}^s\}\Big] \\ &= \sum_s \int \frac{d^3p}{(2\pi)^3 2E_{\mathbf{p}}}\Big[u_a^s(\mathbf{p})u_b^{s\dagger}(\mathbf{p})\,e^{+i\mathbf{p}\cdot(\mathbf{x}-\mathbf{y})} + v_a^s(\mathbf{p})v_b^{s\dagger}(\mathbf{p})\,e^{-i\mathbf{p}\cdot(\mathbf{x}-\mathbf{y})}\Big],\end{aligned} \tag{11.120}$$

where the equal-time deltas $\delta^3(\mathbf{p}-\mathbf{q})$ from Eq. (11.116) collapsed the $\mathbf{q}$ integral and the on-shell energy phases $e^{\pm i(E_{\mathbf{p}}-E_{\mathbf{q}})t}$ became unity. To combine the two terms, substitute $\mathbf{p}\to-\mathbf{p}$ in the v integral, under which the measure and $E_{\mathbf{p}}$ are even and the phase $e^{-i\mathbf{p}\cdot(\mathbf{x}-\mathbf{y})}$ becomes $e^{+i\mathbf{p}\cdot(\mathbf{x}-\mathbf{y})}$, matching the u term; the two spinor outer products then add at a *common* spatial argument. We evaluate them from the spin sums Eq. (11.94) via $u^{s\dagger}=\bar u^s\gamma^0$ (so $u^s u^{s\dagger}=u^s\bar u^s\gamma^0$):

$$\sum_s u^s(\mathbf{p})u^{s\dagger}(\mathbf{p}) = (\not p + m)\gamma^0, \qquad \sum_s v^s(-\mathbf{p})v^{s\dagger}(-\mathbf{p}) = (\not{\tilde p} - m)\gamma^0, \quad \tilde p \equiv (E_{\mathbf{p}}, -\mathbf{p}), \tag{11.121}$$

both evaluated on shell with $p^0=E_{\mathbf{p}}$. Their sum is purely the convective part: since $p+\tilde p=(2E_{\mathbf{p}},\mathbf{0})$ as four-vectors, $\not p+\not{\tilde p}=2E_{\mathbf{p}}\gamma^0$, the mass terms cancel, and

$$\sum_s\Big[u^s(\mathbf{p})u^{s\dagger}(\mathbf{p}) + v^s(-\mathbf{p})v^{s\dagger}(-\mathbf{p})\Big] = (\not p + \not{\tilde p})\gamma^0 = 2E_{\mathbf{p}}\,\gamma^0\gamma^0 = 2E_{\mathbf{p}}\,\mathbf{1}. \tag{11.122}$$

The spin- and frequency-dependent pieces have cancelled, leaving only the identity in spinor space. Hence

$$\{\psi_a(\mathbf{x}), \psi_b^\dagger(\mathbf{y})\} = \int \frac{d^3p}{(2\pi)^3 2E_{\mathbf{p}}}\,2E_{\mathbf{p}}\,\delta_{ab}\,e^{+i\mathbf{p}\cdot(\mathbf{x}-\mathbf{y})} = \delta_{ab}\int\frac{d^3p}{(2\pi)^3}\,e^{+i\mathbf{p}\cdot(\mathbf{x}-\mathbf{y})} = \delta_{ab}\,\delta^3(\mathbf{x}-\mathbf{y}), \tag{11.123}$$

recovering Eq. (11.100). The two postulates are equivalent. □

With Theorem 11.22 in hand, return to the Hamiltonian Eq. (11.110). Anticommutators let us reorder $d\,d^\dagger$ *with* a plus sign: $d_{\mathbf{p}}^s d_{\mathbf{p}}^{s\dagger} = \{d_{\mathbf{p}}^s, d_{\mathbf{p}}^{s\dagger}\} - d_{\mathbf{p}}^{s\dagger}d_{\mathbf{p}}^s$. Therefore $-d\,d^\dagger = +d^\dagger d - \{d, d^\dagger\}$, and

$$H = \sum_s\int\frac{d^3p}{(2\pi)^3 2E_{\mathbf{p}}}\,E_{\mathbf{p}}\Big(b_{\mathbf{p}}^{s\dagger}b_{\mathbf{p}}^s + d_{\mathbf{p}}^{s\dagger}d_{\mathbf{p}}^s\Big) \;-\; \mathcal{E}_0, \qquad \mathcal{E}_0 = \sum_s\int d^3p\;E_{\mathbf{p}}\,\delta^3(\mathbf{0}), \tag{11.124}$$

where the (negative, divergent) constant $\mathcal{E}_0$ is the fermionic zero-point energy, the exact analogue of the scalar's vacuum energy of Section 9.4.1 but with the

opposite sign — a fact whose physical importance (boson and fermion zero-point energies cancel in a supersymmetric theory) is flagged for Chapter 50 and removed here by normal ordering in the next section. The dynamical part of Eq. (11.124) is now manifestly nonnegative: both $b^\dagger b$ and $d^\dagger d$ are nonnegative operators, so $H \geq -\mathcal{E}_0$ on every state, and the vacuum $|0\rangle$ defined by $b^s_{\mathbf{p}}|0\rangle = d^s_{\mathbf{p}}|0\rangle = 0$ is the unique ground state. Both diseases are cured at once: the norm $\|d^{s\dagger}_{\mathbf{p}}|0\rangle\|^2 = \langle 0|\left\{d^s_{\mathbf{p}}, d^{s\dagger}_{\mathbf{p}}\right\}|0\rangle = (2\pi)^3 2E_{\mathbf{p}}\delta^3(\mathbf{0})\langle 0|0\rangle > 0$ is now positive, and the energy is bounded below. Figure 11.2 contrasts the two outcomes.

Caution

The constant $\mathcal{E}_0$ in Eq. (11.124) is negative because it sits in front of a removed $-\left\{d, d^\dagger\right\}$. It is not a sign error: the fermionic vacuum energy is genuinely negative, opposite to the bosonic case. Normal ordering, defined for fermions with the antisymmetric sign convention introduced and executed in the next section, discards it; we do not write a Hamiltonian with $\mathcal{E}_0$ retained.

11.3.6 Consistency: the Heisenberg equation reproduces the Dirac equation

A canonical quantization is only consistent if the Heisenberg equation of motion generated by the resulting Hamiltonian reproduces the field equation we started from. We verify this for the anticommutator quantization. The key tool is the operator identity, valid for any operators,

$$[AB, C] = A\,\{B, C\} - \{A, C\}\,B, \tag{11.125}$$

which is the fermion-friendly form of the Leibniz rule: it lets us evaluate the commutator of the (bosonic) Hamiltonian with a single fermionic ladder operator using only the *anti*commutators Eq. (11.116).

Worked Example 11.23 (The Heisenberg equation gives back the Dirac equation)**.** Work with the normal-ordered Hamiltonian $H = \sum_s \int \frac{d^3q}{(2\pi)^3 2E_{\mathbf{q}}} E_{\mathbf{q}}(b^{s\dagger}_{\mathbf{q}} b^s_{\mathbf{q}} + d^{s\dagger}_{\mathbf{q}} d^s_{\mathbf{q}})$. Apply Eq. (11.125) to $\left[b^{s\dagger}_{\mathbf{q}} b^s_{\mathbf{q}}, b^r_{\mathbf{p}}\right]$, treating $A = b^{s\dagger}_{\mathbf{q}}$, $B = b^s_{\mathbf{q}}$, $C = b^r_{\mathbf{p}}$:

$$\left[b^{s\dagger}_{\mathbf{q}} b^s_{\mathbf{q}}, b^r_{\mathbf{p}}\right] = b^{s\dagger}_{\mathbf{q}} \underbrace{\left\{b^s_{\mathbf{q}}, b^r_{\mathbf{p}}\right\}}_{0} - \underbrace{\left\{b^{s\dagger}_{\mathbf{q}}, b^r_{\mathbf{p}}\right\}}_{(2\pi)^3 2E_{\mathbf{q}}\delta^{rs}\delta^3(\mathbf{p}-\mathbf{q})} b^s_{\mathbf{q}} = -(2\pi)^3 2E_{\mathbf{q}}\,\delta^{rs}\delta^3(\mathbf{p}-\mathbf{q})\,b^s_{\mathbf{q}}. \tag{11.126}$$

Integrating against $\frac{d^3q}{(2\pi)^3 2E_{\mathbf{q}}} E_{\mathbf{q}}$ and summing on s (the d part of H commutes with $b^r_{\mathbf{p}}$ by Eq. (11.117)),

$$\left[H, b^r_{\mathbf{p}}\right] = -E_{\mathbf{p}}\, b^r_{\mathbf{p}}, \qquad \text{and likewise} \qquad \left[H, d^{r\dagger}_{\mathbf{p}}\right] = +E_{\mathbf{p}}\, d^{r\dagger}_{\mathbf{p}}. \tag{11.127}$$

The Heisenberg equation $\dot{\mathcal{O}} = i\,[H, \mathcal{O}]$ then gives the time dependence $b^r_{\mathbf{p}}(t) = b^r_{\mathbf{p}} e^{-iE_{\mathbf{p}}t}$ and $d^{r\dagger}_{\mathbf{p}}(t) = d^{r\dagger}_{\mathbf{p}} e^{+iE_{\mathbf{p}}t}$ — precisely the phases already written explicitly in the mode expansion Eq. (11.95) as part of $e^{\mp ip\cdot x}$. Assembling,

$$\begin{aligned} i\,[H, \psi(x)] &= \sum_s \int \frac{d^3p}{(2\pi)^3 2E_{\mathbf{p}}} \left[i\left[H, b^s_{\mathbf{p}}\right] u^s(p) e^{-ip\cdot x} + i\left[H, d^{s\dagger}_{\mathbf{p}}\right] v^s(p) e^{+ip\cdot x} \right] \\ &= \sum_s \int \frac{d^3p}{(2\pi)^3 2E_{\mathbf{p}}} \left[(-iE_{\mathbf{p}}) b^s_{\mathbf{p}} u^s(p) e^{-ip\cdot x} + (+iE_{\mathbf{p}}) d^{s\dagger}_{\mathbf{p}} v^s(p) e^{+ip\cdot x} \right] = \partial_0 \psi(x). \end{aligned} \tag{11.128}$$

Thus $\dot{\psi} = i\,[H, \psi]$ holds. Since each plane wave already satisfies the Dirac equation Eq. (11.97), the operator $\psi(x)$ solves $(i\partial\!\!\!/ - m)\psi = 0$, Eq. (6.70), and the anticommutator quantization is consistent: the Hamiltonian we derived generates exactly the dynamics we postulated.

The same check fails informatively for the commutator quantization. There the relevant identity is the ordinary $[AB, C] = A\,[B, C] + [A, C]\,B$, and with the negative d-sector commutator Eq. (11.112) one finds $\left[H, d^{r\dagger}_{\mathbf{p}}\right] = -E_{\mathbf{p}} d^{r\dagger}_{\mathbf{p}}$ in the norm-positive relabelling — the wrong sign, signalling once more that the $d^\dagger$ excitation lowers the energy. Only the anticommutator gives a Heisenberg evolution compatible with a Hamiltonian bounded below.

Physical Insight

The logic has been entirely deductive. We did not assume the Pauli principle; we wrote down the most general operator field consistent with the Dirac equation and Lorentz-covariant normalization, computed its energy, and discovered that bosonic quantization is mathematically inconsistent (negative norms or no ground state), while fermionic quantization is consistent. The exclusion principle, $(b^{s\dagger}_{\mathbf{p}})^2 = 0$ from $\left\{b^{s\dagger}_{\mathbf{p}}, b^{s\dagger}_{\mathbf{p}}\right\} = 0$, is now a *theorem* about the spin-$\frac{1}{2}$ field rather than a postulate of atomic physics — the special case of the spin-statistics connection (Theorem 9.33) that Chapter 9 proved for spin 0 and explicitly deferred for half-integer spin. The deferred half is discharged here for the free Dirac field; the general microcausality argument completing the connection is taken up in Section 11.6.4.

This is the principled corroboration promised in the opening: the classical Dirac bracket $\left\{\psi_a(\mathbf{x}), \psi^\dagger_b(\mathbf{y})\right\}_{\mathrm{D}} = -i\delta_{ab}\delta^3(\mathbf{x}-\mathbf{y})$ of Section 6.5.4, symmetric under the bracket exchange because the constraints χ_1, χ_2 are second class, becomes under the quantization rule $\{\cdot,\cdot\}_{\mathrm{D}} \to -i\,\{\cdot,\cdot\}$ exactly the anticommutator Eq. (11.100). The constraint analysis of Chapter 6 predicted Fermi statistics from the structure of the classical theory; the spectrum analysis of this section

has now shown, independently, that nothing else is consistent. Two roads, one destination.

We have promoted the Dirac field to an operator, fixed its algebra, and arrived at a consistent set of creation and annihilation operators $\{b^s_{\mathbf{p}}, b^{s\dagger}_{\mathbf{p}}, d^s_{\mathbf{p}}, d^{s\dagger}_{\mathbf{p}}\}$ obeying the fermionic ladder algebra Eqs. (11.116) and (11.117), together with a positive Hamiltonian Eq. (11.124) and a unique vacuum. The next section builds the antisymmetric Fock space on these operators, normal-orders the energy, momentum, and charge into manifestly sensible observables, and reads off the excitations as the spin-$\frac{1}{2}$ electrons and positrons of mass m that carry QED into its quantum layer.

11.4 Fock Space, the Charge, and the Electron

The previous section ended with an algebra and a warning. Solving the operator Dirac equation by a plane-wave expansion produced, for each spatial momentum $\mathbf{p}$ and each of two spin labels $s \in \{1, 2\}$, two families of operators: $b^s_{\mathbf{p}}$, $b^{s\dagger}_{\mathbf{p}}$ and $d^s_{\mathbf{p}}$, $d^{s\dagger}_{\mathbf{p}}$. The mode expansion of the field, fixed in Eq. (11.95), reads

$$\psi(x) = \sum_{s=1,2} \int \widetilde{dp} \left[b^s_{\mathbf{p}}\, u^s(\mathbf{p})\, e^{-ip\cdot x} + d^{s\dagger}_{\mathbf{p}}\, v^s(\mathbf{p})\, e^{+ip\cdot x} \right], \qquad \int \widetilde{dp} \equiv \int \frac{d^3p}{(2\pi)^3}\, \frac{1}{2E_{\mathbf{p}}}, \quad E_{\mathbf{p}} = \sqrt{\mathbf{p}^2 \, \tag{11.129}$$

and the equal-time canonical relations, which for a half-integer-spin field were forced to be *anti*commutators rather than commutators (this was the entire lesson of Section 11.3), collapsed into

$$\left\{ b^r_{\mathbf{p}}, b^{s\dagger}_{\mathbf{q}} \right\} = \left\{ d^r_{\mathbf{p}}, d^{s\dagger}_{\mathbf{q}} \right\} = (2\pi)^3\, 2E_{\mathbf{p}}\, \delta^{rs}\, \delta^3(\mathbf{p} - \mathbf{q}), \tag{11.130}$$

with every other anticommutator among the ladder operators vanishing. This is the import we work from; it is established in Eq. (11.116) and we shall not rederive it. As in the scalar case (Section 9.3) we use the relativistic normalization throughout, so the factor $(2\pi)^3 2E_{\mathbf{p}}$ rather than a bare $(2\pi)^3$ sits on the right of Eq. (11.130); this is the convention fixed book-wide in Section 9.2.5.

What we have so far is only an algebra. We have no Hilbert space, no states, no energies, and no answer to the question that has hung over the chapter since Chapter 3 promised it: the half-integer-spin representation $(\frac{1}{2}, 0) \oplus (0, \frac{1}{2})$ classified there must, when quantized, describe a relativistic particle of mass m and spin $\frac{1}{2}$ — and it must do so while respecting the antiparticle doubling that Section 3.7 flagged as the inevitable price of building local fields from positive-energy orbits. This section delivers all of it. We build the state space from Eq. (11.130), find that it is forced to be *anti*symmetric and so contains the Pauli exclusion principle as an algebraic identity; we normal-order the Hamiltonian, the momentum, and the $U(1)$ charge into manifestly sensible operators, tracking with care the single extra

minus sign that the anticommutators inject and that the bosonic computation of Chapter 9 never saw; and we identify the two species of excitation as the electron and the positron, equal in mass and spin, opposite in charge. This is the quantum layer of QED: the classical $U(1)$ matter field of Chapter 8 becomes, here, an operator whose elementary quanta are electrons created by $b^{s\dagger}$ and positrons created by $d^{s\dagger}$.

Two structural contrasts with the scalar will recur and are worth stating at the outset, because they are the whole physics of the fermionic case. First, where commuting creation operators built a *symmetric* Fock space and Bose statistics, anticommuting ones will build an *antisymmetric* Fock space and Fermi statistics — and the antisymmetry is exactly the exclusion principle. Second, where the bosonic zero-point energy came out positive (the divergent $E_0 = +\frac{V}{2}\int E_{\mathbf{p}}$ of Eq. (9.98)), the fermionic one will come out *negative*, and the sign flip is not cosmetic: it is the same flip that, had we quantized with commutators, would have produced a Hamiltonian unbounded below. The anticommutators that Section 11.3 forced on us to cure that disease are precisely what we now see paying off in the spectrum.

11.4.1 The vacuum and its uniqueness

A state space built from lowering and raising operators must have a floor. We define it and then show, for the free theory, that it is forced.

Definition 11.24 (The Dirac vacuum)**.** The *vacuum* $|0\rangle$ is the state annihilated by every lowering operator of both families,

$$b^s_{\mathbf{p}}\,|0\rangle = 0, \qquad d^s_{\mathbf{p}}\,|0\rangle = 0 \qquad \text{for all } \mathbf{p},\ s, \tag{11.131}$$

normalized to $\langle 0|0\rangle = 1$.

That *both* families annihilate $|0\rangle$ is the operator content of the statement that the vacuum contains neither electrons nor positrons. The uniqueness argument is the fermionic copy of the scalar one (Section 9.3.1), and the anticommutators make it, if anything, cleaner.

Proposition 11.25 (Uniqueness of the free vacuum)**.** *Up to an overall phase,* $|0\rangle$ *is the only normalized state annihilated by all* $b^s_{\mathbf{p}}$ *and all* $d^s_{\mathbf{p}}$*.*

Proof. The states obtained by acting on $|0\rangle$ with strings of creation operators span the whole space (this is the Fock construction of Section 11.4.3 below). Any candidate $|\Omega\rangle$ therefore expands as a c-number multiple of $|0\rangle$ plus terms each containing at least one creation operator,

$$|\Omega\rangle = c_0\,|0\rangle + \sum_s \int \widetilde{dp}\; c^{(b)}_s(\mathbf{p})\, b^{s\dagger}_{\mathbf{p}}\,|0\rangle + \sum_s \int \widetilde{dp}\; c^{(d)}_s(\mathbf{p})\, d^{s\dagger}_{\mathbf{p}}\,|0\rangle + (\text{two or more creation operators}). \tag{11.132}$$

Apply $b^r_{\mathbf{k}}$. On the left it gives zero by hypothesis. On the right, anticommute $b^r_{\mathbf{k}}$ to the right using Eq. (11.130); against the one-electron term it yields $b^r_{\mathbf{k}}\, b^{s\dagger}_{\mathbf{p}}\,|0\rangle = \left\{b^r_{\mathbf{k}}, b^{s\dagger}_{\mathbf{p}}\right\}|0\rangle = (2\pi)^3 2E_{\mathbf{k}}\,\delta^{rs}\delta^3(\mathbf{k}-\mathbf{p})\,|0\rangle$, which integrates to $c^{(b)}_r(\mathbf{k})\,|0\rangle$; it kills the one-positron term outright (because b anticommutes with $d^\dagger$ and annihilates $|0\rangle$), and it lowers every higher term by one electron. Demanding the total vanish sector by sector forces $c^{(b)}_r \equiv 0$; the identical argument with $d^r_{\mathbf{k}}$ forces $c^{(d)}_r \equiv 0$, and an induction on the number of creation operators kills every coefficient with at least one. Hence $|\Omega\rangle = c_0\,|0\rangle$, and normalization fixes $|c_0| = 1$. □

11.4.2 One-particle states: the electron and the positron

Acting once with a creation operator produces the first excited sector. We adopt the covariant normalization that made the scalar states (Theorem 9.12) transform without stray Jacobians.

Definition 11.26 (One-particle states)**.** For an on-shell momentum $p^\mu = (E_{\mathbf{p}}, \mathbf{p})$ and spin label s,

$$|\mathbf{p}, s\rangle_b \equiv b^{s\dagger}_{\mathbf{p}}\,|0\rangle \qquad (\text{an } \textit{electron}), \qquad\qquad |\mathbf{p}, s\rangle_d \equiv d^{s\dagger}_{\mathbf{p}}\,|0\rangle \qquad (\text{a } \textit{positron}). \tag{11.133}$$

These names are, for the moment, only labels for the two ladder families; what earns the electron the right to its name is its charge and spin, derived below. Their inner products follow directly from Eq. (11.130). For two electrons,

$${}_b\langle \mathbf{p}, r|\mathbf{q}, s\rangle_b = \langle 0|\, b^r_{\mathbf{p}}\, b^{s\dagger}_{\mathbf{q}}\,|0\rangle = \langle 0|\big(\left\{b^r_{\mathbf{p}}, b^{s\dagger}_{\mathbf{q}}\right\} - b^{s\dagger}_{\mathbf{q}} b^r_{\mathbf{p}}\big)|0\rangle = (2\pi)^3\, 2E_{\mathbf{p}}\,\delta^{rs}\,\delta^3(\mathbf{p}-\mathbf{q}), \tag{11.134}$$

the second operator term dying because $b^r_{\mathbf{p}}\,|0\rangle = 0$. The same holds for two positrons, while an electron and a positron are orthogonal because b anticommutes with $d^\dagger$ and both annihilate the vacuum: ${}_b\langle \mathbf{p}, r|\mathbf{q}, s\rangle_d = \langle 0|\, b^r_{\mathbf{p}} d^{s\dagger}_{\mathbf{q}}\,|0\rangle = -\langle 0|\, d^{s\dagger}_{\mathbf{q}} b^r_{\mathbf{p}}\,|0\rangle = 0$. The right-hand side of Eq. (11.134) is the same Lorentz-invariant combination $2E_{\mathbf{p}}(2\pi)^3\delta^3(\mathbf{p}-\mathbf{q})$ whose invariance was proved in Theorem 9.14; the bookkeeping is identical to the scalar, the only novelty being the Kronecker δ^{rs} recording that the two spin states are orthogonal.

11.4.3 Pauli exclusion and the antisymmetric Fock space

Here the anticommutators announce themselves. The single most consequential fact about the fermionic state space is visible already on the second rung of the ladder, and it is an algebraic identity, not a postulate.

Theorem 11.27 (Pauli exclusion principle)**.** *For every momentum* $\mathbf{p}$ *and spin* s*,*

$$\left(b^{s\dagger}_{\mathbf{p}}\right)^2 = 0, \qquad\qquad \left(d^{s\dagger}_{\mathbf{p}}\right)^2 = 0. \tag{11.135}$$

Consequently no quantum-mechanical state can contain two electrons (or two positrons) of identical momentum and spin: the would-be state $b_{\mathbf{p}}^{s\dagger} b_{\mathbf{p}}^{s\dagger} |0\rangle$ is the zero vector.

Proof. Set $r = s$ and $\mathbf{q} = \mathbf{p}$ in the vanishing anticommutator $\left\{ b_{\mathbf{p}}^{r\dagger}, b_{\mathbf{q}}^{s\dagger} \right\} = 0$ (part of Eq. (11.130)). The anticommutator of an operator with itself is twice its square, $\left\{ b_{\mathbf{p}}^{s\dagger}, b_{\mathbf{p}}^{s\dagger} \right\} = 2(b_{\mathbf{p}}^{s\dagger})^2$, so $2(b_{\mathbf{p}}^{s\dagger})^2 = 0$, giving Eq. (11.135); identically for d. A vector of zero norm is the zero vector: applying $b_{\mathbf{p}}^{s\dagger}$ twice to $|0\rangle$ returns nothing to act on. □

Physical Insight

The exclusion principle, which the reader met in nonrelativistic quantum mechanics as an empirical rule grafted onto many-electron atoms, is here a *theorem*: it is the $\mathbf{q} \to \mathbf{p}$, $r \to s$ corner of the anticommutation relations that spin-$\frac{1}{2}$ quantization forced upon us. One cannot put two identical electrons in the same mode for the same reason one cannot square a Grassmann number: the creation operator is nilpotent. Atomic shell structure, the stability of bulk matter, the Fermi surface of a metal — all of chemistry's periodic regularities — trace back to this one line of algebra. The contrast with the scalar is total: there $\left[a_{\mathbf{p}}^{\dagger}, a_{\mathbf{q}}^{\dagger} \right] = 0$ let any number of bosons pile into a mode (Eq. (9.81)); here $\left\{ b_{\mathbf{p}}^{\dagger}, b_{\mathbf{q}}^{\dagger} \right\} = 0$ caps the occupation of each mode at one.

For distinct labels the same vanishing anticommutator gives antisymmetry rather than nullity. The two-electron state obeys

$$b_{\mathbf{p}}^{r\dagger} b_{\mathbf{q}}^{s\dagger} |0\rangle = - b_{\mathbf{q}}^{s\dagger} b_{\mathbf{p}}^{r\dagger} |0\rangle , \tag{11.136}$$

so exchanging the two quanta — both their momenta and their spins together — flips the sign of the state. This is Fermi statistics, and Eq. (11.135) is its diagonal special case: a state antisymmetric under exchange of two identical labels must vanish. The inner product of two such two-electron states exhibits the antisymmetric ("determinant") structure that is the fermionic counterpart of the bosonic permanent of Theorem 9.16.

Worked Example 11.28 (The two-electron inner product is a Slater determinant)**.** We compute ${}_b\langle \mathbf{p}_1 r_1; \mathbf{p}_2 r_2 |\, \mathbf{q}_1 s_1; \mathbf{q}_2 s_2 \rangle_b$ directly from the algebra, where $|\mathbf{p}_1 r_1; \mathbf{p}_2 r_2\rangle_b \equiv b_{\mathbf{p}_1}^{r_1\dagger} b_{\mathbf{p}_2}^{r_2\dagger} |0\rangle$. The bra is $\langle 0|\, b_{\mathbf{p}_2}^{r_2} b_{\mathbf{p}_1}^{r_1}$, so

$${}_b\langle \mathbf{p}_1 r_1; \mathbf{p}_2 r_2 | \mathbf{q}_1 s_1; \mathbf{q}_2 s_2 \rangle_b = \langle 0|\, b_{\mathbf{p}_2}^{r_2} b_{\mathbf{p}_1}^{r_1}\, b_{\mathbf{q}_1}^{s_1\dagger} b_{\mathbf{q}_2}^{s_2\dagger} |0\rangle . \tag{11.137}$$

Anticommute $b_{\mathbf{p}_1}^{r_1}$ to the right through the two creation operators, using $b_{\mathbf{p}_1}^{r_1} b_{\mathbf{q}}^{s\dagger} = \left\{ b_{\mathbf{p}_1}^{r_1}, b_{\mathbf{q}}^{s\dagger} \right\} - b_{\mathbf{q}}^{s\dagger} b_{\mathbf{p}_1}^{r_1}$ each time, picking up a *minus sign* at every step where it

passes a creation operator without contracting:

$$b^{r_1}_{\mathbf{p}_1} b^{s_1\dagger}_{\mathbf{q}_1} b^{s_2\dagger}_{\mathbf{q}_2} = \left\{ b^{r_1}_{\mathbf{p}_1}, b^{s_1\dagger}_{\mathbf{q}_1} \right\} b^{s_2\dagger}_{\mathbf{q}_2} - b^{s_1\dagger}_{\mathbf{q}_1} b^{r_1}_{\mathbf{p}_1} b^{s_2\dagger}_{\mathbf{q}_2}$$
$$= \left\{ b^{r_1}_{\mathbf{p}_1}, b^{s_1\dagger}_{\mathbf{q}_1} \right\} b^{s_2\dagger}_{\mathbf{q}_2} - b^{s_1\dagger}_{\mathbf{q}_1} \left\{ b^{r_1}_{\mathbf{p}_1}, b^{s_2\dagger}_{\mathbf{q}_2} \right\} + b^{s_1\dagger}_{\mathbf{q}_1} b^{s_2\dagger}_{\mathbf{q}_2} b^{r_1}_{\mathbf{p}_1}. \tag{11.138}$$

The last term annihilates $|0\rangle$ on the right of Eq. (11.137). Writing $\left\{ b^{r}_{\mathbf{p}}, b^{s\dagger}_{\mathbf{q}} \right\} \equiv \langle pr|qs\rangle = (2\pi)^3 2E_{\mathbf{p}} \delta^{rs} \delta^3(\mathbf{p}-\mathbf{q})$ for the one-particle norm Eq. (11.134), and then applying $b^{r_2}_{\mathbf{p}_2}$ to the surviving single creation operators,

$$_b\langle \mathbf{p}_1 r_1; \mathbf{p}_2 r_2 | \mathbf{q}_1 s_1; \mathbf{q}_2 s_2 \rangle_b = \langle p_1 r_1 | q_1 s_1 \rangle \langle p_2 r_2 | q_2 s_2 \rangle - \langle p_1 r_1 | q_2 s_2 \rangle \langle p_2 r_2 | q_1 s_1 \rangle. \tag{11.139}$$

The relative minus sign between the two pairings is the entire difference from the bosonic result Eq. (9.85), where both terms appeared with a plus. Equation Eq. (11.139) is a 2×2 determinant — a Slater determinant — and its antisymmetry under $(\mathbf{q}_1 s_1) \leftrightarrow (\mathbf{q}_2 s_2)$ (it changes sign) is the inner-product face of Eq. (11.136). Setting the two outgoing labels equal makes the determinant vanish: two identical fermions have no state, exactly Theorem 11.27.

The pattern generalizes. The n-electron state $b^{s_1\dagger}_{\mathbf{p}_1} \cdots b^{s_n\dagger}_{\mathbf{p}_n} |0\rangle$ is totally antisymmetric under simultaneous exchange of any two label pairs $(\mathbf{p}_i, s_i)$, and an $n \times n$ Slater determinant gives its overlaps. The state space is therefore built not from symmetric tensor powers, as for the boson, but from antisymmetric ones.

Definition 11.29 (The fermionic Fock space)**.** Let $\mathcal{H}_1^{(e)}$ and $\mathcal{H}_1^{(\bar{e})}$ be the one-electron and one-positron spaces spanned by the states Eq. (11.133). The Fock space of the free Dirac field is

$$\mathcal{F} = \bigoplus_{n,\bar{n}=0}^{\infty} \left(\bigwedge^n \mathcal{H}_1^{(e)} \right) \otimes \left(\bigwedge^{\bar{n}} \mathcal{H}_1^{(\bar{e})} \right), \tag{11.140}$$

the direct sum over electron number n and positron number $\bar{n}$ of the *antisymmetric* (exterior) tensor powers $\bigwedge^n$, with $\bigwedge^0 = \mathbb{C}\,|0\rangle$. The exterior power $\bigwedge^n$ implements the Fermi antisymmetry Eq. (11.136) at the level of the space itself, exactly as the symmetric power Sym^n of Theorem 9.17 implemented Bose symmetry.

The occupation-number description is correspondingly stark. In a box, with modes labelled by $(\mathbf{k}, s)$, a basis state is specified by occupation numbers $n_{\mathbf{k},s}$ and $\bar{n}_{\mathbf{k},s}$, each of which — by Theorem 11.27 — can only be 0 or 1. The fermionic Fock space is the antisymmetric counterpart of the scalar's, and "occupation 0 or 1" is the same exclusion principle viewed as a constraint on the basis.

11.4.4 The Hamiltonian: normal ordering and the rescue by anticommutation

We now make contact with dynamics, and meet the place where the fermionic computation diverges from the bosonic one in a way that matters. The energy

and momentum operators are the Noether charges of spacetime translations (Theorem 7.10), the components of the four-momentum built from the Dirac stress tensor. On shell that tensor is $T^{\mu\nu} = i\bar\psi\gamma^\mu\partial^\nu\psi$ (Eq. (6.188)), so

$$P^\mu = \int d^3x\, T^{0\mu} = \int d^3x\, i\,\bar\psi\gamma^0\partial^\mu\psi = \int d^3x\, i\,\psi^\dagger\partial^\mu\psi, \qquad H = P^0 = \int d^3x\, i\,\psi^\dagger\partial_0\psi, \tag{11.141}$$

using $\bar\psi\gamma^0 = \psi^\dagger$. Our task is to substitute Eq. (11.129) and reduce H to the ladder operators. Two ingredients from the spinor algebra of Section 11.2 are needed: the on-shell normalizations

$$u^{r\dagger}(\mathbf{p})\,u^s(\mathbf{p}) = 2E_{\mathbf{p}}\,\delta^{rs}, \qquad v^{r\dagger}(\mathbf{p})\,v^s(\mathbf{p}) = 2E_{\mathbf{p}}\,\delta^{rs}, \tag{11.142}$$

and the orthogonality of a positive-energy spinor against a negative-energy one of reversed three-momentum,

$$u^{r\dagger}(\mathbf{p})\,v^s(-\mathbf{p}) = 0 = v^{r\dagger}(\mathbf{p})\,u^s(-\mathbf{p}), \tag{11.143}$$

both proved in Eqs. (11.65) and (11.67). We now differentiate and integrate.

First, $i\partial_0$ acting on the mode expansion brings down $+E_{\mathbf{p}}$ on each positive-frequency factor $e^{-ip\cdot x}$ and $-E_{\mathbf{p}}$ on each negative-frequency factor $e^{+ip\cdot x}$:

$$i\partial_0\psi(x) = \sum_s \int \widetilde{dq}\; E_{\mathbf{q}}\Big[b^s_{\mathbf{q}}\,u^s(\mathbf{q})\,e^{-iq\cdot x} - d^{s\dagger}_{\mathbf{q}}\,v^s(\mathbf{q})\,e^{+iq\cdot x}\Big]. \tag{11.144}$$

Multiplying by $\psi^\dagger(x) = \sum_r \int \widetilde{dp}\,[\,b^{r\dagger}_{\mathbf{p}}u^{r\dagger}(\mathbf{p})e^{+ip\cdot x} + d^r_{\mathbf{p}}v^{r\dagger}(\mathbf{p})e^{-ip\cdot x}\,]$ and integrating $\int d^3x$ produces, from the spatial parts of the exponentials, either $(2\pi)^3\delta^3(\mathbf{p}-\mathbf{q})$ (for the two "diagonal" pairings $b^\dagger b$ and $d\,d^\dagger$) or $(2\pi)^3\delta^3(\mathbf{p}+\mathbf{q})$ (for the "off-diagonal" pairings $b^\dagger d^\dagger$ and $d\,b$). Consider the four contributions in turn.

The off-diagonal pairings carry the time dependence $e^{\pm 2iE_{\mathbf{p}}t}$ and the spinor factor $u^{r\dagger}(\mathbf{p})v^s(-\mathbf{p})$ or $v^{r\dagger}(\mathbf{p})u^s(-\mathbf{p})$, which vanish by Eq. (11.143). Their disappearance is the operator statement that H is time-independent: had they survived, H would oscillate at $2E_{\mathbf{p}}$. This is the same cancellation seen for the scalar charge in Theorem 9.36, here enforced by the spinor orthogonality rather than by a parity argument. We are left with the two diagonal pairings. The $b^\dagger b$ pairing gives, after the $\widetilde{dq}$ integral collapses $\delta^3(\mathbf{p}-\mathbf{q})$ and Eq. (11.142) collapses the spin sum,

$$\sum_{r,s}\int \widetilde{dp}\,\widetilde{dq}\;(2\pi)^3\delta^3(\mathbf{p}-\mathbf{q})\,E_{\mathbf{q}}\,b^{r\dagger}_{\mathbf{p}}b^s_{\mathbf{q}}\,u^{r\dagger}(\mathbf{p})u^s(\mathbf{q}) = \sum_{r,s}\int \widetilde{dp}\;\frac{E_{\mathbf{p}}}{2E_{\mathbf{p}}}\,b^{r\dagger}_{\mathbf{p}}b^s_{\mathbf{p}}\,(2E_{\mathbf{p}}\delta^{rs}) = \sum_s\int \widetilde{dp}\;E_{\mathbf{p}}\,b^{s\dagger}_{\mathbf{p}}b^s_{\mathbf{p}}, \tag{11.145}$$

where $\int \widetilde{dq}\,(2\pi)^3\delta^3(\mathbf{p}-\mathbf{q}) = 1/2E_{\mathbf{p}}$. The $d\,d^\dagger$ pairing carries the prefactor $-E_{\mathbf{q}}$ from Eq. (11.144) and, after the same reduction,

$$\sum_{r,s}\int \widetilde{dp}\,\widetilde{dq}\;(2\pi)^3\delta^3(\mathbf{p}-\mathbf{q})\,(-E_{\mathbf{q}})\,d^r_{\mathbf{p}}d^{s\dagger}_{\mathbf{q}}\,v^{r\dagger}(\mathbf{p})v^s(\mathbf{q}) = -\sum_s\int \widetilde{dp}\;E_{\mathbf{p}}\,d^s_{\mathbf{p}}d^{s\dagger}_{\mathbf{p}}. \tag{11.146}$$

Adding Eq. (11.145) and Eq. (11.146), the Hamiltonian *before* any reordering is

$$\boxed{H = \sum_s \int \widetilde{dp}\, E_{\mathbf{p}}\, (b^{s\dagger}_{\mathbf{p}} b^s_{\mathbf{p}} - d^s_{\mathbf{p}} d^{s\dagger}_{\mathbf{p}}).} \tag{11.147}$$

Here is the crux. The antiparticle term enters with a *minus sign* and in the *wrong order* $d\,d^\dagger$, and how we resolve that order decides whether the theory is sane. Suppose, against the verdict of Section 11.3, we had quantized with commutators, so that $d\,d^\dagger = d^\dagger d + \left[d, d^\dagger\right]$. Then Eq. (11.147) would read $\int E_{\mathbf{p}}(b^\dagger b - d^\dagger d) - (\text{c-number})$: the positron number operator $d^\dagger d$ would contribute with a *negative* coefficient, and by exciting more and more positrons one could lower the energy without bound. The Hamiltonian would have no ground state. This is precisely the catastrophe that Section 11.3 exhibited and used to reject Bose quantization of the spin-$\frac{1}{2}$ field.

The anticommutators avert it. Using Eq. (11.130) in the form $d^s_{\mathbf{p}} d^{s\dagger}_{\mathbf{p}} = -d^{s\dagger}_{\mathbf{p}} d^s_{\mathbf{p}} + \left\{d^s_{\mathbf{p}}, d^{s\dagger}_{\mathbf{p}}\right\}$, the offending term flips sign:

$$-d^s_{\mathbf{p}} d^{s\dagger}_{\mathbf{p}} = +d^{s\dagger}_{\mathbf{p}} d^s_{\mathbf{p}} - \left\{d^s_{\mathbf{p}}, d^{s\dagger}_{\mathbf{p}}\right\}. \tag{11.148}$$

The positron number operator now appears with a $+$ sign, and Eq. (11.147) becomes

$$H = \sum_s \int \widetilde{dp}\, E_{\mathbf{p}}\, (b^{s\dagger}_{\mathbf{p}} b^s_{\mathbf{p}} + d^{s\dagger}_{\mathbf{p}} d^s_{\mathbf{p}}) + E_0, \qquad E_0 = -\sum_s \int \widetilde{dp}\, E_{\mathbf{p}}\, \left\{d^s_{\mathbf{p}}, d^{s\,\dagger}_{\mathbf{p}}\right\}. \tag{11.149}$$

The constant E_0 is the fermionic zero-point energy. Evaluating the anticommutator at coincident arguments, $\left\{d^s_{\mathbf{p}}, d^{s\dagger}_{\mathbf{p}}\right\} = (2\pi)^3 2E_{\mathbf{p}}\,\delta^3(0) = 2E_{\mathbf{p}} V$ with $\delta^3(0) = V/(2\pi)^3$ the spatial volume, gives

$$E_0 = -\sum_{s=1,2} \int \frac{d^3p}{(2\pi)^3}\, \frac{1}{2E_{\mathbf{p}}}\, E_{\mathbf{p}}\, (2E_{\mathbf{p}} V) = -2\,V \int \frac{d^3p}{(2\pi)^3}\, E_{\mathbf{p}}. \tag{11.150}$$

This is the second contrast promised in the introduction. The scalar zero-point energy was $+\frac{V}{2}\int \frac{d^3p}{(2\pi)^3} E_{\mathbf{p}}$ (Eq. (9.98)); the Dirac one is *negative* and larger in magnitude by the count of fermionic degrees of freedom (the factor 2 from the two spin states, with the sign from the anticommutator). The sign of the vacuum energy is thus a direct readout of statistics.

Physical Insight

That bosonic zero-point energies are positive and fermionic ones negative is not a curiosity but a structural seed. In a theory with equal numbers of bosonic and fermionic degrees of freedom of equal mass, the divergent

vacuum energies Eq. (11.150) and its scalar partner can cancel exactly. This is one of the first things supersymmetry buys, and it is why supersymmetric theories have a vacuum energy under far better control than generic ones. We do not pursue it here; the point is only that the minus sign we just tracked is physical, not bookkeeping.

The constant E_0 is removed exactly as for the scalar (Section 9.4), by normal ordering — with one amendment that the fermionic case forces and that is itself the carrier of all the signs above.

Definition 11.30 (Fermionic normal ordering)**.** Let $:\cdots:$ denote the operation that reorders any product of creation and annihilation operators so that every annihilation operator stands to the right of every creation operator, treating the operators as though they *anti*commuted in the process — that is, *multiplying by* (-1) *for each transposition of two fermionic operators performed during the reordering, and generating no anticommutator (contraction) terms.* For example $:d^s_{\mathbf{p}} d^{s\dagger}_{\mathbf{p}}: \;= -\,d^{s\dagger}_{\mathbf{p}} d^s_{\mathbf{p}}$.

The sign in $:d\,d^\dagger: \;= -d^\dagger d$ is the only difference from the bosonic prescription of Theorem 9.19, and it is exactly the sign of Eq. (11.148): normal ordering keeps the reordered operator product and discards the (here negative, divergent) c-number anticommutator. Applying it to Eq. (11.147),

$$\boxed{:H: \;= \sum_s \int \widetilde{dp}\; E_{\mathbf{p}} \left(b^{s\dagger}_{\mathbf{p}} b^s_{\mathbf{p}} + d^{s\dagger}_{\mathbf{p}} d^s_{\mathbf{p}}\right) = H - E_0.} \tag{11.151}$$

As in the scalar case (Theorem 9.20), subtracting the c-number E_0 changes no commutator and no equation of motion; it only slides the whole spectrum so the vacuum sits at zero energy. We adopt $:H:$ as *the* Hamiltonian of the free Dirac field. Its decisive property, impossible to read off Eq. (11.147) but manifest in Eq. (11.151), is positivity.

Theorem 11.31 (The Hamiltonian is bounded below; the vacuum is its ground state)**.** *The operator* $:H:$ *of Eq. (11.151) satisfies* $:H: \;\geq 0$*, with* $:H:\,|0\rangle = 0$*, and the vacuum is the unique zero-energy state. The one-electron and one-positron states are eigenstates of energy* $E_{\mathbf{p}}$*:*

$$:H:\; b^{s\dagger}_{\mathbf{p}}\,|0\rangle = E_{\mathbf{p}}\, b^{s\dagger}_{\mathbf{p}}\,|0\rangle\,, \qquad :H:\; d^{s\dagger}_{\mathbf{p}}\,|0\rangle = E_{\mathbf{p}}\, d^{s\dagger}_{\mathbf{p}}\,|0\rangle\,. \tag{11.152}$$

Proof. For any state $|\Psi\rangle$, the diagonal matrix element of Eq. (11.151) is

$$\langle\Psi|:H:|\Psi\rangle = \sum_s \int \widetilde{dp}\; E_{\mathbf{p}} \left(\left\| b^s_{\mathbf{p}}\,|\Psi\rangle \right\|^2 + \left\| d^s_{\mathbf{p}}\,|\Psi\rangle \right\|^2\right) \geq 0, \tag{11.153}$$

because each $b^{s\dagger}_{\mathbf{p}} b^s_{\mathbf{p}} = (b^s_{\mathbf{p}})^\dagger b^s_{\mathbf{p}}$ is a positive operator (its expectation is the squared norm of $b^s_{\mathbf{p}}|\Psi\rangle$), each $E_{\mathbf{p}} > 0$, and the measure is positive. The integrand vanishes for all $\mathbf{p}, s$ iff $b^s_{\mathbf{p}}|\Psi\rangle = d^s_{\mathbf{p}}|\Psi\rangle = 0$ for all $\mathbf{p}, s$, which by Theorem 11.25 forces $|\Psi\rangle \propto |0\rangle$; and indeed $:H:|0\rangle = 0$ since every annihilation operator kills $|0\rangle$. Thus 0 is the lowest eigenvalue and $|0\rangle$ its unique eigenstate. For Eq. (11.152) we need the commutator of $:H:$ with a creation operator. The computation uses the fermionic analogue of the identity $[AB, C] = A\,[B, C] + [A, C]\,B$, valid when A, B, C are built from fermionic operators:

$$\left[b^{r\dagger}_{\mathbf{k}} b^r_{\mathbf{k}}, b^{s\dagger}_{\mathbf{q}}\right] = b^{r\dagger}_{\mathbf{k}} \left\{b^r_{\mathbf{k}}, b^{s\dagger}_{\mathbf{q}}\right\} - \left\{b^{r\dagger}_{\mathbf{k}}, b^{s\dagger}_{\mathbf{q}}\right\} b^r_{\mathbf{k}} = b^{r\dagger}_{\mathbf{k}}\,(2\pi)^3 2E_{\mathbf{k}}\delta^{rs}\delta^3(\mathbf{k}-\mathbf{q}), \quad (11.154)$$

the second anticommutator vanishing by Eq. (11.130). (The identity $[AB, C] = A\,\{B, C\} - \{A, C\}\,B$ is checked by expanding both sides; it is the rule that lets a *commutator* of a fermion bilinear with a single fermion be evaluated using *anti*commutators.) Integrating Eq. (11.154) against $E_{\mathbf{k}}$ over the invariant measure gives $\left[:H:, b^{s\dagger}_{\mathbf{q}}\right] = E_{\mathbf{q}}\, b^{s\dagger}_{\mathbf{q}}$, and identically with d. Acting on the vacuum, $:H:\, b^{s\dagger}_{\mathbf{q}}|0\rangle = \left(\left[:H:, b^{s\dagger}_{\mathbf{q}}\right] + b^{s\dagger}_{\mathbf{q}} :H:\right)|0\rangle = E_{\mathbf{q}} b^{s\dagger}_{\mathbf{q}}|0\rangle$, which is Eq. (11.152). □

The number operators $N_b = \sum_s \int \widetilde{dp}\, b^{s\dagger}_{\mathbf{p}} b^s_{\mathbf{p}}$ and $N_d = \sum_s \int \widetilde{dp}\, d^{s\dagger}_{\mathbf{p}} d^s_{\mathbf{p}}$ count electrons and positrons; by the manipulation Eq. (11.154) with $E_{\mathbf{k}} \to 1$ they satisfy $\left[N_b, b^{s\dagger}_{\mathbf{q}}\right] = b^{s\dagger}_{\mathbf{q}}$ and $\left[N_d, d^{s\dagger}_{\mathbf{q}}\right] = d^{s\dagger}_{\mathbf{q}}$, so they return the electron and positron counts of any Fock state. Per mode each takes only the eigenvalues 0 and 1, because $(b^{s\dagger}_{\mathbf{k}})^2 = 0$ (Theorem 11.27) forces $(b^{s\dagger}_{\mathbf{k}} b^s_{\mathbf{k}})^2 = b^{s\dagger}_{\mathbf{k}} b^s_{\mathbf{k}}$ up to the c-number anticommutator, the defining relation of a projector with spectrum $\{0, 1\}$. The exclusion principle is, equivalently, the statement that the occupation of every fermionic mode is a yes/no bit.

11.4.5 Momentum

The spatial momentum is the $\mu = i$ component of Eq. (11.141), $P^i = \int d^3x\, i\psi^\dagger \partial^i \psi$. The computation is the one just done with $i\partial_0$ replaced by $i\partial^i$, which brings down $+p^i$ on the positive-frequency factor and $-p^i$ on the negative-frequency factor. The off-diagonal terms again die by Eq. (11.143), and the diagonal terms give, in exact parallel with Eq. (11.147),

$$\mathbf{P} = \sum_s \int \widetilde{dp}\; \mathbf{p}\,(b^{s\dagger}_{\mathbf{p}} b^s_{\mathbf{p}} - d^s_{\mathbf{p}} d^{s\dagger}_{\mathbf{p}}). \quad (11.155)$$

Anticommuting the d term as in Eq. (11.148) converts $-d\,d^\dagger$ into $+d^\dagger d$ minus a c-number; but this time the c-number, $-\sum_s \int \widetilde{dp}\,\mathbf{p}\left\{d^s_{\mathbf{p}}, d^{s\dagger}_{\mathbf{p}}\right\} \propto \int d^3p\,\mathbf{p}\,\delta^3(0)$, has an *odd* integrand in $\mathbf{p}$ and vanishes identically — there is no zero-point momentum, just as there was none for the scalar (Eq. (9.103)). Hence already

without invoking normal ordering,

$$\boxed{\mathbf{P} = \sum_s \int \widetilde{dp}\, \mathbf{p}\, (b^{s\dagger}_{\mathbf{p}} b^s_{\mathbf{p}} + d^{s\dagger}_{\mathbf{p}} d^s_{\mathbf{p}}).} \tag{11.156}$$

Together with Eq. (11.151) this assembles into the manifestly covariant statement $P^\mu = \sum_s \int \widetilde{dp}\, p^\mu (b^{s\dagger}_{\mathbf{p}} b^s_{\mathbf{p}} + d^{s\dagger}_{\mathbf{p}} d^s_{\mathbf{p}})$ with $p^0 = E_{\mathbf{p}}$, so that

$$P^\mu\, b^{s\dagger}_{\mathbf{p}} |0\rangle = p^\mu\, b^{s\dagger}_{\mathbf{p}} |0\rangle\,, \qquad P^\mu\, d^{s\dagger}_{\mathbf{p}} |0\rangle = p^\mu\, d^{s\dagger}_{\mathbf{p}} |0\rangle\,, \qquad p^\mu = (E_{\mathbf{p}}, \mathbf{p}), \quad p^2 = m^2. \tag{11.157}$$

Both species are on the mass shell $p^2 = m^2$ of a particle of mass m. Notice the relabelling that makes the positron physical: the operator $d^{s\dagger}_{\mathbf{p}}$ multiplies $e^{+ip\cdot x}$ in the field Eq. (11.129), a *negative*-frequency wave, yet it creates a state of *positive* energy $+E_{\mathbf{p}}$ and physical momentum $+\mathbf{p}$. This is the operator resolution of the negative-energy solutions of the classical Dirac equation: rather than describing electrons of negative energy, they are repackaged as positrons of positive energy, exactly the (II),(IV)→ antiparticle reinterpretation anticipated for the backward orbits in Section 3.7.

11.4.6 The charge: electron and positron carry opposite charge

Mass and momentum cannot tell an electron from a positron — Eq. (11.157) treats b and d symmetrically, just as the scalar Hamiltonian treated particle and antiparticle symmetrically (Section 9.7.3). The quantity that distinguishes them is the conserved $U(1)$ charge. The free Dirac Lagrangian Eq. (6.68) is invariant under the global phase rotation $\psi \to e^{-i\alpha}\psi$, $\bar\psi \to e^{+i\alpha}\bar\psi$; by Noether's theorem (Theorem 7.10) this carries the conserved current

$$j^\mu = \bar\psi \gamma^\mu \psi, \qquad \partial_\mu j^\mu = 0, \tag{11.158}$$

the divergence vanishing on shell by the Dirac equation. The associated charge is the spatial integral of $j^0 = \bar\psi\gamma^0\psi = \psi^\dagger\psi$, which we promote to an operator:

$$Q = \int d^3x\, j^0 = \int d^3x\, \psi^\dagger\psi. \tag{11.159}$$

Theorem 11.32 (The Dirac charge operator)**.** *With normal ordering (Theorem 11.30), which fixes the additive constant by demanding $Q|0\rangle = 0$,*

$$Q = \sum_s \int \widetilde{dp}\, (b^{s\dagger}_{\mathbf{p}} b^s_{\mathbf{p}} - d^{s\dagger}_{\mathbf{p}} d^s_{\mathbf{p}}) = N_b - N_d. \tag{11.160}$$

It assigns the ladder operators definite charges,

$$\left[Q, b^{s\dagger}_{\mathbf{p}}\right] = +\, b^{s\dagger}_{\mathbf{p}}, \qquad \left[Q, d^{s\dagger}_{\mathbf{p}}\right] = -\, d^{s\dagger}_{\mathbf{p}}, \qquad \left[Q, b^s_{\mathbf{p}}\right] = -\, b^s_{\mathbf{p}}, \qquad \left[Q, d^s_{\mathbf{p}}\right] = +\, d^s_{\mathbf{p}}, \tag{11.161}$$

so the electron carries $Q = +1$ and the positron $Q = -1$.

Proof. Substitute the mode expansions for $\psi^\dagger$ and ψ into Eq. (11.159) and integrate $\int d^3x$. The structure is the energy computation of Section 11.4.4 with the operator $i\partial_0$ deleted, so every $E_{\mathbf{q}}$ prefactor is replaced by 1 and the relative minus sign between the two frequency components is gone. The off-diagonal pairings again vanish by Eq. (11.143); the diagonal pairings, reduced with Eq. (11.142), give

$$Q = \sum_s \int \widetilde{dp}\, (b^{s\dagger}_{\mathbf{p}} b^s_{\mathbf{p}} + d^s_{\mathbf{p}} d^{s\dagger}_{\mathbf{p}}). \tag{11.162}$$

The positron term is in the wrong order, with a *plus* sign this time (there is no $i\partial_0$ to supply the relative minus that Eq. (11.147) carried). Normal ordering reorders it with the fermionic sign of Theorem 11.30, $:d^s_{\mathbf{p}} d^{s\dagger}_{\mathbf{p}}: \;= -d^{s\dagger}_{\mathbf{p}} d^s_{\mathbf{p}}$, discarding the divergent c-number $+\sum_s \int \widetilde{dp}\, \left\{d^s_{\mathbf{p}}, d^{s\dagger}_{\mathbf{p}}\right\}$ (the charge analogue of the zero-point energy, naturally zero because the vacuum is neutral). This yields Eq. (11.160). The commutators Eq. (11.161) follow from Eq. (11.154): $\left[N_b, b^{s\dagger}_{\mathbf{p}}\right] = +b^{s\dagger}_{\mathbf{p}}$, and the explicit minus in front of N_d in Eq. (11.160) flips the sign for d, giving $\left[Q, d^{s\dagger}_{\mathbf{p}}\right] = -d^{s\dagger}_{\mathbf{p}}$; the annihilation relations are the Hermitian conjugates. Finally, $[Q,\psi] = \sum_s \int \widetilde{dp}(\left[Q, b^s_{\mathbf{p}}\right] u^s e^{-ipx} + \left[Q, d^{s\dagger}_{\mathbf{p}}\right] v^s e^{+ipx}) = -\psi$, so $e^{i\alpha Q}\psi\, e^{-i\alpha Q} = e^{-i\alpha}\psi$: Q generates the very $U(1)$ rotation it was built from, closing the loop with Noether. □

The reading of Eq. (11.160) is the same as for the complex scalar (Theorem 9.36), and that parallel is the point: the scalar furnished the bosonic template — a charge that counts particles minus antiparticles, with the two species of equal mass and opposite charge — and the Dirac field now realizes the identical structure for spin $\frac{1}{2}$. Acting on the one-particle states,

$$Q\,|\mathbf{p},s\rangle_b = +\,|\mathbf{p},s\rangle_b\,, \qquad Q\,|\mathbf{p},s\rangle_d = -\,|\mathbf{p},s\rangle_d\,, \tag{11.163}$$

two species of equal mass m (both on the shell of the single field ψ) and opposite charge. Because $[Q, :H:\,] = 0$ — both are diagonal in N_b, N_d — charge is conserved, and because Q generates the symmetry it superselects: states of different charge never mix.

Notation Watch

The operator Q of Eq. (11.160) is the *number* charge, normalized so that the electron carries $+1$. The physical *electric* charge operator is $q\,Q$ with $q = -e < 0$ the electron's charge, in the convention $D_\mu = \partial_\mu + ieA_\mu$ ($e > 0$) fixed for this chapter and for all of QED. Thus $b^{s\dagger}$ creates the negatively charged electron and $d^{s\dagger}$ the positively charged positron. What is convention-independent is that the two species carry *opposite* charge

of *equal* magnitude and that the vacuum is neutral; the overall sign and unit are tied to the gauge-coupling convention, exactly as flagged for the scalar in Section 9.7.3. No gauge field is switched on in this chapter; the coupling $q\,Q\,A_0$ that makes "$-e$" the measured charge is installed when ψ is minimally coupled to the photon of Chapter 13.

11.4.7 The electron is a mass-m, spin-$\frac{1}{2}$ Poincaré particle

We have shown the excitations carry energy $E_{\mathbf{p}}$, momentum $\mathbf{p}$ on the mass shell, and charge ± 1. To certify that the electron is a *particle* in the precise sense of Chapter 3 — and to read off its spin — we must show the one-electron states furnish an irreducible representation of the Poincaré group and identify which one. The first Casimir is already in hand: Eq. (11.157) gives $P^2\,|\mathbf{p},s\rangle_b = p^2\,|\mathbf{p},s\rangle_b = m^2\,|\mathbf{p},s\rangle_b$, a single sharp mass $m>0$. What is new, and what the two-valued label s exists to encode, is the second Casimir — the spin.

By Wigner's classification (Section 3.7), a positive-energy massive irreducible representation is labelled by $m>0$ together with a representation of the little group, the subgroup that fixes a chosen rest-frame momentum, which for $m>0$ is the rotation group, realized on quantum states as its double cover $SU(2)$ (Section 3.7.2). The spin is the $SU(2)$ representation that the rest-frame states form. We therefore go to the rest frame and watch how rotations act on the two states $b^{1\dagger}_{\mathbf{0}}\,|0\rangle$ and $b^{2\dagger}_{\mathbf{0}}\,|0\rangle$.

The input is the transformation law of the field under the unitary $U(\Lambda)$ that implements a Lorentz transformation Λ on Fock space, established in Eq. (11.164):

$$U(\Lambda)\,\psi(x)\,U(\Lambda)^{-1} = S(\Lambda)^{-1}\psi(\Lambda x), \qquad S(\Lambda)=\exp\!\Big(-\tfrac{i}{2}\,\omega_{\mu\nu}S^{\mu\nu}\Big), \quad S^{\mu\nu}=\tfrac{i}{4}\,[\gamma^{\mu},\gamma^{\nu}]\,, \tag{11.164}$$

where $S^{\mu\nu}$ is the spinor representation of the Lorentz generators built in Eq. (3.114), and $\omega_{\mu\nu}$ parametrizes $\Lambda=\exp(-\frac{i}{2}\omega_{\rho\sigma}M^{\rho\sigma})$. Feeding the mode expansion into both sides of Eq. (11.164) and matching the coefficients of $u^{s}(\mathbf{p})e^{-ip\cdot x}$ — the standard inversion of Eq. (11.101) — determines how $U(\Lambda)$ acts on $b^{s\dagger}_{\mathbf{p}}$. For a general Λ the result is the Wigner construction: $U(\Lambda)b^{s\dagger}_{\mathbf{p}}U(\Lambda)^{-1} = \sum_{s'} D^{(1/2)}\big(W(\Lambda,\mathbf{p})\big)_{s's}\,b^{s'\dagger}_{\Lambda\mathbf{p}}$, where $W(\Lambda,\mathbf{p})$ is the Wigner rotation of Eq. (3.199) and $D^{(1/2)}$ is the spin-$\frac{1}{2}$ representation matrix. We need only the special case that exposes the spin, where the technicalities collapse.

Theorem 11.33 (The one-electron states carry spin $\frac{1}{2}$)**.** *Let R be a rotation by angle θ about $\hat{n}$, represented on four-spinors by $S(R)=\exp(-\frac{i}{2}\theta\,\hat{n}\cdot\mathbf{\Sigma})$, where the rotation generator built from Eq. (3.114) is $S^{ij}=\frac{1}{2}\epsilon^{ijk}\Sigma^{k}$ with $\mathbf{\Sigma}^{k}=\mathrm{diag}(\sigma^{k},\sigma^{k})$*

in the Dirac basis. Acting on the rest-frame one-electron states,

$$U(R)\, b_{\mathbf{0}}^{s\dagger}\, U(R)^{-1} = \sum_{s'} D^{(1/2)}(R)_{s's}\, b_{\mathbf{0}}^{s'\dagger}, \qquad D^{(1/2)}(R) = \exp\Big(-\tfrac{i}{2}\theta\, \hat{n}\cdot\boldsymbol{\sigma}\Big), \tag{11.165}$$

so the rest-frame states $b_{\mathbf{0}}^{1\dagger}|0\rangle$, $b_{\mathbf{0}}^{2\dagger}|0\rangle$ *transform in the two-dimensional (spin-*$\frac{1}{2}$*) representation of the little group* $SU(2)$*. The one-electron space is therefore the mass-*m*, spin-*$\frac{1}{2}$ *irreducible representation of the Poincaré group; likewise the one-positron space.*

Proof. A rotation fixes the rest momentum, $R\mathbf{0} = \mathbf{0}$, so the Wigner rotation degenerates to R itself and the boost technicalities are absent. To see Eq. (11.165) directly, evaluate Eq. (11.164) for $\Lambda = R$ at a point of zero spatial momentum. The rest-frame spinors of Eq. (11.166) are, in the Dirac basis (Eq. (C.56)),

$$u^s(\mathbf{0}) = \sqrt{2m}\begin{pmatrix}\xi^s\\ 0\end{pmatrix}, \qquad \xi^1 = \begin{pmatrix}1\\0\end{pmatrix},\ \xi^2 = \begin{pmatrix}0\\1\end{pmatrix}, \tag{11.166}$$

and the rotation generator acts on them through its upper block: $\boldsymbol{\Sigma}^k u^s(\mathbf{0}) = \sqrt{2m}\binom{\sigma^k \xi^s}{0}$. Hence

$$S(R)\, u^s(\mathbf{0}) = \sqrt{2m}\begin{pmatrix} e^{-\frac{i}{2}\theta\hat{n}\cdot\boldsymbol{\sigma}}\,\xi^s \\ 0\end{pmatrix} = \sum_{s'}\Big(e^{-\frac{i}{2}\theta\hat{n}\cdot\boldsymbol{\sigma}}\Big)_{s's}\, u^{s'}(\mathbf{0}) = \sum_{s'} D^{(1/2)}(R)_{s's}\, u^{s'}(\mathbf{0}), \tag{11.167}$$

the spinor transformation acting purely as the 2×2 rotation $D^{(1/2)}(R)$ on the two-component label. Matching the $\mathbf{p} = \mathbf{0}$ coefficient of the field law Eq. (11.164) (where the argument shift Rx acts trivially on the zero-momentum mode and the invariant measure is rotation-invariant) turns Eq. (11.167) into the operator statement Eq. (11.165): because $U(R)$ rearranges the field's spinor structure by $S(R)^{-1}$ and the rest spinors carry only the $D^{(1/2)}$ action, the rest-frame creation operators mix among themselves by $D^{(1/2)}(R)$. The two states $b_{\mathbf{0}}^{s\dagger}|0\rangle$ thus form the $\mathbf{2}$ of $SU(2)$, the defining feature of spin $\frac{1}{2}$. Combined with $P^2 = m^2$ from Eq. (11.157) and the fact that the full one-electron space is generated from the rest-frame doublet by boosts, Section 3.7.2 identifies the representation as the unique massive spin-$\frac{1}{2}$ irrep. The positron case is identical, with v^s in place of u^s. □

Physical Insight

The two-valuedness of the label s that has ridden along since the mode expansion is now explained: it is the little-group index, the spin-$\frac{1}{2}$ doublet of $SU(2)$. A massive spin-$\frac{1}{2}$ particle has exactly two polarizations, and they are the two rest-frame states $b_{\mathbf{0}}^{1\dagger}|0\rangle$, $b_{\mathbf{0}}^{2\dagger}|0\rangle$ rotated by $D^{(1/2)}$. This is why the Dirac field, with its four components, describes not four but two

physical particles each with two spin states: the $(\frac{1}{2},0)\oplus(0,\frac{1}{2})$ representation of Chapter 3 bundles a particle and its antiparticle, each a spin-$\frac{1}{2}$ doublet, and the extra components are the antiparticle, not redundancy. The mismatch between field components and particle states that plagues the vector field is, for the spinor, no mismatch at all once the antiparticle is counted.

We can now collect the physics of a single electron in one explicit computation, discharging the QED obligation of this chapter.

Worked Example 11.34 (The charge and spin of a one-electron state)**.** Take the rest-frame electron of definite spin along $\hat{z}$, $|e^-,\uparrow\rangle \equiv b_{\mathbf{0}}^{1\dagger}|0\rangle$, normalized informally by setting aside the continuum $\delta^3(0)$. We compute its charge, its energy, and the three quantum numbers J_3, J^2 of its angular momentum.

Charge. From Eq. (11.161) and $Q|0\rangle = 0$,

$$Q|e^-,\uparrow\rangle = \left[Q, b_{\mathbf{0}}^{1\dagger}\right]|0\rangle + b_{\mathbf{0}}^{1\dagger}Q|0\rangle = +b_{\mathbf{0}}^{1\dagger}|0\rangle = +|e^-,\uparrow\rangle\,. \tag{11.168}$$

The number charge is $+1$; the electric charge is $q\cdot(+1) = -e$, the measured electron charge.

Energy. From Eq. (11.152) at $\mathbf{p}=\mathbf{0}$, $:H:\ |e^-,\uparrow\rangle = E_{\mathbf{0}}|e^-,\uparrow\rangle = m|e^-,\uparrow\rangle$: the rest energy is the mass, as it must be.

Spin. The angular momentum operator is $J^k = \frac{1}{2}\epsilon^{kij}M^{ij}$, the rotation part of the Lorentz generators on Fock space; $U(R) = e^{-i\theta\hat{n}\cdot\mathbf{J}}$. Differentiating Eq. (11.165) at $\theta = 0$ about $\hat{n}=\hat{z}$ gives the action of J_3 on the rest-frame ladder operators,

$$\left[J_3, b_{\mathbf{0}}^{s\dagger}\right] = \sum_{s'}\left(\tfrac{1}{2}\sigma^3\right)_{s's} b_{\mathbf{0}}^{s'\dagger}, \tag{11.169}$$

since $D^{(1/2)}(R) = 1 - \frac{i}{2}\theta\,\sigma^3 + \cdots$ for $\hat{n}=\hat{z}$ and $U(R)b^\dagger U(R)^{-1} = b^\dagger - i\theta\left[J_3, b^\dagger\right] + \cdots$. With $\xi^1 = (1,0)^{\mathsf{T}}$ an eigenvector of σ^3 of eigenvalue $+1$,

$$J_3|e^-,\uparrow\rangle = \left[J_3, b_{\mathbf{0}}^{1\dagger}\right]|0\rangle = \tfrac{1}{2}(\sigma^3)_{11}\, b_{\mathbf{0}}^{1\dagger}|0\rangle = +\tfrac{1}{2}\,|e^-,\uparrow\rangle\,. \tag{11.170}$$

The state has $J_3 = +\frac{1}{2}$. The companion $b_{\mathbf{0}}^{2\dagger}|0\rangle$ has $J_3 = -\frac{1}{2}$, so the two rest-frame electrons are the $s_3 = \pm\frac{1}{2}$ states of a spin-$\frac{1}{2}$ doublet. For the Casimir $J^2 = J_1^2 + J_2^2 + J_3^2$, use that on the doublet each J_k acts as $\frac{1}{2}\sigma^k$ and $(\frac{1}{2}\sigma^k)^2 = \frac{1}{4}\mathbf{1}$, so

$$J^2|e^-,\uparrow\rangle = \sum_k\left(\tfrac{1}{2}\sigma^k\right)^2|e^-,\uparrow\rangle = \tfrac{3}{4}\,|e^-,\uparrow\rangle = \tfrac{1}{2}\left(\tfrac{1}{2}+1\right)|e^-,\uparrow\rangle\,, \tag{11.171}$$

the eigenvalue $s(s+1)$ with $s=\frac{1}{2}$. The state is an electron: charge $-e$, mass m, spin $\frac{1}{2}$ with $s_3 = +\frac{1}{2}$ — every quantum number of *the* electron, now an excitation of the quantized Dirac field rather than a postulated particle.

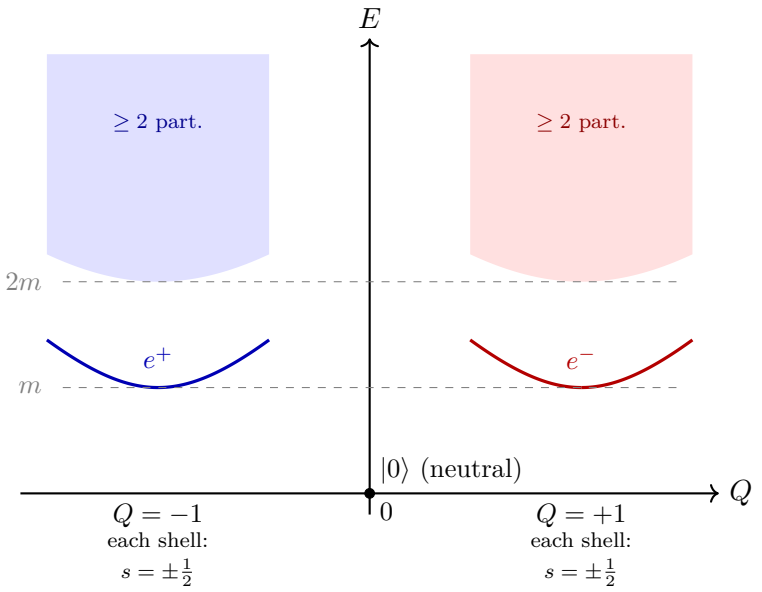


Figure 11.3: Spectrum of the free Dirac field, organized by charge Q (horizontal) and energy E (vertical). The unique vacuum $|0\rangle$ sits neutral at the origin. Two isolated one-particle hyperboloids rise from the mass gap m: electrons ($Q = +1$, electric charge $-e$) and positrons ($Q = -1$, electric charge $+e$), each a spin-$\frac{1}{2}$ doublet ($s_3 = \pm\frac{1}{2}$). Above each lies the multiparticle continuum (threshold $2m$ at rest). Compared with the scalar spectrum of Fig. 9.3, charge doubles the one-particle sector into particle and antiparticle shells, spin gives each shell two states, and the Pauli principle (Theorem 11.27) caps every mode's occupation at one.

Figure 11.3 assembles the resulting spectrum: a unique neutral vacuum, and above it two isolated one-particle hyperboloids — electrons of charge $+1$ and positrons of charge -1 — each carrying two spin states and the same mass gap m, with the multiparticle continuum above. It is the scalar spectrum of Fig. 9.3 doubled by charge, refined by spin, and built on an antisymmetric Fock space.

Caution

The completeness of the physical picture here should not obscure what this chapter has *not* yet proved. We *found* that the spin-$\frac{1}{2}$ field must be quantized with anticommutators (Section 11.3, by the demand for a Hamiltonian bounded below — the very positivity re-derived in Theorem 11.31), but the deep statement that *causality* forces half-integer spin to be fermionic and integer spin bosonic — the spin–statistics connection in full — rests on microcausality of the field anticommutator, which is

the business of Section 11.6.2. There it joins the scalar half established in Theorem 9.33 to complete the theorem the book has been assembling in two pieces.

Handoff

The free Dirac field now has its full physical content: a unique neutral vacuum, an antisymmetric Fock space of electrons and positrons, each a mass-m spin-$\frac{1}{2}$ particle of definite charge, with $:H:$, P^μ, and Q diagonalized on it and the Pauli principle built in. The electron of QED has been promoted from a classical $U(1)$ matter field to a quantum field whose quanta are the particles the rest of the thread will scatter. What remains, before interactions, is the dynamical object that turns this spectrum into amplitudes: the time-ordered two-point function $\langle 0|T\,\psi(x)\bar{\psi}(y)|0\rangle$, whose evaluation on the Fock space just built — and whose covariant momentum-space form S_F with its $i\epsilon$ contour and Green's-function property — is the task of Section 11.5, and the internal fermion line of every diagram from Chapter 17 onward.

11.5 The Dirac Propagator

The previous section completed the kinematic construction of the free Dirac theory: a vacuum $|0\rangle$ annihilated by every lowering operator, an antisymmetric Fock space built on it, a Hamiltonian and a charge that are bounded below and diagonal, and a clean identification of the elementary quanta as electrons and positrons of mass m and spin $\frac{1}{2}$. What that construction does not yet supply is the one object perturbation theory will actually demand: a single distribution that encodes the amplitude for the field to carry a disturbance from one spacetime point to another. For the scalar this was the Feynman propagator D_F of Section 9.5; for the electron it is its spinorial counterpart S_F, the internal fermion line of every diagram from Chapters 15 and 17 onward. This section computes it.

The development runs exactly parallel to the scalar case, and we will lean on that parallel deliberately, importing the scalar machinery wherever it transfers unchanged. Two features are genuinely new, and they are precisely the features that make the electron line different from the scalar line. First, the field is now matrix-valued: the two-point function carries a pair of Dirac indices, and the spin sums $\sum u\bar{u} = \not{p} + m$ and $\sum v\bar{v} = \not{p} - m$ of Theorem 11.12 are what convert the sum over intermediate spin states into a covariant numerator. Second, the fields anticommute, and the time-ordering symbol must be defined with a relative minus sign to respect that. We will see that this single sign is not a blemish to be tolerated but the exact ingredient that makes the assembly work:

it is what allows the manifestly covariant momentum integral to reproduce the operator time-ordered product, and what makes S_F a Green's function of the Dirac operator rather than of its square. The reward, stated once here and quoted thereafter, is the electron propagator

$$\tilde{S_F}(p) = \frac{i(\not{p} + m)}{p^2 - m^2 + i\varepsilon} = \frac{i}{\not{p} - m + i\varepsilon}, \tag{11.172}$$

the object the QED Feynman rules of Chapter 17 will quote for every internal electron line and which we now derive in full.

We work throughout from the quantized field and its algebra as fixed earlier in the chapter. We recall them in the form needed here. The mode expansion is Eq. (11.95),

$$\psi(x) = \sum_{s=1,2} \int \frac{d^3p}{(2\pi)^3\, 2E_{\mathbf{p}}} \Big[b^s_{\mathbf{p}}\, u^s(p)\, e^{-ip\cdot x} + d^{s\dagger}_{\mathbf{p}}\, v^s(p)\, e^{+ip\cdot x} \Big], \qquad E_{\mathbf{p}} = \sqrt{\mathbf{p}^2 + m^2}, \tag{11.173}$$

with $p^0 = E_{\mathbf{p}}$ on shell and the Lorentz-invariant measure of Theorem 9.4, and the Dirac adjoint $\bar\psi = \psi^\dagger \gamma^0$ is, from Eq. (11.96),

$$\bar\psi(y) = \sum_{r=1,2} \int \frac{d^3q}{(2\pi)^3\, 2E_{\mathbf{q}}} \Big[b^{r\dagger}_{\mathbf{q}}\, \bar u^r(q)\, e^{+iq\cdot y} + d^r_{\mathbf{q}}\, \bar v^r(q)\, e^{-iq\cdot y} \Big]. \tag{11.174}$$

The nonzero anticommutators are Eq. (11.116),

$$\Big\{ b^r_{\mathbf{p}}, b^{s\dagger}_{\mathbf{q}} \Big\} = \Big\{ d^r_{\mathbf{p}}, d^{s\dagger}_{\mathbf{q}} \Big\} = (2\pi)^3\, 2E_{\mathbf{p}}\, \delta^{rs}\, \delta^3(\mathbf{p} - \mathbf{q}), \tag{11.175}$$

all others vanishing, and the equal-time field anticommutator is the postulate Eq. (11.100) now established as the consistent quantization,

$$\Big\{ \psi_a(x), \psi^\dagger_b(y) \Big\} \big|_{x^0 = y^0} = \delta_{ab}\, \delta^3(\mathbf{x} - \mathbf{y}), \qquad \{ \psi_a(x), \psi_b(y) \} \big|_{x^0 = y^0} = 0. \tag{11.176}$$

The completeness relations we will use at every step are the spin sums Eq. (11.73),

$$\sum_{s=1,2} u^s(p)\, \bar u^s(p) = \not{p} + m, \qquad \sum_{s=1,2} v^s(p)\, \bar v^s(p) = \not{p} - m, \tag{11.177}$$

holding as 4×4 matrix identities for every on-shell p. Finally we will repeatedly recognize the *scalar* positive-frequency Wightman function of Theorem 9.23,

$$D^+(x - y) \equiv \langle 0 |\, \phi(x) \phi(y)\, | 0 \rangle = \int \frac{d^3p}{(2\pi)^3\, 2E_{\mathbf{p}}}\, e^{-ip\cdot(x-y)} \tag{11.178}$$

of a mass-m scalar (this is Eq. (9.150)); it is the universal positive-frequency kernel out of which both the scalar and the spinor two-point functions are built, and importing it lets us reuse the scalar contour analysis wholesale.

11.5.1 The fermion Wightman functions

The basic correlators are the two vacuum expectation values of an unordered product of ψ and $\bar\psi$. They carry one Dirac index from ψ and one from $\bar\psi$, so each is a 4×4 matrix-valued distribution.

Definition 11.35 (Fermion Wightman functions)**.** The *positive-* and *negative-frequency Wightman functions* of the free Dirac field are

$$S^+_{ab}(x-y)\equiv\langle 0|\,\psi_a(x)\,\bar\psi_b(y)\,|0\rangle\,,\qquad S^-_{ab}(x-y)\equiv\langle 0|\,\bar\psi_b(y)\,\psi_a(x)\,|0\rangle\,. \tag{11.179}$$

S^+ propagates the electron part of the field (a b-quantum created at y, absorbed at x); S^- propagates the positron part (a d-quantum created at x, absorbed at y).

That each depends only on $x-y$ is, as for the scalar, a consequence of translation invariance of the vacuum, and is seen explicitly in the computation. We do both at once.

Theorem 11.36 (The Wightman functions as Dirac-operator images of the scalar kernel)**.** *The fermion Wightman functions are*

$$S^+(x-y)=\int\frac{d^3p}{(2\pi)^3\,2E_{\mathbf p}}\,(\not p+m)\,e^{-ip\cdot(x-y)}=(i\not\partial_x+m)\,D^+(x-y), \tag{11.180}$$

$$S^-(x-y)=\int\frac{d^3p}{(2\pi)^3\,2E_{\mathbf p}}\,(\not p-m)\,e^{+ip\cdot(x-y)}=-(i\not\partial_x+m)\,D^+(y-x), \tag{11.181}$$

where D^+ is the scalar Wightman kernel Eq. (11.178) and the derivatives act on the x-dependence.

Proof. The positive-frequency function. Insert Eqs. (11.173) and (11.174) into the first definition. The double mode sum contains four operator structures, $bb^\dagger$, bd, $d^\dagger b^\dagger$, and $d^\dagger d$. Sandwiched between vacua only $b^s_{\mathbf p}b^{r\dagger}_{\mathbf q}$ survives: any term with an annihilator (b or d) standing to the right is killed by $|0\rangle$, and any term with a creator standing to the left is killed by $\langle 0|$, which removes bd, $d^\dagger b^\dagger$, and $d^\dagger d$ in turn. Using $\langle 0|\,b^s_{\mathbf p}b^{r\dagger}_{\mathbf q}\,|0\rangle=\langle 0|\left\{b^s_{\mathbf p},b^{r\dagger}_{\mathbf q}\right\}|0\rangle=(2\pi)^3 2E_{\mathbf p}\delta^{rs}\delta^3(\mathbf p-\mathbf q)$ from Eq. (11.175),

$$\begin{aligned}S^+_{ab}(x-y)&=\sum_{r,s}\int\frac{d^3p}{(2\pi)^3 2E_{\mathbf p}}\frac{d^3q}{(2\pi)^3 2E_{\mathbf q}}\,u^s_a(p)\,\bar u^r_b(q)\,e^{-ip\cdot x+iq\cdot y}\,(2\pi)^3 2E_{\mathbf p}\,\delta^{rs}\delta^3(\mathbf p-\mathbf q)\\&=\sum_s\int\frac{d^3p}{(2\pi)^3 2E_{\mathbf p}}\,u^s_a(p)\,\bar u^s_b(p)\,e^{-ip\cdot(x-y)}.\end{aligned} \tag{11.182}$$

The spin sum Eq. (11.177) collapses the spin label to a matrix, $\sum_s u^s_a\bar u^s_b=(\not p+m)_{ab}$, giving the first equality in Eq. (11.180). To extract the differential

operator, note that the polynomial $\not{p}+m$ rides on the on-shell exponential, and $i\not{\partial}_x$ acting on $e^{-ip\cdot(x-y)}$ pulls down exactly $\not{p}$:

$$i\not{\partial}_x\, e^{-ip\cdot(x-y)} = i\,\gamma^\mu(-ip_\mu)\, e^{-ip\cdot(x-y)} = \not{p}\, e^{-ip\cdot(x-y)}, \tag{11.183}$$

so that $(\not{p}+m)e^{-ip\cdot(x-y)} = (i\not{\partial}_x+m)e^{-ip\cdot(x-y)}$. Pulling the (momentum-independent) operator outside the integral turns $\int \frac{d^3p}{(2\pi)^3 2E_{\mathbf{p}}} e^{-ip\cdot(x-y)} = D^+(x-y)$ into the second equality of Eq. (11.180).

The negative-frequency function. For S^- the operator order is reversed, $\bar\psi(y)$ standing to the left of $\psi(x)$. Now the only surviving structure is $d^r_{\mathbf{q}} d^{s\dagger}_{\mathbf{p}}$, with $\langle 0|\, d^r_{\mathbf{q}} d^{s\dagger}_{\mathbf{p}}\, |0\rangle = (2\pi)^3 2E_{\mathbf{p}}\delta^{rs}\delta^3(\mathbf{p}-\mathbf{q})$. The spinor that rides with $d^{s\dagger}_{\mathbf{p}}$ in ψ is $v^s(p)e^{+ip\cdot x}$ and the one riding with $d^r_{\mathbf{q}}$ in $\bar\psi$ is $\bar v^r(q)e^{-iq\cdot y}$, so

$$S^-_{ab}(x-y) = \sum_s \int \frac{d^3p}{(2\pi)^3 2E_{\mathbf{p}}}\, v^s_a(p)\, \bar v^s_b(p)\, e^{+ip\cdot(x-y)} = \int \frac{d^3p}{(2\pi)^3 2E_{\mathbf{p}}}\, (\not{p}-m)_{ab}\, e^{+ip\cdot(x-y)}, \tag{11.184}$$

using the v spin sum $\sum_s v^s\bar v^s = \not{p}-m$. This is the first equality in Eq. (11.181). For the second, the relevant derivative identity carries the opposite sign,

$$i\not{\partial}_x\, e^{+ip\cdot(x-y)} = i\,\gamma^\mu(+ip_\mu)\, e^{+ip\cdot(x-y)} = -\not{p}\, e^{+ip\cdot(x-y)}, \tag{11.185}$$

so that $(\not{p}-m)e^{+ip\cdot(x-y)} = -(m-\not{p})e^{+ip\cdot(x-y)} = -(i\not{\partial}_x+m)e^{+ip\cdot(x-y)}$. Pulling the operator out and recognizing $\int \frac{d^3p}{(2\pi)^3 2E_{\mathbf{p}}} e^{+ip\cdot(x-y)} = \int \frac{d^3p}{(2\pi)^3 2E_{\mathbf{p}}} e^{-ip\cdot(y-x)} = D^+(y-x)$ yields the second equality of Eq. (11.181). □

Three observations organize what follows. First, the entire spinor content of both Wightman functions is the single scalar kernel D^+ acted on by the matrix differential operator $i\not{\partial}+m$. Everything we proved about D^+ in Section 9.5 — its positive-frequency analyticity, its Lorentz invariance, its distributional nature, its non-vanishing at spacelike separation — transfers immediately, dressed by a Dirac matrix. This is the structural reason the fermion propagator costs so little once the scalar one is in hand. Second, S^+ and S^- are *not* complex conjugates of one another the way the two scalar orderings were; they are built from the two physically distinct spin sums $\not{p}\pm m$, encoding that the field creates a positron where it annihilates an electron. Third — the fact we will need for the time-ordered product — both Wightman functions individually solve the homogeneous Dirac equation. Acting with $(i\not{\partial}_x - m)$ on Eq. (11.180) and using $(i\not{\partial}-m)(i\not{\partial}+m) = -(\Box+m^2)$ (a one-line Clifford computation, $(\gamma^\mu\partial_\mu)^2 = \frac{1}{2}\{\gamma^\mu,\gamma^\nu\}\,\partial_\mu\partial_\nu = \partial^2$),

$$(i\not{\partial}_x - m)\, S^+(x-y) = -(\Box_x + m^2)\, D^+(x-y) = 0, \qquad (i\not{\partial}_x - m)\, S^-(x-y) = 0, \tag{11.186}$$

since D^+ is built from on-shell modes annihilated by $(\Box + m^2)$ (the scalar statement of Section 9.5.1). The Dirac operator annihilates each Wightman piece; only the boundary between them, encoded in the time-ordering step functions, can produce a delta function.

11.5.2 Time ordering with the fermionic minus sign

Perturbation theory in Chapters 14 and 17 is built from vacuum expectation values of time-ordered products. For anticommuting fields the time-ordering symbol must be defined so that interchanging two fields to put them in temporal order costs a minus sign — the same minus that the equal-time anticommutators Eq. (11.176) demand. Without it the symbol would not even be well defined, because for fermionic operators the two orderings differ by an anticommutator, not a commutator.

Definition 11.37 (Fermionic time ordering)**.** For two Dirac field operators the time-ordered product is

$$\mathcal{T}\,\psi(x)\bar{\psi}(y) \equiv \theta(x^0-y^0)\,\psi(x)\bar{\psi}(y) - \theta(y^0-x^0)\,\bar{\psi}(y)\psi(x), \tag{11.187}$$

the later field standing to the left, with a minus sign whenever ordering them requires interchanging the two fermionic operators. More generally $\mathcal{T}$ of a string of fermionic fields is the temporally ordered string times the sign of the permutation that achieves the ordering.

The minus sign is forced by consistency, not chosen for convenience. Consider the symbol at the instant $x^0 = y^0$, where the two step functions both equal $\frac{1}{2}$ in the symmetric convention and the ambiguity in the definition must cancel. The would-be ambiguity is the equal-time difference $\psi(x)\bar{\psi}(y) - (\pm)\bar{\psi}(y)\psi(x)$; only the choice of the relative minus makes this the equal-time *anti*commutator

$$\psi_a(x)\bar{\psi}_b(y)+\bar{\psi}_b(y)\psi_a(x)\big|_{x^0=y^0} = \Big\{\psi_a(x),\bar{\psi}_b(y)\Big\}\big|_{x^0=y^0} = \Big\{\psi_a(x),\psi_c^\dagger(y)\Big\}\gamma^0_{cb}\big|_{x^0=y^0} = \gamma^0_{ab}\,\delta^3(\mathbf{x}-\mathbf{y} \tag{11.188}$$

a c-number (the unit matrix in field space times γ^0). Had we used a relative plus, the ambiguity at coincident times would have been the equal-time *commutator*, which is operator-valued and does not even vanish for spacelike separation — the symbol would be ill defined. The fermionic minus sign is exactly what renders $\mathcal{T}$ unambiguous, and Eq. (11.188) is the identity that will produce the delta function in the Green's-function property below.

Definition 11.38 (Dirac–Feynman propagator)**.** The *Feynman propagator* of the free Dirac field is the time-ordered two-point function

$$S_F(x-y)_{ab} \equiv \langle 0|\,\mathcal{T}\,\psi_a(x)\bar{\psi}_b(y)\,|0\rangle\,. \tag{11.189}$$

Taking the vacuum expectation value of Eq. (11.187) and inserting the Wightman functions Eq. (11.179) for the two orderings gives at once the position-space form

$$S_F(x-y) = \theta(x^0-y^0)\, S^+(x-y) - \theta(y^0-x^0)\, S^-(x-y), \tag{11.190}$$

the spinor analogue of the scalar Eq. (9.153), distinguished from it by the relative minus sign on the antiparticle term. This is the exact target the covariant momentum integral must reproduce.

11.5.3 Assembling S_F from the scalar propagator

The position-space expression Eq. (11.190) is correct but inherits the awkwardness of the scalar case: it is on-shell integrals glued with step functions, and the relative minus sign sits there unexplained. The clean statement is that S_F is simply the Dirac operator applied to the *scalar* Feynman propagator D_F of Theorem 9.24, and that this single identity packages the relative minus sign automatically.

Theorem 11.39 (S_F as the Dirac image of D_F)**.** *The Dirac–Feynman propagator is*

$$\boxed{S_F(x-y) = (i\not{\partial}_x + m)\, D_F(x-y)} \tag{11.191}$$

where $D_F(x-y) = \theta(x^0-y^0)D^+(x-y) + \theta(y^0-x^0)D^+(y-x)$ is the scalar Feynman propagator of a mass-m field, Eq. (9.153).

Proof. We apply $(i\not{\partial}_x + m)$ to the scalar D_F and show the result is Eq. (11.190). The only subtlety is that $\not{\partial} = \gamma^0\partial_{x^0} + \gamma^i\partial_{x^i}$ contains a time derivative that acts on the step functions. Write $t = x^0 - y^0$ and use $\partial_{x^0}\theta(t) = \delta(t) = -\partial_{x^0}\theta(-t)$:

$$\begin{aligned}(i\not{\partial}_x + m)\, D_F = i\gamma^0\Big[\delta(t)D^+(x-y) - \delta(t)D^+(y-x)\Big] \\ + \theta(t)\,(i\not{\partial}_x + m)D^+(x-y) + \theta(-t)\,(i\not{\partial}_x + m)D^+(y-x).\end{aligned} \tag{11.192}$$

The bracketed delta term is evaluated at $t = 0$, i.e. at equal times, where $D^+(x-y) - D^+(y-x) = \langle 0|\,[\phi(x),\phi(y)]\,|0\rangle$ is the scalar commutator function Eq. (9.173), which vanishes at equal times (the equal-time commutator of the scalar field with itself is zero). Hence the entire $i\gamma^0\delta(t)$ contribution drops:

$$(i\not{\partial}_x + m)\, D_F = \theta(t)\,(i\not{\partial}_x + m)D^+(x-y) + \theta(-t)\,(i\not{\partial}_x + m)D^+(y-x). \tag{11.193}$$

Now compare with the Wightman results. By Eq. (11.180), $(i\not{\partial}_x + m)D^+(x-y) = S^+(x-y)$; by Eq. (11.181), $(i\not{\partial}_x + m)D^+(y-x) = -S^-(x-y)$. Substituting,

$$(i\not{\partial}_x + m)\, D_F = \theta(t)\, S^+(x-y) - \theta(-t)\, S^-(x-y) = S_F(x-y), \tag{11.194}$$

which is exactly Eq. (11.190). □

The proof exposes where the fermionic minus sign comes from and why it is benign. The relative minus in the time-ordered product Eq. (11.187) is met, term for term, by the relative minus that the operator $(i\partial\!\!\!/ + m)$ produces between $e^{-ip\cdot(x-y)}$ and $e^{+ip\cdot(x-y)}$ (compare Eqs. (11.183) and (11.185)): the antiparticle Wightman function S^- enters S_F with the sign $-S^- = +(i\partial\!\!\!/ + m)D^+(y-x)$, which is exactly what $(i\partial\!\!\!/ + m)$ acting on the second piece of D_F delivers. The two minus signs are the same sign, viewed from two sides. Moreover the potentially dangerous contact term — the $i\gamma^0\delta(t)$ contribution from differentiating the step functions — vanishes here because it is proportional to the equal-time scalar commutator, which is zero. (It will *not* vanish when we instead apply the full Dirac operator $(i\partial\!\!\!/ - m)$ to compute the Green's-function property below; there it produces precisely the delta function we want. The difference between the two operators is the difference between $S^{\pm}$ solving the homogeneous equation and the canonical anticommutator surfacing.)

11.5.4 The momentum-space propagator and the $i\varepsilon$ contour

With Theorem 11.39 the covariant momentum-space form is immediate: we apply the Dirac operator to the scalar contour representation Theorem 9.25, inheriting its entire p^0-contour analysis at no extra cost.

Theorem 11.40 (Momentum-space Dirac propagator)**.** *The Dirac–Feynman propagator admits the manifestly covariant representation*

$$S_F(x-y) = \int \frac{d^4p}{(2\pi)^4}\, \tilde{S}_F(p)\, e^{-ip\cdot(x-y)}, \qquad \boxed{\tilde{S}_F(p) = \frac{i(p\!\!\!/ + m)}{p^2 - m^2 + i\varepsilon} = \frac{i}{p\!\!\!/ - m + i\varepsilon}} \tag{11.195}$$

where p^0 ranges over all of $\mathbb{R}$ independently of $\mathbf{p}$, $\varepsilon \to 0^+$, the equality holds as a 4×4 matrix-valued tempered distribution, and the second form is the matrix inverse defined by the first.

Proof. Start from Eq. (11.191) and insert the scalar contour representation Eq. (9.154),

$$D_F(x-y) = \int \frac{d^4p}{(2\pi)^4}\, \frac{i\, e^{-ip\cdot(x-y)}}{p^2 - m^2 + i\varepsilon}. \tag{11.196}$$

Apply $(i\partial\!\!\!/_x + m)$ under the integral. Because p now ranges over all four components off shell, the identity Eq. (11.183) still holds verbatim — it is a property of the exponential, not of the mass shell — so $(i\partial\!\!\!/_x + m)e^{-ip\cdot(x-y)} = (p\!\!\!/ + m)e^{-ip\cdot(x-y)}$ and

$$S_F(x-y) = \int \frac{d^4p}{(2\pi)^4}\, \frac{i(p\!\!\!/ + m)}{p^2 - m^2 + i\varepsilon}\, e^{-ip\cdot(x-y)}, \tag{11.197}$$

which is the first form in Eq. (11.195). The denominator is the same scalar denominator as in Eq. (11.196); the numerator $p\!\!\!/ + m$ is a first-degree matrix

polynomial in p that introduces no new poles in the complex p^0 plane. Therefore the p^0 contour analysis is identical to the scalar one of Theorem 9.25: the poles sit at $p^0 = +E_{\mathbf{p}} - i\varepsilon'$ (below the real axis) and $p^0 = -E_{\mathbf{p}} + i\varepsilon'$ (above it), and for $x^0 > y^0$ the contour closes downward onto the first, for $x^0 < y^0$ upward onto the second. The matrix numerator simply rides along, evaluated at the captured pole. We confirm in Theorem 11.41 below that this reproduces Eq. (11.190) directly, with the spin sums emerging from the residues; here it suffices that the denominator and the contour are exactly the scalar ones, so the equality of Eq. (11.197) with the operator S_F is inherited from the scalar theorem.

It remains to derive the compact second form. Factor the scalar denominator using the Clifford algebra Eq. (11.2) (the canon Eq. (C.1)), which gives

$$\not{p}\not{p} = p_\mu p_\nu \, \gamma^\mu \gamma^\nu = p_\mu p_\nu \, \tfrac{1}{2} \{\gamma^\mu, \gamma^\nu\} = p_\mu p_\nu \, \eta^{\mu\nu} = p^2, \tag{11.198}$$

the symmetrization being legitimate because $p_\mu p_\nu$ is symmetric in $\mu\nu$. Hence

$$(\not{p} + m)(\not{p} - m) = \not{p}\not{p} - m^2 = p^2 - m^2 = (\not{p} - m)(\not{p} + m), \tag{11.199}$$

so $\not{p} + m$ and $\not{p} - m$ commute and their product is the scalar $p^2 - m^2$. Reading Eq. (11.199) as a statement about matrix inverses, away from the mass shell where $p^2 - m^2 \neq 0$,

$$(\not{p} - m)^{-1} = \frac{\not{p} + m}{(\not{p} - m)(\not{p} + m)} = \frac{\not{p} + m}{p^2 - m^2}. \tag{11.200}$$

Therefore the numerator-and-denominator form equals $i(\not{p} - m)^{-1}$ once the $i\varepsilon$ is restored to keep the inverse well defined on the shell:

$$\frac{i(\not{p} + m)}{p^2 - m^2 + i\varepsilon} = \frac{i}{\not{p} - m + i\varepsilon}, \tag{11.201}$$

which is the second form in Eq. (11.195). The symbol $1/(\not{p} - m + i\varepsilon)$ is *defined* to mean $(\not{p}+m)/(p^2-m^2+i\varepsilon)$; it is not a literal scalar division but the matrix inverse Eq. (11.200) with the Feynman prescription, and the two are interchangeable in every computation. □

Two remarks fix the interpretation. First, the $i\varepsilon$ here is the same routing instruction it was for the scalar, and it carries the same physics: it sends positive-energy electrons forward in time and reinterprets negative-energy solutions as positrons running backward. The contour that captures the $+E_{\mathbf{p}}$ pole for $x^0 > y^0$ yields the electron piece S^+, built from $\sum u\bar{u} = \not{p} + m$; the contour that captures the $-E_{\mathbf{p}}$ pole for $x^0 < y^0$ yields the positron piece $-S^-$, built from $\sum v\bar{v} = \not{p} - m$. The numerator's two spin sums are literally the residues at the two poles. Second, the two equivalent forms in Eq. (11.195) serve different purposes: the form $i(\not{p} + m)/(p^2 - m^2 + i\varepsilon)$ is the one used in actual diagram computations, where

$$\tilde{S}_F(p) = \frac{i(\not{p} + m)}{p^2 - m^2 + i\varepsilon} = \frac{i}{\not{p} - m + i\varepsilon}$$

Figure 11.4: The internal electron line. The arrow on a fermion line records the flow of the conserved $U(1)$ charge of Theorem 11.32, here pointing from the $\bar{\psi}_b(y)$ end to the $\psi_a(x)$ end. To this oriented line the QED Feynman rules of Chapter 17 assign the momentum-space propagator $\tilde{S}_F(p)$, with Dirac indices a (at the ψ end) and b (at the $\bar{\psi}$ end) contracted into the vertices at either end. Read with momentum p flowing along the arrow, the same line describes an electron propagating forward in time or, for the opposite sign of p^0, a positron propagating backward, the two being the residues at $p^0 = \pm E_{\mathbf{p}}$.

the explicit numerator feeds the gamma-matrix traces of Chapter 17; the compact form $i/(\not{p} - m + i\varepsilon)$ is the one to remember, and it makes the Green's-function property transparent, as we see next.

Notation Watch

The numerator carries $+i$, and the Dirac propagator is the Green's function of the *first-order* operator $i\not{\partial} - m$ with right-hand side $+i\delta^4$ (proved next), whereas the scalar propagator carried numerator i but was the Green's function of the *second-order* operator $\Box + m^2$ with right-hand side $-i\delta^4$ (Theorem 9.27). The sign difference is not an inconsistency: it is $(i\not{\partial} - m)(i\not{\partial} + m) = -(\Box + m^2)$, the same minus relating the two operators, propagated to their sources. When importing a propagator from another text, check the metric signature, the placement of i, and which operator's Green's function is meant before trusting any sign.

Physical Insight

The Dirac propagator describes one physical process seen two ways, exactly as the scalar one did, but now the two ways are genuinely distinct particles. For $x^0 > y^0$ the line is an electron created at y and absorbed at x, carrying the numerator $\not{p} + m = \sum_s u^s \bar{u}^s$, the projector onto positive-energy electron spin states. For $x^0 < y^0$ it is a positron created at x and absorbed at y, carrying $\not{p} - m = \sum_s v^s \bar{v}^s$. The $i\varepsilon$ is the bookkeeping that routes electrons forward and positrons backward in time so that only positive-energy, forward-in-time propagation of physical quanta ever occurs — the

Stueckelberg–Feynman reinterpretation, now realized on a charged field where particle and antiparticle are not identified.

It is worth confirming the contour claim directly, both to verify that the matrix numerator behaves and to watch the spin sums drop out of the residues as the two physical pieces.

Worked Example 11.41 (The contour integral reproduces the electron and positron pieces)**.** We evaluate the p^0 integral in Eq. (11.197) by residues, exactly as in the scalar Theorem 9.25, and read off the spinor structure. Write $t = x^0 - y^0$ and factor the denominator as in Eq. (9.155), $p^2 - m^2 + i\varepsilon = (p^0 - E_{\mathbf{p}} + i\varepsilon')(p^0 + E_{\mathbf{p}} - i\varepsilon')$, with poles just below $+E_{\mathbf{p}}$ and just above $-E_{\mathbf{p}}$.

Electron piece, $t > 0$. Convergence of $e^{-ip^0 t}$ forces the contour closed in the lower half-plane (clockwise, a factor $-2\pi i$), enclosing only the pole at $p^0 = E_{\mathbf{p}}$. The residue of $i(\not{p} + m)/[(p^0 - E_{\mathbf{p}})(p^0 + E_{\mathbf{p}})]$ there is $i(\not{p} + m)\big|_{p^0 = E_{\mathbf{p}}}/(2E_{\mathbf{p}})$, in which $\not{p} + m$ is now evaluated on shell and is precisely the electron spin sum $\sum_s u^s(p)\bar{u}^s(p)$ of Eq. (11.177). Collecting the $\frac{1}{2\pi}(-2\pi i)$ and the leftover spatial integral exactly as in Eqs. (9.161) and (9.162),

$$S_F(x-y)\big|_{t>0} = \int \frac{d^3p}{(2\pi)^3\, 2E_{\mathbf{p}}}\, (\not{p} + m)\, e^{-ip\cdot(x-y)} = S^+(x-y), \tag{11.202}$$

the positive-frequency Wightman function Eq. (11.180).

Positron piece, $t < 0$. Now the contour closes upward (counterclockwise, $+2\pi i$), enclosing only $p^0 = -E_{\mathbf{p}}$. Write $\bar{p} \equiv (E_{\mathbf{p}}, -\mathbf{p})$; at $p^0 = -E_{\mathbf{p}}$ the four-vector is $p = (-E_{\mathbf{p}}, \mathbf{p}) = -\bar{p}$, so $\not{p}\big|_{p^0 = -E_{\mathbf{p}}} = -\not{\bar{p}}$ and the numerator becomes $\not{p} + m\big|_{p^0 = -E_{\mathbf{p}}} = -(\not{\bar{p}} - m) = -\sum_s v^s(\bar{p})\bar{v}^s(\bar{p})$, minus the positron spin sum. The residue is $i\big(-(\not{\bar{p}} - m)\big)/(-2E_{\mathbf{p}})$, and assembling the $\frac{1}{2\pi}(+2\pi i)$ together with the spatial exponential and then substituting $\mathbf{p} \to -\mathbf{p}$ (so that $\bar{p} \to (E_{\mathbf{p}}, \mathbf{p}) = p$ and the measure is unchanged), one finds, mirroring Eqs. (9.165) and (9.166),

$$S_F(x-y)\big|_{t<0} = -\int \frac{d^3p}{(2\pi)^3\, 2E_{\mathbf{p}}}\, (\not{p} - m)\, e^{+ip\cdot(x-y)} = -\,S^-(x-y), \tag{11.203}$$

the negative-frequency Wightman function with the fermionic minus sign of Eq. (11.190). The two cases combine into $S_F = \theta(t)S^+ - \theta(-t)S^-$, reproducing Eq. (11.190) and confirming Theorem 11.40 independently of Theorem 11.39. The minus sign on the positron piece, which the time-ordering symbol *postulated*, is here *produced* by the contour: it is the relative sign between the on-shell values of $\not{p} + m$ at the two poles, $+\sum u\bar{u}$ versus $-\sum v\bar{v}$.

11.5.5 The propagator is the Green's function of the Dirac operator

We have called S_F a propagator; we now prove it is the Green's function of the Dirac operator. This is the property that makes it the inverse of the kinetic operator, hence the internal line of the perturbative expansion.

Theorem 11.42 (Dirac Green's function)**.** *The Dirac–Feynman propagator satisfies*

$$\boxed{(i\partial\!\!\!/_x - m)\, S_F(x-y) = i\,\delta^4(x-y)\,\mathbf{1}} \tag{11.204}$$

with $\mathbf{1}$ *the* 4×4 *identity in Dirac space, and is therefore (up to the conventional* i*) the Green's function of the first-order Dirac operator* $i\partial\!\!\!/ - m$*.*

Proof, momentum space. Act with $(i\partial\!\!\!/_x - m)$ under the integral in Eq. (11.197). Since $(i\partial\!\!\!/_x - m)e^{-ip\cdot(x-y)} = (p\!\!\!/ - m)e^{-ip\cdot(x-y)}$ by Eq. (11.183),

$$(i\partial\!\!\!/_x - m)\, S_F(x-y) = \int \frac{d^4p}{(2\pi)^4}\, \frac{i\,(p\!\!\!/ - m)(p\!\!\!/ + m)}{p^2 - m^2 + i\varepsilon}\, e^{-ip\cdot(x-y)}. \tag{11.205}$$

By the factorization Eq. (11.199), $(p\!\!\!/ - m)(p\!\!\!/ + m) = p^2 - m^2$, a c-number times the identity matrix, which cancels the denominator up to the $i\varepsilon$:

$$\frac{(p\!\!\!/ - m)(p\!\!\!/ + m)}{p^2 - m^2 + i\varepsilon} = \frac{p^2 - m^2}{p^2 - m^2 + i\varepsilon}\,\mathbf{1} = \Big(1 - \frac{i\varepsilon}{p^2 - m^2 + i\varepsilon}\Big)\mathbf{1}. \tag{11.206}$$

The $i\varepsilon$ term vanishes as a tempered distribution when $\varepsilon \to 0^+$ (its support shrinks to the measure-zero mass shell; this is the scalar statement used in Theorem 9.27). The leading term gives the complete momentum-space delta function $\int \frac{d^4p}{(2\pi)^4} e^{-ip\cdot(x-y)} = \delta^4(x-y)$, so

$$(i\partial\!\!\!/_x - m)\, S_F(x-y) = i\int \frac{d^4p}{(2\pi)^4}\, e^{-ip\cdot(x-y)}\,\mathbf{1} = i\,\delta^4(x-y)\,\mathbf{1}, \tag{11.207}$$

which is Eq. (11.204). □

The momentum-space proof is quickest but hides the physical source of the delta function, which is the canonical equal-time anticommutator. The position-space derivation makes that origin explicit and ties the result back to the quantization postulate Eq. (11.176); it is the fermionic counterpart of the scalar Theorem 9.28, and it is here that the relative minus sign of the time-ordered product earns its keep.

Worked Example 11.43 (Position-space derivation of the Dirac Green's-function identity)**.** We verify Eq. (11.204) starting from the operator form Eq. (11.190),

differentiating the step functions and using the equal-time anticommutator. Write $t = x^0 - y^0$ and split the Dirac operator as $i\partial\!\!\!/_x - m = i\gamma^0\partial_{x^0} + (i\gamma^i\partial_{x^i} - m)$.

The time derivative hits the step functions. Differentiating Eq. (11.190) and using $\partial_{x^0}\theta(t) = \delta(t)$, $\partial_{x^0}\theta(-t) = -\delta(t)$,

$$i\gamma^0\partial_{x^0}S_F = i\gamma^0\,\delta(t)\big[S^+(x-y)+S^-(x-y)\big]+i\gamma^0\Big[\theta(t)\,\partial_{x^0}S^+(x-y)-\theta(-t)\,\partial_{x^0}S^-(x-y)\Big]. \tag{11.208}$$

The crucial sign: S_F carries $-\theta(-t)S^-$, and $\partial_{x^0}\theta(-t) = -\delta(t)$, so the antiparticle term contributes $-(-\delta(t))S^- = +\delta(t)S^-$. The delta term is therefore proportional to the *sum* $S^+ + S^-$, not the difference — this is the fermionic minus sign doing its work. Evaluated at $t = 0$ the coefficient is the equal-time value of

$$\big[S^+ + S^-\big]_{ab}\big|_{t=0} = \langle 0|\,(\psi_a(x)\bar\psi_b(y)+\bar\psi_b(y)\psi_a(x))\,|0\rangle\,\big|_{x^0=y^0} = \langle 0|\,\Big\{\psi_a(x),\bar\psi_b(y)\Big\}\,|0\rangle\,\big|_{x^0=y^0} = \gamma \tag{11.209}$$

using Eq. (11.188), which is itself the canonical anticommutator Eq. (11.176) dressed by γ^0. Thus the delta term in Eq. (11.208) is

$$i\gamma^0\,\delta(t)\,\gamma^0\,\delta^3(\mathbf{x}-\mathbf{y}) = i\,(\gamma^0)^2\,\delta^4(x-y) = i\,\delta^4(x-y)\,\mathbf{1}, \tag{11.210}$$

since $(\gamma^0)^2 = \mathbf{1}$ from the Clifford algebra Eq. (11.2).

The smooth remainder vanishes. Collect the surviving smooth terms: the second bracket of Eq. (11.208) together with the spatial-and-mass part acting on the step-function-weighted Wightman pieces,

$$i\gamma^0\big[\theta(t)\partial_{x^0}S^+ - \theta(-t)\partial_{x^0}S^-\big] + (i\gamma^i\partial_{x^i} - m)\big[\theta(t)S^+ - \theta(-t)S^-\big]. \tag{11.211}$$

The spatial and mass operators pass through the step functions untouched, so Eq. (11.211) reassembles the full Dirac operator on each Wightman piece:

$$\theta(t)\,(i\partial\!\!\!/_x - m)S^+(x-y) - \theta(-t)\,(i\partial\!\!\!/_x - m)S^-(x-y) = 0, \tag{11.212}$$

because each Wightman function solves the homogeneous Dirac equation, $(i\partial\!\!\!/ - m)S^\pm = 0$, established in Eq. (11.186).

Assembly. Only the delta term Eq. (11.210) survives, giving

$$(i\partial\!\!\!/_x - m)\,S_F(x-y) = i\,\delta^4(x-y)\,\mathbf{1}, \tag{11.213}$$

in agreement with Eq. (11.204). As in the scalar case, the delta function is nothing but the canonical equal-time (anti)commutator, here propagated forward by the single time derivative that the first-order Dirac operator supplies — one derivative rather than the scalar's two, because the Dirac equation is first order. The dynamical content of fermionic quantization is made visible in the propagator, and the fermionic minus sign of the time-ordered product is exactly what converts the difference $S^+ - S^-$ that would have vanished into the sum $S^+ + S^-$ that yields the canonical anticommutator.

This completes the construction of the central dynamical object of the free Dirac theory. The propagator Eq. (11.195) is simultaneously the time-ordered vacuum correlator, the Dirac operator applied to the scalar Feynman propagator, the inverse of $i\not{\partial} - m$ with Feynman boundary conditions, and — as Eq. (11.172) — the electron line the QED Feynman rules of Chapter 17 will quote. The contour analysis has also isolated the two Wightman functions $S^{\pm}$ as the residues at the two on-shell poles; whether the local bilinear observables built from ψ commute at spacelike separation — the precise statement of causality, and the requirement that, together with positivity of energy, will be shown to *force* the anticommutator quantization we have used throughout — is the question taken up next, completing the fermionic half of the spin–statistics connection that Chapter 9 deferred.

11.6 Microcausality and the Spin–Statistics Theorem

The previous section assembled the fermion two-point structure: the Wightman functions $S^{\pm}(x-y)$ and, from their time-ordered combination, the Feynman propagator $S_F(x-y)$, the internal electron line of every diagram from Chapter 17 onward. Those objects answer *what amplitude connects two spacetime points.* We now ask the question on which the whole construction stands or falls—the same question the scalar faced in Section 9.6, but with the stakes raised by spin. *Can a measurement made here disturb one made simultaneously outside its light cone?* For the scalar the answer was delivered by a single odd c-number distribution, the Pauli–Jordan function Δ, whose vanishing at spacelike separation *was* relativistic causality; and the same computation, run with the wrong sign, showed that anticommutator quantization of a spin-0 field would have destroyed causality, forcing Bose statistics on the scalar.

This section completes the other half of that story. We compute the anticommutator of the Dirac field, find that it is again controlled by the very same Δ of Theorem 9.29—now dressed by the first-order Dirac operator—and read off two facts at once. First, because Δ vanishes outside the light cone, so does the field anticommutator, and from it the commutator of every *bilinear* observable: the electron field is causal. Second, the calculation run with *commutators* in place of anticommutators produces a c-number of the wrong symmetry—an even function rather than an odd one—which does *not* vanish at spacelike separation, and which, paired with the energy-unboundedness already exposed in Section 11.3, makes the commutator theory inconsistent on two independent counts. The conclusion is the discharge of a debt: the anticommutators we imposed by hand when quantizing the Dirac field were not a choice but a theorem. This is the half-integer instance of the general spin–statistics connection that Theorem 9.33 stated in full generality and explicitly deferred to this chapter.

11.6.1 The anticommutator function

We work in the Heisenberg picture, with the Dirac field carrying its full spacetime dependence through the mode expansion fixed in Section 11.3 and recalled in the normalization of Eq. (11.214),

$$\psi(x) = \int \frac{d^3p}{(2\pi)^3\, 2E_{\mathbf{p}}} \sum_{s=1,2} \Big(b^s_{\mathbf{p}}\, u^s(p)\, e^{-ip\cdot x} + d^{s\dagger}_{\mathbf{p}}\, v^s(p)\, e^{+ip\cdot x} \Big), \tag{11.214}$$

$$\bar\psi(y) = \int \frac{d^3q}{(2\pi)^3\, 2E_{\mathbf{q}}} \sum_{r=1,2} \Big(d^r_{\mathbf{q}}\, \bar v^r(q)\, e^{-iq\cdot y} + b^{r\dagger}_{\mathbf{q}}\, \bar u^r(q)\, e^{+iq\cdot y} \Big), \tag{11.215}$$

with $p^0 = E_{\mathbf{p}} = \sqrt{\mathbf{p}^2 + m^2}$, $p\cdot x = E_{\mathbf{p}} x^0 - \mathbf{p}\cdot\mathbf{x}$ the on-shell Minkowski product in the mostly-minus metric, and the nonzero ladder anticommutators

$$\big\{ b^r_{\mathbf{p}}, b^{s\dagger}_{\mathbf{q}} \big\} = \big\{ d^r_{\mathbf{p}}, d^{s\dagger}_{\mathbf{q}} \big\} = (2\pi)^3\, 2E_{\mathbf{p}}\, \delta^{rs}\, \delta^{(3)}(\mathbf{p}-\mathbf{q}), \tag{11.216}$$

all other pairs vanishing, as fixed in Eq. (11.116). Here $b^{s\dagger}_{\mathbf{p}}$ creates an electron and $d^{s\dagger}_{\mathbf{p}}$ a positron of spin label s; the constant spinors u^s, v^s are the plane-wave solutions of the momentum-space Dirac equation built in Section 11.2, normalized to $\bar u^r u^s = 2m\,\delta^{rs}$, $\bar v^r v^s = -2m\,\delta^{rs}$. This is the relativistic normalization carried throughout the chapter (Eqs. (11.95) and (11.116)): the invariant measure $d^3p/[(2\pi)^3 2E_{\mathbf{p}}]$ and the factor $(2\pi)^3 2E_{\mathbf{p}}$ on the right of the anticommutator.

The basic object of relativistic causality for a Fermi field is the *anticommutator* of ψ with $\bar\psi$, because by Eq. (11.216) it is the anticommutator of ladder operators—not the commutator—that reduces to a c-number. Insert Eqs. (11.214) and (11.215) and expand $\big\{\psi_a(x), \bar\psi_b(y)\big\}$ bilinearly. Of the four operator pairings only $\big\{b, b^\dagger\big\}$ and $\big\{d, d^\dagger\big\}$ survive—the $\{b,b\}$, $\big\{b, d^\dagger\big\}$ and like terms vanish identically because electron and positron ladders anticommute and because $\{b,b\} = \big\{b^\dagger, b^\dagger\big\} = 0$:

$$\begin{aligned}\big\{\psi_a(x), \bar\psi_b(y)\big\} = \int \frac{d^3p}{(2\pi)^3\, 2E_{\mathbf{p}}} \frac{d^3q}{(2\pi)^3\, 2E_{\mathbf{q}}} \sum_{r,s} \Big(&\big\{ b^s_{\mathbf{p}}, b^{r\dagger}_{\mathbf{q}} \big\}\; u^s_a(p)\, \bar u^r_b(q)\, e^{-ip\cdot x + iq\cdot y} \\ &+ \big\{ d^{s\dagger}_{\mathbf{p}}, d^r_{\mathbf{q}} \big\}\; v^s_a(p)\, \bar v^r_b(q)\, e^{+ip\cdot x - iq\cdot y} \Big).\end{aligned} \tag{11.217}$$

Using Eq. (11.216), each ladder anticommutator supplies $(2\pi)^3\, 2E_{\mathbf{p}}\, \delta^{rs}\delta^{(3)}(\mathbf{p}-\mathbf{q})$; the $\mathbf{q}$-integral collapses against the invariant measure (the factor $2E_{\mathbf{p}}$ cancelling one power of $2E_{\mathbf{q}}$), sets $r = s$ and $E_{\mathbf{q}} = E_{\mathbf{p}}$, and turns the two spinor products into spin sums:

$$\big\{\psi_a(x), \bar\psi_b(y)\big\} = \int \frac{d^3p}{(2\pi)^3}\, \frac{1}{2E_{\mathbf{p}}} \Big(\textstyle\sum_s u^s_a(p)\bar u^s_b(p)\, e^{-ip\cdot(x-y)} + \sum_s v^s_a(p)\bar v^s_b(p)\, e^{+ip\cdot(x-y)} \Big). \tag{11.218}$$

The spin sums are the completeness relations derived in this chapter as Eq. (11.73) (and collected, with the trace and contraction technology, in Eq. (C.247)),

$$\sum_s u^s(p)\,\bar{u}^s(p) = \not{p} + m, \qquad \sum_s v^s(p)\,\bar{v}^s(p) = \not{p} - m, \tag{11.219}$$

both understood as 4×4 matrices in the suppressed Dirac indices a, b. Substituting,

$$\Big\{\psi_a(x), \bar{\psi}_b(y)\Big\} = \int \frac{d^3p}{(2\pi)^3}\,\frac{1}{2E_{\mathbf{p}}}\Big[(\not{p}+m)_{ab}\,e^{-ip\cdot(x-y)} + (\not{p}-m)_{ab}\,e^{+ip\cdot(x-y)}\Big]. \tag{11.220}$$

The momentum-space factor $\not{p}$ is now traded for a spacetime derivative, which pulls the entire Dirac structure outside the integral. Acting on a plane wave, the operator $i\not{\partial}_x \equiv i\gamma^\mu\partial_{x^\mu}$ gives

$$i\not{\partial}_x\, e^{-ip\cdot(x-y)} = \not{p}\, e^{-ip\cdot(x-y)}, \qquad i\not{\partial}_x\, e^{+ip\cdot(x-y)} = -\not{p}\, e^{+ip\cdot(x-y)}, \tag{11.221}$$

because $\partial_{x^\mu} e^{\mp ip\cdot(x-y)} = \mp ip_\mu e^{\mp ip\cdot(x-y)}$. Consequently, on the first exponential $(\not{p}+m)e^{-ip\cdot(x-y)} = (i\not{\partial}_x + m)\,e^{-ip\cdot(x-y)}$, while on the second $(i\not{\partial}_x+m)\,e^{+ip\cdot(x-y)} = (-\not{p}+m)\,e^{+ip\cdot(x-y)} = -(\not{p}-m)\,e^{+ip\cdot(x-y)}$, i.e. $(\not{p}-m)e^{+ip\cdot(x-y)} = -(i\not{\partial}_x + m)e^{+ip\cdot(x-y)}$. The single operator $(i\not{\partial}_x + m)$ therefore factors out of *both* terms, leaving the *difference* of the two exponentials:

$$\Big\{\psi_a(x), \bar{\psi}_b(y)\Big\} = (i\not{\partial}_x + m)_{ab}\int \frac{d^3p}{(2\pi)^3}\,\frac{1}{2E_{\mathbf{p}}}\Big(e^{-ip\cdot(x-y)} - e^{+ip\cdot(x-y)}\Big). \tag{11.222}$$

The remaining integral is exactly the one that defined the scalar commutator in Eq. (9.188): it is $i\,\Delta(x-y)$, with Δ the Pauli–Jordan function of Theorem 9.29 for a field of mass m. We have proved:

Theorem 11.44 (The Dirac anticommutator function)**.** *The free Dirac field of mass m satisfies*

$$\boxed{\Big\{\psi_a(x), \bar{\psi}_b(y)\Big\} = (i\not{\partial}_x + m)_{ab}\; i\,\Delta(x-y),} \tag{11.223}$$

where Δ is the scalar Pauli–Jordan function Eq. (9.189), so that $i\Delta(x-y) = [\phi(x),\phi(y)]$ is the c-number commutator of the scalar field of the same mass. Moreover

$$\{\psi_a(x), \psi_b(y)\} = 0, \qquad \Big\{\bar{\psi}_a(x), \bar{\psi}_b(y)\Big\} = 0 \quad \textit{for all } x, y. \tag{11.224}$$

Proof. Equation Eq. (11.223) is Eq. (11.222) with the bracket identified as $i\Delta(x-y)$ via Eq. (9.188). For Eq. (11.224), expand $\{\psi_a(x),\psi_b(y)\}$: every term pairs two annihilation/creation operators of the same statistics, $\{b,b\}$, $\Big\{d^\dagger, d^\dagger\Big\}$,

$\{b, d^\dagger\}$ or $\{d^\dagger, b\}$, each of which vanishes by Eq. (11.216). There is no surviving $\{b, b^\dagger\}$- or $\{d, d^\dagger\}$-type pairing because ψ contains only the operators b and $d^\dagger$. The same argument with $b^\dagger, d$ gives $\{\bar\psi, \bar\psi\} = 0$. □

That the field anticommutator is the scalar Pauli–Jordan function with a Dirac operator in front is the structural fact from which everything in this section follows. The first-order operator $(i\partial\!\!\!/_x + m)$ is precisely the one appearing in the Dirac equation, and applying $(i\partial\!\!\!/_x - m)$ to Eq. (11.223) annihilates the right-hand side, since $(i\partial\!\!\!/ - m)(i\partial\!\!\!/ + m) = -\partial^2 - m^2 = -(\Box + m^2)$ and $(\Box_x + m^2)\Delta(x-y) = 0$ (the Pauli–Jordan function is a solution of the Klein–Gordon equation, as is manifest from its on-shell support); this is the operator statement that ψ obeys its own equation of motion.

Worked Example 11.45 (Equal-time reduction to $\gamma^0\delta^{(3)}$)**.** We confirm that Eq. (11.223) reproduces the canonical equal-time anticommutation relation imposed in quantization. Set $x^0 = y^0$ and recall two equal-time properties of Δ established in Section 9.6.1: it vanishes on the equal-time slice,

$$\Delta(0, \mathbf{x} - \mathbf{y}) = 0, \tag{11.225}$$

(Eq. (9.191)), and its time derivative there is a delta function,

$$\partial_0 \Delta(x)\big|_{x^0=0} = -\,\delta^{(3)}(\mathbf{x}) \tag{11.226}$$

(Eq. (9.192)). Write the Dirac operator as $i\partial\!\!\!/_x + m = i\gamma^0\partial_{x^0} + i\gamma^i\partial_{x^i} + m$ and act on $i\Delta(x-y)$, then set $x^0 = y^0$. The mass term gives $m \cdot i\Delta(0, \mathbf{x}-\mathbf{y}) = 0$ by Eq. (11.225). The spatial-gradient term gives $i\gamma^i\, i\,\partial_{x^i}\Delta(0, \mathbf{x}-\mathbf{y})$; but Δ vanishes *identically* as a function of the spatial argument on the equal-time slice, so its spatial gradient vanishes too. Only the time-derivative term survives:

$$\{\psi_a(x), \bar\psi_b(y)\}\,|_{x^0=y^0} = \gamma^0_{ab}\; i\,\partial_{x^0}\big(i\Delta(x-y)\big)\big|_{x^0=y^0} = \gamma^0_{ab}\,(i)(i)\,\big(-\delta^{(3)}(\mathbf{x}-\mathbf{y})\big) = \gamma^0_{ab}\,\delta^{(3)}(\mathbf{x}-\mathbf{y}), \tag{11.227}$$

using $(i)(i)(-1) = +1$. Multiplying on the right by γ^0 and using $\bar\psi = \psi^\dagger\gamma^0$, $(\gamma^0)^2 = \mathbf{1}$, this is

$$\{\psi_a(\mathbf{x}, t), \psi^\dagger_b(\mathbf{y}, t)\} = \delta_{ab}\,\delta^{(3)}(\mathbf{x} - \mathbf{y}), \tag{11.228}$$

the canonical equal-time anticommutator of Eq. (11.176). The covariant function Eq. (11.223) thus packages the canonical equal-time structure together with its Lorentz-covariant evolution off equal times into a single object—exactly as Δ did for the scalar.

11.6.2 Microcausality of the Dirac field

Everything causal about the elementary field is now inherited from the scalar in one step. The Pauli–Jordan function vanishes at spacelike separation (Theorem 9.31): $\Delta(x-y) = 0$ whenever $(x-y)^2 < 0$, a consequence of Δ being

odd and Lorentz invariant, so that the connectedness of $L_+^\uparrow$ forces $\Delta(x-y) = \Delta(-(x-y)) = -\Delta(x-y)$ on the spacelike orbit. The Dirac anticommutator is a fixed first-order differential operator applied to this function, and a differential operator applied to a function that is *identically zero* on the open spacelike region returns zero there.

Theorem 11.46 (Microcausality of the Dirac field)**.** *For spacelike separation* $(x-y)^2 < 0$*,*

$$\left\{\psi_a(x), \bar{\psi}_b(y)\right\} = 0, \qquad \left\{\psi_a(x), \psi_b^\dagger(y)\right\} = 0. \tag{11.229}$$

Proof. By Theorem 9.31, Δ vanishes on the open set $\{(x-y)^2 < 0\}$. A distribution that is identically zero on an open set has all of its derivatives identically zero there; hence $(i\partial\!\!\!/_x + m)\, i\Delta(x-y) = 0$ throughout that region. By Eq. (11.223) this is $\left\{\psi_a(x), \bar{\psi}_b(y)\right\} = 0$. Multiplying by γ^0 gives the statement for $\psi^\dagger$. (One must check that no derivative acts on the *boundary* of the region, where Δ has light-cone singularities; but spacelike separation is an open condition, and Eq. (11.229) is asserted only in the interior $(x-y)^2 < 0$, where Δ and all its derivatives are honestly zero.) □

Two remarks fix the meaning of this result before we extract its observable consequence. First, the spacelike-vanishing object for the fermion is the *anticommutator*, not the commutator—and that is the entire content of the spin–statistics connection, as we make precise in Section 11.6.4. Second, the field ψ is *not* itself an observable. It carries one unit of electric charge, transforms as a spinor under rotations (acquiring a sign under a 2π rotation), and is in no sense measurable on its own. Microcausality is a statement about *observables*, which are built from *even* numbers of fermion fields; the field anticommutator Eq. (11.229) is the technical lemma, not the physical statement. We now pass to the physical statement.

11.6.3 Causality of bilinear observables

A local fermionic observable is a Hermitian bilinear (or higher even polynomial) in the field and its conjugate at a point,

$$\mathcal{O}_\Gamma(x) = \bar{\psi}(x)\,\Gamma\,\psi(x) = \bar{\psi}_a(x)\,\Gamma_{ab}\,\psi_b(x), \tag{11.230}$$

where Γ is one of the sixteen bilinear covariants of Theorem C.44—the scalar $\mathbf{1}$, the vector γ^μ (the electric current $j^\mu = \bar{\psi}\gamma^\mu\psi$ that couples to the photon in Chapter 13), the tensor $\sigma^{\mu\nu}$, and so on. Each contains exactly two fermion fields, hence is bosonic, and the requirement of microcausality is that two such observables *commute* at spacelike separation. The mechanism by which a vanishing *anti*commutator at the field level produces a vanishing *commutator* at the observable level is a purely algebraic rearrangement, and it is worth isolating because it is the precise point at which fermionic statistics conspires with locality.

Lemma 11.47 (Commutator of bilinears via anticommutators)**.** *For any four operators A, B, C, D,*

$$[AB, CD] = A\,\{B, C\}\,D - \{A, C\}\,BD + CA\,\{B, D\} - C\,\{A, D\}\,B. \tag{11.231}$$

Proof. This is an identity of associative algebra; no assumption on the statistics of A, B, C, D is used. Move CD leftward through AB one factor at a time, replacing each transposition by an anticommutator, $XY = \{X, Y\} - YX$. Starting from $ABCD$ and pushing C to the left,

$$ABCD = A(\,\{B, C\} - CB)D = A\,\{B, C\}\,D - ACBD = A\,\{B, C\}\,D - \{A, C\}\,BD + CABD, \tag{11.232}$$

where in the last step $AC = \{A, C\} - CA$. Now push D to the left through $CABD$,

$$CABD = CA(\,\{B, D\} - DB) = CA\,\{B, D\} - CADB = CA\,\{B, D\} - C\,\{A, D\}\,B + CDAB, \tag{11.233}$$

using $AD = \{A, D\} - DA$. Combining the two and subtracting $CDAB$ gives Eq. (11.231). □

The point of writing the commutator of products through *anticommutators* rather than commutators is that, for the Dirac field, it is the anticommutators that are c-numbers and that vanish at spacelike separation. Identify $A = \bar\psi_a(x)$, $B = \psi_b(x)$, $C = \bar\psi_c(y)$, $D = \psi_d(y)$, and contract with $\Gamma_{ab}\Gamma'_{cd}$:

$$[\mathcal{O}_\Gamma(x), \mathcal{O}_{\Gamma'}(y)] = \Gamma_{ab}\,\Gamma'_{cd}\,\Big[\bar\psi_a(x)\psi_b(x), \bar\psi_c(y)\psi_d(y)\Big]\,. \tag{11.234}$$

Of the four anticommutators generated by Eq. (11.231), two vanish *identically* by Eq. (11.224):

$$\{A, C\} = \Big\{\bar\psi_a(x), \bar\psi_c(y)\Big\} = 0, \qquad \{B, D\} = \{\psi_b(x), \psi_d(y)\} = 0, \tag{11.235}$$

and the surviving two are the mixed anticommutators, each a c-number multiple of the matrix Eq. (11.223):

$$\{B, C\} = \Big\{\psi_b(x), \bar\psi_c(y)\Big\}, \qquad \{A, D\} = \Big\{\bar\psi_a(x), \psi_d(y)\Big\} = \Big\{\psi_d(y), \bar\psi_a(x)\Big\}. \tag{11.236}$$

Therefore

$$[\mathcal{O}_\Gamma(x), \mathcal{O}_{\Gamma'}(y)] = \Gamma_{ab}\Gamma'_{cd}\Big(\bar\psi_a(x)\,\Big\{\psi_b(x), \bar\psi_c(y)\Big\}\,\psi_d(y) - \bar\psi_c(y)\,\Big\{\psi_d(y), \bar\psi_a(x)\Big\}\,\psi_b(x)\Big). \tag{11.237}$$

Each term is now an operator (a single field at x times a single field at y) multiplied by a c-number anticommutator. By Theorem 11.46 both c-number anticommutators vanish for $(x - y)^2 < 0$. We conclude:

Theorem 11.48 (Causality of fermion bilinears)**.** *For any bilinear covariants* Γ, Γ' *and any spacelike separation* $(x-y)^2 < 0$*,*

$$[\mathcal{O}_\Gamma(x), \mathcal{O}_{\Gamma'}(y)] = 0. \tag{11.238}$$

More generally, any two local observables built from even numbers of Dirac fields commute at spacelike separation: the quantized Dirac field is microcausal.

The extension to higher even polynomials is immediate by induction: an observable with $2n$ fields, commuted against another, generates by repeated use of Eq. (11.231) a sum of terms each containing at least one mixed field anticommutator $\{\psi, \bar\psi\}$ or $\{\bar\psi, \psi\}$ (the like-field anticommutators vanish by Eq. (11.224)), and every such anticommutator vanishes spacelike. The crucial bookkeeping is that an *even* number of fermion transpositions is required to bring the two observables past one another, so the rearrangement closes on *anti*commutators with the right signs; an *odd*-field operator (such as ψ itself) would instead *anti*commute spacelike, which is harmless precisely because such an operator is not observable. This is the deep reason fermionic causality is consistent: nature only ever asks even-field operators to commute, and for those the anticommutator algebra delivers exactly that.

Physical Insight

The minus signs of Fermi statistics are not an obstruction to causality—they are its enabler. A vanishing field *anti*commutator would be useless for causality if observables were linear in the field; but observables are bilinear, and the algebra Eq. (11.231) converts the vanishing anticommutator of the constituents into the vanishing commutator of the composite. The scalar achieves the same end with commutators all the way down; the fermion achieves it with one extra layer of signs. Both arrive at the same physical statement: spacelike-separated measurements commute, and no signal outruns light.

Worked Example 11.49 (The electric current commutes with itself spacelike)**.** The single most important fermion bilinear is the electric current $j^\mu(x) = \bar\psi(x)\gamma^\mu\psi(x)$, the operator that will be gauged to the photon in Chapter 13 and whose matrix elements give every QED amplitude of Chapter 17. Causality of the theory requires $[j^\mu(x), j^\nu(y)] = 0$ at spacelike separation; we exhibit the cancellation explicitly. Setting $\Gamma = \gamma^\mu$, $\Gamma' = \gamma^\nu$ in Eq. (11.237),

$$[j^\mu(x), j^\nu(y)] = (\gamma^\mu)_{ab}(\gamma^\nu)_{cd}\Big(\bar\psi_a(x)\, S_{bc}(x-y)\, \psi_d(y) - \bar\psi_c(y)\, S_{da}(y-x)\, \psi_b(x)\Big), \tag{11.239}$$

where we have written the c-number anticommutator as $S_{bc}(x-y) \equiv \{\psi_b(x), \bar\psi_c(y)\} = (i\partial\!\!\!/_x + m)_{bc}\, i\Delta(x-y)$ from Eq. (11.223), and likewise $S_{da}(y-x) = \{\psi_d(y), \bar\psi_a(x)\} =$

$(i\partial\!\!\!/_y + m)_{da}\, i\Delta(y-x)$. Both matrices are $(i\partial\!\!\!/ + m)$ acting on the Pauli–Jordan function evaluated at $\pm(x-y)$. For $(x-y)^2 < 0$ the function Δ and all its derivatives vanish (Theorem 9.31): $\Delta(x-y) = 0$ *and*, since spacelike separation is preserved under $x-y \to y-x$, also $\Delta(y-x) = 0$, the latter equally guaranteed by the oddness $\Delta(-z) = -\Delta(z)$ of Eq. (9.190). Hence $S(x-y) = S(y-x) = 0$ on the spacelike region, both terms of Eq. (11.239) vanish, and $[j^\mu(x), j^\nu(y)] = 0$. The charge density $j^0 = \psi^\dagger\psi$ measured in one laboratory therefore commutes with the current measured simultaneously outside its light cone—no measurement of charge here disturbs a measurement of charge there. This is the local-commutativity property that the Ward–Takahashi identity of Chapter 19 and the whole gauge structure of QED silently presuppose.

11.6.4 The spin–statistics connection for spin $\frac{1}{2}$

We have shown that the anticommutator quantization Eq. (11.216) produces a causal theory. The spin–statistics theorem is the converse and stronger claim: that anticommutators are *forced*—that the alternative, commutator quantization of the spin-$\frac{1}{2}$ field, is inconsistent. We now establish this on two independent grounds, exactly inverting the scalar argument of Section 9.6.5.

Suppose, against the grain, that we had built the Dirac Fock space on *commutators*, declaring

$$\left[b^r_{\mathbf{p}}, b^{s\dagger}_{\mathbf{q}}\right] = \left[d^r_{\mathbf{p}}, d^{s\dagger}_{\mathbf{q}}\right] = (2\pi)^3\, 2E_{\mathbf{p}}\, \delta^{rs}\delta^{(3)}(\mathbf{p}-\mathbf{q}), \tag{11.240}$$

with all other commutators zero—the Bose–Einstein choice. There are two fatal consequences.

First failure: the Hamiltonian is unbounded below. This is the result already obtained in Section 11.3, which we recall in its sharpest form. Expressed in modes, the Dirac Hamiltonian before any reordering is

$$H = \int \frac{d^3p}{(2\pi)^3\, 2E_{\mathbf{p}}}\, E_{\mathbf{p}} \sum_s \left(b^{s\dagger}_{\mathbf{p}} b^s_{\mathbf{p}} - d^s_{\mathbf{p}} d^{s\dagger}_{\mathbf{p}} \right), \tag{11.241}$$

the relative minus sign on the antiparticle term being an unavoidable consequence of the first-order structure of the Dirac Lagrangian (it is the same minus sign that, for the scalar's *second*-order Lagrangian, was absent). Reordering the antiparticle term decides the spectrum. With the *anticommutator* Eq. (11.216), $-d^s_{\mathbf{p}} d^{s\dagger}_{\mathbf{p}} = +d^{s\dagger}_{\mathbf{p}} d^s_{\mathbf{p}} - (2\pi)^3\, 2E_{\mathbf{p}}\, \delta^{(3)}(0)$, so that after dropping the (negative) constant zero-point term,

$$H = \int \frac{d^3p}{(2\pi)^3\, 2E_{\mathbf{p}}}\, E_{\mathbf{p}} \sum_s \left(b^{s\dagger}_{\mathbf{p}} b^s_{\mathbf{p}} + d^{s\dagger}_{\mathbf{p}} d^s_{\mathbf{p}} \right) \;\geq\; 0, \tag{11.242}$$

a sum of manifestly nonnegative number operators (Theorem 11.31): the energy is bounded below and every antiparticle *adds* positive energy. With the *commutator* Eq. (11.240), instead $-d^s_{\mathbf{p}} d^{s\dagger}_{\mathbf{p}} = -d^{s\dagger}_{\mathbf{p}} d^s_{\mathbf{p}} - (2\pi)^3\, 2E_{\mathbf{p}}\, \delta^{(3)}(0)$, and

$$H = \int \frac{d^3p}{(2\pi)^3\, 2E_{\mathbf{p}}}\, E_{\mathbf{p}} \sum_s \left(b^{s\dagger}_{\mathbf{p}} b^s_{\mathbf{p}} - d^{s\dagger}_{\mathbf{p}} d^s_{\mathbf{p}} \right), \tag{11.243}$$

in which each antiparticle quantum *lowers* the energy without limit: piling up d-quanta drives $H \to -\infty$. There is no stable vacuum, no ground state, and the theory is physically meaningless. Commutators are incompatible with positivity of the energy for the Dirac field—hypothesis (ii) of Theorem 9.33.

Second failure: microcausality is violated. Independently of the energy, the commutator choice wrecks locality. With Eq. (11.240) it is now the *commutator* of the fields that reduces to a c-number. Repeating the computation of Section 11.6.1 verbatim, but with the relative sign from $\left[d^{s\dagger}_{\mathbf{p}}, d^r_{\mathbf{q}}\right] = -\left[d^r_{\mathbf{q}}, d^{s\dagger}_{\mathbf{p}}\right] = -(2\pi)^3\, 2E_{\mathbf{p}}\, \delta^{rs}\delta^{(3)}(\mathbf{p}-\mathbf{q})$ flipping the antiparticle term, Eq. (11.220) becomes

$$\left[\psi_a(x), \bar\psi_b(y)\right]_{\text{Bose}} = \int \frac{d^3p}{(2\pi)^3}\, \frac{1}{2E_{\mathbf{p}}} \left[(\not p + m)_{ab}\, e^{-ip\cdot(x-y)} - (\not p - m)_{ab}\, e^{+ip\cdot(x-y)} \right]. \tag{11.244}$$

Now pull out the Dirac operator using Eq. (11.221): the first term is $(i\not\partial_x + m)e^{-ip\cdot(x-y)}$ as before, while the second is $-(\not p - m)e^{+ip\cdot(x-y)} = +(i\not\partial_x + m)e^{+ip\cdot(x-y)}$. The operator factors out of the *sum* of the exponentials this time:

$$\left[\psi_a(x), \bar\psi_b(y)\right]_{\text{Bose}} = (i\not\partial_x + m)_{ab} \int \frac{d^3p}{(2\pi)^3}\, \frac{1}{2E_{\mathbf{p}}} \left(e^{-ip\cdot(x-y)} + e^{+ip\cdot(x-y)} \right) = (i\not\partial_x + m)_{ab} \left[\Delta_+(x-y) + \Delta \right. \tag{11.245}$$

where $\Delta_+(x) = \int \frac{d^3p}{(2\pi)^3} \frac{1}{2E_{\mathbf{p}}} e^{-ip\cdot x} = \langle \phi(x)\phi(0) \rangle$ is the positive-frequency Wightman function of Eq. (9.202). The scalar core has flipped from the *odd* difference $i\Delta = \Delta_+(x-y) - \Delta_+(y-x)$ to the *even* sum $\Delta_+(x-y) + \Delta_+(y-x)$—the very combination that the scalar spin–statistics argument identified as the obstruction. The Lorentz-orbit argument that killed the odd function gives nothing for the even one: for spacelike $x-y$ there is $\Lambda \in L^\uparrow_+$ with $\Lambda(x-y) = -(x-y)$, but the even function is already invariant under this reflection, so we learn only $0 = 0$. Explicit evaluation, carried out in Theorem 9.34, shows the even core is strictly positive at spacelike separation,

$$\left[\Delta_+(x-y) + \Delta_+(y-x)\right]_{(x-y)^2<0} = 2\,\Delta_+(0,\mathbf{r}) = \frac{m}{2\pi^2 r}\, K_1(mr) > 0, \qquad r = \sqrt{-(x-y)^2}, \tag{11.246}$$

with K_1 a modified Bessel function (Eq. (9.203)). Hence the would-be commutator Eq. (11.245) does *not* vanish outside the light cone (Fig. 11.5). Feeding this nonvanishing field commutator into the bilinear rearrangement of Theorem 11.47—which under the Bose assumption must be run with commutators in place of

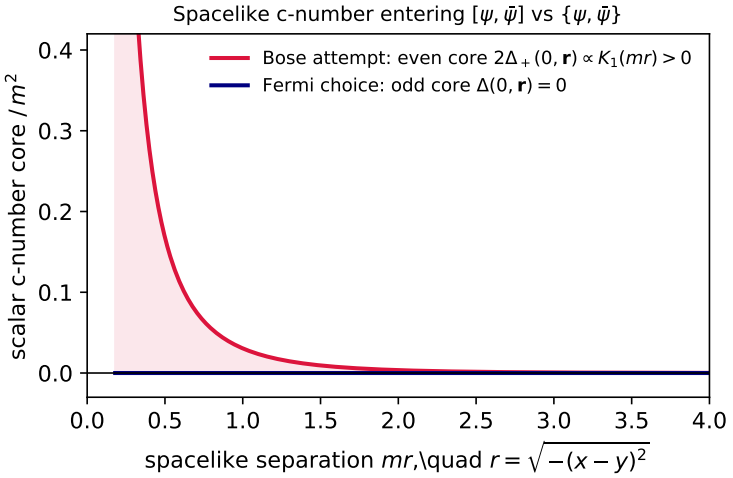

Figure 11.5: The two quantization attempts for the Dirac field, compared on a purely spatial (spacelike) slice $r = \sqrt{-(x-y)^2}$. In both cases the field (anti)commutator is the Dirac operator $(i\partial\!\!\!/ + m)$ acting on a scalar c-number core. For the correct *Fermi* choice the core is the odd Pauli–Jordan function Δ, which vanishes identically at spacelike separation (Theorem 9.31); the field anticommutator is zero and observables commute. For the forbidden *Bose* choice the core is the even combination $2\Delta_+ \propto K_1(mr)$, strictly positive outside the light cone (Eq. (11.246)); the field commutator fails to vanish and causality is destroyed. The accompanying energy argument is independent: Eq. (11.243) shows the Bose Hamiltonian is unbounded below.

anticommutators—leaves the observable commutator $[\mathcal{O}_\Gamma(x), \mathcal{O}_{\Gamma'}(y)]$ operator-valued and nonzero at spacelike separation. Local commutativity Eq. (9.199) fails: the spin-$\frac{1}{2}$ field quantized with commutators is acausal.

Theorem 11.50 (Spin–statistics for the Dirac field)**.** *The free spin-$\frac{1}{2}$ field cannot be consistently quantized with commutators. The Bose algebra Eq. (11.240) produces (i) a Hamiltonian Eq. (11.243) unbounded below, with no stable vacuum, and (ii) a field commutator Eq. (11.245) whose spacelike value Eq. (11.246) is nonzero, violating microcausality. Either failure alone is fatal. Causality and positivity of the energy therefore* force *Fermi–Dirac quantization—the anticommutator algebra Eq. (11.216), for which $H \geq 0$ and $\left\{\psi(x), \bar\psi(y)\right\} = 0$ outside the light cone. A spin-$\frac{1}{2}$ field is necessarily a fermion, and the Pauli exclusion principle $\left(b^{s\dagger}_{\mathbf{p}}\right)^2 = 0$ is its immediate corollary.*

Physical Insight

The decisive sign is again the relative sign between the two exponentials in the field (anti)commutator, and what fixes it is the spin sum Eq. (11.219). For the scalar, the same two-exponential structure carried a coefficient 1 on each term, and microcausality wanted the *odd* difference: commutators, Bose. For the spinor, the antiparticle term carries the spin sum $\sum v\bar{v} = \not{p} - m$, whose mass term has the *opposite* sign to the particle sum $\sum u\bar{u} = \not{p} + m$; this extra relative minus is precisely the $(-1)^{2j} = -1$ of a half-integer-spin field. It converts "odd is wanted" into "even is wanted," so that microcausality now selects the *anticommutator*. Spin dictates statistics through the sign that the field's Lorentz representation deposits in its two-point function—$+1$ for integer spin, -1 for half-integer—and the marriage of relativity (Lorentz invariance plus causality) with quantum mechanics (positivity of the energy) does the rest.

11.6.5 Completing the general spin–statistics theorem

With Theorem 11.50 we discharge, for the free Dirac field, the half-integer half of the general statement that Theorem 9.33 could only assert. It is worth recording precisely what has now been proved in full and what remains without full proof, so the book's honesty about its own scope is exact.

The general theorem (Theorem 9.33) asserts that, given (i) Poincaré invariance with fields in finite-dimensional Lorentz representations labelled by spin j, (ii) a positive-norm Hilbert space with a stable vacuum of lowest energy, and (iii) microcausality, integer-spin fields must be quantized with commutators and half-integer-spin fields with anticommutators, the opposite choice in either case violating one of the hypotheses. The free real scalar gave the $j = 0$ instance completely in Theorem 9.32: there the Lorentz representation is trivial, the spin-sum sign is the bare $+1$, and the argument is the clean even-versus-odd dichotomy. The free Dirac field has now given the $j = \frac{1}{2}$ instance completely: the Lorentz representation is $(\frac{1}{2}, 0) \oplus (0, \frac{1}{2})$, the spin sum supplies the $(-1)^{2j} = -1$, and the two-pronged argument—unbounded H and a spacelike-nonvanishing even commutator—excludes the wrong statistics on both of the theorem's grounds at once. The reader has therefore seen the mechanism in both of its faces: for the boson commutators are forced, for the fermion anticommutators are forced, and in each case it is relativity plus quantum positivity that forces them.

What is *not* proved here is the theorem in full generality, for arbitrary spin and for interacting fields. That proof rests on the analytic structure of the vacuum expectation values $\langle 0|\psi(x_1)\cdots\psi(x_n)|0\rangle$: positivity of the energy (hypothesis (ii)) makes the Wightman functions boundary values of functions holomorphic in a forward tube in the complexified coordinates, and the spacelike

continuation relating $\Delta_+(x)$ to $\Delta_+(-x)$ used above is then a special case of an analytic continuation valid for all spins, with the $(-1)^{2j}$ emerging from the transformation of the field's Lorentz indices under the complex Lorentz rotation by π. This is the Wightman-axiom framework, and it requires the analyticity machinery (the edge-of-the-wedge and Bargmann–Hall–Wightman theorems) that this part of the book has not developed; we therefore quote Theorem 9.33 without full proof and do not reproduce the axiomatic proof. The free spin-0 and spin-$\frac{1}{2}$ cases established are exactly the two on which all of the book's perturbation theory rests, and they have been proved without gaps.

Historical Note

The two-pronged structure of the spin-$\frac{1}{2}$ argument is faithful to its history. Dirac's hole theory (1930) confronted the negative-energy sea of Eq. (11.243) and tamed it by filling the sea and invoking the exclusion principle—a physically correct intuition that the anticommutators of Jordan and Wigner (1928) had already made into an algebra. Pauli's 1940 paper unified the threads, proving that the requirement of a positive energy and the requirement of spacelike (anti)commutativity *both* select Fermi statistics for half-integer spin and Bose statistics for integer spin; the modern axiomatic version, resting on the analyticity of Wightman functions, is due to Lüders, Zumino, and Burgoyne in the 1950s and is set out in the monograph of Streater and Wightman.

The Dirac field is now a fully solved, demonstrably consistent relativistic quantum theory: its excitations are spin-$\frac{1}{2}$ fermions obeying the exclusion principle, its energy is bounded below, its local observables respect the light cone, and the anticommutators imposed in Section 11.3 stand revealed not as a postulate but as the unique quantization compatible with relativity. This causal, positive-energy structure is the bedrock on which the next section builds: having established *that* the bilinear observables are local, we turn to *how* they transform under the discrete operations C, P, and T, and to the CPT combination whose theorem—like spin–statistics—ties the consistency of the field to the geometry of the Lorentz group.

11.7 Discrete Symmetries: C, P, T, and CPT

The previous section closed the structural core of this chapter by proving that the Dirac field is local: its Hermitian bilinear observables commute at spacelike separation, and that microcausality, married to positivity of the energy, is exactly what forces the anticommutator quantization (Section 9.6, Theorem 9.33). We now collect the dividend. A theory that is local, Poincaré invariant, and respects the spin–statistics connection is, almost for free, invariant under a single

antiunitary operation that reflects every spacetime axis and exchanges every particle with its antiparticle. That operation is CPT, and the theorem that guarantees it is one of the deepest structural facts about relativistic quantum field theory. To reach it we must first build its three constituents separately — parity P, charge conjugation C, and time reversal T — as honest operators on the Dirac Fock space, work out how each acts on the field, on the ladder operators, and on the sixteen bilinear covariants, and only then assemble the combination. Along the way we meet a string of physical facts that the rest of the book will lean on: that a fermion and its antifermion carry *opposite* intrinsic parity, that charge conjugation interchanges left- and right-handed quanta, that time reversal reverses both momentum and spin and squares to -1 on a single fermion, and — as a worked aside whose experimental status is still open in the mid-2020s — that a neutral fermion may be its own antiparticle.

The standing conventions of the chapter remain in force: mostly-minus metric $\eta_{\mu\nu} = \mathrm{diag}(+,-,-,-)$, natural units, the Clifford algebra $\{\gamma^\mu, \gamma^\nu\} = 2\eta^{\mu\nu}$ with $\gamma^5 = i\gamma^0\gamma^1\gamma^2\gamma^3$ and $\bar\psi = \psi^\dagger\gamma^0$ (Eq. (11.5)). The discrete-symmetry *matrices* that intertwine $\{\gamma^\mu\}$ with its conjugate sets — the parity matrix γ^0, the charge-conjugation matrix $C = i\gamma^2\gamma^0$, and the time-reversal matrix $T = \gamma^1\gamma^3$ — were constructed once and for all, with all their algebraic properties, in Section C.4; we import them by reference rather than rederive them. We restate only the relations we use at the moment of use. The mode expansion of the quantized field and the ladder algebra are those fixed in Section 11.3; we recall them in the form

$$\psi(x) = \int \frac{d^3p}{(2\pi)^3\, 2E_{\mathbf{p}}} \sum_{s=1,2} \Big(b^s_{\mathbf{p}}\, u^s(p)\, e^{-ip\cdot x} + d^{s\dagger}_{\mathbf{p}}\, v^s(p)\, e^{+ip\cdot x} \Big), \tag{11.247}$$

with $b^s_{\mathbf{p}}$ annihilating an electron and $d^{s\dagger}_{\mathbf{p}}$ creating a positron, both of momentum $\mathbf{p}$ and spin s quantized along a fixed axis, $E_{\mathbf{p}} = +\sqrt{\mathbf{p}^2 + m^2}$, and the nonvanishing anticommutators

$$\{b^r_{\mathbf{p}}, b^{s\dagger}_{\mathbf{q}}\} = \{d^r_{\mathbf{p}}, d^{s\dagger}_{\mathbf{q}}\} = (2\pi)^3\, 2E_{\mathbf{p}}\, \delta^{rs}\, \delta^{(3)}(\mathbf{p}-\mathbf{q}) \tag{11.248}$$

(Eqs. (11.95) and (11.116)). The spinors are normalized by $\bar u^r u^s = 2m\,\delta^{rs} = -\bar v^r v^s$ and obey the completeness relations $\sum_s u^s(p)\bar u^s(p) = \not p + m$, $\sum_s v^s(p)\bar v^s(p) = \not p - m$ from Section 11.2.

Notation Watch

Three pairs of symbols run through this section. The *Fock-space operators* are the calligraphic $\mathcal{P}$ (unitary, parity), $\mathcal{C}$ (unitary, charge conjugation), and $\mathcal{T}$ (*antiunitary*, time reversal); the combined operation is $\Theta = \mathcal{C}\mathcal{P}\mathcal{T}$, also antiunitary. The *spinor matrices* accompanying them are γ^0, $C = i\gamma^2\gamma^0$, and $T = \gamma^1\gamma^3$. Thus $\mathcal{C}$ is an operator on Hilbert space while C is a

4×4 matrix; the parentage is the same but they live in different places. The intrinsic phases are η_P, η_C, η_T, each of unit modulus. We do not use the time-ordering symbol in this section, so no confusion with $\mathcal{T}$ can arise.

11.7.1 Parity

Parity is the spatial reflection $x = (t, \mathbf{x}) \mapsto x_P \equiv (t, -\mathbf{x})$. We seek a unitary operator $\mathcal{P}$ on the Dirac Hilbert space implementing it on the field, $\mathcal{P}\,\psi(t,\mathbf{x})\,\mathcal{P}^{-1} = (\text{matrix})\,\psi(t,-\mathbf{x})$, chosen so that the transformed field again solves the Dirac equation and the Lagrangian is invariant. The matrix is fixed by that demand.

Fixing the matrix from the Dirac equation

Suppose $\psi(x)$ solves $(i\gamma^\mu\partial_\mu - m)\psi(x) = 0$ and write $\psi_P(x) \equiv S_P\,\psi(x_P)$ for some constant 4×4 matrix S_P to be determined. The derivative transforms as $\partial_\mu \mapsto \partial^P_\mu$, where $\partial^P_0 = \partial_0$ and $\partial^P_i = -\partial_i$ when expressed in the reflected coordinate; equivalently ∂_μ acting at x_P is ∂^μ acting at x. Requiring $(i\gamma^\mu\partial_\mu - m)\psi_P(x) = 0$ and using $\psi(x_P)$ as a solution, we need

$$S_P^{-1}\gamma^0 S_P = \gamma^0, \qquad S_P^{-1}\gamma^i S_P = -\gamma^i, \tag{11.249}$$

so that the reflected derivative is compensated. The unique solution up to a phase is $S_P = \gamma^0$, because γ^0 commutes with itself and anticommutes with each γ^i (this is precisely the parity relation $\gamma^0\gamma^\mu\gamma^0 = \gamma_\mu$ proved in Eq. (C.83)). Hence

$$\boxed{\mathcal{P}\,\psi(t,\mathbf{x})\,\mathcal{P}^{-1} = \eta_P\,\gamma^0\,\psi(t,-\mathbf{x})} \qquad |\eta_P| = 1, \tag{11.250}$$

with η_P an undetermined phase, the *intrinsic parity* of the field. Taking the Dirac adjoint of Eq. (11.250) (and using $\gamma^{0\dagger} = \gamma^0$, $(\gamma^0)^2 = \mathbf{1}$),

$$\mathcal{P}\,\bar\psi(t,\mathbf{x})\,\mathcal{P}^{-1} = \eta_P^*\,\bar\psi(t,-\mathbf{x})\,\gamma^0. \tag{11.251}$$

Action on the spinors and on the ladder operators

To read off what $\mathcal{P}$ does to particles and antiparticles we need the action of the matrix γ^0 on the plane-wave spinors. Introduce the parity-reflected momentum $\tilde p \equiv (E_{\mathbf{p}}, -\mathbf{p})$. From $\gamma^0\not{p}\,\gamma^0 = \gamma^0(p_0\gamma^0 + p_i\gamma^i)\gamma^0 = p_0\gamma^0 - p_i\gamma^i = \not{\tilde p}$ we obtain, for any positive-energy solution $(\not{p} - m)u^s(p) = 0$,

$$(\not{\tilde p} - m)\,\gamma^0 u^s(p) = \gamma^0(\not{p} - m)\gamma^0\gamma^0 u^s(p) = \gamma^0(\not{p} - m)u^s(p) = 0, \tag{11.252}$$

so $\gamma^0 u^s(p)$ is a positive-energy solution at momentum $\tilde p$. In the rest frame $\mathbf{p} = 0$ one has $\tilde p = p$ and $\gamma^0 u^s(m) = +u^s(m)$ (the rest-frame spinors live in

the upper two components, the $+1$ eigenspace of γ^0); continuity in the boost fixes the proportionality constant to $+1$ for all $\mathbf{p}$. The same argument with $(\not{p}+m)v^s(p)=0$ and $\gamma^0 v^s(m)=-v^s(m)$ gives the opposite sign:

$$\gamma^0 u^s(p) = u^s(\tilde{p}), \qquad \gamma^0 v^s(p) = -v^s(\tilde{p}). \tag{11.253}$$

The relative minus sign between u and v is the algebraic seed of the opposite intrinsic parities of particle and antiparticle.

Insert Eq. (11.253) into the mode expansion Eq. (11.247). The right-hand side of Eq. (11.250) is

$$\eta_P\,\gamma^0\psi(t,-\mathbf{x}) = \eta_P \int \frac{d^3p}{(2\pi)^3\,2E_{\mathbf{p}}} \sum_s \Big(b^s_{\mathbf{p}}\, u^s(\tilde{p})\, e^{-i(E_{\mathbf{p}}t+\mathbf{p}\cdot\mathbf{x})} - d^{s\dagger}_{\mathbf{p}}\, v^s(\tilde{p})\, e^{+i(E_{\mathbf{p}}t+\mathbf{p}\cdot\mathbf{x})} \Big), \tag{11.254}$$

where we used $p\cdot(t,-\mathbf{x}) = E_{\mathbf{p}}t + \mathbf{p}\cdot\mathbf{x}$. Substituting the integration variable $\mathbf{p}\to-\mathbf{p}$ (the measure and $E_{\mathbf{p}}$ are invariant, $\tilde{p}\to p$, and the exponentials become $e^{\mp ip\cdot x}$) turns this into

$$\eta_P \int \frac{d^3p}{(2\pi)^3\,2E_{\mathbf{p}}} \sum_s \Big(b^s_{-\mathbf{p}}\, u^s(p)\, e^{-ip\cdot x} - d^{s\dagger}_{-\mathbf{p}}\, v^s(p)\, e^{+ip\cdot x} \Big). \tag{11.255}$$

Matching, with the invariant measure $\widetilde{dp} \equiv d^3p/[(2\pi)^3\,2E_{\mathbf{p}}]$ of Eq. (9.211), against the left-hand side

$$\mathcal{P}\psi(t,\mathbf{x})\mathcal{P}^{-1} = \int \widetilde{dp} \sum_s \big((\mathcal{P} b^s_{\mathbf{p}} \mathcal{P}^{-1})\, u^s e^{-ip\cdot x} + (\mathcal{P} d^{s\dagger}_{\mathbf{p}} \mathcal{P}^{-1})\, v^s e^{+ip\cdot x} \big) \tag{11.256}$$

term by term gives the ladder-operator action

$$\mathcal{P}\, b^s_{\mathbf{p}}\, \mathcal{P}^{-1} = \eta_P\, b^s_{-\mathbf{p}}, \qquad \mathcal{P}\, d^s_{\mathbf{p}}\, \mathcal{P}^{-1} = -\eta_P^*\, d^s_{-\mathbf{p}}, \tag{11.257}$$

the second relation being the adjoint of the matched antiparticle term. Parity reverses the momentum and leaves the spin label s untouched (spin, being an axial vector, is invariant under a spatial reflection); consequently it flips the helicity $h = \hat{\mathbf{p}}\cdot\mathbf{S}$. Acting on the one-particle states $|e^-;\mathbf{p},s\rangle = b^{s\dagger}_{\mathbf{p}}|0\rangle$ and $|e^+;\mathbf{p},s\rangle = d^{s\dagger}_{\mathbf{p}}|0\rangle$ (with $\mathcal{P}|0\rangle = |0\rangle$),

$$\mathcal{P}\,|e^-;\mathbf{p},s\rangle = \eta_P^*\,|e^-;-\mathbf{p},s\rangle\,, \qquad \mathcal{P}\,\Big|e^+;\mathbf{p},s\Big\rangle = -\eta_P\,\Big|e^+;-\mathbf{p},s\Big\rangle\,. \tag{11.258}$$

Opposite intrinsic parity of particle and antiparticle

The phase η_P attached to a single field is not observable: it can be absorbed into the definition of $\mathcal{P}$. What *is* observable is a relative parity. From Eq. (11.257),

the intrinsic parity assigned to the electron is η_P and that assigned to the positron is $-\eta_P^*$. Their product,

$$\eta_P \cdot (-\eta_P^*) = -|\eta_P|^2 = -1, \tag{11.259}$$

is independent of the convention for η_P and is therefore physical: *a fermion and its antifermion carry opposite intrinsic parity.* This is not a curiosity. The relative parity of a particle–antiparticle pair shows up directly in the angular-momentum and parity analysis of bound states and decays — it is why the ground state of positronium (a ${}^1S_0$ e^+e^- state) is a pseudoscalar with $P=-1$, and the analogous statement for a quark–antiquark pair is what makes the pion a pseudoscalar. The minus sign in Eq. (11.259) traces back, through Eq. (11.253), to the single fact that u and v sit in opposite eigenspaces of γ^0 in the rest frame.

11.7.2 Charge conjugation

Charge conjugation C is the operation that exchanges particles with antiparticles without touching spacetime. Its spinor matrix is the charge-conjugation matrix $C = i\gamma^2\gamma^0$ of Theorem C.38, characterized abstractly by

$$C^{-1}\gamma^\mu C = -\gamma^{\mu T}, \qquad C^T = -C, \qquad C^\dagger = C^{-1}, \qquad C^2 = -\mathbf{1} \tag{11.260}$$

(Eqs. (C.80) and (C.94)). The charge-conjugate of a Dirac field is, as in Eq. (C.104),

$$\psi^c(x) \equiv C\,\bar\psi^{\,T}(x). \tag{11.261}$$

Invariance of the Dirac equation and the charge flip

That ψ^c again solves the free Dirac equation is the content of the v-spinor computation of Theorem C.40; we recall the mechanism because it is the same algebra that produces the bilinear table below. Start from $(i\partial\!\!\!/ - m)\psi = 0$, take the Dirac adjoint to get $\bar\psi(i\overleftarrow{\partial\!\!\!/} + m) = 0$, i.e. $i\partial_\mu\bar\psi\gamma^\mu + m\bar\psi = 0$, and transpose:

$$(i\gamma^{\mu T}\partial_\mu + m)\bar\psi^{\,T} = 0. \tag{11.262}$$

Now eliminate $\gamma^{\mu T} = -C^{-1}\gamma^\mu C$ from Eq. (11.260) and multiply on the left by C:

$$(-iC\,C^{-1}\gamma^\mu C\,\partial_\mu + mC)\bar\psi^{\,T} = (-i\gamma^\mu\partial_\mu + m)C\bar\psi^{\,T} = -\,(i\partial\!\!\!/ - m)\,\psi^c = 0. \tag{11.263}$$

So ψ^c is a solution of the free equation. The physical content appears the moment a gauge field is switched on. With the QED covariant derivative $D_\mu = \partial_\mu + ieA_\mu$ acting on the electron (charge $-e$, $e>0$), the same manipulation, with $\partial_\mu \to D_\mu$,

sends $+ieA_\mu \to -ieA_\mu$: the conjugate field couples with the opposite charge. Equivalently, the electromagnetic current reverses,

$$j^\mu = \bar\psi\gamma^\mu\psi \xrightarrow{C} \bar\psi^c\gamma^\mu\psi^c = -\bar\psi\gamma^\mu\psi = -j^\mu, \tag{11.264}$$

a sign we rederive carefully (with the indispensable fermionic reordering) in the bilinear table of Section 11.7.4. This is exactly the statement that C turns a charge into its negative.

Action on the ladder operators

Promote Eq. (11.261) to the operator statement $\mathcal{C}\,\psi(x)\,\mathcal{C}^{-1} = \eta_C\, C\bar\psi^{\,T}(x)$ with $\mathcal{C}$ unitary and $|\eta_C| = 1$. The needed spinor inputs are $C\bar u^s(p)^T = v^s(p)$ and $C\bar v^s(p)^T = u^s(p)$, established in Theorem C.40. The conjugate adjoint field is $\bar\psi(x) = \int \widetilde{dp}\sum_s (b^{s\dagger}_{\mathbf p}\bar u^s e^{+ip\cdot x} + d^s_{\mathbf p}\bar v^s e^{-ip\cdot x})$, so

$$\begin{aligned}\eta_C\, C\bar\psi^{\,T}(x) &= \eta_C \int \widetilde{dp}\sum_s \Big(b^{s\dagger}_{\mathbf p}\, C\bar u^s(p)^T e^{+ip\cdot x} + d^s_{\mathbf p}\, C\bar v^s(p)^T e^{-ip\cdot x}\Big)\\ &= \eta_C \int \widetilde{dp}\sum_s \Big(d^s_{\mathbf p}\, u^s(p)\, e^{-ip\cdot x} + b^{s\dagger}_{\mathbf p}\, v^s(p)\, e^{+ip\cdot x}\Big),\end{aligned} \tag{11.265}$$

with $\widetilde{dp}$ the invariant measure introduced above. Comparing coefficients with $\mathcal{C}\psi\mathcal{C}^{-1}$ gives the clean exchange

$$\boxed{\mathcal{C}\, b^s_{\mathbf p}\,\mathcal{C}^{-1} = \eta_C\, d^s_{\mathbf p}, \qquad \mathcal{C}\, d^s_{\mathbf p}\,\mathcal{C}^{-1} = \eta_C^*\, b^s_{\mathbf p}} \tag{11.266}$$

(the second by taking the adjoint of the matched $b^\dagger$ term). Charge conjugation maps an electron of momentum $\mathbf p$ and spin s to a positron of the *same* momentum and spin, and vice versa: $\mathcal{C}\,|e^-;\mathbf p,s\rangle = \eta_C^*\,|e^+;\mathbf p,s\rangle$. Neither momentum nor spin is disturbed; only the sign of the charge is. The same matrix algebra, through $C\gamma^5 C^{-1} = \gamma^{5T}$ (Theorem C.39), is responsible for a fact we will use repeatedly from Chapter 36 onward: in the chiral basis $\gamma^{5T} = \gamma^5$, so charge conjugation commutes with chirality up to a transpose and therefore maps a left-handed antiparticle to a right-handed particle.

11.7.3 Time reversal

Time reversal is the spacetime map $x = (t,\mathbf x) \mapsto x_T \equiv (-t,\mathbf x)$. It differs in kind from P and C. Wigner's theorem, established in Section 3.7 (see Theorem 3.44), permits a symmetry of the quantum theory to be implemented by either a unitary or an antiunitary operator, and the requirement that time reversal preserve the spectrum of the Hamiltonian while reversing the sign of t in e^{-iHt} forces the antiunitary choice: $\mathcal{T}$ is *antiunitary*, $\mathcal{T}\,(\alpha A+\beta B)\,\mathcal{T}^{-1} = \alpha^*\,\mathcal{T}A\mathcal{T}^{-1} + \beta^*\,\mathcal{T}B\mathcal{T}^{-1}$, and in particular $\mathcal{T}\,i\,\mathcal{T}^{-1} = -i$. This single feature reshapes every computation in this subsection.

Fixing the matrix

Write $\mathcal{T}\,\psi(t,\mathbf{x})\,\mathcal{T}^{-1} = \eta_T\, T\,\psi(-t,\mathbf{x})$ with a constant matrix T and $|\eta_T| = 1$. Apply $\mathcal{T}$ to the Dirac equation $(i\gamma^\mu\partial_\mu - m)\psi(x) = 0$. Antiunitarity conjugates the explicit i and the c-number matrices $\gamma^\mu \to \gamma^{\mu *}$, while the field becomes $T\psi(x_T)$:

$$(-i\gamma^{\mu *}\partial_\mu - m)T\psi(x_T) = 0. \tag{11.267}$$

Re-express the derivatives in the reflected coordinate x_T: $\partial_0 = -\partial_{x_T^0}$ and $\partial_i = \partial_{x_T^i}$. Multiplying by $-T^{-1}$ on the left, invariance of the Dirac equation requires

$$T^{-1}\gamma^0 T = \gamma^{0*}, \qquad T^{-1}\gamma^i T = -\gamma^{i*}, \tag{11.268}$$

which is exactly the matrix condition Eq. (C.109). In a representation where only γ^2 is imaginary ($\gamma^{0*} = \gamma^0$, $\gamma^{2*} = -\gamma^2$, $\gamma^{1*} = \gamma^1$, $\gamma^{3*} = \gamma^3$), Eq. (11.268) demands that T commute with γ^0, γ^2 and anticommute with γ^1, γ^3. The unique solution up to phase is

$$\boxed{\mathcal{T}\,\psi(t,\mathbf{x})\,\mathcal{T}^{-1} = \eta_T\, T\,\psi(-t,\mathbf{x}), \qquad T = \gamma^1\gamma^3} \tag{11.269}$$

(Eq. (C.110)), since $\gamma^1\gamma^3$ contains exactly the two matrices it must anticommute with and none of those it must commute with. It satisfies $T^2 = (\gamma^1\gamma^3)^2 = -(\gamma^1)^2(\gamma^3)^2 = -(-1)(-1) = -1$ and $T^\dagger = (\gamma^1\gamma^3)^\dagger = \gamma^{3\dagger}\gamma^{1\dagger} = (-\gamma^3)(-\gamma^1) = \gamma^3\gamma^1 = -\gamma^1\gamma^3 = -T$.

The spin flip and Kramers degeneracy

Time reversal must reverse momentum (a particle moving right, run backwards, moves left) and angular momentum (spin is T-odd). The momentum reversal is forced by the antiunitary conjugation of the plane-wave phase $e^{-ip\cdot x} \to e^{+ip\cdot x}$; the spin reversal is carried by the matrix $T = \gamma^1\gamma^3$. To see the spin flip cleanly, evaluate T on the conjugated rest-frame spinors. In the Dirac basis $\gamma^i = \left(\begin{smallmatrix} 0 & \sigma^i \\ -\sigma^i & 0 \end{smallmatrix}\right)$, a direct block multiplication gives

$$T = \gamma^1\gamma^3 = \begin{pmatrix} -\sigma^1\sigma^3 & 0 \\ 0 & -\sigma^1\sigma^3 \end{pmatrix} = \begin{pmatrix} i\sigma^2 & 0 \\ 0 & i\sigma^2 \end{pmatrix}, \tag{11.270}$$

using $\sigma^1\sigma^3 = -i\sigma^2$. The rest-frame spinors are $u^s(m) = \sqrt{2m}\,(\xi^s, 0)^T$ with $\xi^1 = \binom{1}{0}$, $\xi^2 = \binom{0}{1}$, and they are real, so $u^{s*}(m) = u^s(m)$. Since $i\sigma^2\xi^1 = -\xi^2$ and $i\sigma^2\xi^2 = +\xi^1$,

$$T\,u^{1*}(m) = -\,u^2(m), \qquad T\,u^{2*}(m) = +\,u^1(m), \tag{11.271}$$

and identically on the v-spinors. This is precisely the nonrelativistic time-reversal operator $i\sigma^2 K$ (with K complex conjugation) acting on a two-component spin:

it sends $\Uparrow\rangle \to -\Downarrow\rangle$, $\Downarrow\rangle \to +\Uparrow\rangle$. Boosting Eq. (11.271) and combining with the phase conjugation, the operator action is

$$\mathcal{T}\, b^{s}_{\mathbf{p}}\, \mathcal{T}^{-1} = \eta_T\, (-1)^{\frac{1}{2}-s}\, b^{-s}_{-\mathbf{p}}, \qquad \mathcal{T}\, d^{s}_{\mathbf{p}}\, \mathcal{T}^{-1} = \eta_T^{*}\, (-1)^{\frac{1}{2}-s}\, d^{-s}_{-\mathbf{p}}, \tag{11.272}$$

where $-s$ denotes the flipped spin and the alternating sign records the $i\sigma^2$ of Eq. (11.271) (here $s = \pm\frac{1}{2}$ labels the two states). Time reversal therefore reverses momentum and spin together, leaving helicity invariant. Because the matrix squares to -1, applying $\mathcal{T}$ twice to a single-fermion state returns -1 times the state:

$$\mathcal{T}^2\, |e^-; \mathbf{p}, s\rangle = -\,|e^-; \mathbf{p}, s\rangle\,. \tag{11.273}$$

This is *Kramers' theorem* in field-theoretic dress: any energy eigenstate of an odd number of fermions in a time-reversal-invariant theory is at least doubly degenerate, since $|\Psi\rangle$ and $\mathcal{T}\,|\Psi\rangle$ are orthogonal (an antiunitary squaring to -1 cannot have a one-dimensional invariant subspace). The sign $\mathcal{T}^2 = -1$ is the hallmark of half-integer spin, the mirror of the $\mathcal{T}^2 = +1$ that holds for bosons.

11.7.4 The transformation table of the bilinear covariants

We now compute how each of the sixteen bilinear covariants of Table 11.1 — the scalar $S = \bar\psi\psi$, the pseudoscalar $P = i\bar\psi\gamma^5\psi$, the vector $V^\mu = \bar\psi\gamma^\mu\psi$, the axial vector $A^\mu = \bar\psi\gamma^\mu\gamma^5\psi$, and the tensor $T^{\mu\nu} = \bar\psi\sigma^{\mu\nu}\psi$ — transforms under P, C, and T. Every entry is derived, not quoted. The three operations need three different master identities, and the differences between them are exactly the physics.

Parity

Combining the field transformations Eqs. (11.250) and (11.251), a generic bilinear transforms as

$$\mathcal{P}(\bar\psi\,\Gamma\,\psi)(t,\mathbf{x})\,\mathcal{P}^{-1} = \bar\psi(t,-\mathbf{x})\,(\gamma^0\Gamma\gamma^0)\,\psi(t,-\mathbf{x}), \tag{11.274}$$

the phases $\eta_P^*\eta_P = 1$ cancelling. Everything is fixed by $\gamma^0\Gamma\gamma^0$, computed with $\gamma^0\gamma^\mu\gamma^0 = \gamma_\mu$ and $\gamma^0\gamma^5\gamma^0 = -\gamma^5$:

$$\begin{aligned} \gamma^0\,\mathbf{1}\,\gamma^0 &= \mathbf{1}, & \gamma^0\gamma^\mu\gamma^0 &= \gamma_\mu, \\ \gamma^0\gamma^5\gamma^0 &= -\gamma^5, & \gamma^0\sigma^{\mu\nu}\gamma^0 &= \tfrac{i}{2}[\gamma_\mu,\gamma_\nu] = \sigma_{\mu\nu}, \\ \gamma^0\gamma^\mu\gamma^5\gamma^0 &= (\gamma^0\gamma^\mu\gamma^0)(\gamma^0\gamma^5\gamma^0) & &= -\gamma_\mu\gamma^5. \end{aligned} \tag{11.275}$$

Hence under parity (all fields at $(t,-\mathbf{x})$): $S \to +S$; $P = i\bar\psi\gamma^5\psi \to -P$; $V^\mu \to V_\mu = (V^0, -V^i)$; $A^\mu \to -A_\mu = (-A^0, A^i)$; $T^{\mu\nu} \to T_{\mu\nu}$. The scalar is even and the pseudoscalar odd, the vector flips its spatial part while the axial vector flips its temporal part — the textbook signatures that distinguish S from P and V from A, here obtained as pure γ-algebra.

Charge conjugation

This is the one case where the fermionic anticommutativity of the fields enters with a sign. From the operator statements $\mathcal{C}\psi\mathcal{C}^{-1} = \eta_C C\bar{\psi}^T$ and (its consequence, Section C.4.3) $\mathcal{C}\bar{\psi}\mathcal{C}^{-1} = -\eta_C^*\,\psi^T C^{-1}$,

$$\begin{aligned}\mathcal{C}(\bar{\psi}\Gamma\psi)\mathcal{C}^{-1} &= (-\psi^T C^{-1})\,\Gamma\,(C\bar{\psi}^T) = -\,\psi_\alpha\,(C^{-1}\Gamma C)_{\alpha\beta}\,\bar{\psi}_\beta \\ &= +\,\bar{\psi}_\beta\,(C^{-1}\Gamma C)_{\alpha\beta}\,\psi_\alpha = \bar{\psi}\,(C^{-1}\Gamma C)^T\,\psi, \end{aligned} \tag{11.276}$$

$|\eta_C|^2 = 1$. The crucial step is the second equality on the second line: interchanging the anticommuting operators ψ_α and $\bar{\psi}_\beta$ produces a sign -1 that cancels the explicit minus from $\mathcal{C}\bar{\psi}\mathcal{C}^{-1}$ (we work with the normal-ordered bilinear, dropping the c-number anticommutator). Using $C^T = -C$ and $(C^{-1})^T = -C^{-1}$ one finds $(C^{-1}\Gamma C)^T = C^T\Gamma^T(C^{-1})^T = C\,\Gamma^T\,C^{-1}$, so the master identity is

$$\mathcal{C}(\bar{\psi}\Gamma\psi)\mathcal{C}^{-1} = \bar{\psi}\,(C\,\Gamma^T C^{-1})\,\psi. \tag{11.277}$$

The conjugated matrices follow from $C\gamma^{\mu T}C^{-1} = -\gamma^\mu$ (from Eq. (11.260)), $C\gamma^{5T}C^{-1} = \gamma^5$ and $C\sigma^{\mu\nu T}C^{-1} = -\sigma^{\mu\nu}$ (Theorem C.39):

$$\begin{aligned} C\,\mathbf{1}^T C^{-1} &= \mathbf{1}, & C\gamma^{\mu T}C^{-1} &= -\gamma^\mu, \\ C\gamma^{5T}C^{-1} &= \gamma^5, & C\sigma^{\mu\nu T}C^{-1} &= -\sigma^{\mu\nu}, \\ C(\gamma^\mu\gamma^5)^T C^{-1} &= C\gamma^{5T}\gamma^{\mu T}C^{-1} & &= \gamma^5(-\gamma^\mu) = \gamma^\mu\gamma^5. \end{aligned} \tag{11.278}$$

Thus under charge conjugation: $S \to +S$, $P \to +P$, $V^\mu \to -V^\mu$, $A^\mu \to +A^\mu$, $T^{\mu\nu} \to -T^{\mu\nu}$. The vector current is odd, confirming Eq. (11.264); the axial current is even. These two signs underlie the structural facts that QED inherits: the odd C-parity of the electromagnetic current is the algebraic origin of *Furry's theorem* (amplitudes with an odd number of external photons attached to a single fermion loop vanish), which we deploy in Chapters 18 and 19.

Time reversal

Antiunitarity now conjugates the matrix Γ as well. With $\mathcal{T}\psi\mathcal{T}^{-1} = \eta_T T\psi(x_T)$ and $\mathcal{T}\bar{\psi}\mathcal{T}^{-1} = \eta_T^*\bar{\psi}(x_T)\,\gamma^0 T^\dagger\gamma^0$, and pulling the conjugated c-number matrix Γ^* through, one obtains (with $\gamma^0 T^\dagger\gamma^0 = -T$ and $T^{-1} = -T$, as computed from $T = \gamma^1\gamma^3$)

$$\mathcal{T}\,(\bar{\psi}\Gamma\psi)(t,\mathbf{x})\,\mathcal{T}^{-1} = \bar{\psi}(-t,\mathbf{x})\,(T^{-1}\Gamma^* T)\,\psi(-t,\mathbf{x}). \tag{11.279}$$

The matrix $T = \gamma^1\gamma^3$ is real, so conjugating the defining relation Eq. (11.268) gives the convenient form $T^{-1}\gamma^{\mu *}T = \gamma_\mu$. Then, recalling $\gamma^{5*} = \gamma^5$ and $T^{-1}\gamma^5 T = \gamma^5$ (as γ^5 commutes with $\gamma^1\gamma^3$),

$$T^{-1}\mathbf{1}^* T = \mathbf{1}, \qquad T^{-1}\gamma^{\mu *}T = \gamma_\mu, \qquad T^{-1}(i\gamma^5)^* T = -i\gamma^5,$$

$$T^{-1}(\gamma^\mu\gamma^5)^*T = \gamma_\mu\gamma^5, \qquad T^{-1}\sigma^{\mu\nu *}T = -\sigma_{\mu\nu}. \tag{11.280}$$

The conjugation of the explicit i in the pseudoscalar and tensor is what supplies their extra sign relative to parity. Under time reversal (all fields at $(-t,\mathbf{x})$): $S \to +S$; $P \to -P$; $V^\mu \to V_\mu = (V^0, -V^i)$; $A^\mu \to A_\mu = (A^0, -A^i)$; $T^{\mu\nu} \to -T_{\mu\nu}$. The vector transforms as it must for a current — charge density even, spatial current reversed — while the axial charge A^0 stays even and the axial spatial current reverses, consistent with T reversing spin.

The table, and the combined operations

Table 11.2 collects the entries. We adopt the compact notation $(-1)^\mu \equiv +1$ for $\mu = 0$ and -1 for $\mu = 1,2,3$, so that "$V^\mu \to V_\mu$" reads $V^\mu \to (-1)^\mu V^\mu$ and a rank-two object picks up $(-1)^\mu(-1)^\nu$.

Table 11.2: Transformation of the bilinear covariants under P, C, T, and the combination CPT. Position arguments: P sends fields to $(t,-\mathbf{x})$, T to $(-t,\mathbf{x})$, and CPT to $-x = (-t,-\mathbf{x})$; C leaves the argument fixed. Here $(-1)^\mu = +1$ for $\mu = 0$ and -1 for $\mu = 1,2,3$. The final column shows that a bilinear with n Lorentz (vector/tensor) indices acquires $(-1)^n$ under CPT, evaluated at $-x$.

bilinear	P	C	T	CPT	# indices n
$S = \bar\psi\psi$	$+S$	$+S$	$+S$	$+S$	0
$P = i\bar\psi\gamma^5\psi$	$-P$	$+P$	$-P$	$+P$	0
$V^\mu = \bar\psi\gamma^\mu\psi$	$(-1)^\mu V^\mu$	$-V^\mu$	$(-1)^\mu V^\mu$	$-V^\mu$	1
$A^\mu = \bar\psi\gamma^\mu\gamma^5\psi$	$-(-1)^\mu A^\mu$	$+A^\mu$	$(-1)^\mu A^\mu$	$-A^\mu$	1
$T^{\mu\nu} = \bar\psi\sigma^{\mu\nu}\psi$	$(-1)^\mu(-1)^\nu T^{\mu\nu}$	$-T^{\mu\nu}$	$-(-1)^\mu(-1)^\nu T^{\mu\nu}$	$+T^{\mu\nu}$	2

The CPT column is the product of the other three (for each fixed component, multiplying the three signs). Take the vector: P contributes $(-1)^\mu$, C contributes -1, T contributes $(-1)^\mu$, and the product is $(-1)^\mu\cdot(-1)\cdot(-1)^\mu = -1$, independent of μ; the spacetime argument, reflected by P and again by T, ends at $-x$. The axial vector gives $-(-1)^\mu\cdot(+1)\cdot(-1)^\mu = -1$; the tensor gives $(-1)^\mu(-1)^\nu\cdot(-1)\cdot(-(-1)^\mu(-1)^\nu) = +1$; the scalar and pseudoscalar both give $+1$. The pattern is uniform and is the entire algebraic content of the CPT theorem at the level of bilinears:

$$\boxed{\Theta\left[\bar\psi\,\Gamma_{(n)}\,\psi\,(x)\right]\Theta^{-1} = (-1)^n\,\bar\psi\,\Gamma_{(n)}\,\psi\,(-x), \qquad \Theta = \mathcal{CPT},} \tag{11.281}$$

where $\Gamma_{(n)}$ is any of the covariants carrying n Lorentz vector indices. A Lorentz tensor of rank n flips sign n times and is evaluated at the totally reflected point.

11.7.5 Invariance of the Dirac Lagrangian, and the CPT theorem

We can now verify that the free Dirac Lagrangian $\mathcal{L} = \bar{\psi}(i\gamma^\mu\partial_\mu - m)\psi$ is invariant under each of C, P, T separately, and then assemble CPT.

Parity. The mass term $-m\,S$ is a scalar, invariant. The kinetic term is $i\bar{\psi}\gamma^\mu\partial_\mu\psi$; under P the bilinear factor goes as $V^\mu \to V_\mu$ while the derivative goes as $\partial_\mu \to \partial^\mu$ at $(t, -\mathbf{x})$, and the contraction $\gamma^\mu\partial_\mu \to \gamma_\mu\partial^\mu = \gamma^\mu\partial_\mu$ is restored. Hence $\mathcal{P}\mathcal{L}(t,\mathbf{x})\mathcal{P}^{-1} = \mathcal{L}(t,-\mathbf{x})$, and $\int d^4x\,\mathcal{L}$ is invariant.

Charge conjugation. The mass term is even. For the kinetic term, the field rules and the fermionic reordering give, after one integration by parts,

$$\begin{aligned}\mathcal{C}(i\bar{\psi}\gamma^\mu\partial_\mu\psi)\mathcal{C}^{-1} &= i(-\psi^T C^{-1})\gamma^\mu\partial_\mu(C\bar{\psi}^T) = -i\,\psi^T(C^{-1}\gamma^\mu C)\,\partial_\mu\bar{\psi}^T \\ &= +i\,\psi^T\gamma^{\mu T}\partial_\mu\bar{\psi}^T = -\,i\,\partial_\mu\bar{\psi}\,\gamma^\mu\psi = i\bar{\psi}\gamma^\mu\partial_\mu\psi - i\,\partial_\mu(\bar{\psi}\gamma^\mu\psi),\end{aligned} \tag{11.282}$$

where the third equality used $C^{-1}\gamma^\mu C = -\gamma^{\mu T}$, the fourth the anticommutativity of the fields (a sign -1 from $\psi_\alpha\,\partial_\mu\bar{\psi}_\beta = -\partial_\mu\bar{\psi}_\beta\,\psi_\alpha$), and the last an integration by parts. The kinetic term returns up to the total derivative $-i\,\partial_\mu j^\mu$, so the *action* $\int d^4x\,\mathcal{L}$ is C-invariant.

Time reversal. The mass term is even. The kinetic term carries three time-reversal-sensitive factors: the explicit i (conjugated to $-i$ by antiunitarity), the bilinear $V^\mu \to V_\mu$, and the derivative ($\partial_0 \to -\partial_0$, $\partial_i \to \partial_i$ at $(-t,\mathbf{x})$). For the temporal piece, $i\bar{\psi}\gamma^0\partial_0\psi \to (-i)\,(V^0 \text{ even})\,(-\partial_0) = +i\bar{\psi}\gamma^0\partial_0\psi$; for the spatial piece, $i\bar{\psi}\gamma^i\partial_i\psi \to (-i)\,(V^i \to -V^i)\,(+\partial_i) = +i\bar{\psi}\gamma^i\partial_i\psi$. Each is invariant, so $\mathcal{T}\mathcal{L}(t,\mathbf{x})\mathcal{T}^{-1} = \mathcal{L}(-t,\mathbf{x})$ and the action is T-invariant.

CPT. Combining the three, the free Dirac Lagrangian density obeys $\Theta\,\mathcal{L}(x)\,\Theta^{-1} = \mathcal{L}(-x)$, and since the Jacobian of $x \to -x$ is $+1$ in four dimensions, the action is invariant. The general statement is the celebrated theorem.

Theorem 11.51 (CPT, stated)**.** *Let a quantum field theory be (i) invariant under the proper orthochronous Poincaré group, (ii) local — its fields obey microcausality with the spin–statistics connection of Theorem 9.33, integer-spin fields commuting and half-integer-spin fields anticommuting at spacelike separation — and (iii) governed by a Hermitian Lagrangian density built as a Lorentz scalar from the fields and their derivatives. Then there exists an antiunitary operator $\Theta = \mathcal{C}\mathcal{P}\mathcal{T}$, an exact symmetry of the theory, under which every Hermitian local Lorentz-scalar operator transforms as $\Theta\,\mathcal{O}(x)\,\Theta^{-1} = \mathcal{O}(-x)$.*

The structural reason is laid bare by Eq. (11.281). Any Hermitian Lorentz-scalar interaction is a sum of monomials in which Dirac bilinears, derivatives, and other tensor fields are contracted so that *every* Lorentz index is summed against another. Under Θ, each bilinear of rank n contributes $(-1)^n$ and each derivative $\partial_\mu \to -\partial_\mu$ contributes one more sign per index; in a fully contracted scalar these signs come in pairs and cancel, $(-1)^{\text{even}} = +1$. The antiunitarity of Θ conjugates the explicit factors of i, which is exactly what Hermiticity of the Lagrangian requires for the surviving phases to combine to $+1$ rather than -1. The net effect on any scalar term is the identity up to the reflection $x \to -x$. This is the heart of the matter, and it is genuinely independent of the details of the theory; the only inputs are Lorentz covariance, locality with the right statistics, and Hermiticity — precisely the three hypotheses. A fully rigorous proof, valid beyond the perturbative/Lagrangian setting, rests on the analytic structure of the Wightman functions (the same forward-tube analyticity that powers the general spin–statistics theorem of Theorem 9.33); we have given the complete structural argument here and refer to the axiomatic treatment for the analyticity machinery, which the book develops where it is first needed rather than at this point.

Physical Insight

CPT is the symmetry that survives even when C, P, and T individually fail. The weak interaction violates P and C *maximally* (it couples only to left-handed fermions and right-handed antifermions) and violates the combination CP — and hence, by Theorem 11.51, T — by a small amount; these are the subjects of Chapters 31 and 32. Yet CPT remains exact, because its three hypotheses (Lorentz invariance, locality, spin–statistics) are the non-negotiable scaffolding of relativistic quantum field theory itself. The empirical consequences are sharp and have been tested to extraordinary precision: a particle and its antiparticle have *exactly* equal mass and lifetime, and equal-magnitude opposite charge and magnetic moment. The most stringent single test as of the mid-2020s is the fractional mass difference of K^0 and $\bar{K}^0$, bounded below the 10^{-18} level, together with proton/antiproton charge-to-mass and electron/positron g-factor comparisons at the part-per-billion-and-finer level; no violation has been observed.

Figure 11.6 traces a single electron state through the three operations and their product, making visible the content of the table: P reverses momentum, C flips the charge, T reverses momentum and spin, and the combined Θ maps the electron to a positron of the same momentum and opposite spin — an antiparticle, as the theorem requires.

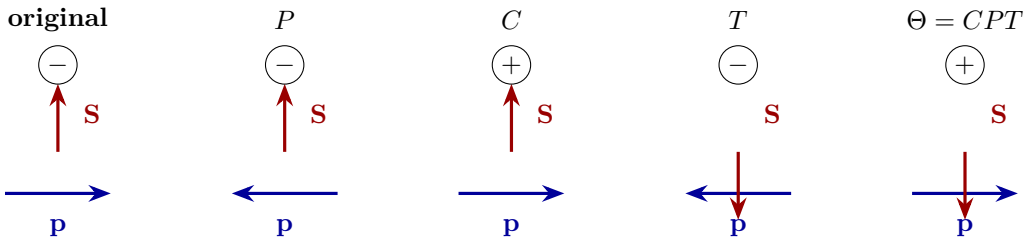

Figure 11.6: Action of P, C, T, and $\Theta = CPT$ on an electron prepared with momentum $\mathbf{p}$ to the right, spin $\mathbf{S}$ up, and charge $-e$ (blue: momentum; red: spin; circle: charge). P reverses $\mathbf{p}$ and preserves the axial $\mathbf{S}$; C flips the charge; T reverses both $\mathbf{p}$ and $\mathbf{S}$. The composite Θ produces a positron ($+e$) of the same momentum and reversed spin — the antiparticle, in accordance with Theorem 11.51.

11.7.6 The Majorana condition: a fermion that is its own antiparticle

The charge-conjugation operation invites a question it does not by itself answer: can a Dirac field be *equal* to its own charge conjugate? Such a field would describe a neutral fermion with no distinction between particle and antiparticle. The condition, in the notation of Theorem C.41, is

$$\psi = \psi^c = C\bar{\psi}^T. \tag{11.283}$$

That Eq. (11.283) is a consistent, Lorentz-covariant constraint in four dimensions — that the antilinear map $\psi \mapsto C\bar{\psi}^T$ squares to the identity, so the constraint has a nontrivial solution space of four real components, the count of a single Weyl spinor — was proved in Theorem C.42. Here we examine what the condition does to the quantized field and its quanta.

Worked Example 11.52 (Construction of a Majorana field and its self-conjugacy)**.** We build a quantized Majorana field directly from a Dirac field by enforcing Eq. (11.283) on the mode operators, and verify the self-conjugacy condition. Begin with the general expansion Eq. (11.247) and apply charge conjugation through the operator rule Eq. (11.266). The charge conjugate of the field is

$$\psi^c(x) = \mathcal{C}\,\psi(x)\,\mathcal{C}^{-1}\big|_{\eta_C=1} = \int \widetilde{dp} \sum_s \Big(d^s_{\mathbf{p}}\, u^s(p)\, e^{-ip\cdot x} + b^{s\dagger}_{\mathbf{p}}\, v^s(p)\, e^{+ip\cdot x} \Big), \tag{11.284}$$

obtained from ψ by the interchange $b^s_{\mathbf{p}} \leftrightarrow d^s_{\mathbf{p}}$ (using $C\bar{u}^T = v$, $C\bar{v}^T = u$ exactly as in Eq. (11.266)). Comparing term by term with ψ itself, the equality $\psi = \psi^c$ holds as an operator identity *iff*

$$d^s_{\mathbf{p}} = b^s_{\mathbf{p}} \qquad \text{for all } \mathbf{p}, s. \tag{11.285}$$

That is, the Majorana condition identifies the antiparticle ladder operators with the particle ladder operators: there is only one species of quantum. The Majorana field then reads

$$\psi_M(x) = \int \widetilde{dp} \sum_s \Big(b^s_{\mathbf{p}}\, u^s(p)\, e^{-ip\cdot x} + b^{s\dagger}_{\mathbf{p}}\, v^s(p)\, e^{+ip\cdot x} \Big), \tag{11.286}$$

with the single ladder algebra $\{b^r_{\mathbf{p}}, b^{s\dagger}_{\mathbf{q}}\} = (2\pi)^3 \delta^{rs} \delta^{(3)}(\mathbf{p}-\mathbf{q})$. We confirm self-conjugacy at the level of the field: applying $\mathcal{C}$ to Eq. (11.286) sends $b \to d = b$ by Eqs. (11.266) and (11.285), returning Eq. (11.286) unchanged, so $\mathcal{C}\psi_M\mathcal{C}^{-1} = \psi_M$ and the state space carries C-eigenvalue structure with no separate antiparticle sector. A Majorana fermion is electrically neutral: the would-be current $\bar\psi_M \gamma^\mu \psi_M$ is odd under C (Table 11.2) yet equal to its own conjugate, hence identically zero as a U(1) charge — a Majorana field cannot couple to the photon. The degrees of freedom have halved exactly as Theorem C.42 predicted: where a Dirac field has two creation operators per momentum-spin cell ($b^\dagger$ and $d^\dagger$), the Majorana field has one. In the chiral basis Eq. (11.283) reduces to $\psi_R = i\sigma^2 \psi_L^*$ (Theorem C.43), exhibiting the four real components as those of a single left-handed Weyl spinor tied to its own conjugate.

A Majorana mass term $-\frac{1}{2} m\, \bar\psi_M \psi_M = -\frac{1}{2} m\, (\psi_M^T C\, \psi_M + \text{h.c.})$ is built from the antisymmetric combination $\psi^T C \psi$, whose nonvanishing relies on $C^T = -C$ together with the anticommutativity of the field components (Table C.1); it violates any U(1) charge under which ψ rotates, by two units, which is exactly why it is forbidden for the charged leptons and quarks and available only for genuinely neutral fermions.

Physical Insight: a dated frontier — are neutrinos Dirac or Majorana?

The only known fundamental fermion that could be its own antiparticle is the neutrino, the unique electrically neutral elementary fermion. Whether the neutrino mass is of Dirac type (requiring a right-handed partner and conserving lepton number) or Majorana type (Eq. (11.283), violating lepton number by two units) is, as of the mid-2020s, *experimentally open*. The decisive observable is neutrinoless double-beta decay ($0\nu\beta\beta$), a nuclear transition $(A, Z) \to (A, Z+2) + 2e^-$ with no emitted neutrinos, which can proceed only if the neutrino is a Majorana particle. No $0\nu\beta\beta$ event has been observed; the leading experiments (KamLAND-Zen, GERDA/LEGEND, CUORE, and the next generation including nEXO) currently set lower bounds on the half-life in the 10^{26}-year range and are pushing toward the parameter region suggested by the inverted-ordering neutrino masses. A positive detection would establish the Majorana nature of the neutrino and lepton-number violation; continued null results progressively constrain

it. We flag this honestly as a live question, not a settled fact, and return to the neutrino mass mechanisms in Chapters 31 and 32.

The discrete-symmetry technology assembled here — the operators $\mathcal{P}, \mathcal{C}, \mathcal{T}$ and their action on fields, states, and bilinears, the table of Table 11.2, and the CPT theorem — is exactly the apparatus the rest of the book draws on when these symmetries become constraints on dynamics: the C-oddness of the electromagnetic current that yields Furry's theorem and organizes the Ward identities of Chapters 18 and 19, the maximal P- and C-violation and the small CP-violation of the electroweak and flavor sectors in Chapters 31 and 32, and the interplay of charge conjugation and chirality that surfaces in the anomaly analysis of Chapter 36. With the discrete symmetries in hand and the Dirac propagator already built, the quantum theory of the free electron is complete.

Further reading

The Dirac equation, its plane-wave solutions, and the spinor technology used here are developed in Peskin and Schroeder [396] ch. 3 and Schwartz [432] chs. 10–11, both of which adopt conventions close to ours; Srednicki [454] chs. 33–43 reorganizes the same material around Weyl spinors and is the cleanest place to see the chiral structure. The forcing of anticommutators by positivity of the energy, and the spin–statistics connection at the level of the free field, are treated carefully in Weinberg [500] ch. 5, and the historical foundation is Pauli [387]; the original equation is of course Dirac [150]. For the axiomatic spin–statistics and CPT theorems in full generality — the analyticity machinery this chapter quotes but does not reproduce — the standard reference remains Streater and Wightman [458]. Zee [532] pt. II and Itzykson and Zuber [278] chs. 3–4 give complementary physical and computational perspectives on the propagator and the discrete symmetries.

Chapter 12

Fermionic Path Integrals

By the end of Chapter 11 the Dirac field stood on the same footing the scalar field had reached in Chapter 9: canonically quantized, with a Fock space built on anticommutators, a Pauli principle, and a time-ordered propagator S_F whose every minus sign is dictated by Fermi statistics. What the electron still lacked was the *other* description of a quantum field—the sum over histories. Chapter 10 earned that description honestly for the scalar, deriving the generating functional $Z[J]$ of Eq. (10.86) from canonical quantization by slicing the evolution operator and inserting a continuous basis at each step. This chapter pays the same debt for the Dirac field, and the entire difficulty is encoded in a single sign. A path integral as built in Chapter 10 sums e^{iS} over ordinary commuting numbers, and a commuting number can never carry the antisymmetry that the fermion propagator demands; the formalism must be rebuilt over a new species of number that anticommutes. Constructing that number system, defining integration on it, and showing that the result reproduces—number for number, sign for sign—the canonical theory of Chapter 11 is the whole of the chapter.

The opening section confronts the obstruction directly: it proves that any integral over commuting field configurations yields a *symmetric* two-point function and an all-plus (permanent) Wick expansion, in flat contradiction with the antisymmetric, determinantal correlators the Dirac field requires, and from that failure it extracts the precise specification the eventual integral must meet. The next two sections build the machinery from nothing. We introduce the Grassmann algebra of anticommuting numbers, its $\mathbb{Z}_2$ grading, and a differential calculus whose canonical relation $\{\partial_i, \theta_j\} = \delta_{ij}$ mirrors the fermionic oscillator algebra of Chapter 11; then we define Berezin integration, fixed uniquely by translation invariance, discover that it coincides with differentiation, and prove the one structural fact that distinguishes it from every ordinary integral—a linear change of variables transforms the measure by the *inverse* of the bosonic Jacobian. That single inversion is the seed of everything fermionic.

With the calculus in hand the chapter computes its central object, the

Gaussian Grassmann integral, and finds the determinant in the numerator, $\int \mathcal{D}\bar{\theta}\,\mathcal{D}\theta\, e^{-\bar{\theta}A\theta} = \det A$, the exact inverse of the bosonic $(\det A)^{-1/2}$ of Chapter 4; the same calculation delivers the Pfaffian for real (Majorana) fields, the sourced generating identity, and a Wick theorem that is a signed sum—a determinant, not a permanent—over contractions. We then close the gap between formalism and physics. Following the coherent-state route of Chapter 10, we show that the eigenvalues of a fermionic annihilation operator are forced to be Grassmann numbers, build the coherent-state resolution of the identity and the trace formula whose extra minus sign is the algebraic face of Fermi statistics, and time-slice the evolution operator to *derive*—not postulate—the Dirac path integral $\int \mathcal{D}\bar{\psi}\,\mathcal{D}\psi\, e^{iS}$, with antiperiodic boundary conditions in imaginary time emerging as the path-integral form of spin and statistics. The penultimate section couples Grassmann sources to write the Dirac generating functional in closed form, recovers the momentum-space propagator Eq. (11.27) of QED from the path integral alone (using the Clifford algebra of Chapter C), and watches every fermionic minus sign fall out of the anticommutation of the sources rather than being inserted by hand.

The final section reads the one object the source differentiation never touched—the normalization $Z[0] = \det(i\partial\!\!\!/ - m)$—as a physical quantity. Through the identity $\det = \exp \mathrm{Tr} \ln$ it becomes the one-loop fermionic effective action, expands into a sum of closed fermion loops, and yields the most consequential bookkeeping rule of perturbation theory: the factor of -1 on every closed fermion loop, derived twice (from the numerator placement of the determinant and from the antiperiodic trace) and shown to agree. The analytic control of these infinite-dimensional determinants—zeta-function and heat-kernel regularization—is imported from Chapter E, where it is built in full. Throughout we work in the mostly-minus metric $\eta_{\mu\nu} = \mathrm{diag}(+,-,-,-)$ with $\hbar = c = 1$, and the Wick rotation $t \to -i\tau$ fixed in Section 10.6. What the chapter hands forward is the complete kit of free fermionic Feynman rules—the propagator S_F, the contraction signs, and the loop factor—ready for the interacting theory of Chapters 15 and 17, the radiative corrections of Chapter 19, the ghosts of Chapter 26, the chiral anomaly of Chapter 36, and the lattice of Chapter 43.

12.1 Why fermions need anticommuting integration variables

The two pillars the reader now holds point in incompatible directions, and the first task of this chapter is to look squarely at the incompatibility before resolving it. From Chapter 10 we have a working path integral for a bosonic field: the generating functional

$$Z[J] = \int \mathcal{D}\phi\, \exp\Big[i \int d^4x\, \big(\mathcal{L}[\phi] + J\phi\big)\Big] \tag{12.1}$$

of Eq. (10.86), whose functional derivatives are the time-ordered correlators (Theorem 10.19) and whose free Gaussian limit reproduced, number for number, the canonical Feynman propagator. From Chapter 11 we have a canonically quantized Dirac field: a mode expansion built on *anti*commutators (Section 11.3), a Fock space on which the exclusion principle is the theorem $\left(b_{\mathbf{p}}^{s\dagger}\right)^2 = 0$ (Eq. (11.135)), and a time-ordered two-point function S_F carrying a minus sign forced by Fermi statistics. The natural ambition is to give the Dirac field the same path-integral description the scalar already enjoys. The obstruction is that the path integral, as built in Chapter 10, sums e^{iS} over *ordinary numbers*, and an ordinary number cannot carry the minus sign that the Dirac field's anticommutators demand. This section makes that statement precise: it shows in full what fails if one tries to integrate over commuting field configurations, and from the wreckage it extracts the exact list of properties the eventual fermionic integral must have. Nothing here is the solution; everything here is the specification the solution must meet.

12.1.1 The path integral is an integral over numbers

It is worth being completely explicit about what kind of object $\phi(x)$ is inside Eq. (12.1). The measure $\mathcal{D}\phi$ was *defined* in Theorem 10.16 as a limit of finite products of ordinary one-dimensional integrals over the field values ϕ_n at the sites n of a spacetime lattice,

$$\int \mathcal{D}\phi\,(\cdots) \;\equiv\; \lim_{a\to 0}\Big(\prod_{n}\mathcal{N}\int_{-\infty}^{\infty} d\phi_n\Big)\,(\cdots), \tag{12.2}$$

each $\phi_n \in \mathbb{R}$ a real integration variable ranging over the real line. The continuum field configuration $\phi(x)$ over which we "sum histories" is therefore, at every stage of the definition, a collection of ordinary real numbers. The single algebraic fact this entails is the only fact we shall need:

$$\phi(x)\,\phi(y) \;=\; \phi(y)\,\phi(x) \qquad \text{for every } x, y, \tag{12.3}$$

because real numbers commute. Equation Eq. (12.3) is not a dynamical statement and has nothing to do with the action or the equations of motion; it is built into the meaning of Eq. (12.2).

Consider now the time-ordered two-point function as the path integral computes it,

$$G^{(2)}(x,y) \;=\; \frac{1}{Z[0]}\int \mathcal{D}\phi\;\phi(x)\,\phi(y)\;e^{iS[\phi]}, \tag{12.4}$$

the construction Eq. (10.97) that reproduced the scalar Feynman propagator $D_F(x-y)$ of Theorem 9.24. Interchange the two insertions $x \leftrightarrow y$ in Eq. (12.4). The action $S[\phi]$, the measure $\mathcal{D}\phi$, and the normalization $Z[0]$ are untouched by relabelling the two points at which we evaluate the field; only the integrand

factor changes, from $\phi(x)\phi(y)$ to $\phi(y)\phi(x)$. By Eq. (12.3) these are the *same* integrand. Therefore

$$G^{(2)}(x,y) = G^{(2)}(y,x), \tag{12.5}$$

the two-point function produced by a path integral over commuting numbers is symmetric under exchange of its two arguments. For the scalar this is exactly correct and is no accident: the canonical $D_F(x-y) = D_F(y-x)$ is symmetric (the bosonic time-ordering symbol of Eq. (9.151) is symmetric, $\mathcal{T}\phi(x)\phi(y) = \mathcal{T}\phi(y)\phi(x)$, because $[\phi(x),\phi(y)] = 0$). The path integral and the canonical theory agree because both encode the same Bose symmetry. The question that organizes the rest of this section is whether the same machinery can encode the *opposite* symmetry that the Dirac field demands.

12.1.2 A commuting Gaussian can only make symmetric two-point functions

The symmetry Eq. (12.5) was read off the interacting integral by relabelling, but its root is in the free Gaussian, and it is the Gaussian that the fermionic theory must eventually imitate. We therefore isolate the obstruction at the level of a finite-dimensional Gaussian, where every step is an elementary integral and nothing is hidden in a continuum limit. This is the honest core of the no-go statement.

Proposition 12.1 (Commuting Gaussians have symmetric covariance)**.** *Let $\theta = (\theta_1, \dots, \theta_n)$ be ordinary real integration variables and let A be a real symmetric positive-definite $n \times n$ matrix. With the Gaussian average $\langle \cdot \rangle$ of Eq. (4.57) relative to the weight $e^{-\frac{1}{2}\theta^{\mathsf{T}} A \theta}$, the two-point function is*

$$\langle \theta_i \, \theta_j \rangle \;=\; \left(A^{-1}\right)_{ij}, \tag{12.6}$$

and it is symmetric, $\langle \theta_i \theta_j \rangle = \langle \theta_j \theta_i \rangle$, for every *choice of the matrix A in the weight. Moreover the integral depends only on the symmetric part of any matrix placed in the quadratic form.*

Proof. The covariance Eq. (12.6) is the second moment read from the normalized generating function Eq. (4.58), $Z(J)/Z(0) = \exp\!\left(\tfrac{1}{2} J^{\mathsf{T}} A^{-1} J\right)$, by differentiating twice in the sources, $\langle \theta_i \theta_j \rangle = \partial_{J_i} \partial_{J_j} \exp\!\left(\tfrac{1}{2} J^{\mathsf{T}} A^{-1} J\right)\big|_{J=0} = (A^{-1})_{ij}$. Symmetry of Eq. (12.6) is immediate from two independent facts, and it is instructive to see that they agree. On one hand A^{-1} is the inverse of a symmetric matrix and is therefore symmetric, $(A^{-1})_{ij} = (A^{-1})_{ji}$. On the other hand, and more fundamentally, the integrand $\theta_i \theta_j$ in

$$\langle \theta_i \theta_j \rangle = \frac{\int d^n\theta \; \theta_i \theta_j \, e^{-\frac{1}{2}\theta^{\mathsf{T}} A \theta}}{\int d^n\theta \; e^{-\frac{1}{2}\theta^{\mathsf{T}} A \theta}} \tag{12.7}$$

satisfies $\theta_i\theta_j = \theta_j\theta_i$ because the θ's are ordinary numbers, so the numerator is unchanged under $i \leftrightarrow j$ while the denominator does not involve i, j at all; hence $\langle\theta_i\theta_j\rangle = \langle\theta_j\theta_i\rangle$ regardless of what A is. The last claim follows from the same commutativity: in the exponent

$$\theta^{\mathsf{T}} A\theta = \sum_{i,j} \theta_i A_{ij} \theta_j = \sum_{i,j} \theta_i \, \tfrac{1}{2}(A_{ij} + A_{ji})\, \theta_j = \theta^{\mathsf{T}} A_{\mathrm{sym}}\, \theta, \tag{12.8}$$

where the middle step relabels $i \leftrightarrow j$ in half of the double sum and uses $\theta_i\theta_j = \theta_j\theta_i$, so the antisymmetric part $A_{\mathrm{anti}} = \frac{1}{2}(A - A^{\mathsf{T}})$ contributes nothing to the integral. A commuting Gaussian is blind to the antisymmetric part of its kinetic matrix. □

The point of Theorem 12.1 is sharper than the bare statement that the answer happens to be symmetric. Even if one were to *try* to force antisymmetry by hand—placing an antisymmetric matrix A_{anti} in the exponent and hoping the integral would return A_{anti}^{-1}, which is antisymmetric—Eq. (12.8) shows the attempt collapses before it begins: a purely antisymmetric quadratic form $\theta^{\mathsf{T}} A_{\mathrm{anti}}\theta$ is identically zero, the "Gaussian" has no exponent at all, and the integral diverges. Commuting variables cannot even *register* an antisymmetric kinetic operator, let alone invert it. A two-variable instance makes this concrete and leaves no room for doubt.

Worked Example 12.2 (The two-variable commuting Gaussian is symmetric, term by term)**.** Take $n = 2$ and the symmetric weight matrix $A = \left(\begin{smallmatrix} a & b \\ b & c \end{smallmatrix}\right)$ with $a, c > 0$ and $ac - b^2 > 0$, so that $A > 0$. The normalization is

$$Z = \int_{-\infty}^{\infty}\!\!\int_{-\infty}^{\infty} d\theta_1\, d\theta_2 \;\exp\Big[-\tfrac{1}{2}\big(a\theta_1^2 + 2b\,\theta_1\theta_2 + c\,\theta_2^2\big)\Big] = \frac{2\pi}{\sqrt{ac - b^2}} = \frac{2\pi}{\sqrt{\det A}}, \tag{12.9}$$

the $n = 2$ case of Eq. (4.50), the cross term $2b\,\theta_1\theta_2$ coming from $\theta^{\mathsf{T}} A\theta$ precisely because $\theta_1\theta_2 = \theta_2\theta_1$ merges the two off-diagonal entries into one. The off-diagonal correlator is obtained by completing the square or, fastest, from $A^{-1} = \frac{1}{ac-b^2}\left(\begin{smallmatrix} c & -b \\ -b & a \end{smallmatrix}\right)$ through Eq. (12.6):

$$\langle\theta_1\theta_2\rangle = (A^{-1})_{12} = \frac{-b}{ac - b^2}, \qquad \langle\theta_2\theta_1\rangle = (A^{-1})_{21} = \frac{-b}{ac - b^2}. \tag{12.10}$$

The two are equal, as they must be, since the integrand $\theta_1\theta_2$ in the defining ratio Eq. (12.7) is literally the same number as $\theta_2\theta_1$. There is no value of a, b, c, and no completing-the-square manoeuvre, that makes $\langle\theta_1\theta_2\rangle = -\langle\theta_2\theta_1\rangle$: an antisymmetric off-diagonal correlator is unreachable by integrating commuting variables. To get one, the integrand itself would have to change sign under $\theta_1 \leftrightarrow \theta_2$, which forces $\theta_1\theta_2 = -\theta_2\theta_1$ on the integration variables. That is the conclusion this section is driving toward; here it is already visible in two real integrals.

Set against this the canonical result of Chapter 11. The Dirac–Feynman propagator $S_F(x-y)_{ab} = \langle 0|\,\mathcal{T}\psi_a(x)\bar{\psi}_b(y)\,|0\rangle$ of Eq. (11.189) inherits its structure from the fermionic time-ordering symbol Eq. (11.187),

$$\mathcal{T}\,\psi(x)\bar{\psi}(y) \;\equiv\; \theta(x^0-y^0)\,\psi(x)\bar{\psi}(y) \;-\; \theta(y^0-x^0)\,\bar{\psi}(y)\psi(x), \tag{12.11}$$

in which the second ordering enters with a *minus sign*, the price of moving one fermionic operator past another. Applying the same definition to the opposite operator product $\mathcal{T}\,\bar{\psi}(y)\psi(x)$—later field to the left, minus for the swap of two fermionic operators—gives $\theta(y^0-x^0)\,\bar{\psi}(y)\psi(x) - \theta(x^0-y^0)\,\psi(x)\bar{\psi}(y)$, which is exactly the negative of Eq. (12.11). Taking the vacuum expectation of both, the time-ordered fermion two-point function obeys

$$\boxed{\;\langle 0|\,\mathcal{T}\,\psi_a(x)\,\bar{\psi}_b(y)\,|0\rangle \;=\; -\,\langle 0|\,\mathcal{T}\,\bar{\psi}_b(y)\,\psi_a(x)\,|0\rangle\;.\;} \tag{12.12}$$

This is the no-go observation in one line. The canonical object the path integral is supposed to reproduce is *antisymmetric* under interchange of its two field operators, whereas Theorem 12.1 proved that any integral over commuting field configurations produces a *symmetric* two-point function, Eq. (12.5). A Berezin-free path integral over commuting $\psi(x)$ cannot reproduce Eq. (12.12): the integrand $\psi_a(x)\bar{\psi}_b(y)$ equals $\bar{\psi}_b(y)\psi_a(x)$ for c-number fields, so the integral hands back $+$ where the canonical theory demands $-$. The sign in Eq. (12.12) is the entire content of Fermi statistics at the level of the propagator, and it is precisely the thing commuting numbers are constitutionally unable to supply.

12.1.3 The Pauli sign in multi-fermion amplitudes

The two-point obstruction is decisive on its own, but the same minus sign reappears, magnified, the moment more than one fermion is present, and it is worth exhibiting there because that is where it is physically most consequential and where it later controls the sign of every closed fermion loop. Consider the four-point function of two electron fields and two adjoint fields,

$$G^{(4)}_{a_1a_2,b_1b_2}(x_1,x_2;y_1,y_2) = \langle 0|\,\mathcal{T}\,\psi_{a_1}(x_1)\,\psi_{a_2}(x_2)\,\bar{\psi}_{b_1}(y_1)\,\bar{\psi}_{b_2}(y_2)\,|0\rangle\,. \tag{12.13}$$

Because $\psi_{a_1}(x_1)$ and $\psi_{a_2}(x_2)$ are both fermionic operators, interchanging them inside the time-ordering symbol costs a minus sign exactly as in Eq. (12.11); the analogue of the operator-level antisymmetry that Eq. (11.136) exhibited for two-electron *states*, $b^{r\dagger}_{\mathbf{p}}b^{s\dagger}_{\mathbf{q}}\,|0\rangle = -b^{s\dagger}_{\mathbf{q}}b^{r\dagger}_{\mathbf{p}}\,|0\rangle$, holds here for two-electron *field insertions*. Hence

$$G^{(4)}(x_1,x_2;y_1,y_2) = -\,G^{(4)}(x_2,x_1;y_1,y_2), \tag{12.14}$$

and likewise a minus under $y_1 \leftrightarrow y_2$. Now $G^{(4)}$ for the free field is a sum of products of two propagators—this is Wick's theorem, established for the

Figure 12.1: The two Wick pairings of the free four-fermion correlator Eq. (12.13). Antisymmetry under $x_1 \leftrightarrow x_2$ forces the two pairings to enter with opposite signs—the Pauli sign of Eq. (12.15). A path integral over commuting fields, whose Wick theorem is a permanent, would assign both pairings a plus sign and so describe bosons.

scalar in Chapter 9 and extended to the fermion with its sign rule alongside Eq. (11.187). There are exactly two ways to pair each ψ with a $\bar\psi$: the *direct* pairing $(\psi_1-\bar\psi_1,\ \psi_2-\bar\psi_2)$ and the *crossed* pairing $(\psi_1-\bar\psi_2,\ \psi_2-\bar\psi_1)$, drawn in Fig. 12.1. Antisymmetry Eq. (12.14) fixes their relative sign uniquely. Under $x_1 \leftrightarrow x_2$ the direct and crossed terms turn into each other; for the sum to flip sign, the two contributions must enter with *opposite* signs, giving the determinant (not permanent) structure

$$G^{(4)}_{a_1a_2,b_1b_2} = -\,S_F(x_1-y_1)_{a_1b_1}\,S_F(x_2-y_2)_{a_2b_2} \;+\; S_F(x_1-y_2)_{a_1b_2}\,S_F(x_2-y_1)_{a_2b_1}. \tag{12.15}$$

The relative minus sign between the two pairings is the *Pauli sign*: it is the field-theoretic statement of the exclusion principle, the same sign that turned the two-electron inner product into a Slater determinant in Theorem 11.28, now appearing as the antisymmetrization of an exchange amplitude. It is what makes identical-fermion scattering interfere destructively where identical bosons interfere constructively.

Contrast this with what a commuting path integral would deliver. For commuting Gaussian variables Wick's theorem is the statement that a $2k$-point function is the sum over *all* pairings with *all* plus signs—a permanent, the bosonic counterpart noted at Theorem 9.16. A commuting integral would therefore return

$$G^{(4)}_{\text{commuting}} = S_F(x_1-y_1)\,S_F(x_2-y_2) \;+\; S_F(x_1-y_2)\,S_F(x_2-y_1), \tag{12.16}$$

symmetric under $x_1 \leftrightarrow x_2$, in flat contradiction with the antisymmetry Eq. (12.14) that the canonical fermion field obeys. The wrong sign on a single crossed pairing is not a normalization slip; it is the difference between Fermi and Bose statistics, between matter that stacks into shells and matter that condenses into a single mode. Any honest fermionic path integral must produce the determinant Eq. (12.15), not the permanent Eq. (12.16), and Theorem 12.1 guarantees that commuting variables produce the permanent.

12.1.4 The classical limit of an anticommuting operator

The diagnosis points to its own cure. In the bosonic case the path-integral variable $\phi(x)$ is the "classical" field configuration—heuristically, the label of a coherent state, the eigenvalue of the field operator $\hat{\phi}(x)$ in the basis the path integral sums over—and it is an ordinary number precisely because the bosonic field operators *commute*: $\left[\hat{\phi}(x), \hat{\phi}(y)\right] = 0$ has, as its classical shadow, the commuting numbers $\phi(x)\phi(y) = \phi(y)\phi(x)$ of Eq. (12.3). The Dirac field operators do the opposite. They were forced in Section 11.3 to obey equal-time *anti*commutators, and the field anticommutators

$$\left\{\hat{\psi}_a(x), \hat{\psi}_b(y)\right\} = 0, \qquad \left\{\hat{\psi}_a(x), \hat{\bar{\psi}}_b(y)\right\} = 0 \quad \text{(equal times, } x \neq y\text{)}, \tag{12.17}$$

together with the nilpotency $\left(b_{\mathbf{p}}^{s\dagger}\right)^2 = 0$ of Eq. (11.135), are the algebraic signature of Fermi statistics. If the classical limit of a commuting operator is a commuting number, then by the same token the classical limit of an *anticommuting* operator must be an *anticommuting* number. The slogan "the classical limit of an anticommuting operator is an anticommuting number" is not a metaphor to be admired and set aside; it is the design requirement, and we state it as such.

Physical Insight: the integration variables must anticommute

A path integral that is to reproduce the canonical Dirac field must sum over field configurations $\psi(x), \bar{\psi}(x)$ that are themselves anticommuting objects:

$$\{\psi(x), \psi(y)\} = 0, \qquad \left\{\psi(x), \bar{\psi}(y)\right\} = 0, \qquad \left\{\bar{\psi}(x), \bar{\psi}(y)\right\} = 0 \tag{12.18}$$

at the level of the integration variables—not as operators on a Hilbert space, but as a new species of number out of which the configurations to be summed are built. In particular each such number squares to zero, $\psi(x)^2 = 0$, the c-number echo of the operator nilpotency $\left(b_{\mathbf{p}}^{s\dagger}\right)^2 = 0$. Only then can the integrand $\psi(x)\bar{\psi}(y) = -\bar{\psi}(y)\psi(x)$ change sign under interchange, and only then can the integral reproduce the antisymmetric Eq. (12.12) and the Pauli sign of Eq. (12.15).

This is a genuinely new demand on the notion of "number," and it forces two constructions that the rest of the chapter supplies. First, an *algebra* of anticommuting numbers in which Eq. (12.18) holds identically and in which one can write down field configurations, actions, and sources: this is the Grassmann (exterior) algebra. Second, a notion of *integration* over such numbers, since the ordinary Riemann integral of Eq. (12.2) presupposes an integration variable that runs over the real line, and an anticommuting number runs over nothing of the kind. That integration—Berezin's—will turn out to be defined not by summing

areas but by a single algebraic rule, and its properties are unlike anything in ordinary calculus. The honest preview, deferred to its proper place, is that the eigenvalues of fermionic field operators in a coherent-state basis are exactly such anticommuting numbers; the path integral over them is then built the same way the bosonic one was, as an integral over field-operator eigenvalues, only now the eigenvalues live in a Grassmann algebra.

12.1.5 The four properties the fermionic integral must have

We close the diagnosis by freezing the target. Whatever integration theory the next sections construct, it earns the name "fermionic path integral" only if it reproduces the canonical results of Chapter 11. There are exactly four such requirements, and the entire remainder of the chapter is the verification, one by one, that Grassmann calculus and Berezin integration meet them. Stating them now fixes the standard against which the construction will be judged and prevents the analogy with the bosonic case from being mistaken for a derivation.

(P1) Bilinear action. The integral must be defined for, and dominated by, the free Dirac action

$$S_0 = \int d^4x\, \bar{\psi}(x)\,(i\partial\!\!\!/ - m)\psi(x), \tag{12.19}$$

the spacetime integral of the Dirac Lagrangian Eq. (11.25). This is a *bilinear* (Gaussian) form in $\psi, \bar{\psi}$, just as the free scalar action was bilinear in ϕ; the fermionic Gaussian integral is therefore the object the theory rests on, and it must exist and be computable in closed form.

(P2) Correct propagator. The Gaussian two-point function defined by that integral, $\left\langle \psi_a(x)\,\bar{\psi}_b(y)\right\rangle$, must equal the canonical Dirac–Feynman propagator obtained operator-theoretically in Section 11.5,

$$\left\langle \psi_a(x)\,\bar{\psi}_b(y)\right\rangle \stackrel{!}{=} S_F(x-y)_{ab}, \qquad \tilde{S}_F(p) = \frac{i(p\!\!\!/ + m)}{p^2 - m^2 + i\varepsilon} = \frac{i}{p\!\!\!/ - m + i\varepsilon}, \tag{12.20}$$

the momentum-space form Eq. (11.27) that is the frozen free-electron propagator of QED. As $\tilde{S}_F = i(p\!\!\!/ - m)^{-1}$ is the inverse of the kinetic operator in Eq. (12.19), this is the fermionic analogue of the bosonic "propagator = inverse of the kinetic operator," but it must come out with the matrix and sign structure of the Dirac operator intact.

(P3) Correct minus signs. The integral must build in the antisymmetry Eq. (12.12) and the Pauli sign Eq. (12.15): its Wick theorem must be a determinant (signed sum over pairings), not a permanent. This is the requirement Theorem 12.1 showed commuting variables fail, and it is what

Eq. (12.18) is designed to enforce; downstream it becomes the minus sign carried by every closed fermion loop.

(P4) Determinant, not inverse square root. The source-free Gaussian must evaluate to the kinetic operator's determinant in the *first positive* power,

$$\int \mathcal{D}\psi\, \mathcal{D}\bar{\psi}\; e^{\,i\int \bar{\psi}(i\not{\partial}-m)\psi} \;\propto\; \det(i\not{\partial}-m), \tag{12.21}$$

in pointed contrast to the bosonic real Gaussian $(\det A)^{-1/2}$ of Eq. (4.50) and the complex bosonic Gaussian $(\det A)^{-1}$ of Eq. (4.60). The inversion from a negative to a positive power of the determinant is the single algebraic fact that distinguishes fermionic from bosonic functional integration, and it is the seed of the relative minus sign that property (P3) demands on closed loops.

These four are not independent wishes; they are facets of the one demand that the integral encode Fermi statistics, and they will be met together the moment the integration variables anticommute. The payoff reaches far beyond this chapter. The determinant of Eq. (12.21), written $\det(i\not{D}-m)$ once the field is coupled to a gauge potential, is the one-loop fermionic effective action computed in Chapter 19; the same Grassmann variables, now scalar rather than spinor, are the Faddeev–Popov ghosts that quantize Yang–Mills in Chapter 26; the transformation of the fermion measure $\mathcal{D}\psi\,\mathcal{D}\bar{\psi}$ under a chiral rotation is where the chiral anomaly lives, in Fujikawa's treatment of Chapter 36; and the difficulty of representing $\det(i\not{D}-m)$ on a finite grid is exactly what makes lattice fermions hard, in Chapter 43. The minus sign we have been unable to manufacture from commuting numbers is, in the end, one of the most consequential signs in physics.

We have therefore fixed the target completely: an integration theory whose variables satisfy Eq. (12.18) and which meets (P1)–(P4). What remains is to build it. The next section answers the first half of the demand by constructing, from nothing, the algebra of anticommuting numbers—its generators, its grading, the finiteness of functions built on it, and the differential calculus on it—providing every algebraic fact the integration theory of the sections that follow will lean on.

12.2 Grassmann algebra and Grassmann calculus

The previous section (Section 12.1) left us with a sharp demand and no machinery to meet it. We saw that a path integral for the Dirac field cannot run over ordinary commuting field configurations: a c-number can never reproduce the minus sign that the Pauli principle, the antisymmetry of the time-ordered propagator S_F, and the very anticommutators $\left\{\hat{a}^{s}_{\mathbf{p}}, \hat{a}^{r\dagger}_{\mathbf{q}}\right\} = (2\pi)^3\delta^{sr}\delta^3(\mathbf{p}-\mathbf{q})$ of Chapter 11 all

insist upon. The classical limit of an anticommuting operator is not a number in the usual sense; it is an *anticommuting* number. The whole of the fermionic path integral therefore rests on first constructing, honestly and from nothing, an algebra in which such objects live and a calculus with which to manipulate them. That is the business of this section. We build the Grassmann algebra, establish the finiteness that makes every function of anticommuting variables a polynomial, develop left and right differentiation with their precise sign rules, fix the complex-conjugation convention that the Dirac bilinears will require, and isolate the single identity, $\{\partial/\partial\theta_i, \theta_j\} = \delta_{ij}$, that mirrors the canonical fermionic structure at the level of calculus. Every algebraic fact the integration theory of the next section leans on is proved here.

The objects we are about to define are not exotic; the same algebra is the home of the exterior forms of differential geometry, of the Faddeev–Popov ghosts that will tame non-abelian gauge fixing in Chapter 26, and of the anticommuting coordinates of superspace in Chapter 44. We construct it once, in full generality, and the later chapters will simply reach for it.

12.2.1 The Grassmann algebra and its generators

We work over the complex numbers throughout, because the Dirac field is complex; the real case is the obvious restriction. The defining move is to introduce symbols that square to zero by being made to anticommute.

Definition 12.3 (Grassmann algebra)**.** Let $n \geq 1$. The *Grassmann algebra* $\mathcal{G}_n$ on n generators $\theta_1, \ldots, \theta_n$ is the associative, unital $\mathbb{C}$-algebra generated by the θ_i subject to the single family of relations

$$\{\theta_i, \theta_j\} = \theta_i\theta_j + \theta_j\theta_i = 0, \qquad i, j = 1, \ldots, n. \tag{12.22}$$

The complex scalars are taken to commute with every θ_i. Elements of $\mathcal{G}_n$ are called *Grassmann numbers*; the θ_i themselves are the *Grassmann variables* or odd generators.

Concretely, $\mathcal{G}_n$ is the quotient of the free associative algebra $\mathbb{C}\langle\theta_1, \ldots, \theta_n\rangle$ on n noncommuting symbols by the two-sided ideal generated by the relations (12.22). Mathematically this is nothing but the exterior algebra $\Lambda(\mathbb{C}^n)$ with the wedge written as juxtaposition; we will not need that identification, but it is reassuring that the structure is a familiar one. The whole content of (12.22) is captured by two consequences we use constantly. First, taking $i = j$,

$$2\theta_i^2 = \{\theta_i, \theta_i\} = 0 \quad \Longrightarrow \quad \theta_i^2 = 0, \tag{12.23}$$

the *nilpotency* of every generator: no Grassmann variable can appear twice in a product without killing it. Second, for $i \neq j$ the variables genuinely *anticommute*,

$$\theta_i\theta_j = -\theta_j\theta_i, \tag{12.24}$$

so the *order* of factors matters up to a sign. These two facts—nilpotency and signed reordering—are the entire algebra; everything below is their bookkeeping.

Remark 12.4 (A worked feel for the algebra). With two generators θ_1, θ_2 a general product simplifies in a few strokes: $\theta_1\theta_2\theta_1 = -\theta_1\theta_1\theta_2 = 0$ by (12.23), and $\theta_2\theta_1 = -\theta_1\theta_2$ by (12.24). The only nonzero products are 1, θ_1, θ_2, and $\theta_1\theta_2$. Every other word in the two letters either repeats a letter (and vanishes) or reorders to one of these (up to sign). This is the prototype of the finiteness we now prove in general.

12.2.2 Monomials, the basis, and the top form

Because every word in the generators either repeats a letter and dies or can be sorted into increasing index order at the cost of a sign, the surviving objects are the *ordered, repetition-free monomials*. We make this precise and count them.

Theorem 12.5 (Basis and dimension of $\mathcal{G}_n$)**.** *The ordered monomials*

$$1, \qquad \theta_{i_1}\theta_{i_2}\cdots\theta_{i_k} \quad \text{with} \quad 1 \le i_1 < i_2 < \cdots < i_k \le n, \quad 1 \le k \le n, \tag{12.25}$$

form a basis of $\mathcal{G}_n$ as a complex vector space. Consequently

$$\dim_{\mathbb{C}} \mathcal{G}_n = \sum_{k=0}^{n} \binom{n}{k} = 2^n, \tag{12.26}$$

and there is, up to a complex scalar, a unique monomial of maximal degree—the top form

$$\theta_{\text{top}} \equiv \theta_1\theta_2\cdots\theta_n, \tag{12.27}$$

which spans the one-dimensional top-degree subspace and is annihilated by left- or right-multiplication by any further generator.

Proof. Spanning. Any element of $\mathcal{G}_n$ is a finite $\mathbb{C}$-linear combination of words $\theta_{j_1}\theta_{j_2}\cdots\theta_{j_m}$ in the generators, since these words span the free algebra and passing to the quotient only adds relations. Take any such word. If two of its letters coincide, $j_a = j_b$ with $a < b$, then move θ_{j_b} leftward past the $b - a - 1$ intervening factors using (12.24); this produces an overall sign $(-1)^{b-a-1}$ and brings the two equal letters adjacent, where $\theta_{j_a}\theta_{j_a} = 0$ by (12.23) annihilates the whole word. Hence only words with *distinct* letters survive. For such a word, repeatedly swapping adjacent out-of-order factors via (12.24) sorts the indices into strictly increasing order; each swap costs a factor -1, so the word equals $\pm$ one of the ordered monomials (12.25). Thus the ordered monomials span $\mathcal{G}_n$.

Linear independence. It remains to show the ordered monomials are not subject to any hidden linear relation, i.e. that the quotient did not collapse them. We exhibit a concrete model on which they act as manifestly independent

operators. Let $W = \Lambda(\mathbb{C}^n)$ be the 2^n-dimensional vector space with formal basis labeled by subsets $S \subseteq \{1, \dots, n\}$, written e_S, and define for each i a linear operator $\hat{\theta}_i$ on W by

$$\hat{\theta}_i \, e_S = \begin{cases} 0, & i \in S, \\ (-1)^{\#\{j \in S \,:\, j < i\}} \, e_{S \cup \{i\}}, & i \notin S, \end{cases} \tag{12.28}$$

the operator of "wedging on the left with θ_i." A direct check on the four cases (whether i, j already lie in S) shows $\hat{\theta}_i \hat{\theta}_j + \hat{\theta}_j \hat{\theta}_i = 0$: when both indices are absent, the two orders deposit $e_{S \cup \{i,j\}}$ with opposite signs because inserting i then j versus j then i differ by exactly one transposition; when either index already lies in S, both orders give zero. Hence (12.28) respects the defining relations (12.22) and so descends to a homomorphism $\rho : \mathcal{G}_n \to \mathrm{End}(W)$. Applying $\rho(\theta_{i_1} \cdots \theta_{i_k})$ to the cyclic vector $e_\varnothing$ yields $\pm e_{\{i_1, \dots, i_k\}}$, and distinct ordered monomials produce distinct basis vectors e_S of W. A linear relation among the ordered monomials would, applied to $e_\varnothing$, force a linear relation among distinct e_S, which is impossible. The ordered monomials are therefore independent, and they form a basis.

Counting. The ordered monomials of degree k are indexed by the k-element subsets of $\{1, \dots, n\}$, of which there are $\binom{n}{k}$; summing over k and using the binomial theorem at $x = 1$ gives $\sum_k \binom{n}{k} = 2^n$, which is (12.26).

Top form. The maximal degree is $k = n$, attained only by the single subset $\{1, \dots, n\}$, so the degree-n subspace is one-dimensional and spanned by $\theta_{\mathrm{top}} = \theta_1 \cdots \theta_n$. Multiplying θ_{top} by any θ_i repeats a generator and gives zero by (12.23), whether the new factor is appended on the left or the right. □

The top form is the single most important object in the whole construction: the next section's integration will be, in essence, the linear functional that reads off the coefficient of θ_{top}. We record the structural payoff of Theorem 12.5 separately, because it is the statement the calculus is built to exploit.

Corollary 12.6 (Functions of Grassmann variables terminate)**.** *Every function of the Grassmann variables $\theta_1, \dots, \theta_n$—meaning every element of $\mathcal{G}_n$, equivalently every formal power series in the θ_i once the relations are imposed—is a* finite *polynomial,*

$$f(\theta) = f_0 + \sum_i f_i \, \theta_i + \sum_{i<j} f_{ij} \, \theta_i \theta_j + \cdots + f_{12\cdots n} \, \theta_1 \theta_2 \cdots \theta_n, \tag{12.29}$$

with 2^n complex coefficients $f_0, f_i, \dots, f_{12\cdots n}$ (antisymmetric in their indices if one chooses to write them with unrestricted, rather than ordered, index ranges), and no term of degree exceeding n.

Proof. By Theorem 12.5 the ordered monomials are a basis, so f is uniquely the displayed linear combination; (12.23) truncates every series at degree n because any monomial of higher degree must repeat a generator and vanish. □

This is a remarkable simplification with no analogue for ordinary variables: a "function" of n anticommuting arguments is determined by finitely many numbers, and the entire apparatus of Taylor expansion stops automatically at the top form. It is the reason Grassmann integration will turn out to be algebra rather than analysis. As a small illustration of how drastically series collapse, the exponential of a Grassmann-even quadratic terminates after one step,

$$e^{\theta_1\theta_2} = 1 + \theta_1\theta_2 + \tfrac{1}{2!}(\theta_1\theta_2)^2 + \cdots = 1 + \theta_1\theta_2, \tag{12.30}$$

since $(\theta_1\theta_2)^2 = \theta_1\theta_2\theta_1\theta_2 = -\theta_1\theta_1\theta_2\theta_2 = 0$. The contrast with the genuinely infinite matrix-exponential series of Section 2.3 is exactly the contrast between nilpotent and generic elements; the Gaussian Grassmann integral of Section 12.4 will live entirely on such terminating exponentials.

12.2.3 The $\mathbb{Z}_2$ grading: even and odd

The algebra splits cleanly according to the parity of the degree, and this splitting controls every sign that follows.

Definition 12.7 (Grading and parity)**.** Write $\mathcal{G}_n = \mathcal{G}_n^0 \oplus \mathcal{G}_n^1$, where the *even* part $\mathcal{G}_n^0$ is spanned by ordered monomials of even degree and the *odd* part $\mathcal{G}_n^1$ by those of odd degree. An element lying entirely in $\mathcal{G}_n^p$ is called *homogeneous of parity* p, and we write $|a| = p \in \{0, 1\}$ for its parity (read mod 2). Even elements are also called *bosonic* or *commuting*, odd elements *fermionic* or *anticommuting*. The classical fermion fields of this chapter are odd; their bilinears, Lagrangian, and action are even.

Multiplying monomials adds degrees, so the grading is multiplicative: $|ab| = |a| + |b| \bmod 2$, i.e. $\mathcal{G}_n^p \mathcal{G}_n^q \subseteq \mathcal{G}_n^{p+q}$. The basic commutation law of the algebra, derived once and used everywhere, follows directly.

Proposition 12.8 (Graded commutativity)**.** *For homogeneous $a, b \in \mathcal{G}_n$,*

$$ab = (-1)^{|a|\,|b|}\, ba. \tag{12.31}$$

In particular even elements are central (they commute with everything), and two odd elements anticommute.

Proof. By bilinearity it suffices to take a and b to be ordered monomials, of degrees $r = |a| \bmod 2$ and $s = |b| \bmod 2$ in the counting sense—say a has r' factors and b has s' factors. To move the block b from the right of a to its left, each of the s' generators in b must be carried past each of the r' generators in a, and every such elementary transposition of distinct generators costs -1 by (12.24) (if any generator is shared the products vanish on both sides and (12.31) holds trivially as $0 = 0$). There are $r's'$ such transpositions, so $ab = (-1)^{r's'} ba$.

Since $(-1)^{r's'}$ depends only on the parities $r' \bmod 2 = |a|$ and $s' \bmod 2 = |b|$, we may replace $r's'$ by $|a||b|$, giving (12.31). If $|a| = 0$ the sign is $+1$ for every b, so even elements are central; if $|a| = |b| = 1$ the sign is -1, so odd elements anticommute. □

12.2.4 Grassmann differentiation

We now build a differential calculus. Because order matters in $\mathcal{G}_n$, there are two natural derivatives—one that strips a generator from the left of a monomial and one that strips it from the right—and we must keep them distinct. The functional derivative of Theorem 4.4 is the commuting, infinite-dimensional ancestor of what we are defining; the Grassmann derivative is its finite, anticommuting analogue, and the price of anticommutativity is precisely the sign rules below.

Definition 12.9 (Left and right Grassmann derivatives)**.** The *left derivative* $\overrightarrow{\partial}_i \equiv \dfrac{\overrightarrow{\partial}}{\partial\theta_i}$ is the linear operator on $\mathcal{G}_n$ defined on the basis monomials by: if θ_i does not occur, the result is 0; if θ_i occurs, first anticommute it to the leftmost slot using (12.24) and then delete it. Explicitly, on an ordered monomial in which θ_i sits in position p (counting from the left, starting at 1),

$$\overrightarrow{\partial}_i(\theta_{i_1}\cdots\theta_{i_{p-1}}\,\theta_i\,\theta_{i_{p+1}}\cdots\theta_{i_k}) = (-1)^{p-1}\,\theta_{i_1}\cdots\theta_{i_{p-1}}\,\theta_{i_{p+1}}\cdots\theta_{i_k}. \tag{12.32}$$

The *right derivative* $\overleftarrow{\partial}_i \equiv \dfrac{\overleftarrow{\partial}}{\partial\theta_i}$, written acting on its argument from the right, anticommutes θ_i to the rightmost slot and deletes it,

$$(\theta_{i_1}\cdots\theta_i\cdots\theta_{i_k})\,\overleftarrow{\partial}_i = (-1)^{k-p}\,\theta_{i_1}\cdots\theta_{i_{p-1}}\,\theta_{i_{p+1}}\cdots\theta_{i_k}, \tag{12.33}$$

again with θ_i in position p, and zero if θ_i is absent. On the generators themselves both reduce to $\overrightarrow{\partial}_i\theta_j = \theta_j\overleftarrow{\partial}_i = \delta_{ij}$, and both annihilate the constant: $\overrightarrow{\partial}_i 1 = 0$.

The signs in (12.32)–(12.33) are not conventions to be memorized in isolation; they are forced by demanding that differentiation obey a Leibniz rule compatible with the grading. We make that precise.

Proposition 12.10 (Graded Leibniz rule)**.** *The left derivative is an* odd antiderivation*: for all homogeneous a and arbitrary b,*

$$\overrightarrow{\partial}_i(ab) = (\overrightarrow{\partial}_i a)\,b + (-1)^{|a|}\,a\,(\overrightarrow{\partial}_i b). \tag{12.34}$$

The right derivative satisfies the mirror rule, for homogeneous b and arbitrary a,

$$(ab)\,\overleftarrow{\partial}_i = a\,(b\,\overleftarrow{\partial}_i) + (-1)^{|b|}\,(a\,\overleftarrow{\partial}_i)\,b. \tag{12.35}$$

Moreover the two derivatives are related on a homogeneous element f by $f\,\overleftarrow{\partial}_i = -(-1)^{|f|}\,\overrightarrow{\partial}_i f$.

Proof. By linearity take $a = \theta_{a_1}\cdots\theta_{a_r}$ and $b = \theta_{b_1}\cdots\theta_{b_s}$ to be monomials, so $|a| = r \bmod 2$. If θ_i appears in neither factor, both sides of (12.34) vanish. If θ_i appears in a, say in position $p \le r$, then in the product ab it still sits in position p, so by (12.32) the left-hand side carries the sign $(-1)^{p-1}$ and deletes that θ_i, which is exactly $(\overrightarrow{\partial}_i a)b$; the second term on the right vanishes since θ_i does not occur in b. If instead θ_i appears in b, in position q within b, then within ab it occupies position $r+q$, so the left-hand side carries $(-1)^{r+q-1} = (-1)^r(-1)^{q-1} = (-1)^{|a|}(-1)^{q-1}$ and deletes it; the surviving factor is a times the q-deleted b, i.e. $(-1)^{|a|}a(\overrightarrow{\partial}_i b)$, and now the first term on the right vanishes. (If θ_i appeared in both a and b, the product ab would repeat a generator and vanish, and so would both terms on the right, since a and b remain monomials with a shared letter.) In every case (12.34) holds. The right rule (12.35) is identical with positions counted from the right. Finally, on a degree-k monomial f with θ_i in position p, the left rule gives sign $(-1)^{p-1}$ and the right rule gives $(-1)^{k-p}$; their ratio is $(-1)^{k-p-(p-1)} = (-1)^{k+1} = -(-1)^k = -(-1)^{|f|}$, which is the stated relation. □

We will use the left derivative as the default and drop the arrow when no confusion can arise, writing $\partial_i \equiv \overrightarrow{\partial}_i$; the right derivative is needed only where the field-theoretic source terms of Section 12.6 make the ordering physical. Both derivatives lower the degree by one, hence flip parity: ∂_i maps $\mathcal{G}_n^p$ to $\mathcal{G}_n^{p+1}$, which is what "odd" means and why the antiderivation sign $(-1)^{|a|}$ appears in (12.34) rather than the $+1$ of an ordinary Leibniz rule.

12.2.5 The canonical anticommutation relations of the calculus

We can now extract the two structural identities the integration theory needs. The first realizes the canonical fermionic algebra at the level of differentiation; the second is the nilpotency of differentiation itself. Throughout, θ_j denotes the operator of *left multiplication* by θ_j, so that an anticommutator $\{\partial_i, \theta_j\}$ is read as an identity of operators on $\mathcal{G}_n$, $\partial_i(\theta_j a) + \theta_j(\partial_i a)$.

Proposition 12.11 (Canonical relation $\{\partial_i, \theta_j\} = \delta_{ij}$)**.** *As operators on $\mathcal{G}_n$,*

$$\{\partial_i, \theta_j\} = \delta_{ij}\,\mathbf{1}, \tag{12.36}$$

where $\mathbf{1}$ is the identity operator.

Proof. Let $a \in \mathcal{G}_n$ be arbitrary; by linearity take it homogeneous. Apply the graded Leibniz rule (12.34) with the first factor equal to the odd generator θ_j (so $|\theta_j| = 1$):

$$\partial_i(\theta_j a) = (\partial_i\theta_j)\,a + (-1)^{|\theta_j|}\theta_j(\partial_i a) = \delta_{ij}\,a - \theta_j(\partial_i a), \tag{12.37}$$

using $\partial_i\theta_j = \delta_{ij}$ from Theorem 12.9. Bringing the last term to the left,

$$\partial_i(\theta_j a) + \theta_j(\partial_i a) = \delta_{ij}\,a, \tag{12.38}$$

which is precisely $\{\partial_i, \theta_j\}\, a = \delta_{ij}\, a$ for every a, i.e. the operator identity (12.36). □

This is the calculus-level avatar of the canonical fermionic structure. Set against the oscillator algebra $\left\{\hat{a}_i, \hat{a}_j^\dagger\right\} = \delta_{ij}$ of the quantized Dirac field in Chapter 11, (12.36) identifies ∂_i as the annihilation operator and θ_j (left multiplication) as the creation operator on the 2^n-dimensional space $\mathcal{G}_n$, which is the fermionic Fock space on n modes with vacuum 1 and filled state θ_{top}. The same algebra that will integrate fermions thus already *is*, structurally, the fermionic Fock space; this is no coincidence but the precise sense in which Grassmann numbers are the classical shadow of anticommuting operators.

Proposition 12.12 (Nilpotency of differentiation)**.** *The left derivatives anticommute among themselves,*

$$\{\partial_i, \partial_j\} = 0, \qquad \textit{in particular} \quad \partial_i^2 = 0. \tag{12.39}$$

Proof. We first show that the anticommutator of two odd antiderivations is an ordinary (even) derivation. Let D_1, D_2 be odd antiderivations, so each obeys $D_\alpha(ab) = (D_\alpha a)b + (-1)^{|a|} a(D_\alpha b)$. Compute, for homogeneous a,

$$\begin{aligned} D_1 D_2(ab) &= D_1\big[(D_2 a)b + (-1)^{|a|} a(D_2 b)\big] \\ &= (D_1 D_2 a)b + (-1)^{|a|+1}(D_2 a)(D_1 b) + (-1)^{|a|}(D_1 a)(D_2 b) + a(D_1 D_2 b), \end{aligned} \tag{12.40}$$

where the sign $(-1)^{|a|+1}$ in the second term arises because $D_2 a$ has parity $|a|+1$. Interchanging $1 \leftrightarrow 2$ gives the same expression with the two cross terms swapped:

$$D_2 D_1(ab) = (D_2 D_1 a)b + (-1)^{|a|+1}(D_1 a)(D_2 b) + (-1)^{|a|}(D_2 a)(D_1 b) + a(D_2 D_1 b). \tag{12.41}$$

Adding (12.40) and (12.41), the two cross terms involving $(D_2 a)(D_1 b)$ combine with coefficient $(-1)^{|a|+1} + (-1)^{|a|} = 0$, and likewise those involving $(D_1 a)(D_2 b)$ cancel, leaving

$$\{D_1, D_2\}\,(ab) = (\,\{D_1, D_2\}\,a)b + a(\,\{D_1, D_2\}\,b). \tag{12.42}$$

Thus $\{D_1, D_2\}$ is an even derivation. An even derivation D is determined by its values on the generators: by (12.42) and induction on degree, if $D\theta_k = 0$ for all k then D annihilates every monomial $\theta_{i_1} \cdots \theta_{i_k} = \theta_{i_1}(\theta_{i_2} \cdots \theta_{i_k})$, since D of a product is the sum of terms each carrying a $D\theta_{i_a} = 0$; and $D1 = 0$ because $D1 = D(1 \cdot 1) = 2D1$. Now specialize $D_1 = \partial_i$, $D_2 = \partial_j$, which are odd antiderivations by Theorem 12.10. On a generator,

$$\{\partial_i, \partial_j\}\,\theta_k = \partial_i(\partial_j \theta_k) + \partial_j(\partial_i \theta_k) = \partial_i\,\delta_{jk} + \partial_j\,\delta_{ik} = 0, \tag{12.43}$$

since the derivative of the constant δ_{jk} vanishes. Hence the even derivation $\{\partial_i, \partial_j\}$ annihilates all generators and is therefore zero on all of $\mathcal{G}_n$, proving (12.39); taking $i = j$ gives $2\partial_i^2 = 0$, so $\partial_i^2 = 0$. □

Worked Example 12.13 (The full operator algebra on two generators, checked by hand)**.** It is worth seeing Theorems 12.11 and 12.12 confirmed by brute force, with no appeal to the abstract derivation argument, on the smallest nontrivial algebra $\mathcal{G}_2$ with basis $\{1, \theta_1, \theta_2, \theta_1\theta_2\}$. We tabulate the action of ∂_1 on the basis using (12.32):

$$\partial_1 1 = 0, \quad \partial_1\theta_1 = 1, \quad \partial_1\theta_2 = 0, \quad \partial_1(\theta_1\theta_2) = \theta_2, \tag{12.44}$$

the last because θ_1 sits in position $p = 1$, giving sign $(-1)^0 = +1$ and leaving θ_2. For ∂_2,

$$\partial_2 1 = 0, \quad \partial_2\theta_1 = 0, \quad \partial_2\theta_2 = 1, \quad \partial_2(\theta_1\theta_2) = -\theta_1, \tag{12.45}$$

where now θ_2 sits in position $p = 2$, giving sign $(-1)^1 = -1$. We verify the three relations.

(i) $\{\partial_1, \theta_1\} = \mathbf{1}$. Take the basis element θ_2. Left multiplication then ∂_1: $\partial_1(\theta_1\theta_2) = \theta_2$. The other order: $\theta_1(\partial_1\theta_2) = \theta_1 \cdot 0 = 0$. Sum $= \theta_2$, reproducing the input. On 1: $\partial_1(\theta_1 \cdot 1) = \partial_1\theta_1 = 1$ and $\theta_1\partial_1 1 = 0$, sum $= 1$. On θ_1: $\partial_1(\theta_1\theta_1) = \partial_1 0 = 0$ and $\theta_1\partial_1\theta_1 = \theta_1$, sum $= \theta_1$. On $\theta_1\theta_2$: $\partial_1(\theta_1\theta_1\theta_2) = 0$ and $\theta_1\partial_1(\theta_1\theta_2) = \theta_1\theta_2$, sum $= \theta_1\theta_2$. In every case the operator returns its input, so $\{\partial_1, \theta_1\} = \mathbf{1}$.

(ii) $\{\partial_1, \theta_2\} = 0$. On 1: $\partial_1(\theta_2) + \theta_2\partial_1 1 = 0 + 0 = 0$. On θ_1: $\partial_1(\theta_2\theta_1) + \theta_2\partial_1\theta_1 = \partial_1(-\theta_1\theta_2) + \theta_2 = -\theta_2 + \theta_2 = 0$, the crucial cancellation that the sign in (12.45) arranges. On the remaining basis elements one finds 0 identically. Hence $\{\partial_1, \theta_2\} = 0 = \delta_{12}\mathbf{1}$.

(iii) $\partial_1^2 = 0$ *and* $\{\partial_1, \partial_2\} = 0$. Since ∂_1 lowers degree and $\partial_1\theta_1 = 1$, $\partial_1^2(\theta_1\theta_2) = \partial_1\theta_2 = 0$ and ∂_1^2 is zero on all lower-degree elements trivially, so $\partial_1^2 = 0$. For the mixed relation, the only basis element on which both derivatives act nontrivially is $\theta_1\theta_2$: $\partial_1\partial_2(\theta_1\theta_2) = \partial_1(-\theta_1) = -1$ while $\partial_2\partial_1(\theta_1\theta_2) = \partial_2\theta_2 = +1$, summing to 0. Thus $\{\partial_1, \partial_2\} = 0$, in agreement with Theorem 12.12.

12.2.6 Complex conjugation and the independent conjugate variable

The Dirac field is complex, and its action contains $\bar{\psi}\,(i\partial\!\!\!/ - m)\psi$, a quantity that must be *real* so that e^{iS} has unit modulus and the theory is unitary. To carry this into the Grassmann setting we need an operation of complex conjugation on $\mathcal{G}_n$ and a convention for how it interacts with products. The right convention is the one that makes Grassmann conjugation behave like the Hermitian conjugation of operators it is meant to model.

Definition 12.14 (Complex conjugation of Grassmann numbers)**.** A *complex conjugation* on a Grassmann algebra is an antilinear involution $a \mapsto a^*$ satisfying, for complex scalars λ and homogeneous a, b,

$$(\lambda a)^* = \bar{\lambda}\, a^*, \qquad (a^*)^* = a, \qquad (ab)^* = b^* a^*. \tag{12.46}$$

The defining feature is the *order reversal* in the last rule: conjugating a product reverses the factors, exactly as $(\hat{A}\hat{B})^\dagger = \hat{B}^\dagger \hat{A}^\dagger$ for operators.

For a single Grassmann variable we declare its conjugate θ^* to be an *independent* odd generator—a genuinely new element of an enlarged algebra, not a function of θ—and we write it $\bar{\theta} \equiv \theta^*$, with $(\bar{\theta})^* = \theta$. A complex Dirac field then contributes, mode by mode, an independent pair $(\theta, \bar{\theta})$, precisely paralleling the way the classical complex scalar carried independent ϕ and ϕ^*, and the way the quantum Dirac field carried independent ψ and $\bar{\psi} = \psi^\dagger \gamma^0$. Treating θ and $\bar{\theta}$ as independent integration variables is what will let Section 12.6 introduce independent sources $\eta, \bar{\eta}$ for $\psi, \bar{\psi}$.

Caution: $\bar{\theta}$ is an independent conjugate, not the strong-CP angle

The bar in $\bar{\theta}$ here denotes Grassmann complex conjugation and marks an *independent* odd generator; it has nothing to do with the macro $\bar{\theta}$ reserved in Appendix F for the physical strong-CP angle. We always write the conjugate Grassmann variable with an explicit bar accent, $\bar{\theta}$, to keep the two meanings apart.

The order reversal is not a stylistic choice: it is forced by reality of the fermion bilinear, and dropping it would make $\bar{\theta}\theta$ *anti*-real, in direct contradiction with the reality of the Dirac mass term. The following worked check is the decisive consistency test of the whole convention.

Worked Example 12.15 (Reality of the bilinear $\bar{\theta}\theta$)**.** Take one complex Grassmann variable θ with independent conjugate $\bar{\theta}$, and form the even element $\bar{\theta}\theta$, the Grassmann model of a single fermionic bilinear such as a mode contribution to $\bar{\psi}\psi$. We test its conjugate two ways.

With order reversal (the adopted convention). Apply the third rule of (12.46) and then $(\bar{\theta})^* = \theta$, $(\theta)^* = \bar{\theta}$:

$$(\bar{\theta}\theta)^* = \theta^* \, (\bar{\theta})^* = \bar{\theta}\, \theta. \tag{12.47}$$

The bilinear equals its own conjugate; it is *real* (more precisely, a self-conjugate Grassmann-even element), exactly the property needed for $m\bar{\psi}\psi$ to enter a real Lagrangian and for e^{iS} to have unit modulus. This is the Grassmann counterpart of $(\hat{a}^\dagger \hat{a})^\dagger = \hat{a}^\dagger \hat{a}$: a number-operator-like bilinear is Hermitian.

Without order reversal (the wrong convention, shown to fail). Had we instead demanded $(ab)^* = a^* b^*$, the same computation would give

$$(\bar{\theta}\theta)^*_{(\text{no reversal})} = \bar{\theta}^* \theta^* = \theta\, \bar{\theta} = -\bar{\theta}\theta, \tag{12.48}$$

using the anticommutativity (12.24) of the two distinct odd generators in the last step. The bilinear would be *anti*-real, $(\bar{\theta}\theta)^* = -\bar{\theta}\theta$, so $m\bar{\theta}\theta$ could never sit

in a real action. The factor of -1 in (12.48) is exactly the one the order-reversal rule (12.47) is designed to absorb. Reality of fermion bilinears therefore *requires* the order-reversal convention; we adopt it permanently.

The same reversal makes longer strings behave correctly. For a quadratic form $\bar{\theta}_i A_{ij} \theta_j$ with a numerical matrix A, repeated use of (12.46) gives $(\bar{\theta}_i A_{ij} \theta_j)^* = \bar{A}_{ij}\, \theta_j^* \bar{\theta}_i^* = \bar{A}_{ij}\, \bar{\theta}_j \theta_i = \bar{\theta}_i\, (A^\dagger)_{ij}\, \theta_j$, after relabeling and one anticommutation; the bilinear is real precisely when A is Hermitian, the exact condition the Dirac operator $i\partial\!\!\!/ - m$ satisfies (in the appropriate inner product) and the reason its Grassmann Gaussian integral in Section 12.4 will produce a sensible $\det(i\partial\!\!\!/ - m)$.

With Theorems 12.5, 12.6 and 12.10 to 12.12 and the conjugation convention of Theorem 12.14 in hand, the Grassmann calculus is now fully operational: we have anticommuting variables, finite functions of them, left and right derivatives with their sign rules, the canonical relation $\{\partial_i, \theta_j\} = \delta_{ij}$, and a complex structure under which fermion bilinears are real. What is still missing is an *integral*—a linear functional on $\mathcal{G}_n$ that can play the role $\int \mathcal{D}\phi$ played for the scalar. The single algebraic fact the next section will exploit is the one this section has made unavoidable: a function of n Grassmann variables is a polynomial whose information caps at the top form $\theta_{\text{top}} = \theta_1 \cdots \theta_n$. Berezin's definition of integration, to which we now turn in Section 12.3, is essentially the unique linear functional that isolates the coefficient of that top form, and its strange-looking properties—translation invariance, the Grassmann delta function, and a Jacobian that inverts rather than multiplies—will all follow from the calculus assembled here.

12.3 Berezin integration

The previous section gave us an algebra and a differential calculus on it. We can multiply Grassmann numbers, expand any function of them into its (necessarily terminating) Taylor series, and differentiate from the left or the right with the sign rules of Section 12.2. One operation is conspicuously missing, and it is exactly the one the path integral cannot do without: integration. The bosonic generating functional of Chapter 10 was built by literally summing e^{iS} over field configurations, that is, by an honest (if formal) integral $\int \mathcal{D}\phi$ over the values a commuting field can take. To give the Dirac field the same description we must learn to integrate a function of *anticommuting* variables — and here ordinary intuition is no help at all. A Grassmann variable θ takes no numerical values; it is not a coordinate on any space, there is no interval to subdivide, no measure to assign, no Riemann sum to refine. The symbol $\int \mathrm{d}\theta$ cannot mean "area under a curve." It must be *defined*, and the only honest way to define it is to decide first what we want an integral to be *for* and then to ask whether anything on the Grassmann algebra does that job.

What we want is contained in two demands. First, integration should be *linear*: the integral of a sum is the sum of the integrals, and constants pull out. Second — and this is the property that does all the work in field theory — it should be *translation invariant*. In the bosonic path integral, the single fact that makes the generating functional manipulable is that $\int_{-\infty}^{\infty} \mathrm{d}x\, f(x+a) = \int_{-\infty}^{\infty} \mathrm{d}x\, f(x)$; shifting the dummy variable changes nothing. This is what lets one complete the square in a Gaussian, shift away a linear source, and read off a propagator. Any integral worth the name for Grassmann variables must share this property, because we will want to perform precisely the same shifts on fermionic fields. The remarkable fact — due to Berezin — is that these two demands, linearity and translation invariance, pin the integral down *completely* up to a single multiplicative constant. There is essentially one notion of integration on a Grassmann algebra, and we are about to discover that it coincides, of all things, with differentiation.

12.3.1 The single variable: uniqueness forces Berezin's rule

Fix one Grassmann generator θ, with $\theta^2 = 0$. Because the algebra it generates is two dimensional — every function is

$$f(\theta) = a + b\,\theta, \qquad a, b \in \mathbb{C}, \tag{12.49}$$

the Taylor series terminating after one term — an integral is nothing more exotic than a linear functional I on this two-dimensional space. Such a functional is fixed by its two values on the basis $\{1, \theta\}$:

$$I[1] \;=\; \alpha, \qquad I[\theta] \;=\; \beta, \tag{12.50}$$

and then $I[f] = a\,\alpha + b\,\beta$ by linearity. Two numbers α, β parametrize every candidate integral. Translation invariance will kill one of them and normalization will fix the other.

To state translation invariance we must say what it means to shift θ. Let η be a new Grassmann constant — a generator of a larger Grassmann algebra that anticommutes with θ and squares to zero, $\eta^2 = 0$, $\{\eta, \theta\} = 0$. "Shift" means replacing θ by $\theta + \eta$ everywhere. The integral is called translation invariant if

$$I\big[f(\theta+\eta)\big] \;=\; I\big[f(\theta)\big] \qquad \text{for every } f \text{ and every Grassmann constant } \eta, \tag{12.51}$$

where I acts only on the θ-dependence, treating η as an external constant exactly as a in $\int \mathrm{d}x\, f(x+a)$ is held fixed while x is integrated.

Theorem 12.16 (Uniqueness of the Berezin integral)**.** *Every linear functional I on the algebra generated by a single Grassmann variable θ that is translation invariant in the sense of Eq. (12.51) annihilates the constants, $I[1] = 0$, and is therefore proportional to the coefficient of the top monomial,*

$$I[a + b\,\theta] \;=\; \beta\, b, \tag{12.52}$$

with $\beta = I[\theta]$ the one free constant. Conversely every functional of this form is translation invariant.

Proof. Expand the shifted function. Since η is Grassmann-odd and $\theta^2 = 0$,

$$f(\theta + \eta) = a + b\,(\theta + \eta) = (a + b\,\eta) + b\,\theta. \tag{12.53}$$

The shift has not changed the coefficient of θ (still b); it has only added the Grassmann-odd constant $b\,\eta$ to the constant term. Apply I, using linearity and holding η fixed:

$$I\big[f(\theta + \eta)\big] = (a + b\,\eta)\,\alpha + b\,\beta = \underbrace{(a\,\alpha + b\,\beta)}_{= I[f(\theta)]} + b\,\eta\,\alpha. \tag{12.54}$$

Translation invariance Eq. (12.51) demands that the difference vanish, $b\,\eta\,\alpha = 0$, for *all* coefficients b and all Grassmann constants η. Since $b\,\eta$ is a nonzero element of the larger algebra for generic b and η, the only way to enforce this is $\alpha = 0$. Hence $I[1] = 0$, and $I[f] = b\,\beta$, which is Eq. (12.52). The converse is immediate: a functional that reads off β times the coefficient of θ ignores the constant term entirely, and by Eq. (12.53) the shift touches only the constant term, so the value is unchanged. □

The theorem says the integral is unique up to the normalization β. We fix it by the single conventional choice $\beta = 1$, and we adopt the notation $\int \mathrm{d}\theta$ for the resulting functional. This is Berezin's definition.

Definition 12.17 (Berezin integral, one variable)**.** Integration over a single Grassmann variable θ is the linear functional fixed by

$$\int \mathrm{d}\theta\; 1 \;=\; 0, \qquad \int \mathrm{d}\theta\; \theta \;=\; 1. \tag{12.55}$$

On a general function it returns the coefficient of θ: $\displaystyle\int \mathrm{d}\theta\,(a + b\theta) = b$.

The first rule, $\int \mathrm{d}\theta\, 1 = 0$, is the one that looks strange and is in fact the heart of the matter: it is forced, not chosen. It is the Grassmann analogue of the statement that $\int_{-\infty}^{\infty} \mathrm{d}x\, 1$ would have to be translation invariant and so cannot depend on any origin — except that here, instead of diverging, the invariant value is simply zero. The second rule is the harmless choice of unit. Everything that follows is a consequence of Eq. (12.55).

Integration is differentiation. Compare Theorem 12.17 with the left derivative $\partial_\theta^{\mathrm{L}}$ built in Section 12.2, which strips a leading θ: $\partial_\theta^{\mathrm{L}} 1 = 0$ and $\partial_\theta^{\mathrm{L}} \theta = 1$.

These are *identical* to the Berezin rules Eq. (12.55). Therefore, as operators on functions of one Grassmann variable,

$$\boxed{\int \mathrm{d}\theta \;=\; \partial_\theta^{\mathrm{L}}} \tag{12.56}$$

Grassmann integration and left differentiation are the same operation. This is not a curiosity but the structural fact that governs every sign and every Jacobian below. It is worth pausing on how sharply it departs from the bosonic functional calculus of Chapter 4: there, differentiation $\delta/\delta\phi(x)$ (Theorem 4.4) and integration $\int \mathcal{D}\phi$ are genuinely different operations, inverse to one another in the sense of the fundamental theorem of calculus, and a Gaussian integral and a functional derivative produce different objects. For Grassmann variables that distinction collapses. One immediate consequence is that there are no boundary terms and no convergence questions: the "integral" is a finite, purely algebraic operation that always returns a definite element of the algebra. A second consequence is integration by parts in its cleanest possible form. Because $\partial_\theta^{\mathrm{L}}$ obeys a graded Leibniz rule and $\partial_\theta^{\mathrm{L}}(\partial_\theta^{\mathrm{L}} f) = 0$ (a leading θ, once removed, cannot be removed again), for any two functions f, g one has

$$\int \mathrm{d}\theta\, (\partial_\theta^{\mathrm{L}} f)\, g \;=\; (-1)^{|f|} \int \mathrm{d}\theta\, f\, (\partial_\theta^{\mathrm{L}} g), \tag{12.57}$$

with $|f|$ the Grassmann parity of f, and no surface term ever appears because $\int \mathrm{d}\theta\, \partial_\theta^{\mathrm{L}}(fg) = \partial_\theta^{\mathrm{L}}\partial_\theta^{\mathrm{L}}(fg) = 0$. The sign $(-1)^{|f|}$ is the only residue of "moving the derivative across," inherited directly from Eq. (12.56) and the graded Leibniz rule of Section 12.2.

Caution

The identity $\int \mathrm{d}\theta = \partial_\theta^{\mathrm{L}}$ tempts one to read $\mathrm{d}\theta$ as if it transformed like the differential of a coordinate, the way $\mathrm{d}x$ does. It does not. Under a rescaling $\theta \to c\,\theta$ an ordinary differential scales as $\mathrm{d}(cx) = c\,\mathrm{d}x$, but the Berezin symbol scales the *opposite* way, $\mathrm{d}(c\theta) = c^{-1}\mathrm{d}\theta$, precisely because $\int \mathrm{d}\theta$ measures the coefficient of θ rather than a length. This inverse scaling is the one-variable shadow of the inverse-determinant law proved in Theorem 12.19; keeping it straight is the difference between landing the fermionic Gaussian on $\det A$ and on $(\det A)^{-1}$.

12.3.2 Several Grassmann variables

Pass now to n generators $\theta_1, \dots, \theta_n$, all anticommuting, $\{\theta_i, \theta_j\} = 0$ (so $\theta_i^2 = 0$). A general function is a finite sum over subsets $S \subseteq \{1, \dots, n\}$,

$$f(\theta) = \sum_{S} c_S\, \theta_S, \qquad \theta_S := \theta_{i_1}\theta_{i_2}\cdots\theta_{i_k} \quad (i_1 < \cdots < i_k,\; S = \{i_1, \dots, i_k\}), \tag{12.58}$$

with the convention $\theta_\varnothing = 1$. The series terminates at the *top monomial* $\theta_{\{1,\dots,n\}} = \theta_1\theta_2\cdots\theta_n$, the unique (up to sign) element of maximal degree n; there is no room for any θ_i to appear twice. We integrate variable by variable, each $\int \mathrm{d}\theta_i$ acting by the single-variable rule Theorem 12.17, that is, as the left derivative $\partial^{\mathrm{L}}_{\theta_i}$. The only new ingredient is the *order* of the iterated operations and the bookkeeping of signs, and for this it is cleanest to declare that the symbols $\mathrm{d}\theta_i$ are themselves Grassmann-odd: they anticommute with one another and with every θ_j,

$$\{\mathrm{d}\theta_i, \mathrm{d}\theta_j\} = 0, \qquad \{\mathrm{d}\theta_i, \theta_j\} = 0. \tag{12.59}$$

This is the only convention consistent with $\int \mathrm{d}\theta_i = \partial^{\mathrm{L}}_{\theta_i}$ and the graded calculus, and it is what makes the multi-variable measure transform cleanly.

Definition 12.18 (Berezin integral, several variables)**.** The multiple Berezin integral is the iterated functional

$$\int \mathrm{d}\theta_n\, \mathrm{d}\theta_{n-1}\cdots\mathrm{d}\theta_1\; f(\theta) \;:=\; \partial^{\mathrm{L}}_{\theta_n}\partial^{\mathrm{L}}_{\theta_{n-1}}\cdots\partial^{\mathrm{L}}_{\theta_1}\, f(\theta), \tag{12.60}$$

the innermost differential $\mathrm{d}\theta_1$ acting first. Equivalently, it returns the coefficient of the top monomial:

$$\int \mathrm{d}\theta_n\cdots\mathrm{d}\theta_1\; f \;=\; c_{\{1,\dots,n\}}, \qquad \text{where } f = c_{\{1,\dots,n\}}\,\theta_1\cdots\theta_n + (\text{lower degree}). \tag{12.61}$$

The equivalence of the two formulas is the basic computation of the subject, so we do it once in full rather than assert it. Take $f = \theta_1\theta_2\cdots\theta_n$, the top monomial with unit coefficient. Apply the innermost operator: θ_1 already stands at the far left, so $\partial^{\mathrm{L}}_{\theta_1}(\theta_1\theta_2\cdots\theta_n) = \theta_2\cdots\theta_n$. Now θ_2 stands at the far left of what remains, so $\partial^{\mathrm{L}}_{\theta_2}(\theta_2\cdots\theta_n) = \theta_3\cdots\theta_n$, and so on; after all n operators,

$$\int \mathrm{d}\theta_n\cdots\mathrm{d}\theta_1\; \theta_1\theta_2\cdots\theta_n = 1. \tag{12.62}$$

Any monomial θ_S with $S \neq \{1,\dots,n\}$ is missing at least one generator, say $\theta_j \notin S$; the corresponding $\partial^{\mathrm{L}}_{\theta_j}$ acts on something with no θ_j in it and gives zero. Hence only the top monomial survives, with the matching of orders in Eq. (12.60) arranged precisely so that its coefficient comes out with a plus sign, which is Eq. (12.61). The pairing of the descending measure $\mathrm{d}\theta_n\cdots\mathrm{d}\theta_1$ with the ascending monomial $\theta_1\cdots\theta_n$ is not an accident of taste: it is what removes every intermediate sign, and any other pairing differs from it only by the sign of a permutation, which we now make explicit.

If we reverse the measure to the ascending order, the price is the sign of the order-reversing permutation. For $n = 2$, $\int \mathrm{d}\theta_1\,\mathrm{d}\theta_2\,\theta_1\theta_2 = \partial^{\mathrm{L}}_{\theta_1}\partial^{\mathrm{L}}_{\theta_2}(\theta_1\theta_2) = \partial^{\mathrm{L}}_{\theta_1}(-\theta_1) = -1$, because $\partial^{\mathrm{L}}_{\theta_2}(\theta_1\theta_2) = -\theta_1$ (the operator must anticommute past θ_1 before it meets θ_2). The same computation done with the descending measure $\mathrm{d}\theta_2\,\mathrm{d}\theta_1$ gives $+1$ by Eq. (12.62). These relative signs are not a nuisance to be papered over; they are the combinatorial seed of the antisymmetry of fermionic amplitudes, and we keep them visible throughout.

12.3.3 Change of variables: the inverse determinant

We come to the property that distinguishes Grassmann integration from every integral the reader has met before, and that — traced forward two sections — is the reason the fermionic Gaussian produces $\det A$ rather than $(\det A)^{-1/2}$, and the reason every closed fermion loop carries a minus sign. Consider a linear change of variables

$$\theta_i = \sum_{j=1}^{n} M_{ij}\,\theta'_j, \qquad i = 1, \dots, n, \tag{12.63}$$

with M an invertible $n \times n$ matrix of ordinary (commuting) numbers. For an *ordinary* integral over $\mathbb{R}^n$, such a substitution multiplies the measure by the Jacobian $\det M$ (its absolute value): $\mathrm{d}^n x = |\det M|\,\mathrm{d}^n x'$. For Berezin integration the factor is the *reciprocal*.

Theorem 12.19 (Change of variables; the inverse-determinant Jacobian)**.** *Under the linear change Eq. (12.63) with $M \in \mathrm{GL}(n)$ over the commuting scalars,*

$$\int \mathrm{d}\theta_n \cdots \mathrm{d}\theta_1\; f(\theta) \;=\; (\det M)^{-1} \int \mathrm{d}\theta'_n \cdots \mathrm{d}\theta'_1\; f(M\theta'), \tag{12.64}$$

where $f(M\theta')$ denotes f with each θ_i replaced by $\sum_j M_{ij}\theta'_j$. Equivalently, the Berezin measure transforms as $\mathrm{d}\theta_n \cdots \mathrm{d}\theta_1 = (\det M)^{-1}\,\mathrm{d}\theta'_n \cdots \mathrm{d}\theta'_1$ — the inverse of the ordinary Jacobian, with no absolute value and no square root.

The whole content sits in how the top monomial transforms, so we isolate that as a lemma.

Lemma 12.20 (The top form scales by $\det M$)**.** *Under Eq. (12.63),*

$$\theta_1\theta_2 \cdots \theta_n = (\det M)\;\theta'_1\theta'_2 \cdots \theta'_n. \tag{12.65}$$

Proof. Substitute and expand the product:

$$\theta_1\theta_2 \cdots \theta_n = \sum_{j_1,\dots,j_n=1}^{n} M_{1j_1} M_{2j_2} \cdots M_{nj_n}\;\theta'_{j_1}\theta'_{j_2} \cdots \theta'_{j_n}. \tag{12.66}$$

The coefficients M_{ij} commute, so they were freely pulled out front. A summand vanishes whenever two of the indices $j_1, \dots, j_n$ coincide, because then the product $\theta'_{j_1} \cdots \theta'_{j_n}$ repeats a generator and is zero. Only the terms in which $(j_1, \dots, j_n)$ is a permutation σ of $(1, \dots, n)$ survive. For such a term, reordering the θ' factors into ascending order costs the sign of the permutation,

$$\theta'_{\sigma(1)}\theta'_{\sigma(2)} \cdots \theta'_{\sigma(n)} = \operatorname{sgn}(\sigma)\,\theta'_1\theta'_2 \cdots \theta'_n, \tag{12.67}$$

since each transposition of adjacent factors flips one sign. Therefore

$$\theta_1 \cdots \theta_n = \Big(\sum_{\sigma \in S_n} \operatorname{sgn}(\sigma)\, M_{1\sigma(1)} M_{2\sigma(2)} \cdots M_{n\sigma(n)}\Big)\theta'_1 \cdots \theta'_n = (\det M)\,\theta'_1 \cdots \theta'_n, \tag{12.68}$$

the bracket being exactly the Leibniz formula for $\det M$. □

The fact that the antisymmetry of the Grassmann product manufactures a determinant out of a linear substitution is the algebraic miracle on which the whole fermionic path integral runs. The minus signs that defeat the bosonic intuition — the ones that turn the would-be $(\det A)^{-1/2}$ into $\det A$ — are nothing but the antisymmetrization in Eq. (12.67), performed automatically by the algebra.

Proof of Theorem 12.19. Both sides of Eq. (12.64) are linear in f, so it suffices to verify the identity on each basis monomial θ_S, $S \subseteq \{1,\dots,n\}$. By Eq. (12.61) the left-hand side $\int \mathrm{d}\theta_n \cdots \mathrm{d}\theta_1\, \theta_S$ is 1 if $S = \{1,\dots,n\}$ and 0 otherwise.

Now examine the right-hand side. Substituting Eq. (12.63) turns θ_S, a product of $|S| = k$ generators, into a product of k linear forms in the θ', which is a homogeneous element of degree k in the θ'-algebra. The right-hand integral $\int \mathrm{d}\theta'_n \cdots \mathrm{d}\theta'_1$ extracts the coefficient of the degree-n top monomial $\theta'_1 \cdots \theta'_n$ (Eq. (12.61)). A degree-k element can contain the degree-n monomial only if $k = n$. Hence for every S with $|S| < n$ the right-hand side is 0, matching the left-hand side. The single remaining case is $S = \{1,\dots,n\}$, the top monomial, for which Theorem 12.20 gives

$$\int \mathrm{d}\theta'_n \cdots \mathrm{d}\theta'_1\; \theta_1 \cdots \theta_n = \int \mathrm{d}\theta'_n \cdots \mathrm{d}\theta'_1\; (\det M)\, \theta'_1 \cdots \theta'_n = \det M, \tag{12.69}$$

using Eq. (12.62) for the last step. Multiplying by the prefactor $(\det M)^{-1}$ in Eq. (12.64) returns 1, again matching the left-hand side. The identity holds on every basis element, hence on all f by linearity. □

Worked Example 12.21 (The 2×2 change of variables, explicitly)**.** It is worth seeing the determinant assemble itself by hand, with no appeal to the Leibniz formula. Take $n = 2$ and

$$\theta_1 = a\,\theta'_1 + b\,\theta'_2, \qquad \theta_2 = c\,\theta'_1 + d\,\theta'_2, \qquad M = \begin{pmatrix} a & b \\ c & d \end{pmatrix}, \quad \det M = ad - bc. \tag{12.70}$$

Form the top monomial and multiply out, dropping the $\theta_i'^2 = 0$ terms:

$$\begin{aligned} \theta_1\theta_2 &= (a\theta'_1 + b\theta'_2)(c\theta'_1 + d\theta'_2) \\ &= ac\,\underbrace{\theta'_1\theta'_1}_{0} + ad\,\theta'_1\theta'_2 + bc\,\theta'_2\theta'_1 + bd\,\underbrace{\theta'_2\theta'_2}_{0} \\ &= ad\,\theta'_1\theta'_2 + bc\,\theta'_2\theta'_1 = ad\,\theta'_1\theta'_2 - bc\,\theta'_1\theta'_2 = (ad - bc)\,\theta'_1\theta'_2, \end{aligned} \tag{12.71}$$

where the single sign flip came from $\theta'_2\theta'_1 = -\theta'_1\theta'_2$. This is Eq. (12.65) for $n = 2$. Now integrate. On the one hand $\int \mathrm{d}\theta_2\, \mathrm{d}\theta_1\, \theta_1\theta_2 = 1$ by Eq. (12.62); on the other,

$$\int \mathrm{d}\theta'_2\, \mathrm{d}\theta'_1\; \theta_1\theta_2 = \int \mathrm{d}\theta'_2\, \mathrm{d}\theta'_1\; (ad - bc)\, \theta'_1\theta'_2 = ad - bc = \det M. \tag{12.72}$$

The two are consistent with Theorem 12.19: $1 = (\det M)^{-1} \det M$. The lone minus sign in Eq. (12.71) is, in miniature, the entire reason fermion loops sign the way they do.

Physical Insight

The inverse determinant is the formal origin of the fermion-loop minus sign. When in Section 12.4 we evaluate the Gaussian $\int\prod \mathrm{d}\bar\theta_i\,\mathrm{d}\theta_i\, e^{-\bar\theta A\theta}$, the change of variables that diagonalizes the quadratic form will, by Theorem 12.19, contribute the reciprocal of the Jacobian, and the answer will be $\det A$ — the *numerator* placement that is the exact inverse of the bosonic $(\det A)^{-1/2}$. Carried into perturbation theory, that single inversion is what assigns (-1) to every closed fermion loop and reappears as the one-loop effective action $\log\det(i\not{D}-m)$ of Section 12.7. Every later occurrence of a fermionic minus sign — the relative sign between exchange diagrams, the sign of the QED vacuum polarization, the very existence of the chiral anomaly in Chapter 36 — can be traced back to the reordering Eq. (12.67) that turned a substitution into a determinant.

12.3.4 The Grassmann delta function

An integral worthy of the name should possess a delta function: an object that, placed under $\int\mathrm{d}\theta$, reproduces the value of a function at a chosen point. For ordinary integration $\int\mathrm{d}x\,\delta(x-y)\,f(x)=f(y)$. The Grassmann analogue is startlingly simple, and it follows directly from Berezin's rule with no distribution theory whatsoever.

Definition 12.22 (Grassmann delta function)**.** For Grassmann variables θ,θ' the delta function is the degree-one element

$$\delta(\theta-\theta') \;:=\; \theta-\theta'. \tag{12.73}$$

That the delta function "is" just the difference of the two variables is a consequence of Eq. (12.56): since integration is differentiation, the object that sifts must itself be linear in θ. We verify the sifting property in full, signs included, because the placement of δ relative to f matters in a graded calculus.

Proposition 12.23 (Sifting)**.** *For any function $f(\theta)=a+b\theta$, with θ' treated as a Grassmann constant anticommuting with θ,*

$$\int \mathrm{d}\theta\;\delta(\theta-\theta')\,f(\theta) \;=\; f(\theta'). \tag{12.74}$$

Worked Example 12.24 (Verifying the sifting property)**.** We compute the left-hand side of Eq. (12.74) term by term. Expand the product $\delta(\theta-\theta')f(\theta)=(\theta-\theta')(a+b\theta)$, keeping every sign and using $\theta^2=0$:

$$\begin{aligned}(\theta-\theta')(a+b\theta) &= a\theta + b\,\theta\theta - a\theta' - b\,\theta'\theta\\ &= a\theta - a\theta' - b\,\theta'\theta = a\theta - a\theta' + b\,\theta\theta',\end{aligned} \tag{12.75}$$

where $\theta\theta = 0$ was dropped and the last step used $\theta'\theta = -\theta\theta'$ (the constant θ' anticommutes with θ). Now apply $\int \mathrm{d}\theta = \partial_\theta^{\mathrm{L}}$, which keeps the coefficient of a *leading* θ and discards anything with no θ:

- $\int \mathrm{d}\theta\,(a\theta) = a$;
- $\int \mathrm{d}\theta\,(-a\theta') = 0$, since θ' carries no θ;
- $\int \mathrm{d}\theta\,(b\,\theta\theta') = b\,\theta'$, since θ stands to the left and is stripped, leaving $b\,\theta'$.

Summing the three contributions,

$$\int \mathrm{d}\theta\;(\theta - \theta')(a + b\theta) = a + b\,\theta' = f(\theta'), \tag{12.76}$$

which is exactly Eq. (12.74). The sign in the middle line of Eq. (12.75) was essential: had we mishandled the anticommutation of θ' past θ, the third contribution would have come out as $-b\theta'$ and the sifting would have failed. The order matters, too — with δ to the *right*, one finds $\int \mathrm{d}\theta\, f(\theta)\,\delta(\theta - \theta') = -f(\theta')$ for Grassmann-even f, the extra sign tracking the graded commutation of f past δ. We adopt the convention of Eq. (12.74), δ on the left, so that sifting reproduces $f(\theta')$ cleanly.

For several variables the delta function is the ordered product $\delta^{(n)}(\theta - \theta') = \prod_{i=n}^{1}(\theta_i - \theta_i') = (\theta_n - \theta_n')\cdots(\theta_1 - \theta_1')$, and the analogous computation gives $\int \mathrm{d}\theta_n \cdots \mathrm{d}\theta_1\, \delta^{(n)}(\theta - \theta')\, f(\theta) = f(\theta')$; the ordering of the factors is chosen to match the descending measure so that the iterated sifting Eq. (12.74) chains together without stray signs.

12.3.5 Conjugate pairs and reality conventions

Fermionic actions are built from a field and its Dirac adjoint, so the integration variables come in conjugate pairs $(\theta, \bar\theta)$. Here $\bar\theta$ is the conjugate generator introduced in Section 12.2, with the involution $(\theta)^* = \bar\theta$, $(\bar\theta)^* = \theta$, and the order-reversing rule for products $(\theta_1\theta_2)^* = \bar\theta_2\,\bar\theta_1$. For the purposes of *integration*, θ and $\bar\theta$ are treated as two *independent* generators — the bar is a notational reminder of how they conjugate, not a constraint relating them under the integral. This is the Grassmann counterpart of writing a bosonic Gaussian over the independent real and imaginary parts of a complex field.

For a single pair we order the measure as $\mathrm{d}\bar\theta\,\mathrm{d}\theta$ and fix the normalization by the single rule

$$\int \mathrm{d}\bar\theta\,\mathrm{d}\theta\;\theta\,\bar\theta \;=\; 1, \tag{12.77}$$

which follows from the iterated single-variable rules: $\int \mathrm{d}\theta\,(\theta\bar\theta) = \partial_\theta^{\mathrm{L}}(\theta\bar\theta) = \bar\theta$ strips the leading θ, and then $\int \mathrm{d}\bar\theta\,\bar\theta = 1$. Because $\bar\theta\theta = -\theta\bar\theta$, the same measure

gives $\int \mathrm{d}\bar\theta\,\mathrm{d}\theta\,\bar\theta\theta = -1$. With this convention the elementary one-pair Gaussian comes out right way up: expanding the exponential, which terminates because $(\bar\theta\theta)^2 = 0$,

$$\int \mathrm{d}\bar\theta\,\mathrm{d}\theta\; e^{-\bar\theta a\theta} = \int \mathrm{d}\bar\theta\,\mathrm{d}\theta\;(1 - a\,\bar\theta\theta) = -a\int \mathrm{d}\bar\theta\,\mathrm{d}\theta\;\bar\theta\theta = -a\,(-1) = a, \tag{12.78}$$

for any commuting number a. The constant term integrates to zero by Berezin's first rule, leaving only the quadratic term, and the answer is a in the numerator — the $n = 1$ instance of the $\det A$ that Section 12.4 will establish in general, and already the opposite of the bosonic $\int \mathrm{d}x\,\mathrm{d}y\, e^{-a(x^2+y^2)/2} \propto a^{-1}$.

Definition 12.25 (Paired Berezin measure)**.** For n conjugate pairs $(\theta_i, \bar\theta_i)$, $i = 1, \dots, n$, the integration measure is the ordered product

$$\int \prod_{i=1}^{n} \mathrm{d}\bar\theta_i\,\mathrm{d}\theta_i \;:=\; \int \mathrm{d}\bar\theta_n\,\mathrm{d}\theta_n \cdots \mathrm{d}\bar\theta_1\,\mathrm{d}\theta_1, \tag{12.79}$$

normalized by Eq. (12.77) on each pair. It picks out the coefficient of the top monomial $\prod_i \theta_i\bar\theta_i$ in the integrand.

The change-of-variables theorem Theorem 12.19 applies to each set of variables independently. If the θ_i are transformed by a matrix M and the $\bar\theta_i$ by a matrix N — as happens when one diagonalizes a fermionic bilinear $\bar\theta A\theta$ by $\theta = M\theta''$, $\bar\theta = \bar\theta'' N^{\mathsf T}$ — the measure picks up $(\det M)^{-1}(\det N)^{-1}$. This is precisely the bookkeeping that, in the next section, converts $\int\prod \mathrm{d}\bar\theta_i\,\mathrm{d}\theta_i\, e^{-\bar\theta A\theta}$ into $\det A$, and we flag here that the two inverse determinants from the two independent variable sets reinforce rather than cancel — the hallmark that fermionic Gaussians land on a positive power of the determinant.

We now hold a complete integration theory for anticommuting variables: a unique translation-invariant functional fixed by $\int \mathrm{d}\theta\,\theta = 1$, its identification with left differentiation, the multi-variable measure that reads off the top form, the Grassmann delta function, and — the load-bearing result — the inverse-determinant change-of-variables law. With the inverse Jacobian in hand, the central computation of the chapter is now a short step away: the Gaussian Grassmann integral of Section 12.4, whose value is $\det A$ rather than the bosonic $(\det A)^{-1/2}$, and from which Wick's theorem for fermions and the entire diagrammatic minus-sign structure will follow.

12.4 Gaussian Grassmann integrals: determinants, Pfaffians, and Wick's theorem

The previous section built Berezin integration from nothing and isolated the one feature that makes it strange: a linear change of variables $\theta = M\theta'$ transforms

the measure with the *inverse* of the bosonic Jacobian,

$$\int \mathcal{D}\theta\, f(\theta) = (\det M)^{-1} \int \mathcal{D}\theta'\, f(M\theta') \qquad (\textit{Theorem } 12.19).$$

That single inversion is the seed of everything that follows. In ordinary calculus the Gaussian integral $\int d^n x\, e^{-\frac{1}{2}x^{\mathsf{T}}Ax}$ returns $(\det A)^{-1/2}$ because the measure must absorb $(\det A)^{-1/2}$ when one rescales to principal axes (Theorem 4.14); the determinant lands in the *denominator*. For Grassmann variables the measure absorbs the *opposite* power, so the same Gaussian returns $\det A$ in the *numerator*. This section computes the fundamental Gaussian Grassmann integrals in full, contrasts them sharply with their bosonic ancestors of Chapter 4, and extracts from them the sourced generating identity and the Grassmann form of Wick's theorem. These are the entire computational engine of the fermionic path integral: once A is promoted to the Dirac operator in Section 12.6, the formulas proved here become the generating functional $Z[\eta, \bar{\eta}]$ and the propagator S_F.

We work throughout over a fixed Grassmann algebra. For the *complex* (paired) case we have $2n$ independent generators $\theta_1, \dots, \theta_n$ and $\bar{\theta}_1, \dots, \bar{\theta}_n$, all mutually anticommuting; here $\bar{\theta}_i$ is the conjugate generator of Theorem 12.14, treated under the integral as a second *independent* generator, not a constraint relating it to θ_i (Section 12.3.5). For the *real* case we have $2n$ generators $\theta_1, \dots, \theta_{2n}$ with $\{\theta_i, \theta_j\} = 0$. We take from Section 12.3 the facts we need about the measure. It is the unique (up to normalization) translation-invariant linear functional (Theorem 12.16), with

$$\int \mathcal{D}\bar{\theta}\,\mathcal{D}\theta\; \theta_i \bar{\theta}_i = 1 \quad (\text{no sum, hence } \int \mathcal{D}\bar{\theta}\mathcal{D}\theta\, \bar{\theta}_i\theta_i = -1), \qquad \int \mathcal{D}\theta\; \theta_1\theta_2\cdots\theta_{2n} = 1, \tag{12.80}$$

where $\mathcal{D}\bar{\theta}\,\mathcal{D}\theta \equiv d\bar{\theta}_n\, d\theta_n \cdots d\bar{\theta}_1\, d\theta_1$ (Theorem 12.25, Eq. (12.77)) and $\mathcal{D}\theta \equiv d\theta_{2n}\cdots d\theta_1$ (Eq. (12.62)), every monomial that fails to saturate all generators integrating to zero; and it is translation invariant, $\int \mathcal{D}\theta\, f(\theta+\xi) = \int \mathcal{D}\theta\, f(\theta)$ for any constant Grassmann shift ξ (Eq. (12.51)). Everything below is built from these and from anticommutation.

12.4.1 The complex Gaussian: $\int e^{-\bar{\theta}A\theta} = \det A$

The central identity inverts the bosonic complex Gaussian of Theorem 4.17 ($\det A$ becomes $\det^{-1} A$) by promoting the integration variables from commuting complex numbers to anticommuting generators. We follow the sign convention of Section 12.3.5, in which the quadratic form carries a minus, matching the one-pair result $\int d\bar{\theta}\, d\theta\, e^{-\bar{\theta}a\theta} = a$ established there (Eq. (12.78)).

Theorem 12.26 (Complex Gaussian Grassmann integral)**.** *Let A be an arbitrary $n \times n$ complex matrix. Then*

$$\int \mathcal{D}\bar{\theta}\,\mathcal{D}\theta\; e^{-\bar{\theta}A\theta} \;=\; \det A, \qquad \bar{\theta}A\theta \equiv \sum_{i,j=1}^{n} \bar{\theta}_i\, A_{ij}\, \theta_j. \tag{12.81}$$

There is no *hypothesis of symmetry, Hermiticity, or positivity on A: the integral exists as a finite polynomial expression and equals the determinant of any square matrix.*

The contrast with the bosonic results of Chapter 4 could not be sharper. The real bosonic Gaussian gives $(\det A)^{-1/2}$ (Theorem 4.15); the complex bosonic Gaussian gives $(\det A)^{-1}$ (Theorem 4.17), and both demand $A > 0$ for convergence. The Grassmann integral gives $(\det A)^{+1}$, converges trivially because the integrand is a polynomial (the exponential of a nilpotent quantity terminates), and asks nothing of A. We give three proofs: a direct expansion for $n = 1, 2$ that makes the mechanism visible, a one-line proof for general A via the inverse Jacobian, and the explicit combinatorial expansion that exhibits the determinant's permutation sum term by term.

Proof for $n = 1$ and $n = 2$ by direct expansion. For $n = 1$ the exponent is nilpotent of order two, $(\bar\theta_1\theta_1)^2 = \bar\theta_1\theta_1\bar\theta_1\theta_1 = 0$, so the exponential terminates after one term:

$$e^{-\bar\theta A\theta} = 1 - A\,\bar\theta_1\theta_1. \tag{12.82}$$

The constant integrates to zero (it fails to saturate the generators), while by (12.80), $\int d\bar\theta_1 d\theta_1\,(1 - A\bar\theta_1\theta_1) = -A\cdot(-1) = A = \det A$.

For $n = 2$ write $S = \bar\theta A\theta = \sum_{i,j}\bar\theta_i A_{ij}\theta_j$. The exponential is $e^{-S} = 1 - S + \frac{1}{2}S^2$ (all higher powers vanish, since S^3 would need a generator repeated). Only the degree-four piece $\frac{1}{2}S^2$ can saturate all four generators, so

$$\int \mathcal{D}\bar\theta\,\mathcal{D}\theta\; e^{-S} = \tfrac{1}{2}\int \mathcal{D}\bar\theta\,\mathcal{D}\theta\; S^2. \tag{12.83}$$

Of the sixteen terms in $S^2 = \sum_{ijkl}\bar\theta_i A_{ij}\theta_j\,\bar\theta_k A_{kl}\theta_l$, only the four with $\{i,k\} = \{1,2\}$ and $\{j,l\} = \{1,2\}$ survive integration. Reducing each to the reference order $\bar\theta_1\theta_1\bar\theta_2\theta_2$, which equals the top monomial $\theta_1\bar\theta_1\theta_2\bar\theta_2$ and so integrates to 1:

$$\begin{aligned}
(i,j,k,l) = (1,1,2,2): &\quad A_{11}A_{22}\,\bar\theta_1\theta_1\bar\theta_2\theta_2 \;\to\; +A_{11}A_{22},\\
(i,j,k,l) = (2,2,1,1): &\quad A_{22}A_{11}\,\bar\theta_2\theta_2\bar\theta_1\theta_1 \;\to\; +A_{11}A_{22},\\
(i,j,k,l) = (1,2,2,1): &\quad A_{12}A_{21}\,\bar\theta_1\theta_2\bar\theta_2\theta_1 \;\to\; -A_{12}A_{21},\\
(i,j,k,l) = (2,1,1,2): &\quad A_{21}A_{12}\,\bar\theta_2\theta_1\bar\theta_1\theta_2 \;\to\; -A_{12}A_{21}.
\end{aligned} \tag{12.84}$$

In the second line $\bar\theta_2\theta_2$ and $\bar\theta_1\theta_1$ are each Grassmann-even, so they commute and the order is restored with no sign. In the third line, moving θ_1 left past the even block $\bar\theta_2\theta_2$ costs nothing and transposing $\theta_2\bar\theta_2 \to \bar\theta_2\theta_2$ costs -1, net -1; the fourth line is identical under $1 \leftrightarrow 2$. Summing and dividing by 2,

$$\tfrac{1}{2}(2A_{11}A_{22} - 2A_{12}A_{21}) = A_{11}A_{22} - A_{12}A_{21} = \det A, \tag{12.85}$$

which is (12.81) for $n = 2$. □

The $n = 2$ computation already displays the whole phenomenon: the determinant's *signs* are not put in by hand; they are produced by the anticommutation of the generators. The off-diagonal product $A_{12}A_{21}$ arrives with a relative minus because reordering the Grassmann generators to a common reference costs an odd permutation. This is the algebraic root of every fermionic minus sign in the book.

Proof for general A via the inverse Jacobian. Suppose first that A is invertible. Change variables on the θ generators alone, leaving the $\bar\theta$ untouched: set $\theta = A^{-1}\theta'$. By the Berezin change-of-variables theorem (Theorem 12.19), which acts on each set of variables independently (Section 12.3.5), the substitution $M = A^{-1}$ produces the reciprocal Jacobian $(\det A^{-1})^{-1} = \det A$:

$$\int \mathcal{D}\bar\theta\, \mathcal{D}\theta\; e^{-\bar\theta A\theta} = (\det A) \int \mathcal{D}\bar\theta\, \mathcal{D}\theta'\; e^{-\bar\theta A A^{-1}\theta'} = (\det A) \int \mathcal{D}\bar\theta\, \mathcal{D}\theta'\; e^{-\bar\theta\theta'}, \tag{12.86}$$

the inverse power being exactly the feature that distinguishes Berezin from Lebesgue integration. The remaining integral factorizes, because the cross terms $\bar\theta_i\theta'_i$ are mutually commuting (even) and each is nilpotent:

$$\int \mathcal{D}\bar\theta\, \mathcal{D}\theta'\; e^{-\bar\theta\theta'} = \prod_{i=1}^{n} \int d\bar\theta_i\, d\theta'_i\, (1 - \bar\theta_i\theta'_i) = \prod_{i=1}^{n} \big(-(-1)\big) = 1, \tag{12.87}$$

using $\int d\bar\theta_i d\theta'_i\, \bar\theta_i\theta'_i = -1$ from (12.80). Hence (12.81) holds for invertible A. If A is singular, $\det A = 0$; correspondingly the columns of A are linearly dependent, so the bilinear form $\bar\theta A\theta$ omits some independent combination of the θ generators, no term of $e^{-\bar\theta A\theta}$ can saturate all $2n$ generators, and the integral vanishes. Both sides equal zero, and (12.81) holds for all A by continuity (both sides are polynomials in the entries of A). □

This is the "diagonalize/triangularize" route in its cleanest form: rather than rotate to eigenvectors as in the bosonic proof of Theorem 4.14, we absorb A wholesale into the measure, where the inverse Jacobian flips the power. The same calculation done with the change of variables that triangularizes $A = UTU^{-1}$ with T upper triangular produces $\det A = \prod_i T_{ii}$ as the product over the now-decoupled diagonal modes; the substitution $\theta \to A^{-1}\theta'$ short-circuits the triangularization and is preferable. For completeness we also display the determinant's permutation sum explicitly.

Proof for general A by combinatorial expansion. Write the exponent so that the conjugate generators stand in the order $\theta\bar\theta$ that integrates with a plus sign: since $-\bar\theta_i A_{ij}\theta_j = A_{ij}\theta_j\bar\theta_i$,

$$-\bar\theta A\theta = \sum_{i,j} A_{ij}\, \theta_j\bar\theta_i. \tag{12.88}$$

Only the term of degree $2n$ survives integration, and that is the $k = n$ term of the exponential series:

$$\int \mathcal{D}\bar\theta\,\mathcal{D}\theta\; e^{-\bar\theta A\theta} = \frac{1}{n!}\int \mathcal{D}\bar\theta\,\mathcal{D}\theta\,\Big(\sum_{i,j} A_{ij}\,\theta_j\bar\theta_i\Big)^n = \frac{1}{n!}\sum_{\substack{i_1,\dots,i_n\\ j_1,\dots,j_n}} A_{i_1 j_1}\cdots A_{i_n j_n}\int \mathcal{D}\bar\theta\,\mathcal{D}\theta\;\theta_{j_1}\bar\theta_{i_1}\cdots\theta_{j_n}\bar\theta_{i_n}. \tag{12.89}$$

For the surviving monomial each generator appears once, so $(j_1,\dots,j_n)$ and $(i_1,\dots,i_n)$ are each permutations of $\{1,\dots,n\}$. The blocks $\theta_{j_a}\bar\theta_{i_a}$ are Grassmann-even, so we may reorder them to put the θ indices in increasing order $\theta_1,\dots,\theta_n$ at no sign cost; this fixes the j's and identifies $i_a = \rho(a)$ for a permutation ρ. Bringing the trailing $\bar\theta_{\rho(a)}$ into the reference order $\bar\theta_a$ costs $\operatorname{sgn}(\rho)$, and the top monomial then integrates to $+1$ by (12.80). Each of the $n!$ initial orderings contributes equally, cancelling $1/n!$, and the result is

$$\int \mathcal{D}\bar\theta\,\mathcal{D}\theta\; e^{-\bar\theta A\theta} = \sum_{\rho\in S_n}\operatorname{sgn}(\rho)\,A_{\rho(1)\,1}A_{\rho(2)\,2}\cdots A_{\rho(n)\,n} = \det A, \tag{12.90}$$

the Leibniz formula for $\det A^{\mathsf T} = \det A$. □

Worked Example 12.27 (The two-point function and the contraction sign)**.** It is worth verifying that the convention (12.80) reproduces the expected propagator structure already at $n = 1$, since this fixes the sign that propagates into S_F. With $A = a$ a single number, the normalized average of $\theta\bar\theta$ against $e^{-a\bar\theta\theta}$ is

$$\frac{\int d\bar\theta\,d\theta\;\theta\bar\theta\,e^{-a\bar\theta\theta}}{\int d\bar\theta\,d\theta\;e^{-a\bar\theta\theta}} = \frac{\int d\bar\theta\,d\theta\;\theta\bar\theta\,(1-a\bar\theta\theta)}{a} = \frac{\int d\bar\theta\,d\theta\;\theta\bar\theta}{a} = \frac{1}{a} = A^{-1}, \tag{12.91}$$

because $\theta\bar\theta\cdot a\bar\theta\theta = 0$ (repeated generator). The contraction $\langle\theta\bar\theta\rangle$ is therefore A^{-1}, the inverse of the matrix in the action — exactly as for the bosonic two-point function (Theorem 4.18) — while the opposite order gives $\langle\theta\bar\theta\rangle \to \langle\bar\theta\theta\rangle = -A^{-1}$, since $\bar\theta\theta = -\theta\bar\theta$. The sign of a fermion two-point function depends on the order in which the generators are written, a fact with no bosonic analogue and the seed of the ordered "θ before $\bar\theta$" bookkeeping that becomes the time-ordering of ψ and $\bar\psi$ in S_F.

Physical Insight: why the determinant is upstairs, and the closed-loop minus sign

The one fact to carry away from Theorem 12.26 is the *position* of the determinant. Schematically, integrating out a field produces

$$\text{boson:}\quad \int \mathcal{D}\phi\, e^{-\frac{1}{2}\phi^{\mathsf T}A\phi} \propto (\det A)^{-1/2}, \qquad \text{fermion:}\quad \int \mathcal{D}\bar\psi\,\mathcal{D}\psi\, e^{-\bar\psi A\psi} = \det A.$$

Both reappear as functional determinants in the one-loop effective action.

When that determinant is written as $\det A = \exp \operatorname{Tr} \ln A$ and expanded, each term is a closed loop of the field being integrated out. Because the fermionic determinant sits at power $+1$ while the bosonic sits at power $-\frac{1}{2}$, the fermionic loop expansion carries the *opposite overall sign*: every closed fermion loop comes with a relative factor of -1. This is the celebrated "-1 per fermion loop" Feynman rule, and it is visible here, in finite dimensions, before a single momentum integral has been written. We discharge it as a diagrammatic rule when we evaluate $\det(i\not{D} - m)$ as a one-loop fermion effective action; the minus sign is not an extra postulate but the inverse Jacobian of (12.86) in disguise.

12.4.2 The real Gaussian and the Pfaffian

When there is no natural pairing of the generators into $\theta, \bar{\theta}$ — the situation for a *real* (Majorana) fermion, and for the antisymmetric part of any bilinear — the relevant object is a single set $\theta_1, \dots, \theta_{2n}$ and a quadratic form built from an antisymmetric matrix. The result is not the determinant but its square root, the Pfaffian.

A quadratic form $\theta^{\mathsf{T}} A \theta = \sum_{ij} \theta_i A_{ij} \theta_j$ in anticommuting variables sees only the antisymmetric part of A: since $\theta_i \theta_j = -\theta_j \theta_i$, any symmetric piece $A_{ij} = A_{ji}$ cancels in the sum. We therefore take A antisymmetric, $A^{\mathsf{T}} = -A$, of even dimension $2n$ (an odd-dimensional real antisymmetric matrix is singular, and its Pfaffian is defined to be zero).

Definition 12.28 (Pfaffian)**.** For a $2n \times 2n$ antisymmetric matrix A, define its *Pfaffian* by the Berezin integral

$$\operatorname{Pf}(A) \;\equiv\; \int \mathcal{D}\theta \; e^{\frac{1}{2}\theta^{\mathsf{T}} A \theta}, \qquad \tfrac{1}{2}\,\theta^{\mathsf{T}} A \theta = \tfrac{1}{2} \sum_{i,j=1}^{2n} \theta_i A_{ij} \theta_j. \tag{12.92}$$

That this matches the standard combinatorial definition follows by expanding the exponential as in (12.89): only the degree-$2n$ term survives, giving the signed sum over perfect matchings,

$$\operatorname{Pf}(A) = \frac{1}{2^n\, n!} \sum_{\sigma \in S_{2n}} \operatorname{sgn}(\sigma)\, A_{\sigma(1)\sigma(2)} A_{\sigma(3)\sigma(4)} \cdots A_{\sigma(2n-1)\sigma(2n)}, \tag{12.93}$$

the $2^n n!$ accounting for the reorderings within and among the n pairs that leave a matching unchanged. For $n = 1$ this reads $\operatorname{Pf}\left(\begin{smallmatrix} 0 & a \\ -a & 0 \end{smallmatrix}\right) = a$, and the explicit check $\int d\theta_2 d\theta_1 \, e^{\frac{1}{2}\theta^{\mathsf{T}} A \theta} = \int d\theta_2 d\theta_1 \, (1 + a\,\theta_1\theta_2) = a$ uses $\frac{1}{2}\theta^{\mathsf{T}} A \theta = \frac{1}{2}(a\theta_1\theta_2 - a\theta_2\theta_1) = a\theta_1\theta_2$ and (12.80).

The fundamental relation between the Pfaffian and the determinant is that the Pfaffian is a square root of the determinant. We prove it by reducing A to a

canonical antisymmetric normal form, which requires the following standard fact of real linear algebra; we prove it in full so that nothing is imported on faith.

Lemma 12.29 (Real antisymmetric normal form)**.** *For every real antisymmetric $2n \times 2n$ matrix A there is a real orthogonal matrix R ($R^{\mathsf{T}} R = \mathbf{1}$) such that*

$$R^{\mathsf{T}} A R = \bigoplus_{k=1}^{n} \lambda_k \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix}, \qquad \lambda_k \in \mathbb{R}. \tag{12.94}$$

Proof. The matrix iA is Hermitian: $(iA)^\dagger = -iA^{\mathsf{T}} = -i(-A) = iA$. By the spectral theorem it has real eigenvalues and an orthonormal eigenbasis. If $iA\,w = \mu\, w$ with $\mu \in \mathbb{R}$ and $w \in \mathbb{C}^{2n}$, taking complex conjugates and using that A is real gives $iA\,\bar{w} = -\mu\,\bar{w}$, so the nonzero eigenvalues occur in pairs $\pm\mu$ with complex-conjugate eigenvectors. Fix a pair with $\mu = \lambda > 0$ and normalized eigenvector $w = \frac{1}{\sqrt{2}}(u - iv)$, $u, v \in \mathbb{R}^{2n}$. Separating real and imaginary parts of $iA\,w = \lambda w$ gives $Au = -\lambda v$ and $Av = \lambda u$. The vectors u, v are real and orthonormal (from $w^\dagger w = 1$ and $w^{\mathsf{T}} w = 0$, which give $u \cdot u = v \cdot v = 1$, $u \cdot v = 0$), and span a two-dimensional real subspace on which A acts as $\lambda \left(\begin{smallmatrix} 0 & 1 \\ -1 & 0 \end{smallmatrix}\right)$ in the basis (u, v). This subspace and its orthogonal complement are both A-invariant (because A is antisymmetric: if $x \perp u, v$ then $u \cdot Ax = -Au \cdot x = \lambda v \cdot x = 0$ and likewise $v \cdot Ax = 0$). Iterating on the orthogonal complement, which carries the remaining $\pm$ pairs (zero eigenvalues contribute zero blocks, $\lambda_k = 0$), assembles an orthonormal basis in which A is block-diagonal with the stated 2×2 blocks; collecting these basis vectors as the columns of R gives (12.94). □

Theorem 12.30 (Pfaffian identities)**.** *For any $2n \times 2n$ antisymmetric matrix A and any $2n \times 2n$ matrix M,*

$$\mathrm{Pf}(M^{\mathsf{T}} A M) = \det(M)\ \mathrm{Pf}(A), \tag{12.95}$$

$$\mathrm{Pf}(A)^2 = \det A. \tag{12.96}$$

Proof. Congruence covariance. Let $F(\theta) = e^{\frac{1}{2}\theta^{\mathsf{T}} A \theta}$ and substitute $\theta = M\theta'$. By Theorem 12.19, $\int \mathcal{D}\theta\, F(\theta) = (\det M)^{-1} \int \mathcal{D}\theta'\, F(M\theta')$, i.e. $\int \mathcal{D}\theta'\, F(M\theta') = \det(M) \int \mathcal{D}\theta\, F(\theta)$. Since $F(M\theta') = e^{\frac{1}{2}(M\theta')^{\mathsf{T}} A (M\theta')} = e^{\frac{1}{2}\theta'^{\mathsf{T}} (M^{\mathsf{T}} A M)\theta'}$, the left side is precisely $\mathrm{Pf}(M^{\mathsf{T}} A M)$, and therefore

$$\mathrm{Pf}(M^{\mathsf{T}} A M) = \det(M) \int \mathcal{D}\theta\, e^{\frac{1}{2}\theta^{\mathsf{T}} A \theta} = \det(M)\ \mathrm{Pf}(A), \tag{12.97}$$

which is (12.95).

Square root of the determinant. Let $\Sigma = R^{\mathsf{T}} A R$ be the canonical form (12.94) from Theorem 12.29, so $A = R \Sigma R^{\mathsf{T}}$. The Pfaffian of Σ factorizes over its blocks because the integral does: with θ split into pairs, $e^{\frac{1}{2}\theta^{\mathsf{T}}\Sigma\theta} = \prod_k e^{\lambda_k \theta_{2k-1}\theta_{2k}}$, the top monomial is $\prod_k \theta_{2k-1}\theta_{2k} = \theta_1 \cdots \theta_{2n}$ with coefficient

$\prod_k \lambda_k$, and so $\mathrm{Pf}(\Sigma) = \prod_{k=1}^{n} \lambda_k$ by (12.80). Applying (12.95) with $M = R^{\mathsf{T}}$, $\mathrm{Pf}(A) = \mathrm{Pf}\big((R^{\mathsf{T}})^{\mathsf{T}} \Sigma R^{\mathsf{T}}\big) = \det(R^{\mathsf{T}})\,\mathrm{Pf}(\Sigma) = \det(R) \prod_k \lambda_k$. Squaring and using $\det(R)^2 = 1$ together with $\det A = \det(R \Sigma R^{\mathsf{T}}) = \det \Sigma = \prod_k \lambda_k^2$,

$$\mathrm{Pf}(A)^2 = \big(\det R\big)^2 \prod_k \lambda_k^2 = \prod_k \lambda_k^2 = \det A, \tag{12.98}$$

establishing (12.96). □

The Pfaffian thus carries strictly more information than the determinant: it is a genuine square root, with a definite sign, and that sign — the relative phase of the fermionic measure — is precisely what controls the sign problem of Majorana and lattice fermions. The complex result $\int \mathcal{D}\bar\theta \mathcal{D}\theta\, e^{-\bar\theta A \theta} = \det A$ is recovered from the real one by pairing: assembling $(\theta_i, \bar\theta_i)$ into a single column Θ of $2n$ real generators with antisymmetric form $\mathcal{A} = \left(\begin{smallmatrix} 0 & A \\ -A^{\mathsf{T}} & 0 \end{smallmatrix}\right)$ gives $\mathrm{Pf}(\mathcal{A}) = \pm \det A$, consistent with $\mathrm{Pf}(\mathcal{A})^2 = \det \mathcal{A} = (\det A)^2$ (the determinant of a block antidiagonal matrix).

12.4.3 The sourced generating identity

Everything dynamical comes from adding linear sources, exactly as the bosonic $Z(J)$ of Theorem 4.15 came from the source-free Gaussian. We add *anticommuting* sources $\bar\eta_i, \eta_i$ (Grassmann generators independent of $\theta, \bar\theta$), so that differentiation with respect to them will deposit the fermionic fields with their correct relative signs.

Theorem 12.31 (Sourced Grassmann Gaussian)**.** *For invertible A and Grassmann sources $\bar\eta, \eta$,*

$$Z[\bar\eta, \eta] \;\equiv\; \int \mathcal{D}\bar\theta\, \mathcal{D}\theta\; e^{\,-\bar\theta A \theta + \bar\eta \theta + \bar\theta \eta} \;=\; \det A\; \exp(\bar\eta\, A^{-1} \eta), \tag{12.99}$$

where $\bar\eta\theta = \sum_i \bar\eta_i \theta_i$, $\bar\theta\eta = \sum_i \bar\theta_i \eta_i$, and $\bar\eta A^{-1} \eta = \sum_{ij} \bar\eta_i (A^{-1})_{ij} \eta_j$.

Proof. Complete the square by the Grassmann shift

$$\theta = \theta' + A^{-1}\eta, \qquad \bar\theta = \bar\theta' + \bar\eta A^{-1}, \tag{12.100}$$

a translation of the integration variables by the constant Grassmann vectors $A^{-1}\eta$ and $\bar\eta A^{-1}$, which leaves the Berezin measure and the integral invariant (Eq. (12.51)); this is the fermionic analogue of $d^n x = d^n y$ under $x = y + A^{-1} J$ in the bosonic proof of Theorem 4.15. Substituting and using $A A^{-1} = A^{-1} A = \mathbf{1}$,

$$\begin{aligned} -\bar\theta A \theta &= -(\bar\theta' + \bar\eta A^{-1}) A (\theta' + A^{-1}\eta) = -\bar\theta' A \theta' - \bar\theta' \eta - \bar\eta \theta' - \bar\eta A^{-1} \eta, \\ \bar\eta\theta &= \bar\eta\theta' + \bar\eta A^{-1}\eta, \qquad \bar\theta\eta = \bar\theta'\eta + \bar\eta A^{-1}\eta. \end{aligned} \tag{12.101}$$

Adding the three lines, the linear terms cancel in pairs, $-\bar\theta'\eta+\bar\theta'\eta=0$ and $-\bar\eta\theta'+\bar\eta\theta'=0$, and the three quadratic constants combine as $-\bar\eta A^{-1}\eta+\bar\eta A^{-1}\eta+\bar\eta A^{-1}\eta=+\bar\eta A^{-1}\eta$, leaving

$$-\bar\theta A\theta+\bar\eta\theta+\bar\theta\eta=-\bar\theta' A\theta'+\bar\eta A^{-1}\eta. \tag{12.102}$$

The constant $+\bar\eta A^{-1}\eta$ is Grassmann-even (a product of two odd sources), commutes with everything, and factors out of the integral; the remaining θ'-integral is the source-free Gaussian (12.81). Hence $Z[\bar\eta,\eta]=e^{\bar\eta A^{-1}\eta}\int\mathcal{D}\bar\theta'\mathcal{D}\theta'\,e^{-\bar\theta' A\theta'}=\det A\,e^{\bar\eta A^{-1}\eta}$, which is (12.99). □

The structure mirrors the bosonic $Z(J)\propto e^{\frac12 J^{\mathsf T}A^{-1}J}$ (Theorem 4.15): the source dependence is again the exponential of a quadratic form built from A^{-1}, the inverse of the operator in the action. The two differences are that fermions carry two independent sources rather than one (the form $\bar\eta A^{-1}\eta$ rather than a symmetric $JA^{-1}J$), and that the overall prefactor is $\det A$ rather than $(\det A)^{-1/2}$. Both signs will be tracked again at field level, where the prefactor $\bar\eta A^{-1}\eta$ inherited here combines with the factors of i of the Dirac action to produce the standard Feynman propagator.

12.4.4 Wick's theorem for Grassmann variables

We can now harvest the Gaussian moments. Define the normalized Gaussian average of a Grassmann-valued function F by

$$\langle F\rangle\;\equiv\;\frac{1}{\det A}\int\mathcal{D}\bar\theta\,\mathcal{D}\theta\;F\,e^{-\bar\theta A\theta}=\frac{1}{Z[0,0]}\int\mathcal{D}\bar\theta\,\mathcal{D}\theta\;F\,e^{-\bar\theta A\theta}, \tag{12.103}$$

the exact fermionic analogue of Theorem 4.16. The whole content of the free theory is that these averages are determined by the two-point function, with one decisive difference from the bosonic Theorem 4.19: pairings now carry signs.

To extract moments we differentiate $Z[\bar\eta,\eta]$ using the left derivatives of Theorem 12.9, which act by anticommuting through to the variable and stripping it: $\partial^{\mathrm L}_{\eta_i}(\eta_i X)=X$ and $\partial^{\mathrm L}_{\eta_i}(\eta_j X)=-\eta_j\,\partial^{\mathrm L}_{\eta_i}X$ for $j\neq i$. Each θ_p in the integrand is produced from the source term $\bar\eta\theta$ by $\partial^{\mathrm L}_{\bar\eta_p}$, and each $\bar\theta_q$ from $\bar\theta\eta$ by $\partial^{\mathrm L}_{\eta_q}$. Tracking the single sign that arises when $\partial^{\mathrm L}_{\eta_q}$ anticommutes past the already-extracted (Grassmann-odd) θ_p, one finds

$$\partial^{\mathrm L}_{\eta_q}\,\partial^{\mathrm L}_{\bar\eta_p}\,Z[\bar\eta,\eta]\Big|_{\bar\eta=\eta=0}=\int\mathcal{D}\bar\theta\,\mathcal{D}\theta\;\theta_p\bar\theta_q\,e^{-\bar\theta A\theta}=\det A\,\langle\theta_p\bar\theta_q\rangle. \tag{12.104}$$

Differentiating instead the closed form $\det A\,e^{\bar\eta A^{-1}\eta}=\det A\,(1+\sum_{ij}\bar\eta_i(A^{-1})_{ij}\eta_j+\cdots)$, the only term surviving two derivatives and the $\bar\eta=\eta=0$ limit is the

bilinear one: $\partial^{\mathrm{L}}_{\bar\eta_p}$ brings down $(A^{-1})_{pj}\eta_j$, and $\partial^{\mathrm{L}}_{\eta_q}$ then yields $(A^{-1})_{pq}$, all times $\det A$. Equating with (12.104) gives the fundamental contraction:

$$\boxed{\langle \theta_p\, \bar\theta_q \rangle = +\,(A^{-1})_{pq}, \qquad \langle \bar\theta_q\, \theta_p \rangle = -\,(A^{-1})_{pq}.} \tag{12.105}$$

The two orderings differ by a sign because $\theta_p\bar\theta_q = -\bar\theta_q\theta_p$; the contraction is A^{-1}, the inverse of the matrix in the action, exactly as in the bosonic Theorem 4.18, but its sign is order-dependent. This A^{-1} is the finite-dimensional fermion propagator; promoted to fields it becomes S_F.

Theorem 12.32 (Grassmann Wick's theorem)**.** *For the Gaussian average* (12.103)*, any moment with unequal numbers of θ's and $\bar\theta$'s vanishes, and a moment with n of each is the* determinant *of the matrix of contractions:*

$$\langle \theta_{i_1}\bar\theta_{j_1}\,\theta_{i_2}\bar\theta_{j_2}\cdots\theta_{i_n}\bar\theta_{j_n}\rangle = \sum_{\sigma\in S_n}\operatorname{sgn}(\sigma)\,\prod_{a=1}^{n}\langle \theta_{i_a}\bar\theta_{j_{\sigma(a)}}\rangle = \det\Big[\langle \theta_{i_a}\bar\theta_{j_b}\rangle\Big]_{a,b=1}^{n} = \det\big[(A^{-1})_{i_a j_b}\big]. \tag{12.106}$$

Equivalently, the moment is the signed sum over all ways of pairing each θ with a $\bar\theta$, each pairing contributing the product of contractions (12.105) *times the sign of the permutation σ that effects it.*

Proof. Each θ_{i_a} is produced by $\partial^{\mathrm{L}}_{\bar\eta_{i_a}}$ and each $\bar\theta_{j_b}$ by $\partial^{\mathrm{L}}_{\eta_{j_b}}$ acting on $Z[\bar\eta,\eta]$, generalizing (12.104). Since the differentiation strips generators only in conjugate pairs $\bar\eta \leftrightarrow \theta$ and $\eta \leftrightarrow \bar\theta$, a moment with unequal counts of θ and $\bar\theta$ cannot be saturated and vanishes — the Grassmann counterpart of the vanishing of odd bosonic moments in Theorem 4.19, sharpened to a separate conservation law for barred and unbarred indices (it is, at field level, fermion-number conservation). For equal counts n, apply $2n$ derivatives to the closed form $\det A\,\exp(\bar\eta A^{-1}\eta)$. Each surviving contribution pairs one $\partial_{\bar\eta_{i_a}}$ with one $\partial_{\eta_{j_b}}$ through a single factor $\bar\eta_{i_a}(A^{-1})_{i_a j_b}\eta_{j_b}$ of the expanded exponential, contributing the contraction $\langle\theta_{i_a}\bar\theta_{j_b}\rangle$ of (12.105); the different ways of matching the n unbarred derivatives to the n barred derivatives are the permutations $\sigma \in S_n$. Because the derivatives anticommute, reordering them to bring each matched pair together produces exactly the signature $\operatorname{sgn}(\sigma)$ — one factor of -1 for each transposition, i.e. for each *crossing* of two contraction lines. The signed sum over matchings is the Leibniz expansion of the determinant, giving (12.106). □

Physical Insight: determinant versus permanent, the combinatorial face of statistics

Bosonic and fermionic Wick's theorems are the same sum over pairings with one difference — the sign. The bosonic moment (4.66) is the *permanent* of the contraction matrix (every pairing enters with a $+$); the fermionic moment (12.106) is its *determinant* (each pairing weighted by $\operatorname{sgn}\sigma$).

Symmetry under exchange versus antisymmetry under exchange — Bose versus Fermi statistics — is, at the level of correlation functions, precisely permanent versus determinant. The minus sign on a crossing of two contraction lines is what forbids two identical fermions from occupying the same state: set two external labels equal and the determinant, having two equal rows, vanishes, which is the Pauli principle written as a Wick contraction.

Worked Example 12.33 (The four-point function and a closed fermion loop)**.** Take $n = 2$. Theorem 12.32 gives the four-point function as a 2×2 determinant of contractions,

$$\begin{aligned}\langle \theta_{i_1} \bar\theta_{j_1} \theta_{i_2} \bar\theta_{j_2} \rangle &= \langle \theta_{i_1} \bar\theta_{j_1} \rangle \langle \theta_{i_2} \bar\theta_{j_2} \rangle - \langle \theta_{i_1} \bar\theta_{j_2} \rangle \langle \theta_{i_2} \bar\theta_{j_1} \rangle \\ &= (A^{-1})_{i_1 j_1} (A^{-1})_{i_2 j_2} - (A^{-1})_{i_1 j_2} (A^{-1})_{i_2 j_1}, \end{aligned} \tag{12.107}$$

using (12.105): the "direct" pairing $(i_1 j_1)(i_2 j_2)$ enters with $+$, the "crossed" pairing $(i_1 j_2)(i_2 j_1)$ with $-$. Compare the bosonic four-point function (10.138), whose three terms all carry $+$: there the analogue of the crossed term is added, here it is subtracted. The relative minus is the entire content of fermion antisymmetry at one loop.

The closed-loop minus sign now follows by closing the indices into a cycle. A closed fermion loop of length n is assembled from n vertices, each a bilinear $\bar\theta_a(\cdots)\theta_a$ in which the adjoint stands first, with the loop contraction joining θ_a to $\bar\theta_{a+1}$ cyclically ($\bar\theta_{n+1} \equiv \bar\theta_1$). The relevant average is therefore

$$L_n = \langle \bar\theta_1 \theta_1 \, \bar\theta_2 \theta_2 \cdots \bar\theta_n \theta_n \rangle \Big|_{\text{loop}} = (-1)^n \langle \theta_1 \bar\theta_1 \, \theta_2 \bar\theta_2 \cdots \theta_n \bar\theta_n \rangle \Big|_{\text{loop}}, \tag{12.108}$$

the factor $(-1)^n$ from reversing each of the n even vertex blocks $\bar\theta_a \theta_a = -\theta_a \bar\theta_a$. By (12.106) the single connected loop is the cyclic permutation $\sigma = (1\,2\,\cdots\,n)$ with signature $\operatorname{sgn}(\sigma) = (-1)^{n-1}$, contributing $(-1)^{n-1} \prod_a (A^{-1})_{i_a i_{a+1}} = (-1)^{n-1} \operatorname{tr}[(A^{-1})^n]$. The two signs combine into a single overall minus, independent of the loop length:

$$L_n = (-1)^n (-1)^{n-1} \operatorname{tr}[(A^{-1})^n] = -\operatorname{tr}[(A^{-1})^n]. \tag{12.109}$$

Every closed fermion loop carries one minus sign and one trace, for any n — the $n = 1$ tadpole $\langle \bar\theta \theta \rangle = -\operatorname{tr}(A^{-1})$ being the smallest instance. This is the diagrammatic "-1 per fermion loop, trace around it" rule, derived here from nothing but the determinant structure of (12.106).

We have now computed the complete set of Gaussian Grassmann integrals: the source-free determinant (12.81), its real Pfaffian counterpart (12.92), the sourced generating identity (12.99), and the Wick contractions (12.105)–(12.106)

that read all higher moments off the propagator A^{-1} with a sign per crossing. Assembled, these are the finite-dimensional master formula

$$\int \mathcal{D}\bar{\psi}\,\mathcal{D}\psi\; e^{-\bar{\psi}A\psi+\bar{\eta}\psi+\bar{\psi}\eta} = \det A\;\exp(\bar{\eta}A^{-1}\eta), \tag{12.110}$$

written here with the field letters $\psi, \bar{\psi}$ in anticipation. The next section derives the fermionic path integral from canonical quantization via coherent states, showing that the continuum measure $\mathcal{D}\bar{\psi}\,\mathcal{D}\psi$ and the bilinear action $\bar{\psi}A\psi$ arise honestly from the operator formalism of Chapter 11 rather than by analogy; (12.110) is then promoted to fields in Section 12.6, with A built from the Dirac operator $i(\not{\partial} - m)$ (the precise placement of the factors of i and the $i\epsilon$ prescription fixed there), turning $Z[\bar{\eta}, \eta]$ into the Dirac generating functional and the contraction A^{-1} into the Feynman propagator S_F.

12.5 Fermionic coherent states and the path integral from canonical quantization

The Gaussian Berezin machinery of Section 12.4 gave us an algebra of integration over anticommuting variables and, as its central output, the Gaussian identity $\int \prod_i d\bar{\theta}_i\, d\theta_i\, e^{-\bar{\theta}M\theta} = \det M$ — the determinant in the numerator, the precise inversion of the bosonic $(\det M)^{-1/2}$. So far that identity is a piece of pure algebra, a fact about finitely many Grassmann generators. It does not yet say anything about a quantum field. The scalar story of Chapter 10 earned the right to write $\int \mathcal{D}\phi\, e^{iS}$ by *deriving* it from canonical quantization: one starts from the Hilbert space and the Hamiltonian, slices the evolution operator into infinitesimal steps, inserts a resolution of the identity at each step, and watches the sum over intermediate states condense into a sum over histories weighted by e^{iS}. Nothing was postulated; the path integral was an identity. We owe the Dirac field exactly the same honest derivation, and this section pays the debt. The integration variables will turn out to be Grassmann numbers, the measure $\mathcal{D}\bar{\psi}\,\mathcal{D}\psi$ will be a product of Berezin measures, and the Gaussian identity just recalled will be what evaluates the free theory — but all of this will be *forced* by the operator formalism of Chapter 11, not adopted by analogy.

The one ingredient Chapter 10 had for free, and which we must build, is a continuous basis adapted to the creation and annihilation operators. For the scalar, position eigenstates $|x\rangle$ did the job: they are a continuous, overcomplete family in which $\hat{x}$ is diagonal, and the resolution of the identity $\int dx\; |x\rangle\langle x| = \mathbf{1}$ is what gets inserted between time slices. A fermionic mode has no position operator and a two-dimensional state space; the natural continuous family is instead the set of *coherent states*, the eigenstates of the annihilation operator. The reader has met their bosonic cousins in elementary quantum mechanics: for a harmonic oscillator, $|z\rangle = e^{za^\dagger}|0\rangle$ satisfies $a\,|z\rangle = z\,|z\rangle$ with $z \in \mathbb{C}$, and

$\frac{1}{\pi}\int d^2z\, e^{-|z|^2}\,|z\rangle\langle z| = \mathbf{1}$. We will construct the fermionic analogue. The single obstruction — the entire reason a fermionic path integral could never be an integral over ordinary numbers — appears at the very first step: the eigenvalue of a fermionic annihilation operator *cannot* be an ordinary number. It must be a Grassmann number. Once that is conceded, everything else follows mechanically, and the antiperiodic boundary condition that distinguishes fermionic statistics drops out of the trace at the end.

12.5.1 One fermionic mode

The quantized Dirac field of Chapter 11 is, mode by mode, a collection of independent fermionic oscillators: the ladder algebra Eq. (11.116) assigns to each momentum and spin an annihilation/creation pair obeying canonical anticommutation relations, and the full Fock space is the tensor product over modes (Theorem 11.29). The whole construction of this section therefore reduces to a *single* mode, after which we tensor over the (continuum of) modes and pass to the field. We isolate one such pair and drop all labels. Write $a, a^\dagger$ for the annihilation and creation operators of one fermionic mode, with the algebra extracted from Theorem 11.22,

$$\left\{a, a^\dagger\right\} = 1, \qquad a^2 = (a^\dagger)^2 = 0, \qquad \{a, a\} = \left\{a^\dagger, a^\dagger\right\} = 0. \tag{12.111}$$

The nilpotency $a^2 = 0$ is the Pauli principle (Theorem 11.27) in its sharpest form. The state space is exactly two-dimensional, spanned by the vacuum $|0\rangle$ and the one-particle state $|1\rangle$,

$$a\,|0\rangle = 0, \qquad |1\rangle \equiv a^\dagger\,|0\rangle\,, \qquad a\,|1\rangle = |0\rangle\,, \qquad a^\dagger\,|1\rangle = 0, \tag{12.112}$$

orthonormal, $\langle 0|0\rangle = \langle 1|1\rangle = 1$, $\langle 0|1\rangle = 0$, and the number operator $\hat{n} = a^\dagger a$ reads off the occupation, $\hat{n}\,|0\rangle = 0$, $\hat{n}\,|1\rangle = |1\rangle$. There is nothing else: every operator on this space is a linear combination of $\mathbf{1}$, a, $a^\dagger$, and $a^\dagger a$. This two-state system is small enough that every claim below can be, and will be, checked by direct matrix computation, which is precisely why the single mode is the right laboratory.

12.5.2 Coherent states require Grassmann eigenvalues

We want a state $|\theta\rangle$ obeying $a\,|\theta\rangle = \theta\,|\theta\rangle$. Suppose first, for the sake of the contradiction that motivates everything, that θ were an ordinary complex number. Write the most general state $|\theta\rangle = \alpha\,|0\rangle + \gamma\,|1\rangle$. Then $a\,|\theta\rangle = \gamma\,a\,|1\rangle = \gamma\,|0\rangle$, while $\theta\,|\theta\rangle = \theta\alpha\,|0\rangle + \theta\gamma\,|1\rangle$. Matching coefficients of the two basis vectors gives $\gamma = \theta\alpha$ from $|0\rangle$ and $0 = \theta\gamma$ from $|1\rangle$. The second equation forces either $\theta = 0$ or $\gamma = 0$; in both cases the eigenstate collapses to a multiple of $|0\rangle$ with eigenvalue zero. There is no nontrivial coherent state with a c-number eigenvalue. The

Pauli principle has killed it: because a lowers the only nonempty level straight to the vacuum, its sole c-number eigenvalue is 0.

The escape is to let θ be an *anticommuting* number. Adjoin to the theory a Grassmann algebra (Section 12.2.1) with generators $\theta, \bar{\theta}$ — two independent generators related by the conjugation of Section 12.2.6, not a complex number and its conjugate — declared to anticommute among themselves and, crucially, *with the fermionic operators and with the odd states they create*:

$$\theta^2 = \bar{\theta}^2 = 0, \quad \left\{\theta, \bar{\theta}\right\} = 0, \quad \{\theta, a\} = \left\{\theta, a^\dagger\right\} = 0, \quad \left\{\bar{\theta}, a\right\} = \left\{\bar{\theta}, a^\dagger\right\} = 0. \tag{12.113}$$

The bookkeeping rule that makes all of this consistent is a $\mathbb{Z}_2$ grading: θ, $\bar{\theta}$, a, $a^\dagger$, and the one-particle ket $|1\rangle = a^\dagger |0\rangle$ are all *odd*; $|0\rangle$, $\mathbf{1}$, and $\hat{n} = a^\dagger a$ are *even*; two odd objects anticommute, anything even commutes with everything. With θ odd, the equation $0 = \theta\gamma$ that doomed the c-number case is no longer forced, and a genuine coherent state exists.

Definition 12.34 (Fermionic coherent states)**.** For one fermionic mode Eq. (12.111) and a Grassmann generator θ obeying Eq. (12.113), the *(right) coherent state* is

$$|\theta\rangle \;\equiv\; e^{-\theta a^\dagger} |0\rangle \;=\; (1 - \theta a^\dagger) |0\rangle \;=\; |0\rangle - \theta |1\rangle , \tag{12.114}$$

the exponential truncating after one term because $(\theta a^\dagger)^2 = \theta a^\dagger \theta a^\dagger = -\theta^2 (a^\dagger)^2 = 0$. The corresponding *(left) coherent state* is its conjugate,

$$\langle\theta| \;\equiv\; \langle 0|\, e^{-a\bar{\theta}} \;=\; \langle 0| \,(1 - a\bar{\theta}) \;=\; \langle 0| - \langle 1|\, \bar{\theta}. \tag{12.115}$$

The two defining algebraic properties are immediate and we prove them in full, since every later manipulation rests on them.

Proposition 12.35 (Eigenvalue property and overlap)**.** *The coherent states satisfy*

$$a\,|\theta\rangle = \theta\,|\theta\rangle\,, \qquad \langle\theta|\, a^\dagger = \langle\theta|\,\bar{\theta}, \qquad \langle\theta|\theta'\rangle = e^{\bar{\theta}\theta'} = 1 + \bar{\theta}\theta'. \tag{12.116}$$

Proof. For the first relation, act with a on Eq. (12.114), using $a\,|0\rangle = 0$ and the anticommutation $a\theta = -\theta a$ from Eq. (12.113):

$$a\,|\theta\rangle = a\big(|0\rangle - \theta\,|1\rangle\big) = -a\,\theta\,|1\rangle = +\theta\, a\,|1\rangle = \theta\,|0\rangle\,. \tag{12.117}$$

On the other hand $\theta\,|\theta\rangle = \theta(|0\rangle - \theta\,|1\rangle) = \theta\,|0\rangle - \theta^2\,|1\rangle = \theta\,|0\rangle$, because $\theta^2 = 0$. The two right-hand sides agree, so $a\,|\theta\rangle = \theta\,|\theta\rangle$. The left eigenrelation is the conjugate computation: $\langle\theta|\, a^\dagger = (\langle 0| - \langle 1|\,\bar{\theta}) a^\dagger$, and $\langle 0|\, a^\dagger = (a\,|0\rangle)^\dagger = 0$, while $\langle 1|\,\bar{\theta} a^\dagger = -\langle 1|\, a^\dagger \bar{\theta} = -\langle 0|\,\bar{\theta}$ since $\langle 1|\, a^\dagger = (a\,|1\rangle)^\dagger = \langle 0|$; hence $\langle\theta|\, a^\dagger = \langle 0|\,\bar{\theta} = \langle\theta|\,\bar{\theta}$, the last step using $\langle\theta|\,\bar{\theta} = (\langle 0| - \langle 1|\,\bar{\theta})\bar{\theta} = \langle 0|\,\bar{\theta}$ because $\bar{\theta}^2 = 0$. For the overlap, multiply Eq. (12.115) into Eq. (12.114):

$$\langle\theta|\theta'\rangle = \big(\langle 0| - \langle 1|\,\bar{\theta}\big)\big(|0\rangle - \theta'\,|1\rangle\big) = \langle 0|0\rangle - \langle 0|\,\theta'\,|1\rangle - \langle 1|\,\bar{\theta}\,|0\rangle + \langle 1|\,\bar{\theta}\theta'\,|1\rangle\,. \tag{12.118}$$

The middle two terms vanish ($\langle 0|1\rangle = \langle 1|0\rangle = 0$); the first is 1 and the last is $\bar\theta\theta' \langle 1|1\rangle = \bar\theta\theta'$. Therefore $\langle\theta|\theta'\rangle = 1 + \bar\theta\theta'$, which is precisely $e^{\bar\theta\theta'}$ since the exponential terminates at first order. □

The structural content is worth pausing on. The coherent state Eq. (12.114) is a superposition of the empty and the filled state with a Grassmann coefficient; it is not a vector in the original Hilbert space but in the space tensored with the Grassmann algebra. Its norm is not a number but the even Grassmann element $\langle\theta|\theta\rangle = e^{\bar\theta\theta} = 1 + \bar\theta\theta$. This is exactly parallel to the bosonic $\langle z|z\rangle = e^{|z|^2}$, with the modulus-squared $|z|^2 = \bar z z$ replaced by the Grassmann bilinear $\bar\theta\theta$; the entire formalism is the bosonic one with every c-number promoted to a Grassmann number and every det inverted. That promotion is not cosmetic — it is what allows the closure relation below to carry the minus sign the Pauli principle demands.

12.5.3 The resolution of the identity

We can now build the object that the time-slicing will insert at every step. As with position eigenstates in Section 10.1, the coherent states are overcomplete — there are "more" of them than the dimension of the space — and they resolve the identity against a Gaussian Berezin measure.

Theorem 12.36 (Coherent-state completeness)**.** *With the Berezin conventions of Section 12.3 (so that $\int d\bar\theta\, d\theta\, e^{-\bar\theta\theta} = 1$), the fermionic coherent states resolve the identity on the one-mode Hilbert space:*

$$\int d\bar\theta\, d\theta\; e^{-\bar\theta\theta}\; |\theta\rangle\langle\theta| \;=\; |0\rangle\langle 0| + |1\rangle\langle 1| \;=\; \mathbf{1}. \tag{12.119}$$

Proof. Expand the projector $|\theta\rangle\langle\theta|$ from Eqs. (12.114) and (12.115), keeping the Grassmann factors in the order in which they appear:

$$|\theta\rangle\langle\theta| = (|0\rangle - \theta\,|1\rangle)(\langle 0| - \langle 1|\,\bar\theta) = |0\rangle\langle 0| - |0\rangle\langle 1|\,\bar\theta - \theta\,|1\rangle\langle 0| + \theta\,|1\rangle\langle 1|\,\bar\theta. \tag{12.120}$$

Multiply on the left by the Gaussian weight $e^{-\bar\theta\theta} = 1 - \bar\theta\theta$. Any product containing θ twice or $\bar\theta$ twice vanishes, so from the $-\bar\theta\theta$ piece only its product with the c-number-coefficient term $|0\rangle\langle 0|$ survives, while the three terms already carrying a single Grassmann factor survive only through multiplication by 1:

$$e^{-\bar\theta\theta}\,|\theta\rangle\langle\theta| = |0\rangle\langle 0| - |0\rangle\langle 1|\,\bar\theta - \theta\,|1\rangle\langle 0| + \theta\,|1\rangle\langle 1|\,\bar\theta - \bar\theta\theta\;|0\rangle\langle 0|\,. \tag{12.121}$$

Now integrate. The Berezin integral $\int d\bar\theta\, d\theta$ annihilates the constant and the two single-Grassmann terms (Section 12.3: an integral picks out the top form). Two terms survive. For the last term in Eq. (12.121), $\int d\bar\theta\, d\theta\,(-\bar\theta\theta) = -(-1) = +1$ in the stated convention, leaving $+\,|0\rangle\langle 0|$. For the fourth term, the even operator

$|1\rangle\langle 1|$ commutes through $\bar\theta$, so $\theta\,|1\rangle\langle 1|\,\bar\theta = \theta\bar\theta\;|1\rangle\langle 1|$, and $\int d\bar\theta\, d\theta\, \theta\bar\theta = +1$, leaving $+\,|1\rangle\langle 1|$. The sum is $|0\rangle\langle 0| + |1\rangle\langle 1|$, which by Eq. (12.112) is the identity on the two-dimensional space. □

The completeness relation Eq. (12.119) is the fermionic counterpart of $\int dx\; |x\rangle\langle x| = \mathbf{1}$, with one decisive difference: the Gaussian damping factor $e^{-\bar\theta\theta}$ is no decoration but part of the measure, exactly because the coherent states are not normalized to unity. It is itself a Gaussian Berezin integral, and the fact that it integrates to $\det(1) = 1$ rather than to the bosonic $1/\pi$ is the simplest instance of the determinant-versus-inverse-determinant contrast of Section 12.4. With Eq. (12.119) in hand we have the single tool the time-slicing needs.

12.5.4 Matrix elements of normal-ordered operators

The short-time kernel of the path integral is a coherent-state matrix element of the (nearly trivial) evolution over one slice, and the only operators we ever feed it are normal-ordered: in $:A(a^\dagger, a):$ every $a^\dagger$ stands to the left of every a. For such operators the matrix element is read off without any further integration.

Proposition 12.37 (Coherent matrix element of a normal-ordered operator)**.** *For any operator written in normal-ordered form* $:A(a^\dagger, a):$*,*

$$\Big\langle \theta \Big| :A(a^\dagger, a): \Big| \theta' \Big\rangle = A(\bar\theta, \theta')\, e^{\bar\theta\theta'}. \tag{12.122}$$

Proof. In a normal-ordered monomial every $a^\dagger$ sits to the left and acts on the bra by the left eigenrelation $\langle\theta|\, a^\dagger = \bar\theta\,\langle\theta|$ (Eq. (12.116)); every a sits to the right and acts on the ket by $a\,|\theta'\rangle = \theta'\,|\theta'\rangle$. Each replacement converts an operator into its Grassmann eigenvalue, $a^\dagger \to \bar\theta$ and $a \to \theta'$, and because the operators were already in the order "all $a^\dagger$, then all a" the Grassmann eigenvalues appear in the same order, reproducing the symbol $A(\bar\theta, \theta')$ with no reordering signs. What remains after all operators are eaten is the overlap $\langle\theta|\theta'\rangle = e^{\bar\theta\theta'}$ of Eq. (12.116). □

The one matrix element we will actually need, for the free Hamiltonian $\hat H = \omega\, a^\dagger a$ of a single mode (already normal-ordered, the $\hat H$ of Section 11.4 restricted to one mode), is the case $A = \omega\, a^\dagger a$:

$$\Big\langle \theta \Big| \hat H \Big| \theta' \Big\rangle = \omega\, \bar\theta\theta'\, e^{\bar\theta\theta'}. \tag{12.123}$$

It is worth confirming Eq. (12.123) by the bare-handed route, both as a check on Theorem 12.37 and because the same manipulation will recur. Acting $a^\dagger a$ to the right, $a^\dagger a\,|\theta'\rangle = a^\dagger\theta'\,|\theta'\rangle = -\theta' a^\dagger\,|\theta'\rangle$, so $\Big\langle \theta \Big| a^\dagger a \Big| \theta' \Big\rangle = -\theta' \Big\langle \theta \Big| a^\dagger \Big| \theta' \Big\rangle = -\theta'\bar\theta\;\langle\theta|\theta'\rangle = \bar\theta\theta'\, e^{\bar\theta\theta'}$, where the final sign flip is the anticommutation $-\theta'\bar\theta = +\bar\theta\theta'$. The two routes agree.

12.5.5 The trace, and where the minus sign comes from

The partition function and every thermal or vacuum amplitude is a trace of an operator, and the path integral is built by writing that trace in the coherent-state basis. Here a single sign — absent in the bosonic case — enters, and it is the algebraic seed of fermionic statistics.

Theorem 12.38 (Coherent-state trace formula)**.** *For any operator $\hat{A}$ with even Grassmann parity (in particular any function of $\hat{n}$, and any $e^{-\beta\hat{H}}$),*

$$\operatorname{Tr}\hat{A} \;=\; \int d\bar{\theta}\, d\theta\; e^{-\bar{\theta}\theta}\, \Big\langle -\theta\Big|\hat{A}\Big|\theta\Big\rangle . \tag{12.124}$$

The argument of the bra carries the crucial extra minus sign: it is $\langle -\theta|$, not $\langle\theta|$.

Proof. The trace over the two-dimensional space is $\operatorname{Tr}\hat{A} = A_{00} + A_{11}$ with $A_{mn} = \big\langle m\big|\hat{A}\big|n\big\rangle$. We evaluate the right-hand side of Eq. (12.124) and show it equals this. From $\langle -\theta| = \langle 0| + \langle 1|\,\bar{\theta}$ (replace $\theta \to -\theta$, hence $\bar{\theta} \to -\bar{\theta}$, in Eq. (12.115)) and $|\theta\rangle = |0\rangle - \theta\,|1\rangle$,

$$\Big\langle -\theta\Big|\hat{A}\Big|\theta\Big\rangle = (\langle 0| + \langle 1|\,\bar{\theta})\hat{A}(|0\rangle - \theta\,|1\rangle) = A_{00} - \theta A_{01} + A_{10}\bar{\theta} - A_{11}\,\bar{\theta}\theta, \tag{12.125}$$

where in the last term $\hat{A}$ even lets $\bar{\theta}$ commute through, $\langle 1|\,\bar{\theta}\hat{A}\theta\,|1\rangle = A_{11}\bar{\theta}\theta$, and the leading sign comes from $\hat{A}(-\theta)$. Multiplying by $e^{-\bar{\theta}\theta} = 1 - \bar{\theta}\theta$ and integrating, only two terms survive the Berezin integral: $\int d\bar{\theta}\, d\theta\,(-A_{11}\bar{\theta}\theta) = +A_{11}$ from the bulk term and $\int d\bar{\theta}\, d\theta\,(-\bar{\theta}\theta\, A_{00}) = +A_{00}$ from the cross term of $(-\bar{\theta}\theta)$ with A_{00}. The single-Grassmann terms integrate to zero. The total is $A_{00} + A_{11} = \operatorname{Tr}\hat{A}$. □

The minus sign is not optional, and the cleanest way to see this is to compute what the *naive* choice $\langle +\theta|$ would give. Repeating Eq. (12.125) without the sign flip yields $\big\langle \theta\big|\hat{A}\big|\theta\big\rangle = A_{00} - \theta A_{01} - A_{10}\bar{\theta} + A_{11}\bar{\theta}\theta$, and the same Berezin integration now produces $A_{00} - A_{11}$ — the *supertrace* $\operatorname{Str}\hat{A}$, which counts the filled state with a relative minus and is not the quantity we want.

$$\int d\bar{\theta}\, d\theta\; e^{-\bar{\theta}\theta}\, \Big\langle +\theta\Big|\hat{A}\Big|\theta\Big\rangle = A_{00} - A_{11} = \operatorname{Str}\hat{A}. \tag{12.126}$$

The genuine trace is recovered only by reversing the sign of the bra's Grassmann label. For bosonic coherent states the analogous formula is $\operatorname{Tr}\hat{A} = \frac{1}{\pi}\int d^2z\, e^{-|z|^2}\big\langle z\big|\hat{A}\big|z\big\rangle$ with the *same* z on both sides — no sign flip. The fermionic minus sign in Eq. (12.124) is therefore a genuinely new feature with no bosonic precedent, and we will see in Section 12.5.7 that it is precisely what forces fields to be antiperiodic in imaginary time.

Physical Insight — the sign is the statistics

Everything that distinguishes fermions from bosons in the path-integral formalism descends from a single algebraic fact: tracing a fermionic operator in the coherent-state basis costs a sign that tracing a bosonic operator does not. We have just isolated that sign in its barest form, on a two-state system, where it is nothing more than the statement $\int d\bar\theta\, d\theta\, \theta\bar\theta = +1$ together with the eigenvalue flip $\langle -\theta|$. Downstream it becomes the antiperiodic boundary condition, the Matsubara frequencies $(2n+1)\pi/\beta$, the minus sign on every closed fermion loop, and — traced all the way back through Section 12.4 — the determinant in the numerator. They are one sign wearing different clothes.

12.5.6 Time-slicing: the path integral for one mode

We now assemble the path integral by the method of Section 10.1: write the evolution operator as a product of many short-time factors and insert the resolution of the identity Eq. (12.119) between each pair. The target is the transition amplitude between coherent states,

$$\mathcal{K}(\bar\theta_f, \theta_i; T) \equiv \left\langle \theta_f \middle| e^{-i\hat H T} \middle| \theta_i \right\rangle , \tag{12.127}$$

with $\hat H = \omega\, a^\dagger a$ the one-mode Hamiltonian and the boundary data $\theta_i, \bar\theta_f$ fixed Grassmann numbers (the analogues of the fixed endpoints x_i, x_f in Eq. (10.16)). Slice T into N steps of length $\epsilon = T/N$ and write $e^{-i\hat H T} = \left(e^{-i\epsilon \hat H}\right)^N$. Between the N factors insert $N-1$ copies of Eq. (12.119), labelling the inserted variables $\theta_1, \dots, \theta_{N-1}$ and setting $\theta_0 \equiv \theta_i$, $\theta_N \equiv \theta_f$. The amplitude becomes a chain of short-time kernels,

$$\mathcal{K} = \int \prod_{k=1}^{N-1} d\bar\theta_k\, d\theta_k\; e^{-\sum_{k=1}^{N-1} \bar\theta_k \theta_k} \prod_{k=0}^{N-1} \left\langle \theta_{k+1} \middle| e^{-i\epsilon \hat H} \middle| \theta_k \right\rangle . \tag{12.128}$$

Each short-time kernel is evaluated to first order in ϵ by Theorem 12.37: since $\hat H$ is normal-ordered, $e^{-i\epsilon \hat H} =: e^{-i\epsilon \hat H} : + O(\epsilon^2)$ (the reordering corrections are higher order in ϵ, exactly as the Trotter error is in Theorem 10.2), so

$$\left\langle \theta_{k+1} \middle| e^{-i\epsilon \hat H} \middle| \theta_k \right\rangle = e^{\bar\theta_{k+1}\theta_k}\, e^{-i\epsilon\, H(\bar\theta_{k+1}, \theta_k)} (1 + O(\epsilon^2)), \qquad H(\bar\theta, \theta) = \omega\, \bar\theta\theta. \tag{12.129}$$

Collecting the exponents from the N kernels Eq. (12.129) and the $N-1$ Gaussian measure factors, the integrand is e^{S_N} with

$$S_N = \sum_{k=0}^{N-1} \bar\theta_{k+1}\theta_k - \sum_{k=1}^{N-1} \bar\theta_k \theta_k - i\epsilon \sum_{k=0}^{N-1} H(\bar\theta_{k+1}, \theta_k). \tag{12.130}$$

The first two sums combine into a discrete time derivative. Peel off the $k = N-1$ boundary term from the first sum and relabel:

$$\sum_{k=0}^{N-1} \bar\theta_{k+1}\theta_k - \sum_{k=1}^{N-1} \bar\theta_k\theta_k = \bar\theta_N\theta_{N-1} - \sum_{k=1}^{N-1} \bar\theta_k(\theta_k - \theta_{k-1}). \tag{12.131}$$

As $N \to \infty$ with T fixed, the intermediate variables become a Grassmann-valued path $\theta_k \to \psi(t)$, $\bar\theta_k \to \bar\psi(t)$, $t = k\epsilon$, the difference $\theta_k - \theta_{k-1} \to \epsilon\,\dot\psi(t)$, the sums become integrals $\epsilon\sum \to \int_0^T dt$, and the boundary term is $\bar\theta_N\theta_{N-1} \to \bar\theta_f\,\psi(T)$. The discrete action Eq. (12.130) tends to

$$S_N \;\longrightarrow\; \bar\theta_f\,\psi(T) - \int_0^T dt\,\bar\psi\,\dot\psi - i\int_0^T dt\,H(\bar\psi,\psi) = \bar\theta_f\,\psi(T) + i\int_0^T dt\;\bar\psi(i\partial_t - \omega)\psi, \tag{12.132}$$

where the bulk terms were combined using $-\bar\psi\dot\psi = i(i\bar\psi\dot\psi)$. We have arrived at the continuum coherent-state path integral.

Theorem 12.39 (Fermionic path integral from canonical quantization)**.** *The coherent-state transition amplitude Eq. (12.127) of a fermionic mode is the Berezin functional integral*

$$\Big\langle \theta_f \Big| e^{-i\hat H T} \Big| \theta_i \Big\rangle = \int \mathcal{D}\bar\psi\,\mathcal{D}\psi\;\exp\Big(\bar\theta_f\,\psi(T) + i\int_0^T dt\;\bar\psi(t)(i\partial_t - H)\psi(t)\Big), \tag{12.133}$$

the integral running over all Grassmann paths $\psi(t), \bar\psi(t)$ on $[0,T]$ with the boundary conditions $\psi(0) = \theta_i$ and $\bar\psi(T) = \bar\theta_f$ fixed by the external coherent states, and the measure $\mathcal{D}\bar\psi\,\mathcal{D}\psi \equiv \prod_k d\bar\theta_k\,d\theta_k$ the continuum limit of the product of Berezin measures. For the free mode $H = \omega\,\bar\psi\psi$; for an interacting normal-ordered Hamiltonian, $H(\bar\psi,\psi)$ is its symbol.

This is the central result. It was obtained, exactly as the scalar result of Theorem 10.4, by an identity — inserting completeness between slices and evaluating elementary matrix elements — not by analogy. The bulk weight is e^{iS} with the first-order action

$$S[\bar\psi,\psi] = \int dt\;\bar\psi\,(i\partial_t - H)\psi, \tag{12.134}$$

the Lagrangian $\bar\psi\,i\partial_t\psi - \bar\psi H\psi$ being precisely the Legendre structure of a first-order system: the canonical momentum conjugate to ψ is $\bar\psi$ itself (the operator statement of which was $\pi_\psi = i\psi^\dagger$ in Section 11.1.4), so there is no separate $\dot{\bar\psi}$ kinetic term. The boundary term $\bar\theta_f\psi(T)$ is the price of holding a first-order system fixed at both ends; it will be absorbed automatically when we form the trace, and it never appears in a correlation function.

12.5.7 The trace, antiperiodicity, and KMS

The transition amplitude Eq. (12.133) still depends on external boundary data. Physical quantities are traces, and forming the trace is where fermionic statistics announces itself. Apply the trace formula Eq. (12.124) to the evolution operator. We must set $\theta_f = -\theta_i$ and integrate the endpoint over a final Gaussian measure:

$$\mathrm{Tr}\; e^{-i\hat{H}T} = \int d\bar{\theta}_0\, d\theta_0\; e^{-\bar{\theta}_0\theta_0}\; \Big\langle -\theta_0 \Big| e^{-i\hat{H}T} \Big| \theta_0 \Big\rangle . \tag{12.135}$$

The single instruction "$\langle -\theta_0|$ at the top, $|\theta_0\rangle$ at the bottom" is the statement that the path closes up onto *minus* its starting value:

$$\psi(T) = -\psi(0), \qquad \bar{\psi}(T) = -\bar{\psi}(0). \tag{12.136}$$

With the endpoint now integrated, the boundary term $\bar{\theta}_f\psi(T)$ of Eq. (12.133) merges with the final Gaussian factor $e^{-\bar{\theta}_0\theta_0}$ and is reabsorbed into the bulk action evaluated on closed antiperiodic paths; nothing of it is left over. The trace is therefore a functional integral over *antiperiodic* Grassmann fields, with no surviving boundary data:

$$\mathrm{Tr}\; e^{-i\hat{H}T} = \oint_{\mathrm{AP}} \mathcal{D}\bar{\psi}\,\mathcal{D}\psi\; \exp\Big(i\int_0^T dt\; \bar{\psi}(i\partial_t - H)\psi \Big), \qquad \psi(T) = -\psi(0). \tag{12.137}$$

The contrast with the scalar is exact and instructive. The bosonic trace formula carries the *same* label on both coherent states, so the bosonic path closes onto $+$ its start: bosonic fields obey *periodic* boundary conditions, $\phi(T) = \phi(0)$, as the closed Euclidean cylinder of Section 10.6.5 required. The fermionic minus sign of Eq. (12.124) flips periodic to antiperiodic. This is the path-integral face of spin and statistics: the same anticommutators that forced antisymmetric Fock space and the Pauli principle in Chapter 11 reappear here as a sign on the boundary condition.

The physics of Eq. (12.136) is sharpest in imaginary time. Following the Wick rotation of Section 10.6, set $T = -i\beta$, i.e. $t = -i\tau$ with $\tau \in [0, \beta]$; the evolution operator becomes the Boltzmann operator $e^{-\beta\hat{H}}$ and its trace is the thermal partition function $Z(\beta) = \mathrm{Tr}\; e^{-\beta\hat{H}}$ at inverse temperature β. Under $t = -i\tau$ the bulk weight rotates exactly as in Eq. (10.160): $i\int dt\,\bar{\psi} i\partial_t\psi \to -\int_0^\beta d\tau\,\bar{\psi}\partial_\tau\psi$ and $-i\int dt\, H \to -\int_0^\beta d\tau\, H$, so

$$Z(\beta) = \mathrm{Tr}\; e^{-\beta\hat{H}} = \oint_{\mathrm{AP}} \mathcal{D}\bar{\psi}\,\mathcal{D}\psi\; e^{-S_E[\bar{\psi},\psi]}, \qquad S_E = \int_0^\beta d\tau\; \bar{\psi}(\partial_\tau + H)\psi, \tag{12.138}$$

the field now living on a circle of circumference β with the antiperiodic gluing $\psi(\tau+\beta) = -\psi(\tau)$ (Fig. 12.2). The boson on the same cylinder is glued periodically, $\phi(\tau+\beta) = \phi(\tau)$, exactly the compactified Euclidean time of Section 10.6.5.

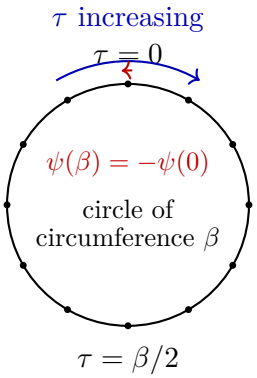

Figure 12.2: The imaginary-time path integral lives on a circle of circumference $\beta = 1/T$ (the Wick-rotated time of Section 10.6). Dots are the time slices of Eq. (12.128). The trace glues the two ends, $\tau = 0$ to $\tau = \beta$; for a boson the gluing is periodic, for a fermion it is *antiperiodic*, $\psi(\beta) = -\psi(0)$, the geometric form of the minus sign in the coherent-state trace Eq. (12.124). Expanding an antiperiodic field in Fourier modes on the circle forces the fermionic Matsubara frequencies $\omega_n = (2n+1)\pi/\beta$.

The antiperiodicity is exactly the *Kubo–Martin–Schwinger* (KMS) condition specialized to fermions, and it is worth stating the argument once because it is the structural reason the boundary condition is forced by thermal equilibrium and not merely by our bookkeeping. For any two Heisenberg operators A, B and the thermal average $\langle \cdots \rangle_\beta = Z^{-1} \operatorname{Tr}(e^{-\beta \hat{H}} \cdots)$, cyclicity of the trace gives

$$\langle A(\tau) B(0) \rangle_\beta = Z^{-1} \operatorname{Tr}\!\left(e^{-\beta \hat{H}} e^{\hat{H}\tau} A e^{-\hat{H}\tau} B\right) = \pm \langle B(0) A(\tau - \beta) \rangle_\beta , \qquad (12.139)$$

where the upper sign holds for bosonic operators and the lower for fermionic ones, the sign being the cost of moving the fermionic B past the fermionic A under the trace. The thermal two-point function is thus periodic in imaginary time for bosons and antiperiodic for fermions with period β — which is precisely the boundary condition on the field that the coherent-state derivation produced from the bra-label flip. The two derivations agree because they are the same statistics seen from two sides: Eq. (12.124) is the microscopic minus sign, Eq. (12.139) is its thermodynamic shadow. This antiperiodicity is the single most consequential output of the section for later chapters: it is the entire content of the imaginary-time (Matsubara) formalism of finite-temperature field theory, and it is what makes fermions on a Euclidean lattice obey antiperiodic boundary conditions in the time direction (Chapter 43). We flag it here as the rigorous underpinning, derived rather than postulated.

Worked Example 12.40 (The single-mode partition function, three ways)**.** Nothing certifies the construction like computing one number by independent

routes and finding them equal. Take the one-mode free Hamiltonian $\hat{H} = \omega\, a^\dagger a$ and compute $Z(\beta) = \operatorname{Tr} e^{-\beta \hat{H}}$ (i) from the operator spectrum, (ii) from the *discrete* antiperiodic Berezin integral with finite N, and (iii) from the continuum determinant.

(i) Operator route. The spectrum is $\{0, \omega\}$ on $\{|0\rangle, |1\rangle\}$, so directly

$$Z(\beta) = \left\langle 0 \middle| e^{-\beta \hat{H}} \middle| 0 \right\rangle + \left\langle 1 \middle| e^{-\beta \hat{H}} \middle| 1 \right\rangle = 1 + e^{-\beta\omega}. \tag{12.140}$$

This is the answer the path integral must reproduce.

(ii) Discrete Berezin route. Discretize Eq. (12.138) on N slices, $\epsilon = \beta/N$. Reading the Euclidean discrete action off Eq. (12.130) with the rotation $i\epsilon H \to \epsilon H$ and imposing the antiperiodic closure $\theta_N = -\theta_0$, $\bar{\theta}_N = -\bar{\theta}_0$, the integrand is $\exp(-\bar{\theta}_j M_{jk} \theta_k)$ over the N variables $\theta_0, \ldots, \theta_{N-1}$, with

$$M = \mathbf{1} - a\,\mathsf{S}, \qquad a \equiv 1 - \epsilon\omega, \tag{12.141}$$

where S is the antiperiodic shift: $\mathsf{S}_{k,k-1} = 1$ on the subdiagonal and $\mathsf{S}_{0,N-1} = -1$ in the corner, the corner minus coming from $\bar{\theta}_N = -\bar{\theta}_0$. By the Gaussian Grassmann identity of Eq. (12.81), the integral is $\det M$ — the determinant in the numerator, the hallmark of a fermion. Since $\mathsf{S}^N = -\mathbf{1}$, the eigenvalues of S are the N roots of $\mu^N = -1$, and its characteristic polynomial is $\det(x\mathbf{1} - \mathsf{S}) = x^N + 1$. Therefore

$$\begin{aligned} Z_N = \det(\mathbf{1} - a\,\mathsf{S}) &= \prod_{\mu^N = -1} (1 - a\mu) = a^N \prod_{\mu^N = -1} (a^{-1} - \mu) \\ &= a^N (a^{-N} + 1) = 1 + a^N = 1 + (1 - \epsilon\omega)^N. \end{aligned} \tag{12.142}$$

Taking $N \to \infty$ at fixed β, $(1 - \beta\omega/N)^N \to e^{-\beta\omega}$, so $Z_N \to 1 + e^{-\beta\omega}$, matching Eq. (12.140) exactly. The calculation is fully finite at every stage; no regularization was needed because the discrete determinant is an honest polynomial identity.

(iii) Continuum determinant and Matsubara modes. In the continuum, Eq. (12.138) is the Gaussian integral of $\bar{\psi}(\partial_\tau + \omega)\psi$ over antiperiodic fields, so $Z = \det(\partial_\tau + \omega)$. Antiperiodicity, $\psi(\tau + \beta) = -\psi(\tau)$, is solved by the modes $e^{-i\omega_n \tau}$ with the *fermionic Matsubara frequencies*

$$\omega_n = \frac{(2n+1)\pi}{\beta}, \qquad n \in \mathbb{Z}, \tag{12.143}$$

on which $\partial_\tau + \omega$ has eigenvalues $-i\omega_n + \omega$, whence formally $Z = \prod_n (\omega - i\omega_n)$. This infinite product needs the regularization the discrete route bypassed; carrying it out (dividing by the $\omega = 0$ value and using $\prod_{n \geq 0} [1 + x^2/(2n+1)^2\pi^2] = \cosh(x/2)$) gives $Z \propto \cosh(\beta\omega/2) \propto 1 + e^{-\beta\omega}$, the same answer once more. The odd integers $2n + 1$ in Eq. (12.143) are the direct imprint of the antiperiodic gluing; a boson, periodic, would carry the even frequencies $2n\pi/\beta$.

The bosonic comparison sharpens the lesson and ties the section back to Section 12.4. The same single-mode partition function for a *bosonic* oscillator is $Z_{\mathrm{B}} = \sum_{n\geq 0} e^{-\beta\omega n} = (1-e^{-\beta\omega})^{-1}$, reproduced by a path integral over *periodic* ordinary-number fields whose Gaussian gives $\det(\partial_\tau+\omega)^{-1}$ — the inverse determinant, with the periodic (even) Matsubara modes. Side by side,

$$Z_{\mathrm{F}} = \det(\partial_\tau+\omega) = 1+e^{-\beta\omega}, \qquad Z_{\mathrm{B}} = \det(\partial_\tau+\omega)^{-1} = \frac{1}{1-e^{-\beta\omega}}, \tag{12.144}$$

the two facts that distinguish the statistics — det versus $\det^{-1}$, and antiperiodic versus periodic — are visibly the same fact, the coherent-state trace sign, expressed in the measure and in the boundary condition respectively. The numerator determinant the reader first met as the bare algebraic output of Section 12.4 has now acquired its physical meaning: it is the fermionic partition function, and the minus sign it secretly carries is the Pauli principle.

12.5.8 From one mode to the Dirac field

The passage to the field is now purely a matter of restoring the labels we suppressed in Section 12.5.1. The Dirac field is a continuum of independent fermionic modes, one annihilation/creation pair $\{a, a^\dagger\} = 1$ for each momentum, spin, and particle/antiparticle channel, all tensored together (Eq. (11.116), Theorem 11.29). The coherent state of the whole field is the tensor product of single-mode coherent states, labelled now by a Grassmann *field* $\psi(\mathbf{x})$ (and its conjugate $\bar\psi(\mathbf{x})$) rather than a single Grassmann number; the resolution of the identity Eq. (12.119) becomes a Berezin functional integral $\int \mathcal{D}\bar\psi\,\mathcal{D}\psi\, e^{-\int d^3x\,\bar\psi\psi}\,|\psi\rangle\langle\psi| = \mathbf{1}$; and the trace formula Eq. (12.124) carries the antiperiodic identification Eq. (12.136) for every mode at once. Repeating the time-slicing of Section 12.5.6 mode by mode, the bulk action Eq. (12.134) becomes

$$S = \int dt\,\Big[\int d^3x\;\bar\psi\, i\partial_t\psi \;-\; \hat H[\bar\psi,\psi]\Big], \qquad \mathcal{H}_{\mathrm{D}} = \psi^\dagger(-i\gamma^0\boldsymbol{\gamma}\cdot\nabla + \gamma^0 m)\psi, \tag{12.145}$$

with $\mathcal{H}_{\mathrm{D}}$ the normal-ordered Dirac Hamiltonian density of Section 11.3.4 (its symbol obtained by the rule of Theorem 12.37, $\psi^\dagger \to \bar\psi\gamma^0$, $\psi\to\psi$). The Legendre structure collapses exactly as in the single mode: using $\bar\psi = \psi^\dagger\gamma^0$, the time-derivative term is $\psi^\dagger i\partial_0\psi = \bar\psi\, i\gamma^0\partial_0\psi$, and the Hamiltonian density rewrites as $\bar\psi(-i\gamma^i\partial_i + m)\psi$, so that

$$\bar\psi\, i\partial_t\psi - \mathcal{H}_{\mathrm{D}} = \bar\psi\, i\gamma^0\partial_0\psi + \bar\psi(i\gamma^i\partial_i - m)\psi = \bar\psi(i\partial\!\!\!/ - m)\psi. \tag{12.146}$$

The coherent-state Lagrangian is exactly the Dirac Lagrangian $\bar\psi(i\partial\!\!\!/ - m)\psi$ of Eq. (11.25). The continuum path integral for the free Dirac field is therefore

$$Z = \int \mathcal{D}\bar\psi\,\mathcal{D}\psi\;\exp\Big(i\int d^4x\;\bar\psi(i\partial\!\!\!/ - m)\psi\Big), \tag{12.147}$$

the measure $\mathcal{D}\bar{\psi}\,\mathcal{D}\psi$ a product of Berezin measures over independent Grassmann fields $\psi(x), \bar{\psi}(x)$, treated as the four-component spinor fields of Chapter 11 but valued in a Grassmann algebra. We have derived Eq. (12.147) from the operator theory of Chapter 11, with the measure defined, the weight e^{iS} explained, and — when a trace is taken — the antiperiodic boundary condition Eq. (12.136) established. Nothing here was postulated by analogy with the scalar; the analogy is now a theorem.

This is the object the next section consumes. With the measure $\mathcal{D}\bar{\psi}\,\mathcal{D}\psi$ and the action Eq. (12.147) in hand, Section 12.6 couples Grassmann sources $\bar{\eta}, \eta$ to the field, performs the functional Gaussian integral of Section 12.4 to write down the generating functional $Z[\bar{\eta}, \eta]$, identifies its normalization as $\det(i\not{\partial} - m)$, and extracts by functional differentiation the fermion propagator — which, because the sources anticommute, will reappear carrying exactly the minus sign of the canonical S_F of Theorem 11.38.

12.6 The Dirac generating functional and the fermion propagator

The finite-dimensional sourced Gaussian of Section 12.4 gave us, for anticommuting variables, a master formula whose entire content was a single matrix inverse: the sourced integral Eq. (12.99) returned the determinant of the kinetic matrix times the exponential of a quadratic in the sources, with the kernel of that quadratic the *inverse* of the kinetic matrix. Section 12.5 then promoted those Grassmann numbers from a formal device to the genuine integration variables of a path integral, derived from the operator formalism of Chapter 11 through fermionic coherent states exactly as Chapter 10 derived the bosonic path integral from the scalar coherent states. We now hold both pieces: a Gaussian master formula and a legitimate functional integral to apply it to. This section assembles them. We write the Dirac generating functional $Z[\eta, \bar{\eta}]$, perform its functional Gaussian integral in closed form, read off the normalization as a functional determinant and the source kernel as the Feynman propagator S_F, and recover from it—by two anticommuting functional derivatives—the time-ordered two-point function $\langle 0|\mathcal{T}\,\psi(x)\bar{\psi}(y)|0\rangle$ built operator-theoretically in Chapter 11. The reward is that the minus sign which the Pauli principle and the antisymmetry of S_F demand is no longer something to be inserted by hand: it falls out of the anticommutation of the sources, automatically and in the right place. The free electron propagator of QED reappears here as a path-integral object, in exact agreement with the canonical S_F frozen for the rest of the book.

12.6.1 The generating functional with Grassmann sources

The bosonic generating functional $Z[J]$ of Section 4.4 and Eq. (10.86) was built by coupling the field ϕ to an external c-number source J through a term $J\phi$ in the action, so that functional differentiation with respect to J pulls factors of ϕ down from the exponent. For the Dirac field the same strategy must respect the algebra: ψ and $\bar{\psi}$ are anticommuting (Grassmann-valued) fields, and a source term must be Grassmann-even for e^{iS} to make sense. The unique local bilinear options are $\bar{\eta}\psi$ and $\bar{\psi}\eta$ with the sources $\eta(x)$ and $\bar{\eta}(x)$ themselves anticommuting spinors—independent Grassmann generators carrying one Dirac index each. Each source term is then a product of two odd objects and hence even, as required. The two sources are genuinely independent: η couples to $\bar{\psi}$ and $\bar{\eta}$ to ψ, so differentiating with respect to η extracts a $\bar{\psi}$ and differentiating with respect to $\bar{\eta}$ extracts a ψ.

Definition 12.41 (Dirac generating functional)**.** For the free Dirac field of Chapter 11, with independent anticommuting spinor sources $\eta(x), \bar{\eta}(x)$, the *generating functional* is

$$Z[\eta,\bar{\eta}] \;=\; \int \mathcal{D}\bar{\psi}\,\mathcal{D}\psi \;\exp\Big[\, i\int d^4x\,\big(\,\bar{\psi}(i\partial\!\!\!/ - m)\psi + \bar{\eta}\psi + \bar{\psi}\eta\,\big)\Big], \tag{12.148}$$

where $\mathcal{D}\bar{\psi}\,\mathcal{D}\psi$ is the Berezin field measure of Section 12.5, and every product of fields and sources is understood with its Grassmann ordering kept intact.

The action in the exponent is exactly the free Dirac action $S_0 = \int d^4x\,\bar{\psi}(i\partial\!\!\!/ - m)\psi$ whose stationarity is the Dirac equation $(i\partial\!\!\!/ - m)\psi = 0$ of Section 11.1.2, now with the two linear source couplings appended. The convergence tilt $m^2 \to m^2 - i\varepsilon$ that the Wick rotation of Section 10.6 imposed on the bosonic measure is inherited here in the same way; we keep it implicit until it is needed to fix the propagator's contour below. As in the bosonic case, all physical content lives in *normalized* derivatives—ratios $Z[\eta,\bar{\eta}]/Z[0]$—so any field-independent constant multiplying Eq. (12.148) is immaterial and may be absorbed into the measure.

12.6.2 Performing the functional Gaussian integral

The integral Eq. (12.148) is Gaussian in the Grassmann fields: the exponent is bilinear in $\psi, \bar{\psi}$ plus terms linear in them. It is therefore the field-space instance of the finite-dimensional sourced Gaussian Eq. (12.99), which we recall in the form

$$\int \Big(\prod_i d\bar{\theta}_i\, d\theta_i\Big)\, e^{-\bar{\theta}_i A_{ij}\theta_j + \bar{\zeta}_i\theta_i + \bar{\theta}_i\zeta_i} \;=\; (\det A)\, e^{\,\bar{\zeta}_i (A^{-1})_{ij}\zeta_j}, \tag{12.149}$$

proved in Theorem 12.26 by completing the square in the anticommuting variables. The decisive structural fact, established there, is that the Gaussian integral over

Grassmann variables produces $\det A$ in the numerator—not the $(\det A)^{-1/2}$ of the bosonic Gaussian. This single inversion of power is the algebraic seed of every minus sign on a closed fermion loop, and Section 12.7 is devoted to its consequences; here we use Eq. (12.149) as an established identity.

To apply it, discretize spacetime exactly as the bosonic measure was discretized in Section 10.6: replace the continuum index x by a lattice index i, $\int d^4x \to \sum_i \Delta V$ with ΔV the cell four-volume, and read $\psi(x) \to \theta_i$, $\bar\psi(x) \to \bar\theta_i$. The continuum and discrete dictionaries are

$$-\bar\theta_i A_{ij}\theta_j \;\longleftrightarrow\; i\int d^4x\,\bar\psi(i\not\partial - m)\psi, \qquad \bar\zeta_i\theta_i \;\longleftrightarrow\; i\int d^4x\,\bar\eta\psi, \qquad \bar\theta_i\zeta_i \;\longleftrightarrow\; i\int d^4x\,\bar\psi\eta. \tag{12.150}$$

Reading off the kinetic operator and the effective sources,

$$A \;=\; -\,i\,(i\not\partial - m), \qquad \bar\zeta \;=\; i\,\bar\eta, \qquad \zeta \;=\; i\,\eta, \tag{12.151}$$

where A is now an operator on the space of Dirac spinor fields (a matrix in both spacetime and spinor indices). Substituting Eq. (12.151) into Eq. (12.149), the source exponent is

$$\bar\zeta\, A^{-1}\zeta \;=\; (i\bar\eta)\, A^{-1}(i\eta) \;=\; -\,\bar\eta\, A^{-1}\,\eta, \tag{12.152}$$

and the prefactor is $\det A$. It remains to identify A^{-1}. From Eq. (12.151),

$$A^{-1} \;=\; \big[-i(i\not\partial - m)\big]^{-1} \;=\; \frac{1}{-i}\,(i\not\partial - m)^{-1} \;=\; i\,(i\not\partial - m)^{-1}. \tag{12.153}$$

The remaining inverse is precisely the Green's function of the Dirac operator. Equation (11.204) established that the Feynman propagator S_F obeys $(i\not\partial_x - m)S_F(x-y) = i\,\delta^4(x-y)$; as an operator identity this reads $(i\not\partial - m)\,S_F = i\,\mathbf{1}$, so that

$$(i\not\partial - m)^{-1} \;=\; \frac{1}{i}\,S_F \;=\; -\,i\,S_F, \qquad \text{hence} \qquad A^{-1} \;=\; i\,(-i\,S_F) \;=\; S_F. \tag{12.154}$$

The kinetic operator's inverse *is* the fermion propagator. Inserting Eq. (12.154) into Eq. (12.152) and restoring the continuum gives the closed form.

Theorem 12.42 (Closed form of the Dirac generating functional)**.** *The functional integral Eq. (12.148) evaluates to*

$$\boxed{\,Z[\eta,\bar\eta] \;=\; Z[0]\,\exp\Big[-\int d^4x\,d^4y\;\bar\eta(x)\,S_F(x-y)\,\eta(y)\Big]\,,\,} \tag{12.155}$$

with the field-independent normalization

$$Z[0] \;=\; \det A \;=\; \det\big[-\,i\,(i\not\partial - m)\big] \;=\; \mathcal{N}\,\det(i\not\partial - m), \tag{12.156}$$

where $\mathcal{N}$ is the (field-independent, formally divergent) constant collecting the factor $-i$ per mode, absorbed into the measure normalization.

Proof. The discretized integral is Eq. (12.149) with the identifications Eq. (12.151). Its value is $(\det A)\exp(\bar{\zeta}A^{-1}\zeta)$; the source exponent was reduced in Eqs. (12.152) and (12.154) to $-\bar{\eta}\,S_F\,\eta$, which is Eq. (12.155) once the lattice sums are returned to integrals. The prefactor is $\det A = \det[-i(i\not{\partial} - m)]$. Pulling the scalar $-i$ out of the determinant over the (infinite) mode space yields a field-independent constant $\mathcal{N} = \det(-i\,\mathbf{1})$ times $\det(i\not{\partial} - m)$; since only the ratio $Z[\eta,\bar{\eta}]/Z[0]$ enters every correlator, $\mathcal{N}$ never appears in a physical quantity, and the content of $Z[0]$ is the determinant of the Dirac operator. The convergence of the underlying finite-dimensional integral, and hence the legitimacy of the analytic continuation in A, is guaranteed by the same $m^2 \to m^2 - i\varepsilon$ tilt that made the bosonic Gaussian of Section 10.6 convergent: it gives A a definite signature, exactly as in the scalar discretization of Eq. (10.111). □

The structural parallel with the bosonic result Eq. (10.111) is exact, with one telling sign difference. Both functionals are $Z[0]$ times the exponential of a quadratic in the sources whose kernel is the free propagator. For the scalar the kernel entered as $-\frac{1}{2}\int J D_F J$, a single source species contracted symmetrically; for the Dirac field it enters as $-\int \bar{\eta}\,S_F\,\eta$, two distinct source species contracted in a fixed order, with no factor of $\frac{1}{2}$ because $\bar{\eta}$ and η are independent and there is exactly one way to pair them. The factor $Z[0]$ differs more fundamentally: it is $\det(i\not{\partial} - m)$ rather than the bosonic $[\det(\text{kinetic})]^{-1/2}$, the determinant sitting upstairs rather than downstairs. We isolate the source-dependent piece by defining the normalized functional

$$\widehat{Z}[\eta,\bar{\eta}] \;\equiv\; \frac{Z[\eta,\bar{\eta}]}{Z[0]} \;=\; \exp\Big[-\int d^4x\, d^4y\;\bar{\eta}(x)\,S_F(x-y)\,\eta(y)\Big], \qquad \widehat{Z}[0,0]=1, \tag{12.157}$$

which is all that any correlation function will use.

12.6.3 The momentum-space fermion propagator

Theorem 12.42 identified the source kernel as S_F through the operator relation Eq. (12.154), i.e. as the inverse of $(i\not{\partial} - m)$ up to the factor i. We now invert that operator explicitly, recovering the momentum-space propagator from the path integral alone—the self-contained QED computation this section owes. Pass to momentum space with the Fourier convention of Section 10.6, $\psi(x) = \int \frac{d^4p}{(2\pi)^4}\, e^{-ip\cdot x}\,\tilde{\psi}(p)$, under which $\partial_\mu \to -ip_\mu$ and hence

$$i\not{\partial} \;=\; i\gamma^\mu\partial_\mu \;\longrightarrow\; i\gamma^\mu(-ip_\mu) \;=\; \gamma^\mu p_\mu \;=\; \not{p}. \tag{12.158}$$

The Dirac operator becomes the algebraic matrix $\not{p} - m$, and the operator equation $(i\not{\partial} - m)S_F = i\,\mathbf{1}$ of Eq. (11.204) reduces, mode by mode, to $(\not{p} - m)\,\tilde{S}_F(p) = i\,\mathbf{1}$. The momentum-space propagator is therefore

$$\tilde{S}_F(p) \;=\; i\,(\not{p} - m)^{-1}. \tag{12.159}$$

This is a 4×4 matrix inverse, but it is rationalized by a single gamma-matrix identity. Using only the Clifford relation $\{\gamma^\mu, \gamma^\nu\} = 2\eta^{\mu\nu}$ of Eq. (C.1),

$$\not{p}\not{p} \;=\; p_\mu p_\nu\, \gamma^\mu\gamma^\nu \;=\; p_\mu p_\nu\, \tfrac{1}{2}\{\gamma^\mu, \gamma^\nu\} \;=\; p_\mu p_\nu\, \eta^{\mu\nu} \;=\; p^2, \tag{12.160}$$

where the symmetric combination $p_\mu p_\nu$ projects onto the symmetric (anticommutator) part of $\gamma^\mu\gamma^\nu$. Consequently $(\not{p} - m)(\not{p} + m) = \not{p}\not{p} - m^2 = p^2 - m^2$, a scalar, so the inverse of $\not{p} - m$ is obtained by multiplying numerator and denominator by $\not{p} + m$:

$$(\not{p} - m)^{-1} \;=\; \frac{\not{p} + m}{(\not{p} - m)(\not{p} + m)} \;=\; \frac{\not{p} + m}{p^2 - m^2}. \tag{12.161}$$

Substituting Eq. (12.161) into Eq. (12.159) gives the propagator up to its contour prescription.

The boundary condition—which root of $p^2 - m^2 = 0$ the inverse is defined across, and hence the $i\varepsilon$—is not fixed by the algebra; it is fixed by the convergence of the path integral, exactly as for the scalar. The $m^2 \to m^2 - i\varepsilon$ tilt that Section 10.6 attached to the bosonic measure, and which the Wick rotation $t \to -i\tau$ makes geometrically inevitable, displaces the poles off the real p^0 axis into the Feynman configuration: it sends $p^2 - m^2 \to p^2 - m^2 + i\varepsilon$ in the denominator. (Equivalently, after rotation the Euclidean Dirac operator has denominator $-(p_E^2 + m^2)$ with $p_E^2 + m^2 > 0$ everywhere, so its inverse is unambiguous; rotating back lands on $+i\varepsilon$.) This is the same prescription, fixed by the same rotation, that produced the canonical propagator Eq. (11.27) by the operator route. We have therefore proved, from the path integral alone:

$$\boxed{\tilde{S}_F(p) \;=\; \frac{i(\not{p} + m)}{p^2 - m^2 + i\varepsilon} \;=\; \frac{i}{\not{p} - m + i\varepsilon}\,.} \tag{12.162}$$

This is identical, term for term and sign for sign, to the canonical Feynman propagator Eq. (11.27) obtained in Chapter 11 by time-ordering operators on the fermionic Fock space. The two pillars agree: the electron propagator that QED will use unaltered from Chapter 17 onward emerges equally from a sum over Grassmann field histories and from a vacuum matrix element of ordered field operators. The numerator $\not{p} + m$ is, as Section 11.5 stressed, the on-shell spin projector $\sum_s u^s(p)\bar{u}^s(p)$ at the electron pole; the path integral reproduces it without ever mentioning the spinors u, v, because it is encoded entirely in the matrix structure of the inverse Eq. (12.161).

12.6.4 The two-point function from functional differentiation

We can now extract correlation functions by differentiating Eq. (12.155), and watch the fermionic minus signs appear of their own accord. Functional differentiation with respect to anticommuting sources requires care about the side from

which the derivative acts; we adopt the *left* derivative $\dfrac{\delta_L}{\delta\eta(x)}$ throughout, defined by anticommuting the variation through to the matching source from the left,

$$\frac{\delta_L}{\delta\eta(x)}\,\eta(y) = \delta^4(x-y), \qquad \frac{\delta_L}{\delta\eta(x)}\big(\chi\,\eta(y)\big) = -\,\chi\,\frac{\delta_L}{\delta\eta(x)}\eta(y) \;\text{ for any odd } \chi, \tag{12.163}$$

and likewise for $\bar\eta$; the second rule is just the statement that $\delta_L/\delta\eta(x)$ is itself a Grassmann-odd operation, so it picks up a sign on passing any odd object. The prescription that converts Z into correlators follows directly from the source term in Eq. (12.148). Acting on the integrand, $\delta_L/\delta\bar\eta(x)$ brings down a factor $i\psi(x)$ (the source $\bar\eta$ sits to the left of ψ, so no reordering sign), while $\delta_L/\delta\eta(y)$ brings down $-i\bar\psi(y)$ (the source η sits to the right of $\bar\psi$, so the derivative must pass $\bar\psi$, generating one minus). The two factors of i, together with the reordering sign incurred when the second derivative passes the field produced by the first, conspire to cancel exactly, leaving the clean rule

$$\Big\langle 0|\mathcal{T}\,\psi(x)\bar\psi(y)|0\Big\rangle \;=\; \frac{1}{Z[0]}\,\frac{\delta_L}{\delta\bar\eta(x)}\,\frac{\delta_L}{\delta\eta(y)}\,Z[\eta,\bar\eta]\Big|_{\eta=\bar\eta=0} \;=\; \frac{\delta_L}{\delta\bar\eta(x)}\,\frac{\delta_L}{\delta\eta(y)}\,\widehat{Z}[\eta,\bar\eta]\Big|_{0}. \tag{12.164}$$

That this prescription, with the derivatives ordered as the operators are ordered and with no compensating signs or factors inserted by hand, reproduces the operator string $\psi(x)\bar\psi(y)$ inside the integral is verified by the explicit i-counting just sketched; we now evaluate the right-hand side on the closed form Eq. (12.157).

Theorem 12.43 (Fermion propagator from the path integral)**.** *The free Dirac two-point function obtained from Eq. (12.164) is*

$$\Big\langle 0|\mathcal{T}\,\psi(x)\bar\psi(y)|0\Big\rangle \;=\; S_F(x-y), \tag{12.165}$$

in exact agreement with the canonical Feynman propagator of Theorem 11.38.

Proof. Write $E[\eta,\bar\eta] = -\int d^4u\,d^4v\;\bar\eta(u)S_F(u-v)\eta(v)$, so $\widehat{Z} = e^{E}$. The exponent E is Grassmann-even, so a single left derivative passes through the exponential as $\frac{\delta_L}{\delta\eta(y)}e^{E} = (\frac{\delta_L}{\delta\eta(y)}E)e^{E}$. Compute the inner derivative using Eq. (12.163): the derivative reaches $\eta(v)$ only after passing the odd factor $\bar\eta(u)$, incurring one sign,

$$\frac{\delta_L}{\delta\eta(y)}E = -\int d^4u\,d^4v\;\bar\eta(u)S_F(u-v)\big(-\delta^4(y-v)\big) = \int d^4u\;\bar\eta(u)\,S_F(u-y) \;\equiv\; \mathcal{A}(y), \tag{12.166}$$

an odd functional of $\bar\eta$ alone. Thus $\frac{\delta_L}{\delta\eta(y)}\widehat{Z} = \mathcal{A}(y)\,e^{E}$. Now apply $\frac{\delta_L}{\delta\bar\eta(x)}$ by the Leibniz rule, remembering that $\mathcal{A}(y)$ is odd:

$$\frac{\delta_L}{\delta\bar\eta(x)}\big[\mathcal{A}(y)\,e^{E}\big] = \Big(\frac{\delta_L}{\delta\bar\eta(x)}\mathcal{A}(y)\Big)e^{E} - \mathcal{A}(y)\,\frac{\delta_L}{\delta\bar\eta(x)}e^{E}. \tag{12.167}$$

The first factor is a clean derivative ($\bar\eta(u)$ sits leftmost in $\mathcal{A}$),

$$\frac{\delta_L}{\delta\bar\eta(x)}\mathcal{A}(y) = \int d^4u\, \delta^4(x-u)\, S_F(u-y) = S_F(x-y), \tag{12.168}$$

a c-number matrix. Setting $\eta = \bar\eta = 0$ at the end kills the second term of Eq. (12.167), which retains the explicit factor $\mathcal{A}(y) \to 0$, and sets $e^E \to 1$ in the first. Hence $\frac{\delta_L}{\delta\bar\eta(x)}\frac{\delta_L}{\delta\eta(y)}\widehat{Z}|_0 = S_F(x-y)$, which is Eq. (12.165). □

Three features of this proof deserve to be drawn out. First, no minus sign was inserted anywhere: the only sign that appeared, in Eq. (12.166), came forced from the anticommutation rule Eq. (12.163), and it is precisely the sign that the antisymmetry of the fermionic time-ordering demands. Had we instead computed $\big\langle 0|\mathcal{T}\,\bar\psi(y)\psi(x)|0\big\rangle$ by reversing the order of the two derivatives, the same bookkeeping would yield $-S_F(x-y)$, reproducing the relative minus sign carried by the time-ordering symbol on fermion fields (Theorem 11.38). Second, the equal-source "diagonal" correlators vanish identically: $\langle 0|\mathcal{T}\,\psi(x)\psi(y)|0\rangle = \frac{\delta_L}{\delta\bar\eta(x)}\frac{\delta_L}{\delta\bar\eta(y)}\widehat{Z}|_0 = 0$, because $\widehat{Z}$ in Eq. (12.157) contains $\bar\eta$ and η only in the paired combination $\bar\eta\, S_F\, \eta$, so two $\bar\eta$-derivatives leave no surviving term at $\eta = \bar\eta = 0$; likewise $\big\langle 0|\mathcal{T}\,\bar\psi\bar\psi|0\big\rangle = 0$. Charge conservation—one ψ for each $\bar\psi$—is thereby automatic, not imposed. Third, the agreement with Chapter 11 is now total: the path integral reproduces the propagator Eq. (12.162), its position-space form Eq. (12.165), and the antisymmetry sign, with the determinant $Z[0]$ left over as the genuinely new object, to be interpreted in Section 12.7.

12.6.5 The fermionic Wick theorem

Higher correlators follow by further differentiation of Eq. (12.157), and the combinatorial pattern that emerges is the fermionic Wick theorem—the exact analog of the bosonic statement Theorem 10.23, but carrying signs. The structure is dictated by the same observation that organized the bosonic case in Section 10.5: $\widehat{Z}$ is the exponential of a quadratic in the sources, so differentiating it down to $\eta = \bar\eta = 0$ survives only when every source brought down by one derivative is matched against a source removed by another, each surviving match contributing one factor of the kernel S_F. For Grassmann sources the matching is constrained and signed: a $\delta/\delta\bar\eta$ (extracting ψ) can only pair with a $\delta/\delta\eta$ (extracting $\bar\psi$), because the kernel couples $\bar\eta$ to η; and each rearrangement of the anticommuting derivatives needed to bring a pairing together contributes a sign.

Theorem 12.44 (Wick's theorem for free Dirac fields)**.** *The free $2n$-point function vanishes unless it contains an equal number n of ψ's and $\bar\psi$'s, and only ψ–$\bar\psi$ contractions are nonzero, with*

$$\overbrace{\psi(x)\,\bar\psi(y)} = S_F(x-y), \qquad \overbrace{\psi(x)\,\psi(y)} = 0, \qquad \overbrace{\bar\psi(x)\,\bar\psi(y)} = 0. \tag{12.169}$$

The full correlator is the signed sum over all ways of pairing each ψ with a distinct $\bar\psi$,

$$\Big\langle 0|\mathcal{T}\,\psi(x_1)\cdots\psi(x_n)\,\bar\psi(y_1)\cdots\bar\psi(y_n)|0\Big\rangle \;=\; \sum_{\sigma\in S_n}\operatorname{sgn}(\sigma_{\text{eff}})\,\prod_{i=1}^{n} S_F(x_i-y_{\sigma(i)}), \tag{12.170}$$

where the sign of each term is the parity of the permutation of field operators required to bring every contracted ψ–$\bar\psi$ pair into adjacency in the order $\psi\,\bar\psi$.

The vanishing of ψ–ψ and $\bar\psi$–$\bar\psi$ contractions is the structural statement already seen in Theorem 12.43: $\widehat{Z}$ pairs $\bar\eta$ with η only, so two like-type derivatives can never both find partners. The signed sum Eq. (12.170) is the Grassmann counterpart of the unsigned sum over pairings Eq. (10.138) of the scalar theory: where the boson sums all pairings with weight $+1$ (a permanent), the fermion sums them with the signature of the pairing permutation (a determinant of propagators). This is the combinatorial input that the Feynman rules of Chapters 15 and 17 consume: every fermion line is an S_F, and the relative sign between diagrams that differ by an exchange of identical external fermions, or that contain a closed fermion loop, is the sign in Eq. (12.170). The worked example below establishes the rule in full at $n=2$, the case that all higher combinatorics are built from.

Worked Example 12.45 (The free four-point function and its relative minus sign)**.** We compute the simplest correlator that exhibits a fermionic sign, $\big\langle 0|\mathcal{T}\,\psi(x_1)\psi(x_2)\bar\psi(y_1)\bar\psi(y_2)|0\big\rangle$, directly from Eq. (12.157), and contrast it with its bosonic cousin Eq. (10.138). By the prescription Eq. (12.164) extended to four fields—the derivatives ordered as the operators, $\psi(x_i)\leftrightarrow\delta_L/\delta\bar\eta(x_i)$ and $\bar\psi(y_j)\leftrightarrow\delta_L/\delta\eta(y_j)$—we must evaluate

$$W \;=\; \frac{\delta_L}{\delta\bar\eta(x_1)}\frac{\delta_L}{\delta\bar\eta(x_2)}\frac{\delta_L}{\delta\eta(y_1)}\frac{\delta_L}{\delta\eta(y_2)}\,\widehat{Z}\,\Big|_0. \tag{12.171}$$

Step 1: the η-derivatives. Reusing Eq. (12.166), $\frac{\delta_L}{\delta\eta(y_2)}\widehat{Z}=\mathcal{A}(y_2)e^{E}$ with $\mathcal{A}(y)=\int d^4u\,\bar\eta(u)S_F(u-y)$. Applying the second η-derivative, and noting $\mathcal{A}(y_2)$ contains no η (only $\bar\eta$), the only surviving Leibniz term comes from e^{E}, with one sign from passing the odd $\mathcal{A}(y_2)$:

$$\frac{\delta_L}{\delta\eta(y_1)}\frac{\delta_L}{\delta\eta(y_2)}\widehat{Z} \;=\; -\,\mathcal{A}(y_2)\,\mathcal{A}(y_1)\,e^{E}. \tag{12.172}$$

Step 2: the first $\bar\eta$-derivative. Recall $\frac{\delta_L}{\delta\bar\eta(x)}\mathcal{A}(y)=S_F(x-y)$ from Eq. (12.168), a c-number, and write $\frac{\delta_L}{\delta\bar\eta(x)}e^{E}=\mathcal{B}(x)e^{E}$ with $\mathcal{B}(x)=-\int d^4v\,S_F(x-v)\eta(v)$ odd. Differentiating Eq. (12.172) and tracking the sign incurred when $\delta_L/\delta\bar\eta(x_2)$ passes the odd $\mathcal{A}(y_2)$,

$$\frac{\delta_L}{\delta\bar\eta(x_2)}\big[-\mathcal{A}(y_2)\mathcal{A}(y_1)e^{E}\big] = -\,S_F(x_2-y_2)\,\mathcal{A}(y_1)\,e^{E}+\,\mathcal{A}(y_2)\,S_F(x_2-y_1)\,e^{E}$$

$$- \mathcal{A}(y_2)\,\mathcal{A}(y_1)\,\mathcal{B}(x_2)\,e^{E}. \tag{12.173}$$

Step 3: the last $\bar\eta$-derivative, then set sources to zero. Apply $\frac{\delta_L}{\delta\bar\eta(x_1)}$ and evaluate at $\eta=\bar\eta=0$. Any term that still carries an undifferentiated $\mathcal{A}$ or $\mathcal{B}$ vanishes at zero sources, so only the contractions that remove the last surviving $\bar\eta$ contribute. From the first term of Eq. (12.173), $\frac{\delta_L}{\delta\bar\eta(x_1)}\mathcal{A}(y_1)=S_F(x_1-y_1)$; from the second, $\frac{\delta_L}{\delta\bar\eta(x_1)}\mathcal{A}(y_2)=S_F(x_1-y_2)$; the third term has two $\mathcal{A}$'s and one $\mathcal{B}$ and cannot be exhausted by a single derivative, so it dies. The result is

$$\boxed{\left\langle 0|\mathcal{T}\,\psi(x_1)\psi(x_2)\bar\psi(y_1)\bar\psi(y_2)|0\right\rangle \;=\; -\,S_F(x_1-y_1)S_F(x_2-y_2)\;+\;S_F(x_1-y_2)S_F(x_2-y_1)\,.} \tag{12.174}$$

Reading the result. There are exactly two terms, one for each way of pairing the two ψ's with the two $\bar\psi$'s—half as many as the three pairings of the bosonic four-point function Eq. (10.138), because here a ψ can contract only with a $\bar\psi$, never with another ψ. The two pairings carry *opposite* signs. This relative minus is the entire content of fermionic statistics at the level of free correlators: it is the determinant structure of Eq. (12.170) at $n=2$, the antisymmetrized combination $S_F(x_1-y_2)S_F(x_2-y_1)-S_F(x_1-y_1)S_F(x_2-y_2)$, in contrast to the symmetric (all-plus) sum of Eq. (10.138). The signs themselves were not put in by hand; they were forced, one at a time, by the anticommutation rule Eq. (12.163)—in Eq. (12.172), in the second term of Eq. (12.173). The overall sign of any single term depends on the chosen ordering of the operators in the correlator (here, all ψ's before all $\bar\psi$'s); what is physical, and convention-independent, is the relative sign between the two pairings, which is exactly the sign distinguishing the exchange diagram from the direct one in every fermionic scattering amplitude of Chapters 17 and 18. Figure 12.3 records the topological origin of the minus: the second pairing differs from the first by a crossing of the contraction lines, and each crossing is one transposition of adjacent fermion operators, hence one factor of -1.

We have now closed the loop opened at the start of the chapter. The Dirac field has the same path-integral description as the scalar: a generating functional Eq. (12.155) whose source kernel is the Feynman propagator Eq. (12.162), whose two anticommuting functional derivatives return the time-ordered two-point function Eq. (12.165) in exact agreement with the canonical S_F of Chapter 11, and whose higher correlators are the signed Wick sums Eq. (12.170). This is the complete kit of free fermionic Feynman rules in position and momentum space—the propagator S_F, the source insertions, and the contraction signs—ready to be combined with vertices in Chapters 15 and 17. The one object the differentiation never touched is the normalization $Z[0]=\det(i\partial\!\!\!/-m)$: it factored out of every correlator and waited. That determinant, sitting upstairs where the boson's sits downstairs, is the subject of Section 12.7, where it becomes the one-loop

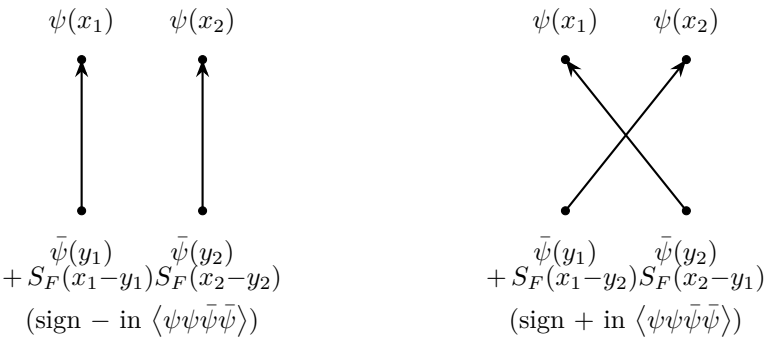

Figure 12.3: The two contraction patterns of the free fermionic four-point function Eq. (12.174). Each oriented line is a propagator S_F running from a $\bar\psi$ to a ψ, in the fermion-number direction of Fig. 11.4. A ψ may contract only with a $\bar\psi$, so there are two patterns rather than the three of the bosonic case Eq. (10.138). The exchange pattern (right) is obtained from the direct one (left) by a single crossing of the contraction lines, i.e. one transposition of adjacent anticommuting operators; that crossing is the geometric source of the relative minus sign between the two terms, and ultimately of every closed-fermion-loop sign in Section 12.7.

fermionic effective action through Tr ln, and where the inverted power first noted under Eq. (12.149) is revealed as the algebraic origin of the (-1) carried by every closed fermion loop.

12.7 Functional determinants and the fermion loop

The previous section (Section 12.6) performed the functional Gaussian integral over the Dirac field and delivered the normalization of the generating functional in a single compact symbol,

$$Z[0] \;=\; \det(i\not{\partial} - m), \tag{12.175}$$

the Berezin counterpart of the bosonic $(\det)^{-1/2}$ and the exact statement that integrating out a free fermion costs a determinant rather than its inverse square root. So far this is a closed formula and nothing more: a number (a badly divergent one) attached to the vacuum. The business of this closing section is to open it up. We will read (12.175) as a *physical* object—the one-loop fermionic effective action—by turning the determinant into a trace of a logarithm and expanding that logarithm into a sum of diagrams, each of which is a single closed fermion loop. Along the way we extract, from the bare algebra of (12.175), the most consequential bookkeeping rule in perturbative field theory: the factor of -1 that decorates every closed fermion loop. We derive that sign twice, from two independent starting points, and check that the two derivations agree. We

then promote the free operator $i\partial\!\!\!/ - m$ to its background-field form $iD\!\!\!/ - m$, identify $\det(iD\!\!\!/ - m)$ as the generator of the gauge field's one-loop effective action, and state honestly how an infinite-dimensional determinant is made finite. A worked computation on a single mode makes the sign tangible by producing equal-and-opposite vacuum energies for a boson and a fermion built on the same frequency.

Throughout, we reserve tr for the finite trace over the four Dirac indices and Tr for the full functional trace—Dirac indices *and* the continuous spacetime label—so that $\operatorname{Tr}\mathcal{O} = \int d^4x\, \operatorname{tr}\langle x|\mathcal{O}|x\rangle$ for an integral kernel $\mathcal{O}$. This matches the convention of Chapter E, to which the analytic control of these traces is deferred.

12.7.1 The determinant is the exponential of the trace-log

The bridge from a determinant to a sum of diagrams is the identity $\det = \exp\operatorname{Tr}\ln$. It is elementary for finite matrices and we prove it there in full; its extension to the Dirac operator is then a matter of saying precisely what the symbols mean, which we do at the end of the subsection.

Lemma 12.46 (First variation of the determinant)**.** *Let A be an invertible $n\times n$ complex matrix and B arbitrary. Then*

$$\det(A+\varepsilon B) = \det A\,(1+\varepsilon\,\operatorname{tr}(A^{-1}B))+O(\varepsilon^2), \qquad \textit{equivalently} \qquad \frac{d}{d\varepsilon}\Big|_{\varepsilon=0}\det(A+\varepsilon B) = \det A\,\operatorname{tr}(A^{-1}B). \tag{12.176}$$

Proof. Write $\det(\mathbf{1}+\varepsilon C)$ for $C = A^{-1}B$ and use the Leibniz expansion over permutations,

$$\det(\mathbf{1}+\varepsilon C) = \sum_{\sigma\in S_n}\operatorname{sgn}(\sigma)\prod_{i=1}^{n}\left(\delta_{i,\sigma(i)} + \varepsilon\, C_{i,\sigma(i)}\right). \tag{12.177}$$

The identity permutation contributes $\prod_i(1+\varepsilon C_{ii}) = 1+\varepsilon\sum_i C_{ii}+O(\varepsilon^2)$. Any non-identity σ moves at least two indices, so the product $\prod_i(\delta_{i,\sigma(i)}+\varepsilon C_{i,\sigma(i)})$ contains at least two factors with $\delta_{i,\sigma(i)}=0$, each of which must be supplied by an explicit ε; such a term is $O(\varepsilon^2)$. Hence $\det(\mathbf{1}+\varepsilon C) = 1+\varepsilon\,\operatorname{tr}C + O(\varepsilon^2)$. Multiplying by $\det A$ and using $\det(A+\varepsilon B) = \det A\,\det(\mathbf{1}+\varepsilon A^{-1}B)$ gives (12.176). □

Theorem 12.47 ($\det = \exp\operatorname{Tr}\ln$)**.** *For every $X\in \operatorname{Mat}_n(\mathbb{C})$,*

$$\det\left(e^{X}\right) = e^{\operatorname{tr}X}. \tag{12.178}$$

Consequently, for any invertible M that can be written $M = e^X$ (every $M\in \mathrm{GL}_n(\mathbb{C})$ can, and we call any such X a logarithm $\ln M$),

$$\det M = e^{\operatorname{tr}\ln M}. \tag{12.179}$$

Proof. Fix X and define $f(t) = \det(e^{tX})$ for real t. By Theorem 12.46 applied with $A = e^{tX}$ and $A + \varepsilon B = e^{(t+\varepsilon)X} = e^{tX} + \varepsilon X e^{tX} + O(\varepsilon^2)$, so that $B = Xe^{tX}$,

$$f'(t) = \det(e^{tX})\ \mathrm{tr}(e^{-tX}\, X\, e^{tX}) = f(t)\ \mathrm{tr}\, X, \tag{12.180}$$

where the last equality is the cyclicity of the finite trace, $\mathrm{tr}(e^{-tX}Xe^{tX}) = \mathrm{tr}(Xe^{tX}e^{-tX}) = \mathrm{tr}\, X$. This is a linear first-order equation with $f(0) = \det \mathbf{1} = 1$; its unique solution is $f(t) = e^{t\ \mathrm{tr}\, X}$. Setting $t = 1$ gives (12.178). For (12.179), write $M = e^X$ with $X = \ln M$; then $\det M = \det e^X = e^{\mathrm{tr}\, X} = e^{\mathrm{tr} \ln M}$. (The value $e^{\mathrm{tr}\, X}$ is independent of the branch chosen for $\ln M$: two logarithms of the same M differ by something whose exponential is $\mathbf{1}$, and on the diagonalizable dense set this shifts each $\ln \lambda_i$ by an integer multiple of $2\pi i$, leaving $e^{\mathrm{tr} \ln M} = \prod_i \lambda_i = \det M$ unchanged; the general case follows by continuity.) □

The cleanest way to remember (12.179) is through eigenvalues: if M is diagonalizable with eigenvalues $\lambda_1, \dots, \lambda_n$, then $\det M = \prod_i \lambda_i$ while $\mathrm{tr} \ln M = \sum_i \ln \lambda_i$, and $\exp \sum_i \ln \lambda_i = \prod_i \lambda_i$. Theorem 12.47 is the statement that this survives non-diagonalizability and the passage through the exponential map.

For the Dirac operator the eigenvalue product over the infinitely many modes of $i\partial\!\!\!/ - m$ diverges, and so does the sum $\sum \ln \lambda$; neither side of (12.179) exists in the naive sense. The resolution, carried out in Section E.3, is to *adopt* the trace-log as the definition of the regularized determinant: one continues the spectral zeta function $\zeta_K(s) = \sum_n \lambda_n^{-s}$ to $s = 0$ and sets $\ln \det K \equiv -\zeta_K'(0)$ (Theorem E.16), a prescription that reproduces $\sum_n \ln \lambda_n = \mathrm{Tr} \ln K$ wherever the latter converges and supplies a finite number where it does not. With that understanding the symbol $\mathrm{Tr} \ln(i\partial\!\!\!/ - m)$ is well defined and (12.179) reads

$$Z[0] = \det(i\partial\!\!\!/ - m) = \exp \mathrm{Tr} \ln(i\partial\!\!\!/ - m). \tag{12.181}$$

The exponent $\mathrm{Tr} \ln(i\partial\!\!\!/ - m)$ is, up to a field-independent constant, the free fermionic vacuum energy times the spacetime volume; on its own it is a pure number. Its physics emerges the moment a background is switched on, which is what we do next.

12.7.2 The loop expansion: Tr ln as a sum of closed fermion loops

Put the fermion in a background electromagnetic field A_μ. The Dirac operator becomes $iD\!\!\!/ - m$ with $D_\mu = \partial_\mu + ieA_\mu$ acting on the electron (charge $-e$, $e > 0$; Chapter 11 and the QED conventions), so that $iD\!\!\!/ = i\partial\!\!\!/ - eA\!\!\!/$ and

$$iD\!\!\!/ - m = (i\partial\!\!\!/ - m) - eA\!\!\!/. \tag{12.182}$$

The same Gaussian Berezin integral that produced (12.175)—now with the quadratic kernel $iD\!\!\!/ - m$ in place of $i\partial\!\!\!/ - m$, the action still being bilinear in

$\psi, \bar\psi$—gives $Z[A] = \det(i\not{D} - m)$ up to the same field-independent constant (Theorem E.3). The vacuum amplitude in the background, normalized to the no-background vacuum, is therefore

$$e^{iW[A]} \equiv \frac{Z[A]}{Z[0]} = \frac{\det(i\not{D} - m)}{\det(i\not{\partial} - m)}, \qquad iW[A] = \operatorname{Tr}\ln(i\not{D} - m) - \operatorname{Tr}\ln(i\not{\partial} - m), \tag{12.183}$$

using Theorem 12.47 in the regularized sense of (12.181). To expand the difference of trace-logs, factor the free operator out of (12.182),

$$i\not{D} - m = (i\not{\partial} - m)\Big[\mathbf{1} - (i\not{\partial} - m)^{-1} e\not{A}\Big]. \tag{12.184}$$

The inverse free operator is the Feynman propagator of Chapter 11: from $(i\not{\partial} - m)S_F(x-y) = i\,\delta^4(x-y)$ (Eq. (11.204)) one reads, as integral kernels,

$$(i\not{\partial} - m)^{-1} = -i\,S_F, \tag{12.185}$$

so $-(i\not{\partial} - m)^{-1} e\not{A} = +i\,e\,S_F\not{A}$. Taking $\operatorname{Tr}\ln$ of the product (12.184), the multiplicative free factor cancels against $\operatorname{Tr}\ln(i\not{\partial} - m)$ in (12.183), leaving

$$iW[A] = \operatorname{Tr}\ln\Big[\mathbf{1} + i\,e\,S_F\not{A}\Big]. \tag{12.186}$$

The operator $eS_F\not{A}$ is small in the sense that carries the expansion (one power of the background per factor), so the matrix logarithm may be expanded in its Mercator series $\ln(\mathbf{1}+Y) = \sum_{n\ge1} \frac{(-1)^{n+1}}{n} Y^n$, valid term by term inside the trace:

$$iW[A] = \sum_{n=1}^{\infty} \frac{(-1)^{n+1}}{n}\, \operatorname{Tr}\big[(i\,e\,S_F\not{A})^n\big]. \tag{12.187}$$

This is the loop series, and reading off what each term *is* is the whole point. Write the functional trace as nested position integrals. The n-th term contains n propagators and n insertions of the background, contracted head-to-tail and closed into a ring by the single trace:

$$\operatorname{Tr}\big[(ieS_F\not{A})^n\big] = (ie)^n \int d^4x_1 \cdots d^4x_n\ \operatorname{tr}\Big[S_F(x_1-x_2)\not{A}(x_2)\, S_F(x_2-x_3)\not{A}(x_3)\cdots S_F(x_n-x_1)\not{A}(x_1)\Big] \tag{12.188}$$

Diagrammatically this is exactly a single closed fermion line—a loop—onto which n external photon legs $A(x_k)$ are attached, the Dirac trace tr closing the spinor indices around the loop and the integrals $\int d^4x_k$ summing over the vertex positions. The factor $1/n$ in (12.187) is the order of the cyclic symmetry $\mathbb{Z}_n$ of the ring: the n cyclic relabelings of the vertices all give the same diagram, and the trace's cyclicity makes (12.188) invariant under them, so dividing by n avoids overcounting. We have thus proved the structural statement promised by the section:

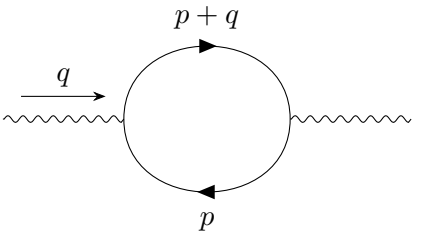

Figure 12.4: The closed fermion loop with two background (photon) insertions—the $n = 2$ term (12.189) of the trace-log expansion (12.187), i.e. the vacuum polarization. The arrows on the internal line show the fermion-number flow circulating consistently around the loop; the single Dirac trace tr closes the spinor indices. Every such closed fermion loop carries an overall factor of $\boxed{-1}$ relative to the corresponding bosonic loop, derived two ways in Theorem 12.49: from the determinant sitting in the numerator (Berezin) rather than the denominator (Gaussian), and equivalently from the antiperiodic trace around the loop.

Theorem 12.48 (The fermion trace-log is a sum of closed-loop vacuum diagrams)**.** *The fermionic vacuum functional* (12.183) *in a background* A_μ *is the sum* (12.187) *over closed single-fermion-loop diagrams, the* n*-th term* (12.188) *being the one-loop diagram with* n *background insertions, weighted by its cyclic symmetry factor* $1/n$*.*

The individual terms are the working vertices of one-loop QED. The $n = 1$ term is a tadpole and vanishes; the odd terms vanish quite generally by Furry's theorem (charge-conjugation invariance forces an odd number of photons attached to a fermion loop to give zero, a fact established with the discrete symmetries of Section 11.7.2). The first surviving term is $n = 2$,

$$\tfrac{(-1)^3}{2}\,\mathrm{Tr}\big[(ieS_F\not{A})^2\big] = \tfrac{e^2}{2}\int d^4x_1 d^4x_2\ \mathrm{tr}\big[S_F(x_1-x_2)\not{A}(x_2)S_F(x_2-x_1)\not{A}(x_1)\big], \tag{12.189}$$

the *vacuum polarization*: a single fermion loop with two photon legs, the object that screens the electric charge and whose explicit evaluation is the heart of one-loop QED in Chapter 19. The $n = 4$ term is the light-by-light box. Figure 12.4 draws the $n = 2$ loop and records, ahead of the next subsection, the factor of -1 it must carry.

12.7.3 The minus sign of a closed fermion loop, two ways

We come to the rule. In the Feynman rules assembled from this machinery, every closed fermion loop is multiplied by -1 (and more generally a diagram with L closed fermion loops by $(-1)^L$). The sign is not a convention bolted on by hand; it is forced, and we now derive it from two genuinely independent places—the

placement of the determinant in the generating functional, and the boundary condition on the fermion trace—and verify they say the same thing.

Theorem 12.49 (The closed-fermion-loop sign)**.** *Integrating out a fermion contributes its closed loops with overall sign opposite to that of a boson of the same charge: the fermionic vacuum functional is* $iW_{\mathrm{f}}[A] = +\operatorname{Tr}\ln(i\not{D} - m)$*, whereas a complex scalar of charge* e *contributes* $iW_{\mathrm{b}}[A] = -\operatorname{Tr}\ln(-D^2 - m^2)$*. Consequently each closed fermion loop carries a relative factor of* -1*, and a diagram with* L *closed fermion loops carries* $(-1)^L$*.*

First derivation: numerator versus denominator. The fermionic Berezin Gaussian places the determinant in the *numerator*,

$$\int \mathcal{D}\bar{\psi}\,\mathcal{D}\psi\; e^{\,i\int \bar{\psi}(i\not{D}-m)\psi} \;\propto\; \det(i\not{D} - m) \qquad \text{(Theorem E.3)}, \tag{12.190}$$

so that, taking the logarithm as in (12.183), the fermion delivers $iW_{\mathrm{f}}[A] = +\operatorname{Tr}\ln(i\not{D} - m)$ and hence the loop series (12.187) with the signs displayed there. Contrast a complex scalar field Φ of charge e, with quadratic action $\int \Phi^*(-D^2 - m^2)\Phi$. Its ordinary (commuting) Gaussian integral places the determinant in the *denominator*,

$$\int \mathcal{D}\Phi^*\,\mathcal{D}\Phi\; e^{\,i\int \Phi^*(-D^2-m^2)\Phi} \;\propto\; \big[\det(-D^2 - m^2)\big]^{-1} \qquad \text{(Theorem E.2)}, \tag{12.191}$$

so its vacuum functional is $iW_{\mathrm{b}}[A] = -\operatorname{Tr}\ln(-D^2 - m^2)$. Expanding this in the background by the identical steps that led to (12.187) produces the same family of closed single-particle loops—now built from scalar propagators and scalar vertices—but multiplied by the *opposite* overall sign, because the trace-log enters with a minus rather than a plus. The single algebraic fact responsible is the inversion of the Gaussian answer between Grassmann and ordinary variables: $\det^{+1}$ for the fermion (Theorem E.3) versus $\det^{-1}$ for the complex boson (Theorem E.2); a real scalar would give $\det^{-1/2}$, i.e. $iW = -\frac{1}{2}\operatorname{Tr}\ln$, the same sign with half the weight. The exponent of the determinant, not the source structure, is what flips: this is precisely the inversion flagged when the Berezin Gaussian was first computed, now cashed out as the loop sign.

Second derivation: the antiperiodic trace. The closed loop is also a trace in the literal Hilbert-space sense—a particle propagating once around the Euclidean time circle and returning to its starting state, summed over states. For a single mode the coherent-state construction of Section 12.5 expresses the trace of any operator $\hat{\mathcal{O}}$ over the fermionic Fock space as a Berezin integral over one Grassmann pair,

$$\operatorname{Tr}\,\hat{\mathcal{O}} = \int d\bar{\theta}\, d\theta\; e^{-\bar{\theta}\theta}\,\langle -\theta|\,\hat{\mathcal{O}}\,|\theta\rangle, \tag{12.192}$$

to be set against the bosonic coherent-state trace $\mathrm{Tr}\,\hat{\mathcal{O}} = \int \frac{d\bar{z}\,dz}{2\pi i}\, e^{-\bar{z}z}\,\langle z|\hat{\mathcal{O}}|z\rangle$. The two formulas are identical but for one decisive feature: the fermionic bra carries $\langle -\theta|$ where the bosonic one carries $\langle z|$. That single minus sign—an unavoidable consequence of having to anticommute the Grassmann label past the inserted state to close the trace—is what distinguishes a fermion trace from a boson trace. Threaded through the time-sliced path integral, $\langle -\theta|$ versus $\langle z|$ becomes the boundary condition that the path satisfies after one circuit:

$$\psi(\beta) = -\,\psi(0) \quad \text{(fermion, antiperiodic)}, \qquad \phi(\beta) = +\,\phi(0) \quad \text{(boson, periodic)}. \tag{12.193}$$

A closed loop is a worldline that comes back to where it began; the antiperiodicity (12.193) multiplies the fermionic closed loop by exactly -1 relative to the periodic bosonic one. This is the same -1, now seen as the cost of carrying a fermion once around the loop rather than as the cost of moving a determinant from the denominator to the numerator.

The two agree. Both derivations attach a single overall factor of -1 to one closed fermion loop, and both attach $(-1)^L$ to L independent loops: in the first because each separate determinant contributes its own sign flip, in the second because each independent loop is a separate trace and carries its own antiperiodicity. They are not merely consistent but the same statement read in two languages. The trace-log $\mathrm{Tr}\ln(i\not{D} - m)$ is literally a sum of single closed loops (Theorem 12.48); evaluating each loop as a Hilbert-space trace around antiperiodic Euclidean time reproduces precisely the sign that the numerator placement of $\det(i\not{D} - m)$ assigns it. The worked example of Theorem 12.50 below exhibits both faces at once on a single mode: the antiperiodic fermion determinant $1 + e^{-\beta\omega}$ against the periodic bosonic $1 - e^{-\beta\omega}$, the relative sign of the $e^{-\beta\omega}$ being exactly the loop's -1.

Why the Pauli principle wears the sign

The minus sign on a fermion loop is the same fact, viewed dynamically, as the antisymmetry of the multi-fermion wavefunction. A closed loop is a quantum process in which an identical particle is created and reabsorbed; for fermions the amplitude for such a closed exchange enters with the opposite sign demanded by the antisymmetrization that the Berezin measure automates. The vacuum-energy consequence is immediate and physical: a fermionic mode lowers the zero-point energy where a bosonic mode raises it, the seed of the boson–fermion cancellation that supersymmetry later makes exact.

12.7.4 The fermion determinant in a background: the one-loop effective action

Theorems 12.48 and 12.49 together identify $\det(i\not{D} - m)$ as a generator of physics, not a normalization to be discarded. Define the fermionic contribution to the effective action of the gauge field by integrating out the fermion in a fixed background,

$$\Gamma_{\mathrm{f}}[A] \;=\; -\,i\,\ln\det(i\not{D} - m) \;=\; -\,i\,\operatorname{Tr}\ln(i\not{D} - m), \tag{12.194}$$

the Legendre-transform/effective-action language of Section 4.5 specialized to a background that is not itself fluctuating. This is the one-loop effective action carried by the fermion loop; its Euclidean form is exactly the $\Gamma^{(1),\,\mathrm{ferm}} = -\operatorname{Tr}\ln D$ of Eq. (E.137), the sign there being the same loop sign derived here. Two downstream programs read directly off (12.194).

First, expanding $\Gamma_{\mathrm{f}}[A]$ to second order in A gives the vacuum polarization (12.189); differentiating twice with respect to A extracts the photon self-energy $\Pi^{\mu\nu}(q)$, the central one-loop object of QED. Chapter 19 takes (12.189) as its starting integrand, regularizes it dimensionally, and finds the running of α together with the Ward identity that keeps $\Pi^{\mu\nu}$ transverse. The closed-loop sign (12.49) is not optional there: it fixes the sign of charge screening.

Second, (12.194) is gauge invariant as it stands—$\operatorname{Tr}\ln(i\not{D} - m)$ depends on A only through the gauge-covariant D—and yet the chiral anomaly is real. The resolution, which (12.194) sets up but does not contain, is that the anomaly lives not in the action but in the *measure* $\mathcal{D}\bar{\psi}\,\mathcal{D}\psi$: under a chiral rotation the Berezin measure transforms by a nontrivial Jacobian whose regularized value is a heat-kernel coefficient (Eq. (E.197)). Chapter 36 (Fujikawa) computes that Jacobian and finds the Adler–Bell–Jackiw anomaly; the present determinant, and the fact that the fermion sign and the fermion measure are inseparable, is exactly the object it acts on.

12.7.5 Honest regularization, and the limits of the formal measure

We have manipulated $\det(i\not{D} - m)$ and $\operatorname{Tr}\ln(i\not{D} - m)$ as if they were finite. They are not: the Dirac operator has infinitely many eigenvalues growing without bound, so $\prod\lambda$ and $\sum\ln\lambda$ both diverge. Intellectual honesty requires saying exactly what tames them, and where the formal manipulations are made rigorous.

The key idea, developed in full in Section E.3, is spectral. One forms the zeta function $\zeta_K(s) = \sum_n \lambda_n^{-s}$ of the relevant operator K (for the Dirac case, $K = (i\not{D})^2$-type after the squaring of Eq. (E.138)), which converges for $\operatorname{Re} s$ large by Weyl's law, continues analytically to a neighborhood of $s = 0$ through its Mellin/heat-kernel representation, and *defines*

$$\ln\det K = -\,\zeta_K'(0), \qquad \det K = e^{-\zeta_K'(0)} \tag{12.195}$$

(Theorem E.16). This reproduces $\sum_n \ln \lambda_n$ whenever that sum is finite and assigns a finite, scheme-controlled number when it is not; the residual scale dependence is carried by the μ of $\overline{\text{MS}}$, exactly as in dimensional regularization. The heat-kernel route makes the ultraviolet structure manifest: the small-time expansion of $\operatorname{Tr} e^{-tK}$ has Seeley–DeWitt coefficients that are local, gauge-invariant densities, and it is these that feed both the renormalization of $\Gamma_{\text{f}}[A]$ and the anomaly. We do not reproduce that machinery here; it is the dedicated business of Chapter E, which this section imports rather than rebuilds.

The infinite-dimensional Berezin measure is formal

The symbol $\mathcal{D}\bar{\psi}\,\mathcal{D}\psi$ stands for a Berezin integral over uncountably many Grassmann modes, and unlike its finite-dimensional ancestor of Section 12.4 it has no construction as a genuine measure: there is no Grassmann analogue of Lebesgue measure on an infinite-dimensional space. What is rigorous is the *ratio* of determinants (12.183) after zeta- or heat-kernel regularization, and the perturbative series (12.187) it generates. A nonperturbative, fully rigorous definition of the fermionic functional integral exists only constructively—on a finite lattice, where the integral is a genuine finite-dimensional Berezin integral and $\det(i\not{D} - m)$ is an honest finite determinant, followed by a controlled continuum limit. That lattice determinant, and the notorious difficulty that it can fail to be real and positive (the sign problem), is the subject of Chapter 43. The formula (12.175) is therefore best read as a generating device for the convergent expansion (12.187), made nonperturbatively precise only on the lattice.

12.7.6 The sign made concrete: a single mode

The cleanest place to watch $\det^{+1}$ (fermion, numerator) and $\det^{-1/2}$ (boson, denominator) produce opposite-sign contributions to the *same* physical quantity is a single harmonic mode of frequency ω, thermalized on a Euclidean time circle of circumference β. We compute the fermionic determinant in full on a finite lattice, take the continuum limit, and read off a vacuum energy of the opposite sign to the boson's.

Worked Example 12.50 (Boson and fermion vacuum energies from $\det^{\mp}$)**.** Consider one bosonic oscillator and one fermionic oscillator, both of frequency ω, with symmetric (Weyl-ordered) Hamiltonians

$$\hat{H}_{\text{b}} = \omega(\hat{a}^\dagger \hat{a} + \tfrac{1}{2}), \qquad \hat{H}_{\text{f}} = \omega(\hat{b}^\dagger \hat{b} - \tfrac{1}{2}), \tag{12.196}$$

with $[\hat{a}, \hat{a}^\dagger] = 1$ and $\{\hat{b}, \hat{b}^\dagger\} = 1$. We compute the partition functions $Z = \operatorname{Tr} e^{-\beta \hat{H}}$ two ways—directly and as functional determinants—and extract the vacuum energy $E_0 = -\lim_{\beta\to\infty} \beta^{-1} \ln Z$.

Direct traces. The bosonic Fock space has states $|n\rangle$, $n \geq 0$, with energies $\omega(n + \frac{1}{2})$, so

$$Z_{\mathrm{b}} = \sum_{n=0}^{\infty} e^{-\beta\omega(n+1/2)} = \frac{e^{-\beta\omega/2}}{1 - e^{-\beta\omega}} = \frac{1}{2\sinh(\beta\omega/2)}, \tag{12.197}$$

giving $E_0^{\mathrm{b}} = +\omega/2$. The fermionic Fock space has only $|0\rangle, |1\rangle$ with energies $\mp\omega/2$, so

$$Z_{\mathrm{f}} = e^{+\beta\omega/2} + e^{-\beta\omega/2} = 2\cosh(\beta\omega/2), \tag{12.198}$$

giving $E_0^{\mathrm{f}} = -\omega/2$. The two zero-point energies are equal and opposite; the combined system $Z_{\mathrm{b}}Z_{\mathrm{f}}$ has $E_0 = 0$. We now see this sign emerge from the determinants.

The fermion as a Berezin determinant. The Euclidean action of the single Grassmann mode is $S_E^{\mathrm{f}} = \int_0^\beta d\tau\, \bar\psi(\partial_\tau + \omega)\psi$, with antiperiodic boundary conditions (12.193) forced by the trace formula (12.192). Discretize the circle into N steps of size $a = \beta/N$, writing $\psi_k = \psi(ka)$ and approximating $\partial_\tau\psi \to (\psi_k - \psi_{k-1})/a$. The action becomes, after multiplying through by a and writing $r \equiv 1 - a\omega$,

$$S_E^{\mathrm{f}} = \sum_{k=1}^{N} \bar\psi_k\big[\psi_k - r\,\psi_{k-1}\big], \qquad \psi_0 \equiv -\psi_N \quad \text{(antiperiodic)}, \tag{12.199}$$

so that $Z_{\mathrm{f}} = \int \prod_k d\bar\psi_k\, d\psi_k\, e^{-S_E^{\mathrm{f}}} = \det M_{\mathrm{AP}}$ by Theorem E.3, where M_{AP} is the $N \times N$ matrix with 1 on the diagonal, $-r$ on the subdiagonal, and the boundary entry $(M_{\mathrm{AP}})_{1,N} = +r$ produced by $\psi_0 = -\psi_N$. Expand the determinant along the first row. Two minors survive:

- deleting row 1, column 1 leaves an $(N-1)\times(N-1)$ lower-bidiagonal matrix with unit diagonal, determinant 1;
- deleting row 1, column N leaves rows $2,\dots,N$ and columns $1,\dots,N-1$, a lower-triangular matrix with $-r$ along its diagonal, determinant $(-r)^{N-1}$.

Hence

$$\det M_{\mathrm{AP}} = 1\cdot 1 + (-1)^{1+N}\,(+r)\,(-r)^{N-1} = 1 + (-1)^{1+N}(-1)^{N-1} r^N = 1 + r^N = 1 + (1-a\omega)^N. \tag{12.200}$$

Taking $N \to \infty$ with $a = \beta/N$ gives $(1 - \beta\omega/N)^N \to e^{-\beta\omega}$, so

$$Z_{\mathrm{f}} = \det M_{\mathrm{AP}} \;\longrightarrow\; 1 + e^{-\beta\omega}. \tag{12.201}$$

This is the partition function of $\hat H = \omega\,\hat b^\dagger \hat b$ (energies $0, \omega$); restoring the symmetric zero-point of (12.196) multiplies by $e^{\beta\omega/2}$ and recovers $e^{\beta\omega/2}(1 + e^{-\beta\omega}) = 2\cosh(\beta\omega/2)$, in exact agreement with (12.198).

The boson as the inverse square root. Repeating the construction for the real bosonic mode with second-order Euclidean action $S_E^{\mathrm{b}} = \frac{1}{2}\int_0^\beta d\tau\, \phi(-\partial_\tau^2 + \omega^2)\phi$ and *periodic* boundary conditions, the Gaussian integral gives $Z_{\mathrm{b}} = [\det{}_{\mathrm{P}}(-\partial_\tau^2 + \omega^2)]^{-1/2}$. The same circulant method—or, most transparently, the factorization $-\partial_\tau^2 + \omega^2 = (-\partial_\tau + \omega)(\partial_\tau + \omega)$ on the periodic circle, each first-order factor giving the periodic version of (12.200) with corner sign $-r$ and hence $\det{}_{\mathrm{P}} \to 1 - e^{-\beta\omega}$—yields

$$\det{}_{\mathrm{P}}(-\partial_\tau^2 + \omega^2) \;\longrightarrow\; e^{\beta\omega}\big(1 - e^{-\beta\omega}\big)^2 = \big(2\sinh(\beta\omega/2)\big)^2, \tag{12.202}$$

the factor $e^{\beta\omega}$ being the same zero-point/normal-ordering constant that the symmetric ordering fixes. Therefore $Z_{\mathrm{b}} = [\,(2\sinh(\beta\omega/2))^2\,]^{-1/2} = 1/(2\sinh(\beta\omega/2))$, reproducing (12.197).

The sign, isolated. Compare the two answers as trace-logs:

$$\ln Z_{\mathrm{f}} = +\,\mathrm{Tr}\ln(\partial_\tau + \omega)\big|_{\mathrm{AP}}, \qquad \ln Z_{\mathrm{b}} = -\tfrac{1}{2}\,\mathrm{Tr}\ln(-\partial_\tau^2 + \omega^2)\big|_{\mathrm{P}}. \tag{12.203}$$

Two independent features distinguish them, and each is one face of Theorem 12.49. The *exponent* of the determinant is $+1$ for the fermion (numerator, Berezin, Theorem E.3) and $-\frac{1}{2}$ for the boson (denominator, Gaussian); and the *boundary condition* is antiperiodic for the fermion and periodic for the boson, so the determinants differ in the sign of $e^{-\beta\omega}$: $1 + e^{-\beta\omega}$ versus $1 - e^{-\beta\omega}$. Both effects pull the same way. The fermionic $\det{}_{\mathrm{AP}}^{+1}$ delivers $E_0^{\mathrm{f}} = -\omega/2$; the bosonic $\det{}_{\mathrm{P}}^{-1/2}$ delivers $E_0^{\mathrm{b}} = +\omega/2$. The ratio $Z_{\mathrm{f}}/Z_{\mathrm{b}} = 2\cosh(\beta\omega/2)\cdot 2\sinh(\beta\omega/2) = 2\sinh(\beta\omega)$ has $E_0 = -\omega/2 - (+\omega/2) = -\omega$: integrating out one fermionic mode lowers the vacuum energy by exactly the amount that integrating out one bosonic mode raises it. This is the closed-fermion-loop -1, made arithmetic on a single mode.

The pattern of Theorem 12.50 is universal. A determinant in the numerator, traced around an antiperiodic loop, is a fermion; the same determinant inverted, traced around a periodic loop, is a boson; the difference is the sign on every closed fermion loop, and on the vacuum energy that sums them. With this the chapter's mission is complete: the Dirac field now has the same path-integral description the scalar enjoyed, built honestly on Grassmann variables and Berezin integration, with its generating functional, propagator, and determinant all in hand.

The determinant we have interpreted here is the hinge on which much of the rest of the book turns. Chapter 19 takes the closed fermion loop (12.189), with the sign (12.49) fixed, and computes the one-loop vacuum polarization and running coupling of QED; Chapter 26 re-encounters the determinant from the other side, re-exponentiating a *bosonic* determinant as a Grassmann (Faddeev–Popov ghost) integral precisely to flip its sign back, so that gauge-fixing leaves the right number of degrees of freedom—the same numerator/denominator inversion run in reverse; Chapter 36 acts on the fermion measure $\mathcal{D}\bar\psi\,\mathcal{D}\psi$ behind (12.194)

with a chiral rotation and finds the anomaly in its Jacobian; and Chapter 43 makes the formal Berezin integral of Section 12.7.5 rigorous as a finite lattice determinant, where the very positivity we assumed becomes the sign problem.

Further reading

The construction of integration over anticommuting variables is due to Berezin [63], still the cleanest source for the algebra and the inverse-determinant law. The fermionic coherent-state derivation of the path integral, the antiperiodic trace, and the boson/fermion vacuum-energy contrast are developed thoroughly in Negele and Orland [360]; Zinn-Justin [534] and Itzykson and Zuber [278] give complementary treatments of the Grassmann generating functional and the functional determinant. The trace-log interpretation of the fermion determinant and its closed-loop expansion, with care for the loop sign, are in Peskin and Schroeder [396], Schwartz [432], and Weinberg [500]. Zeta-function and heat-kernel regularization of functional determinants originate with Dowker and Critchley [161] and Hawking [257]; the lattice fermion determinant and the sign problem are surveyed in Gattringer and Lang [211]; the role of the fermion measure in the chiral anomaly is Fujikawa [203], carried out in Chapter 36.

Chapter 13

The Electromagnetic Field

The scalar and the spinor came to us almost willingly. Their Lagrangians were regular, their Legendre transforms invertible, and canonical quantization in Chapters 9 and 11 was a matter of promoting Poisson brackets to (anti)commutators and reading off a Fock space. The photon refuses this script. Already at the classical level—in Chapter 8, where electromagnetism was *derived* from local U(1) invariance—the field A_μ carried a redundancy: configurations related by $A_\mu \to A_\mu + \partial_\mu \alpha$ describe the same physics, because only the field strength $F_{\mu\nu}$ enters the action. That redundancy is not a blemish to be tidied away; it is the source of every difficulty and every subtlety in this chapter. It makes the Maxwell Lagrangian singular, it obstructs the naive canonical commutators, and it forces a choice—made differently by every consistent quantization scheme—about how to dispose of the unphysical degrees of freedom while keeping a positive-norm Hilbert space and, ideally, manifest Lorentz covariance. The whole chapter is the story of paying that price in full, by three complementary routes that are then shown to describe one and the same photon.

We open by diagnosing the obstruction precisely. Treating the Maxwell field as a constrained Hamiltonian system—the Dirac–Bergmann analysis whose classical groundwork was laid in Chapter 6—we find a primary constraint $\pi^0 \approx 0$ and, from its consistency under time evolution, the secondary Gauss constraint $\partial_i \pi^i \approx 0$. Both are first-class: they generate the gauge transformations of Chapter 8, and they reduce the naive four phase-space pairs to two physical polarizations. The same count that makes the photon a massless helicity-± 1 particle is what makes the four naive equal-time commutators mutually contradictory, so that some treatment of the constraints *before* quantization is mandatory. Two principled options present themselves, and they organize the rest of the chapter: solve the constraints classically and quantize only what survives, or keep everything covariant and impose the constraints weakly on states.

The first route is Coulomb gauge. Fixing $\nabla \cdot \mathbf{A} = 0$ eliminates A_0 and the longitudinal mode outright; the surviving transverse field is quantized with the

Dirac bracket, whose kernel is the transverse delta function, and the result is a manifestly positive-norm Fock space of two oscillators per momentum plus an instantaneous Coulomb energy of the sources. The price is manifest covariance. The second route, Gupta–Bleuler, quantizes all four components of A_μ covariantly on an indefinite-metric space and then carves out the physical sector by the subsidiary condition $\partial^\mu A_\mu^{(+)} |\text{phys}\rangle = 0$; its central theorem is that the physical subspace, modulo null states, is isometric to the Coulomb-gauge space built the section before. With a covariant operator in hand we assemble the photon propagator, follow its dependence on the gauge parameter ξ across the R_ξ family, and prove that the gauge-dependent $k_\mu k_\nu$ term never reaches an observable because it is annihilated by the conserved matter current of Chapter 11—the same fact that, for external lines, replaces the polarization sum by $-\eta_{\mu\nu}$.

The third route returns to first principles in the path-integral language of Chapters 10 and 12. The naive functional integral $\int \mathcal{D}A\, e^{iS}$ diverges, and the divergence is exactly the volume of the gauge orbit. The abelian Faddeev–Popov construction slices transverse to the orbits, produces the gauge-fixing term and the R_ξ propagator from a Gaussian average, and shows that the Faddeev–Popov determinant is field-independent—so QED, unlike its non-abelian cousin, carries no coupled ghost. We close by reuniting the routes: the minimal coupling $-e\bar{\psi}\gamma^\mu\psi A_\mu$ is installed, the instantaneous-Coulomb-plus-transverse description is shown to coincide with covariant one-photon exchange on conserved currents, and a static calculation recovers Coulomb's law $V(r) = e_1 e_2/4\pi r$ with the correct sign and the fine-structure constant out front—the photon propagator certified against a classical fact. What leaves this chapter is precisely what Part V runs on: the photon propagator, the vertex, and the polarization rule of QED, exported unchanged to Chapter 17.

13.1 Maxwell as a Constrained System: The Obstruction to Quantization

We have just declared that gauge invariance is a redundancy of description rather than a symmetry that relates physically distinct states, and that this single fact is what stands between us and a photon. It is time to make the obstruction precise. The instinct fresh from Chapter 9 is irresistible: we quantized the real scalar by computing its conjugate momentum $\pi = \partial\mathcal{L}/\partial\dot{\phi}$, postulating the equal-time commutator $[\phi(\mathbf{x}), \pi(\mathbf{y})] = i\,\delta^{(3)}(\mathbf{x}-\mathbf{y})$ (Eq. (9.7)), expanding in modes, and reading off a Fock space of particles. The electromagnetic potential A_μ has four components; surely we repeat the recipe four times and obtain a particle with four polarizations, to be trimmed later. The recipe breaks at the very first step. The Legendre transform that defines the momenta is *not invertible*: one of the four momenta is not a momentum at all but an identity, $\pi^0 \equiv 0$, holding before any equation of motion is imposed. A relation among the phase-space variables

that holds identically is a *constraint*, and a system that has them is *singular*. The scalar was regular and the recipe worked; Maxwell is singular and the recipe must be rebuilt.

This section carries out the rebuilding at the level Dirac taught us to: we compute the momenta and expose the primary constraint, write the canonical Hamiltonian, demand that the constraint be preserved in time and so generate a secondary one, classify both constraints as *first-class*, and show that in their smeared form they generate exactly the gauge transformation $\delta A_\mu = \partial_\mu \Lambda$. The first-class character is not a technicality; it is the canonical fingerprint of gauge redundancy, and it is what forces the degree-of-freedom count from four down to two. By the end we will have named the disease in full clinical detail. The two cures—fixing the gauge completely, or imposing the constraints weakly on states—occupy the rest of the chapter.

13.1.1 The frozen photon sector and its conventions

We continue QED. The classical theory was built in Chapter 8 from the gauge principle: the demand that the global U(1) phase symmetry of the electron be promoted to a local one forced into existence a connection A_μ, a covariant derivative, and the curvature

$$F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu \tag{13.1}$$

(Theorem 8.8), gauge invariant by construction. The connection's own dynamics is the Maxwell Lagrangian

$$\mathcal{L} = -\tfrac{1}{4} F_{\mu\nu} F^{\mu\nu}, \tag{13.2}$$

recalled from Eq. (8.75). Throughout this chapter we work with the free field, $J^\mu = 0$; the coupling to the electron current was assembled in Chapter 8 and is reinstated only when we write Feynman rules. We use the mostly-minus metric $\eta_{\mu\nu} = \mathrm{diag}(+,-,-,-)$ and natural units $\hbar = c = 1$, and we adopt the conventions of Chapter 8 for the electric and magnetic fields,

$$E^i = F^{i0}, \qquad B^i = -\tfrac{1}{2}\epsilon^{ijk} F_{jk}, \tag{13.3}$$

so that in three-vector form $\mathbf{E} = -\nabla A^0 - \partial_t \mathbf{A}$ and $\mathbf{B} = \nabla \times \mathbf{A}$, with $\mathbf{A} = (A^1, A^2, A^3)$ and A^0 the scalar potential. In terms of these the Lagrangian density is

$$\mathcal{L} = -\tfrac{1}{4} F_{\mu\nu} F^{\mu\nu} = \tfrac{1}{2}(\mathbf{E}^2 - \mathbf{B}^2), \tag{13.4}$$

the standard identity $F_{\mu\nu}F^{\mu\nu} = 2(\mathbf{B}^2 - \mathbf{E}^2)$ for mostly-minus signature. Finally, the gauge freedom we must reckon with is

$$A_\mu \;\longrightarrow\; A_\mu + \partial_\mu \Lambda, \tag{13.5}$$

for an arbitrary function $\Lambda(x)$, recalled from Eq. (8.113); it leaves Eq. (13.1) and hence Eq. (13.2) untouched. (We write the parameter Λ where Chapter 8 wrote α; the orbit is the same.) That Λ is an arbitrary *function*, not a single constant, is the whole story: by Noether's second theorem (Theorem 7.36) a local invariance produces not a conserved charge but an off-shell identity among the field equations, the signal that the description is redundant. We now watch that redundancy resurface inside the canonical formalism.

13.1.2 The singular Legendre transform and the primary constraint

The Hamiltonian formulation of a field theory (Section 6.4) takes the time derivatives $\dot{A}_\mu \equiv \partial_0 A_\mu$ as velocities and Legendre-transforms in them, treating the spatial gradients $\partial_i A_\mu$ as spectators. The momentum conjugate to A_μ is

$$\pi^\mu \equiv \frac{\partial \mathcal{L}}{\partial(\partial_0 A_\mu)}. \tag{13.6}$$

The derivative $\partial\mathcal{L}/\partial(\partial_\rho A_\sigma) = -F^{\rho\sigma}$ was computed once and for all in Eq. (6.190); setting $\rho = 0$,

$$\pi^\mu = -F^{0\mu}. \tag{13.7}$$

Read this component by component. For the spatial momenta,

$$\pi^i = -F^{0i} = F^{i0} = E^i, \tag{13.8}$$

using Eq. (13.3): the momentum conjugate to the vector potential is the electric field, exactly as one would hope. But for the time component the antisymmetry of F is fatal:

$$\boxed{\pi^0 = -F^{00} \equiv 0.} \tag{13.9}$$

This is not a value that π^0 happens to take on some solution. It is an identity in the phase-space variables, true for *every* field configuration, because $F^{00} = \partial^0 A^0 - \partial^0 A^0$ vanishes algebraically. The Lagrangian Eq. (13.2) simply contains no $\dot{A}_0$: the time derivative of the scalar potential never appears, so A_0 carries no momentum and no second-order evolution equation. Equation (13.9) is the *primary constraint* of the Maxwell field—"primary" because it follows from the definition of the momenta alone, before any dynamics.

Definition 13.1 (Constraint, primary and secondary)**.** A *constraint* is a relation $\phi(A, \pi) \approx 0$ among the canonical variables that holds on the physically accessible region of phase space. A constraint is *primary* if it follows from the definition of the momenta Eq. (13.6) alone, and *secondary* if it is produced only by demanding that a primary constraint be preserved under time evolution. Following Dirac, we write $\approx$ ("weakly equal to zero") to mean that a quantity vanishes *on* the constraint surface but may have nonzero Poisson brackets with the canonical variables; this is to be distinguished from a strong identity, set equal with $=$.

The distinction in Theorem 13.1 is the heart of the matter and is easy to mishandle. Although Eq. (13.9) reads $\pi^0 \equiv 0$ as an algebraic identity, we must *not* substitute $\pi^0 = 0$ into the Poisson brackets and forget about it. The variable π^0 remains a coordinate on the full phase space, canonically conjugate to A_0 with $\{A_0(\mathbf{x}), \pi^0(\mathbf{y})\}_{\mathrm{P}} = \delta^{(3)}(\mathbf{x}-\mathbf{y})$; the constraint $\pi^0 \approx 0$ merely tells us we are confined to the surface where it vanishes. Setting it strongly to zero too early would discard precisely the information—the bracket of the constraint with the Hamiltonian—that generates the secondary constraint below. This is why Dirac's weak-equality symbol exists.

The singular Hessian. The obstruction is invertibility of the Legendre map, and that is governed by the Hessian of $\mathcal{L}$ with respect to the velocities,

$$W^{\mu\nu} \equiv \frac{\partial^2 \mathcal{L}}{\partial(\partial_0 A_\mu)\partial(\partial_0 A_\nu)} = \frac{\partial \pi^\mu}{\partial(\partial_0 A_\nu)}. \tag{13.10}$$

If $W^{\mu\nu}$ is invertible, the relation $\pi^\mu(\dot{A})$ can be solved for $\dot{A}_\mu(\pi)$ and the Legendre transform is regular, as it was for the scalar. We compute it directly from Eq. (13.7). Writing $F^{0\mu} = \partial^0 A^\mu - \partial^\mu A^0$ and differentiating with respect to $\partial_0 A_\nu$,

$$\frac{\partial(\partial^0 A^\mu)}{\partial(\partial_0 A_\nu)} = \frac{\partial(\eta^{\mu\alpha}\partial_0 A_\alpha)}{\partial(\partial_0 A_\nu)} = \eta^{\mu\nu}, \tag{13.11}$$

$$\frac{\partial(\partial^\mu A^0)}{\partial(\partial_0 A_\nu)} = \frac{\partial(\eta^{\mu\alpha}\partial_\alpha A_0)}{\partial(\partial_0 A_\nu)} = \eta^{\mu 0}\,\delta^\nu{}_0, \tag{13.12}$$

where the second line is nonzero only when the derivative is the time derivative, $\alpha = 0$, acting on the component A_0, i.e. $\nu = 0$. Hence

$$W^{\mu\nu} = -\frac{\partial F^{0\mu}}{\partial(\partial_0 A_\nu)} = -\eta^{\mu\nu} + \eta^{\mu 0}\,\delta^\nu{}_0. \tag{13.13}$$

The matrix Eq. (13.13) is manifestly singular. Its entries in the time row are $W^{0\nu} = -\eta^{0\nu} + \eta^{00}\delta^\nu{}_0 = -\eta^{0\nu} + \delta^\nu{}_0 = 0$ for every ν: the entire $\mu = 0$ row vanishes. Therefore

$$\det W^{\mu\nu} = 0, \tag{13.14}$$

and the velocity $\dot{A}_0$ cannot be recovered from the momenta—consistent with the fact that it never entered $\mathcal{L}$ in the first place. In the spatial block the Hessian is perfectly healthy, $W^{ij} = -\eta^{ij} = \delta^{ij}$, so the three velocities $\dot{A}_i$ are invertibly related to $\pi^i = E^i$; only the time direction is degenerate. A singular Hessian is the precise mathematical content of "constrained system," and it is exactly what the scalar lacked: there $W = \partial^2\mathcal{L}/\partial\dot{\phi}^2 = 1 \neq 0$, the Legendre transform was a bijection, and the canonical recipe ran without incident.

Physical Insight

The failure is structural, not a defect of bookkeeping. The Lagrangian Eq. (13.2) is built from $F_{\mu\nu}$ alone, and $F_{0\nu}$ involves the velocity $\dot{A}_\nu$ only through the *antisymmetric* combination $\dot{A}_\nu - \partial_\nu A_0$. There is no way to form a velocity-quadratic term in $\dot{A}_0$ out of an object antisymmetric in its two indices: $F_{00} = 0$. Gauge invariance demands that the action depend only on F, and F structurally refuses to give A_0 a kinetic term. The non-dynamical status of A_0, the primary constraint, and the singular Hessian are three faces of the same fact—and that fact is gauge invariance.

13.1.3 The canonical Hamiltonian

To build the Hamiltonian we Legendre-transform in the velocities we *can* invert. From Eq. (13.8), $E^i = \dot{A}_i - \partial_i A_0$ (this is Eq. (13.3) written out, $F^{i0} = \partial^i A^0 - \partial^0 A^i = \dot{A}_i - \partial_i A_0$ after lowering), so the spatial velocity is

$$\dot{A}_i = \pi^i + \partial_i A_0. \tag{13.15}$$

The Hamiltonian density is $\mathcal{H} = \pi^\mu \dot{A}_\mu - \mathcal{L}$. The $\mu = 0$ term contributes nothing: $\pi^0 \dot{A}_0 \approx 0$ by the primary constraint, and in any case $\dot{A}_0$ is not expressible through momenta and must drop out of a well-defined Hamiltonian. Thus $\mathcal{H} = \pi^i \dot{A}_i - \mathcal{L}$. Substituting Eq. (13.15) and Eq. (13.4) with $E^i = \pi^i$,

$$\begin{aligned} \mathcal{H} &= \pi^i(\pi^i + \partial_i A_0) - \tfrac{1}{2}(\boldsymbol{\pi}^2 - \mathbf{B}^2) \\ &= \boldsymbol{\pi}^2 + \pi^i \partial_i A_0 - \tfrac{1}{2}\boldsymbol{\pi}^2 + \tfrac{1}{2}\mathbf{B}^2 \\ &= \tfrac{1}{2}(\boldsymbol{\pi}^2 + \mathbf{B}^2) + \pi^i\, \partial_i A_0. \end{aligned} \tag{13.16}$$

The first group $\frac{1}{2}(\boldsymbol{\pi}^2 + \mathbf{B}^2) = \frac{1}{2}(\mathbf{E}^2 + \mathbf{B}^2)$ is the familiar electromagnetic energy density, gauge invariant and positive. The second term carries A_0. Integrating the total Hamiltonian $H = \int \mathrm{d}^3x\, \mathcal{H}$ by parts in the second term, $\int \mathrm{d}^3x\, \pi^i \partial_i A_0 = -\int \mathrm{d}^3x\, A_0\, \partial_i \pi^i$ (the surface term vanishes for fields decaying at spatial infinity), we obtain the canonical Hamiltonian density up to a total spatial derivative,

$$\boxed{\mathcal{H} = \tfrac{1}{2}(\mathbf{E}^2 + \mathbf{B}^2) - A_0\, \partial_i \pi^i.} \tag{13.17}$$

This is the central object of the analysis. The scalar potential A_0 appears in Eq. (13.17) *linearly* and *undifferentiated in time*—not as a dynamical variable with its own energy, but as a Lagrange multiplier multiplying the quantity $\partial_i \pi^i = \nabla \cdot \mathbf{E}$. A field that enters the Hamiltonian as an undetermined multiplier is the hallmark of a constrained system: varying H with respect to it does not give an equation of motion but enforces a constraint. We turn to that next.

13.1.4 Consistency in time and the secondary Gauss constraint

Because A_0 is not determined by the momenta, its velocity $\dot{A}_0$ is arbitrary; equivalently, the primary constraint $\pi^0 \approx 0$ leaves a direction in phase space along which the dynamics is not fixed. Dirac's prescription handles this by adjoining the primary constraint to the Hamiltonian with an undetermined multiplier $u(x)$, forming the *total Hamiltonian*

$$H_T = \int \mathrm{d}^3x \left[\tfrac{1}{2}(\mathbf{E}^2 + \mathbf{B}^2) - A_0\, \partial_i \pi^i + u\, \pi^0 \right]. \tag{13.18}$$

The dynamics of any phase-space functional is $\dot{F} = \{F, H_T\}_{\mathrm{P}}$, with the fundamental equal-time brackets (Theorem 6.17)

$$\{A_\mu(\mathbf{x}), \pi^\nu(\mathbf{y})\}_{\mathrm{P}} = \delta_\mu{}^\nu\, \delta^{(3)}(\mathbf{x}-\mathbf{y}), \qquad \{A_\mu, A_\nu\}_{\mathrm{P}} = \{\pi^\mu, \pi^\nu\}_{\mathrm{P}} = 0, \tag{13.19}$$

all others vanishing. A constraint is only meaningful if it is preserved by the evolution: if $\pi^0 \approx 0$ at one instant but $\dot{\pi}^0 \not\approx 0$, the system would leave the constraint surface and the theory would be inconsistent. We therefore impose the *consistency condition* $\dot{\pi}^0 \approx 0$ and read off what it demands.

Compute $\dot{\pi}^0 = \{\pi^0(\mathbf{x}), H_T\}_{\mathrm{P}}$. The momentum π^0 has vanishing bracket with the kinetic piece $\frac{1}{2}(\mathbf{E}^2 + \mathbf{B}^2)$ (which depends only on π^i and A_i, all of which commute with π^0) and with the multiplier term $u\,\pi^0$ (a function of momenta only). The single surviving contribution is from $-A_0\,\partial_i\pi^i$, through the bracket of π^0 with A_0:

$$\dot{\pi}^0(\mathbf{x}) = \left\{ \pi^0(\mathbf{x}), -\int \mathrm{d}^3y\, A_0(\mathbf{y})\, \partial_i \pi^i(\mathbf{y}) \right\}_{\mathrm{P}} = -\int \mathrm{d}^3y\, \big(-\delta^{(3)}(\mathbf{x}-\mathbf{y})\big)\, \partial_i \pi^i(\mathbf{y}) = \partial_i \pi^i(\mathbf{x}), \tag{13.20}$$

where we used $\{\pi^0(\mathbf{x}), A_0(\mathbf{y})\}_{\mathrm{P}} = -\delta^{(3)}(\mathbf{x}-\mathbf{y})$ from Eq. (13.19). Demanding $\dot{\pi}^0 \approx 0$ therefore produces a brand-new constraint,

$$\boxed{\mathcal{G}(\mathbf{x}) \equiv \partial_i \pi^i = \nabla \cdot \mathbf{E} \approx 0.} \tag{13.21}$$

This is the *secondary* constraint, and we recognize it on sight: Eq. (13.21) is Gauss's law for the source-free field, $\nabla \cdot \mathbf{E} = 0$. In ordinary electrodynamics this is one of Maxwell's equations, derived as an equation of motion. Here it has reappeared as a *constraint*—a restriction on the initial data, not a statement about time evolution. That Gauss's law is a constraint rather than a dynamical law is the canonical expression of the fact that it contains no time derivatives of the dynamical fields: it is the $\mu = 0$ component of $\partial_\mu F^{\mu\nu} = 0$, which involves only $\partial_i F^{i0} = \partial_i E^i$.

Does the chain continue? We must now ask whether $\mathcal{G} \approx 0$ is itself preserved in time, lest it spawn a tertiary constraint. Compute $\dot{\mathcal{G}} = \{\mathcal{G}, H_T\}_{\mathrm{P}}$. The

constraint $\mathcal{G} = \partial_i \pi^i$ is built from spatial momenta alone; its bracket with the $\mathbf{B}^2$ term vanishes because $\mathbf{B}$ depends only on A_i and $\{\pi^i, A_j\}_{\mathrm{P}}$ produces only the magnetic field's own gradient structure, which integrates to give $\left\{\mathcal{G}, \int \frac{1}{2}\mathbf{B}^2\right\}_{\mathrm{P}} = 0$ identically. Concretely, $\mathbf{B} = \nabla \times \mathbf{A}$ is gauge invariant and $\mathcal{G} = \partial_i \pi^i$ generates spatial gauge transformations of $\mathbf{A}$ (as we prove in Section 13.1.5); a gauge-invariant functional has vanishing bracket with the generator of gauge transformations. The bracket of $\mathcal{G}$ with $\frac{1}{2}\boldsymbol{\pi}^2$ vanishes because both are functions of momenta only, and with $A_0\, \partial_j \pi^j$ and $u\, \pi^0$ because $\mathcal{G}$ has zero bracket with π^0 and with the momentum-only $\partial_j \pi^j$. Hence

$$\dot{\mathcal{G}} = \left\{\partial_i \pi^i, H_T\right\}_{\mathrm{P}} = 0, \tag{13.22}$$

identically—not merely weakly. The consistency algorithm terminates: Gauss's law is automatically preserved, no further constraints are generated, and the multiplier u is never fixed. That u remains undetermined is not a failure but the signature of the situation we are diagnosing: an arbitrary function in the solution of the equations of motion is the canonical face of an arbitrary function $\Lambda(x)$ in the gauge freedom Eq. (13.5). The system has exactly two constraints,

$$\phi_1 \equiv \pi^0 \approx 0, \qquad \phi_2 \equiv \partial_i \pi^i \approx 0, \tag{13.23}$$

and we now classify them.

13.1.5 First-class constraints and the gauge generator

Dirac's classification turns on the Poisson brackets the constraints make among themselves and with the Hamiltonian.

Definition 13.2 (First- and second-class constraints)**.** A set of constraints $\{\phi_a \approx 0\}$ is *first-class* if every pairwise Poisson bracket vanishes weakly, $\{\phi_a, \phi_b\}_{\mathrm{P}} \approx 0$, and each bracket with the Hamiltonian also vanishes weakly, $\{\phi_a, H\}_{\mathrm{P}} \approx 0$. A constraint that is not first-class is *second-class*. First-class constraints generate gauge transformations: motions along the constraint surface that connect physically identical configurations. Second-class constraints, by contrast, come in conjugate pairs with non-vanishing bracket and are eliminated by passing to Dirac brackets—this is the route the Dirac field took in Section 11.3, and the contrast is exactly the point.

Proposition 13.3 (The Maxwell constraints are first-class)**.** *The constraints $\phi_1 = \pi^0$ and $\phi_2 = \partial_i \pi^i$ of Eq. (13.23) satisfy*

$$\{\phi_1(\mathbf{x}), \phi_1(\mathbf{y})\}_P = \{\phi_1(\mathbf{x}), \phi_2(\mathbf{y})\}_P = \{\phi_2(\mathbf{x}), \phi_2(\mathbf{y})\}_P = 0 \tag{13.24}$$

identically, and each has weakly vanishing bracket with the canonical Hamiltonian. Both constraints are therefore first-class.

Proof. All three brackets in Eq. (13.24) vanish for the same elementary reason: every constraint in Eq. (13.23) is a function of the momenta π^μ alone, and momenta have vanishing Poisson brackets with one another, $\{\pi^\mu(\mathbf{x}), \pi^\nu(\mathbf{y})\}_{\mathrm{P}} = 0$ by Eq. (13.19). Explicitly,

$$\left\{\pi^0(\mathbf{x}), \partial_i^{(\mathbf{y})}\pi^i(\mathbf{y})\right\}_{\mathrm{P}} = \partial_i^{(\mathbf{y})}\left\{\pi^0(\mathbf{x}), \pi^i(\mathbf{y})\right\}_{\mathrm{P}} = 0, \tag{13.25}$$

and identically for the other two pairs; the spatial derivative passes through the bracket because it acts on a different argument. The constraints commute not just weakly but strongly. For the brackets with the Hamiltonian, $\{\phi_1, H\}_{\mathrm{P}} = \{\pi^0, H\}_{\mathrm{P}} = \partial_i\pi^i = \phi_2 \approx 0$ by Eq. (13.20), which is weakly zero, and $\{\phi_2, H\}_{\mathrm{P}} = \dot{\mathcal{G}} = 0$ by Eq. (13.22), which is strongly zero. Both conditions of Theorem 13.2 are met. □

The first-class property is the canonical diagnosis we came for. It guarantees, by Dirac's theorem, that the constraints generate transformations under which the physics is invariant—gauge transformations—and we now exhibit this generation explicitly. Form the *smeared generator*, the constraints integrated against an arbitrary spacetime function $\Lambda(x)$ in the combination that the structure of H_T dictates,

$$G[\Lambda] \equiv \int \mathrm{d}^3x \left[\,(\partial_0\Lambda)\,\pi^0 \;+\; (\partial_i\Lambda)\,\pi^i\,\right] = \int \mathrm{d}^3x \left[\,(\partial_0\Lambda)\,\pi^0 \;-\; \Lambda\,\partial_i\pi^i\,\right], \tag{13.26}$$

the second form following by parts. This is a sum of the primary constraint smeared against $\dot{\Lambda}$ and the secondary constraint smeared against Λ; the relative structure is exactly Castellani's recipe for assembling a gauge generator out of a first-class chain, and we will see it produces a clean result. Compute its bracket with the spatial potential, using Eq. (13.19):

$$\begin{aligned}\{A_j(\mathbf{x}), G[\Lambda]\}_{\mathrm{P}} &= \int \mathrm{d}^3y\,(\partial_i\Lambda)(\mathbf{y})\,\left\{A_j(\mathbf{x}), \pi^i(\mathbf{y})\right\}_{\mathrm{P}} \\ &= \int \mathrm{d}^3y\,(\partial_i\Lambda)(\mathbf{y})\,\delta_j{}^i\,\delta^{(3)}(\mathbf{x}-\mathbf{y}) = \partial_j\Lambda(\mathbf{x}).\end{aligned} \tag{13.27}$$

Only the π^i term contributes, since A_j has no bracket with π^0. For the time component, only the π^0 term survives,

$$\{A_0(\mathbf{x}), G[\Lambda]\}_{\mathrm{P}} = \int \mathrm{d}^3y\,(\partial_0\Lambda)(\mathbf{y})\,\left\{A_0(\mathbf{x}), \pi^0(\mathbf{y})\right\}_{\mathrm{P}} = \partial_0\Lambda(\mathbf{x}). \tag{13.28}$$

Assembling Eqs. (13.27) and (13.28) into a single four-vector statement,

$$\boxed{\delta A_\mu(\mathbf{x}) = \{A_\mu(\mathbf{x}), G[\Lambda]\}_{\mathrm{P}} = \partial_\mu\Lambda(\mathbf{x}).} \tag{13.29}$$

The smeared first-class constraints generate precisely the gauge transformation Eq. (13.5). This is the punch line of the canonical analysis: gauge invariance,

which entered in Chapter 8 as a redundancy of the Lagrangian, reappears in the Hamiltonian formulation as a pair of first-class constraints whose generator moves A_μ along its gauge orbit without changing any physical quantity. The arbitrariness of $\Lambda(x)$ is the same arbitrariness as the undetermined multiplier u in Eq. (13.18): motions generated by first-class constraints are physically null.

Physical Insight

The two structures we have met—"A_0 is a Lagrange multiplier" and "the constraints are first-class"—are the same statement read at two levels. A first-class primary constraint always appears in the total Hamiltonian multiplied by an arbitrary function (here u, equivalently A_0 once $\dot{A}_0$ is folded in); that arbitrary function parametrizes a gauge transformation; and the secondary constraint it forces is the generator of the residual gauge freedom on the dynamical fields. Counting first-class constraints *is* counting independent gauge parameters. For Maxwell there are two first-class constraints and one gauge function $\Lambda(x)$ together with its time derivative, exactly accounting for the single arbitrary function of the gauge group.

13.1.6 The degree-of-freedom count

We can now perform the count that the whole apparatus was built to deliver, and do it honestly in phase space, where the rule is sharp. The unconstrained phase space of the Maxwell field has, at each point of space, the four fields A_μ and their four conjugate momenta π^μ:

$$\text{phase-space dimension (per space point)} = 4 + 4 = 8. \tag{13.30}$$

Each *first-class* constraint removes *two* dimensions from the physical phase space, not one. The reasoning is Dirac's: a single first-class constraint $\phi_a \approx 0$ both restricts the dynamics to the surface $\phi_a = 0$ (one dimension lost) *and* generates a gauge orbit along which all points are physically identified (a second dimension lost, the direction conjugate to the constraint). We have two first-class constraints, $\pi^0 \approx 0$ and $\partial_i \pi^i \approx 0$, so

$$\text{physical phase-space dimension} = 8 - 2 \times 2 = 4. \tag{13.31}$$

A physical phase space of dimension four corresponds to two configuration-space degrees of freedom—two coordinates and their two conjugate momenta. Equivalently, counting in configuration space: of the four fields A_μ, the primary constraint removes the non-dynamical A_0, and the gauge freedom generated by the Gauss constraint removes one combination of the three A_i (the longitudinal

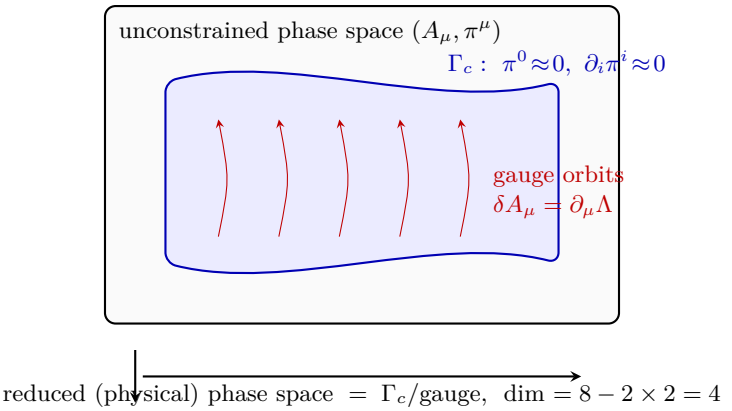

Figure 13.1: The first-class structure geometrically. The two constraints cut the 8-dimensional unconstrained phase space down to the constraint surface Γ_c (each constraint removes one dimension). Along Γ_c the first-class generator $G[\Lambda]$ sweeps out gauge orbits (red), each a one-parameter family of physically identical configurations related by $\delta A_\mu = \partial_\mu \Lambda$ (Eq. (13.29)); quotienting by these orbits removes a second dimension per constraint. The physical phase space is the quotient Γ_c/gauge, of dimension $8 - 2 \times 2 = 4$, i.e. two polarizations.

part), leaving

$$\boxed{4 \text{ components} - \underbrace{1}_{A_0 \text{ non-dynamical}} - \underbrace{1}_{\text{gauge}} = 2 \text{ physical polarizations.}} \tag{13.32}$$

The two countings agree: two physical field degrees of freedom, four physical phase-space dimensions. This is the resolution of the paradox we opened with. The four components of A_μ do *not* describe a particle with four polarizations; after the redundancy is excised, exactly two survive.

Tying the two to helicity. The number two is not an accident of the count; it is fixed by representation theory, and we can say which two. The photon is massless, and a massless particle is classified by the little group ISO(2) of a lightlike momentum, whose finite-dimensional unitary representations are labelled by a single helicity h (Chapter 3 built the little-group classification of one-particle states). For the field A_μ, which carries the vector representation of the Lorentz group, the two physical states are the helicity eigenstates $h = +1$ and $h = -1$—the right- and left-circular polarizations of light. The would-be helicity-0 longitudinal state is exactly the one the gauge freedom Eq. (13.29) removes, and the timelike component A_0 is the one the primary constraint forbids from propagating. Masslessness is essential here: a massive vector (ISO(2) $\to$ SO(3)) would carry all three helicities $0, \pm 1$, but gauge invariance forces $m = 0$ and amputates the middle one. The two surviving degrees of freedom

of the constrained Maxwell field *are* the two transverse photon polarizations of helicity ± 1, and Section 13.2 will exhibit them as honest oscillators.

13.1.7 Why naive canonical quantization is inconsistent

We have diagnosed the classical disease; the worked example below shows that it metastasizes the instant one tries to quantize without treating it. The naive prescription—copy Eq. (9.7) four times—postulates the equal-time commutators

$$[A_\mu(\mathbf{x}), \pi^\nu(\mathbf{y})] = i\,\delta_\mu{}^\nu\,\delta^{(3)}(\mathbf{x}-\mathbf{y}), \tag{13.33}$$

the operator translation of the brackets Eq. (13.19). This is mathematically inconsistent with the primary constraint, and the contradiction is immediate.

Worked Example 13.4 (The primary constraint kills the naive commutator)**.** Suppose we promote A_μ and π^ν to operators obeying Eq. (13.33), while also insisting—as we must, since it is an algebraic identity of the classical theory—that the primary constraint $\pi^0 \equiv 0$ hold as an operator equation. Take the $\mu = \nu = 0$ component of Eq. (13.33):

$$\Big[A_0(\mathbf{x}), \pi^0(\mathbf{y})\Big] = i\,\delta^{(3)}(\mathbf{x}-\mathbf{y}). \tag{13.34}$$

The right-hand side is a nonzero c-number. But if $\pi^0 = 0$ identically as an operator, then the left-hand side is the commutator of A_0 with the zero operator, which is zero:

$$\Big[A_0(\mathbf{x}), \pi^0(\mathbf{y})\Big] = [A_0(\mathbf{x}), 0] = 0. \tag{13.35}$$

Equations Eqs. (13.34) and (13.35) are flatly contradictory: $i\,\delta^{(3)}(\mathbf{x}-\mathbf{y}) \neq 0$. There is no representation of the algebra Eq. (13.33) in which π^0 is the zero operator. The naive quantization is not merely unphysical—it is impossible. The same lethal collision afflicts the secondary constraint: if $\partial_i \pi^i = 0$ as an operator, then commuting it with A_j and using Eq. (13.33) gives $[A_j(\mathbf{y}), \partial_i \pi^i(\mathbf{x})] = i\,\partial_j^{(\mathbf{x})}\delta^{(3)}(\mathbf{x}-\mathbf{y}) \neq 0$, again contradicting the vanishing of a commutator with the zero operator.

Theorem 13.4 is the obstruction in its sharpest form. One cannot simply write down four canonical commutators for A_μ; the constraints forbid it. Every honest quantization of the photon must therefore do something to the constraints *before* imposing commutation relations. There are exactly two principled options, and they organize the remainder of this chapter.

Caution

A tempting shortcut is to "solve $\pi^0 = 0$" by dropping A_0 and π^0 from the phase space at the outset, then quantizing the surviving A_i, π^i. This is on the right track but incomplete: it disposes of the primary constraint while leaving the secondary Gauss constraint $\partial_i \pi^i \approx 0$ unaccounted for, and Theorem 13.4 shows that $[A_j, \partial_i \pi^i] \neq 0$ would again be inconsistent with imposing $\partial_i \pi^i = 0$ as an operator on the full space. One must additionally remove the longitudinal degree of freedom that the Gauss constraint generates. Doing so completely—fixing the gauge so that only transverse modes remain—is the Coulomb-gauge program of Section 13.2; imposing the constraint instead as a condition on physical *states* is Gupta–Bleuler.

The first option honors the constraints by *solving them classically*: fix the gauge completely, eliminate A_0 and the longitudinal part of $\mathbf{A}$ once and for all, and quantize only the two transverse degrees of freedom that Eq. (13.32) isolated. This buys a manifestly positive-norm Hilbert space—every surviving mode is a genuine oscillator—at the price of manifest Lorentz covariance, since the gauge condition singles out a frame. That is the Coulomb-gauge construction of Section 13.2, where the two helicity-± 1 states promised above are built explicitly and the photon emerges as a massless spin-one particle. The second option keeps all four components and manifest covariance, paying with an enlarged, indefinite-metric space in which the first-class constraints are imposed not as operator identities but *weakly*, as conditions selecting a physical subspace—the Gupta–Bleuler method developed later in the chapter. Both roads begin from the diagnosis made here: the photon is a constrained system with two first-class constraints, two physical polarizations, and no consistent naive quantization.

13.2 Canonical Quantization in Coulomb Gauge

The constraint analysis of the preceding section diagnosed the disease precisely: the electromagnetic field is a singular (constrained) system. The Legendre transform is non-invertible because $\pi^0 \equiv \partial \mathcal{L}/\partial \dot{A}_0 = 0$ is a primary constraint, Gauss's law $\nabla \cdot \mathbf{E} \approx 0$ appears as a secondary constraint, and the two together are *first class* — they generate the gauge transformations $A_\mu \to A_\mu + \partial_\mu \alpha$ rather than relating physically distinct states. A first-class system cannot be quantized by blindly imposing $[A_\mu, \pi^\nu] = i\delta_\mu^\nu \delta^3$: the constraints would then fail to hold as operator equations, and the would-be Hilbert space would contain gauge copies of every physical state. There are exactly two honest cures. The first, pursued here, is to *use up* the gauge freedom completely by a gauge condition, solve the constraints explicitly so that only genuinely independent data remain, and quantize those. The reward is a manifestly positive-norm Fock space containing nothing but physical photons; the price, paid knowingly, is that one component

of the construction — the instantaneous Coulomb interaction — is not Lorentz covariant in form, even though the final physics is. This section carries out that program in full and ends by identifying the quantum it produces: a massless particle of helicity ± 1, the photon.

Throughout we work in natural units $\hbar = c = 1$ with the mostly-minus metric $\eta_{\mu\nu} = \mathrm{diag}(+,-,-,-)$, and we take the free Maxwell theory coupled to an external or matter conserved current $j^\mu = (\rho, \mathbf{j})$,

$$\mathcal{L} = -\tfrac{1}{4} F_{\mu\nu} F^{\mu\nu} - j^\mu A_\mu, \qquad F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu, \tag{13.36}$$

the free theory being the special case $j^\mu = 0$. We write the physical fields in terms of the upper-index spatial vector potential $\mathbf{A} = (A^i)$ as $\mathbf{E} = -\nabla A^0 - \dot{\mathbf{A}}$ and $\mathbf{B} = \nabla \times \mathbf{A}$, so that $\mathcal{L} = \tfrac{1}{2}(\mathbf{E}^2 - \mathbf{B}^2) - \rho A^0 + \mathbf{j}\cdot\mathbf{A}$. To avoid the index gymnastics of raising and lowering spatial labels, in the canonical analysis we treat all three-vector indices i, j, k as Cartesian (summed when repeated, no sign from the metric); A_i denotes the i-th Cartesian component of $\mathbf{A}$.

13.2.1 Completing the gauge fixing: the Coulomb condition

The classical groundwork is in hand from Chapter 8. There the *Coulomb gauge* (equivalently radiation or transverse gauge) was defined by

$$\nabla\cdot\mathbf{A} = 0, \tag{13.37}$$

shown to be reachable from any configuration (Eq. (8.128)), and shown to leave only a physically inert global constant as residual freedom. We recall the two structural facts we will quantize, recasting them in canonical language.

Coulomb gauge is attainable and essentially unique. Given an arbitrary potential $\mathbf{A}$, the gauge transformation $\mathbf{A} \to \mathbf{A}' = \mathbf{A} + \nabla\chi$ obeys $\nabla\cdot\mathbf{A}' = \nabla\cdot\mathbf{A} + \nabla^2\chi$, so choosing χ to solve the Poisson equation $\nabla^2\chi = -\nabla\cdot\mathbf{A}$ makes $\mathbf{A}'$ transverse. The residual freedom consists of further transformations with $\nabla^2\chi = 0$; for fields decaying at spatial infinity the only spatially harmonic functions are constants, whose gradient vanishes. Hence Eq. (13.37) fixes the gauge completely up to a global constant that acts trivially on $\mathbf{A}$. This is the crucial point that distinguishes Coulomb gauge from the covariant gauges of the next section: there is no residual local gauge freedom left to contaminate the quantization.

Gauss's law fixes A^0 with no dynamics of its own. The $\mu = 0$ Euler–Lagrange equation of Eq. (13.36) is Gauss's law $\nabla\cdot\mathbf{E} = \rho$. Writing $\mathbf{E} = -\nabla A^0 - \dot{\mathbf{A}}$,

$$\nabla\cdot\mathbf{E} = -\nabla^2 A^0 - \partial_0(\nabla\cdot\mathbf{A}) = -\nabla^2 A^0 = \rho, \tag{13.38}$$

where the gauge condition Eq. (13.37) annihilated the second term. Equation Eq. (13.38) contains no time derivative of A^0: it is a *constraint*, not an equation of motion. It is solved at each instant by the instantaneous Coulomb potential

$$A^0(t,\mathbf{x}) = \int d^3y \, \frac{\rho(t,\mathbf{y})}{4\pi\,|\mathbf{x}-\mathbf{y}|}, \tag{13.39}$$

the inverse of $-\nabla^2$ with the Green function $G(\mathbf{x}) = 1/(4\pi|\mathbf{x}|)$ satisfying $-\nabla^2 G = \delta^3$ (this is Eq. (8.130)). The timelike component A^0 is therefore not an independent dynamical variable at all: it is a fixed functional of the charge density at the same instant, with no canonical conjugate of its own ($\pi^0 = 0$). In the free theory $\rho = 0$ forces $A^0 = 0$ identically. We have thereby eliminated, explicitly and once and for all, two of the four components of A_μ: the non-dynamical A^0 via Eq. (13.39), and the longitudinal part of $\mathbf{A}$ via Eq. (13.37). What remains are the two transverse components of $\mathbf{A}$ — exactly the degree-of-freedom count the constraint analysis predicted, now realized field by field.

13.2.2 The canonical momentum and the obstruction to the naive bracket

The momentum conjugate to the surviving field $\mathbf{A}$ follows from Eq. (13.36). With A_i a Cartesian component and $\dot{A}_i = \partial_0 A_i$,

$$\pi_i \equiv \frac{\partial \mathcal{L}}{\partial \dot{A}_i} = \frac{\partial}{\partial \dot{A}_i}\Big[\tfrac{1}{2}E_k E_k - \tfrac{1}{2}B_k B_k\Big] = E_k \frac{\partial E_k}{\partial \dot{A}_i} = -E_i, \tag{13.40}$$

since $E_k = -\partial_k A^0 - \dot{A}_k$ gives $\partial E_k/\partial \dot{A}_i = -\delta_{ki}$, and $\mathbf{B}$ contains no time derivatives. Thus

$$\boldsymbol{\pi} = -\mathbf{E}, \tag{13.41}$$

the momentum conjugate to the vector potential is (minus) the electric field. In the free theory, where $A^0 = 0$, this reads $\boldsymbol{\pi} = \dot{\mathbf{A}}$, and Gauss's law $\nabla\cdot\mathbf{E} = 0$ becomes $\nabla\cdot\boldsymbol{\pi} = 0$: the conjugate momentum is transverse, exactly as the coordinate $\mathbf{A}$ is.

Here is the obstruction in its sharpest form. The naive canonical postulate $[A_i(\mathbf{x}), \pi_j(\mathbf{y})] = i\delta_{ij}\delta^3(\mathbf{x}-\mathbf{y})$ is *inconsistent* with the two facts we have just established. Apply ∂^x_i to both sides: the left side gives $[\nabla\cdot\mathbf{A}(\mathbf{x}), \pi_j(\mathbf{y})] = 0$ because $\nabla\cdot\mathbf{A} = 0$ is an operator identity in this gauge, yet the right side gives $i\,\partial_j\delta^3(\mathbf{x}-\mathbf{y}) \neq 0$. The same contradiction follows from applying ∂^y_j and using $\nabla\cdot\boldsymbol{\pi} = 0$. A field that is transverse cannot have a canonical bracket whose kernel $\delta_{ij}\delta^3$ has a longitudinal part. The cure is to replace the naive bracket by the unique transverse object compatible with both constraints — the transverse delta function.

13.2.3 The transverse delta function

Definition 13.5 (Transverse delta function)**.** The *transverse delta function* is the kernel

$$\delta^T_{ij}(\mathbf{x}) = \int \frac{d^3k}{(2\pi)^3}\,(\delta_{ij} - \hat{k}_i\hat{k}_j)\,e^{i\mathbf{k}\cdot\mathbf{x}}, \qquad \hat{k}_i = \frac{k_i}{|\mathbf{k}|}, \tag{13.42}$$

the Fourier transform of the transverse projector $P_{ij}(\mathbf{k}) = \delta_{ij} - \hat{k}_i\hat{k}_j$.

The matrix $P_{ij}(\mathbf{k})$ is the orthogonal projector onto the plane perpendicular to $\mathbf{k}$: it is symmetric, satisfies $P_{ij}\hat{k}_j = 0$, $P_{ik}P_{kj} = P_{ij}$, and $P_{ii} = 3 - 1 = 2$. Every property of δ^T_{ij} that we will use is a direct transcript of a property of P_{ij}, as the following worked example records.

Worked Example 13.6 (Properties of the transverse delta)**.** We establish the four facts about Eq. (13.42) that the quantization relies on.

(i) Transversality. Differentiating under the integral,

$$\partial_i\, \delta^T_{ij}(\mathbf{x}) = \int \frac{d^3k}{(2\pi)^3}\, (ik_i)(\delta_{ij} - \hat{k}_i\hat{k}_j)e^{i\mathbf{k}\cdot\mathbf{x}} = \int \frac{d^3k}{(2\pi)^3}\, i(k_j - |\mathbf{k}|\,\hat{k}_j)e^{i\mathbf{k}\cdot\mathbf{x}} = 0, \tag{13.43}$$

because $k_i\hat{k}_i = |\mathbf{k}|$ and $k_j = |\mathbf{k}|\hat{k}_j$. By symmetry $\partial_j\delta^T_{ij} = 0$ as well. The transverse delta is divergence-free on either index — precisely the property the naive $\delta_{ij}\delta^3$ lacked.

(ii) Action on a transverse field. Let $\mathbf{V}(\mathbf{x})$ be any transverse field, $\nabla\cdot\mathbf{V} = 0$, with Fourier transform $\tilde{\mathbf{V}}(\mathbf{k})$ obeying $\mathbf{k}\cdot\tilde{\mathbf{V}} = 0$. Then

$$\int d^3y\, \delta^T_{ij}(\mathbf{x}-\mathbf{y})\, V_j(\mathbf{y}) = \int \frac{d^3k}{(2\pi)^3}(\delta_{ij}-\hat{k}_i\hat{k}_j)\tilde{V}_j(\mathbf{k})e^{i\mathbf{k}\cdot\mathbf{x}} = \int \frac{d^3k}{(2\pi)^3}\tilde{V}_i(\mathbf{k})e^{i\mathbf{k}\cdot\mathbf{x}} = V_i(\mathbf{x}), \tag{13.44}$$

since $\hat{k}_j\tilde{V}_j = 0$. Thus δ^T_{ij} acts as the identity on the transverse subspace: it is the delta function *of* that subspace. On a longitudinal field $\mathbf{W} = \nabla\phi$ it gives zero by the same step.

(iii) Trace. Setting $j = i$ and summing, $\delta^T_{ii}(\mathbf{x}) = \int \frac{d^3k}{(2\pi)^3}(\delta_{ii} - \hat{k}_i\hat{k}_i)e^{i\mathbf{k}\cdot\mathbf{x}} = \int \frac{d^3k}{(2\pi)^3}(3-1)e^{i\mathbf{k}\cdot\mathbf{x}} = 2\,\delta^3(\mathbf{x})$, the trace of the projector being 2, one count per physical polarization.

(iv) Position-space form. Splitting off the full delta, $\delta^T_{ij}(\mathbf{x}) = \delta_{ij}\delta^3(\mathbf{x}) - \int \frac{d^3k}{(2\pi)^3}\frac{k_ik_j}{\mathbf{k}^2}e^{i\mathbf{k}\cdot\mathbf{x}} = \delta_{ij}\delta^3(\mathbf{x}) + \partial_i\partial_j\int \frac{d^3k}{(2\pi)^3}\frac{1}{\mathbf{k}^2}e^{i\mathbf{k}\cdot\mathbf{x}} = \delta_{ij}\delta^3(\mathbf{x}) + \partial_i\partial_j\frac{1}{4\pi|\mathbf{x}|}$, using $\int \frac{d^3k}{(2\pi)^3}\mathbf{k}^{-2}e^{i\mathbf{k}\cdot\mathbf{x}} = 1/(4\pi|\mathbf{x}|)$ from Eq. (13.39). The longitudinal piece is the double gradient of the Coulomb kernel — the first sign that the same object governs both the transverse photon bracket and the instantaneous Coulomb field.

13.2.4 The equal-time commutators

We can now state the canonical structure. The cleanest derivation treats the gauge condition and Gauss's law as a pair of second-class constraints and forms the Dirac bracket; we give that argument in Theorem 13.8 below. First the statement.

Theorem 13.7 (Transverse equal-time commutators)**.** *In Coulomb gauge the quantized vector potential and its conjugate momentum $\boldsymbol{\pi} = -\mathbf{E}$ obey, at equal times,*

$$[A_i(\mathbf{x}), \pi_j(\mathbf{y})] = i\,\delta^T_{ij}(\mathbf{x}-\mathbf{y}), \tag{13.45}$$

$$[A_i(\mathbf{x}), A_j(\mathbf{y})] = 0, \qquad [\pi_i(\mathbf{x}), \pi_j(\mathbf{y})] = 0. \tag{13.46}$$

These relations are consistent with the gauge condition and the constraints: applying ∂_i^x to Eq. (13.45) gives $[\nabla\cdot\mathbf{A}(\mathbf{x}), \pi_j(\mathbf{y})] = i\,\partial_i\delta_{ij}^T = 0$ by part (i) of Theorem 13.6, and applying ∂_j^y gives $[A_i(\mathbf{x}), \nabla\cdot\boldsymbol{\pi}(\mathbf{y})] = 0$ likewise.

The replacement $\delta_{ij}\delta^3 \to \delta_{ij}^T$ is the entire content of canonical quantization in this gauge: it is the minimal modification of the naive bracket that respects the constraints, and it is forced — not chosen — once one demands that $\mathbf{A}$ and $\boldsymbol{\pi}$ remain transverse as operators. The following worked example derives Eq. (13.45) from first principles via the Dirac bracket, so that no step is taken on faith.

Worked Example 13.8 (The transverse bracket from the Dirac construction)**.** After gauge fixing, the system carries two second-class constraints on each time slice,

$$\Phi_1(\mathbf{x}) = \nabla\cdot\mathbf{A}(\mathbf{x}), \qquad \Phi_2(\mathbf{x}) = \nabla\cdot\boldsymbol{\pi}(\mathbf{x}), \tag{13.47}$$

the gauge condition and (free) Gauss's law. They are second class because their mutual Poisson bracket does not vanish on the constraint surface. With the unmodified bracket $\{A_i(\mathbf{x}), \pi_j(\mathbf{y})\} = \delta_{ij}\delta^3(\mathbf{x}-\mathbf{y})$,

$$C(\mathbf{x},\mathbf{y}) \equiv \{\Phi_1(\mathbf{x}), \Phi_2(\mathbf{y})\} = \partial_i^x\partial_j^y\{A_i(\mathbf{x}), \pi_j(\mathbf{y})\} = \partial_i^x\partial_i^y\delta^3(\mathbf{x}-\mathbf{y}) = -\nabla_x^2\,\delta^3(\mathbf{x}-\mathbf{y}), \tag{13.48}$$

which is nonzero (and invertible): the 2×2 antisymmetric constraint matrix C_{ab} has $C_{12} = -C_{21} = -\nabla^2\delta^3$, $C_{11} = C_{22} = 0$. Its inverse kernel is the Coulomb Green function: $(C^{-1})_{21}(\mathbf{x},\mathbf{y}) = G(\mathbf{x}-\mathbf{y}) = 1/(4\pi|\mathbf{x}-\mathbf{y}|)$, because $-\nabla^2 G = \delta^3$, and $(C^{-1})_{12} = -G$. The Dirac bracket is

$$\{A,B\}_D = \{A,B\} - \sum_{a,b}\int d^3u\,d^3v\,\{A,\Phi_a(\mathbf{u})\}\,(C^{-1})_{ab}(\mathbf{u},\mathbf{v})\,\{\Phi_b(\mathbf{v}),B\}. \tag{13.49}$$

We evaluate it for $A = A_i(\mathbf{x})$, $B = \pi_j(\mathbf{y})$. The needed elementary brackets are

$$\{A_i(\mathbf{x}),\Phi_1(\mathbf{u})\} = 0, \quad \{A_i(\mathbf{x}),\Phi_2(\mathbf{u})\} = \partial_i^u\delta^3(\mathbf{x}-\mathbf{u}), \quad \{\Phi_1(\mathbf{v}),\pi_j(\mathbf{y})\} = \partial_j^v\delta^3(\mathbf{v}-\mathbf{y}), \quad \{\Phi_2(\tag{13.50}$$

the first and last vanishing because A commutes with A and π with π. Only the $(a,b) = (2,1)$ term of the double sum survives, and it carries $(C^{-1})_{21} = G$:

$$\{A_i(\mathbf{x}),\pi_j(\mathbf{y})\}_D = \delta_{ij}\delta^3(\mathbf{x}-\mathbf{y}) - \int d^3u\,d^3v\,[\partial_i^u\delta^3(\mathbf{x}-\mathbf{u})]G(\mathbf{u}-\mathbf{v})[\partial_j^v\delta^3(\mathbf{v}-\mathbf{y})]. \tag{13.51}$$

Integrating by parts in $\mathbf{u}$ and then $\mathbf{v}$ to move the derivatives onto G and collapse the delta functions, the double integral becomes $-\partial_i^x\partial_j^x G(\mathbf{x}-\mathbf{y})$, so

$$\{A_i(\mathbf{x}),\pi_j(\mathbf{y})\}_D = \delta_{ij}\delta^3(\mathbf{x}-\mathbf{y}) + \partial_i\partial_j\,G(\mathbf{x}-\mathbf{y}) = \delta_{ij}^T(\mathbf{x}-\mathbf{y}), \tag{13.52}$$

the last equality being part (iv) of Theorem 13.6. Quantization by the rule $[\,\cdot\,,\,\cdot\,] = i\{\,\cdot\,,\,\cdot\,\}_D$ then yields exactly Eq. (13.45). The Dirac bracket has automatically projected out the longitudinal directions in which the constraints live, leaving a consistent symplectic structure on the two-dimensional transverse phase space.

13.2.5 Mode expansion over two transverse polarizations

We now solve the free Heisenberg equation of motion and read off the particle content, following exactly the logic of the scalar field in Section 9.2, with the single new ingredient that each momentum mode carries a two-dimensional polarization label rather than none. In the free theory ($A^0 = 0$, $j^\mu = 0$) the surviving field obeys the massless wave equation $\Box\,\mathbf{A} = 0$ subject to $\nabla\cdot\mathbf{A} = 0$, so each Fourier mode is a transverse plane wave on the light cone $k^0 = \omega_k = |\mathbf{k}|$.

Definition 13.9 (Polarization vectors)**.** For each $\mathbf{k}$ choose two real unit vectors $\boldsymbol{\epsilon}_1(\mathbf{k}), \boldsymbol{\epsilon}_2(\mathbf{k})$ such that $\{\boldsymbol{\epsilon}_1, \boldsymbol{\epsilon}_2, \hat{\mathbf{k}}\}$ is a right-handed orthonormal triad:

$$\boldsymbol{\epsilon}_\lambda(\mathbf{k})\cdot\boldsymbol{\epsilon}_{\lambda'}(\mathbf{k}) = \delta_{\lambda\lambda'}, \qquad \mathbf{k}\cdot\boldsymbol{\epsilon}_\lambda(\mathbf{k}) = 0, \qquad \boldsymbol{\epsilon}_1 \times \boldsymbol{\epsilon}_2 = \hat{\mathbf{k}} \quad (\lambda, \lambda' = 1, 2). \tag{13.53}$$

The completeness of the triad gives the polarization sum that drives every later manipulation. Since $\{\boldsymbol{\epsilon}_1, \boldsymbol{\epsilon}_2, \hat{\mathbf{k}}\}$ is an orthonormal basis of $\mathbb{R}^3$, the resolution of the identity reads $\delta_{ij} = \epsilon_1^i\epsilon_1^j + \epsilon_2^i\epsilon_2^j + \hat{k}_i\hat{k}_j$, hence

$$\sum_{\lambda=1,2} \epsilon_\lambda^i(\mathbf{k})\,\epsilon_\lambda^j(\mathbf{k}) = \delta_{ij} - \hat{k}_i\hat{k}_j = P_{ij}(\mathbf{k}). \tag{13.54}$$

The polarization sum *is* the transverse projector: this is why the mode commutators will reproduce Eq. (13.45) on the nose.

The mode expansion mirrors Theorem 9.6, with the relativistic measure $\widetilde{dk} = d^3k/[(2\pi)^3\,2\omega_k]$ and one ladder pair per polarization:

$$\mathbf{A}(x) = \int \frac{d^3k}{(2\pi)^3\,2\omega_k} \sum_{\lambda=1,2} \boldsymbol{\epsilon}_\lambda(\mathbf{k})\Big(a_\lambda(\mathbf{k})\,e^{-ik\cdot x} + a_\lambda^\dagger(\mathbf{k})\,e^{+ik\cdot x}\Big)\Big|_{k^0=\omega_k}, \tag{13.55}$$

$$\boldsymbol{\pi}(x) = \dot{\mathbf{A}}(x) = \int \frac{d^3k}{(2\pi)^3\,2\omega_k} \sum_{\lambda=1,2} \boldsymbol{\epsilon}_\lambda(\mathbf{k})\,(-i\omega_k)\Big(a_\lambda(\mathbf{k})\,e^{-ik\cdot x} - a_\lambda^\dagger(\mathbf{k})\,e^{+ik\cdot x}\Big)\Big|_{k^0=\omega_k}, \tag{13.56}$$

with $k\cdot x = \omega_k x^0 - \mathbf{k}\cdot\mathbf{x}$. Each term is manifestly transverse because $\boldsymbol{\epsilon}_\lambda \perp \mathbf{k}$, so $\nabla\cdot\mathbf{A} = 0$ holds identically, and $\mathbf{A}^\dagger = \mathbf{A}$ because the second term is the adjoint of the first. The expansion solves $\Box\,\mathbf{A} = 0$ mode by mode since $\Box\,e^{\mp ik\cdot x} = -k^2 e^{\mp ik\cdot x} = 0$ on the light cone.

Theorem 13.10 (Mode commutators reproduce the ETCR)**.** *The expansions Eq. (13.55)–Eq. (13.56) satisfy the transverse commutators Eq. (13.45)–Eq. (13.46) if and only if the ladder operators obey*

$$\left[a_\lambda(\mathbf{k}), a^\dagger_{\lambda'}(\mathbf{k}')\right] = (2\pi)^3\, 2\omega_k\, \delta_{\lambda\lambda'}\, \delta^3(\mathbf{k}-\mathbf{k}'), \qquad [a_\lambda(\mathbf{k}), a_{\lambda'}(\mathbf{k}')] = 0, \quad (13.57)$$

the relativistically normalized oscillator algebra, one independent oscillator pair per momentum and per transverse polarization.

Proof. We verify the forward direction by computing the equal-time $[A_i(\mathbf{x}), \pi_j(\mathbf{y})]$ from Eq. (13.57). Inserting the expansions and keeping only the surviving $\left[a, a^\dagger\right]$ and $\left[a^\dagger, a\right]$ pairings,

$$[A_i(\mathbf{x}), \pi_j(\mathbf{y})] = \int \frac{d^3k}{(2\pi)^3 2\omega_k} \int \frac{d^3k'}{(2\pi)^3 2\omega_{k'}} \sum_{\lambda\lambda'} \epsilon^i_\lambda(\mathbf{k})\, \epsilon^j_{\lambda'}(\mathbf{k}')\, (-i\omega_{k'}) \\ \times \Big(- \left[a_\lambda(\mathbf{k}), a^\dagger_{\lambda'}(\mathbf{k}')\right] e^{-ik\cdot x + ik'\cdot y} + \left[a^\dagger_\lambda(\mathbf{k}), a_{\lambda'}(\mathbf{k}')\right] e^{+ik\cdot x - ik'\cdot y} \Big). \quad (13.58)$$

Both commutators carry $(2\pi)^3 2\omega_k\, \delta_{\lambda\lambda'}\delta^3(\mathbf{k}-\mathbf{k}')$, the second with a minus sign. Doing the $\mathbf{k}'$ integral collapses $\mathbf{k}' \to \mathbf{k}$, $\omega_{k'} \to \omega_k$, $\lambda' \to \lambda$, and cancels the measure factor $(2\pi)^3 2\omega_k$. At equal times $x^0 = y^0$ the time exponentials cancel, leaving $e^{\mp i\mathbf{k}\cdot(\mathbf{x}-\mathbf{y})}$ for the two terms:

$$[A_i(\mathbf{x}), \pi_j(\mathbf{y})] = \int \frac{d^3k}{(2\pi)^3\, 2\omega_k}\, (i\omega_k) \sum_\lambda \epsilon^i_\lambda(\mathbf{k}) \epsilon^j_\lambda(\mathbf{k}) \Big(e^{i\mathbf{k}\cdot(\mathbf{x}-\mathbf{y})} + e^{-i\mathbf{k}\cdot(\mathbf{x}-\mathbf{y})} \Big). \quad (13.59)$$

In the second exponential substitute $\mathbf{k} \to -\mathbf{k}$; the projector Eq. (13.54) is even in $\mathbf{k}$, $P_{ij}(-\mathbf{k}) = P_{ij}(\mathbf{k})$, so the two terms combine. The factor ω_k cancels one power in the measure, giving

$$[A_i(\mathbf{x}), \pi_j(\mathbf{y})] = i \int \frac{d^3k}{(2\pi)^3} (\delta_{ij} - \hat{k}_i \hat{k}_j) e^{i\mathbf{k}\cdot(\mathbf{x}-\mathbf{y})} = i\, \delta^T_{ij}(\mathbf{x}-\mathbf{y}), \quad (13.60)$$

which is Eq. (13.45). The $[A_i, A_j]$ and $[\pi_i, \pi_j]$ vanish because each receives equal and opposite contributions from the two exponentials after the $\mathbf{k} \to -\mathbf{k}$ symmetrization. Conversely, inverting Eq. (13.55) for $a_\lambda(\mathbf{k})$ exactly as in Theorem 9.9, with the extra contraction $\boldsymbol{\epsilon}_\lambda \cdot \boldsymbol{\epsilon}_{\lambda'} = \delta_{\lambda\lambda'}$ projecting out a single polarization, reproduces Eq. (13.57) from the ETCR; the algebra is identical to the scalar case mode by mode and we do not repeat it. □

The Fock space is built precisely as in Section 9.3: a unique vacuum $|0\rangle$ annihilated by every $a_\lambda(\mathbf{k})$, and one-photon states

$$|\mathbf{k}, \lambda\rangle = a^\dagger_\lambda(\mathbf{k})\, |0\rangle\,, \qquad \langle \mathbf{k}, \lambda | \mathbf{k}', \lambda' \rangle = (2\pi)^3\, 2\omega_k\, \delta_{\lambda\lambda'}\, \delta^3(\mathbf{k}-\mathbf{k}'). \quad (13.61)$$

Because the algebra Eq. (13.57) has the standard oscillator sign (positive norm $\||\mathbf{k},\lambda\rangle\|^2 > 0$), *every* state of this Fock space has non-negative norm. This is the headline reward of Coulomb gauge: there are no negative-norm or null states to excise, no subsidiary condition to impose; the Hilbert space is physical by construction. The cost — the absence of manifest Lorentz covariance — is hidden in the frame-dependent split into $\boldsymbol{\epsilon}_1$, $\boldsymbol{\epsilon}_2$, $\hat{\mathbf{k}}$ and in the instantaneous Coulomb term we turn to next.

13.2.6 The Hamiltonian: two transverse oscillators plus the Coulomb energy

The canonical Hamiltonian density is $\mathcal{H} = \pi_i \dot{A}_i - \mathcal{L}$. Using $\dot{A}_i = \pi_i - \partial_i A^0$ (from Eq. (13.41) and $\mathbf{E} = -\nabla A^0 - \dot{\mathbf{A}}$, i.e. $\dot{\mathbf{A}} = \boldsymbol{\pi} - \nabla A^0$ with $\boldsymbol{\pi} = -\mathbf{E}$),

$$\begin{aligned}\mathcal{H} &= \pi_i(\pi_i - \partial_i A^0) - \tfrac{1}{2}(\mathbf{E}^2 - \mathbf{B}^2) + \rho A^0 - \mathbf{j}\cdot\mathbf{A} \\ &= \boldsymbol{\pi}^2 - \boldsymbol{\pi}\cdot\nabla A^0 - \tfrac{1}{2}\boldsymbol{\pi}^2 + \tfrac{1}{2}\mathbf{B}^2 + \rho A^0 - \mathbf{j}\cdot\mathbf{A} = \tfrac{1}{2}(\mathbf{E}^2 + \mathbf{B}^2) + \mathbf{E}\cdot\nabla A^0 + \rho A^0 - \mathbf{j}\cdot\mathbf{A},\end{aligned} \tag{13.62}$$

where $\boldsymbol{\pi}^2 = \mathbf{E}^2$ and $-\boldsymbol{\pi}\cdot\nabla A^0 = \mathbf{E}\cdot\nabla A^0$. Integrating the term $\mathbf{E}\cdot\nabla A^0$ by parts over all space and using Gauss's law $\nabla\cdot\mathbf{E} = \rho$,

$$\int d^3x\, \mathbf{E}\cdot\nabla A^0 = -\int d^3x\, A^0\, \nabla\cdot\mathbf{E} = -\int d^3x\, A^0 \rho, \tag{13.63}$$

which exactly cancels the ρA^0 piece of Eq. (13.62). The Hamiltonian collapses to

$$H = \int d^3x \left[\tfrac{1}{2}(\mathbf{E}^2 + \mathbf{B}^2) - \mathbf{j}\cdot\mathbf{A}\right]. \tag{13.64}$$

This is not yet in oscillator form because $\mathbf{E}$ still contains the longitudinal piece $-\nabla A^0$. We split it cleanly. Write $\mathbf{E} = \mathbf{E}_T + \mathbf{E}_L$ with $\mathbf{E}_T = -\dot{\mathbf{A}} = -\boldsymbol{\pi}$ transverse and $\mathbf{E}_L = -\nabla A^0$ longitudinal. Their cross term integrates to zero, $\int \mathbf{E}_T\cdot\mathbf{E}_L = -\int \mathbf{E}_T\cdot\nabla A^0 = \int A^0\, \nabla\cdot\mathbf{E}_T = 0$, because $\nabla\cdot\mathbf{E}_T = 0$. Hence $\int \mathbf{E}^2 = \int \mathbf{E}_T^2 + \int \mathbf{E}_L^2$, and the longitudinal part is the Coulomb self-energy: using Eq. (13.39) and $-\nabla^2 A^0 = \rho$,

$$\tfrac{1}{2}\int d^3x\, \mathbf{E}_L^2 = \tfrac{1}{2}\int d^3x\, (\nabla A^0)^2 = -\tfrac{1}{2}\int d^3x\, A^0 \nabla^2 A^0 = \tfrac{1}{2}\int d^3x\, A^0 \rho = \tfrac{1}{2}\int d^3x\, d^3y\, \frac{\rho(\mathbf{x})\rho(\mathbf{y})}{4\pi|\mathbf{x}-\mathbf{y}|}. \tag{13.65}$$

The Hamiltonian is therefore the sum of a radiation part built from the transverse field alone and an instantaneous Coulomb energy:

$$H = \underbrace{\tfrac{1}{2}\int d^3x\, (\boldsymbol{\pi}^2 + \mathbf{B}^2)}_{H_{\rm rad}} \; - \int d^3x\, \mathbf{j}\cdot\mathbf{A} \; + \underbrace{\tfrac{1}{2}\int d^3x\, d^3y\, \frac{\rho(\mathbf{x})\rho(\mathbf{y})}{4\pi|\mathbf{x}-\mathbf{y}|}}_{H_{\rm Coul}}. \tag{13.66}$$

Three features deserve emphasis. First, $H_{\rm Coul}$ is the familiar electrostatic interaction energy of the charge density with itself — it is *not* a dynamical photon degree of freedom but a non-local, instantaneous functional of the matter, the direct quantum-canonical descendant of Eq. (13.39). In the free theory it is absent. Second, the instantaneity is the explicit signature of broken manifest covariance: $H_{\rm Coul}$ couples charges at spatially separated points at the *same time*, a frame-dependent statement. (That the full theory is nonetheless Lorentz invariant — the apparent action-at-a-distance being exactly compensated by the retarded transverse exchange — is the deep fact the next section makes manifest.) Third, the radiation part $H_{\rm rad}$ is precisely two copies of the free scalar Hamiltonian, one per polarization.

Theorem 13.11 (Diagonal photon Hamiltonian)**.** *With* $\mathbf{B} = \nabla \times \mathbf{A}$ *and* $\boldsymbol{\pi} = \dot{\mathbf{A}}$ *in the free theory, the radiation Hamiltonian of Eq. (13.66) is, after normal ordering (Section 9.4),*

$$H_{\rm rad} = \int \frac{d^3k}{(2\pi)^3\, 2\omega_k}\, \omega_k \sum_{\lambda=1,2} a^\dagger_\lambda(\mathbf{k})\, a_\lambda(\mathbf{k}), \qquad \omega_k = |\mathbf{k}|. \tag{13.67}$$

Proof. Insert Eq. (13.55) into $H_{\rm rad} = \frac{1}{2}\int d^3x(\dot{\mathbf{A}}^2 + (\nabla\times\mathbf{A})^2)$. The electric piece $\frac{1}{2}\int \dot{\mathbf{A}}^2$ produces, through the $\int d^3x$ over a product of two mode integrals, the factor $(2\pi)^3\delta^3(\mathbf{k}\pm\mathbf{k}')$ pairing the momenta. For the magnetic piece, each plane-wave mode obeys $\nabla\times[\boldsymbol{\epsilon}_\lambda e^{\pm ik\cdot x}] = \pm i\,\mathbf{k}\times\boldsymbol{\epsilon}_\lambda\, e^{\pm ik\cdot x}$, and since $\boldsymbol{\epsilon}_\lambda \perp \mathbf{k}$ with $|\boldsymbol{\epsilon}_\lambda| = 1$,

$$(\mathbf{k}\times\boldsymbol{\epsilon}_\lambda(\mathbf{k}))\cdot(\mathbf{k}\times\boldsymbol{\epsilon}_{\lambda'}(\mathbf{k})) = \mathbf{k}^2\,\boldsymbol{\epsilon}_\lambda\cdot\boldsymbol{\epsilon}_{\lambda'} - (\mathbf{k}\cdot\boldsymbol{\epsilon}_\lambda)(\mathbf{k}\cdot\boldsymbol{\epsilon}_{\lambda'}) = \omega_k^2\,\delta_{\lambda\lambda'}. \tag{13.68}$$

Thus the magnetic energy density per mode equals ω_k^2 times the polarization overlap, identical in magnitude to the electric one ($\dot{\mathbf{A}}$ carried $(-i\omega_k)$, giving ω_k^2 as well). The two combine so that the $a_\lambda(\mathbf{k})a_{\lambda'}(-\mathbf{k})$ and $a^\dagger_\lambda(\mathbf{k})a^\dagger_{\lambda'}(-\mathbf{k})$ cross terms — which have opposite signs in the electric and magnetic parts because of the relative sign in Eq. (13.56) and the factor $i^2 = -1$ from the curl — cancel exactly, precisely as in the scalar computation of Section 9.2. What remains is the number-operator combination

$$H_{\rm rad} = \int \frac{d^3k}{(2\pi)^3 2\omega_k}\, \tfrac{1}{2}\,\omega_k \sum_\lambda (a^\dagger_\lambda(\mathbf{k})a_\lambda(\mathbf{k}) + a_\lambda(\mathbf{k})a^\dagger_\lambda(\mathbf{k})). \tag{13.69}$$

Normal ordering drops the c-number zero-point term $\frac{1}{2}\sum_\lambda \left[a_\lambda, a^\dagger_\lambda\right] = \frac{1}{2}\cdot 2\cdot (2\pi)^3 2\omega_k\,\delta^3(0)\,V$ — now *twice* the scalar vacuum energy, one half per transverse polarization, the same divergence handled and interpreted in Section 9.4 — leaving Eq. (13.67). □

The photon energy is $E = \omega_k = |\mathbf{k}|$, the dispersion of a *massless* particle: $E^2 - \mathbf{k}^2 = 0$, i.e. $k^2 = 0$. The one-photon state Eq. (13.61) is an eigenstate

of $H_{\rm rad}$ with eigenvalue ω_k and, by the same diagonalization applied to the momentum operator $\mathbf{P} = \int \widetilde{dk}\,\mathbf{k}\sum_\lambda a_\lambda^\dagger a_\lambda$, of $\mathbf{P}$ with eigenvalue $\mathbf{k}$. The photon is the massless quantum of the transverse electromagnetic field; the field carries two such quanta per momentum, exactly the count Wigner's classification demanded for a massless particle.

13.2.7 The photon as a massless helicity-±1 particle

We have built two transverse states per momentum. The representation theory of Chapter 3 predicted exactly this: a massless particle is classified not by spin but by *helicity*, the projection of angular momentum on the direction of motion, taking a single value h for a single irreducible representation, with parity-invariant theories carrying the pair $\pm h$. We now make the dictionary precise and confirm $h = \pm 1$ for the photon.

The linear polarizations $\boldsymbol{\epsilon}_1, \boldsymbol{\epsilon}_2$ are not helicity eigenstates: a rotation about $\hat{\mathbf{k}}$ rotates them into each other. The combinations diagonal under that rotation are the circular polarizations.

Definition 13.12 (Helicity polarization vectors)**.** The *circular* (helicity) polarization vectors are

$$\boldsymbol{\epsilon}_\pm(\mathbf{k}) = \mp\frac{1}{\sqrt{2}}\big(\boldsymbol{\epsilon}_1(\mathbf{k}) \pm i\,\boldsymbol{\epsilon}_2(\mathbf{k})\big), \tag{13.70}$$

with corresponding ladder operators $a_\pm(\mathbf{k}) = \mp\frac{1}{\sqrt{2}}(a_1(\mathbf{k}) \mp i\,a_2(\mathbf{k}))$ (the signs arranged so that $\mathbf{A}$ is unchanged by the change of basis). They satisfy $\boldsymbol{\epsilon}_\pm^* \cdot \boldsymbol{\epsilon}_\pm = 1$, $\boldsymbol{\epsilon}_\pm^* \cdot \boldsymbol{\epsilon}_\mp = 0$, and the same completeness relation Eq. (13.54) since the transformation is unitary on the polarization index.

Worked Example 13.13 (The circular polarizations carry helicity ±1)**.** Take $\mathbf{k} = k\hat{\mathbf{z}}$ and the standard transverse frame $\boldsymbol{\epsilon}_1 = \hat{\mathbf{x}}$, $\boldsymbol{\epsilon}_2 = \hat{\mathbf{y}}$. A rotation R_θ by angle θ about $\hat{\mathbf{z}}$ (which fixes $\mathbf{k}$, hence belongs to the little group of this momentum) acts as

$$\hat{\mathbf{x}} \mapsto \cos\theta\,\hat{\mathbf{x}} + \sin\theta\,\hat{\mathbf{y}}, \qquad \hat{\mathbf{y}} \mapsto -\sin\theta\,\hat{\mathbf{x}} + \cos\theta\,\hat{\mathbf{y}}. \tag{13.71}$$

Applying this to $\hat{\mathbf{x}} \pm i\hat{\mathbf{y}}$,

$$\hat{\mathbf{x}} \pm i\hat{\mathbf{y}} \mapsto (\cos\theta \mp i\sin\theta)\hat{\mathbf{x}} + (\sin\theta \pm i\cos\theta)\hat{\mathbf{y}} = e^{\mp i\theta}(\hat{\mathbf{x}} \pm i\hat{\mathbf{y}}), \tag{13.72}$$

so $\boldsymbol{\epsilon}_\pm \mapsto e^{\mp i\theta}\boldsymbol{\epsilon}_\pm$: the circular polarizations are eigenvectors of the rotation about the momentum, with eigenvalues $e^{\mp i\theta}$. A state of helicity h transforms under a rotation by θ about its momentum as $e^{-ih\theta}$; matching, the one-photon state created with $\boldsymbol{\epsilon}_+$ has $h = +1$ and the one with $\boldsymbol{\epsilon}_-$ has $h = -1$. The photon is therefore a massless particle of helicity ±1 — the two values realized by the two transverse states, never a third (longitudinal) value.

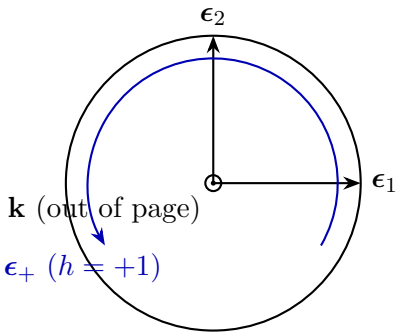

Figure 13.2: The two physical polarizations of a photon of momentum $\mathbf{k}$ live in the plane transverse to $\mathbf{k}$. The linear basis $\boldsymbol{\epsilon}_1, \boldsymbol{\epsilon}_2$ is rotated into itself by rotations about $\hat{\mathbf{k}}$; the circular combinations $\boldsymbol{\epsilon}_\pm = \mp(\boldsymbol{\epsilon}_1 \pm i\boldsymbol{\epsilon}_2)/\sqrt{2}$ are the eigenvectors of that rotation, carrying definite helicity $h = \pm 1$.

Connection to the little group. This identification is not an analogy; it is the realization, on the photon Fock space, of the ISO(2) little-group classification of massless particles built in Section 3.7.3. There the little group of a null momentum was found to be $\mathrm{ISO}(2) \cong E(2)$, with two non-compact "translation" generators A, B and one compact "rotation" generator J_3 about the momentum. The unitary irreducible representations of finite-dimensional type require $A = B = 0$, leaving the abelian J_3 whose eigenvalue is the helicity. The question that section deferred — why nature realizes $A = B = 0$ rather than the continuous-spin representations — is answered here, concretely, by gauge invariance. Acting with the non-compact generators on a polarization four-vector $\epsilon^\mu = (0, \boldsymbol{\epsilon}_\lambda)$ does not produce a new transverse polarization; it shifts ϵ^μ by a term proportional to the momentum,

$$\epsilon^\mu \;\longmapsto\; \epsilon^\mu + \beta(\mathbf{k})\, k^\mu, \tag{13.73}$$

which in position space is exactly a gauge transformation $A_\mu \to A_\mu + \partial_\mu \Lambda$ of the form Eq. (8.113) (a plane wave $\Lambda \propto e^{-ik\cdot x}$ gives $\partial_\mu \Lambda \propto k_\mu$). The would-be translation generators of the little group thus act on physical states as gauge transformations — and gauge-equivalent potentials are the *same* physical state. On the transverse, gauge-fixed Fock space they act trivially. This is why the photon carries no continuous internal label and no longitudinal state: the non-compact part of the little group is rendered invisible by the very gauge redundancy that forced us into this construction. What survives is the compact J_3, and its two eigenvalues $h = \pm 1$ are the two photons we built. Parity (Chapter 3) exchanges $\boldsymbol{\epsilon}_+ \leftrightarrow \boldsymbol{\epsilon}_-$, i.e. $h \to -h$, so a parity-invariant theory like electrodynamics necessarily contains both, in agreement with the two-state count.

Physical Insight

The deepest lesson of Coulomb-gauge quantization is that the "missing" degrees of freedom of the gauge field are not lost — they are reorganized. Of the four components of A_μ, one (A^0) is frozen into the instantaneous Coulomb field of the charges, one (the longitudinal part of $\mathbf{A}$) is pure gauge and eliminated, and the two transverse components are the dynamical photon. The non-compact directions of the massless little group, which for a generic field would threaten a continuum of polarizations, collapse onto gauge transformations and disappear from the physical spectrum. Masslessness and gauge redundancy are two faces of one fact: a massless helicity-1 particle *requires* a gauge description, because only gauge invariance can quotient the little group down to its compact, two-state core.

We have a complete, consistent, manifestly positive-norm quantum theory of the photon: two transverse oscillators per momentum, a Fock space of helicity-±1 massless quanta, and a Hamiltonian that splits into transverse radiation plus an instantaneous Coulomb energy of the sources. The price was visible at every turn — the frame-dependent transverse projection, the non-covariant δ^T_{ij}, the action-at-a-distance of H_{Coul}. That the resulting physics is nonetheless exactly Lorentz invariant is a theorem, not a manifest fact, and the awkwardness of proving covariance term by term is strong motivation to seek a scheme in which it is built in from the start. The next section pays the opposite price: it quantizes all four components of A_μ covariantly, on an indefinite-metric space, and then carves out this same transverse, positive-norm physics by the Gupta–Bleuler subsidiary condition — proving, as its central result, that the covariant construction is isometric to the Coulomb-gauge Fock space we have just built.

13.3 Covariant Quantization and the Gupta–Bleuler Construction

The Coulomb-gauge construction of the previous section delivered everything a quantum theory must have—a positive-definite Fock space, a vacuum, and two transverse photon modes of helicity ±1—but it paid for that success with the one thing a *relativistic* theory most wants to keep manifest: Lorentz covariance. The split into instantaneous Coulomb interaction plus radiation field, the elimination of A^0 and the longitudinal part of $\mathbf{A}$, the transverse delta function δ^{T}_{ij} in the commutator Eq. (13.45)—all of these single out a particular Lorentz frame. The physics is covariant (the S-matrix one eventually computes does not know which frame fixed the gauge), but the apparatus is not, and at every step of a calculation one must trust that frame-dependent intermediate objects will

conspire to give a covariant answer. For tree-level QED this is tolerable; for loops, where one integrates over all four components of internal momenta and wants to use covariant regulators, it is intolerable. We therefore start over with the opposite strategy: keep all four components of A_μ as independent quantum fields, quantize them covariantly, and pay the price elsewhere. The price, as we will see, is an indefinite-metric state space containing negative-norm "photons"; the discipline that makes the theory consistent is the Gupta–Bleuler subsidiary condition, which carves a genuine, non-negative-norm physical Hilbert space out of the enlarged space and—this is the headline result of the whole chapter—returns us *isometrically* to the two-polarization transverse space we already trust. This is the deepest argument in the chapter, and we give it in full.

13.3.1 The gauge-fixing term and the restored Legendre map

The obstruction to quantizing A_μ "the way we quantized ϕ" was diagnosed at the start of the chapter: the Maxwell Lagrangian $\mathcal{L}_{\rm Max} = -\frac{1}{4}F_{\mu\nu}F^{\mu\nu}$ has a singular Legendre map. Its momentum conjugate to A_μ is

$$\pi^\mu \;=\; \frac{\partial \mathcal{L}_{\rm Max}}{\partial(\partial_0 A_\mu)} \;=\; -F^{0\mu}, \tag{13.74}$$

so that $\pi^0 = -F^{00} \equiv 0$ identically: the time component of A_μ has no conjugate momentum, the velocity $\dot{A}^0$ cannot be solved for, and the canonical bracket $[A^0, \pi^0] = i\delta^{(3)}$ is inconsistent from the outset. This is not a technical nuisance to be patched; it is the imprint, at the level of phase space, of the gauge redundancy Eq. (8.113). A redundancy means there are fewer genuine degrees of freedom than fields, and a constrained (singular) Lagrangian is exactly how that surplus announces itself.

The covariant cure, due to Fermi, is to break the redundancy by adding a term that does not vanish on the gauge orbit. We replace $\mathcal{L}_{\rm Max}$ by the *gauge-fixed* (Fermi) Lagrangian

$$\mathcal{L} \;=\; -\tfrac{1}{4}F_{\mu\nu}F^{\mu\nu} \;-\; \frac{1}{2\xi}\,(\partial_\mu A^\mu)^2, \tag{13.75}$$

with a real parameter $\xi > 0$, the *gauge parameter*. The added term is not gauge invariant: under $A_\mu \to A_\mu + \partial_\mu\alpha$ it shifts by $-\frac{1}{\xi}(\partial\cdot A)\Box\alpha + \dots$, so distinct points on a gauge orbit now have distinct actions and the orbit degeneracy is lifted. We are, strictly, quantizing a *different* classical theory from Maxwell's; the entire art of what follows is to show that the physical content of Maxwell's theory is recovered exactly, on a subspace selected by a condition we impose by hand. The path integral will later reveal Eq. (13.75) as the natural output of the Faddeev–Popov procedure with a Gaussian average over gauges, but here we take it as a postulate and test it.

The Legendre map of Eq. (13.75) is invertible. Differentiating,

$$\pi^\mu \;=\; \frac{\partial \mathcal{L}}{\partial(\partial_0 A_\mu)} \;=\; -F^{0\mu} \;-\; \frac{1}{\xi}\,\eta^{0\mu}\,(\partial_\nu A^\nu), \tag{13.76}$$

so the dangerous time component is now

$$\pi^0 \;=\; -\frac{1}{\xi}\,(\partial_\nu A^\nu) \;=\; -\frac{1}{\xi}\,(\dot{A}^0 - \partial_i A^i) \;\neq\; 0, \tag{13.77}$$

and crucially it *depends on the velocity* $\dot{A}^0$. All four velocities $\dot{A}^\mu$ can be solved for in terms of the momenta, the map $(A_\mu, \dot{A}_\mu) \mapsto (A_\mu, \pi^\mu)$ is a genuine change of variables, and canonical quantization proceeds as for any nonsingular system. The Euler–Lagrange equations of Eq. (13.75) read

$$\partial_\mu F^{\mu\nu} + \frac{1}{\xi}\,\partial^\nu(\partial_\mu A^\mu) \;=\; \Box A^\nu - \Big(1 - \frac{1}{\xi}\Big)\partial^\nu(\partial_\mu A^\mu) \;=\; 0, \tag{13.78}$$

using $\partial_\mu F^{\mu\nu} = \Box A^\nu - \partial^\nu(\partial \cdot A)$. The full apparatus simplifies dramatically at the special value $\xi = 1$, the *Feynman gauge*, where the second term cancels and the four components decouple into four independent massless wave equations,

$$\boxed{\Box A^\mu \;=\; 0} \qquad (\xi = 1). \tag{13.79}$$

Feynman gauge is the computational default for the rest of the book (the convention recorded in Chapter A); we adopt it now and carry the general ξ only where the ξ-dependence is the point, principally in the next section. In Feynman gauge the Lagrangian Eq. (13.75) differs from $\mathcal{L} = -\frac{1}{2}\,\partial_\mu A_\nu\,\partial^\mu A^\nu$ by a total derivative, and the latter form—a quartet of decoupled scalars, one per Lorentz index, with a metric-dependent sign—makes the structure of the quantization transparent.

Caution

The wave equation Eq. (13.79) is *not* Maxwell's equation. Maxwell's equation $\partial_\mu F^{\mu\nu} = 0$ is recovered from Eq. (13.78) only if $\partial_\mu A^\mu = 0$; the gauge-fixed theory enforces $\Box(\partial \cdot A) = 0$ (take ∂_ν of Eq. (13.78)) but not $\partial \cdot A = 0$ itself. Restoring the Lorenz condition $\partial \cdot A = 0$—as an operator statement it would be too strong, as we will see—is precisely the job of the Gupta–Bleuler condition. Until that condition is imposed, Eq. (13.75) describes four propagating fields, not the two physical photon polarizations.

13.3.2 Covariant equal-time commutators

With the Legendre map repaired we impose the standard equal-time canonical commutation relations on all four components,

$$[A_\mu(\mathbf{x}, t), \pi^\nu(\mathbf{y}, t)] = i\,\delta_\mu{}^\nu\,\delta^{(3)}(\mathbf{x} - \mathbf{y}), \qquad [A_\mu, A_\nu] = [\pi^\mu, \pi^\nu] = 0 \;\; \text{(equal time)}. \tag{13.80}$$

In Feynman gauge the conjugate momentum from $\mathcal{L} = -\frac{1}{2}\partial_\mu A_\nu \partial^\mu A^\nu$ is $\pi^\mu = -\dot{A}^\mu$, so Eq. (13.80) becomes $\left[A_\mu(\mathbf{x},t), \dot{A}^\nu(\mathbf{y},t)\right] = -i\,\delta_\mu{}^\nu \delta^{(3)}(\mathbf{x}-\mathbf{y})$, i.e.

$$\left[A_\mu(\mathbf{x},t), \dot{A}_\nu(\mathbf{y},t)\right] \;=\; -\,i\,\eta_{\mu\nu}\,\delta^{(3)}(\mathbf{x}-\mathbf{y}). \tag{13.81}$$

The metric tensor $\eta_{\mu\nu}$ on the right is the seed of everything that follows. For the spatial components $\mu = \nu = i$ it carries the same sign as a scalar field (with $\eta_{ii} = -1$); but for the *time* component $\mu = \nu = 0$ it carries the *opposite* sign ($\eta_{00} = +1$), and that single relative sign will turn out to be the negative norm of the scalar photon. There is no freedom here: the sign is dictated by Lorentz covariance, which demands the indices on both sides match.

Because each component obeys the free wave equation Eq. (13.79) with the canonical data Eq. (13.81), the unequal-time commutator is fixed by exactly the argument that fixed the scalar commutator in Section 9.6: it is a c-number (the ladder operators cancel), it solves the wave equation in each argument, and it matches Eq. (13.81) at coincident times. The unique answer is the massless Pauli–Jordan function, one copy per index, weighted by the metric.

Definition 13.14 (Massless commutator function)**.** The *massless Pauli–Jordan function* is the $m \to 0$ limit of the commutator function Theorem 9.29,

$$D(x) \;=\; \Delta(x)\big|_{m=0} \;=\; -\,i\int \frac{d^3k}{(2\pi)^3}\,\frac{1}{2\omega_{\mathbf{k}}}\Big(e^{-ik\cdot x} - e^{+ik\cdot x}\Big), \qquad \omega_{\mathbf{k}} = |\mathbf{k}|,\; k^0 = \omega_{\mathbf{k}}. \tag{13.82}$$

It is real and odd, $D(-x) = -D(x)$, satisfies $\Box D = 0$, vanishes for spacelike x (microcausality, by the orbit argument of Theorem 9.31 run at $m = 0$), and has the equal-time data $D(0,\mathbf{x}) = 0$, $\dot{D}(0,\mathbf{x}) = -\delta^{(3)}(\mathbf{x})$.

Proposition 13.15 (Covariant photon commutator)**.** *In Feynman gauge the free electromagnetic field satisfies*

$$[A_\mu(x), A_\nu(y)] \;=\; -\,i\,\eta_{\mu\nu}\,D(x-y). \tag{13.83}$$

Proof. The right-hand side is a c-number, so it commutes with everything, as the left-hand side must (the field commutator of a free theory is a c-number by the same cancellation as in Section 9.6.1). It satisfies $\Box_x[\,\cdot\,] = -i\eta_{\mu\nu}\Box D(x-y) = 0$, matching Eq. (13.79) applied to $A_\mu(x)$. At equal times $x^0 = y^0$ it vanishes (because $D(0,\mathbf{r}) = 0$), reproducing $[A_\mu, A_\nu] = 0$; and its time derivative at equal times is $-i\eta_{\mu\nu}\,\partial_{x^0} D(x-y)\big|_{x^0=y^0} = -i\eta_{\mu\nu}\,\dot{D}(0,\mathbf{x}-\mathbf{y}) = +i\eta_{\mu\nu}\delta^{(3)}(\mathbf{x}-\mathbf{y})$, which is $-\left[A_\mu, \dot{A}_\nu\right]$ with the sign of Eq. (13.81) after using antisymmetry of the commutator under $x \leftrightarrow y$. A c-number solving the wave equation in each argument is determined by these Cauchy data, so Eq. (13.83) is the unique answer. □

Equation Eq. (13.83) is manifestly Lorentz covariant: both sides carry the index structure $\mu\nu$ and depend only on $x-y$. Microcausality is automatic and covariant—$D(x-y)=0$ for spacelike separation makes all four components, hence every local observable built from A_μ and $F_{\mu\nu}$, commute outside the light cone. This is exactly the manifest covariance the Coulomb gauge surrendered. The cost is hidden in the sign of η_{00}, and we now make it explicit.

13.3.3 Four polarizations and the indefinite metric

Expand each component in plane-wave modes. Because all four components are independent massless fields, the expansion carries four polarization labels:

$$A_\mu(x) \;=\; \int \widetilde{dk} \sum_{\lambda=0}^{3} \Big[\, \epsilon_\mu(k,\lambda)\, a(k,\lambda)\, e^{-ik\cdot x} \;+\; \epsilon_\mu(k,\lambda)\, a^\dagger(k,\lambda)\, e^{+ik\cdot x} \,\Big], \tag{13.84}$$

where $\widetilde{dk} \equiv \dfrac{d^3k}{(2\pi)^3\, 2\omega_{\mathbf{k}}}$ is the Lorentz-invariant measure of Section 9.2.1 and the four real four-vectors $\epsilon^\mu(k,\lambda)$ are the *polarization vectors*. Their job is to span the four-dimensional space of Lorentz indices for each k, and we choose them to be orthonormal with respect to the Minkowski metric. For a wave travelling along the z-axis, $k^\mu=\omega(1,0,0,1)$, the canonical choice is

$$\epsilon^\mu(k,0)=\begin{pmatrix}1\\0\\0\\0\end{pmatrix},\;\; \epsilon^\mu(k,1)=\begin{pmatrix}0\\1\\0\\0\end{pmatrix},\;\; \epsilon^\mu(k,2)=\begin{pmatrix}0\\0\\1\\0\end{pmatrix},\;\; \epsilon^\mu(k,3)=\begin{pmatrix}0\\0\\0\\1\end{pmatrix}. \tag{13.85}$$

We name them by their physical character: $\lambda=0$ is the *timelike* or *scalar* polarization; $\lambda=1,2$ are the two *transverse* polarizations, orthogonal to $\mathbf{k}$; and $\lambda=3$ is the *longitudinal* polarization, along $\mathbf{k}$ in the spatial sense. (For a general k direction one boosts/rotates Eq. (13.85); the inner products below are Lorentz scalars and hold for all k.) Their defining algebraic properties are orthonormality and completeness:

$$\epsilon(k,\lambda)\cdot\epsilon(k,\lambda') \;=\; \eta_{\lambda\lambda'} \;=\; \mathrm{diag}(+1,-1,-1,-1)_{\lambda\lambda'}, \tag{13.86}$$

$$\sum_{\lambda=0}^{3} \zeta_\lambda\, \epsilon^\mu(k,\lambda)\, \epsilon^\nu(k,\lambda) \;=\; \eta^{\mu\nu}, \qquad \zeta_\lambda \equiv \eta_{\lambda\lambda} = (+1,-1,-1,-1). \tag{13.87}$$

Both are immediate from Eq. (13.85): Eq. (13.86) is the statement that the $\epsilon(k,\lambda)$ are an orthonormal tetrad, and Eq. (13.87) is the resolution of the identity in that basis, with the signature factors ζ_λ inserted because the basis is orthonormal in an indefinite metric. The decisive entry is $\epsilon(k,0)\cdot\epsilon(k,0)=+1>0$ while $\epsilon(k,i)\cdot\epsilon(k,i)=-1<0$: the scalar polarization is "timelike" and is the troublemaker.

Substituting Eq. (13.84) into the covariant commutator Eq. (13.83) and using Eq. (13.87) (the calculation is the photonic version of the scalar inversion in Section 9.2.3, with the polarization sum doing the index bookkeeping) yields the ladder algebra

$$\boxed{\left[a(k,\lambda),a^\dagger(k',\lambda')\right] \;=\; -\,\eta_{\lambda\lambda'}\,(2\pi)^3\,2\omega_{\mathbf{k}}\,\delta^{(3)}(\mathbf{k}-\mathbf{k}')} \tag{13.88}$$

with all other commutators vanishing. Spelled out by polarization, the three spatial labels behave normally,

$$\left[a(k,i),a^\dagger(k',j)\right] = +\,\delta_{ij}\,(2\pi)^3 2\omega_{\mathbf{k}}\,\delta^{(3)}(\mathbf{k}-\mathbf{k}'),\qquad i,j\in\{1,2,3\}, \tag{13.89}$$

but the scalar label carries the wrong sign,

$$\left[a(k,0),a^\dagger(k',0)\right] = -\,(2\pi)^3 2\omega_{\mathbf{k}}\,\delta^{(3)}(\mathbf{k}-\mathbf{k}'). \tag{13.90}$$

The minus sign in Eq. (13.90) is the price of manifest covariance, traced back through Eq. (13.88) and Eq. (13.83) to the $\eta_{00}=+1$ in the canonical relation Eq. (13.81). We confront its consequence directly.

Proposition 13.16 (The scalar photon has negative norm)**.** *The one-particle scalar state has strictly negative norm. Concretely, for a normalizable wave packet f define $|f;0\rangle \equiv \int \widetilde{dk}\, f(\mathbf{k})\, a^\dagger(k,0)\,|0\rangle$. Then*

$$\langle f;0|f;0\rangle \;=\; -\int \widetilde{dk}\,|f(\mathbf{k})|^2 \;<\; 0. \tag{13.91}$$

Proof. Using $a(k,0)\,|0\rangle = 0$ and Eq. (13.90),

$$\begin{aligned}\langle f;0|f;0\rangle &= \int \widetilde{dk}\,\widetilde{dk'}\,\bar f(\mathbf{k}) f(\mathbf{k}')\,\Big\langle 0\Big|a(k,0)\,a^\dagger(k',0)\Big|0\Big\rangle = \int \widetilde{dk}\,\widetilde{dk'}\,\bar f(\mathbf{k}) f(\mathbf{k}')\,\Big\langle 0\Big|\Big[a(k,0),a^\dagger(k\\ &= -\int \widetilde{dk}\,\widetilde{dk'}\,\bar f(\mathbf{k}) f(\mathbf{k}')\,(2\pi)^3 2\omega_{\mathbf{k}}\,\delta^{(3)}(\mathbf{k}-\mathbf{k}') = -\int \widetilde{dk}\,|f(\mathbf{k})|^2. \qquad \square\end{aligned}$$

A state of negative norm is a catastrophe for the probability interpretation: $\langle\psi|\psi\rangle$ is supposed to be a probability, and probabilities are non-negative. The covariant Fock space built by acting with all four $a^\dagger(k,\lambda)$ on the vacuum is therefore not a Hilbert space at all but an *indefinite-metric* space (a Krein space): it has states of positive, negative, and—as we will find essential—zero norm. The free field is perfectly well defined on it; what is not well defined is the physical interpretation. The remainder of the section is the disciplined extraction of a true Hilbert space from this larger object.

Physical Insight

The indefinite metric is not a defect of the formalism to be apologized for; it is the unavoidable cost of writing a redundancy-laden object (A_μ, four components) covariantly while quantizing it as if it had four independent degrees of freedom. We over-counted, and Minkowski signature charges interest on the over-count in the currency of negative norm. The Gupta–Bleuler condition is the bill-payment: it removes exactly the surplus, leaving the two transverse degrees of freedom Coulomb gauge found directly. Seen this way, the negative-norm scalar photon and the longitudinal photon are bookkeeping ghosts—the abelian ancestors of the Faddeev–Popov ghosts of Chapter 26.

13.3.4 The Gupta–Bleuler subsidiary condition

The classical theory we want is Maxwell's, whose Lagrangian we modified; the difference is the gauge-fixing term, which is harmless precisely when $\partial_\mu A^\mu = 0$. The natural idea is to impose the Lorenz condition $\partial_\mu A^\mu = 0$ to select the physical states. As an *operator* identity it is fatal: $\partial_\mu A^\mu$ is a nontrivial free field (it satisfies $\Box(\partial \cdot A) = 0$ but is not zero), and setting it to zero as an operator contradicts the commutator Eq. (13.83), exactly as the constraint $\pi^0 = 0$ contradicted the canonical bracket in the ungauged theory. As a condition on *states*, $\partial_\mu A^\mu \,|\text{phys}\rangle = 0$, it is still too strong: split $\partial \cdot A$ into its positive- and negative-frequency parts,

$$\partial^\mu A_\mu \;=\; (\partial^\mu A_\mu)^{(+)} + (\partial^\mu A_\mu)^{(-)}, \qquad (\partial^\mu A_\mu)^{(-)} = \big[(\partial^\mu A_\mu)^{(+)}\big]^\dagger, \tag{13.92}$$

where the positive-frequency part collects the annihilation ($e^{-ik\cdot x}$) terms and the negative-frequency part the creation ($e^{+ik\cdot x}$) terms. The creation part $(\partial \cdot A)^{(-)}$ does not annihilate even the vacuum, so $\partial_\mu A^\mu \,|0\rangle \neq 0$ and the bare vacuum would fail to be physical—absurd.

Gupta and Bleuler saw that the right condition keeps only the annihilation half:

Definition 13.17 (Gupta–Bleuler subsidiary condition)**.** A state $|\text{phys}\rangle$ is *physical* if it is annihilated by the positive-frequency part of the four-divergence,

$$\boxed{(\partial^\mu A_\mu)^{(+)}(x)\;|\text{phys}\rangle \;=\; 0 \quad \text{for all } x.} \tag{13.93}$$

The set of all such states is denoted V_{phys}.

This is weaker than the operator condition—it constrains states, and only through the annihilation part—yet it is exactly strong enough. First, it is consistent: the vacuum satisfies it, since $(\partial \cdot A)^{(+)}$ is built from annihilation

operators and $(\partial\cdot A)^{(+)}\,|0\rangle = 0$. Second, it is Lorentz invariant, because $(\partial^\mu A_\mu)^{(+)}$ is a Lorentz scalar field. Third, and most importantly, it implies the Lorenz condition in the *weak* (matrix-element) sense rather than as an operator equation: for any two physical states $|\text{phys}\rangle$, $|\text{phys}'\rangle$,

$$\langle\text{phys}|\partial^\mu A_\mu|\text{phys}'\rangle = \underbrace{\Big\langle\text{phys}\Big|(\partial^\mu A_\mu)^{(+)}\Big|\text{phys}'\Big\rangle}_{=0 \text{ by } (13.93)} + \underbrace{\Big\langle\text{phys}\Big|(\partial^\mu A_\mu)^{(-)}\Big|\text{phys}'\Big\rangle}_{=0 \text{ by h.c. of } (13.93)} = 0, \tag{13.94}$$

where the second term vanishes because $(\partial\cdot A)^{(-)} = [(\partial\cdot A)^{(+)}]^\dagger$ acts to the left on $\langle\text{phys}|$ as the adjoint of Eq. (13.93). So $\partial_\mu A^\mu$ has vanishing expectation value between physical states; the Lorenz condition holds "on average," which is all the physics requires and all that is consistent. We return to the physical reading of Eq. (13.94) after proving the central theorem.

It is worth recasting Eq. (13.93) in terms of ladder operators, because the carving of the physical space then becomes an algebra problem. The positive-frequency part of $\partial^\mu A_\mu$ is

$$(\partial^\mu A_\mu)^{(+)}(x) = \int \widetilde{dk}\,(-ik^\mu)\sum_\lambda \epsilon_\mu(k,\lambda)\,a(k,\lambda)\,e^{-ik\cdot x}, \tag{13.95}$$

so the condition Eq. (13.93) holds for all x iff $\sum_\lambda (k\cdot\epsilon(k,\lambda))\,a(k,\lambda)\,|\text{phys}\rangle = 0$ for every k. With the explicit polarizations Eq. (13.85) for $k^\mu = \omega(1,0,0,1)$ we have $k\cdot\epsilon(k,0) = \omega$, $k\cdot\epsilon(k,1) = k\cdot\epsilon(k,2) = 0$, and $k\cdot\epsilon(k,3) = k^\mu\epsilon_\mu(k,3) = \omega\cdot 0 - \omega\cdot(+1) = -\omega$ (recall $\epsilon_\mu(k,3) = (0,0,0,-1)$ with the lowered index). Hence $\sum_\lambda (k\cdot\epsilon)\,a(k,\lambda) = \omega\,[a(k,0) - a(k,3)]$, and Eq. (13.93) is equivalent to

$$\boxed{L(k)\,|\text{phys}\rangle \;=\; 0 \quad \text{for all } k, \qquad L(k)\equiv a(k,0) - a(k,3).} \tag{13.96}$$

The physical condition is that every physical state be annihilated by the combination of scalar minus longitudinal annihilation operators. Only this one combination is constrained; the transverse operators $a(k,1), a(k,2)$ are unconstrained, and the orthogonal combination $a(k,0) + a(k,3)$ is unconstrained. This is the algebraic form we will exploit.

13.3.5 Physical states have non-negative norm

Everything now turns on the commutation algebra of the combination $L(k)$ and its conjugate. This is where the negative-norm scalar and the positive-norm longitudinal modes meet and cancel.

Lemma 13.18 (The null algebra)**.** *With $L(k) = a(k,0) - a(k,3)$,*

$$\Big[L(k), L^\dagger(k')\Big] \;=\; 0, \qquad [L(k), L(k')] = 0, \tag{13.97}$$

and $L(k)$ commutes with every transverse operator $a(k',1), a(k',2)$ and their conjugates.

Proof. By bilinearity and Eq. (13.88) (cross terms between $\lambda = 0$ and $\lambda = 3$ vanish, since $\eta_{03} = 0$),

$$\Big[L(k), L^\dagger(k')\Big] = \Big[a(k,0), a^\dagger(k',0)\Big] + \Big[a(k,3), a^\dagger(k',3)\Big] = (-1+1)(2\pi)^3 2\omega_{\mathbf{k}}\, \delta^{(3)}(\mathbf{k}-\mathbf{k}') = 0. \tag{13.98}$$

The crucial cancellation is the $(-1) + (+1) = 0$ in Eq. (13.98): the scalar contributes $\Big[a_0, a_0^\dagger\Big] = -(2\pi)^3 2\omega\delta$ from Eq. (13.90), the longitudinal contributes $\Big[a_3, a_3^\dagger\Big] = +(2\pi)^3 2\omega\delta$ from Eq. (13.89), and they are equal and opposite. The vanishing of $[L, L]$ and of the transverse commutators is immediate from Eq. (13.88). □

The lemma says $L(k)$ and $L^\dagger(k)$ generate a *null* (degenerate) subalgebra: $L^\dagger$ creates states of zero norm. Indeed, for any normalizable g, writing $L^\dagger(g) \equiv \int \widetilde{dk}\, \bar{g}(\mathbf{k}) L^\dagger(k)$,

$$\| L^\dagger(g)\ |0\rangle \|^2 = \Big\langle 0 \Big| L(g)\, L^\dagger(g) \Big| 0 \Big\rangle = \Big\langle 0 \Big| \Big[L(g), L^\dagger(g)\Big] \Big| 0 \Big\rangle = 0. \tag{13.99}$$

We can now prove the headline result. The strategy is to organize the scalar/longitudinal sector around the null pair, separating it cleanly from the transverse sector.

Theorem 13.19 (Non-negativity of physical norms)**.** *Every physical state* $|\Psi\rangle \in V_{\text{phys}}$ *has non-negative norm,* $\langle\Psi|\Psi\rangle \geq 0$.

Proof. The full Fock space factorizes as $\mathcal{F} = \mathcal{F}_{\text{T}} \otimes \mathcal{F}_{\text{sl}}$, where $\mathcal{F}_{\text{T}}$ is generated from the vacuum by the transverse creation operators $a^\dagger(k,1), a^\dagger(k,2)$ and $\mathcal{F}_{\text{sl}}$ by the scalar/longitudinal operators $a^\dagger(k,0), a^\dagger(k,3)$. The transverse sector has the positive-definite algebra Eq. (13.89); it is an honest Fock space, and it is exactly the two-polarization space of the Coulomb-gauge construction, Eq. (13.45). Since $L(k)$ commutes with all transverse operators (Lemma 13.18), the condition Eq. (13.96) acts only on the $\mathcal{F}_{\text{sl}}$ factor: writing a general state as $|\Psi\rangle = \sum_n |T_n\rangle \otimes |\chi_n\rangle$ with $|T_n\rangle \in \mathcal{F}_{\text{T}}$ orthonormal and $|\chi_n\rangle \in \mathcal{F}_{\text{sl}}$, the physical condition is $L(k)\,|\chi_n\rangle = 0$ for every n and k. By orthonormality of the $|T_n\rangle$,

$$\langle\Psi|\Psi\rangle = \sum_n \langle T_n|T_n\rangle\ \langle\chi_n|\chi_n\rangle = \sum_n \|\,T_n\|^2\ \langle\chi_n|\chi_n\rangle\,, \tag{13.100}$$

with $\|T_n\|^2 \geq 0$. It remains to prove that any $|\chi\rangle \in \mathcal{F}_{\text{sl}}$ obeying $L(k)\,|\chi\rangle = 0$ for all k has $\langle\chi|\chi\rangle \geq 0$.

Diagonalize the scalar/longitudinal sector by passing to the null basis. Define

$$b(k) \equiv \tfrac{1}{\sqrt{2}}\,[a(k,0) - a(k,3)] = \tfrac{1}{\sqrt{2}} L(k), \qquad c(k) \equiv \tfrac{1}{\sqrt{2}}\,[a(k,0) + a(k,3)]. \tag{13.101}$$

Their algebra follows from Eq. (13.88) (again $\eta_{03} = 0$):

$$\Big[b(k), b^\dagger(k')\Big] = 0, \quad \Big[c(k), c^\dagger(k')\Big] = 0, \quad \Big[b(k), c^\dagger(k')\Big] = -(2\pi)^3 2\omega_{\mathbf{k}}\, \delta^{(3)}(\mathbf{k} - \mathbf{k}'), \tag{13.102}$$

the first because $\left[b, b^\dagger\right] = \frac{1}{2}\left[L, L^\dagger\right] = 0$, the second because $\left[c, c^\dagger\right] = \frac{1}{2}(\left[a_0, a_0^\dagger\right] + \left[a_3, a_3^\dagger\right]) = \frac{1}{2}(-1+1)(\dots) = 0$, and the third by direct expansion. So b and c are conjugate *null* oscillators: each is self-null ($\left[b, b^\dagger\right] = \left[c, c^\dagger\right] = 0$), and they pair only with each other. The sector $\mathcal{F}_{\mathrm{sl}}$ is built by $b^\dagger$ and $c^\dagger$ acting on $|0\rangle$.

The physical condition $L(k)\,|\chi\rangle = 0$ is $b(k)\,|\chi\rangle = 0$. Because b commutes with $b^\dagger$ but has $\left[b(k), c^\dagger(k')\right] \neq 0$, the operator b acts as the annihilator conjugate to the creator $c^\dagger$: it sees $c^\dagger$ excitations and is blind to $b^\dagger$ excitations. Concretely, any monomial in $b^\dagger$'s and $c^\dagger$'s acting on $|0\rangle$ is mapped by $b(k)$ to a sum of terms each missing one $c^\dagger$; the only states killed by every $b(k)$ are those built from $b^\dagger$'s alone (no $c^\dagger$ factor). Hence a physical $|\chi\rangle$ has the form

$$|\chi\rangle = c_0\,|0\rangle \;+\; |\chi_b\rangle\,, \qquad |\chi_b\rangle \in \text{span of states with at least one } b^\dagger, \tag{13.103}$$

with $c_0 \in \mathbb{C}$ and $|\chi_b\rangle$ containing no $c^\dagger$ excitations. Now compute its norm. Every state with at least one $b^\dagger$ has zero norm and zero overlap with any other $b^\dagger$-only state, because all the relevant inner products reduce, by moving b's to the right through Eq. (13.102), to vacuum matrix elements containing at least one factor $\left[b, b^\dagger\right] = 0$ (no $c^\dagger$ is ever present to supply the nonzero $\left[b, c^\dagger\right]$). The same argument gives $\langle 0|\chi_b\rangle = 0$. Therefore the cross terms and the $|\chi_b\rangle$ self-overlap all vanish, leaving

$$\langle\chi|\chi\rangle = |c_0|^2\,\langle 0|0\rangle + 2\,\mathrm{Re}(\bar{c}_0\,\langle 0|\chi_b\rangle\,) + \langle\chi_b|\chi_b\rangle = |c_0|^2 \;\geq\; 0. \tag{13.104}$$

Substituting into Eq. (13.100) gives $\langle\Psi|\Psi\rangle = \sum_n \|T_n\|^2\,|c_0^{(n)}|^2 \geq 0$, which is the claim. □

The proof exposes the mechanism with no hand-waving: the would-be negative-norm scalar photon never appears alone in a physical state. The physical condition forces scalar and longitudinal quanta to enter only in the null combination $b^\dagger \propto a_0^\dagger - a_3^\dagger$, and that combination has *zero* norm because the negative scalar norm Eq. (13.90) cancels the positive longitudinal norm Eq. (13.89) term by term, Eq. (13.98). Negativity is impossible because the dangerous mode has been algebraically married to a partner of opposite norm, and the marriage is exactly what the Lorenz condition enforces.

13.3.6 Zero-norm states decouple

Theorem 13.19 leaves a residue: physical states of *zero* norm, those with $c_0 = 0$ in Eq. (13.103), i.e. physical states whose scalar/longitudinal part is built purely from $b^\dagger$'s (with no vacuum component). Denote this set $V_0 \subset V_{\mathrm{phys}}$. Zero-norm states are not yet a contradiction, but a probability interpretation cannot tolerate a state $|n\rangle$ with $\langle n|n\rangle = 0$ unless that state is physically invisible. We now prove it is.

Proposition 13.20 (Null states decouple)**.** *Every zero-norm physical state is orthogonal to all physical states: if* $|n\rangle \in V_0$ *and* $|\Psi\rangle \in V_{\text{phys}}$ *then* $\langle\Psi|n\rangle = 0$*. Consequently the addition of a null state to any physical state changes no physical matrix element, and null states contribute nothing to expectation values of observables.*

Proof. By the factorization of Theorem 13.19 it suffices to work in $\mathcal{F}_{\text{sl}}$. A null physical state has scalar/longitudinal part $|\chi_b\rangle$ of the $b^\dagger$-only form, and a general physical state has part $|\chi'\rangle = c'_0\,|0\rangle + |\chi'_b\rangle$. Their overlap is

$$\langle\chi'|\chi_b\rangle = \bar{c}'_0\,\langle 0|\chi_b\rangle + \langle\chi'_b|\chi_b\rangle = 0, \tag{13.105}$$

since $\langle 0|\chi_b\rangle = 0$ and $\langle\chi'_b|\chi_b\rangle = 0$ by the same null-overlap argument used for Eq. (13.104). Hence $V_0 \perp V_{\text{phys}}$. For the second statement, let $\mathcal{O}$ be any physical observable—an operator that maps physical states to physical states and is built gauge-invariantly, in particular the field strength $F_{\mu\nu}$, the Hamiltonian, momentum, and angular momentum. Then for physical $|\Psi\rangle, |\Psi'\rangle$ and null $|n\rangle, |n'\rangle$,

$$\langle\Psi + n|\mathcal{O}|\Psi' + n'\rangle = \langle\Psi|\mathcal{O}|\Psi'\rangle + \langle\Psi|\mathcal{O}|n'\rangle + \langle n|\mathcal{O}|\Psi'\rangle + \langle n|\mathcal{O}|n'\rangle = \langle\Psi|\mathcal{O}|\Psi'\rangle, \tag{13.106}$$

because $\mathcal{O}\,|n'\rangle$ and $\mathcal{O}^\dagger\,|n\rangle$ are again physical (observables preserve V_{phys}) and hence orthogonal to the null states $|n\rangle, |n'\rangle$ by the first part. Every cross term and the null–null term vanish. □

The cleanest illustration is the energy. The Hamiltonian of the gauge-fixed theory, expressed in ladder operators, takes the form (after normal ordering) $H = \int \widetilde{dk}\,\omega_{\mathbf{k}}\big[\sum_{i=1,2} a^\dagger(k,i)a(k,i) - a^\dagger(k,0)a(k,0) + a^\dagger(k,3)a(k,3)\big]$, where the scalar term carries a minus sign inherited from Eq. (13.90). Acting on a physical state and using $a(k,0) = a(k,3) + L(k)$ with $L(k)\,|\text{phys}\rangle = 0$, the scalar and longitudinal contributions to $\langle H\rangle$ cancel exactly, $\langle -a_0^\dagger a_0 + a_3^\dagger a_3\rangle_{\text{phys}} = 0$, leaving the transverse energy $\langle H\rangle_{\text{phys}} = \int \widetilde{dk}\,\omega_{\mathbf{k}} \sum_{i=1,2}\langle a^\dagger(k,i)a(k,i)\rangle \geq 0$. The energy is non-negative and is carried entirely by transverse photons; scalar and longitudinal quanta are energetically invisible. This is Eq. (13.106) made concrete for $\mathcal{O} = H$.

13.3.7 The quotient and the isometry to the transverse space

Theorem 13.20 licenses the final step. Inside V_{phys} the null states V_0 are orthogonal to everything, including themselves; they are exactly the directions along which the (semi-definite) inner product is degenerate. To obtain a Hilbert space we must remove this degeneracy, and the canonical way is to pass to the quotient: declare two physical states equivalent if they differ by a null state, $|\Psi\rangle \sim |\Psi\rangle + |n\rangle$ for $|n\rangle \in V_0$, and define the physical Hilbert space as the space of equivalence classes, completed in the resulting norm.

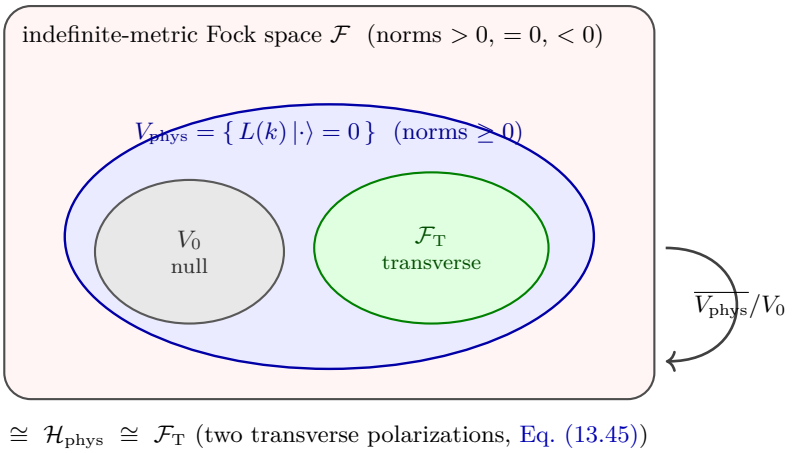

Figure 13.3: The Gupta–Bleuler construction. The covariant quantization lives on an indefinite-metric Fock space $\mathcal{F}$ with states of positive, zero, and negative norm. The subsidiary condition Eq. (13.96) selects the non-negative-norm subspace V_{phys}, inside which the zero-norm states V_0 form a subspace orthogonal to everything. Quotienting them out yields the physical Hilbert space $\mathcal{H}_{\text{phys}}$, isometric to the two-polarization transverse Fock space $\mathcal{F}_{\text{T}}$ of the Coulomb-gauge construction.

Definition 13.21 (Physical Hilbert space)**.** The *physical Hilbert space* of the covariantly quantized photon is

$$\mathcal{H}_{\text{phys}} \;\equiv\; \overline{V_{\text{phys}}}\,/\,V_0, \tag{13.107}$$

the completion of the physical subspace modulo null states, with inner product $([\Psi],[\Psi']) \equiv \langle\Psi|\Psi'\rangle$.

The inner product on classes is well defined precisely because of Theorem 13.20: if $|\Psi_1\rangle \sim |\Psi_2\rangle$ and $|\Psi_1'\rangle \sim |\Psi_2'\rangle$ then $\langle\Psi_1|\Psi_1'\rangle = \langle\Psi_2|\Psi_2'\rangle$, since the differences are null and orthogonal to all physical states. On classes the inner product is positive-definite—$([\Psi],[\Psi]) = \langle\Psi|\Psi\rangle = 0$ forces $|\Psi\rangle \in V_0$, i.e. $[\Psi] = 0$—so $\mathcal{H}_{\text{phys}}$ is a genuine Hilbert space. We can now identify it.

Theorem 13.22 (Isometry to the transverse space)**.** *The map sending each physical class to its transverse representative,*

$$U:\ \mathcal{H}_{\text{phys}} \;\longrightarrow\; \mathcal{F}_{\text{T}}, \qquad U\big[\ |T\rangle \otimes |\chi\rangle\ \big] \;=\; c_0\ |T\rangle\,, \tag{13.108}$$

where $|\chi\rangle = c_0\,|0\rangle + |\chi_b\rangle$ as in Eq. (13.103), is a well-defined unitary isomorphism onto the transverse two-polarization Fock space $\mathcal{F}_{\text{T}}$ of Eq. (13.45). The covariant and Coulomb-gauge constructions therefore describe the same physical photon.

Proof. Each physical class has a unique representative with scalar/longitudinal part proportional to $|0\rangle_{\rm sl}$: given any physical $|\Psi\rangle = \sum_n |T_n\rangle \otimes |\chi_n\rangle$ with $|\chi_n\rangle = c_0^{(n)}|0\rangle + \left|\chi_b^{(n)}\right\rangle$, subtract the null state $\sum_n |T_n\rangle \otimes \left|\chi_b^{(n)}\right\rangle \in V_0$ to obtain the equivalent representative $\sum_n c_0^{(n)} |T_n\rangle \otimes |0\rangle_{\rm sl}$, which is purely transverse. Two such transverse representatives in the same class differ by a transverse null state, but $\mathcal{F}_{\rm T}$ has positive-definite norm and so has no nonzero null states; the transverse representative is therefore unique, and U in Eq. (13.108) is well defined and independent of the chosen decomposition.

U preserves the inner product. For representatives $|\Psi\rangle = \sum_n c_0^{(n)} |T_n\rangle \otimes |0\rangle_{\rm sl}$ and $|\Psi'\rangle = \sum_m c_0^{\prime(m)} |T'_m\rangle \otimes |0\rangle_{\rm sl}$, using $\langle 0|0\rangle_{\rm sl} = 1$,

$$([\Psi],[\Psi']) = \langle\Psi|\Psi'\rangle = \sum_{n,m} \bar{c}_0^{(n)} c_0^{\prime(m)} \langle T_n|T'_m\rangle = \big(U[\Psi],\, U[\Psi']\big)_{\mathcal{F}_{\rm T}}. \tag{13.109}$$

U is surjective: every transverse state $|T\rangle \in \mathcal{F}_{\rm T}$ is the image of the physical class $[|T\rangle \otimes |0\rangle_{\rm sl}]$ (which satisfies Eq. (13.96) since $L(k)|0\rangle = 0$). And U is injective because $U[\Psi] = 0$ means every transverse representative vanishes, i.e. $|\Psi\rangle \in V_0$, i.e. $[\Psi] = 0$. A norm-preserving bijection of Hilbert spaces is unitary. The target $\mathcal{F}_{\rm T}$, built from $a^\dagger(k,1), a^\dagger(k,2)$ with the positive algebra Eq. (13.89), is precisely the transverse Fock space whose commutator is recorded in Eq. (13.45); its excitations are the two helicity-±1 photons identified there. □

This is the chapter's central result. Manifest Lorentz covariance has been bought with an indefinite metric, four polarizations, and a negative-norm scalar photon; and yet, after imposing the single covariant condition Eq. (13.93) and discarding the null directions it permits, the physics is identical to the manifestly positive Coulomb-gauge theory—two transverse photons, no more. The two "honest exits" from the gauge redundancy promised in the chapter introduction meet here, in Theorem 13.22: they are the same Hilbert space, reached by opposite routes. The structure is summarized in Fig. 13.3.

13.3.8 The weak Lorenz condition and Maxwell's equations in the mean

We close the logical circle by returning to Eq. (13.94). The Lorenz condition $\partial_\mu A^\mu = 0$, which we could not impose as an operator identity without contradicting the commutator Eq. (13.83), holds in the weak sense: $\langle{\rm phys}|\partial_\mu A^\mu|{\rm phys}'\rangle = 0$ for all physical states. This is exactly enough to recover Maxwell's equations as statements about physical matrix elements. Taking the matrix element of the gauge-fixed equation of motion Eq. (13.78) at $\xi = 1$, $\Box A^\nu = 0$, between physical states, and adding ∂^ν of the weak Lorenz condition, gives

$$\langle{\rm phys}|\partial_\mu F^{\mu\nu}|{\rm phys}'\rangle = \langle{\rm phys}|\Box A^\nu - \partial^\nu(\partial_\mu A^\mu)|{\rm phys}'\rangle = 0, \tag{13.110}$$

the source-free Maxwell equation holding between physical states. The free covariant photon thus reproduces electromagnetism not as an operator identity for A_μ—which would be false, the gauge-fixed A_μ obeys $\Box A_\mu = 0$, not Maxwell's equation—but as a statement true in every physical expectation value. Observable electromagnetism is recovered exactly on $\mathcal{H}_{\text{phys}}$.

We now make the structure tactile with two worked computations. The first traces the cancellation of negative norm through a concrete one-photon state; the second reveals the null states as the quantum residue of the classical gauge freedom Eq. (8.113), closing the conceptual loop opened in Chapter 8.

Worked Example 13.23 (A physical scalar/longitudinal photon is null)**.** Consider the most general one-photon state built from the scalar and longitudinal modes with a common wave packet $f(\mathbf{k})$ and complex amplitudes α, β,

$$|\psi\rangle = \int \widetilde{dk}\, f(\mathbf{k}) \left[\, \alpha\, a^\dagger(k,0) + \beta\, a^\dagger(k,3) \,\right] |0\rangle\,. \tag{13.111}$$

We ask which such states are physical, and what their norm is. The physical condition Eq. (13.96) requires $L(k)\,|\psi\rangle = 0$. Compute, using $L(k) = a(k,0) - a(k,3)$ and Eq. (13.88):

$$\begin{aligned} L(k)\,|\psi\rangle &= \int \widetilde{dk'}\, f(\mathbf{k}') \Big(\alpha \, \Big[a(k,0), a^\dagger(k',0)\Big] - \beta \, \Big[a(k,3), a^\dagger(k',3)\Big] \Big)\, |0\rangle \\ &= \int \widetilde{dk'}\, f(\mathbf{k}') \, (-\alpha - \beta)(2\pi)^3 2\omega_{\mathbf{k}}\, \delta^{(3)}(\mathbf{k}-\mathbf{k}')\, |0\rangle = -(\alpha+\beta)\, f(\mathbf{k})\, |0\rangle\,. \end{aligned} \tag{13.112}$$

The cross terms vanished because $\Big[a_0, a_3^\dagger\Big] = \Big[a_3, a_0^\dagger\Big] = 0$. The state is physical iff

$$\alpha + \beta = 0, \qquad \text{i.e.} \qquad \beta = -\alpha. \tag{13.113}$$

A physical scalar/longitudinal photon must therefore be the combination $|\psi\rangle = \alpha \int \widetilde{dk}\, f\, (a_0^\dagger - a_3^\dagger)\,|0\rangle = \alpha\sqrt{2}\, L^\dagger(f)\,|0\rangle$, proportional to the null creation operator $L^\dagger$. Its norm follows from Eq. (13.99):

$$\langle\psi|\psi\rangle = 2|\alpha|^2 \left\langle 0 \middle| L(f) L^\dagger(f) \middle| 0 \right\rangle = 2|\alpha|^2 \left\langle 0 \middle| \Big[L(f), L^\dagger(f)\Big] \middle| 0 \right\rangle = 0. \tag{13.114}$$

We can also see the cancellation in the original variables: with $\beta = -\alpha$,

$$\langle\psi|\psi\rangle = \int \widetilde{dk} |f|^2 \Big(\underbrace{|\alpha|^2 \Big[a_0, a_0^\dagger\Big]}_{=-|\alpha|^2(\cdots)} + \underbrace{|\beta|^2 \Big[a_3, a_3^\dagger\Big]}_{=+|\alpha|^2(\cdots)} \Big) = \int \widetilde{dk} |f|^2\, |\alpha|^2 (-1+1)(2\pi)^3 2\omega_{\mathbf{k}}\, \delta^{(3)}(0) \cdots = \tag{13.115}$$

the negative scalar norm cancelling the positive longitudinal norm. Every physical mixture of scalar and longitudinal photons is null—there is no positive-norm one-particle state outside the transverse sector—in concrete agreement with Theorem 13.19 and Theorem 13.22.

Worked Example 13.24 (Null states are residual gauge transformations)**.** The null states of Theorem 13.23 are not arbitrary; they implement, at the quantum level, the residual gauge freedom that survives Feynman gauge. We show that adding a null state to a physical state shifts the expectation value of A_μ by a pure gradient $\partial_\mu\Lambda$ with $\Box\Lambda = 0$—exactly a gauge transformation Eq. (8.113) preserving the wave equation Eq. (13.79).

Start from the commutator of the field with the null creation operator. With $L^\dagger(k) = a^\dagger(k,0) - a^\dagger(k,3)$ and the positive-frequency field $A_\mu^{(+)}(x) = \int \widetilde{dk'} \sum_\lambda \epsilon_\mu(k',\lambda) a(k',\lambda) e^{-ik'\cdot x}$,

$$\begin{aligned}\Big[A_\mu^{(+)}(x), L^\dagger(k)\Big] &= \int \widetilde{dk'} \sum_\lambda \epsilon_\mu(k',\lambda) e^{-ik'\cdot x} \Big(\Big[a(k',\lambda), a^\dagger(k,0)\Big] - \Big[a(k',\lambda), a^\dagger(k,3)\Big] \Big) \\ &= \int \widetilde{dk'} \sum_\lambda \epsilon_\mu(k',\lambda) e^{-ik'\cdot x} \big(-\eta_{\lambda 0} + \eta_{\lambda 3} \big) (2\pi)^3 2\omega_{\mathbf{k}} \delta^{(3)}(\mathbf{k}' - \mathbf{k}) \\ &= -\epsilon_\mu(k,0)\, e^{-ik\cdot x} \;-\; \epsilon_\mu(k,3)\, e^{-ik\cdot x}, \end{aligned} \tag{13.116}$$

where in the last line $-\eta_{\lambda 0}$ picks out $\lambda = 0$ with coefficient -1 and $+\eta_{\lambda 3}$ picks out $\lambda = 3$ with coefficient $\eta_{33} = -1$. For $k^\mu = \omega(1,0,0,1)$ the lowered polarizations are $\epsilon_\mu(k,0) = (1,0,0,0)$ and $\epsilon_\mu(k,3) = (0,0,0,-1)$, whose sum is $(1,0,0,-1) = k_\mu/\omega$. Hence

$$\Big[A_\mu^{(+)}(x), L^\dagger(k)\Big] = -\frac{k_\mu}{\omega}\, e^{-ik\cdot x} = \partial_\mu\Big(-\frac{i}{\omega} e^{-ik\cdot x} \Big) \equiv \partial_\mu \Lambda_k(x), \tag{13.117}$$

using $\partial_\mu e^{-ik\cdot x} = -ik_\mu e^{-ik\cdot x}$, with $\Lambda_k(x) = -\frac{i}{\omega} e^{-ik\cdot x}$ satisfying $\Box\Lambda_k = 0$. Now let $|\Psi\rangle$ be a normalized physical state and form a different representative of the same physical class by adding a null admixture, $|\Psi_\theta\rangle = |\Psi\rangle + \theta\, L^\dagger(g)\,|\Psi\rangle$ with θ a small real parameter and $L^\dagger(g) = \int \widetilde{dk}\, \bar g(\mathbf{k}) L^\dagger(k)$. The shift in the expectation value of the field is, to first order in θ,

$$\delta\langle A_\mu(x)\rangle = \theta\, \Big\langle \Psi \Big| \Big[A_\mu(x), L^\dagger(g)\Big] \Big| \Psi \Big\rangle + \text{c.c.} = \theta \int \widetilde{dk}\, \bar g(\mathbf{k})\, \partial_\mu \Lambda_k(x)\; \langle\Psi|\Psi\rangle + \text{c.c.} = \partial_\mu \Lambda(x), \tag{13.118}$$

where only the positive-frequency part of A_μ contributed to the commutator (the negative-frequency part commutes with $L^\dagger$, being built from creation operators), and $\Lambda(x) = 2\,\mathrm{Re}\big[\theta \int \widetilde{dk}\, \bar g(\mathbf{k}) \Lambda_k(x)\big]$ is a real c-number function with $\Box\Lambda = 0$. The conclusion is exact and structural: *changing the null content of a physical state is a gauge transformation* $A_\mu \to A_\mu + \partial_\mu\Lambda$, with Λ a harmonic gauge function—the residual freedom that the Feynman-gauge condition does not fix. Quotienting by V_0 in Eq. (13.107) is thus the quantum implementation of fixing the residual gauge: physically equivalent (gauge-related) field configurations are collapsed to a single ray of $\mathcal{H}_{\text{phys}}$. The classical redundancy of Chapter 8 and the quantum null states are one and the same phenomenon, seen at two levels.

Physical Insight

The three faces of the gauge redundancy now coincide. *Classically* (Chapter 8) it was the freedom $A_\mu \to A_\mu + \partial_\mu \alpha$ that left $F_{\mu\nu}$ untouched. In *Coulomb gauge* (previous section) it was eliminated outright by solving the constraints, at the cost of covariance. In *Gupta–Bleuler* it survives as the null subspace V_0, whose elements are the residual gauge transformations Eq. (13.117), and the physical Hilbert space is the covariant configuration space modulo this freedom. The Faddeev–Popov path integral of Chapter 26 will unify these descriptions and, in the non-abelian case, promote the null modes to dynamical ghost fields whose cohomology—the BRST refinement of the Gupta–Bleuler condition—is the modern statement of Theorem 13.22.

We have what the rest of QED needs: a covariant operator A_μ on an explicit (if indefinite-metric) Fock space, a Lorentz-covariant commutator Eq. (13.83), and a physical-state condition Eq. (13.93) that guarantees unitarity on $\mathcal{H}_{\text{phys}}$ and justifies dropping scalar and longitudinal polarizations from physical amplitudes. The next section assembles from this operator the time-ordered two-point function $\langle 0|\mathcal{T}A_\mu(x)A_\nu(y)|0\rangle$—the photon propagator—tracks its dependence on the gauge parameter ξ across the R_ξ family, and shows that the gauge-dependent part never touches a physical amplitude because it couples only to conserved currents, exactly the weak-Lorenz mechanism of Eq. (13.110) seen from the propagator side.

13.4 The Photon Propagator and Its Gauge Dependence

The covariant quantization of Section 13.3 delivered a fully Lorentz-covariant field $A_\mu(x)$ at the cost of an indefinite-metric Fock space, and then carved a genuine physical Hilbert space out of it by the Gupta–Bleuler subsidiary condition. We now collect the dividend. The single object that all of perturbative QED is built from is the time-ordered two-point function $\langle 0|\,\mathcal{T}A_\mu(x)A_\nu(y)\,|0\rangle$ — the amplitude for a disturbance of the electromagnetic field to propagate from y to x, the internal photon line of every diagram from Chapter 17 onward. Computing it is the goal of this section, and it forces us to confront, in its sharpest and most practical form, the redundancy that has organized the entire chapter: the answer is *not unique*. It carries a free parameter ξ, the gauge-fixing parameter, and different choices of ξ give genuinely different propagators. The resolution — that this gauge dependence is invisible in every physical amplitude because the matter it couples to carries a conserved current — is the second half of the section, and it is the precise statement, at the level of the propagator, of the fact

that gauge is a redundancy of description and not a property of the world.

We work throughout in the mostly-minus metric $\eta_{\mu\nu} = \mathrm{diag}(+,-,-,-)$, natural units, with the covariant derivative on the electron $D_\mu = \partial_\mu + ieA_\mu$ ($e > 0$, electron charge $-e$) of QED, used in Chapter 11, and the Feynman $i\varepsilon$ prescription inherited from the scalar propagator Eq. (9.154). The computational default, stated and used below, is Feynman gauge $\xi = 1$.

13.4.1 The coordinate-space propagator in Feynman gauge

The cleanest derivation starts from the field itself. Recall from the covariant construction (Section 13.3) that in Feynman gauge the gauge-fixed Lagrangian is

$$\mathcal{L} = -\tfrac{1}{4}F_{\mu\nu}F^{\mu\nu} - \frac{1}{2\xi}\left(\partial_\mu A^\mu\right)^2, \qquad F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu, \tag{13.119}$$

whose Euler–Lagrange equation $\left[\eta_{\mu\nu}\Box - (1-\xi^{-1})\partial_\mu\partial_\nu\right]A^\nu = 0$ collapses, at $\xi = 1$, to four decoupled massless wave equations $\Box A_\mu = 0$. Each component of A_μ then propagates like a massless scalar field, and the equal-time and covariant commutation relations established in Section 13.3 take the compact covariant form

$$[A_\mu(x), A_\nu(y)] = -\,i\,\eta_{\mu\nu}\,D(x-y)\Big|_{m=0}, \tag{13.120}$$

where $D(x-y)$ is the Pauli–Jordan commutator function of the free scalar, evaluated at zero mass (the $m \to 0$ limit of the function whose causal support property was the content of Section 9.6). The crucial structural fact, and the one feature that distinguishes the photon from a scalar, is the index tensor $-\eta_{\mu\nu}$: the spacelike components carry the ordinary sign while the timelike component A_0 carries the *opposite* sign $-\eta_{00} = -1$. That single minus is the indefinite metric of the covariant Fock space, written in field language. It is harmless here precisely because it factors out of the spacetime dynamics, which is identical for all four components.

The positive-frequency Wightman function inherits the same structure. With the covariant mode expansion of Section 13.3, whose creation/annihilation operators obey $\left[a_\mu(\mathbf{k}), a_\nu^\dagger(\mathbf{k}')\right] = -\eta_{\mu\nu}(2\pi)^3\,2\omega_{\mathbf{k}}\,\delta^3(\mathbf{k}-\mathbf{k}')$, one finds

$$\langle 0|\,A_\mu(x)A_\nu(y)\,|0\rangle = -\eta_{\mu\nu}\int\frac{d^3k}{(2\pi)^3\,2\omega_{\mathbf{k}}}\,e^{-ik\cdot(x-y)}\Big|_{k^0=\omega_{\mathbf{k}}=|\mathbf{k}|} = -\eta_{\mu\nu}\,D^+(x-y)\big|_{m=0}, \tag{13.121}$$

the index tensor $-\eta_{\mu\nu}$ pulled directly through from the commutator and D^+ the massless scalar Wightman function. Everything that depends on the spacetime points x, y is a single scalar function; only the constant tensor $-\eta_{\mu\nu}$ remembers that we are dealing with a vector field.

We can now assemble the time-ordered product. By the definition of time ordering,

$$\mathcal{T} A_\mu(x) A_\nu(y) = \theta(x^0 - y^0)\, A_\mu(x) A_\nu(y) + \theta(y^0 - x^0)\, A_\nu(y) A_\mu(x), \tag{13.122}$$

so that, taking the vacuum expectation value and using Eq. (13.121) for both orderings,

$$\langle 0 |\, \mathcal{T} A_\mu(x) A_\nu(y)\, | 0 \rangle = -\eta_{\mu\nu} \Big[\theta(x^0 - y^0) D^+(x - y) + \theta(y^0 - x^0) D^+(y - x) \Big] \Big|_{m=0}. \tag{13.123}$$

The bracket is, term for term, the time-ordered combination of Wightman functions that *defined* the scalar Feynman propagator in Eq. (9.153); the constant tensor $-\eta_{\mu\nu}$ rides along untouched. We have therefore proved the following.

Theorem 13.25 (Coordinate-space photon propagator, Feynman gauge)**.** *In Feynman gauge ($\xi = 1$) the time-ordered photon two-point function is the scalar Feynman propagator at zero mass, times the constant tensor $-\eta_{\mu\nu}$:*

$$D^F_{\mu\nu}(x-y) \;\equiv\; \langle 0 |\, \mathcal{T} A_\mu(x) A_\nu(y)\, | 0 \rangle \;=\; -\,\eta_{\mu\nu}\, D_F(x-y)\big|_{m=0} \;=\; \int \frac{d^4k}{(2\pi)^4}\, \frac{-\,i\,\eta_{\mu\nu}}{k^2 + i\varepsilon}\, e^{-ik\cdot(x-y)}. \tag{13.124}$$

Proof. Eq. (13.123) identifies the bracket as the time-ordered scalar correlator, i.e. $D_F(x-y)|_{m=0}$ by Theorem 9.24. Substituting the momentum-space form of the massless scalar Feynman propagator Eq. (9.154) (set $m = 0$) and pulling out $-\eta_{\mu\nu}$ gives the displayed integral. The $i\varepsilon$ is inherited intact from the scalar: it is the statement that positive-frequency modes propagate forward and negative-frequency modes backward in time, the same Stueckelberg–Feynman boundary condition that Section 9.5 attached to the scalar poles. As a tempered distribution the equality holds for all $x - y$, on or off the light cone. □

The momentum-space integrand in Eq. (13.124) is the Feynman-gauge propagator. Reading it off,

$$D_{\mu\nu}(k)\big|_{\xi=1} = \frac{-\,i\,\eta_{\mu\nu}}{k^2 + i\varepsilon}, \tag{13.125}$$

which is exactly the $\xi = 1$ specialization of the general formula we are about to derive. It is worth pausing on how economical this is: the photon propagator in Feynman gauge is four copies of the massless scalar propagator, three with a relative minus sign. The minus signs are the indefinite metric; they will be exactly what is needed for the unphysical (timelike and longitudinal) polarizations to cancel in physical amplitudes.

13.4.2 The R_ξ family from inverting the quadratic operator

Feynman gauge is one point in a one-parameter family. To see the family, and to understand why a free parameter is unavoidable, we compute the propagator the way the path integral of Section 13.5 will demand: as the inverse of the quadratic differential operator in the action. This is the standard route to any free propagator — the two-point function of a Gaussian theory is the inverse of the kernel of its quadratic form — and it makes the role of the gauge-fixing term unmistakable.

Begin with the gauge-fixed Lagrangian Eq. (13.119) and bring the quadratic action into the canonical form $S = \frac{1}{2}\int d^4x\, A^\mu(x)\, \mathcal{O}_{\mu\nu}\, A^\nu(x)$ by integrating by parts (discarding surface terms, legitimate for fields decaying at infinity). For the Maxwell term, expand $-\frac{1}{4}F_{\mu\nu}F^{\mu\nu} = -\frac{1}{2}(\partial_\mu A_\nu \partial^\mu A^\nu - \partial_\mu A_\nu \partial^\nu A^\mu)$ and integrate each piece by parts:

$$-\tfrac{1}{2}\partial_\mu A_\nu\, \partial^\mu A^\nu \;\longrightarrow\; +\tfrac{1}{2}\, A_\nu\, \Box A^\nu, \tag{13.126}$$

$$+\tfrac{1}{2}\partial_\mu A_\nu\, \partial^\nu A^\mu \;\longrightarrow\; -\tfrac{1}{2}\, A_\nu\, \partial^\nu \partial_\mu A^\mu, \tag{13.127}$$

while the gauge-fixing term gives $-\frac{1}{2\xi}(\partial_\mu A^\mu)^2 \to +\frac{1}{2\xi} A_\mu\, \partial^\mu \partial^\nu A_\nu$. Collecting,

$$S = \tfrac{1}{2}\int d^4x\; A^\mu \Big[\eta_{\mu\nu}\Box - \Big(1 - \tfrac{1}{\xi}\Big)\partial_\mu\partial_\nu\Big] A^\nu, \tag{13.128}$$

so the differential kernel is $\mathcal{O}_{\mu\nu} = \eta_{\mu\nu}\Box - (1-\xi^{-1})\partial_\mu\partial_\nu$. Passing to momentum space with the standing Fourier convention $A(x) = \int \frac{d^4k}{(2\pi)^4} e^{-ik\cdot x}\widetilde{A}(k)$, every ∂_μ becomes $-ik_\mu$, so $\Box \to -k^2$ and $\partial_\mu\partial_\nu \to -k_\mu k_\nu$, giving the algebraic operator

$$\mathcal{O}_{\mu\nu}(k) = -k^2\eta_{\mu\nu} + \Big(1 - \tfrac{1}{\xi}\Big) k_\mu k_\nu. \tag{13.129}$$

The propagator $D_{\mu\nu}(k)$ is fixed by the requirement that it be the Green's function of this operator with the i of the Minkowski path integral,

$$\mathcal{O}^{\mu\rho}(k)\, D_{\rho\nu}(k) = i\, \delta^\mu{}_\nu, \tag{13.130}$$

the exact tensor analogue of the scalar relation $(k^2 - m^2)D_F = i$ that produced Eq. (9.154).

To invert $\mathcal{O}$ we use the two natural projectors built from k_μ. Define the *transverse* and *longitudinal* projectors

$$\theta_{\mu\nu} = \eta_{\mu\nu} - \frac{k_\mu k_\nu}{k^2}, \qquad \omega_{\mu\nu} = \frac{k_\mu k_\nu}{k^2}. \tag{13.131}$$

They satisfy the projector algebra $\theta + \omega = \eta$, $\theta^2 = \theta$, $\omega^2 = \omega$, $\theta\,\omega = \omega\,\theta = 0$ (each identity follows from $k^\mu\theta_{\mu\nu} = 0$ and $k^\mu\omega_{\mu\nu} = k_\nu$, which are immediate from

Eq. (13.131)). They diagonalize $\mathcal{O}$. Writing $\eta = \theta + \omega$ and $k_\mu k_\nu = k^2 \omega_{\mu\nu}$ in Eq. (13.129),

$$\mathcal{O}_{\mu\nu}(k) = -k^2(\theta_{\mu\nu} + \omega_{\mu\nu}) + \Big(1 - \tfrac{1}{\xi}\Big) k^2 \omega_{\mu\nu} = -k^2\, \theta_{\mu\nu} - \frac{k^2}{\xi}\, \omega_{\mu\nu}. \tag{13.132}$$

Thus $\mathcal{O}$ acts as the scalar $-k^2$ on the transverse subspace and as $-k^2/\xi$ on the longitudinal direction. On each eigenspace inversion is scalar division, and because θ and ω are orthogonal idempotents the inverse of $a\theta + b\omega$ is $a^{-1}\theta + b^{-1}\omega$:

$$\big(\mathcal{O}^{-1}\big)_{\mu\nu}(k) = -\frac{1}{k^2}\, \theta_{\mu\nu} - \frac{\xi}{k^2}\, \omega_{\mu\nu}. \tag{13.133}$$

Multiplying by i as Eq. (13.130) requires, and re-expanding the projectors via Eq. (13.131),

$$D_{\mu\nu}(k) = i\big(\mathcal{O}^{-1}\big)_{\mu\nu} = \frac{-i}{k^2}(\theta_{\mu\nu} + \xi\, \omega_{\mu\nu}) = \frac{-i}{k^2}\Big[\eta_{\mu\nu} - (1-\xi)\frac{k_\mu k_\nu}{k^2}\Big], \tag{13.134}$$

where the last step used $\theta + \xi\omega = \eta - \omega + \xi\omega = \eta - (1-\xi)\omega$. Restoring the Feynman prescription that selects the physical (causal) Green's function exactly as for the scalar — the same pole displacement $k^2 \to k^2 + i\varepsilon$ established in Section 9.5 — we have the central result of the section.

Theorem 13.26 (The R_ξ photon propagator)**.** *The momentum-space time-ordered photon two-point function in the R_ξ gauge family is*

$$\boxed{D_{\mu\nu}(k) = \frac{-i}{k^2 + i\varepsilon}\Big[\eta_{\mu\nu} - (1-\xi)\frac{k_\mu k_\nu}{k^2}\Big]} \tag{13.135}$$

This is the carried object of QED's photon stage: the single tensor that becomes a Feynman rule in Chapter 17 and is dressed into the full photon propagator by vacuum polarization in Chapter 19. Three values of ξ are in common use and earn names; we record them, with their defining virtues.

Definition 13.27 (Named gauges in the R_ξ family)**.** The standard members of Eq. (13.135) are

$$\text{Feynman ('t Hooft–Feynman) gauge,}\quad \xi = 1: \quad D_{\mu\nu}(k) = \frac{-i\,\eta_{\mu\nu}}{k^2 + i\varepsilon}, \tag{13.136}$$

$$\text{Landau gauge,}\quad \xi = 0: \quad D_{\mu\nu}(k) = \frac{-i}{k^2 + i\varepsilon}\Big[\eta_{\mu\nu} - \frac{k_\mu k_\nu}{k^2}\Big] = \frac{-i}{k^2 + i\varepsilon}\,\theta_{\mu\nu} \tag{13.137}$$

$$\text{Yennie gauge,}\quad \xi = 3: \quad D_{\mu\nu}(k) = \frac{-i}{k^2 + i\varepsilon}\Big[\eta_{\mu\nu} + 2\,\frac{k_\mu k_\nu}{k^2}\Big]. \tag{13.138}$$

Each has a reason to exist. Feynman gauge gives the simplest possible numerator $\eta_{\mu\nu}$ and is the default for almost every explicit computation in this book; we adopt it unless stated otherwise. Landau gauge makes the propagator exactly transverse, $k^\mu D_{\mu\nu} = 0$ (immediate since $k^\mu \theta_{\mu\nu} = 0$), which is convenient whenever transversality must be manifest, for example in studies of the gauge-dependence of off-shell Green's functions or in confining-phase analyses of the gluon propagator. Yennie gauge, $\xi = 3$, is engineered so that the infrared behavior of the photon propagator softens the leading infrared singularities of QED radiative corrections, simplifying the bookkeeping of infrared divergences in the program of Chapter 19. That three such different-looking objects are all legitimate propagators for the *same* theory is the puzzle that the next subsection resolves.

Physical Insight

The single free parameter ξ is the propagator's memory of gauge redundancy. The transverse part of the propagator, $-i\theta_{\mu\nu}/k^2$, is ξ-independent and physical: it is the part that propagates the two genuine helicity states of the photon. The longitudinal part, $-i\xi\,\omega_{\mu\nu}/k^2$, is pure gauge artefact — its coefficient is whatever the gauge-fixing term was told to make it. A physical answer cannot depend on ξ, so it cannot depend on the longitudinal part. This is the same two-physical-degrees-of-freedom count that has organized the whole chapter, now visible in the tensor structure of a single propagator.

13.4.3 Why the operator must be gauge-fixed: the non-invertible limit

The inversion in Eq. (13.132)–Eq. (13.133) required the longitudinal eigenvalue $-k^2/\xi$ to be nonzero. Tracking what happens when it is not exposes precisely why the gauge-fixing term in Eq. (13.119) is not optional but mandatory, and what role ξ plays.

Consider the pure Maxwell theory, with no gauge fixing. This is recovered formally as $\xi \to \infty$, where the gauge-fixing coefficient $\xi^{-1} \to 0$ and Eq. (13.129) reduces to $\mathcal{O}^{\mathrm{Max}}_{\mu\nu} = -k^2\eta_{\mu\nu} + k_\mu k_\nu = -k^2\theta_{\mu\nu}$. This operator annihilates the longitudinal direction outright:

$$\mathcal{O}^{\mathrm{Max}}_{\mu\nu}(k)\, k^\nu = -k^2\, \theta_{\mu\nu} k^\nu = 0, \tag{13.139}$$

because $\theta_{\mu\nu}k^\nu = k_\mu - k_\mu(k\cdot k)/k^2 = 0$. A linear operator with a nonzero null vector is not invertible: there is no tensor $D_{\rho\nu}$ satisfying Eq. (13.130), since contracting that equation with k^μ would give $0 = i\,k_\nu \neq 0$, a contradiction. The pure Maxwell quadratic form simply does not have a propagator.

The null vector is not an accident; it is gauge invariance, read in momentum space. A gauge transformation $A_\mu \to A_\mu + \partial_\mu \alpha$ shifts $\widetilde{A}_\mu(k) \to \widetilde{A}_\mu(k) - ik_\mu \widetilde{\alpha}(k)$, i.e. it adds a multiple of k_μ — precisely the direction Eq. (13.139) kills. The action is flat along gauge orbits, the quadratic form is degenerate in the longitudinal direction, and a degenerate quadratic form cannot be inverted. The gauge-fixing term $-\frac{1}{2\xi}(\partial A)^2$ does exactly one thing: it supplies a nonzero longitudinal eigenvalue $-k^2/\xi$, lifting the flat direction so that the operator becomes invertible, with the lift controlled by ξ. The price is that the longitudinal part of the resulting propagator depends on the arbitrary lift parameter ξ. The path-integral derivation of Section 13.5 will make this geometry literal: the divergence of $\int \mathcal{D}A\, e^{iS}$ over gauge orbits is exactly the non-invertibility Eq. (13.139), and the Faddeev–Popov insertion is the systematic device that fixes a gauge and produces Eq. (13.135) with ξ as a free choice. For now the lesson stands on its own: *you cannot have a photon propagator without breaking the gauge invariance, and the breaking leaves a fingerprint ξ that physics must not see.*

13.4.4 Gauge independence of physical amplitudes

We now prove the fingerprint is invisible. The mechanism is current conservation, and it is exact and elementary at tree level; the all-orders generalization is the Ward–Takahashi identity proved in Chapter 19.

The propagator never appears alone. Wherever an internal photon line of momentum k joins the rest of a diagram, both of its ends attach to the matter content through the interaction vertex, and the object that multiplies the propagator is, on each side, a current. Concretely, the simplest gauge-invariant building block is one-photon exchange between two matter currents J_1^μ and J_2^ν (Fig. 13.4), whose amplitude is the contraction

$$i\mathcal{M} = \big(i\widetilde{J}_1^{\mu}(k)\big)\, D_{\mu\nu}(k)\, \big(i\widetilde{J}_2^{\nu}(-k)\big), \tag{13.140}$$

where $\widetilde{J}_i^{\mu}$ is the Fourier transform of the matter current to which the photon couples through the minimal-coupling interaction $-eA_\mu \bar{\psi}\gamma^\mu\psi$. That current is the conserved Dirac current of Chapter 11: the global $U(1)$ symmetry $\psi \to e^{-i\alpha}\psi$ gave, by Noether's theorem, the conserved current Eq. (11.158), $j^\mu = \bar{\psi}\gamma^\mu\psi$ with $\partial_\mu j^\mu = 0$, and it is $e\, j^\mu$ that sits at each photon vertex. Conservation in position space, $\partial_\mu J^\mu(x) = 0$, becomes in momentum space, under $\partial_\mu \to -ik_\mu$,

$$k_\mu\, \widetilde{J}^{\mu}(k) = 0. \tag{13.141}$$

This one identity does all the work.

Theorem 13.28 (ξ-independence of current-coupled amplitudes)**.** *If the photon of momentum k couples at both ends to conserved currents, $k_\mu \widetilde{J}_1^{\mu} = k_\nu \widetilde{J}_2^{\nu} = 0$, then the contraction $\widetilde{J}_1^{\mu} D_{\mu\nu} \widetilde{J}_2^{\nu}$ is independent of the gauge parameter ξ, and equals its Feynman-gauge value.*

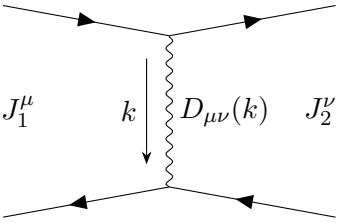

Figure 13.4: One-photon exchange between two conserved matter currents. The internal photon line carries the R_ξ propagator $D_{\mu\nu}(k)$ of Eq. (13.135); each vertex attaches it to a conserved current $\widetilde{J}_i^\mu$ obeying $k_\mu \widetilde{J}_i^\mu = 0$ (Eq. (13.141)). The gauge-dependent $k_\mu k_\nu$ piece of the propagator is annihilated on contact with either current, so the amplitude is independent of ξ. This is the tree-level kernel of $e^-e^- \to e^-e^-$ (Møller) and, by crossing, of e^+e^- scattering, computed in full in Chapters 17 and 18.

Proof. Insert the full propagator Eq. (13.135) into the contraction and split it into its ξ-independent and ξ-dependent pieces:

$$\widetilde{J}_1^\mu \, D_{\mu\nu} \, \widetilde{J}_2^\nu = \frac{-i}{k^2 + i\varepsilon}\Big[\widetilde{J}_1 \cdot \widetilde{J}_2 \; - \; (1-\xi)\, \frac{(\widetilde{J}_1 \cdot k)\,(k \cdot \widetilde{J}_2)}{k^2} \Big]. \tag{13.142}$$

The entire ξ-dependence resides in the second term, and that term is proportional to $\widetilde{J}_1 \cdot k = k_\mu \widetilde{J}_1^\mu$ and to $k \cdot \widetilde{J}_2 = k_\nu \widetilde{J}_2^\nu$, each of which vanishes by Eq. (13.141). Hence

$$\widetilde{J}_1^\mu \, D_{\mu\nu} \, \widetilde{J}_2^\nu = \frac{-i}{k^2 + i\varepsilon} \, \widetilde{J}_1 \cdot \widetilde{J}_2, \tag{13.143}$$

which is exactly the Feynman-gauge ($\xi = 1$) result and contains no ξ. The gauge-dependent term has been annihilated on contact with the conserved current. □

The structure of Eq. (13.142) is worth stating as a slogan: *the gauge (ξ) dependence of the photon propagator lives entirely in the $k_\mu k_\nu$ term, and the $k_\mu k_\nu$ term is annihilated by conserved currents.* Because every photon in QED couples to the conserved electromagnetic current, this is why ξ drops out of every physical amplitude — one may compute in Feynman gauge, Landau gauge, or Yennie gauge and obtain the same cross section. It also furnishes a powerful and constantly used *check*: a correct gauge-invariant amplitude must be ξ-independent, so carrying a general ξ through a computation and watching it cancel is a standard internal consistency test, exploited repeatedly from Chapter 17 onward.

Worked Example 13.29 (The Møller kernel is the same in three gauges)**.** Consider the t-channel one-photon exchange between two electron currents, the kernel of $e^-e^- \to e^-e^-$ (Møller scattering) computed fully in Chapter 17. With incoming/outgoing momenta giving photon momentum $k = p_1 - p_3$, the two currents are the on-shell Dirac bilinears

$$\widetilde{J}_1^\mu = \bar{u}(p_3)\gamma^\mu u(p_1), \qquad \widetilde{J}_2^\nu = \bar{u}(p_4)\gamma^\nu u(p_2). \tag{13.144}$$

We verify current conservation directly and then watch ξ cancel. Contract the first current with $k_\mu = (p_1 - p_3)_\mu$ and use the Dirac equations $\not{p}_1 u(p_1) = m\,u(p_1)$ and $\bar{u}(p_3)\not{p}_3 = m\,\bar{u}(p_3)$ (with m the electron mass) from Chapter 11:

$$k_\mu \widetilde{J}_1^{\mu} = \bar{u}(p_3)(\not{p}_1 - \not{p}_3)u(p_1) = \bar{u}(p_3)(m - m)u(p_1) = 0, \tag{13.145}$$

and identically $k_\nu \widetilde{J}_2^{\nu} = 0$. This is the tree-level Ward identity in the flesh; it is the statement Eq. (13.141) for the specific on-shell electron current. Now form the exchange amplitude with the general-ξ propagator:

$$\begin{aligned} i\mathcal{M} &= \big[\bar{u}(p_3)(ie\gamma^\mu)u(p_1)\big]\,\frac{-i}{k^2 + i\varepsilon}\Big[\eta_{\mu\nu} - (1-\xi)\tfrac{k_\mu k_\nu}{k^2}\Big]\,\big[\bar{u}(p_4)(ie\gamma^\nu)u(p_2)\big] \\ &= \frac{-i\,(ie)^2}{k^2 + i\varepsilon}\Big[\,\widetilde{J}_1\!\cdot\!\widetilde{J}_2 - (1-\xi)\tfrac{(k\cdot\widetilde{J}_1)(k\cdot\widetilde{J}_2)}{k^2}\Big] = \frac{i\,e^2}{k^2 + i\varepsilon}\,\big[\bar{u}_3\gamma^\mu u_1\big]\big[\bar{u}_4\gamma_\mu u_2\big]. \end{aligned} \tag{13.146}$$

The bracketed ξ-term vanished by Eq. (13.145). The surviving amplitude is the Feynman-gauge result, manifestly independent of ξ; Landau ($\xi = 0$), Feynman ($\xi = 1$), and Yennie ($\xi = 3$) gauges return identical numbers. This is the explicit promise of Theorem 13.28 and the working procedure used throughout Chapters 17 and 18.

13.4.5 External photons: the polarization sum becomes $-\eta_{\mu\nu}$

The same conservation argument controls a second object that pervades cross-section calculations: the sum over the polarizations of a real, external photon. When a physical photon of momentum k ($k^2 = 0$) appears in the initial or final state, its two transverse polarization vectors $\epsilon_\mu(k,\lambda)$, $\lambda = \pm$, must be summed over (squared and summed for an unobserved final-state polarization, averaged for an unprepared initial one). The object that arises is

$$\Pi_{\mu\nu}(k) \equiv \sum_{\lambda=\pm} \epsilon_\mu(k,\lambda)\,\epsilon_\nu^*(k,\lambda). \tag{13.147}$$

This sum is *not* simply $-\eta_{\mu\nu}$ on its own — it cannot be, since a Lorentz-covariant object built only from a single null k_μ must contain k-dependent terms, while $\eta_{\mu\nu}$ does not. The transverse polarizations span only a two-dimensional space, so $\Pi_{\mu\nu}$ is a rank-two object, not the rank-four $-\eta_{\mu\nu}$. What is true, and what is all that is ever needed, is that $\Pi_{\mu\nu}$ may be *replaced* by $-\eta_{\mu\nu}$ whenever it is contracted into a conserved current. We make this precise.

Choose a frame in which $k^\mu = (\omega, 0, 0, \omega)$ (a photon moving in the $+z$ direction, $k^2 = 0$). The two transverse linear polarizations are $\epsilon^\mu(k,1) = (0,1,0,0)$ and $\epsilon^\mu(k,2) = (0,0,1,0)$; they satisfy $k\cdot\epsilon(k,\lambda) = 0$ and $\epsilon(k,\lambda)\cdot\epsilon^*(k,\lambda') = -\delta_{\lambda\lambda'}$ (the spatial minus of the mostly-minus metric). To express the sum covariantly introduce a reference null vector $\bar{k}^\mu = (\omega, 0, 0, -\omega)$, the momentum of a photon

moving the other way, with $\bar{k}^2 = 0$ and $k \cdot \bar{k} = 2\omega^2 \neq 0$. Direct evaluation of the four-by-four matrix $\sum_{\lambda=1,2} \epsilon_\mu \epsilon_\nu^*$ in this frame gives entries only in the $1,2$ (i.e. x, y) block, equal to δ_{ij} there; this is reproduced covariantly by

$$\sum_{\lambda=\pm} \epsilon_\mu(k,\lambda)\, \epsilon_\nu^*(k,\lambda) = -\eta_{\mu\nu} + \frac{k_\mu \bar{k}_\nu + \bar{k}_\mu k_\nu}{k \cdot \bar{k}}. \tag{13.148}$$

One checks this by components: the $-\eta_{\mu\nu}$ supplies $+1$ in each of the x, y, z diagonal slots and -1 in the 00 slot, while the second term, built from k and $\bar{k}$ which have no x, y components, cancels the unwanted 00, 03, 30, 33 entries and leaves exactly the transverse δ_{ij} in the x, y block. The reference vector $\bar{k}$ is arbitrary; the left-hand side does not know about it, so the $\bar{k}$-dependence on the right must cancel against anything physical it touches — and it does, again by current conservation.

Theorem 13.30 (Polarization-sum replacement)**.** *Let $\mathcal{M}^\mu(k)$ be a physical amplitude with one external photon of momentum k stripped of its polarization vector, so that the photon contributes $\epsilon_\mu^* \mathcal{M}^\mu$. If the amplitude obeys the Ward identity $k_\mu \mathcal{M}^\mu = 0$, then summing $|\epsilon^* \cdot \mathcal{M}|^2$ over physical polarizations may be performed with the replacement $\sum_\lambda \epsilon_\mu \epsilon_\nu^* \to -\eta_{\mu\nu}$:*

$$\sum_{\lambda=\pm} \left|\epsilon^*(k,\lambda)\cdot\mathcal{M}\right|^2 = \sum_{\lambda=\pm} \epsilon_\mu \epsilon_\nu^*\, \mathcal{M}^\mu \mathcal{M}^{*\nu} = -\eta_{\mu\nu}\, \mathcal{M}^\mu \mathcal{M}^{*\nu}. \tag{13.149}$$

Proof. Contract the completeness relation Eq. (13.148) into $\mathcal{M}^\mu \mathcal{M}^{*\nu}$:

$$\sum_\lambda \epsilon_\mu \epsilon_\nu^*\, \mathcal{M}^\mu \mathcal{M}^{*\nu} = -\eta_{\mu\nu} \mathcal{M}^\mu \mathcal{M}^{*\nu} + \frac{(k_\mu \mathcal{M}^\mu)(\bar{k}_\nu \mathcal{M}^{*\nu}) + (\bar{k}_\mu \mathcal{M}^\mu)(k_\nu \mathcal{M}^{*\nu})}{k \cdot \bar{k}}. \tag{13.150}$$

Both numerators in the second term contain a factor $k_\mu \mathcal{M}^\mu$ or its conjugate $k_\nu \mathcal{M}^{*\nu} = (k_\mu \mathcal{M}^\mu)^*$, which vanish by the Ward identity hypothesis. The reference-vector dependence disappears with them, leaving $-\eta_{\mu\nu} \mathcal{M}^\mu \mathcal{M}^{*\nu}$ as claimed. That the $\bar{k}$-dependence cancels is the consistency check that the physical answer is independent of the arbitrary reference vector, as it must be. □

This replacement is one of the most heavily used identities in the book: it turns every external-photon spin sum into a metric contraction, and it is what makes the unpolarized cross sections of Chapters 17 and 18 tractable. Note that it is the *same* fact as ξ-independence wearing a different hat. In both cases a k_μ-proportional piece — the longitudinal part of the propagator, or the reference-dependent part of the polarization sum — is the entire content of the unphysical degrees of freedom, and in both cases it is annihilated by current conservation. The propagator carries four index-pairs of which two are physical; the polarization sum carries two physical states out of a naive four; current conservation is the bridge that lets us pretend, inside any gauge-invariant amplitude, that all four are present with the simple metric weight.

Physical Insight

The replacement $\sum \epsilon\epsilon^* \to -\eta_{\mu\nu}$ is the amplitude-level shadow of the Gupta–Bleuler decoupling of Section 13.3. There, the subsidiary condition guaranteed that timelike and longitudinal photons — the would-be extra polarizations carried by $-\eta_{\mu\nu}$ relative to the two physical states — have cancelling contributions to all physical matrix elements, leaving a positive-norm transverse space. Here that same cancellation is what lets us add back the unphysical polarizations (the full $-\eta_{\mu\nu}$, not just the transverse projector) without changing the answer: their net contribution is zero precisely because the current is conserved. The two-degree-of-freedom photon is being counted the same way twice, once in the state space and once in the amplitude.

The argument given here is exact at tree level, where the Ward identity $k_\mu \mathcal{M}^\mu = 0$ follows directly from the Dirac equation, as the explicit calculation Eq. (13.145) showed. At higher orders the relevant statement is the all-orders Ward–Takahashi identity, which promotes current conservation to an operator identity among full Green's functions and guarantees both the ξ-independence of Theorem 13.28 and the polarization replacement Theorem 13.30 to every order in the loop expansion. That identity, and the diagrammatic and path-integral proofs of it, are the business of Chapter 19; we flag the upgrade here so that nothing in Chapters 17 and 18 relies on tree-level conservation in a way that would fail at one loop.

13.4.6 What has been built, and where the gauge term comes from

We have produced the object Part V runs on. The time-ordered photon two-point function is, in coordinate space and Feynman gauge, the massless scalar Feynman propagator times $-\eta_{\mu\nu}$ (Theorem 13.25); across the R_ξ family it is the boxed momentum-space tensor Eq. (13.135), obtained by inverting the gauge-fixed quadratic operator and recognizing the obstruction Eq. (13.139) to inverting the unfixed one. Its gauge-dependent $k_\mu k_\nu$ term is annihilated by the conserved matter current Eq. (11.158), so it never touches a physical amplitude (Theorem 13.28), and the corresponding statement for external photons replaces the polarization sum by $-\eta_{\mu\nu}$ inside any current-conserving amplitude (Theorem 13.30). This propagator is exported, unchanged, to the QED Feynman rules of Chapter 17 and is dressed by vacuum polarization in Chapter 19.

One question has been deferred at every turn and must now be answered: by what right did we add the gauge-fixing term $-\frac{1}{2\xi}(\partial A)^2$ to the Lagrangian in the first place? Canonically it was forced on us to make the Legendre transform non-singular; here it was forced on us to make the quadratic operator invertible.

But its true origin — the precise sense in which it is not an arbitrary modification of the theory but the unavoidable Jacobian of slicing the path integral transverse to gauge orbits — is the subject of the next section. There the redundancy is re-derived as the divergence of $\int \mathcal{D}A\, e^{iS}$ over the orbits of the gauge group, the Faddeev–Popov determinant is shown to be field-independent in the abelian case (so QED has no propagating ghosts), and the R_ξ generating functional and the propagator Eq. (13.135) re-emerge from first principles — with the warning, paid in full in Part VII, that the non-abelian case will not let the determinant be ignored.

13.5 The Path Integral, Gauge Orbits, and Abelian Faddeev–Popov

The propagator we extracted in Section 13.4 carried a free parameter ξ that entered the Lagrangian through a term $-\frac{1}{2\xi}(\partial_\mu A^\mu)^2$ we were forced to *add by hand* before the kinetic operator could be inverted. We justified that addition operationally — it lifts the longitudinal zero mode, it produces a propagator, and the ξ-dependence drops out of physical amplitudes by current conservation — but we never explained where it comes from. From the canonical side there is no fully satisfying answer: one either fixes the gauge completely and works with the genuine two degrees of freedom (Coulomb gauge), or enlarges the state space and carves out the physical sector afterwards (Gupta–Bleuler). Neither route delivers $-\frac{1}{2\xi}(\partial \cdot A)^2$ as a *derived* object. The path integral does, and that is the business of this section. We will re-derive the entire structure of the quantized photon — the gauge-fixing term, the R_ξ propagator, the free generating functional — from the single starting point $\int \mathcal{D}A\, e^{iS}$, and in doing so we will meet, in its simplest abelian incarnation, the Faddeev–Popov construction that Chapter 26 turns into the engine of non-abelian gauge theory. The abelian case is the right place to learn the machinery precisely because here it does something almost trivial: the determinant it produces is a field-independent constant, so QED has no propagating ghosts. Seeing exactly *why* it is trivial here is the cleanest possible preparation for seeing why it is not trivial there.

13.5.1 The naive photon path integral and its divergence

We begin where the path-integral programme of Chapter 10 tells us to begin: write the generating functional as a sum over field histories weighted by e^{iS}. For the free electromagnetic field, with the Maxwell action of Eq. (8.75),

$$Z \;=\; \int \mathcal{D}A\; \exp\Big(i \int d^4x\; \big(-\tfrac{1}{4} F_{\mu\nu} F^{\mu\nu} \big) \Big), \qquad F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu, \tag{13.151}$$

the measure $\mathcal{D}A = \prod_x \prod_{\mu=0}^{3} dA_\mu(x)$ ranging over all four components of A_μ at every spacetime point, in exact analogy with the scalar measure of Theorem 10.16.

This is the obvious thing to write down, and it is wrong — or rather, it is ill-defined — in a way we can diagnose precisely.

To expose the trouble, put the action into the canonical quadratic form $S = \frac{1}{2}\int A\,\mathcal{O}\,A$ that Chapter 10 taught us to read a propagator off of. Expand the field strength,

$$-\tfrac{1}{4}F_{\mu\nu}F^{\mu\nu} = -\tfrac{1}{2}(\partial_\mu A_\nu\,\partial^\mu A^\nu - \partial_\mu A_\nu\,\partial^\nu A^\mu), \tag{13.152}$$

where the factor $\frac{1}{2}$ comes from $F_{\mu\nu}F^{\mu\nu} = 2(\partial_\mu A_\nu \partial^\mu A^\nu - \partial_\mu A_\nu \partial^\nu A^\mu)$. Integrate each term by parts, discarding boundary terms as the vacuum boundary conditions of Section 10.3.4 permit: the first term gives $+\frac{1}{2}\,A_\nu\,\partial^2 A^\nu$ and the second $-\frac{1}{2}\,A_\nu\,\partial^\nu\partial_\mu A^\mu$. Collecting,

$$S \;=\; \tfrac{1}{2}\int d^4x\; A_\mu\,(\partial^2 g^{\mu\nu} - \partial^\mu\partial^\nu)\,A_\nu \;\equiv\; \tfrac{1}{2}\int d^4x\; A_\mu\,\mathcal{O}^{\mu\nu}\,A_\nu, \tag{13.153}$$

so the kinetic operator is $\mathcal{O}^{\mu\nu} = \partial^2 g^{\mu\nu} - \partial^\mu\partial^\nu$. Pass to momentum space with the book convention $A_\mu(x) = \int \frac{d^4k}{(2\pi)^4} e^{-ik\cdot x}\widetilde{A}_\mu(k)$, under which $\partial_\mu \to -ik_\mu$, $\partial^2 \to -k^2$, and the operator becomes the matrix

$$\widetilde{\mathcal{O}}^{\mu\nu}(k) \;=\; -k^2 g^{\mu\nu} + k^\mu k^\nu \;=\; -k^2\Big(g^{\mu\nu} - \frac{k^\mu k^\nu}{k^2}\Big) \;=\; -k^2\,P_T^{\mu\nu}(k), \tag{13.154}$$

where in the last step we have recognized the *transverse projector*

$$P_T^{\mu\nu}(k) \;\equiv\; g^{\mu\nu} - \frac{k^\mu k^\nu}{k^2}, \qquad P_L^{\mu\nu}(k) \;\equiv\; \frac{k^\mu k^\nu}{k^2}, \qquad P_T + P_L = g. \tag{13.155}$$

These satisfy the projector algebra $P_T^2 = P_T$, $P_L^2 = P_L$, $P_T P_L = 0$, as one checks directly: ${P_L}^\mu{}_\rho {P_L}^\rho{}_\nu = \frac{k^\mu k_\rho}{k^2}\frac{k^\rho k^\nu}{k^2} = \frac{k^\mu k^\nu}{k^2} = P_L^{\mu\nu}$, whence $P_T^2 = (g - P_L)^2 = g - 2P_L + P_L = P_T$.

Now the obstruction is manifest. The kinetic operator Eq. (13.154) is $-k^2$ times a *projector onto a three-dimensional subspace*; it has a zero eigenvalue on the orthogonal one-dimensional subspace spanned by k^μ. Explicitly,

$$\widetilde{\mathcal{O}}^{\mu\nu}(k)\,k_\nu \;=\; -k^2 k^\mu + k^\mu\,k^2 \;=\; 0. \tag{13.156}$$

An operator with a nontrivial kernel cannot be inverted, so there is no propagator: the Gaussian integral Eq. (13.151), viewed mode by mode, is flat (its quadratic form vanishes) along every longitudinal direction $\widetilde{A}_\mu(k) \propto k_\mu$, and an integral $\int dA\, e^{i\cdot 0} = \int dA$ over such a direction is simply infinite. The path integral Eq. (13.151) diverges, and it diverges in a structured way: along precisely the directions $\widetilde{A}_\mu \propto k_\mu$, i.e. $A_\mu(x) = \partial_\mu\alpha(x)$ in position space.

This is not a pathology to be regulated away; it is gauge redundancy made quantitative. The configurations A_μ and $A_\mu + \partial_\mu\alpha$ are related by the abelian gauge transformation of Theorem 8.1, they have identical field strength (Eq. (8.164)),

and therefore identical action, $S[A] = S[A+\partial\alpha]$. The integrand of Eq. (13.151) is exactly constant along the direction $A \to A+\partial\alpha$, and the measure $\mathcal{D}A$ integrates over that direction without bound. The path integral is summing the same physics infinitely many times — once for every gauge function α — and the divergence is the volume of that overcounting.

Physical Insight

The longitudinal flat direction Eq. (13.156) is the path-integral face of the same fact that defeated naive canonical quantization in Section 13.1: the conjugate momentum to A^0 vanishes identically, $\pi^0 \equiv 0$, because the Lagrangian contains no $\dot{A}^0$. There the non-invertibility was of the Legendre map; here it is of the kinetic operator. Both are statements that A_μ has four components but only the physical, transverse part carries dynamics, and both are cured by the same idea — remove the redundant direction from the integration — implemented once with constraints and Dirac brackets, once with the Faddeev–Popov insertion we now build.

13.5.2 Gauge orbits and the geometry of the redundancy

The diagnosis points straight to the cure. We are integrating over a space $\mathcal{A}$ of gauge fields that is foliated into *gauge orbits*, and we are double-counting because each orbit is traversed in full.

Definition 13.31 (Gauge orbit and gauge group)**.** For a fixed configuration A_μ, its *gauge orbit* is the set of all configurations reachable from it by an abelian gauge transformation,

$$\mathcal{O}_A \;\equiv\; \{\, A^\alpha_\mu \;=\; A_\mu + \partial_\mu\alpha \;:\; \alpha \in \mathcal{G} \,\}, \tag{13.157}$$

where the *gauge group* $\mathcal{G}$ is the abelian group of smooth functions $\alpha : \mathbb{R}^{1,3} \to \mathbb{R}$ under pointwise addition, $\alpha \cdot \beta = \alpha + \beta$, acting on $\mathcal{A}$ by Eq. (8.161). The action, the measure, and every gauge-invariant observable are constant on each orbit.

The space of physically distinct field configurations is the quotient $\mathcal{A}/\mathcal{G}$, in which each orbit collapses to a single point. The integral we *want* runs over $\mathcal{A}/\mathcal{G}$; the integral we *have*, Eq. (13.151), runs over $\mathcal{A}$ and therefore overshoots by the "volume" $\int_{\mathcal{G}}\mathcal{D}\alpha$ of a single orbit — an infinite constant identical for every orbit, since the abelian orbits are all copies of the same group $\mathcal{G}$. The task is to factor that constant out cleanly, keeping the Jacobian honest.

The cleanest way to learn the mechanism is to watch it work in a finite-dimensional model where every integral is elementary. We do this first, then promote it to fields.

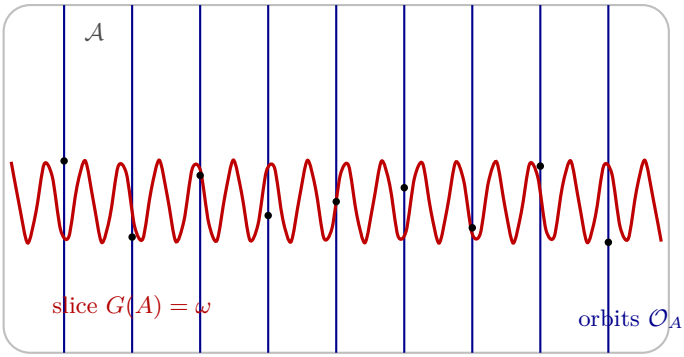

Figure 13.5: The configuration space $\mathcal{A}$ of gauge fields, foliated into gauge orbits $\mathcal{O}_A$ (blue), the curves $\alpha \mapsto A + \partial\alpha$ along which the action is constant. The naive integral Eq. (13.151) sums over all of $\mathcal{A}$ and so counts every orbit infinitely often. The Faddeev–Popov gauge-fixing surface $G(A) = \omega$ (red) is chosen to cut each orbit exactly once (black dots); integrating over the slice, with the Jacobian Δ_{FP} that corrects for the angle of intersection, replaces the integral over $\mathcal{A}$ by an integral over $\mathcal{A}/\mathcal{G}$ times the (factored-out) orbit volume. In the abelian theory the orbits are parallel straight lines, every slice $\partial\cdot A = \omega$ meets each exactly once, and the Jacobian is a field-independent constant.

Worked Example 13.32 (The Faddeev–Popov trick in two dimensions)**.** Consider an ordinary integral over the plane, $I = \int d^2x\, e^{iS(\mathbf{x})}$, where the "action" $S(\mathbf{x}) = S(r)$ depends only on the radius $r = |\mathbf{x}|$ — a model of a theory with a rotational "gauge symmetry," the rotation group $SO(2)$ playing the role of $\mathcal{G}$. The orbits are circles $r = \text{const}$; the integral overcounts by the angular volume $\int_0^{2\pi} d\theta = 2\pi$ of each orbit. We extract that factor by the Faddeev–Popov method, without ever using polar coordinates, so that the steps transcribe verbatim to the field theory.

Pick a "gauge condition" — a function $g(\mathbf{x})$ whose vanishing selects one point on each orbit. Take $g(\mathbf{x}) = x_2$ (the positive x_1-axis is the slice $g = 0$, $x_1 > 0$). Let $\mathbf{x}^\theta = R(\theta)\mathbf{x}$ be the rotated point. Define the Faddeev–Popov "determinant" $\Delta(\mathbf{x})$ by the identity

$$1 \;=\; \Delta(\mathbf{x}) \int_0^{2\pi} d\theta\; \delta(g(\mathbf{x}^\theta)), \qquad \Longrightarrow \qquad \Delta(\mathbf{x})^{-1} = \int_0^{2\pi} d\theta\; \delta(g(\mathbf{x}^\theta)). \quad (13.158)$$

With $\mathbf{x} = (r\cos\phi, r\sin\phi)$ we have $g(\mathbf{x}^\theta) = r\sin(\phi + \theta)$, which vanishes (for $r \neq 0$, within a period) at $\theta_* = -\phi$ where it crosses with slope $\frac{d}{d\theta} g(\mathbf{x}^\theta)\big|_{\theta_*} = r\cos(\phi + \theta_*) = r$. The delta function then gives $\Delta(\mathbf{x})^{-1} = 1/\big|\frac{d}{d\theta} g(\mathbf{x}^\theta)\big|_{\theta_*} = 1/r$, so

$$\Delta(\mathbf{x}) \;=\; \Big|\frac{\partial g(\mathbf{x}^\theta)}{\partial\theta}\Big|_{g=0} \;=\; r. \quad (13.159)$$

The determinant is the rate at which the gauge condition changes as we move along

the orbit, evaluated on the slice — exactly the geometric "angle of intersection" factor of Fig. 13.5. Insert Eq. (13.158) into I and interchange integrals:

$$I = \int_0^{2\pi} d\theta \int d^2x\, e^{iS(r)}\, \Delta(\mathbf{x})\, \delta\big(g(\mathbf{x}^\theta)\big). \tag{13.160}$$

Now substitute $\mathbf{x} \to \mathbf{x}^{-\theta}$ in the inner integral. The measure d^2x is rotation-invariant, $S(r)$ is rotation-invariant, and Δ is rotation-invariant (it depends only on r); only the delta function moves, $g(\mathbf{x}^\theta) \to g(\mathbf{x})$. The integrand is then independent of θ, and the θ-integral factors out as the orbit volume $\int_0^{2\pi} d\theta = 2\pi$:

$$I = \Big(\int_0^{2\pi} d\theta\Big) \int d^2x\, e^{iS(r)}\, \Delta(\mathbf{x})\, \delta\big(g(\mathbf{x})\big) = 2\pi \int d^2x\, e^{iS(r)}\, r\, \delta(x_2). \tag{13.161}$$

The last integral over the slice $x_2 = 0$, $x_1 = r > 0$, is $\int_0^\infty dr\, e^{iS(r)}\, r$ — precisely $\frac{1}{2\pi}$ of $\int d^2x\, e^{iS} = 2\pi \int_0^\infty r\, dr\, e^{iS}$, as it must be. The redundant angular volume has been split off cleanly, and the price was a single Jacobian factor $\Delta = r$ supplied by Eq. (13.158). Every structural feature of the field-theory derivation below — the inserted "1," the determinant as $\partial(\text{gauge condition})/\partial(\text{gauge parameter})$, the change of variables that frees the orbit volume, the leftover integral over a single slice — is already present here.

13.5.3 The Faddeev–Popov identity

We now repeat Theorem 13.32 for the photon, with the rotation angle θ replaced by the gauge function α, the radius r by the field A_μ, and the slice $g(\mathbf{x}) = 0$ by a gauge condition on A.

Definition 13.33 (Gauge-fixing function)**.** A *gauge-fixing function* is a functional $G(A)$ of the gauge field, chosen so that the surface $G(A) = \omega$ (for a prescribed function $\omega(x)$) intersects each gauge orbit Eq. (13.157) exactly once. The Lorenz family is generated by

$$G(A)(x) \;\equiv\; \partial_\mu A^\mu(x), \tag{13.162}$$

so that $G(A) = \omega$ reads $\partial_\mu A^\mu = \omega$, reducing to the Lorenz gauge $\partial_\mu A^\mu = 0$ when $\omega = 0$.

Following Eq. (13.158) verbatim, define the *Faddeev–Popov determinant* $\Delta_{\mathrm{FP}}[A]$ by inserting unity:

$$1 \;=\; \Delta_{\mathrm{FP}}[A] \int \mathcal{D}\alpha\;\, \delta\big(G(A^\alpha) - \omega\big), \tag{13.163}$$

where $\delta(\cdots) = \prod_x \delta\big(G(A^\alpha)(x) - \omega(x)\big)$ is a functional delta and $\mathcal{D}\alpha = \prod_x d\alpha(x)$ is the (translation-invariant) Haar measure on the abelian group $\mathcal{G}$. We now compute Δ_{FP} and prove the two facts that make abelian gauge theory special.

Theorem 13.34 (The abelian Faddeev–Popov determinant)**.** *With the Lorenz gauge-fixing function Eq. (13.162), the determinant defined by Eq. (13.163) is*

$$\Delta_{\mathrm{FP}}[A] \;=\; \det(\partial^2), \tag{13.164}$$

independent of the gauge field A_μ and of the function ω. *It is therefore an (infinite) multiplicative constant that may be pulled outside the functional integral.*

Proof. Under a gauge transformation the Lorenz function shifts by the d'Alembertian of the gauge parameter,

$$G(A^\alpha) = \partial_\mu(A^\mu + \partial^\mu\alpha) = \partial_\mu A^\mu + \partial^2\alpha = G(A) + \partial^2\alpha, \tag{13.165}$$

so the constraint $G(A^\alpha) - \omega = 0$ is the linear equation $\partial^2\alpha = \omega - G(A)$ for α. To evaluate $\Delta_{\mathrm{FP}}^{-1} = \int \mathcal{D}\alpha\, \delta\big(G(A) + \partial^2\alpha - \omega\big)$, change integration variable from α to $\eta \equiv G(A^\alpha) - \omega = G(A) + \partial^2\alpha - \omega$. The two are related linearly, with functional Jacobian

$$\frac{\delta\eta(x)}{\delta\alpha(y)} = \frac{\delta}{\delta\alpha(y)}\big(\partial^2\alpha(x)\big) = \partial_x^2\,\delta^4(x-y), \qquad \mathcal{D}\eta = \det\!\Big(\frac{\delta\eta}{\delta\alpha}\Big)\,\mathcal{D}\alpha = \det(\partial^2)\,\mathcal{D}\alpha. \tag{13.166}$$

The crucial observation is that this Jacobian, $\delta\eta/\delta\alpha = \partial^2$, *does not contain A at all*: the shift Eq. (13.165) is linear in α with a constant (A-independent) coefficient operator ∂^2, because the gauge transformation $A \to A + \partial\alpha$ is itself an affine shift of A rather than a transformation whose generator depends on A. Therefore

$$\Delta_{\mathrm{FP}}[A]^{-1} = \int \mathcal{D}\alpha\; \delta(\eta) = \int \frac{\mathcal{D}\eta}{\det(\partial^2)}\; \delta(\eta) = \frac{1}{\det(\partial^2)}, \tag{13.167}$$

which is Eq. (13.164). There is no A- or ω-dependence anywhere in the result: the single solution α_* of $\partial^2\alpha_* = \omega - G(A)$ exists and is unique once boundary conditions fix the kernel of ∂^2, and the height of the delta-function spike is governed entirely by the constant operator ∂^2. □

Two points deserve emphasis, because they are exactly the points where the non-abelian theory will diverge from this one. First, the determinant is the functional analogue of the factor $r = \partial g(\mathbf{x}^\theta)/\partial\theta$ in Eq. (13.159): it is the variation of the gauge condition with respect to the gauge parameter, $\delta G(A^\alpha)/\delta\alpha = \partial^2$, evaluated on the constraint surface. Second, and decisively, that variation is field-independent. We isolate the reason as a proposition, since its failure is what creates ghosts.

Proposition 13.35 (Why the abelian determinant decouples)**.** *The Faddeev–Popov operator is the derivative of the gauge condition along the orbit, $M(x,y) \equiv \delta G(A^\alpha)(x)/\delta\alpha(y)\big|_{\alpha=0}$. In the abelian theory $M = \partial^2$ is independent of A, so* $\det M$ *factors out of the path integral as a constant. In a non-abelian theory it is not.*

Proof. For an abelian gauge field the orbit map is the affine shift $A_\mu^\alpha = A_\mu + \partial_\mu \alpha$ of Theorem 8.1, so $\delta A_\mu^\alpha / \delta \alpha = \partial_\mu$ is constant and $M = \partial_\mu \, \delta A^{\alpha\,\mu}/\delta\alpha = \partial^2$, as in Eq. (13.166). For a non-abelian gauge field with gauge group elements labelled by $\alpha^a(x)$ and covariant derivative $D_\mu = \partial_\mu - igA_\mu^a T^a$ (the convention of Yang–Mills theory, Chapter 25), the infinitesimal gauge transformation is $A_\mu^a \to A_\mu^a + \frac{1}{g} D_\mu^{ab} \alpha^b$ with $D_\mu^{ab} = \partial_\mu \delta^{ab} + g f^{acb} A_\mu^c$, so the variation of the gauge condition $G^a(A) = \partial^\mu A_\mu^a$ is

$$M^{ab}(x,y) = \frac{\delta G^a(A^\alpha)(x)}{\delta \alpha^b(y)}\Big|_{\alpha=0} = \frac{1}{g}\,\partial^\mu D_\mu^{ab}\,\delta^4(x-y) = \frac{1}{g}\,\partial^\mu\big(\partial_\mu \delta^{ab} + g f^{acb} A_\mu^c\big)\delta^4(x-y). \tag{13.168}$$

The term $f^{acb} A_\mu^c$ depends explicitly on the gauge field, so $\det M = \det(\partial^\mu D_\mu)$ is a nontrivial *functional of* A and cannot be pulled outside the integral. Setting the structure constants $f^{acb} = 0$ collapses Eq. (13.168) to the abelian $M = \partial^2$ of Eq. (13.166), recovering Theorem 13.34. □

Physical Insight

The whole difference between QED and Yang–Mills, at the level of gauge fixing, is the single clause "$f^{abc} = 0$." Abelian gauge orbits are parallel straight lines (an affine action), so a flat slice cuts every one at the same constant angle and the Jacobian is a number. Non-abelian orbits are curved (the group acts nonlinearly on A), the angle of intersection varies from orbit to orbit and depends on where on $\mathcal{A}$ you are, and the Jacobian becomes a field-dependent determinant. That determinant, written as a Gaussian integral over anticommuting fields in Chapter 26, *is* the Faddeev–Popov ghost. QED has ghosts too, in the formal sense that $\det(\partial^2)$ can be written as a ghost integral — but the ghosts are free, decoupled from A_μ, and contribute only an overall constant, so we never speak of them. The reader should leave this section knowing that the absence of ghosts in QED is not an accident of the abelian theory's simplicity but a precise consequence of the linearity of its gauge action.

For completeness we record the gauge invariance of Δ_{FP} as a functional, which in the abelian case is automatic (the determinant is constant) but which is the load-bearing property in the general construction and which we will reuse in the next subsection.

Lemma 13.36 (Gauge invariance of Δ_{FP})**.** *The functional defined by Eq. (13.163) is invariant under gauge transformations of its argument,* $\Delta_{\mathrm{FP}}[A^\beta] = \Delta_{\mathrm{FP}}[A]$ *for any* $\beta \in \mathcal{G}$.

Proof. By definition $\Delta_{\mathrm{FP}}[A^\beta]^{-1} = \int \mathcal{D}\alpha \; \delta\big(G(A^{\beta\,\alpha}) - \omega\big)$. Because $\mathcal{G}$ is a group, the composition of the gauge transformation by β followed by that by α is the

transformation by their product, $A^{\beta\,\alpha} = A^{\beta\cdot\alpha}$; for the abelian group $\beta\cdot\alpha = \alpha+\beta$. Change integration variable to $\alpha' = \alpha + \beta$. The Haar measure is translation-invariant, $\mathcal{D}\alpha' = \mathcal{D}\alpha$, so

$$\Delta_{\mathrm{FP}}[A^{\beta}]^{-1} = \int \mathcal{D}\alpha'\; \delta\big(G(A^{\alpha'}) - \omega\big) = \Delta_{\mathrm{FP}}[A]^{-1}, \tag{13.169}$$

proving the claim. (In the abelian Lorenz gauge both sides equal $1/\det(\partial^2)$ outright, but the proof uses only the group law and the invariance of $\mathcal{D}\alpha$, and so carries over unchanged to the non-abelian case, where it is essential.) □

13.5.4 Factoring out the gauge volume

We now insert the resolution of unity Eq. (13.163) into the divergent generating functional Eq. (13.151) and disentangle the infinity, exactly as in Eq. (13.161):

$$Z = \int \mathcal{D}A\; e^{iS[A]} = \int \mathcal{D}A\; e^{iS[A]}\,\Delta_{\mathrm{FP}}[A] \int \mathcal{D}\alpha\; \delta\big(G(A^{\alpha}) - \omega\big) = \int \mathcal{D}\alpha \int \mathcal{D}A\; e^{iS[A]}\,\Delta_{\mathrm{FP}}[A]\,\delta(G($$

(13.170)

the order of integration interchanged in the last step. Now change variables in the inner integral by relabelling $A \to A^{-\alpha}$, equivalently writing the dummy field as $A = B^{-\alpha}$ so that $B = A^{\alpha}$. Three invariances conspire:

- the action is gauge invariant, $S[A] = S[B^{-\alpha}] \equiv S[B]$, because $F_{\mu\nu}$ is (Eq. (8.164));
- the measure is gauge invariant, $\mathcal{D}A = \mathcal{D}B$, since a gauge transformation is the constant shift $A_\mu \to A_\mu + \partial_\mu\alpha$ of the integration variable, with unit Jacobian (the shift is independent of A);
- the Faddeev–Popov determinant is gauge invariant, $\Delta_{\mathrm{FP}}[A] = \Delta_{\mathrm{FP}}[B]$, by Theorem 13.36 (and trivially by Theorem 13.34, being constant).

Under the relabelling the constraint becomes $G(A^{\alpha}) = G(B)$, so the entire integrand loses its α-dependence and the α-integral factors off as the gauge-group volume:

$$Z = \underbrace{\Big(\int \mathcal{D}\alpha\Big)}_{V_{\mathcal{G}}} \int \mathcal{D}B\; e^{iS[B]}\,\Delta_{\mathrm{FP}}[B]\,\delta\big(G(B) - \omega\big). \tag{13.171}$$

The divergence of Eq. (13.151) has been isolated in the single multiplicative constant $V_{\mathcal{G}} = \int\mathcal{D}\alpha$, the (infinite) volume of the gauge group. It is the field-theoretic counterpart of the 2π in Eq. (13.161). Because every physical observable is computed from *normalized* correlators $\langle\cdots\rangle = (\text{numerator})/Z$ in which the same $V_{\mathcal{G}}$ appears upstairs and downstairs, it cancels identically and may be

dropped. Renaming $B \to A$, the well-defined, gauge-fixed generating functional is

$$Z[\omega] \;=\; \det(\partial^2) \int \mathcal{D}A \; e^{iS[A]} \, \delta(\partial_\mu A^\mu - \omega), \tag{13.172}$$

having substituted Eq. (13.164) for the constant determinant and Eq. (13.162) for G. The delta function now restricts the integral to a single representative of each orbit — one point per orbit, the dots of Fig. 13.5 — and the overcounting is gone.

Caution

The Faddeev–Popov construction assumes the slice $G(A) = \omega$ meets each orbit *exactly* once, so that Eq. (13.163) really is a resolution of unity. In the abelian theory on $\mathbb{R}^{1,3}$ this holds: $\partial^2\alpha = \omega - \partial\cdot A$ has a unique solution with vanishing boundary conditions, so the slice is hit once. In non-abelian theories, beyond perturbation theory, a covariant slice generally intersects an orbit *several* times — the Gribov ambiguity — and Eq. (13.163) overcounts the residual copies. This does not affect perturbation theory (it concerns large gauge fields far from $A = 0$) and is invisible in QED; we flag it here and treat it where it bites, in the non-perturbative chapters. As of the mid-2020s a fully satisfactory global gauge fixing of non-abelian theory remains an open problem; the perturbative construction we use throughout is unaffected.

13.5.5 The Gaussian average over ω: origin of the gauge-fixing term

Equation Eq. (13.172) is correct but inconvenient: the delta function $\delta(\partial\cdot A - \omega)$ is awkward inside a perturbative expansion, and we are still carrying the arbitrary function ω. Both annoyances are removed by one observation. The left-hand side $Z[\omega]$ does *not actually depend on* ω: changing ω slides the slice from one representative of each orbit to another, and since the integrand on Eq. (13.171) is constant along orbits, the value is unchanged. (Concretely, in Eq. (13.172) a shift $\omega \to \omega + \partial^2\lambda$ is undone by the gauge transformation $A \to A - \partial\lambda$ under which the measure and action are invariant.) We are therefore free to average $Z[\omega]$ over ω with *any* normalized weight we like; the result is still Z up to a constant. Choose the Gaussian weight

$$Z \;\propto\; \int \mathcal{D}\omega \; \exp\Big(-\frac{i}{2\xi} \int d^4x \, \omega^2 \Big) \, Z[\omega], \qquad \xi \in (0, \infty), \tag{13.173}$$

where ξ is a real parameter and the proportionality absorbs the (ω-independent, hence physically irrelevant) normalization of the Gaussian. Substituting Eq. (13.172)

and pulling the field-independent constant $\det(\partial^2)$ out front,

$$Z \;\propto\; \det(\partial^2)\int \mathcal{D}A\; e^{iS[A]} \int \mathcal{D}\omega\; \exp\Big(-\frac{i}{2\xi}\int \omega^2\Big)\,\delta(\partial_\mu A^\mu - \omega). \tag{13.174}$$

The ω-integral is now trivial: the delta function sets $\omega = \partial_\mu A^\mu$ everywhere, replacing $\int \omega^2$ by $\int (\partial_\mu A^\mu)^2$ and removing the delta. We are left with

$$Z \;\propto\; \det(\partial^2)\int \mathcal{D}A\; \exp\Big(i\int d^4x\,\Big[-\tfrac{1}{4}F_{\mu\nu}F^{\mu\nu} - \frac{1}{2\xi}(\partial_\mu A^\mu)^2\Big]\Big). \tag{13.175}$$

This is the result the section was aimed at. The term $-\frac{1}{2\xi}(\partial_\mu A^\mu)^2$ that we were forced to insert by fiat in Section 13.4 has now *emerged*, with its sign and its factor of $\frac{1}{2\xi}$ fixed, as nothing more than the Gaussian average over the family of Lorenz slices. It is not a modification of electromagnetism — the physics is independent of ξ exactly because $Z[\omega]$ was independent of ω — but a bookkeeping device for integrating over orbits once. The constant $\det(\partial^2)$ stands outside the A-integral and cancels in every normalized correlator: *this is the precise statement that QED has no propagating ghost.* The effective gauge-fixed action under the path integral is

$$S_\xi[A] = \int d^4x\,\Big[-\tfrac{1}{4}F_{\mu\nu}F^{\mu\nu} - \frac{1}{2\xi}(\partial_\mu A^\mu)^2\Big], \tag{13.176}$$

the R_ξ family, with the Feynman gauge $\xi = 1$ the computational default recorded in Chapter A. Had the determinant been field-dependent — the non-abelian case of Theorem 13.35 — we could not have pulled it out, and we would have been forced to represent $\det M[A]$ as a Gaussian integral over anticommuting scalar fields $c, \bar{c}$, the Faddeev–Popov ghosts, added to the action as $\bar{c}\,M[A]\,c$ and coupled to A through M. That is the construction of Chapter 26; here $M = \partial^2$ is a constant and the ghosts are free spectators we discard.

13.5.6 The R_ξ propagator from the Gaussian integral

With the gauge-fixing term in place the kinetic operator is no longer degenerate, and the Gaussian integral Eq. (13.175) can be done by the inversion method of Section 10.4.3. Integrating the new term by parts, $-\frac{1}{2\xi}(\partial_\mu A^\mu)(\partial_\nu A^\nu) \to +\frac{1}{2\xi}A_\mu \partial^\mu\partial^\nu A_\nu$, and adding it to Eq. (13.153), the gauge-fixed action takes the quadratic form $S_\xi = \frac{1}{2}\int A_\mu\, \mathcal{O}_\xi^{\mu\nu} A_\nu$ with

$$\mathcal{O}_\xi^{\mu\nu} = \partial^2 g^{\mu\nu} - \Big(1 - \tfrac{1}{\xi}\Big)\partial^\mu\partial^\nu, \qquad \widetilde{\mathcal{O}}_\xi^{\mu\nu}(k) = -k^2 g^{\mu\nu} + \Big(1 - \tfrac{1}{\xi}\Big)k^\mu k^\nu \tag{13.177}$$

in momentum space. The single new term $+\frac{1}{\xi}k^\mu k^\nu$ has lifted the longitudinal zero mode: where Eq. (13.154) annihilated k_ν, now

$$\widetilde{\mathcal{O}}_\xi^{\mu\nu}(k)\,k_\nu = -k^2 k^\mu + \Big(1 - \tfrac{1}{\xi}\Big)k^2 k^\mu = -\tfrac{1}{\xi}\,k^2 k^\mu \neq 0. \tag{13.178}$$

The operator is invertible, and the cleanest inversion uses the projectors Eq. (13.155). Decompose $\widetilde{\mathcal{O}}_\xi$ on the transverse and longitudinal subspaces using $g = P_T + P_L$ and $k^\mu k^\nu = k^2 P_L$:

$$\widetilde{\mathcal{O}}_\xi = -k^2(P_T + P_L) + \Big(1 - \tfrac{1}{\xi}\Big)k^2 P_L = -k^2\, P_T - \frac{k^2}{\xi}\, P_L. \tag{13.179}$$

On each eigenspace $\widetilde{\mathcal{O}}_\xi$ is now a nonzero scalar, so its inverse is obtained by inverting those scalars projector by projector,

$$\widetilde{\mathcal{O}}_\xi^{-1} = -\frac{1}{k^2}\, P_T - \frac{\xi}{k^2}\, P_L, \tag{13.180}$$

as one verifies by direct multiplication using $P_T^2 = P_T$, $P_L^2 = P_L$, $P_T P_L = 0$:

$$\widetilde{\mathcal{O}}_\xi\, \widetilde{\mathcal{O}}_\xi^{-1} = \Big(-k^2 P_T\Big)\Big(-\tfrac{1}{k^2}P_T\Big) + \Big(-\tfrac{k^2}{\xi}P_L\Big)\Big(-\tfrac{\xi}{k^2}P_L\Big) = P_T + P_L = g = \mathbf{1}. \tag{13.181}$$

The photon propagator is $\widetilde{D}_{\mu\nu} = i\,\widetilde{\mathcal{O}}_\xi^{-1}$, with the factor of i in the same convention as the scalar Eq. (10.110) (so that $\mathcal{O}_\xi D = i\delta$, matching the canonical normalization). Substituting the projectors back,

$$\widetilde{D}_{\mu\nu}(k) = i\,\widetilde{\mathcal{O}}_\xi^{-1}{}_{\mu\nu} = -\frac{i}{k^2}\big(P_T + \xi P_L\big)_{\mu\nu} = \frac{-i}{k^2 + i\varepsilon}\Big(g_{\mu\nu} - (1-\xi)\frac{k_\mu k_\nu}{k^2}\Big), \tag{13.182}$$

where we used $P_T + \xi P_L = g_{\mu\nu} - \frac{k_\mu k_\nu}{k^2} + \xi\frac{k_\mu k_\nu}{k^2} = g_{\mu\nu} - (1-\xi)\frac{k_\mu k_\nu}{k^2}$, and restored the $i\varepsilon$ inherited from the vacuum tilt of Section 10.3.4 exactly as in the scalar case. This is, character for character, the R_ξ propagator Eq. (13.135) obtained from canonical considerations in the previous section: the Feynman gauge $\xi = 1$ gives the simple $-ig_{\mu\nu}/(k^2 + i\varepsilon)$, the Landau gauge $\xi = 0$ projects onto the purely transverse $-iP_{T\,\mu\nu}/k^2$, and the longitudinal piece carries the entire ξ-dependence. The path integral has reproduced the propagator the perturbation theory of Part V is built on, and — unlike the canonical derivation — it produced the gauge-fixing term that defines ξ rather than postulating it.

13.5.7 The free photon generating functional

Having a non-degenerate Gaussian, we can now couple a source and read off the full free generating functional, the object that will deliver the QED Feynman rules in Chapter 17. Add to the gauge-fixed action a linear source term $\int d^4x\, J^\mu A_\mu$ — with J^μ an external current, the photon's analogue of the scalar source J of Eq. (10.86) — and define

$$Z_0[J] = \int \mathcal{D}A\, \exp\Big(i\int d^4x\, \Big[\tfrac{1}{2}A_\mu \mathcal{O}_\xi^{\mu\nu} A_\nu + J^\mu A_\mu\Big]\Big), \tag{13.183}$$

where the free determinant $\det(\partial^2)$ has been absorbed into the overall normalization $Z_0[0]$, since it is J-independent. This is a Gaussian integral identical in

structure to the scalar one of Section 10.4, with the scalar kinetic operator $\mathcal{O}$ promoted to the matrix $\mathcal{O}_\xi^{\mu\nu}$ and the source contracted with a Lorentz index. Completing the square exactly as there — shift $A_\mu \to A_\mu - \mathcal{O}_\xi^{-1}{}_{\mu\nu} J^\nu$, the leftover fluctuation integral being $Z_0[0]$ — yields the closed form

$$\boxed{Z_0[J] = Z_0[0]\,\exp\Big(-\tfrac{1}{2}\int d^4x\, d^4y\; J^\mu(x)\, D_{\mu\nu}(x-y)\, J^\nu(y)\Big),} \tag{13.184}$$

the photon image of the scalar master formula Eq. (10.111), with the kernel the very propagator $D_{\mu\nu} = i\,\mathcal{O}_\xi^{-1}$ just computed in Eq. (13.182). (Writing $D_{\mu\nu} = i\,\mathcal{O}_\xi^{-1}{}_{\mu\nu}$, the exponent is the familiar $-\frac{i}{2}\int J^\mu \mathcal{O}_\xi^{-1}{}_{\mu\nu} J^\nu$ of the generating-functional master identity.) We record the statement formally.

Theorem 13.37 (Free photon generating functional)**.** *The free, gauge-fixed electromagnetic generating functional is Eq. (13.184), with $D_{\mu\nu}$ the R_ξ propagator Eq. (13.182). Its connected two-point function is the photon propagator,*

$$\langle 0|\,\mathcal{T} A_\mu(x) A_\nu(y)\,|0\rangle = \frac{1}{i^2}\,\frac{\delta^2}{\delta J^\mu(x)\,\delta J^\nu(y)}\,\frac{Z_0[J]}{Z_0[0]}\bigg|_{J=0} = D_{\mu\nu}(x-y) = D^F_{\mu\nu}(x-y), \tag{13.185}$$

in exact agreement with the canonical time-ordered correlator of Section 13.4.

The proof is a functional differentiation identical in form to the scalar computation of Theorem 10.22; we carry it out so the index bookkeeping is on the page.

Worked Example 13.38 (The photon two-point function from $Z_0[J]$)**.** Write the normalized functional $\widehat{Z}_0[J] \equiv Z_0[J]/Z_0[0] = \exp\big[-\frac{1}{2}\int J^\rho D_{\rho\sigma} J^\sigma\big]$, so that, by the generating-functional master identity for sourced correlators (the photon instance of Eq. (10.86) with one $1/i$ per derivative),

$$\langle 0|\mathcal{T} A_\mu(x) A_\nu(y)|0\rangle = \frac{1}{i^2}\,\frac{\delta^2 \widehat{Z}_0[J]}{\delta J^\mu(x)\,\delta J^\nu(y)}\bigg|_{J=0}. \tag{13.186}$$

The exponent is quadratic and the kernel $D_{\rho\sigma}$ is symmetric under simultaneous exchange of its indices and arguments, $D_{\rho\sigma}(x-y) = D_{\sigma\rho}(y-x)$ (it is built from $g_{\rho\sigma}$ and $k_\rho k_\sigma$, both symmetric). The first derivative therefore brings down one factor of the propagator, the factor of 2 from the two ways of hitting the symmetric quadratic form cancelling the $\frac{1}{2}$:

$$\frac{\delta \widehat{Z}_0[J]}{\delta J^\mu(x)} = \Big[-\int d^4z\, D_{\mu\sigma}(x-z)\, J^\sigma(z)\Big]\,\widehat{Z}_0[J]. \tag{13.187}$$

Differentiate again with respect to $J^\nu(y)$. The product rule gives a term from differentiating the bracket and a term from differentiating $\widehat{Z}_0$:

$$\frac{\delta^2 \widehat{Z}_0[J]}{\delta J^\nu(y)\,\delta J^\mu(x)} = \Big[-D_{\mu\nu}(x-y)\Big]\widehat{Z}_0[J] + \Big[-\int D_{\mu\sigma}(x-z) J^\sigma\Big]\Big[-\int D_{\nu\tau}(y-w) J^\tau\Big]\widehat{Z}_0[J]. \tag{13.188}$$

Set $J = 0$. The second term is quadratic in J and vanishes; $\widehat{Z}_0[0] = 1$. Dividing by $i^2 = -1$,

$$\langle 0|\mathcal{T} A_\mu(x) A_\nu(y)|0\rangle = \frac{-D_{\mu\nu}(x-y)}{i^2} = D_{\mu\nu}(x-y), \tag{13.189}$$

the R_ξ propagator Eq. (13.182), establishing Eq. (13.185). The structure of Eq. (13.188) is Wick's theorem (Theorem 10.23) for the photon in embryo: each pair of functional derivatives either contracts into a propagator joining the two points or leaves a source behind, and at $J = 0$ only the fully contracted term survives. Every higher free correlator of A_μ is, by the same mechanism, a sum over pairings into copies of $D_{\mu\nu}$ — the free photon is a Gaussian field whose entire content is the two-point function Eq. (13.182).

One caveat completes the picture and ties back to the previous section. The generating functional Eq. (13.184) depends on ξ through the longitudinal part of $D_{\mu\nu}$. That dependence is harmless precisely when the source is conserved: if $\partial_\mu J^\mu = 0$, then in momentum space $k_\mu \widetilde{J}^\mu(k) = 0$, and the longitudinal term in Eq. (13.182) contracts to zero,

$$\widetilde{J}^\mu(-k)\,(1-\xi)\frac{k_\mu k_\nu}{k^2}\,\widetilde{J}^\nu(k) = 0, \tag{13.190}$$

so that $J^\mu D_{\mu\nu} J^\nu$ — and hence $Z_0[J]$ itself — is independent of ξ for conserved currents. This is the generating-functional restatement of the physical-amplitude argument of Section 13.4: gauge-parameter dependence lives entirely in a longitudinal term that any conserved current annihilates. The path integral has thus reproduced not only the propagator but the reason its gauge ambiguity never reaches an observable.

With the free photon now described entirely by the covariant generating functional Eq. (13.184) and its single datum the R_ξ propagator, the path-integral quantization of electromagnetism is complete, and the abelian Faddeev–Popov construction has shown both where the gauge-fixing term legitimately comes from and why QED carries no coupled ghost. The two threads now part toward their continuations: the field-dependent determinant of Theorem 13.35 is the seed that Chapter 26 grows into the propagating Faddeev–Popov ghosts and BRST symmetry of Yang–Mills theory, while the generating functional $Z_0[J]$ of Eq. (13.184) is the object from which Chapter 17 reads off the photon line of the QED Feynman rules and assembles its first cross sections.

13.6 Synthesis: Coupling to Matter and the Recovery of the Coulomb Law

The free photon is now a finished object. Its two-point function exists in coordinate and momentum space across the entire R_ξ family (Eq. (13.135)), and

the path-integral derivation of Section 13.5 has shown that this propagator is exactly the object the Gaussian generating functional $\int \mathcal{D}A\, e^{iS}$ produces once a gauge has been fixed. What it has never yet done is *propagate* anything: the source that creates and absorbs photons has been left abstract, a placeholder current J^μ whose only stated property was conservation. We close the chapter by installing the real source. The gauge principle of Chapter 8 already told us, classically, exactly how a charged field must couple to A_μ; the quantized Dirac field of Chapter 11 provides the current. Joining them produces the complete interacting field content of quantum electrodynamics, and lets us run the one computation that certifies the whole construction — normalization, sign, and all three quantization routes at once — against a fact every reader already knows: the Coulomb law. If the photon we have built does not reproduce $V(r) = e_1 e_2/4\pi r$ with the right magnitude and the right sign, something upstream is wrong. It does, and showing so is the synthesis this section delivers.

13.6.1 Minimal coupling and the photon source current

The coupling is not a free choice. In Chapter 8 the demand that the global U(1) phase symmetry of the electron — the symmetry whose Noether current is the conserved charge of QED — be promoted to a *local* symmetry $\psi(x) \to e^{-i\alpha(x)}\psi(x)$ forced the replacement of the ordinary derivative by the covariant derivative $D_\mu = \partial_\mu + ieA_\mu$, with A_μ transforming as $A_\mu \to A_\mu + \frac{1}{e}\partial_\mu \alpha$ to absorb the inhomogeneous term (Eq. (8.27)). There is no other local-U(1)-invariant coupling of a Dirac field to a single vector potential at this order in fields and derivatives. Assembling the gauge-invariant matter action with the Maxwell term Eq. (13.2) gives the standard Lagrangian of QED,

$$\mathcal{L}_{\text{QED}} = \bar\psi\,(i\not{D} - m)\,\psi - \tfrac{1}{4}F_{\mu\nu}F^{\mu\nu} = \underbrace{\bar\psi\,(i\not{\partial} - m)\,\psi}_{\text{free electron}}\ \underbrace{-\tfrac{1}{4}F_{\mu\nu}F^{\mu\nu}}_{\text{free photon}}\ \underbrace{-\,e\,\bar\psi\gamma^\mu\psi\,A_\mu}_{\text{interaction}}, \tag{13.191}$$

where the interaction term is extracted by expanding $i\not{D} = i\not{\partial} - e\not{A}$ (since $D_\mu = \partial_\mu + ieA_\mu$ gives $i\gamma^\mu D_\mu = i\not{\partial} + i(ie)\not{A} = i\not{\partial} - e\not{A}$). The free pieces are precisely the theories quantized in this chapter and in Chapter 11; everything new lives in the last term. We give it its own name,

$$\mathcal{L}_{\text{int}} = -\,e\,\bar\psi\gamma^\mu\psi\,A_\mu = -\,e\,J^\mu A_\mu, \qquad J^\mu \equiv \bar\psi\gamma^\mu\psi, \tag{13.192}$$

and we recognize J^μ at once: it is the Dirac number current Eq. (11.158), the conserved Noether current of the electron's U(1) symmetry, now doing double duty as the source that the photon couples to. The physical electromagnetic current — the thing that appears on the right of Maxwell's equation — is $j^\mu_{\text{em}} = -eJ^\mu$: the Euler–Lagrange equation for A_ν from Eq. (13.191) reads $\partial_\mu F^{\mu\nu} = e\bar\psi\gamma^\nu\psi = -\,j^\nu_{\text{em}}$ with $j^\nu_{\text{em}} = -e\bar\psi\gamma^\nu\psi$, whose charge density $j^0_{\text{em}} = -e\,\psi^\dagger\psi$ is negative for a positive number density — the electron carries charge $-e$, exactly the convention of

QED. The structure is identical for scalar matter: a complex scalar of charge $-e$ couples through its own conserved U(1) current (Section 9.7) by the same minimal substitution, the only difference being that the scalar current $i(\phi^* \overleftrightarrow{\partial^\mu} \phi)$ contains a derivative and therefore also generates a seagull term $e^2 A^2 |\phi|^2$. For the Dirac field the coupling is purely linear in A_μ and the photon source is simply J^μ.

The single defining property we will lean on is conservation. At the operator level the Heisenberg equations of motion for the interacting field still give

$$\partial_\mu J^\mu = (\partial_\mu \bar{\psi})\gamma^\mu \psi + \bar{\psi}\gamma^\mu(\partial_\mu \psi) = 0, \tag{13.193}$$

because the full Dirac equation in the presence of the gauge field, $(i\not{D} - m)\psi = 0$, and its adjoint $\bar{\psi}(i\overleftarrow{\not{D}} + m) = 0$, conspire so that the A_μ-dependent terms cancel in pairs: $\bar{\psi}\gamma^\mu\psi$ is gauge-covariant of charge zero, and its divergence is the same whether one uses ∂_μ or D_μ precisely because the current is neutral. Conservation of J^μ is therefore not an accident of the free theory; it survives the coupling, and it is what will make the gauge artefact in the propagator invisible.

To do quantum-mechanical perturbation theory we need the interaction Hamiltonian, not the Lagrangian. Because $\mathcal{L}_{\text{int}}$ contains no time derivatives of any field, the canonical momenta are unchanged by the coupling and the Legendre transform simply flips the sign of the interaction term,

$$H_{\text{int}} = -\int d^3x\, \mathcal{L}_{\text{int}} = e\int d^3x\, \bar{\psi}\gamma^\mu\psi\, A_\mu = e\int d^3x\, J^\mu A_\mu. \tag{13.194}$$

This is the operator whose Dyson series, organized in Chapter 14 and turned into Feynman rules in Chapters 15 and 17, generates every QED amplitude.

Caution

Equation (13.194) is the manifestly covariant interaction Hamiltonian, valid when A_μ is quantized covariantly (Gupta–Bleuler, Section 13.3) or in the path integral. In the Coulomb gauge of Eq. (13.45) the story looks different: there A^0 is not an independent field but is solved from the Gauss constraint Eq. (13.21), and substituting that solution back into the Hamiltonian produces an *instantaneous* Coulomb interaction $\frac{1}{2}\int d^3x\, d^3y\, \rho(\mathbf{x})\rho(\mathbf{y})/4\pi|\mathbf{x}-\mathbf{y}|$ between charge densities, plus a coupling of the transverse photon to the transverse current. The two descriptions are not in conflict; the next subsections show they compute the same physics, with the instantaneous term of the Coulomb route being the operator avatar of the timelike piece of the covariant propagator.

13.6.2 Quantum gauge invariance of the coupling, and a word on charge quantization

The propagator carries a free gauge parameter ξ, and a different ξ is a genuinely different two-point function. The coupling we have just installed is what guarantees that no measurable quantity remembers the choice. The mechanism was proved in general in Theorem 13.28: in any current-coupled amplitude the propagator appears contracted with currents, $\widetilde{J}_1^{*\mu}\, D_{\mu\nu}(k)\, \widetilde{J}_2^{\nu}$, and the entire ξ-dependence of Eq. (13.135) sits in the term proportional to $k_\mu k_\nu$, which dies the instant it touches a conserved current. What was abstract there is now concrete: the current is $J^\mu = \bar\psi\gamma^\mu\psi$, and its conservation Eq. (13.193) is supplied by the electron's own dynamics. For the on-shell matrix element relevant to a tree amplitude, $\widetilde{J}^\mu(k) = \bar u(p')\gamma^\mu u(p)$ with $k = p' - p$, conservation is the elementary identity

$$k_\mu\, \bar u(p')\gamma^\mu u(p) = \bar u(p')\,(\not p' - \not p)\, u(p) = \bar u(p')\,(m - m)\, u(p) = 0, \tag{13.195}$$

using the Dirac equations $\not p\, u(p) = m\, u(p)$ and $\bar u(p')\not p' = m\, \bar u(p')$ from Chapter 11; this is the same on-shell Ward identity Eq. (13.145) that drove the Møller computation. We therefore record the synthesis as a proposition, citing rather than repeating the contraction.

Proposition 13.39 (The minimal coupling is gauge-invariant)**.** *The interaction $\mathcal{L}_{\rm int} = -eJ^\mu A_\mu$ with $J^\mu = \bar\psi\gamma^\mu\psi$ couples the photon to a current that is conserved by the electron's equation of motion, Eq. (13.193). Consequently, by Theorem 13.28, every amplitude built from Eq. (13.191) in which photons appear only as internal lines or as external lines summed over physical polarizations is independent of the gauge parameter ξ, and is invariant under $A_\mu \to A_\mu + \frac{1}{e}\partial_\mu\alpha$ accompanied by $\psi \to e^{-i\alpha}\psi$. Gauge invariance is thus a property of the* coupled *theory at the quantum level, inherited from the conservation of the source.*

This is the precise quantum content of the gauge principle: the classical statement "minimal coupling is forced by local U(1) invariance" becomes the quantum statement "the resulting amplitudes cannot depend on the gauge-fixing artefact, because the source is conserved." The two are the same fact seen from the two ends of the quantization.

Physical Insight

Local gauge invariance is not a symmetry relating distinct physical states; it is a redundancy in the labelling of one state. Theorem 13.39 is the cleanest place to see why that redundancy is harmless: a redundancy of *description* can leave a fingerprint in intermediate, description-dependent objects (the propagator's ξ, the polarization vectors' reference momentum) but must cancel in anything that is a property of the *world*. Conservation

of the matter current is exactly the bookkeeping rule that enforces the cancellation. A theory whose matter current were not conserved would couple to the $k_\mu k_\nu$ piece, the ξ-dependence would survive into cross sections, and the theory would be inconsistent — which is the dynamical reason charged matter must come with a conserved current.

A remark on charge quantization belongs here, kept honestly within scope. Perturbative QED as written in Eq. (13.191) fixes the electron's charge to be $-e$ but says nothing about why every observed charge is an integer multiple of a common unit; the coupling e is a free continuous parameter and a second fermion could in principle be assigned any real charge q via $D_\mu = \partial_\mu + iqA_\mu$. Two non-perturbative considerations force quantization. First, if a magnetic monopole of magnetic charge g exists anywhere in the universe, single-valuedness of the charged matter's wavefunction around the monopole's Dirac string requires $eg = 2\pi n$ for integer n (the Dirac quantization condition), so the mere consistency of one charge with one monopole quantizes all electric charges in units of $2\pi/g$. Second, if the U(1) is embedded in a compact, semisimple gauge group — as it is in any grand unified extension — the allowed charges become the discrete weights of the group's representations, and quantization is automatic. Within the Standard Model the cancellation of gauge anomalies (Chapters 36 and 37) ties the hypercharges together so tightly that charge quantization emerges from consistency of the quantum theory itself. Each of these is a statement about physics beyond the free photon of this chapter; we flag them and defer their derivations to the chapters that own them.

13.6.3 The two routes agree: instantaneous Coulomb plus transverse equals covariant exchange

We have quantized the photon three ways, and it is time to verify explicitly that they describe one physics. The Coulomb-gauge route (Eq. (13.45)) quantizes only the two transverse polarizations as genuine oscillators and relegates the static interaction to an instantaneous term; manifest positivity, hidden covariance. The Gupta–Bleuler route (Section 13.3) keeps all four components and an indefinite metric; manifest covariance, positivity restored only on the physical subspace. The path integral (Section 13.5) produces the R_ξ propagator directly. Theorem 13.39 already tells us the R_ξ members agree among themselves; what remains is to connect the manifestly covariant propagator to the manifestly positive Coulomb-gauge one, since these differ not by a continuous parameter but in their very tensor structure.

In Coulomb gauge the photon two-point function, read off from the transverse quantization Eq. (13.45) and the elimination of A^0 through the Gauss constraint,

has the components (momentum space, $k^\mu = (k^0, \mathbf{k})$, all indices down)

$$\widetilde{D}^C_{00}(k) = \frac{i}{|\mathbf{k}|^2}, \qquad \widetilde{D}^C_{0i}(k) = 0, \qquad \widetilde{D}^C_{ij}(k) = \frac{i}{k^2 + i\varepsilon}\Big(\delta_{ij} - \frac{k_i k_j}{|\mathbf{k}|^2}\Big). \tag{13.196}$$

The interpretation is exactly the one the Hamiltonian Eq. (13.194) (Coulomb-gauge version) demanded: $\widetilde{D}^C_{00}$ is k^0-independent — it does not propagate in time — and is the instantaneous Coulomb interaction $i/|\mathbf{k}|^2$; the spatial $\widetilde{D}^C_{ij}$ carries the transverse projector $\delta_{ij} - k_i k_j/|\mathbf{k}|^2$ and propagates only the two physical helicities. Compare the Feynman-gauge propagator Eq. (13.136), whose components are $\widetilde{D}^F_{00} = -i/k^2$, $\widetilde{D}^F_{0i} = 0$, and $\widetilde{D}^F_{ij} = -i\eta_{ij}/k^2 = +i\delta_{ij}/k^2$ (using $\eta_{ij} = -\delta_{ij}$). These look nothing alike. Their difference is

$$\begin{aligned} \Delta_{00} &\equiv \widetilde{D}^C_{00} - \widetilde{D}^F_{00} = \frac{i}{|\mathbf{k}|^2} + \frac{i}{k^2} = i\,\frac{k^2 + |\mathbf{k}|^2}{|\mathbf{k}|^2\,k^2} = \frac{i\,(k^0)^2}{|\mathbf{k}|^2\,k^2}, \\ \Delta_{0i} &= 0, \qquad \Delta_{ij} = \widetilde{D}^C_{ij} - \widetilde{D}^F_{ij} = \frac{i}{k^2}\Big(\delta_{ij} - \frac{k_i k_j}{|\mathbf{k}|^2}\Big) - \frac{i\,\delta_{ij}}{k^2} = -\frac{i}{k^2}\,\frac{k_i k_j}{|\mathbf{k}|^2}, \end{aligned} \tag{13.197}$$

where the Δ_{00} result used $k^2 + |\mathbf{k}|^2 = (k^0)^2 - |\mathbf{k}|^2 + |\mathbf{k}|^2 = (k^0)^2$. Every component of $\Delta_{\mu\nu}$ carries an explicit factor of a momentum component on each free index: $\Delta_{00} \propto k^0 k^0$ and $\Delta_{ij} \propto k_i k_j$. That is precisely the structure that current conservation annihilates. We make this exact.

Proposition 13.40 (Coulomb and covariant exchange coincide on conserved currents)**.** *For any two conserved currents, $k_\mu \widetilde{J}^\mu_1 = k_\mu \widetilde{J}^\mu_2 = 0$, the Coulomb-gauge and Feynman-gauge photon propagators give identical exchange amplitudes:*

$$\widetilde{J}^{*\mu}_1\, \widetilde{D}^C_{\mu\nu}(k)\, \widetilde{J}^\nu_2 = \widetilde{J}^{*\mu}_1\, \widetilde{D}^F_{\mu\nu}(k)\, \widetilde{J}^\nu_2. \tag{13.198}$$

Proof. The two sides differ by $\widetilde{J}^{*\mu}_1 \Delta_{\mu\nu} \widetilde{J}^\nu_2$ with $\Delta_{\mu\nu}$ from Eq. (13.197). Since $\Delta_{0i} = 0$,

$$\widetilde{J}^{*\mu}_1 \Delta_{\mu\nu} \widetilde{J}^\nu_2 = \frac{i(k^0)^2}{|\mathbf{k}|^2 k^2}\, \widetilde{J}^{*0}_1 \widetilde{J}^0_2 - \frac{i}{k^2|\mathbf{k}|^2}\,(\mathbf{k}\cdot\widetilde{\mathbf{J}}^*_1)(\mathbf{k}\cdot\widetilde{\mathbf{J}}_2) = \frac{i}{k^2|\mathbf{k}|^2}\Big[(k^0)^2\, \widetilde{J}^{*0}_1 \widetilde{J}^0_2 - (\mathbf{k}\cdot\widetilde{\mathbf{J}}^*_1)(\mathbf{k}\cdot\widetilde{\mathbf{J}}_2)\Big], \tag{13.199}$$

where $\mathbf{k}\cdot\widetilde{\mathbf{J}} \equiv \sum_i k^i \widetilde{J}^i$ is the ordinary three-vector dot product of the spatial momentum and the spatial current. Current conservation reads $k_\mu \widetilde{J}^\mu = k^0 \widetilde{J}^0 - \mathbf{k}\cdot\widetilde{\mathbf{J}} = 0$ (the relative sign is the mostly-minus metric, $k_i \widetilde{J}^i = -k^i \widetilde{J}^i$), so $\mathbf{k}\cdot\widetilde{\mathbf{J}} = k^0 \widetilde{J}^0$ for each current. Substituting, the bracket in Eq. (13.199) becomes $(k^0)^2 \widetilde{J}^{*0}_1 \widetilde{J}^0_2 - (k^0 \widetilde{J}^{*0}_1)(k^0 \widetilde{J}^0_2) = 0$. Hence $\widetilde{J}^{*\mu}_1 \Delta_{\mu\nu} \widetilde{J}^\nu_2 = 0$, which is Eq. (13.198). □

The reconciliation is therefore complete and exact: the manifestly covariant Feynman-gauge tensor $-i\eta_{\mu\nu}/k^2$ is nothing but the Coulomb-gauge content — one instantaneous timelike piece plus two transverse helicities — repackaged into a single Lorentz-covariant object, with a longitudinal redistribution between

the timelike and spatial sectors that conserved currents cannot detect. The Coulomb route makes positivity manifest at the price of hiding covariance inside the instantaneous term; the covariant route makes Lorentz invariance manifest at the price of carrying gauge artefacts that Theorems 13.39 and 13.40 guarantee never reach an observable. There is no third fact to choose between them, and this is the precise meaning of the claim that the three quantization routes of this chapter agree on physics.

13.6.4 The Coulomb law from one-photon exchange

We now run the carried computation. The cleanest fully rigorous route uses only objects already built in this chapter: the Gaussian generating functional of Section 13.5 and the propagator Eq. (13.135). Couple the photon to a prescribed, conserved, c-number external current J^μ through the source term $J^\mu A_\mu$ in the Lagrangian. Completing the square in the quadratic photon path integral — the same Gaussian manipulation that produced the propagator as the inverse quadratic operator in Eq. (13.130) — gives the vacuum persistence amplitude

$$\langle 0_+|0_-\rangle_J = \exp\Big[-\tfrac{1}{2}\int d^4x\, d^4y\; J^\mu(x)\, D_{\mu\nu}(x-y)\, J^\nu(y)\Big], \tag{13.200}$$

with $D_{\mu\nu}(x-y) = \int \frac{d^4k}{(2\pi)^4}\, e^{-ik\cdot(x-y)}\, D_{\mu\nu}(k)$ the Feynman propagator (the factors of i from e^{iS} and from $D = i$ (inverse operator) combine to leave the clean $-\frac{1}{2}$). By Theorem 13.39 the result is ξ-independent for conserved J, so we may read $D_{\mu\nu}$ in Feynman gauge. The phase of $\langle 0_+|0_-\rangle_J$ over a long time T measures the energy of the ground state in the presence of the source, $\langle 0_+|0_-\rangle_J = e^{-iE_0T}$ (with the source-free vacuum energy subtracted), so the interaction energy is extracted directly from Eq. (13.200). The Fourier transform we need is isolated first.

Worked Example 13.41 (The static Fourier transform: $1/|\mathbf{k}|^2 \to 1/4\pi r$)**.** We evaluate, with a mass regulator $\mu > 0$ that we send to zero at the end,

$$I_\mu(\mathbf{r}) = \int \frac{d^3k}{(2\pi)^3}\, \frac{e^{i\mathbf{k}\cdot\mathbf{r}}}{|\mathbf{k}|^2 + \mu^2}. \tag{13.201}$$

Choose polar axes along $\mathbf{r}$ and write $k = |\mathbf{k}|$, $r = |\mathbf{r}|$, θ the angle between them. The angular integral is elementary:

$$\int d\Omega\; e^{i\mathbf{k}\cdot\mathbf{r}} = 2\pi \int_{-1}^{1} d(\cos\theta)\, e^{ikr\cos\theta} = 2\pi\, \frac{e^{ikr} - e^{-ikr}}{ikr} = \frac{4\pi \sin kr}{kr}. \tag{13.202}$$

Therefore

$$I_\mu(\mathbf{r}) = \frac{1}{(2\pi)^3} \int_0^\infty dk\, k^2\, \frac{1}{k^2+\mu^2}\, \frac{4\pi \sin kr}{kr} = \frac{1}{2\pi^2 r} \int_0^\infty dk\, \frac{k \sin kr}{k^2+\mu^2}. \tag{13.203}$$

The remaining integral is computed by contour methods. The integrand is even in k, so $\int_0^\infty = \frac{1}{2}\int_{-\infty}^{\infty}$, and we write $\sin kr = \mathrm{Im}\, e^{ikr}$:

$$\int_0^\infty dk\, \frac{k \sin kr}{k^2+\mu^2} = \tfrac{1}{2}\,\mathrm{Im}\int_{-\infty}^{\infty} dk\, \frac{k\, e^{ikr}}{k^2+\mu^2}. \tag{13.204}$$

For $r>0$ the factor e^{ikr} decays in the upper half-plane, so we close the contour there, enclosing the single pole at $k=+i\mu$. Its residue is $\left.\frac{k\,e^{ikr}}{2k}\right|_{k=i\mu} = \frac{1}{2}e^{-\mu r}$, and the integral equals $2\pi i\cdot\frac{1}{2}e^{-\mu r} = i\pi e^{-\mu r}$, whose imaginary part is $\pi e^{-\mu r}$. Hence $\int_0^\infty dk\,(k\sin kr)/(k^2+\mu^2) = \frac{\pi}{2}e^{-\mu r}$, and

$$I_\mu(\mathbf{r}) = \frac{1}{2\pi^2 r}\cdot\frac{\pi}{2}\,e^{-\mu r} = \frac{e^{-\mu r}}{4\pi r} \xrightarrow{\mu\to 0} \frac{1}{4\pi r}. \tag{13.205}$$

The finite-μ result is the Yukawa potential of a massive mediator; the $\mu\to 0$ limit, the massless photon, is the bare Coulomb kernel. This single integral fixes both the 4π in the denominator and the overall positive sign that the next computation propagates into the potential.

Worked Example 13.42 (The Coulomb potential between two static charges)**.** Take two static point charges $q_1 = e_1$ and $q_2 = e_2$ at positions $\mathbf{x}_1, \mathbf{x}_2$, separated by $r = |\mathbf{x}_1 - \mathbf{x}_2|$. As a classical conserved source the configuration is purely timelike and time-independent,

$$J^\mu(x) = \eta^{\mu 0}\,\rho(\mathbf{x}), \qquad \rho(\mathbf{x}) = e_1\,\delta^3(\mathbf{x}-\mathbf{x}_1) + e_2\,\delta^3(\mathbf{x}-\mathbf{x}_2), \tag{13.206}$$

manifestly conserved since $\partial_\mu J^\mu = \partial_0\rho = 0$. Only the $\mu=\nu=0$ component of Eq. (13.200) contributes, with $D_{00}(k) = -i\eta_{00}/(k^2+i\varepsilon) = -i/(k^2+i\varepsilon)$. Insert the Fourier representation and do the time integrals first:

$$\int dx^0\, dy^0\; e^{-ik^0(x^0-y^0)} = 2\pi\,\delta(k^0)\cdot T, \qquad T \equiv \int dx^0, \tag{13.207}$$

the $\delta(k^0)$ arising from the relative time and the factor T from the overall time translation. Setting $k^0=0$ collapses $k^2\to -|\mathbf{k}|^2$, so $D_{00}\to -i/(-|\mathbf{k}|^2) = i/|\mathbf{k}|^2$ — the instantaneous Coulomb kernel reappearing, exactly the $\widetilde{D}^C_{00}$ of Eq. (13.196), as Theorem 13.40 guarantees it must. The double space integral then factorizes through Theorem 13.41:

$$\int d^4x\, d^4y\; J^\mu D_{\mu\nu} J^\nu = T\int d^3x\, d^3y\;\rho(\mathbf{x})\rho(\mathbf{y})\int\frac{d^3k}{(2\pi)^3}\,\frac{i}{|\mathbf{k}|^2}\,e^{i\mathbf{k}\cdot(\mathbf{x}-\mathbf{y})} = T\,i\int d^3x\, d^3y\;\frac{\rho(\mathbf{x})\rho(\mathbf{y})}{4\pi|\mathbf{x}-\mathbf{y}|}. \tag{13.208}$$

Comparing the exponent of Eq. (13.200), $-\frac{1}{2}(\cdots) = -iE_0T$, gives the energy

$$E_0 = \frac{1}{2iT}\int d^4x\, d^4y\; J^\mu D_{\mu\nu} J^\nu = \frac{1}{2iT}\cdot T\,i\int d^3x\, d^3y\;\frac{\rho(\mathbf{x})\rho(\mathbf{y})}{4\pi|\mathbf{x}-\mathbf{y}|} = \frac{1}{2}\int d^3x\, d^3y\;\frac{\rho(\mathbf{x})\rho(\mathbf{y})}{4\pi|\mathbf{x}-\mathbf{y}|}. \tag{13.209}$$

The factors of i have cancelled to leave a real, positive-definite electrostatic field energy — the first nontrivial sign check of the whole construction. Inserting the two-charge density, the integral splits into self-energies (e_1^2 and e_2^2 terms, divergent as the points coincide; these are r-independent and subtracted as the rest energies of the isolated charges) and a finite cross term in which $\mathbf{x}$ sits at one charge and $\mathbf{y}$ at the other. The cross term occurs twice in the symmetric double sum, cancelling the $\frac{1}{2}$, and yields the interaction potential

$$\boxed{V(r) = \frac{e_1 e_2}{4\pi r}}. \tag{13.210}$$

The sign is correct in both cases. Two electrons, $e_1 = e_2 = -e$, give $V = +e^2/4\pi r > 0$: like charges repel, the potential rises as they approach. An electron and a positron (or an electron and a proton), $e_1 = -e$, $e_2 = +e$, give $V = -e^2/4\pi r < 0$: unlike charges attract. Restoring conventional units, $e^2/4\pi = \alpha \approx 1/137$ is the fine-structure constant of QED, and Eq. (13.210) is the familiar $V(r) = \alpha/r$ between unit charges. The same number that will set the size of every QED cross section in Part V here sets the strength of the static force, with the normalization and sign of the photon propagator certified against a classical fact.

The diagrammatic content of Eq. (13.210) is the single tree graph of Fig. 13.4: each static charge is a source vertex, the internal line is the photon propagator, and the static limit projects onto the timelike, instantaneous part. The same result is reached from the particle-physics side by taking the nonrelativistic Born limit of the one-photon-exchange amplitude — the tree-level matrix element $\widetilde{J}_1^{*\mu} D_{\mu\nu} \widetilde{J}_2^{\nu}$ with on-shell spinor currents, related to a potential through the first Born approximation of nonrelativistic scattering. In that language the heavy-fermion current reduces to $\bar{u}\gamma^0 u \to 2m$ in the rest frame, the spatial currents are velocity-suppressed, and the same kernel $e_1 e_2/|\mathbf{k}|^2$ Fourier-transforms to Eq. (13.210). We do not need that route here, because the external-source computation is already complete and rigorous; the systematic translation between amplitudes and potentials, with all kinematic factors, is built in Chapters 14 and 17.

13.6.5 The interacting QED field content, assembled

The chapter set out to quantize the photon and resolve the redundancy that obstructs it; with the matter coupling installed, the full field content of quantum electrodynamics is now in hand and internally consistent. The dynamical degrees of freedom are the Dirac electron ψ of Chapter 11 — two spin states of a particle and two of its antiparticle — and the two transverse helicities of the photon quantized in this chapter, all governed by the single Lagrangian Eq. (13.191). The free propagators are the Dirac propagator $S_F(p) = i(\not{p} + m)/(p^2 - m^2 + i\varepsilon)$

and the photon propagator $D_{\mu\nu}(k)$ of Eq. (13.135); the unique interaction is the minimal vertex Eq. (13.192), which by the standard reading of $i\mathcal{L}_{\text{int}}$ becomes the momentum-space Feynman rule

$$\text{photon–electron vertex} = i\times(\text{coefficient of } A_\mu \text{ in } \mathcal{L}_{\text{int}}) = i\,(-e)\,\gamma^\mu = -\,ie\,\gamma^\mu \qquad \text{(equivalent} \tag{13.211}$$

to be derived systematically, with its symmetry factors and external-leg conventions, in Chapters 15 and 17. Every ingredient that perturbative QED requires — propagators with certified normalization and sign, a gauge-invariant vertex coupling a conserved current, and a physical Hilbert space carved out by the routes of Sections 13.3 and 13.5 — now exists, and the gauge redundancy that opened the chapter has been shown to leave no fingerprint on any observable.

This is the direct bridge Part V was promised. The propagator Eq. (13.135), the vertex Eq. (13.211), and the polarization-sum rule Eq. (13.149) are exported unchanged to Chapter 17, where they assemble into the QED Feynman rules and produce the first complete cross section of QED, $e^+e^- \to \mu^+\mu^-$, with its full spin sums and gamma-matrix traces; the same propagator is dressed by vacuum polarization, and the vertex by its radiative correction, in the one-loop program of Chapter 19, where the conservation of J^μ proved here matures into the Ward–Takahashi identity that organizes the entire renormalization of the theory.

Further reading

The constrained-Hamiltonian view of the Maxwell field that opens this chapter is Dirac's own; his [152] remains the most readable account of primary and secondary constraints and the first/second-class distinction. The two covariant-quantization papers, [244] and [80], are the primary sources for the indefinite-metric construction and the subsidiary condition that carry their names, and the abelian determinant trick was isolated, on the way to the non-abelian theory, in [182]. Among textbooks, the canonical and Gupta–Bleuler routes are developed with conventions closest to ours in [396, 432, 500]; [278] gives an especially careful treatment of the photon propagator's gauge dependence and the R_ξ family, and [454] the cleanest path-integral derivation of the gauge-fixing term. For why Lorentz invariance forces the indefinite metric on the covariant state space, the discussion in [500] is the standard reference; [532] offers the most physically motivated overview of why the gauge-fixing term may be added without changing physics.

Part IV

Interactions and Perturbation Theory

Chapter 14

Interactions and the S-Matrix

Part III handed us a quantum field theory we can solve to the last decimal: the free scalar of Chapter 9, with its quadratic Hamiltonian, its Fock space built by hand from ladder operators, and its closed-form Feynman propagator. Nothing in it scatters. The business of this chapter is to switch on the quartic interaction of ϕ^4 theory and ask the only question a collider ever asks: given a few particles prepared far apart in the distant past, with what amplitude do a few particles emerge far apart in the distant future? The object that answers is the scattering operator $\mathbf{S}$, and the chapter is, end to end, the construction of a computable bridge from the interacting Lagrangian to the matrix elements of $\mathbf{S}$ and the Lorentz-invariant amplitude $\mathcal{M}$ they contain.

The construction proceeds in a fixed logical order, and each section installs one span of the bridge. We begin in the interaction picture, where the fields evolve freely—so the entire free-theory apparatus of Chapter 9 survives verbatim—and all the dynamics is pushed into the time evolution of states, summed by the Dyson series into the time-ordered exponential $\mathbf{S} = \mathcal{T}\exp(-i\int H_I)$. We then say precisely what states this operator acts between: the asymptotic in- and out-states a scattering experiment actually prepares and measures, built on the *interacting* vacuum, with $\mathbf{S}$ the unitary map between the two complete bases and $\mathcal{M}$ the kinematic-delta-stripped amplitude inside it. Honesty about that formal apparatus is part of the work, and Haag's theorem is met head-on (Section 14.2.6) rather than buried. The middle of the chapter then makes the bridge load-bearing. The Gell-Mann–Low theorem rewrites the time-ordered vacuum correlators of interacting Heisenberg fields as a ratio of *free*-field Dyson expectation values—Wick-computable order by order, with the vacuum bubbles cancelled by the denominator—and reconciles this canonical route with the path-integral generating functional of Chapter 10. The Källén–Lehmann spectral representation then establishes, nonperturbatively, the one analytic fact LSZ consumes: the exact propagator carries an isolated single-particle pole of residue iZ, with $0 \le Z \le 1$, beneath a multiparticle continuum. With the pole located,

the LSZ reduction formula identifies an S-matrix element as the amputated, connected, on-shell correlator dressed with one factor of $\sqrt{Z}$ per external leg.

The penultimate section turns the crank for the first time, chaining Dyson, Gell-Mann–Low, Wick, and LSZ to compute the leading $\phi\phi \to \phi\phi$ amplitude of ϕ^4 theory with every factor on the page—the 4! contraction multiplicity cancelling the 1/4! of the coupling—and arrives at the first genuinely interacting number of the book, $i\mathcal{M} = -i\lambda$. The chapter then closes with the one statement that is not perturbative: the unitarity of $\mathbf{S}$, pressed into the optical theorem, partial-wave unitarity and the Argand circle, and the perturbative reach of λ. That nonperturbative constraint is the fixed point of certainty against which every later loop calculation will be checked.

The chapter imports the free mode expansion, Fock space, and Feynman propagator D_F from Chapter 9; the path-integral generating functional and Wick's theorem from Chapter 10; the theory of tempered distributions, the $i\epsilon$ prescription, analytic continuation, and the dispersion-relation preview from Chapter 5; the one-particle relativistic normalization, the invariant measure, and the Poincaré/translation machinery from Chapter 3; and the Legendre transform to the Hamiltonian together with the $\mathbb{Z}_2$ symmetry of ϕ^4 theory from Chapters 6 and 7. It exports, in turn, the operational LSZ recipe and the tree amplitude $-i\lambda$ to the Feynman-rules and cross-section chapters Chapters 15 and 16, the field-strength renormalization Z and the self-energy structure to the renormalization program of Chapters 19 and 22, and the optical theorem to the analyticity-and-dispersion and cutting-rules developments of Chapter 60. Conventions are those of Chapter A: mostly-minus metric $\eta_{\mu\nu} = \mathrm{diag}(+,-,-,-)$, natural units $\hbar = c = 1$, and the Feynman $i\epsilon$ throughout.

14.1 The Interaction Picture and the Dyson Series

Part III left us with a quantum field theory we can solve completely. The free real scalar of Chapter 9 has a Hamiltonian quadratic in the field, a linear equation of motion, and a Hilbert space—the Fock space of Theorem 9.17—whose every state is built by hand from the ladder operators. The field itself carries the explicit mode expansion of Theorem 9.6, and its time-ordered two-point function is the closed-form Feynman propagator of Theorem 9.24. Everything is exact because nothing in the theory couples the modes to one another: a quantum of momentum $\mathbf{p}$ created at $\lambda = 0$ propagates forever, undisturbed. The whole edifice rests on that linearity.

The moment we restore the quartic term of ϕ^4 theory, that linearity is gone. The interacting Lagrangian

$$\mathcal{L} = \tfrac{1}{2}(\partial_\mu\phi)(\partial^\mu\phi) - \tfrac{1}{2}m^2\phi^2 - \frac{\lambda}{4!}\phi^4, \qquad \phi \text{ real},\ \lambda > 0, \tag{14.1}$$

produces a cubic source in its equation of motion, $(\Box + m^2)\phi = -\frac{\lambda}{3!}\phi^3$, so the modes scatter off one another and no closed-form solution of the operator dynamics exists. We are not, however, helpless. The coupling λ is dimensionless and—this is the working assumption of the entire chapter, to be examined critically when we renormalize—small. The strategy that organizes all of perturbative field theory is therefore to treat the interaction as a controlled deformation of the solvable free theory: split the Hamiltonian into the free part we have already diagonalized and a small remainder, and develop every quantity as a power series in that remainder. This section builds the apparatus that performs the split cleanly and produces, order by order in λ, the operator that propagates states forward in time under the interaction. That operator, taken between the distant past and the distant future, will be the S-matrix.

The device that makes the split usable is the *interaction picture*, a third choice of how to apportion time dependence between states and operators, intermediate between the Schrödinger and Heisenberg pictures of Section 9.1. Its defining virtue is that the fields evolve with the *free* Hamiltonian alone, so they retain—verbatim—the mode expansion, the commutators, and the propagator we built in the free theory, while all the genuine dynamics of the interaction is pushed into the time evolution of the states. We adopt throughout the conventions in force for the chapter: the mostly-minus metric $\eta_{\mu\nu} = \mathrm{diag}(+,-,-,-)$, natural units $\hbar = c = 1$, and the Feynman $i\varepsilon$ prescription of Section 5.3.5.

14.1.1 Splitting the Hamiltonian

The Hamiltonian of the interacting theory is obtained from Eq. (14.1) by the Legendre transform of Chapter 6. The interaction term carries no derivatives of the field, so it does not touch the definition of the canonical momentum: $\pi = \partial\mathcal{L}/\partial\dot{\phi} = \dot{\phi}$ exactly as in the free theory. The transform therefore goes through unchanged except for the extra potential term, and the Hamiltonian density is the one already recorded as Eq. (6.180),

$$\mathcal{H} = \tfrac{1}{2}\pi^2 + \tfrac{1}{2}(\nabla\phi)^2 + \tfrac{1}{2}m^2\phi^2 + \frac{\lambda}{4!}\phi^4. \tag{14.2}$$

Integrating over a constant-time slice and grouping the terms by their power of the field splits the total Hamiltonian into two pieces,

$$H = H_0 + H_{\mathrm{int}}, \qquad H_0 = \int \mathrm{d}^3x \left[\tfrac{1}{2}\pi^2 + \tfrac{1}{2}(\nabla\phi)^2 + \tfrac{1}{2}m^2\phi^2\right], \qquad H_{\mathrm{int}} = \frac{\lambda}{4!}\int \mathrm{d}^3x\, \phi^4, \tag{14.3}$$

where H_0 is precisely the free Hamiltonian of Eqs. (6.122) and (9.3), whose spectrum and eigenstates we own completely, and H_{int} collects the interaction. The cleanliness of this split—that H_0 is unmodified and H_{int} is just the spatial integral of the potential—is a special feature of a non-derivative coupling.

Caution

For interactions that *do* contain derivatives of the field—a $(\partial\phi)^2\phi^2$ coupling, the minimal coupling of QED, or the non-abelian self-interaction of Yang–Mills theory—the canonical momentum is itself altered by the interaction, and H_{int} is no longer simply minus the interaction Lagrangian density integrated over space. Extra, non-covariant "Schwinger" terms appear, and they conspire with the non-covariant pieces of the propagator to restore covariance in the end. None of this afflicts ϕ^4, where Eq. (14.3) is exact; the derivative-coupling subtlety is taken up where it first bites, in the gauge theories of Chapters 13 and 26.

A word on what these operators are. In Eq. (14.3) the field ϕ and momentum π are Schrödinger-picture operators, defined on a single time slice, which we take to be $t = 0$: write them $\phi(\mathbf{x}) \equiv \phi(0, \mathbf{x})$ and $\pi(\mathbf{x}) \equiv \pi(0, \mathbf{x})$. They obey the equal-time canonical commutators of Theorem 9.1 on that slice. In the Schrödinger picture all time dependence resides in the state $|\psi(t)\rangle_S$, which evolves under the *full* Hamiltonian according to $i\,\partial_t\,|\psi(t)\rangle_S = H\,|\psi(t)\rangle_S$. The trouble is that we cannot solve this: e^{-iHt} is the exponential of an operator we have not diagonalized. The interaction picture reorganizes the problem so that what we must exponentiate is, at each order, only the small piece.

14.1.2 The interaction picture and the free evolution of fields

Definition 14.1 (Interaction picture)**.** Let A_S be any Schrödinger-picture operator on the $t = 0$ slice and $|\psi(t)\rangle_S$ a Schrödinger-picture state evolving under the full Hamiltonian $H = H_0 + H_{\text{int}}$. The corresponding *interaction-picture* operator and state are obtained by conjugating away, and respectively rotating away, the *free* evolution generated by H_0:

$$A_I(t) \equiv e^{iH_0 t}\, A_S\, e^{-iH_0 t}, \tag{14.4}$$

$$|\psi(t)\rangle_I \equiv e^{iH_0 t}\; |\psi(t)\rangle_S\,. \tag{14.5}$$

The three pictures coincide at the reference time $t = 0$, where $A_I(0) = A_S$ and $|\psi(0)\rangle_I = |\psi(0)\rangle_S$.

The definition is engineered so that matrix elements are picture independent: inserting $e^{-iH_0 t}e^{iH_0 t} = 1$ on each side of any operator,

$$ {}_S\langle\chi(t)|\, A_S\, |\psi(t)\rangle_S = {}_I\langle\chi(t)|\; e^{iH_0 t} A_S e^{-iH_0 t}\; |\psi(t)\rangle_I = {}_I\langle\chi(t)|\, A_I(t)\, |\psi(t)\rangle_I\,, \tag{14.6}$$

so every physical prediction is unchanged. What we have bought is a redistribution of the time dependence: the operators now move with H_0, and the states will be shown to move with the interaction alone.

Consider first the operators. Differentiating Eq. (14.4), the only t-dependence is in the two exponentials, and H_0 commutes with itself, so

$$\frac{dA_I}{dt} = iH_0\, e^{iH_0t} A_S e^{-iH_0t} - e^{iH_0t} A_S e^{-iH_0t}\, iH_0 = i\, e^{iH_0t}\,[H_0, A_S]\, e^{-iH_0t} = i\,[H_0, A_I(t)]\,. \tag{14.7}$$

This is the Heisenberg equation of motion—but with the *free* Hamiltonian H_0 in place of the full H. An interaction-picture operator therefore evolves exactly as it would in a world with no interaction at all. Note also that H_0 itself is picture independent, $e^{iH_0t} H_0 e^{-iH_0t} = H_0$, because it commutes with its own exponential; we may write H_0 without a subscript.

Apply this to the field. The Schrödinger field $\phi(\mathbf{x}) = \phi(0,\mathbf{x})$ promotes to the interaction-picture field

$$\phi_I(t,\mathbf{x}) \equiv e^{iH_0t}\,\phi(0,\mathbf{x})\,e^{-iH_0t}, \tag{14.8}$$

which by Eq. (14.7) obeys $\dot\phi_I = i\,[H_0, \phi_I]$ and, after a second derivative, the free Heisenberg equations driven by H_0. But these are exactly the equations solved in Section 9.1: ϕ_I satisfies the operator Klein–Gordon equation $(\Box + m^2)\phi_I = 0$, and the evolution $\phi_I(t,\mathbf{x}) = e^{iH_0t}\phi(0,\mathbf{x})e^{-iH_0t}$ is precisely the construction by which the free Heisenberg field was built from its $t = 0$ data. We have proved the first key result.

Theorem 14.2 (Interaction-picture fields are free fields)**.** *The interaction-picture scalar field Eq. (14.8) is identical to the free Heisenberg field of Chapter 9. It satisfies the free equation of motion $(\Box + m^2)\phi_I = 0$ and carries verbatim the free mode expansion of Theorem 9.6,*

$$\phi_I(x) = \int \frac{d^3p}{(2\pi)^3\, 2E_{\mathbf{p}}} \Big(a_{\mathbf{p}}\, e^{-ip\cdot x} + a^\dagger_{\mathbf{p}}\, e^{+ip\cdot x} \Big)\Big|_{p^0 = E_{\mathbf{p}}}, \tag{14.9}$$

with the same ladder operators, the same Fock vacuum $|0\rangle$ of Theorem 9.17 annihilated by every $a_{\mathbf{p}}$, the same equal-time commutators Theorem 9.1, and the same time-ordered two-point function $\langle 0|\,\mathcal{T}\,\phi_I(x)\phi_I(y)\,|0\rangle = D_F(x-y)$, the Feynman propagator of Theorem 9.24.

Proof. By Eq. (14.7) the operator $\phi_I(t,\mathbf{x})$ satisfies $\dot\phi_I = i\,[H_0, \phi_I]$ and $\dot\pi_I = i\,[H_0, \pi_I]$ with $\pi_I = e^{iH_0t}\pi(0,\mathbf{x})e^{-iH_0t}$, where H_0 is the free Hamiltonian Eq. (14.3). These are word-for-word the free Heisenberg equations established in Section 9.1; with the initial data on the $t = 0$ slice being the canonical pair obeying Theorem 9.1, the solution is unique and is the free Heisenberg field. Conjugation by the unitary e^{iH_0t} preserves the equal-time commutators, $[\phi_I(t,\mathbf{x}), \pi_I(t,\mathbf{y})] = e^{iH_0t}\,[\phi(0,\mathbf{x}), \pi(0,\mathbf{y})]\,e^{-iH_0t} = i\delta^3(\mathbf{x}-\mathbf{y})$, so the mode algebra is unchanged and Eq. (14.9) follows by the same Fourier inversion that produced Eq. (9.42). The vacuum $|0\rangle$ is the free Fock vacuum because $H_0\,|0\rangle$ is a c-number times $|0\rangle$, hence

$e^{-iH_0t}|0\rangle \propto |0\rangle$ and $a_{\mathbf{p}}|0\rangle = 0$ is preserved. Finally, the time-ordered product of two interaction-picture fields is, by Eq. (9.151), exactly the object computed in Theorem 9.26, giving $D_F(x-y)$. □

This theorem is the entire reason the interaction picture is worth introducing. Every tool of the free theory—the mode expansion, the ladder algebra, the Fock space, Wick's theorem of Chapter 10, the propagator—applies to ϕ_I unaltered. The price is that the interaction, having been evicted from the fields, must reappear somewhere; it reappears in the time evolution of the states, governed by the operator we now define.

Definition 14.3 (Interaction-picture interaction Hamiltonian)**.** The *interaction Hamiltonian in the interaction picture* is the Schrödinger interaction H_{int} of Eq. (14.3) dressed with the free evolution:

$$H_I(t) \equiv e^{iH_0t}\, H_{\text{int}}\, e^{-iH_0t}. \tag{14.10}$$

For ϕ^4 theory, $H_{\text{int}} = \frac{\lambda}{4!}\int \mathrm{d}^3x\, \phi(0,\mathbf{x})^4$, and conjugation distributes over the product of four fields, $e^{iH_0t}\phi^4 e^{-iH_0t} = (e^{iH_0t}\phi\, e^{-iH_0t})^4 = \phi_I^4$, so

$$\boxed{H_I(t) = \frac{\lambda}{4!}\int \mathrm{d}^3x\; \phi_I(t,\mathbf{x})^4} \tag{14.11}$$

is built entirely from the free field Eq. (14.9).

Equation Eq. (14.11) is the concrete object this chapter will compute with. It is $O(\lambda)$, it is Hermitian (it is the conjugate of a Hermitian operator by a unitary), and—crucially—it is a polynomial in free creation and annihilation operators. Its matrix elements between Fock states are therefore evaluable by the same combinatorics that governs the free theory. We have fixed the interaction-picture interaction Hamiltonian and prepared, but not yet performed, the first $O(\lambda)$ computation; carrying it out is the business of the LSZ and amplitude sections that follow.

14.1.3 The interaction-picture evolution equation

We now find how interaction-picture states move. Differentiate the defining relation Eq. (14.5), using the Schrödinger equation $i\,\partial_t|\psi(t)\rangle_S = H|\psi(t)\rangle_S$ for the second factor:

$$\begin{aligned} i\,\partial_t|\psi(t)\rangle_I &= i(iH_0)e^{iH_0t}|\psi(t)\rangle_S + e^{iH_0t}\, i\,\partial_t|\psi(t)\rangle_S \\ &= -H_0\, e^{iH_0t}|\psi(t)\rangle_S + e^{iH_0t}\, H\, |\psi(t)\rangle_S \\ &= e^{iH_0t}(H-H_0)|\psi(t)\rangle_S = e^{iH_0t}\, H_{\text{int}}\, e^{-iH_0t}\, e^{iH_0t}|\psi(t)\rangle_S\,. \end{aligned} \tag{14.12}$$

The first factor in the last line is $H_I(t)$ by Eq. (14.10), and the remaining $e^{iH_0t}\,|\psi(t)\rangle_S = |\psi(t)\rangle_I$ by Eq. (14.5). Hence the free part of the Hamiltonian has cancelled out of the state's evolution entirely, leaving the *Tomonaga–Schwinger equation*,

$$i\,\partial_t\,|\psi(t)\rangle_I = H_I(t)\;|\psi(t)\rangle_I\,. \tag{14.13}$$

This is the central dynamical statement. An interaction-picture state is driven only by the (small) interaction $H_I(t)$, which is itself constructed from free fields. We have traded the unsolvable problem of exponentiating the full H for a Schrödinger-like equation in which the generator is the perturbation. Note that $H_I(t)$ is genuinely time dependent—through the free evolution of the fields inside it—even though H_{int} and H are not; this time dependence is exactly what will require time ordering below.

To solve Eq. (14.13) we encode the evolution in an operator.

Definition 14.4 (Interaction-picture time-evolution operator)**.** The *time-evolution operator* $U(t,t_0)$ is the unitary that propagates interaction-picture states from time t_0 to time t,

$$|\psi(t)\rangle_I = U(t,t_0)\;|\psi(t_0)\rangle_I\,. \tag{14.14}$$

Substituting Eq. (14.14) into Eq. (14.13), and using that $|\psi(t_0)\rangle_I$ is an arbitrary fixed state, U obeys the operator equation and initial condition

$$i\,\partial_t\,U(t,t_0) = H_I(t)\,U(t,t_0), \qquad U(t_0,t_0) = \mathbf{1}. \tag{14.15}$$

An explicit closed form follows by tracking the same operator through the pictures. From Eq. (14.5) and the Schrödinger evolution $|\psi(t)\rangle_S = e^{-iH(t-t_0)}\,|\psi(t_0)\rangle_S$,

$$|\psi(t)\rangle_I = e^{iH_0t}\,e^{-iH(t-t_0)}\,e^{-iH_0t_0}\,|\psi(t_0)\rangle_I\,, \qquad \Longrightarrow \qquad U(t,t_0) = e^{iH_0t}\,e^{-iH(t-t_0)}\,e^{-iH_0t_0}. \tag{14.16}$$

This formula is exact and instructive—it shows U interpolating between the free evolution it strips off at each end and the full evolution in the middle, and one checks immediately that $U(t_0,t_0)=\mathbf{1}$. But it is useless for computation, because it still contains the unexpanded $e^{-iH(t-t_0)}$. The content of the next subsection is to convert Eq. (14.15) into a power series in H_I, which is a power series in λ, every term of which is a free-field matrix element.

14.1.4 The Dyson series

The differential equation Eq. (14.15) together with its initial condition is equivalent to the integral equation

$$U(t,t_0) = \mathbf{1} - i\int_{t_0}^{t}\mathrm{d}t_1\;H_I(t_1)\,U(t_1,t_0), \tag{14.17}$$

as one verifies by differentiating (the integral's upper limit returns the integrand $-iH_I(t)U(t,t_0)$) and by setting $t = t_0$ (the integral vanishes, giving $U(t_0,t_0) = \mathbf{1}$). The virtue of the integral form is that it is solvable by iteration: the unknown U appears under the integral, and substituting the whole right-hand side back into itself repeatedly generates a series in powers of H_I. We carry out the iteration explicitly.

Zeroth and first order. Substituting $U(t_1,t_0) \to \mathbf{1}$ in Eq. (14.17) gives the first two terms,

$$U = \mathbf{1} + (-i)\int_{t_0}^{t} \mathrm{d}t_1\, H_I(t_1) + \dots \tag{14.18}$$

Second order. Substitute the first-order expression for $U(t_1,t_0)$ back into Eq. (14.17):

$$U = \mathbf{1} + (-i)\int_{t_0}^{t} \mathrm{d}t_1\, H_I(t_1) + (-i)^2 \int_{t_0}^{t} \mathrm{d}t_1 \int_{t_0}^{t_1} \mathrm{d}t_2\, H_I(t_1)H_I(t_2) + \dots \tag{14.19}$$

The structure is already visible. The upper limit of the inner integral is the running variable t_1 of the outer one, so the two times are *nested*: t_1 ranges up to t, and t_2 ranges only up to t_1. Continuing to all orders, the n-th term is

$$U^{(n)} = (-i)^n \int_{t_0}^{t} \mathrm{d}t_1 \int_{t_0}^{t_1} \mathrm{d}t_2 \cdots \int_{t_0}^{t_{n-1}} \mathrm{d}t_n\, H_I(t_1)H_I(t_2)\cdots H_I(t_n), \tag{14.20}$$

in which the integration domain is the ordered simplex $t \geq t_1 \geq t_2 \geq \cdots \geq t_n \geq t_0$ and the operators stand in the same order—latest time on the left. The ordering is forced: $H_I(t_1)$ and $H_I(t_2)$ do not commute (they are built from fields at different times), so we may not freely rearrange them. Summing Eq. (14.20) over n already *is* a complete solution of Eq. (14.15); the remaining work is purely a matter of rewriting it in the symmetric form that exposes its structure and connects it to the time-ordered correlators the rest of the chapter needs.

The rewriting rests on the time-ordering symbol. For two bosonic operators the symbol $\mathcal{T}$ was defined in Eq. (9.151); the only new ingredient is its extension to n factors, which simply places them in order of decreasing time.

Definition 14.5 (Time-ordered product of n operators)**.** For bosonic operators $A_1(t_1),\dots,A_n(t_n)$ the time-ordered product is

$$\mathcal{T}\{A_1(t_1)\,A_2(t_2)\cdots A_n(t_n)\} \equiv A_{\sigma(1)}(t_{\sigma(1)})\,A_{\sigma(2)}(t_{\sigma(2)})\cdots A_{\sigma(n)}(t_{\sigma(n)}), \tag{14.21}$$

where σ is the permutation of $\{1,\dots,n\}$ for which $t_{\sigma(1)} > t_{\sigma(2)} > \cdots > t_{\sigma(n)}$, i.e. the symbol reorders the factors so that times decrease from left to right, regardless of the order in which they were written. (Coincident times occur on a measure-zero set and, for the equal-time-commuting fields at hand, cause no ambiguity, exactly as in Eq. (9.151).)

The reordering is what undoes the nesting. Consider the symmetric integral of the time-ordered product over the *full* hypercube $[t_0, t]^n$, with no ordering imposed on the limits:

$$J_n \equiv \int_{t_0}^{t} \mathrm{d}t_1 \cdots \int_{t_0}^{t} \mathrm{d}t_n \, \mathcal{T}\{H_I(t_1) \cdots H_I(t_n)\}. \tag{14.22}$$

The hypercube is the disjoint union (up to the measure-zero coincidence locus) of $n!$ simplices, one for each strict ordering of the n times. On the simplex where $t_{\sigma(1)} > \cdots > t_{\sigma(n)}$, the time-ordering symbol resolves to the single product $H_I(t_{\sigma(1)}) \cdots H_I(t_{\sigma(n)})$. Within that simplex, rename the integration variables by $t_{\sigma(k)} \to s_k$; this is a relabelling of dummy variables and a permutation of the orthonormal integration axes, with unit Jacobian, that maps the simplex onto the canonical one $s_1 > s_2 > \cdots > s_n$ and turns the integrand into $H_I(s_1) \cdots H_I(s_n)$. Every one of the $n!$ simplices is thereby mapped to the *same* integral—the ordered integral of Eq. (14.20). Hence

$$J_n = n! \int_{t_0}^{t} \mathrm{d}t_1 \int_{t_0}^{t_1} \mathrm{d}t_2 \cdots \int_{t_0}^{t_{n-1}} \mathrm{d}t_n \, H_I(t_1) \cdots H_I(t_n), \tag{14.23}$$

which is exactly $n!$ times the nested integral appearing in $U^{(n)}$. Solving Eq. (14.23) for the nested integral and inserting it into Eq. (14.20),

$$U^{(n)} = \frac{(-i)^n}{n!} \int_{t_0}^{t} \mathrm{d}t_1 \cdots \int_{t_0}^{t} \mathrm{d}t_n \, \mathcal{T}\{H_I(t_1) \cdots H_I(t_n)\}. \tag{14.24}$$

The factor $1/n!$ is not inserted by hand: it is precisely the count of simplices that tile the hypercube, the price paid for trading the rigid nested limits of Eq. (14.20) for the symmetric, fully time-ordered limits of Eq. (14.24). Summing over n gives the central result.

Theorem 14.6 (Dyson series)**.** *The interaction-picture time-evolution operator solving Eq. (14.15) is*

$$\boxed{U(t, t_0) = \sum_{n=0}^{\infty} \frac{(-i)^n}{n!} \int_{t_0}^{t} \mathrm{d}t_1 \cdots \int_{t_0}^{t} \mathrm{d}t_n \, \mathcal{T}\{H_I(t_1) \cdots H_I(t_n)\} \;\equiv\; \mathcal{T} \exp\Big(-i \int_{t_0}^{t} \mathrm{d}t' \, H_I(t') \Big).} \tag{14.25}$$

The right-hand object is the time-ordered exponential*: the formal exponential series with the time-ordering symbol applied term by term, defined to mean exactly the sum on the left.*

Proof. Summing Eq. (14.24) over $n \geq 0$ (with $U^{(0)} = \mathbf{1}$) yields the displayed series; it is a rewriting of the iterated solution Eq. (14.20), which solves Eq. (14.17) and hence Eq. (14.15) by construction. The notation $\mathcal{T}\exp$ is defined to abbreviate the same series: expanding $\exp(-i \int H_I)$ formally produces $\frac{(-i)^n}{n!}(\int H_I)^n = \frac{(-i)^n}{n!} \int \cdots \int H_I(t_1) \cdots H_I(t_n)$, and applying $\mathcal{T}$ to each term inserts exactly the symbol in Eq. (14.25). □

The time-ordered exponential is a genuine generalization of the ordinary one. If the $H_I(t')$ at different times commuted, $\mathcal{T}$ would be inert and Eq. (14.25) would collapse to $\exp(-i\int_{t_0}^{t} H_I\,\mathrm{d}t')$; the whole nontrivial content lives in the failure of $H_I(t_1)$ and $H_I(t_2)$ to commute, which the time ordering keeps track of. The reader who recognizes Eq. (14.17) as the field-theoretic image of the Dyson series from time-dependent perturbation theory in nonrelativistic quantum mechanics is exactly right; the construction is identical, with the interaction-picture interaction $H_I(t)$ playing the role of the time-dependent perturbing potential.

Worked Example 14.7 (The $n = 2$ combinatorics, drawn)**.** We verify the $1/n!$ at second order by performing the simplex decomposition explicitly, which is where the geometry is easiest to see. The symmetric integral Eq. (14.22) at $n = 2$ is

$$J_2 = \int_{t_0}^{t} \mathrm{d}t_1 \int_{t_0}^{t} \mathrm{d}t_2\, \mathcal{T}\{H_I(t_1)H_I(t_2)\} \tag{14.26}$$

over the square $[t_0, t]^2$ of Fig. 14.1. The diagonal $t_1 = t_2$ splits the square into two triangles. In the lower-right triangle $t_1 > t_2$, the symbol resolves as $\mathcal{T}\{H_I(t_1)H_I(t_2)\} = H_I(t_1)H_I(t_2)$, contributing

$$\int_{t_0}^{t} \mathrm{d}t_1 \int_{t_0}^{t_1} \mathrm{d}t_2\, H_I(t_1)H_I(t_2). \tag{14.27}$$

In the upper-left triangle $t_2 > t_1$, the symbol resolves as $\mathcal{T}\{H_I(t_1)H_I(t_2)\} = H_I(t_2)H_I(t_1)$ (later operator left), contributing

$$\int_{t_0}^{t} \mathrm{d}t_2 \int_{t_0}^{t_2} \mathrm{d}t_1\, H_I(t_2)H_I(t_1). \tag{14.28}$$

In Eq. (14.28) relabel the dummy variables $t_1 \leftrightarrow t_2$: the integral becomes $\int_{t_0}^{t} \mathrm{d}t_1 \int_{t_0}^{t_1} \mathrm{d}t_2\, H_I(t_1)H_I(t_2)$, identical to Eq. (14.27). The two triangles thus contribute equally, and

$$J_2 = 2\int_{t_0}^{t} \mathrm{d}t_1 \int_{t_0}^{t_1} \mathrm{d}t_2\, H_I(t_1)H_I(t_2), \tag{14.29}$$

confirming Eq. (14.23) at $n = 2$ with the factor $2! = 2$. Dividing by $2!$ recovers exactly the nested second-order term of Eq. (14.19): the $1/n!$ is the reciprocal of the number of orderings, here the two triangles. The same picture in n dimensions has the hypercube cut by the $\binom{n}{2}$ hyperplanes $t_i = t_j$ into $n!$ congruent simplices, one per ordering, giving the general factor $n!$.

14.1.5 The group law and formal unitarity

The evolution operator inherits from its definition the algebraic properties any sensible propagator must have. We establish them directly from the differential equation Eq. (14.15), which is the most economical route and the one that does not lean on the formal closed form Eq. (14.16).

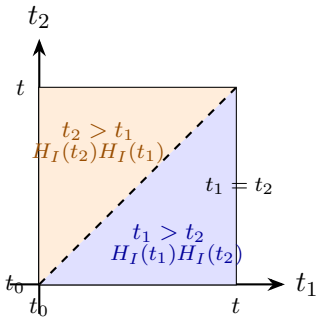

Figure 14.1: The second-order simplex decomposition of Theorem 14.7. The diagonal $t_1 = t_2$ splits the integration square $[t_0, t]^2$ into two triangles. On each, the time-ordering symbol selects the product with the later operator on the left; after relabelling the dummy variables the two triangles give equal contributions, so the symmetric integral over the square is 2! times the nested integral over either triangle. In n dimensions the hypercube splits into $n!$ such simplices, producing the $1/n!$ of the Dyson series.

Theorem 14.8 (Composition law)**.** *For any three times the evolution operator composes,*

$$U(t_1, t_2)\, U(t_2, t_3) = U(t_1, t_3), \tag{14.30}$$

and in particular $U(t, t_0)$ is invertible with

$$U(t, t_0)^{-1} = U(t_0, t). \tag{14.31}$$

Proof. Fix t_2 and t_3 and regard both sides of Eq. (14.30) as functions of the upper time, which we call τ. Define $F(\tau) \equiv U(\tau, t_2)\, U(t_2, t_3)$ and $G(\tau) \equiv U(\tau, t_3)$. Each satisfies the same first-order equation in τ: by Eq. (14.15),

$$i\,\partial_\tau F(\tau) = \big[i\,\partial_\tau U(\tau, t_2)\big] U(t_2, t_3) = H_I(\tau) U(\tau, t_2) U(t_2, t_3) = H_I(\tau) F(\tau), \tag{14.32}$$

and likewise $i\,\partial_\tau G(\tau) = H_I(\tau) G(\tau)$, the constant operator $U(t_2, t_3)$ passing through the τ-derivative untouched. At $\tau = t_2$ the initial data agree: $F(t_2) = U(t_2, t_2) U(t_2, t_3) = U(t_2, t_3) = G(t_2)$, using $U(t_2, t_2) = \mathbf{1}$. A first-order linear operator equation with prescribed value at one point has a unique solution, so $F \equiv G$ for all τ, which is Eq. (14.30). Setting $t_1 = t_3 = t_0$ and $t_2 = t$ gives $U(t_0, t) U(t, t_0) = U(t_0, t_0) = \mathbf{1}$; setting $t_1 = t_3 = t$ and $t_2 = t_0$ gives the reverse product, so $U(t_0, t)$ is the two-sided inverse Eq. (14.31). □

Theorem 14.9 (Formal unitarity)**.** *If $H_I(t)$ is Hermitian for every t, then $U(t, t_0)$ is unitary:*

$$U(t, t_0)^\dagger\, U(t, t_0) = \mathbf{1} = U(t, t_0)\, U(t, t_0)^\dagger. \tag{14.33}$$

Proof. That $H_I(t)$ is Hermitian is immediate from Eq. (14.10): H_{int} is Hermitian (it is the spatial integral of a real power of the Hermitian field), and conjugation by the unitary $e^{iH_0 t}$ preserves Hermiticity, so $H_I(t)^\dagger = H_I(t)$; for ϕ^4 this is manifest in Eq. (14.11). Take the Hermitian conjugate of the evolution equation Eq. (14.15). Since ∂_t and $\dagger$ commute and $(H_I U)^\dagger = U^\dagger H_I^\dagger = U^\dagger H_I$,

$$-i\,\partial_t\, U(t,t_0)^\dagger = U(t,t_0)^\dagger\, H_I(t). \tag{14.34}$$

Now differentiate the product $U^\dagger U$ with the product rule, using Eq. (14.34) and Eq. (14.15):

$$\partial_t(U^\dagger U) = (\partial_t U^\dagger)U + U^\dagger(\partial_t U) = (iU^\dagger H_I)U + U^\dagger(-iH_I U) = i\,U^\dagger H_I U - i\,U^\dagger H_I U = 0. \tag{14.35}$$

The combination $U^\dagger U$ is therefore constant in t; at $t = t_0$ it equals $U(t_0,t_0)^\dagger U(t_0,t_0) = \mathbf{1}$, so $U^\dagger U = \mathbf{1}$ for all t. The opposite product $UU^\dagger = \mathbf{1}$ then follows because a one-sided inverse of an invertible operator is two-sided—and U is invertible by Eq. (14.31). Indeed taking the dagger of Eq. (14.31) and combining with $U^\dagger U = \mathbf{1}$ identifies $U^\dagger = U(t_0,t)$, consistent with reading Eq. (14.34) as the evolution equation in the second argument. □

We have called this unitarity *formal*, and the qualifier is deliberate. Each manipulation above is exact at the level of symbols, but every object in it—H_0, H_{int}, the interaction picture itself—has been treated as if it acted on the free Fock space of Theorem 9.17. In an interacting theory in infinite volume that assumption is, strictly, false: the free and interacting Hamiltonians are not unitarily equivalent, the interaction picture in the literal sense does not exist (Haag's theorem), and the time integrals in the Dyson series do not converge as written. The series is nonetheless the correct generator of the perturbative expansion, and the algebraic identities Eqs. (14.30) and (14.33) survive order by order in λ once the construction is given its proper, regularized meaning. Confronting this honestly—explaining in what sense the formal apparatus computes the right thing despite the obstruction—is the first task of the next section, and the unitarity proved here will return there as the exact statement that the S-matrix preserves probability.

With the Dyson series Eq. (14.25) in hand we have the explicit, λ-by-λ operator that propagates states under the interaction, together with its group and unitarity properties. The single object the scattering theory needs is its limit between the distant past and the distant future, $\mathbf{S} = U(\infty,-\infty) = \mathcal{T}\exp\!\big(-i\int_{-\infty}^{\infty} \mathrm{d}t'\, H_I(t')\big)$. The next section gives this limit a precise meaning by defining the asymptotic in- and out-states between which its matrix elements are taken, identifies those matrix elements as scattering amplitudes, and faces squarely the formal status flagged above.

14.2 Asymptotic States and the S-Matrix

The previous section ended with a concrete operator. Solving the interaction-picture Schrödinger equation by Dyson's time-ordered exponential produced the evolution operator $U(t,t_0)$ (Theorem 14.6), and as the time interval was opened to the whole real line there appeared a single, suggestive object,

$$\mathbf{S} \;\overset{?}{=}\; U(\infty,-\infty) \;=\; \mathcal{T}\exp\!\Big(-i\int_{-\infty}^{\infty} dt\; H_I(t)\Big), \tag{14.36}$$

the operator that propagates a state from the distant past to the distant future under the full interaction. We placed a question mark over it deliberately. A formula is not yet a physical statement: we have not said *what states* Eq. (14.36) acts between, nor why the limits $t\to\pm\infty$ exist, nor what the matrix entries of $\mathbf{S}$ have to do with a number a detector reports. This section supplies all three. It defines the asymptotic in- and out-states that a scattering experiment actually prepares and measures, identifies the S-matrix as the unitary map between them, extracts from each matrix element the Lorentz-invariant amplitude $\mathcal{M}$ that carries all the physics, and states honestly — via Haag's theorem — why Eq. (14.36) is at this stage only a *formal* expression, made meaningful not by the free-field interaction picture but by the renormalized perturbation theory the rest of the chapter constructs.

We keep the conventions in force for the chapter: mostly-minus metric $\eta_{\mu\nu}=\mathrm{diag}(+,-,-,-)$ so that on shell $p^2=m^2$; natural units $\hbar=c=1$; the Feynman $i\epsilon$ prescription; and ϕ^4 theory with $\lambda>0$. One-particle states carry the relativistic normalization fixed in Eq. (3.193) and rebuilt for the free scalar in Theorem 9.12, and we abbreviate the Lorentz-invariant momentum measure $\widetilde{dp}\equiv d^3p/[(2\pi)^3\,2E_{\mathbf{p}}]$ exactly as in Chapter 9.

14.2.1 What a scattering experiment prepares and measures

A collider, stripped to essentials, does three things in sequence. Long before the collision it prepares a small number of particles, far apart from one another and moving freely, each a localized wavepacket with well-controlled momentum. These packets are aimed so that their future trajectories overlap inside a tiny interaction region. Long after the collision a bank of detectors, again far from the interaction region, registers some number of outgoing particles, again effectively free and localized, and records their momenta. The experiment measures the *probability* that a specified incoming configuration emerges as a specified outgoing one. The S-matrix is precisely the table of complex amplitudes whose squared moduli are those probabilities.

The crucial physical input is the separation of scales. The range of the force is microscopic, while "before" and "after" mean times enormously larger than any interaction time. During those long epochs the particles are so widely

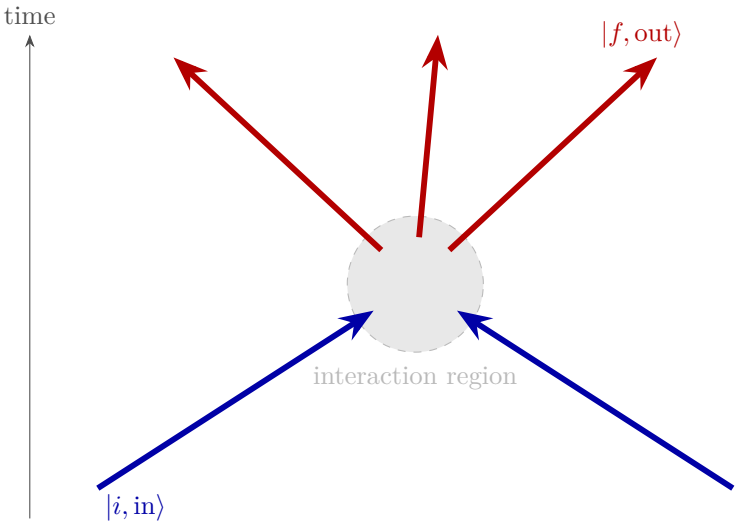

Figure 14.2: The scattering geometry. Widely separated incoming wavepackets (blue) propagate freely out of the distant past, overlap briefly in a microscopic interaction region (shaded), and emerge as freely propagating outgoing packets (red) into the distant future. The in- and out-states are defined by the limits in which the packets are taken infinitely far from the interaction.

separated that the interaction between them is utterly negligible, and each packet propagates as if it were a free, stable, single particle. This is what licenses describing the prepared and detected states in the language of free particles *even though the underlying dynamics is interacting*: not because interactions are absent, but because in the asymptotic regions the constituents are too far apart to feel them. We will make this precise with the device of *adiabatic switching*, and then be candid about exactly where the device oversimplifies.

14.2.2 In-states, out-states, and the adiabatic hypothesis

Let $H = H_0 + H_{\text{int}}$ be the full Hamiltonian of the interacting theory. The genuine, interacting theory has its own ground state and its own stable single-particle states, and these are emphatically *not* the free Fock states of Chapter 9: the physical vacuum is polarized, the physical one-particle state is dressed by virtual quanta, and (as we will see at the end) the two Hilbert-space structures are not even unitarily related. We therefore must define asymptotic states intrinsically, in terms of the full dynamics, and only afterwards connect them to the free states that perturbation theory can compute with.

Definition 14.10 (Physical vacuum and one-particle states)**.** Let $|\Omega\rangle$ denote the unique, Poincaré-invariant, normalized ground state of the full Hamiltonian, $H|\Omega\rangle = 0$ (the energy origin is fixed by this condition), to be contrasted with the

free vacuum $|0\rangle$ of Theorem 9.11. Let $|\mathbf{p}\rangle$ denote a stable single-particle eigenstate of the full H and momentum $\mathbf{P}$ with relativistic dispersion $P^\mu|\mathbf{p}\rangle = p^\mu|\mathbf{p}\rangle$, $p^0 = E_{\mathbf{p}} = \sqrt{\mathbf{p}^2 + m^2}$, normalized as in Eq. (3.193).

Plane-wave momentum eigenstates are not normalizable; they are continuum objects, and any equation written with them is shorthand for a statement about normalizable *wavepackets*

$$|f_\alpha\rangle \;=\; \int \widetilde{dp}\; f_\alpha(\mathbf{p})\,|\mathbf{p}\rangle\,, \qquad \int \widetilde{dp}\;|f_\alpha(\mathbf{p})|^2 = 1, \tag{14.37}$$

with smooth profiles f_α sharply peaked about chosen central momenta. This is not pedantry: the S-matrix elements between plane waves are *distributions* (Theorem 5.2), not functions — they will turn out to contain a Dirac delta enforcing energy–momentum conservation — and a distribution acquires meaning only when smeared against test functions, which is exactly what the profiles f_α do. We write formulæ with plane waves for transparency and understand them as smeared in this way whenever a finite number is required.

To build a multiparticle asymptotic state, take several such packets with central momenta $\mathbf{p}_1, \dots, \mathbf{p}_n$ and spatial supports that, in the far past, are mutually distant and non-overlapping. Because each packet is then localized far from the others, the interaction among them is negligible and the multiparticle state is, to arbitrary accuracy, a tensor product of single-particle states built on the physical vacuum. The *in-state* $|\mathbf{p}_1, \dots, \mathbf{p}_n;\,\mathrm{in}\rangle$ is defined as the Heisenberg-picture state that, evolved back to $t \to -\infty$, looks like n such widely separated, freely propagating physical one-particle wavepackets converging on the interaction region; the *out-state* $|\mathbf{q}_1, \dots, \mathbf{q}_m;\,\mathrm{out}\rangle$ is defined symmetrically as the state that, at $t \to +\infty$, looks like m widely separated, freely propagating physical one-particle packets diverging from it. Both are complete bases of the full Hilbert space — any state can be expanded in either — because in either limit one is describing free, well-separated particles, of which the multiparticle states form a complete set.

Adiabatic switching. A constructive handle on these limits, due to Gell-Mann and Low, is to multiply the interaction by a slowly varying envelope,

$$H_{\mathrm{int}}(t) \;\longrightarrow\; g_\epsilon(t)\, H_{\mathrm{int}}(t), \qquad g_\epsilon(t) = e^{-\epsilon|t|}, \quad \epsilon \to 0^+, \tag{14.38}$$

so that in the remote past and future ($|t| \to \infty$) the interaction is switched off and the dynamics is exactly free, while near $t = 0$ the full interaction is restored. With the switch in place the asymptotic regions are governed by H_0, the in/out states reduce to honest free states, and the limits defining $U(\pm\infty, 0)$ in Eq. (14.36) are tamed: the rapid oscillations $e^{-iH_0 t}$ that would otherwise make the $t \to \pm\infty$ limits ill-defined are damped by g_ϵ. The adiabatic theorem

then asserts that switching the interaction on infinitely slowly carries each free eigenstate continuously into the corresponding interacting eigenstate, up to a phase — the precise statement and the survival of that phase are the content of the Gell-Mann–Low theorem proved in the next section. We adopt Eq. (14.38) as the working definition of the asymptotic limits and as the bridge from physical states to the free states perturbation theory manipulates, while flagging at the end of the section the sense in which it is a formal device rather than a rigorous construction.

14.2.3 The S-operator and its matrix elements

In- and out-states are two complete descriptions of the same physical Hilbert space, one natural in the past, one in the future. There must exist a single operator carrying one basis to the other.

Definition 14.11 (The S-operator)**.** The S-operator is the unitary operator that maps the out-basis to the in-basis,

$$|\alpha;\,\mathrm{in}\rangle \;=\; \mathbf{S}\;|\alpha;\,\mathrm{out}\rangle \qquad \text{for every label } \alpha, \tag{14.39}$$

equivalently the change-of-basis whose entries are the overlaps of out- with in-states. The *S-matrix element* for a transition from an initial configuration i to a final configuration f is

$$S_{fi} \;\equiv\; \langle f,\mathrm{out}|i,\mathrm{in}\rangle \;=\; \langle f,\mathrm{out}|\mathbf{S}|i,\mathrm{out}\rangle \;\equiv\; \langle f|\mathbf{S}|i\rangle\,, \tag{14.40}$$

where in the last form a single reference basis (say the out-basis, or equivalently the free in/out basis once the adiabatic identification is made) is understood.

The middle equality of Eq. (14.40) is just Eq. (14.39) read inside an overlap; the final, basis-free notation $\langle f|\mathbf{S}|i\rangle$ is the one we use from here on. The number S_{fi} is the amplitude for the experiment to begin with i and end with f; the probability is $|S_{fi}|^2$, properly understood as a probability density to be integrated against the wavepacket profiles of Eq. (14.37) and binned by the detector acceptance.

The connection to the Dyson series is now visible. In the adiabatically switched theory the in- and out-states are free states in the remote past and future, and the operator that evolves a remote-past free state into a remote-future free state, in the interaction picture, is exactly $U(\infty,-\infty)$. Hence the formal identification

$$\mathbf{S} \;=\; U(\infty,-\infty) \;=\; \mathcal{T}\exp\!\Big(-i\int_{-\infty}^{\infty} dt\; H_I(t)\Big), \tag{14.41}$$

promoting Eq. (14.36) from a guess to a definition — formal, because it leans on the interaction picture, whose existence Section 14.2.6 will call into question.

This is the object the rest of the chapter learns to compute: expanding the time-ordered exponential order by order in λ and taking matrix elements between free multiparticle states generates the perturbation series for S_{fi}.

14.2.4 Unitarity and the conservation of probability

The single most important structural property of the S-matrix is that it is unitary. Physically it must be: if the initial state is normalized to total probability one, the probabilities of all possible outcomes must sum to one, since *something* happens. Mathematically it follows from the unitarity of the time-evolution operator.

Theorem 14.12 (Unitarity of the S-matrix)**.** *The S-operator is unitary,*

$$\mathbf{S}^\dagger \mathbf{S} \;=\; \mathbf{S}\,\mathbf{S}^\dagger \;=\; \mathbf{1}. \tag{14.42}$$

Proof. The interaction-picture evolution operator satisfies $U(t_2,t_1)^\dagger = U(t_1,t_2)$ and the composition law $U(t_3,t_2)U(t_2,t_1) = U(t_3,t_1)$, both established for the Dyson series in Theorem 14.6: the first because $H_I(t)$ is Hermitian, so the generator of U is anti-Hermitian and U is a product (time-ordered limit of products) of unitary infinitesimal factors $e^{-iH_I(t)\,dt}$; the second by concatenating adjacent time slices. In particular

$$U(\infty,-\infty)^\dagger\, U(\infty,-\infty) \;=\; U(-\infty,\infty)\, U(\infty,-\infty) \;=\; U(-\infty,-\infty) \;=\; \mathbf{1}, \tag{14.43}$$

and identically with the factors in the opposite order, giving $U(\infty,-\infty)U(\infty,-\infty)^\dagger = \mathbf{1}$. With $\mathbf{S} = U(\infty,-\infty)$ from Eq. (14.41) this is Eq. (14.42). The same conclusion follows directly from Theorem 14.11: Eq. (14.39) maps one orthonormal (in the continuum, delta-normalized) complete basis onto another, and any operator carrying one orthonormal basis to another is unitary. □

The physical content is read off by inserting a complete set of final states. Sandwiching $\mathbf{S}^\dagger\mathbf{S} = \mathbf{1}$ between a normalized initial state $|i\rangle$ and itself and inserting $\mathbf{1} = \sum_f |f\rangle\langle f|$ (a continuum sum over all multiparticle configurations, with the invariant measure understood) gives

$$1 = \Big\langle i\Big|\mathbf{S}^\dagger\mathbf{S}\Big|i\Big\rangle = \sum_f \Big\langle i\Big|\mathbf{S}^\dagger\Big|f\Big\rangle\,\langle f|\mathbf{S}|i\rangle = \sum_f |S_{fi}|^2\,. \tag{14.44}$$

The probabilities of all final states, given the initial state i, sum to one. Unitarity is conservation of probability, no more and no less. It is a nonperturbative constraint — true to all orders — and it will reappear in sharpened form as the optical theorem at the close of the chapter.

14.2.5 The trivial part, the invariant amplitude, and the momentum-conserving delta

Most of the time nothing happens: the particles miss each other and emerge unchanged. This "forward," no-scattering possibility is contained in $\mathbf{S}$ as an identity piece, and it is convenient to separate it out so that what remains is pure interaction.

Definition 14.13 (The transition operator)**.** The transition operator T is defined by extracting the identity from $\mathbf{S}$,

$$\mathbf{S} \;=\; \mathbf{1} + i\,T. \tag{14.45}$$

The factor of i is conventional and chosen so that the Born approximation reproduces the nonrelativistic scattering amplitude with the standard sign.

The matrix element $\langle f|\mathbf{1}|i\rangle = \langle f|i\rangle$ is the trivial overlap: it is nonzero only when the final configuration coincides with the initial one (same particles, same momenta), and it describes no scattering. All scattering — everything a detector at wide angle ever sees — lives in $\langle f|iT|i\rangle$. We now show that this nontrivial part carries a kinematic factor that can be pulled out once and for all, leaving a function of the momenta alone.

Theorem 14.14 (Factorization of the momentum-conserving delta)**.** *Let $|i\rangle$ and $|f\rangle$ be momentum eigenstates with total four-momenta p_i^μ and p_f^μ. Then the matrix element of T is supported on $p_f = p_i$ and factorizes as*

$$\langle f|iT|i\rangle \;=\; (2\pi)^4\,\delta^4\!\Big(\textstyle\sum_f p_f - \sum_i p_i\Big)\; i\,\mathcal{M}(i\to f), \tag{14.46}$$

where $\mathcal{M}(i\to f)$, the invariant amplitude*, contains all the dynamics and is free of the overall conservation delta.*

Proof. The dynamics is invariant under spacetime translations: the full four-momentum operator P^μ generates translations, $U(a) = e^{iP\cdot a}$, and commutes with the Hamiltonian and hence with the S-operator, $[\,\mathbf{S}, P^\mu\,] = 0$. This is the operator statement of translation invariance established in Eq. (3.136); since $\mathbf{S} = U(\infty,-\infty)$ is built from the translation-invariant interaction, it inherits the symmetry. The identity piece $\mathbf{1}$ commutes with P^μ trivially, so T commutes with P^μ as well: $[\,T, P^\mu\,] = 0$.

Now act with a finite translation on both sides of the matrix element. Because $|i\rangle$ and $|f\rangle$ are momentum eigenstates, $U(a)\,|i\rangle = e^{ip_i\cdot a}\,|i\rangle$ and $\langle f|\,U(a)^\dagger = \langle f|\,e^{-ip_f\cdot a}$. Inserting $U(a)^\dagger U(a) = \mathbf{1}$ around T and using $[T, P^\mu] = 0$, i.e. $U(a)^\dagger\,T\,U(a) = T$,

$$\langle f|T|i\rangle = \Big\langle f\Big|U(a)^\dagger\,T\,U(a)\Big|i\Big\rangle = e^{-ip_f\cdot a}\,e^{+ip_i\cdot a}\;\langle f|T|i\rangle = e^{-i(p_f-p_i)\cdot a}\;\langle f|T|i\rangle\,. \tag{14.47}$$

This must hold for *every* constant four-vector a^μ. If $p_f \neq p_i$ the phase $e^{-i(p_f-p_i)\cdot a}$ is not identically one, so consistency forces $\langle f|T|i\rangle = 0$. The matrix element is therefore supported entirely on the hypersurface $p_f = p_i$, and as a distribution in the total momentum difference it must be proportional to $\delta^4(p_f - p_i)$ — the unique (up to normalization) translation-covariant distribution vanishing off $p_f = p_i$. Indeed, integrating Eq. (14.47) against $\int d^4a$ converts the constraint into the Fourier representation $\int d^4a\, e^{-i(p_f-p_i)\cdot a} = (2\pi)^4\delta^4(p_f - p_i)$, exhibiting the delta explicitly. Writing the proportionality constant as $i\mathcal{M}$ with the conventional $(2\pi)^4$ and the i inherited from *Eq.* (14.45) gives Eq. (14.46). That the residual factor $\mathcal{M}$ is well defined (the delta carries all the singular support, leaving an ordinary function of the on-shell momenta) is the statement that energy–momentum conservation is the only kinematic constraint the symmetry imposes. □

Proposition 14.15 (Lorentz invariance of the amplitude)**.** *For a scalar theory $\mathcal{M}(i \to f)$ is a Lorentz scalar: it depends on the external momenta only through their Lorentz-invariant combinations $p_a \cdot p_b$.*

Proof. The S-operator commutes not only with translations but with the full Poincaré group; in particular $U(\Lambda)\,\mathbf{S}\,U(\Lambda)^{-1} = \mathbf{S}$ for every proper orthochronous Lorentz transformation Λ, again because the interaction is Lorentz invariant (Eq. (3.136) and its Lorentz extension). For scalar particles the states transform as $U(\Lambda)\,|\mathbf{p}\rangle = |\Lambda\mathbf{p}\rangle$ with the invariant normalization of Eq. (3.193), so

$$\langle f|iT|i\rangle = \langle \Lambda f|iT|\Lambda i\rangle\,. \tag{14.48}$$

The delta $\delta^4(\sum p)$ is Lorentz invariant on the mass shell, hence so is the cofactor $\mathcal{M}$. A Lorentz-invariant function of the external momenta can depend on them only through their invariant dot products $p_a \cdot p_b$ (for $2 \to 2$ scattering, the Mandelstam invariants s, t, u), which is the assertion. For particles with spin the same argument applies with the states carrying little-group indices and $\mathcal{M}$ becoming a Lorentz-covariant tensor/spinor built from those, but the scalar case is all ϕ^4 theory requires. □

The invariant amplitude $\mathcal{M}$ is now the central computational target of the book: everything from cross sections and decay rates (Chapter 16) to the optical theorem is built on it. We pause to extract from unitarity the seed of that last result, both because it is short and because it shows the $\mathbf{1} + iT$ decomposition earning its keep.

Worked Example 14.16 (Unitarity in T-language: the optical-theorem seed)**.** Substitute $\mathbf{S} = \mathbf{1} + iT$ into the unitarity relation $\mathbf{S}^\dagger\mathbf{S} = \mathbf{1}$ of Theorem 14.12 and expand:

$$\mathbf{1} = (\mathbf{1} - iT^\dagger)(\mathbf{1} + iT) = \mathbf{1} + iT - iT^\dagger + T^\dagger T, \tag{14.49}$$

so the identity cancels and the remaining terms give the exact operator relation

$$-i\,(T - T^\dagger) \;=\; T^\dagger T, \qquad \text{equivalently} \qquad i\,(T^\dagger - T) = T^\dagger T. \tag{14.50}$$

Take the diagonal matrix element in a normalized state $|i\rangle$. The left side is

$$-i(\langle i|T|i\rangle - \left\langle i\middle|T^\dagger\middle|i\right\rangle) = -i(\langle i|T|i\rangle - \langle i|T|i\rangle^*) = -i\cdot 2i\ \mathrm{Im}\,\langle i|T|i\rangle = 2\ \mathrm{Im}\,\langle i|T|i\rangle\,, \tag{14.51}$$

using $\left\langle i\middle|T^\dagger\middle|i\right\rangle = \langle i|T|i\rangle^*$. The right side, with a complete set of intermediate states $\mathbf{1} = \sum_f |f\rangle\langle f|$ inserted, is

$$\left\langle i\middle|T^\dagger T\middle|i\right\rangle = \sum_f \left\langle i\middle|T^\dagger\middle|f\right\rangle \langle f|T|i\rangle = \sum_f |\langle f|T|i\rangle|^2\,. \tag{14.52}$$

Equating the two,

$$2\ \mathrm{Im}\,\langle i|T|i\rangle \;=\; \sum_f |\langle f|T|i\rangle|^2\,. \tag{14.53}$$

The imaginary part of the forward (initial = final) transition amplitude equals the total "probability" summed over all final states. This is unitarity rewritten as a statement about a *single* amplitude and a sum of squared amplitudes; converting both sides to invariant amplitudes $\mathcal{M}$ via Eq. (14.46) and stripping the shared deltas turns it into the optical theorem $2\ \mathrm{Im}\,\mathcal{M}(i\to i) = \sum_f \int d\Pi_f\ |\mathcal{M}(i\to f)|^2$, related to the total cross section. We carry that final step out in the chapter's closing section on the optical theorem (Section 14.7); here the point is only that the entire content of the optical theorem is already present in Eq. (14.53), which is nothing but $\mathbf{S}^\dagger\mathbf{S} = \mathbf{1}$ in disguise.

Worked Example 14.17 (The ϕ^4 four-point target)**.** The machinery of this chapter exists to produce numbers. The first interacting number ϕ^4 theory owes is the invariant amplitude for two-particle elastic scattering,

$$\mathcal{M}\big(\phi(p_1)\,\phi(p_2)\to\phi(p_3)\,\phi(p_4)\big), \tag{14.54}$$

the four-point amplitude of the real scalar with Lagrangian $\mathcal{L} = \frac{1}{2}(\partial\phi)^2 - \frac{1}{2}m^2\phi^2 - \frac{\lambda}{4!}\phi^4$. By Theorem 14.15 it is a Lorentz scalar, hence a function of the Mandelstam invariants $s = (p_1+p_2)^2$, $t = (p_1-p_3)^2$, $u = (p_1-p_4)^2$ alone (with $s+t+u = 4m^2$ on shell). Theorem 14.14 guarantees the kinematic prefactor $(2\pi)^4\delta^4(p_1+p_2-p_3-p_4)$; everything physical sits in $\mathcal{M}$. We do not yet have a value: computing $\mathcal{M}$ requires the time-ordered correlation functions of the next section, the spectral input of the Källén–Lehmann section, and the LSZ reduction that converts correlators into S-matrix elements. The reader should hold Eq. (14.54) in mind as the concrete destination; the chapter's payoff, computed two sections hence, is the leading result $\mathcal{M} = -\lambda + O(\lambda^2)$, equivalently $i\mathcal{M} = -i\lambda$ at order λ.

14.2.6 Honesty about the construction: Haag's theorem

We have written $\mathbf{S} = U(\infty, -\infty)$ and manipulated the interaction-picture field as though it were a free field carrying the full interacting dynamics in its time evolution. It is time to admit that this picture, taken literally, does not exist. The defect is not a technicality at the edges; it sits at the foundation, and naming it precisely is what lets us see why the perturbative manipulations nonetheless deliver correct physics.

Haag's theorem and what saves the formalism

The contradiction. The interaction picture assumes a single Hilbert space on which one unitary operator relates the interacting Heisenberg field $\phi(\mathbf{x}, t)$ to a free field $\phi_I(\mathbf{x}, t)$ at each time, with ϕ_I built on a free Fock vacuum. Trace the assumptions:

1. At a fixed time the interacting and free fields and their conjugate momenta are related by a unitary $V(t)$: $\phi(\mathbf{x}, t) = V(t)\,\phi_I(\mathbf{x}, t)\,V(t)^{-1}$, with the same equal-time commutation relations on both sides.
2. Both fields transform covariantly under the same unitary representation of spatial translations and rotations, with the *same* invariant vacuum.

Haag's theorem states that these hypotheses, taken together with Poincaré covariance and the uniqueness of the vacuum, force $V(t)$ to be a trivial (c-number phase) transformation: the two fields must then have *identical* vacuum expectation values to all orders, in particular the same two-point function and the same vacuum. But the whole point of an interaction is that the interacting vacuum is polarized and its correlators differ from the free ones — if they did not, there would be no scattering. The assumptions are mutually inconsistent: *no* nontrivial unitary $V(t)$ on a single Fock space can intertwine a free and an interacting field while preserving the vacuum. The interaction picture, as a rigorous object, does not exist.

The mechanism. The collision is between the uniqueness of the Fock representation and the inequivalence of representations in a system with infinitely many degrees of freedom. In ordinary quantum mechanics (finitely many degrees of freedom) the Stone–von Neumann theorem guarantees that all irreducible representations of the canonical commutation relations are unitarily equivalent, so a $V(t)$ relating two of them always exists. In quantum field theory that theorem fails: the free and interacting theories build *unitarily inequivalent* representations of the canonical commutation relations, and no unitary on one carries the vacuum of one to the vacuum of the other. The dressed, polarized interacting vacuum literally has infinite overlap deficit with the free vacuum ($\langle 0|\Omega\rangle \to 0$ in infinite volume). This is the same infinity that the adiabatic switch Eq. (14.38) and the Gell-Mann–Low phase quietly absorb.

The resolution. Haag's theorem forbids the interaction picture as a literal construction; it does not forbid the answers it formally produces. Two repairs make the manipulations legitimate. First, work in a finite spatial volume with a momentum cutoff: then there are finitely many degrees of freedom, Stone–von Neumann applies, $V(t)$ exists, and the interaction picture and the Dyson series are perfectly well defined. The pathology returns only in the limits of infinite volume and infinite cutoff — and those limits are precisely where renormalization operates. Second, the physical outputs of the formalism are not the (representation-dependent, ill-defined) bare correlators but *renormalized*, on-shell S-matrix elements, in which the field-strength renormalization Z, the mass renormalization, and the vacuum-overlap phase are systematically removed. The upshot, made operational by the LSZ formula and the renormalization program of Part VI, is the working stance of this book: treat $\mathbf{S} = U(\infty, -\infty)$ and the Dyson series as a generating algorithm for renormalized perturbation theory, whose individual ingredients may be formal but whose properly renormalized predictions are finite, unique, and spectacularly confirmed. Haag's theorem is the precise reason the next four sections are necessary: they are what turns Eq. (14.41) from a symbol into a calculation.

With the target defined — a Lorentz-invariant amplitude $\mathcal{M}$ extracted from $\langle f|\mathbf{S}|i\rangle$ — and the honest caveat recorded that the interaction-picture route to it is only formal, the path forward is forced. To compute $\langle f|\mathbf{S}|i\rangle$ we need objects that are genuinely calculable order by order in λ, and the only such objects the free theory hands us are the time-ordered vacuum correlation functions of free interaction-picture fields, evaluated by Wick's theorem. The next section, on correlation functions and the Gell-Mann–Low theorem, builds exactly that bridge: it rewrites the vacuum expectation values of time-ordered Heisenberg fields as Dyson-series expectation values of free fields, making the abstract $\langle f|\mathbf{S}|i\rangle$ of this section into something a diagram can evaluate.

14.3 Correlation Functions and the Gell-Mann–Low Theorem

The previous section left us with a demand and an obstruction. The demand is that every scattering probability be expressible through the S-operator $\mathbf{S} = U(+\infty, -\infty)$ acting between asymptotic states (Section 14.2); the obstruction is that those asymptotic states are eigenstates of the *full* interacting Hamiltonian H, whose spectrum we cannot diagonalize, and that the interacting vacuum $|\Omega\rangle$ is not the free Fock vacuum $|0\rangle$ of Theorem 9.11. The way forward, anticipated there, is not to solve for the eigenstates but to route everything through objects we *can*

compute order by order in the coupling: the time-ordered vacuum correlation functions

$$G^{(n)}(x_1,\dots,x_n) \;=\; \langle\Omega|\; \mathcal{T}\,\phi(x_1)\cdots\phi(x_n)\;|\Omega\rangle\,, \tag{14.55}$$

where $\phi(x)$ is the Heisenberg field of the interacting theory and $|\Omega\rangle$ its normalized ground state, $\langle\Omega|\Omega\rangle = 1$. The LSZ reduction of Section 14.5 will turn these correlators, evaluated near their mass-shell poles, into S-matrix elements; the present section manufactures the tool that makes them computable. That tool is the Gell-Mann–Low theorem, which rewrites Eq. (14.55) — an expectation value of *interacting* Heisenberg fields in the *unknown* interacting vacuum — as a ratio of expectation values of *free* interaction-picture fields in the *known* free vacuum, weighted by the Dyson exponential of the interaction. In that form Wick's theorem (Theorem 10.25) applies term by term, and the entire perturbative apparatus opens up.

Throughout we work with the frozen ϕ^4 theory theory,

$$\mathcal{L} = \tfrac{1}{2}(\partial_\mu\phi)(\partial^\mu\phi) - \tfrac{1}{2}m^2\phi^2 - \frac{\lambda}{4!}\phi^4, \qquad \lambda > 0, \tag{14.56}$$

in the mostly-minus metric and natural units, with the Feynman $i\varepsilon$ in force. The Legendre transform of Eq. (14.56) (Theorem 6.15) splits the Hamiltonian as

$$H = H_0 + H_{\text{int}}, \qquad H_0 = \int d^3x\,\left[\tfrac{1}{2}\pi^2 + \tfrac{1}{2}(\nabla\phi)^2 + \tfrac{1}{2}m^2\phi^2\right], \qquad H_{\text{int}} = \int d^3x\,\frac{\lambda}{4!}\phi^4, \tag{14.57}$$

because the ϕ^4 interaction carries no derivatives, so the canonical momentum $\pi = \dot\phi$ is unmodified and the interaction Hamiltonian density is simply minus the interaction Lagrangian density, $\mathcal{H}_{\text{int}} = +\frac{\lambda}{4!}\phi^4$. This sign — positive in H, hence producing the $e^{-iH_{\text{int}}t}$ that becomes the Dyson factor $e^{-i\int H_I}$ — is the one that ultimately delivers the vertex $-i\lambda$; we track it with care.

14.3.1 From Heisenberg fields to interaction-picture fields

The interaction picture interpolates between the Schrödinger picture, where states evolve and operators are fixed, and the Heisenberg picture, where operators carry all the time dependence. We fix the reference time at which all three pictures coincide to be $t = 0$; this choice costs nothing and removes a clutter of t_0's from every formula. At $t = 0$, then, the Schrödinger field $\phi(\mathbf{x})$, the Heisenberg field $\phi(0,\mathbf{x})$, and the interaction-picture field $\phi_I(0,\mathbf{x})$ are one and the same operator.

The Heisenberg field evolves with the full Hamiltonian,

$$\phi(t,\mathbf{x}) = e^{iHt}\,\phi(\mathbf{x})\,e^{-iHt}, \tag{14.58}$$

while the interaction-picture field evolves with the *free* Hamiltonian alone,

$$\phi_I(t,\mathbf{x}) = e^{iH_0t}\,\phi(\mathbf{x})\,e^{-iH_0t}. \tag{14.59}$$

Equation Eq. (14.59) is the crucial simplification: because ϕ_I is generated by the quadratic H_0, it obeys the free Heisenberg equation of motion $(\Box + m^2)\phi_I = 0$ and therefore *is* a free field. It admits exactly the mode expansion of Theorem 9.6, with the same creation and annihilation operators and the same free vacuum $|0\rangle$ satisfying $a_{\mathbf{p}}\,|0\rangle = 0$ and $H_0\,|0\rangle = 0$ (the zero-point energy having been removed by normal ordering in Chapter 9). All the free-field technology — the commutators, the propagator D_F of Theorem 9.24, and Wick's theorem — is available for ϕ_I and for it alone. The interacting Heisenberg field ϕ has none of this structure; the content of this subsection is that it can nonetheless be expressed through ϕ_I.

Define the *interaction-picture evolution operator*

$$U(t_1, t_2) \;\equiv\; e^{iH_0 t_1}\, e^{-iH(t_1 - t_2)}\, e^{-iH_0 t_2}, \tag{14.60}$$

which propagates interaction-picture states from time t_2 to time t_1. This is the operator whose perturbative expansion is the Dyson series established earlier in this chapter: differentiating Eq. (14.60) with respect to t_1 gives $i\partial_{t_1} U(t_1, t_2) = H_I(t_1)\, U(t_1, t_2)$, with the interaction Hamiltonian in the interaction picture

$$H_I(t) \;=\; e^{iH_0 t}\, H_{\text{int}}\, e^{-iH_0 t} \;=\; \int d^3x\, \frac{\lambda}{4!}\, \phi_I(t, \mathbf{x})^4, \tag{14.61}$$

and the solution, subject to $U(t, t) = \mathbf{1}$, is the time-ordered exponential of Theorem 14.6,

$$U(t_1, t_2) \;=\; \mathcal{T} \exp\Big[-i \int_{t_2}^{t_1} dt'\, H_I(t') \Big], \qquad t_1 > t_2. \tag{14.62}$$

We will need three algebraic properties of U, all immediate from the definition Eq. (14.60) and visible without recourse to the series:

$$U(t_1, t_2)\, U(t_2, t_3) = U(t_1, t_3) \qquad \text{(composition)}, \tag{14.63}$$

$$U(t_1, t_2)^{-1} = U(t_2, t_1) \qquad \text{(invertibility)}, \tag{14.64}$$

$$U(t_1, t_2)^{\dagger} = U(t_2, t_1) \qquad \text{(unitarity)}. \tag{14.65}$$

The first two follow by cancelling the inner exponentials in Eq. (14.60); the third because H and H_0 are Hermitian, so $U(t_1, t_2)^{\dagger} = e^{-iH_0 t_2} e^{+iH(t_1 - t_2)} e^{iH_0 t_1} = U(t_2, t_1)$. Together they say that the U's form a two-parameter family of unitaries that compose like a flow.

We can now express the Heisenberg field through the interaction-picture field. Combining Eqs. (14.58) to (14.60),

$$\begin{aligned} U^{\dagger}(t, 0)\, \phi_I(t, \mathbf{x})\, U(t, 0) &= \Big(e^{iHt} e^{-iH_0 t} \Big) \Big(e^{iH_0 t} \phi(\mathbf{x}) e^{-iH_0 t} \Big) \Big(e^{iH_0 t} e^{-iHt} \Big) \\ &= e^{iHt}\, \phi(\mathbf{x})\, e^{-iHt} \;=\; \phi(t, \mathbf{x}), \end{aligned} \tag{14.66}$$

where the free exponentials $e^{-iH_0t}e^{iH_0t} = \mathbf{1}$ collapse in the middle. Using $U^\dagger(t,0) = U(0,t)$ from Eq. (14.65), this is the relation we sought,

$$\boxed{\phi(t,\mathbf{x}) \;=\; U(0,t)\,\phi_I(t,\mathbf{x})\,U(t,0)\;.} \tag{14.67}$$

Every interacting field is a free field conjugated by the Dyson evolution. The same identity holds for any local operator built from ϕ: products, derivatives, and composites all transform by the same conjugation, since $U(0,t)\,AB\,U(t,0) = \big(U(0,t)A\,U(t,0)\big)\big(U(0,t)B\,U(t,0)\big)$. This is the lever that converts a correlator of interacting fields into a correlator of free fields glued together by U's.

Caution

The construction Eq. (14.60)–Eq. (14.67) is, taken literally, only formal: by Haag's theorem (flagged in Section 14.2) no unitary $U(t,0)$ can intertwine the free and interacting fields on a common Hilbert space, because the two representations of the canonical commutation relations are inequivalent. What survives the theorem, and what we actually use, is the *perturbative* content: each side of Eq. (14.67), expanded order by order in λ through Eq. (14.62), is a well-defined (after renormalization) formal power series, and it is those series the Gell-Mann–Low formula manipulates. We are computing the asymptotic expansion of a correlator, not asserting the existence of the operators that would sum it.

14.3.2 Projecting the interacting vacuum from the free vacuum

The relation Eq. (14.67) expresses interacting fields through free ones, but the correlator Eq. (14.55) is still taken in the interacting vacuum $|\Omega\rangle$, which we do not know. The second ingredient of the theorem is a way to manufacture $|\Omega\rangle$ out of the free vacuum $|0\rangle$, which we do know. The mechanism is adiabatic: if we let the free vacuum evolve for an enormous time under the full Hamiltonian, and tilt that time infinitesimally into the complex plane, every state above the ground state is exponentially suppressed relative to it, and what remains is the interacting vacuum.

Make this precise. Let the eigenstates of the full Hamiltonian be $|\Omega\rangle$ (the ground state, energy E_0) and a tower of excited eigenstates $|n\rangle$ with energies $E_n > E_0$; they form a complete set, $\mathbf{1} = |\Omega\rangle\langle\Omega| + \sum_{n\neq\Omega}|n\rangle\langle n|$. Resolve the free vacuum in this basis and evolve it backward through a large time T:

$$e^{-iHT}\,|0\rangle \;=\; e^{-iE_0T}\,|\Omega\rangle\langle\Omega|0\rangle \;+\; \sum_{n\neq\Omega} e^{-iE_nT}\,|n\rangle\langle n|0\rangle\,. \tag{14.68}$$

The phases e^{-iE_nT} all have unit modulus for real T, so no term is preferred. Now continue T into the lower-right of the complex plane, $T \to \infty(1-i\varepsilon)$ with $\varepsilon > 0$

infinitesimal — the same Feynman $i\varepsilon$ tilt that defined the propagator contour in Section 5.1 and projected the path integral onto its ground state in Chapter 10. Each phase acquires a real damping factor,

$$e^{-iE_nT} \longrightarrow e^{-iE_n\infty(1-i\varepsilon)} = \underbrace{e^{-iE_n\infty}}_{\text{unit modulus}} \cdot e^{-E_n\,\varepsilon\,\infty}, \tag{14.69}$$

and the relative size of the excited terms to the ground-state term is governed by $e^{-(E_n-E_0)\varepsilon\infty} \to 0$, because $E_n - E_0 > 0$ for every excited state (the assumption that $|\Omega\rangle$ is the unique, isolated ground state — the same gap that Section 14.4 will display as the separation between the one-particle pole and the continuum). In the limit only the $|\Omega\rangle$ term survives:

$$\lim_{T\to\infty(1-i\varepsilon)} e^{-iHT}\,|0\rangle = \lim_{T\to\infty(1-i\varepsilon)} e^{-iE_0T}\,|\Omega\rangle\,\langle\Omega|0\rangle\,. \tag{14.70}$$

Provided $\langle\Omega|0\rangle \neq 0$ — the interacting vacuum has nonzero overlap with the free vacuum, which is exactly the statement that perturbation theory around $|0\rangle$ is meaningful — we may solve for $|\Omega\rangle$:

$$|\Omega\rangle = \lim_{T\to\infty(1-i\varepsilon)} \Big(e^{-iE_0T}\,\langle\Omega|0\rangle\Big)^{-1} e^{-iHT}\,|0\rangle\,. \tag{14.71}$$

This is already a projection of $|\Omega\rangle$ from $|0\rangle$, but it is written with the full evolution e^{-iHT}; to feed it into the Dyson series we convert it to a U. Since $H_0\,|0\rangle = 0$, we may insert a free phase for free, $e^{-iHT}\,|0\rangle = e^{-iHT}e^{-iH_0T}\,|0\rangle$, and Eq. (14.60) identifies $e^{-iHT}e^{-iH_0T} = e^{iH_0\cdot 0}e^{-iH(0-(-T))}e^{-iH_0(-T)} = U(0,-T)$. Hence

$$|\Omega\rangle = \lim_{T\to\infty(1-i\varepsilon)} \Big(e^{-iE_0T}\,\langle\Omega|0\rangle\Big)^{-1} U(0,-T)\,|0\rangle\,. \tag{14.72}$$

The mirror computation evolves $|0\rangle$ forward by the same tilted time and produces the bra. Taking the Hermitian conjugate of Eq. (14.72) and using $U(0,-T)^\dagger = U(-T,0)$ would give $\langle\Omega|$ in terms of $U(-T,0)$; it is more useful to run the spectral argument forward, $e^{-iHT}\,|0\rangle \to (\dots)\,|\Omega\rangle$ replaced by $\langle 0|\,e^{+iHT} \to (\dots)\,\langle\Omega|$ under $T\to\infty(1-i\varepsilon)$, which gives

$$\langle\Omega| = \lim_{T\to\infty(1-i\varepsilon)} \langle 0|\,U(T,0)\,\Big(e^{-iE_0T}\,\langle 0|\Omega\rangle\Big)^{-1}, \tag{14.73}$$

where $U(T,0) = e^{iH_0T}e^{-iHT}$ and again $H_0\,|0\rangle = 0$ lets the free phase be inserted at no cost. Equations Eqs. (14.72) and (14.73) are the two halves of the projection; the awkward normalization factors $\big(e^{-iE_0T}\,\langle\Omega|0\rangle\,\big)^{-1}$ they carry are precisely what the denominator of the Gell-Mann–Low formula will cancel.

Physical Insight

The $i\varepsilon$ tilt is the operator-language version of adiabatic switching. In Gell-Mann and Low's original argument one multiplies the interaction by an envelope $e^{-\varepsilon|t|}$ that turns the coupling on slowly from the far past and off again in the far future; the free vacuum, dragged along adiabatically, deforms continuously into the interacting vacuum. Tilting T into the complex plane achieves the same suppression of excited states with less bookkeeping, and ties the construction to the same contour that defines the Feynman propagator. Physically: wait long enough, with the faintest absorption switched on, and any state relaxes to its ground state.

14.3.3 The Gell-Mann–Low formula

We now assemble the two ingredients into the central result.

Theorem 14.18 (Gell-Mann–Low)**.** *For the interacting theory Eq. (14.56), the time-ordered correlation functions of Heisenberg fields in the interacting vacuum are given by*

$$\langle\Omega|\,\mathcal{T}\,\phi(x_1)\cdots\phi(x_n)\,|\Omega\rangle \;=\; \frac{\langle 0|\,\mathcal{T}\Big[\phi_I(x_1)\cdots\phi_I(x_n)\,\exp\Big(-i\int_{-\infty}^{\infty}dt\,H_I(t)\Big)\Big]\,|0\rangle}{\langle 0|\,\mathcal{T}\exp\Big(-i\int_{-\infty}^{\infty}dt\,H_I(t)\Big)\,|0\rangle}\,, \tag{14.74}$$

where ϕ_I are free interaction-picture fields, $|0\rangle$ the free vacuum, $H_I(t)$ the interaction Hamiltonian of Eq. (14.61), and the time integrals run along the contour tilted by $T\to\infty(1-i\varepsilon)$. Equivalently, writing the exponent as a spacetime integral,

$$-i\int_{-\infty}^{\infty}dt\,H_I(t) \;=\; -\frac{i\lambda}{4!}\int d^4z\;\phi_I(z)^4, \tag{14.75}$$

so that each power of λ inserts a four-field vertex integrated over spacetime.

Proof. The strategy is to use Eq. (14.67) to convert the string of Heisenberg fields into interaction-picture fields linked by U's, fold those links into a single time-ordered Dyson exponential, and then replace the interacting vacuum at each end by the free vacuum via Eqs. (14.72) and (14.73). The annoying normalization factors that appear are then disposed of by the denominator.

Step 1: assemble the field string. It suffices to prove the identity for one time ordering of the arguments, since both sides are symmetric under permutations of the x_i (the left side by the time-ordering symbol, the right side because the ϕ_I sit inside a time-ordering symbol as well). Label the points so that

$t_1 > t_2 > \cdots > t_n$. By Eq. (14.67) each field is $\phi(x_i) = U(0,t_i)\,\phi_I(x_i)\,U(t_i,0)$, and the ordered product is

$$\begin{aligned}\phi(x_1)\cdots\phi(x_n) &= U(0,t_1)\,\phi_I(x_1)\,\big[U(t_1,0)U(0,t_2)\big]\,\phi_I(x_2)\,\big[U(t_2,0)U(0,t_3)\big]\cdots \\ &\quad \cdots\big[U(t_{n-1},0)U(0,t_n)\big]\,\phi_I(x_n)\,U(t_n,0) \\ &= U(0,t_1)\,\phi_I(x_1)\,U(t_1,t_2)\,\phi_I(x_2)\,U(t_2,t_3)\cdots U(t_{n-1},t_n)\,\phi_I(x_n)\,U(t_n,0),\end{aligned} \tag{14.76}$$

where each bracket collapsed by the composition law Eq. (14.63). The interaction-picture fields are now interleaved with evolution operators that bridge consecutive insertion times.

Step 2: insert the asymptotic times and recognize a single time-ordered exponential. Choose a time T larger than every t_i and split the outer factors with Eq. (14.63): $U(0,t_1) = U(0,T)U(T,t_1)$ and $U(t_n,0) = U(t_n,-T)U(-T,0)$. Equation Eq. (14.76) becomes

$$\phi(x_1)\cdots\phi(x_n) = U(0,T)\,\Big[\,U(T,t_1)\,\phi_I(x_1)\,U(t_1,t_2)\cdots\phi_I(x_n)\,U(t_n,-T)\,\Big]\,U(-T,0). \tag{14.77}$$

Examine the bracket. Reading from left to right, the times descend monotonically from T through $t_1 > t_2 > \cdots > t_n$ down to $-T$; every $U(t_a,t_b)$ inside has $t_a > t_b$ and is, by Eq. (14.62), the time-ordered exponential of H_I over the interval $[t_b,t_a]$. The whole bracket is therefore a product of objects already arranged in decreasing time, with the fields $\phi_I(x_i)$ sitting at their proper places in the chronological sequence. Such a product is exactly what the time-ordering symbol reconstructs: it equals

$$\Big[\ \cdots\ \Big] = \mathcal{T}\Big[\phi_I(x_1)\cdots\phi_I(x_n)\,\exp\Big(-i\int_{-T}^{T}dt\,H_I(t)\Big)\Big]. \tag{14.78}$$

To see this, note that $\mathcal{T}$ orders everything inside it by time regardless of how it is written; expanding the exponential on the right produces all the $H_I(t')$ factors, and $\mathcal{T}$ slots each one, together with the n fields, into chronological order, which is precisely the order displayed explicitly in Eq. (14.77). The U-intervals tile $[-T,T]$ without gaps or overlaps by construction, so the single integral from $-T$ to T reproduces all the segment integrals at once. Substituting Eq. (14.78) into Eq. (14.77),

$$\phi(x_1)\cdots\phi(x_n) = U(0,T)\,\mathcal{T}\Big[\phi_I(x_1)\cdots\phi_I(x_n)\,e^{-i\int_{-T}^{T}H_I}\Big]\,U(-T,0). \tag{14.79}$$

Because the left side was the ordered product for our chosen ordering $t_1 > \cdots > t_n$, and the right side is manifestly symmetric in the x_i once the $\mathcal{T}$ is in place, we may drop the ordering assumption and read Eq. (14.79) with a $\mathcal{T}$ on the left as well: it holds as an identity for the time-ordered product.

Step 3: replace the vacua. Sandwich Eq. (14.79) between $\langle\Omega|$ and $|\Omega\rangle$ and use the projections. On the right end, Eq. (14.72) gives $U(-T,0)\,|\Omega\rangle$ when read backwards: from $|\Omega\rangle = \big(e^{-iE_0T}\,\langle\Omega|0\rangle\,\big)^{-1}U(0,-T)\,|0\rangle$ we get, applying $U(-T,0)$ and using $U(-T,0)U(0,-T)=\mathbf{1}$,

$$U(-T,0)\,|\Omega\rangle = \Big(e^{-iE_0T}\,\langle\Omega|0\rangle\,\Big)^{-1}\,|0\rangle\,. \tag{14.80}$$

On the left end, Eq. (14.73) gives $\langle\Omega|\,U(0,T)$: from $\langle\Omega| = \langle 0|\,U(T,0)\big(e^{-iE_0T}\,\langle 0|\Omega\rangle\,\big)^{-1}$ and $U(T,0)U(0,T)=\mathbf{1}$,

$$\langle\Omega|\,U(0,T) = \Big(e^{-iE_0T}\,\langle 0|\Omega\rangle\,\Big)^{-1}\,\langle 0|\,. \tag{14.81}$$

Both replacements are understood in the limit $T\to\infty(1-i\varepsilon)$. Inserting Eqs. (14.80) and (14.81) into the sandwiched Eq. (14.79),

$$\langle\Omega|\,\mathcal{T}\,\phi(x_1)\cdots\phi(x_n)\,|\Omega\rangle = \frac{\langle 0|\,\mathcal{T}\big[\phi_I(x_1)\cdots\phi_I(x_n)\,e^{-i\int_{-T}^{T}H_I}\big]\,|0\rangle}{e^{-2iE_0T}\,\langle 0|\Omega\rangle\,\langle\Omega|0\rangle}\,, \tag{14.82}$$

where the two normalization factors have combined into the single c-number prefactor $e^{-2iE_0T}\,\langle 0|\Omega\rangle\,\langle\Omega|0\rangle$ in the denominator. This prefactor is the same for *every* correlator — it does not depend on n or on the points x_i, only on the overlap and the vacuum energy. That universality is what lets us eliminate it.

Step 4: the denominator. Apply Eq. (14.82) to the case $n=0$, i.e. to the vacuum normalization $\langle\Omega|\,|\Omega\rangle = 1$. With no fields inserted the left side is $\langle\Omega|\Omega\rangle = 1$, and the right side is

$$1 = \frac{\langle 0|\,\mathcal{T}\,e^{-i\int_{-T}^{T}H_I}\,|0\rangle}{e^{-2iE_0T}\,\langle 0|\Omega\rangle\,\langle\Omega|0\rangle} \quad\Longrightarrow\quad e^{-2iE_0T}\,\langle 0|\Omega\rangle\,\langle\Omega|0\rangle = \langle 0|\,\mathcal{T}\,e^{-i\int_{-T}^{T}H_I}\,|0\rangle\,. \tag{14.83}$$

The unknown prefactor is therefore nothing but the vacuum-to-vacuum amplitude of the Dyson exponential. Substituting Eq. (14.83) into Eq. (14.82) and taking $T\to\infty(1-i\varepsilon)$ gives Eq. (14.74), with Eq. (14.75) following from Eq. (14.61) on writing $\int dt\int d^3x = \int d^4z$. This completes the proof. □

The formula Eq. (14.74) is the workhorse of the rest of the book. Its right side contains only free fields ϕ_I and the free vacuum $|0\rangle$; expanding the exponential in powers of λ produces, at each order, a vacuum expectation value of a time-ordered product of finitely many free fields, which Wick's theorem (Theorem 10.25) evaluates as a sum of products of Feynman propagators D_F (Eq. (9.154)). Every interacting correlator is thereby reduced, order by order, to propagators and combinatorics — the seed of the Feynman diagram, whose systematic rules Chapter 15 will codify.

Notation Watch

Two distinct "vacua" and two distinct "fields" appear in Eq. (14.74) and must never be confused. On the left, $|\Omega\rangle$ is the true ground state of the interacting H and ϕ is the full Heisenberg field; these are the physical, exact objects and we cannot compute with them directly. On the right, $|0\rangle$ is the free Fock vacuum of Theorem 9.11 and ϕ_I is the free interaction-picture field; these are the computable objects. The theorem is the bridge between the two columns. Some texts (including Chapter 10's path-integral derivation) write the left side's vacuum as $|0\rangle$ as well, relying on the $i\varepsilon$ projection to mean the interacting one; we keep $|\Omega\rangle$ explicit here precisely to mark the distinction the LSZ reduction will exploit.

14.3.4 The denominator removes the vacuum bubbles

The denominator in Eq. (14.74) is not a cosmetic normalization; it performs a precise diagrammatic surgery. When the numerator is expanded by Wick's theorem, many of the resulting contraction patterns split into a piece tied to the external points $x_1, \dots, x_n$ and a piece floating free — a closed cluster of propagators and vertices with no external legs at all. These free-floating clusters are the *vacuum bubbles*. They are pure, x_i-independent numbers (in fact divergent ones), and they would spoil any correlator. The denominator is exactly the sum of all such bubbles, and dividing by it deletes them from the answer. We first see the mechanism in a concrete low-order computation, then prove it to all orders.

An explicit demonstration: the two-point function at $O(\lambda)$

Take $n = 2$ and expand the numerator of Eq. (14.74) to first order in λ, using Eq. (14.75):

$$\mathcal{N}^{(2)} = \langle 0|\,\mathcal{T}\,\phi_I(x)\phi_I(y)\,|0\rangle \;-\; \frac{i\lambda}{4!}\int d^4z\;\langle 0|\,\mathcal{T}\,\phi_I(x)\phi_I(y)\,\phi_I(z)^4\,|0\rangle \;+\; O(\lambda^2). \tag{14.84}$$

The zeroth-order term is just the free propagator, $\langle 0|\,\mathcal{T}\phi_I(x)\phi_I(y)\,|0\rangle = D_F(x-y)$ by Theorem 9.24. The $O(\lambda)$ term is a vacuum expectation value of six free fields; Wick's theorem expresses it as the sum over all $5!! = 15$ ways of pairing them into propagators. The pairings fall into two classes:

(a) $\phi_I(x)$ pairs with $\phi_I(y)$, and the four vertex fields $\phi_I(z)^4$ pair among themselves. There are 3 such pairings (the $3!! = 3$ ways to pair four fields), each contributing $D_F(x-y)\,D_F(0)^2$, where $D_F(0) = D_F(z-z)$ is the propagator at coincident points.

(b) $\phi_I(x)$ pairs with one of the four vertex fields (4 choices) and $\phi_I(y)$ with one of the remaining three (3 choices), and the last two vertex fields pair

together (1 way). There are $4\times3\times1=12$ such pairings, each contributing $D_F(x-z)\,D_F(z-y)\,D_F(0)$.

Indeed $3+12=15$. Collecting,

$$\mathcal{N}^{(2)}=D_F(x-y)-\frac{i\lambda}{4!}\int d^4z\Big[3\,D_F(x-y)D_F(0)^2+12\,D_F(x-z)D_F(z-y)D_F(0)\Big]+O(\lambda^2). \tag{14.85}$$

The factor $3/4!=1/8$ and $12/4!=1/2$ are the symmetry factors of the two diagrams. Write the class-(a) contribution as the free propagator times a number,

$$-\frac{i\lambda}{4!}\,3\int d^4z\,D_F(x-y)D_F(0)^2=D_F(x-y)\cdot V_1,\qquad V_1\equiv-\frac{i\lambda}{8}\int d^4z\,D_F(0)^2, \tag{14.86}$$

where V_1 is the value of the single $O(\lambda)$ vacuum bubble — the "figure-eight" formed by two propagators looping back on one vertex, with symmetry factor 8. The class-(b) contribution is the connected "tadpole" correction to the propagator,

$$\mathcal{T}(x,y)\equiv-\frac{i\lambda}{2}\int d^4z\,D_F(x-z)D_F(z-y)D_F(0). \tag{14.87}$$

So the numerator is $\mathcal{N}^{(2)}=D_F(x-y)(1+V_1)+\mathcal{T}(x,y)+O(\lambda^2)$. Now the denominator to the same order: with no external fields, only class-(a)-type pairings of the four vertex fields exist, giving

$$\mathcal{D}=\langle0|\,\mathcal{T}\,e^{-i\int H_I}\,|0\rangle=1-\frac{i\lambda}{4!}\,3\int d^4z\,D_F(0)^2+O(\lambda^2)=1+V_1+O(\lambda^2). \tag{14.88}$$

The denominator is precisely 1 plus the same bubble V_1. Dividing,

$$\frac{\mathcal{N}^{(2)}}{\mathcal{D}}=\frac{D_F(x-y)(1+V_1)+\mathcal{T}(x,y)}{1+V_1}+O(\lambda^2)=D_F(x-y)+\mathcal{T}(x,y)+O(\lambda^2). \tag{14.89}$$

The disconnected piece $D_F(x-y)\,V_1$ — a free propagator multiplied by a vacuum bubble — has cancelled exactly against the denominator's V_1, leaving only the free propagator and its genuine, *connected* radiative correction $\mathcal{T}$. This is the surgery promised: the bubbles are gone, and what survives is exactly the set of diagrams in which every vertex is tied, through propagators, to an external point.

The cancellation to all orders

The cancellation in Eq. (14.89) is not an accident of first order; it is the shadow of an exact factorization. We prove it in general.

Theorem 14.19 (Exponentiation of vacuum bubbles)**.** *Let the numerator of Eq. (14.74) be expanded by Wick's theorem into a sum over diagrams. Each*

diagram factorizes uniquely into a part connected (through propagators) to at least one external point and a part disconnected from all external points; the disconnected part is a product of vacuum bubbles. Summing over all diagrams,

$$\langle 0|\,\mathcal{T}\Big[\phi_I(x_1)\cdots\phi_I(x_n)\,e^{-i\int H_I}\Big]\,|0\rangle = \Big(\sum\ \textit{diagrams attached to externals}\Big)\times\exp\Big(\textstyle\sum_i V_i\Big), \tag{14.90}$$

where $\{V_i\}$ is the set of connected *vacuum-bubble values, and the same exponential is the denominator,*

$$\langle 0|\,\mathcal{T}\,e^{-i\int H_I}\,|0\rangle = \exp\Big(\textstyle\sum_i V_i\Big). \tag{14.91}$$

Consequently the Gell-Mann–Low ratio retains only the diagrams in which every vertex connects to an external point,

$$\langle\Omega|\,\mathcal{T}\,\phi(x_1)\cdots\phi(x_n)\,|\Omega\rangle = \sum\big(\textit{diagrams with all vertices attached to externals}\big). \tag{14.92}$$

Proof. Fix a Wick diagram in the expansion of the numerator at order λ^N, i.e. with N vertices arising from the N-th term $\frac{1}{N!}\big(-\frac{i\lambda}{4!}\int d^4z\,\phi_I^4\big)^N$ of the exponential. Partition its N vertices into those lying in the connected component(s) of at least one external point — call there be k of them — and the remaining $N-k$ vertices, which form closed clusters touching no external point. The closed clusters are, by definition, vacuum bubbles. Group the bubbles by isomorphism type: suppose the diagram contains n_i copies of the i-th distinct connected bubble, so that $\sum_i n_i\,(\text{vertices in bubble } i) = N-k$.

Now count the multiplicity with which this diagram arises. The $\frac{1}{N!}$ from the exponential is accompanied by $N!$ ways to assign the N labelled vertex-integration variables $z_1,\dots,z_N$ to the N vertex *positions* in the diagram. Of these assignments, $\binom{N}{k}\,k!\,/\,k!$ distribute vertices between the external-attached part and the bubbles; more usefully, the assignment factorizes: choose which k vertices attach to externals and arrange them ($\to$ generates the external-attached sub-sum), and arrange the rest into bubbles. The arrangements that merely relabel vertices *within* a single bubble, or permute identical bubbles among themselves, do not produce new diagrams and are exactly compensated by the symmetry factors. The net combinatorial statement is the standard one: the value of a diagram equals (value of its external-attached part) $\times\ \prod_i \frac{1}{n_i!}\,V_i^{\,n_i}$, where the $1/n_i!$ accounts for the indistinguishability of the n_i identical bubbles of type i, and V_i is the value of one such connected bubble (its own internal symmetry factor included, as in Eq. (14.86)).

Summing over all numbers $n_i \geq 0$ of each bubble type, independently, and over all external-attached parts, the sum factorizes:

$$\sum_{\text{diagrams}}(\cdots) = \Big(\sum_{\text{attached}}(\cdots)\Big)\times\prod_i\sum_{n_i=0}^{\infty}\frac{1}{n_i!}V_i^{\,n_i} = \Big(\sum_{\text{attached}}(\cdots)\Big)\times\prod_i e^{V_i} = \Big(\sum_{\text{attached}}(\cdots)\Big)\,e^{\sum_i V_i} \tag{14.93}$$

which is Eq. (14.90). The geometric-to-exponential resummation $\sum_n V^n/n! = e^V$ is where the disconnected pieces collect into a single exponential; it is the diagrammatic analogue of the elementary fact that the exponential of a sum of independent contributions is the product of their exponentials. For the denominator there are no external points, so the "attached" sum is just 1 (the empty diagram), and Eq. (14.93) collapses to Eq. (14.91). Dividing numerator by denominator cancels the common factor $e^{\sum_i V_i}$ identically, leaving Eq. (14.92). □

This is the all-orders justification of what we watched happen at $O(\lambda)$ in Eq. (14.89): the figure-eight V_1 was the lone bubble available at first order, $e^{V_1} = 1 + V_1 + \dots$ matched the denominator term for term, and the quotient kept only the connected tadpole. The lesson is structural and permanent: *vacuum bubbles never contribute to correlation functions*, and from Chapter 15 onward we simply never draw them.

Physical Insight

The vacuum bubbles are not meaningless — their sum is the phase and amplitude $e^{-2iE_0T}\,\langle 0|\Omega\rangle\,\langle\Omega|0\rangle$ of Eq. (14.83), i.e. the vacuum energy and the wavefunction overlap. They encode how the interaction shifts the ground-state energy and tilts the vacuum away from the free one. But these are properties of the vacuum alone; they are common to every correlator and therefore carry no information about the propagation or scattering of particles. The denominator's job is to subtract this universal background so that the numerator's particle physics stands clear. Dividing by $\langle 0|\,\mathcal{T}e^{-i\int H_I}\,|0\rangle$ is the field-theory way of measuring energies relative to the vacuum.

14.3.5 Reconciliation with the path-integral generating functional

We built two pillars in Part III, and consistency demands they compute the same correlators. The path integral of Chapter 10 defined the n-point Green's functions Theorem 10.18 as normalized functional derivatives of the generating functional,

$$G^{(n)}(x_1,\dots,x_n) = \frac{1}{Z[0]}\frac{1}{i^n}\,\frac{\delta^n Z[J]}{\delta J(x_1)\cdots\delta J(x_n)}\bigg|_{J=0} = \frac{\int\mathcal{D}\phi\;\phi(x_1)\cdots\phi(x_n)\,e^{iS}}{\int\mathcal{D}\phi\;e^{iS}}, \tag{14.94}$$

and Theorem 10.19 proved that these equal the time-ordered vacuum correlators $\langle\Omega|\,\mathcal{T}\phi(x_1)\cdots\phi(x_n)\,|\Omega\rangle$ — the very left side of the Gell-Mann–Low formula Eq. (14.74). The two routes must therefore agree, and it is worth seeing the agreement explicitly, because it reveals the same numerator/denominator structure in both languages.

Split the action $S = S_0 + S_{\text{int}}$ with $S_{\text{int}} = -\int d^4z\, \frac{\lambda}{4!}\phi^4$, and expand the interacting weight as $e^{iS} = e^{iS_0}\, e^{iS_{\text{int}}} = e^{iS_0}\, e^{-i\frac{\lambda}{4!}\int \phi^4}$. The numerator of Eq. (14.94) becomes

$$\int \mathcal{D}\phi\; \phi(x_1)\cdots\phi(x_n)\, e^{-\frac{i\lambda}{4!}\int \phi^4}\, e^{iS_0} = \Big\langle\, \phi(x_1)\cdots\phi(x_n)\, e^{-\frac{i\lambda}{4!}\int \phi^4} \,\Big\rangle_0 \;\times\; Z_0[0], \tag{14.95}$$

where $\langle\,\cdot\,\rangle_0 \equiv Z_0[0]^{-1}\int \mathcal{D}\phi\,(\cdot)\, e^{iS_0}$ is the *free* (Gaussian) field average and $Z_0[0] = \int \mathcal{D}\phi\, e^{iS_0}$ is the free partition function. The same split applied to the denominator gives $Z[0] = \langle e^{-\frac{i\lambda}{4!}\int \phi^4}\rangle_0\, Z_0[0]$. The common factor $Z_0[0]$ cancels in the ratio Eq. (14.94), leaving

$$G^{(n)} = \frac{\big\langle\, \phi(x_1)\cdots\phi(x_n)\, e^{-\frac{i\lambda}{4!}\int \phi^4} \,\big\rangle_0}{\big\langle\, e^{-\frac{i\lambda}{4!}\int \phi^4} \,\big\rangle_0}. \tag{14.96}$$

Compare Eq. (14.96) with Eq. (14.74). The structures are identical line for line: a free average of the fields times the exponentiated interaction, over the same free average of the interaction alone. The only translation needed is between the two notions of "free average." On the path-integral side, $\langle\,\cdot\,\rangle_0$ is the Gaussian average with weight e^{iS_0}; by the path-integral Wick theorem Theorem 10.23 (equivalently, by Theorem 10.19 applied to the free theory), this Gaussian average of a product of fields equals the free vacuum expectation value of their time-ordered product, $\langle\phi(y_1)\cdots\phi(y_m)\rangle_0 = \langle 0|\,\mathcal{T}\phi_I(y_1)\cdots\phi_I(y_m)\,|0\rangle$, with the time-ordering supplied automatically by the slicing (the $i\varepsilon$ contour of the Minkowski path integral being the same tilt $T \to \infty(1-i\varepsilon)$ that defined the projection in Section 14.3.2). Under this dictionary the numerator of Eq. (14.96) is the numerator of Eq. (14.74) and the denominators likewise. The spacetime integral $\int \phi^4$ in the exponent is the same object as the time integral of H_I through Eq. (14.75), and the factor of $-i$ matches: the canonical Dyson exponential carries $-iH_I = -i\int d^3x\, \frac{\lambda}{4!}\phi_I^4$ per unit time, while the path integral carries $iS_{\text{int}} = -i\int d^4z\, \frac{\lambda}{4!}\phi^4$, and the two coincide because the interaction has no derivatives and so $\mathcal{H}_{\text{int}} = -\mathcal{L}_{\text{int}}$.

Proposition 14.20 (The two routes agree)**.** *For the theory Eq. (14.56), the canonical Gell-Mann–Low formula Eq. (14.74) and the path-integral ratio Eq. (14.96) define the same time-ordered correlation functions order by order in λ. The cancellation of vacuum bubbles is the same phenomenon in both: in Section 14.3.4 the denominator $\langle 0|\,\mathcal{T}e^{-i\int H_I}\,|0\rangle$ removes the bubbles; in the path integral the denominator $Z[0]$, equal to $\langle e^{-\frac{i\lambda}{4!}\int \phi^4}\rangle_0\, Z_0[0]$, does the identical job, as already exhibited at low order in Theorem 10.20.*

Proof. Expand both exponentials in powers of λ. At order λ^N each route produces, in its own denominator-free numerator, a free average (canonical: free vacuum expectation value; path-integral: Gaussian average) of the n external fields together with $4N$ vertex fields, integrated over the N vertex positions

with weight $(-i\lambda/4!)^N/N!$. By the free Wick theorem — Theorem 10.23 on the path-integral side, the operator Wick theorem that Chapter 10 proved equivalent to it on the canonical side — both free averages evaluate to the identical sum over pairings into Feynman propagators D_F (Eq. (9.154)). Term by term the two numerators are equal; the same argument equates the two denominators. The ratios therefore agree to all orders, and Theorem 14.19 (canonical) and Theorem 10.20 (path-integral) are two derivations of one fact. The two pillars of Part III thus deliver one and the same perturbative correlator, as required by Theorem 10.19. □

The upshot is that the Feynman-diagram expansion of Chapter 15 is route-independent: one may reach it from operators, via the interaction picture and the Dyson series of this section, or from the path integral, via the master formula Eq. (10.186). Both arrive at the same numerator-over-denominator ratio, the same Wick pairings, and the same deletion of vacuum bubbles. We will use whichever is more convenient and trust that they coincide.

14.3.6 Scalar ϕ^4 theory: the four-point correlator set up for Wick expansion

We close by preparing the object that the first interacting amplitude of ϕ^4 theory will be built from: the connected four-point correlator at leading order in λ. The Gell-Mann–Low formula reduces it to free correlators; the worked example writes those out and isolates the single term that LSZ will turn into $i\mathcal{M} = -i\lambda$.

Worked Example 14.21 (The $O(\lambda)$ four-point function of the ϕ^4 theory)**.** We continue ϕ^4 theory from the free-field stage of Chapters 9 and 10 and apply Theorem 14.18 to

$$G^{(4)}(x_1, x_2, x_3, x_4) = \langle \Omega | \, \mathcal{T}\, \phi(x_1)\phi(x_2)\phi(x_3)\phi(x_4) \, | \Omega \rangle \, . \tag{14.97}$$

By Theorem 14.19 we may drop the denominator and the vacuum bubbles outright and keep only diagrams whose every vertex attaches to an external point. Expanding the numerator in λ:

Order λ^0. The free four-point function. Wick's theorem pairs four fields in $3!! = 3$ ways:

$$G^{(4)}\big|_{\lambda^0} = D_F(x_1{-}x_2)D_F(x_3{-}x_4)+D_F(x_1{-}x_3)D_F(x_2{-}x_4)+D_F(x_1{-}x_4)D_F(x_2{-}x_3). \tag{14.98}$$

Every term is a product of two independent propagators: two pairs of points exchange a particle, with nothing connecting one pair to the other. These are *disconnected* as far as the four points are concerned, and they describe no scattering — they are just two particles propagating past each other. LSZ will discard them because amputation on all four legs annihilates a diagram that does not link all four points.

Order λ^1. Insert one vertex from Eq. (14.75):

$$G^{(4)}|_{\lambda^1} = -\frac{i\lambda}{4!}\int d^4z\ \langle 0|\,\mathcal{T}\,\phi_I(x_1)\phi_I(x_2)\phi_I(x_3)\phi_I(x_4)\,\phi_I(z)^4\,|0\rangle\,. \tag{14.99}$$

This is a free vacuum expectation value of eight fields; Wick's theorem expands it into $7!! = 105$ pairings. They organize into three topological classes, of which only one is connected to all four external points:

- **Fully connected (the term we want).** Each external field $\phi_I(x_a)$ contracts with one of the four vertex fields $\phi_I(z)$. There are $4! = 24$ ways to match the four externals to the four vertex legs, each giving $D_F(x_1-z)D_F(x_2-z)D_F(x_3-z)D_F(x_4-z)$. The factor $24/4! = 1$ cancels the vertex's $1/4!$ exactly:

$$G^{(4)}|^{\text{conn}}_{\lambda^1} = -i\lambda\int d^4z\ D_F(x_1-z)D_F(x_2-z)D_F(x_3-z)D_F(x_4-z). \tag{14.100}$$

  All four external points meet at the single vertex z: this is the tree-level four-point "star," the diagram that represents two particles meeting, interacting once, and emerging.

- **Disconnected with a one-loop correction on one line.** Two externals contract with each other (giving a D_F between them), the other two each contract with a vertex leg, and the two leftover vertex legs contract together (a loop $D_F(0)$ at z). These reproduce the tadpole correction Eq. (14.87) on one propagator while the other propagator is a free spectator; they do not connect all four points and are removed by amputation, exactly as the disconnected λ^0 terms are.

- **External pair times a vacuum bubble.** Two externals contract with each other, the other two with each other, and the four vertex fields pair among themselves into the figure-eight V_1. These are (free $G^{(4)}|_{\lambda^0}$ term) $\times$ V_1 — precisely the bubble-times-correlator pieces that the denominator cancels by Theorem 14.19. They are already gone.

The only genuinely new, fully connected contribution at this order is Eq. (14.100). It is the four-point correlator's first piece of scattering content, and it is now in exactly the form LSZ requires: a single spacetime integral of four propagators meeting at a vertex carrying the factor $-i\lambda$. Amputating the four external legs and continuing to the mass shell will strip the four D_F's and the integral, leaving the invariant amplitude $i\mathcal{M} = -i\lambda$ — the first interacting number of ϕ^4 theory, to be extracted in Section 14.5 and re-derived diagrammatically in Chapter 15.

The worked example has delivered what the chapter's logical chain asked of this section: the interacting four-point function, expressed by Theorem 14.18 as

a Wick-expandable ratio of free correlators, with the vacuum bubbles removed by the denominator and the connected core Eq. (14.100) isolated and ready for amputation. The next section establishes the exact analytic structure of the interacting two-point function — the isolated single-particle pole and its residue Z — so that Section 14.5 knows precisely which pole of these correlators carries the S-matrix, and how to extract it.

14.4 The Källén–Lehmann Spectral Representation

The previous section handed us a single, exact object: the time-ordered two-point function of the interacting Heisenberg field,

$$G(x-y) \;\equiv\; \langle \Omega | \mathcal{T}\, \phi(x)\phi(y) | \Omega \rangle \,, \tag{14.101}$$

where $|\Omega\rangle$ is the true (interacting) vacuum and ϕ is the Heisenberg field of the theory $\mathcal{L} = \frac{1}{2}(\partial_\mu\phi)(\partial^\mu\phi) - \frac{1}{2}m^2\phi^2 - \frac{\lambda}{4!}\phi^4$ with $\lambda > 0$. The Gell-Mann–Low theorem of the preceding section told us how to *compute* G as a Dyson series of free-field Wick contractions, order by order in λ. But the LSZ formula of the next section will not consume G as a power series; it will consume one specific analytic feature of G — the location of a pole and the number sitting on top of it. The purpose of the present section is to establish, *exactly and nonperturbatively*, what the analytic structure of G must be in *any* relativistic quantum field theory with a stable particle, before a single diagram is drawn. The result, due to Källén and Lehmann, is that G is a positively-weighted superposition of free propagators of every possible mass, and that this superposition has an isolated single-particle pole carrying a residue Z with $0 \le Z \le 1$. That pole and that residue are precisely what LSZ extracts, so this section is the structural prerequisite for the chapter's central formula.

Everything that follows uses only three inputs: the Poincaré covariance of the theory, the completeness of its physical state space, and the canonical normalization of the field. No perturbation theory enters. The conclusions therefore hold to all orders and beyond.

14.4.1 The spectral hypotheses

We make explicit the structural assumptions about the interacting theory; they are the standard Wightman-style axioms restricted to exactly what the derivation needs.

(H1) **Poincaré covariance.** There is a unitary representation $U(\Lambda, a)$ of the Poincaré group on the Hilbert space, with P^μ the energy–momentum generators, $U(\mathbf{1}, a) = e^{iP\cdot a}$. The scalar field transforms as $U(\Lambda, a)\,\phi(x)\,U(\Lambda, a)^{-1} = \phi(\Lambda x + a)$. In particular spacetime translation acts as

$$\phi(x) = e^{iP\cdot x}\,\phi(0)\,e^{-iP\cdot x}. \tag{14.102}$$

(H2) **Spectral condition and a unique vacuum.** The joint spectrum of P^μ lies in the closed forward light cone, $p^0 \geq 0$ and $p^2 \geq 0$. There is a unique, Poincaré-invariant, normalized vacuum $|\Omega\rangle$ with $P^\mu |\Omega\rangle = 0$, $U(\Lambda, a)|\Omega\rangle = |\Omega\rangle$, and $\langle\Omega|\Omega\rangle = 1$.

(H3) **A stable one-particle state.** The spectrum contains an isolated mass-$m_{\rm ph}$ hyperboloid of one-particle states $|\mathbf{p}\rangle$ with $p^2 = m_{\rm ph}^2$, $p^0 > 0$, normalized covariantly (Eq. (3.193)),

$$\langle \mathbf{p}'|\mathbf{p}\rangle = (2\pi)^3\, 2E_{\mathbf{p}}\, \delta^3(\mathbf{p}-\mathbf{p}'), \qquad E_{\mathbf{p}} = \sqrt{\mathbf{p}^2 + m_{\rm ph}^2}. \tag{14.103}$$

"Isolated" means $m_{\rm ph}^2$ is strictly below the threshold of the multiparticle continuum, so the one-particle states form a discrete sheet of the spectrum, not its edge.

(H4) **Canonical normalization and no tadpole.** The Heisenberg field obeys the equal-time canonical commutation relation inherited from the Lagrangian (Eq. (9.7)), $\big[\phi(t,\mathbf{x}), \dot\phi(t,\mathbf{y})\big] = i\,\delta^3(\mathbf{x}-\mathbf{y})$, and the vacuum expectation value of the field vanishes, $\langle\Omega|\phi(x)|\Omega\rangle = 0$.

Remark 14.22 (On (H4)). The condition $\langle\Omega|\phi|\Omega\rangle = 0$ is automatic for $\lambda\phi^4$ because the Lagrangian is invariant under the $\mathbb{Z}_2$ symmetry $\phi \to -\phi$ (ϕ^4 theory, Chapter 7), which is unbroken in the symmetric phase $\lambda > 0$, $m^2 > 0$; the vacuum is $\mathbb{Z}_2$-even and ϕ is $\mathbb{Z}_2$-odd, so its expectation value must vanish. In a theory where it did not, one simply works with the shifted field $\phi - \langle\Omega|\phi|\Omega\rangle$, which has zero vacuum value and identical commutators; the analysis below applies verbatim to the shifted field. The canonical normalization of the kinetic term, coefficient $\frac{1}{2}$, is what fixes the right-hand side of the equal-time commutator to be exactly $i\,\delta^3$ with no extra constant, and it is this that will pin the sum rule and hence the bound on Z.

The physical mass $m_{\rm ph}$ named in (H3) is, by definition, the pole position of the exact propagator; we will see this emerge below. It is logically distinct from the Lagrangian parameter m, which is merely the coefficient in $\mathcal{L}$ and which we will henceforth call the *bare* mass. The two coincide only when interactions are switched off; the shift $m \to m_{\rm ph}$ generated by λ is mass renormalization, computed at one loop in Chapter 22.

14.4.2 Inserting a complete set of states

The strategy is the oldest one in spectral analysis: take the operator product, slip the resolution of the identity between the two fields, and let Poincaré covariance dictate everything that can possibly appear. We organize the complete set of states by their total four-momentum.

By (H2) and (H3), the physical spectrum consists of the vacuum, the one-particle hyperboloid, and a continuum of multiparticle states. Group all non-vacuum states into Lorentz-invariant families labelled by an index λ (which ranges over the one-particle states and over every multiparticle configuration); within each family the states $|\lambda_{\mathbf{p}}\rangle$ are obtained by boosting a zero-momentum representative $|\lambda_0\rangle$ and carry total four-momentum p^μ with $p^2 = M_\lambda^2$, $p^0 = E_{\mathbf{p}}(\lambda) = \sqrt{\mathbf{p}^2 + M_\lambda^2} > 0$. The completeness relation on the physical Hilbert space (Theorem 3.44) reads, with the Lorentz-invariant measure Eq. (3.191),

$$\mathbf{1} = |\Omega\rangle\langle\Omega| + \sum_\lambda \int \frac{d^3p}{(2\pi)^3\, 2E_{\mathbf{p}}(\lambda)}\; |\lambda_{\mathbf{p}}\rangle\langle\lambda_{\mathbf{p}}|\,, \tag{14.104}$$

each family normalized exactly as in Eq. (14.103) with $m_{\mathrm{ph}} \to M_\lambda$. Here $\sum_\lambda$ is shorthand for a sum over discrete families and an integral over the internal continuous parameters of each multiparticle family; the only feature we will use is that the invariant masses M_λ are real and bounded below.

Insert Eq. (14.104) into the Wightman function $\langle\Omega|\phi(x)\phi(y)|\Omega\rangle$ (the ordinary, not time-ordered, product). The vacuum term drops by (H4): $\langle\Omega|\phi(x)|\Omega\rangle\langle\Omega|\phi(y)|\Omega\rangle = 0$. What remains is

$$\langle\Omega|\phi(x)\phi(y)|\Omega\rangle = \sum_\lambda \int \frac{d^3p}{(2\pi)^3\, 2E_{\mathbf{p}}(\lambda)}\; \langle\Omega|\phi(x)|\lambda_{\mathbf{p}}\rangle\langle\lambda_{\mathbf{p}}|\phi(y)|\Omega\rangle\,. \tag{14.105}$$

Now use translation covariance Eq. (14.102) together with $P|\Omega\rangle = 0$ and $P^\mu|\lambda_{\mathbf{p}}\rangle = p^\mu|\lambda_{\mathbf{p}}\rangle$:

$$\langle\Omega|\phi(x)|\lambda_{\mathbf{p}}\rangle = \Big\langle\Omega\Big|e^{iP\cdot x}\phi(0)e^{-iP\cdot x}\Big|\lambda_{\mathbf{p}}\Big\rangle = e^{-ip\cdot x}\,\langle\Omega|\phi(0)|\lambda_{\mathbf{p}}\rangle\,, \tag{14.106}$$

and similarly $\langle\lambda_{\mathbf{p}}|\phi(y)|\Omega\rangle = e^{+ip\cdot y}\langle\lambda_{\mathbf{p}}|\phi(0)|\Omega\rangle$. The two single-field matrix elements at the origin are complex conjugates, so their product is $\big|\langle\Omega|\phi(0)|\lambda_{\mathbf{p}}\rangle\big|^2$.

The final reduction is Lorentz invariance applied to that matrix element. Because $\phi(0)$ is a scalar, $U(\Lambda)\phi(0)U(\Lambda)^{-1} = \phi(0)$, and because the vacuum is invariant, $\langle\Omega|\,U(\Lambda) = \langle\Omega|$, we have for any Lorentz transformation Λ

$$\langle\Omega|\phi(0)|\lambda_{\mathbf{p}}\rangle = \langle\Omega|\phi(0)\,U(\Lambda)|\lambda_0\rangle = \langle\Omega|U(\Lambda)\,\phi(0)|\lambda_0\rangle = \langle\Omega|\phi(0)|\lambda_0\rangle\,, \tag{14.107}$$

choosing $\Lambda = L(p)$, the boost that carries the rest-frame momentum to $\mathbf{p}$, so that $U(L(p))\,|\lambda_0\rangle = |\lambda_{\mathbf{p}}\rangle$. The matrix element is therefore *independent of* $\mathbf{p}$: it depends on the family only through its rest-frame value $\langle\Omega|\phi(0)|\lambda_0\rangle$, a single complex number for each λ.

Collect the constants and the $\mathbf{p}$-dependence separately. Define the *spectral density*

$$\rho(M^2) \;\equiv\; \sum_\lambda (2\pi)\,\delta(M^2 - M_\lambda^2)\,\big|\langle\Omega|\phi(0)|\lambda_0\rangle\big|^2. \tag{14.108}$$

By construction $\rho(M^2) \geq 0$ pointwise, since it is a sum of δ-functions weighted by squared moduli; this positivity is the linchpin of the whole story and we record it as a proposition below. With Eq. (14.108), the family sum in Eq. (14.105) reorganizes as an integral over a single variable M^2:

$$\begin{aligned}\langle\Omega|\phi(x)\phi(y)|\Omega\rangle &= \sum_{\lambda} \big|\langle\Omega|\phi(0)|\lambda_0\rangle\big|^2 \int \frac{d^3p}{(2\pi)^3\, 2E_{\mathbf{p}}(\lambda)}\, e^{-ip\cdot(x-y)}\Big|_{p^0=E_{\mathbf{p}}(\lambda)} \\ &= \int_0^\infty \frac{dM^2}{2\pi}\,\rho(M^2)\, \underbrace{\int \frac{d^3p}{(2\pi)^3\, 2E_{\mathbf{p}}}\, e^{-ip\cdot(x-y)}\Big|_{p^0=\sqrt{\mathbf{p}^2+M^2}}}_{=\; D_+(x-y;M^2)}.\end{aligned} \tag{14.109}$$

The inner integral is exactly the positive-frequency Wightman function $D_+(x-y;M^2)$ of a *free* scalar of mass M — the same object built in Chapter 9 (Eq. (9.148)), now read at the variable mass M. We have proved the spectral representation of the Wightman function: the interacting two-point function is a continuous, positively-weighted superposition of free Wightman functions of all masses.

14.4.3 The Källén–Lehmann representation

Restoring the time ordering is now immediate, because time ordering acts identically inside each fixed-mass term. The time-ordered product is $\mathcal{T}\phi(x)\phi(y) = \theta(x^0-y^0)\phi(x)\phi(y) + \theta(y^0-x^0)\phi(y)\phi(x)$, and applying Eq. (14.109) to each ordering gives

$$\langle\Omega|\mathcal{T}\phi(x)\phi(y)|\Omega\rangle = \int_0^\infty \frac{dM^2}{2\pi}\,\rho(M^2)\,\Big[\theta(x^0-y^0)D_+(x-y;M^2)+\theta(y^0-x^0)D_+(y-x;M^2)\Big]. \tag{14.110}$$

The bracket is, term by term, precisely the construction of the *free* Feynman propagator of mass M from its Wightman functions (Eq. (9.153)). Hence the bracket equals $D_F(x-y;M^2)$, and we arrive at the central result.

Theorem 14.23 (Källén–Lehmann spectral representation)**.** *Under hypotheses* (H1)–(H4)*, the exact time-ordered two-point function of the interacting scalar field is*

$$\boxed{\langle\Omega|\mathcal{T}\phi(x)\phi(y)|\Omega\rangle = \int_0^\infty \frac{dM^2}{2\pi}\,\rho(M^2)\,D_F(x-y;M^2)} \tag{14.111}$$

where $D_F(x-y;M^2)$ is the free Feynman propagator of mass M (Eq. (9.154)) *and the spectral density $\rho(M^2)$ of Eq. (14.108) satisfies $\rho(M^2) \geq 0$. Equivalently,*

Fourier transforming term by term with $\int d^4x\, e^{ip\cdot x} D_F(x;M^2) = i/(p^2 - M^2 + i\varepsilon)$, *the momentum-space propagator is*

$$\boxed{\widetilde{G}(p) \equiv \int d^4x\; e^{ip\cdot x}\; \langle\Omega|\mathcal{T}\phi(x)\phi(0)|\Omega\rangle = \int_0^\infty \frac{dM^2}{2\pi}\, \frac{i\,\rho(M^2)}{p^2 - M^2 + i\varepsilon}}. \tag{14.112}$$

Proof. Equation (14.111) was assembled in Eqs. (14.109) and (14.110); positivity of ρ is manifest from Eq. (14.108). For Eq. (14.112), interchange the (absolutely convergent, in the distributional sense) M^2 and x integrations and use the momentum-space form of the free Feynman propagator Eq. (9.154): $\int d^4x\, e^{ip\cdot x} \int \frac{d^4q}{(2\pi)^4} \frac{i\,e^{-iq\cdot x}}{q^2 - M^2 + i\varepsilon} = \frac{i}{p^2 - M^2 + i\varepsilon}$. The $i\varepsilon$ is inherited unchanged from the free propagators, which is consistent because the analytic continuation that defines the Feynman contour is the same for every mass M (Section 5.4.1). □

Proposition 14.24 (Positivity of the spectral density)**.** $\rho(M^2) \geq 0$ *for all* M^2, *and* $\rho(M^2) = 0$ *for* $M^2 < 0$ *and (by the spectral condition (H2)) for* M^2 *below the lowest physical invariant mass.*

Proof. Immediate from Eq. (14.108): each term is a non-negative number $|\,\langle\Omega|\phi(0)|\lambda_0\rangle\,|^2$ times a δ-function supported at the physical mass $M_\lambda^2 \geq 0$. There are no states with $M_\lambda^2 < 0$ by (H2), so ρ vanishes there. □

Positivity is not a technical decoration. It is the statement that the spectral density is a genuine probability-like weight — it measures how strongly the field ϕ acting on the vacuum overlaps with a physical state of squared mass M^2. Everything physical we extract below (the sign of the residue, the bound on Z) is a consequence of $\rho \geq 0$.

Physical Insight: the field as a state-creation amplitude

Read Eq. (14.108) backwards: $\rho(M^2)\, dM^2/2\pi$ is the total squared amplitude for the local operation "act once with $\phi(0)$ on the vacuum" to produce a physical state of invariant mass in $[M, M + dM]$. A *free* field can only make a single quantum: all of ρ sits at one mass. An *interacting* field, applied once, also shakes loose multiparticle states — $\phi(0)\,|\Omega\rangle$ is a superposition of one particle, three particles, five particles, … — and ρ spreads out to record exactly that. The Källén–Lehmann representation is the precise bookkeeping of this spreading.

14.4.4 The pole, the continuum, and the residue Z

We now separate the one-particle contribution, which is the part LSZ will use. By (H3) the one-particle states form an isolated family with $M_\lambda^2 = m_{\text{ph}}^2$. Its rest-frame matrix element defines the *field-strength renormalization.*

Definition 14.25 (Field-strength renormalization Z)**.** The square root of the residue, $\sqrt{Z}$, is the amplitude for the field to create the one-particle state from the vacuum:

$$\langle \Omega | \phi(0) | \mathbf{p} \rangle \;\equiv\; \sqrt{Z}, \qquad Z \equiv \left| \langle \Omega | \phi(0) | \mathbf{p} \rangle \right|^2 \geq 0, \tag{14.113}$$

a real non-negative constant independent of $\mathbf{p}$ by Eq. (14.107). (Any phase in the matrix element is absorbed into the definition of the one-particle state; Z is the modulus squared.)

Splitting the one-particle family off the rest of the sum in Eq. (14.108) gives the canonical decomposition of the spectral density,

$$\boxed{\rho(M^2) = 2\pi\, Z\, \delta(M^2 - m_{\mathrm{ph}}^2) + \rho_{\mathrm{cont}}(M^2)} \tag{14.114}$$

where $\rho_{\mathrm{cont}}(M^2) \geq 0$ collects all multiparticle (and any bound-state) contributions and, by the spectral condition, is supported at and above the multiparticle threshold $M^2 \geq M_{\mathrm{th}}^2$. For ϕ^4 theory in the symmetric phase the $\mathbb{Z}_2$ symmetry forces ϕ to create only odd numbers of particles, so the lightest multiparticle state with nonzero overlap has three quanta and the continuum begins at $M_{\mathrm{th}}^2 = (3m_{\mathrm{ph}})^2$; in a theory without that selection rule the threshold would be $(2m_{\mathrm{ph}})^2$. Inserting Eq. (14.114) into the momentum-space representation Eq. (14.112) and doing the δ-function integral isolates the pole:

$$\widetilde{G}(p) = \frac{iZ}{p^2 - m_{\mathrm{ph}}^2 + i\varepsilon} + \int_{M_{\mathrm{th}}^2}^{\infty} \frac{dM^2}{2\pi}\, \frac{i\,\rho_{\mathrm{cont}}(M^2)}{p^2 - M^2 + i\varepsilon}. \tag{14.115}$$

The two terms have completely different analytic characters in the complex p^2 plane, and this difference is the whole point.

- The first term is an *isolated simple pole* at $p^2 = m_{\mathrm{ph}}^2$ with residue iZ. It is the imprint of the stable single particle.
- The second term is analytic except for a *branch cut* along the real axis from $p^2 = M_{\mathrm{th}}^2$ to $+\infty$. Indeed, for p^2 approaching the cut, the denominator $p^2 - M^2 + i\varepsilon$ produces, via $\frac{1}{x+i\varepsilon} = \mathrm{PV}\,\frac{1}{x} - i\pi\delta(x)$, a discontinuity proportional to $\rho_{\mathrm{cont}}(p^2)$. Concretely, the discontinuity across the cut measures the continuum spectral density directly,

  $$\mathrm{disc}\,\widetilde{G}(p^2) \equiv \widetilde{G}(p^2 + i\varepsilon) - \widetilde{G}(p^2 - i\varepsilon) = \rho_{\mathrm{cont}}(p^2) \quad \text{for } p^2 > M_{\mathrm{th}}^2, \tag{14.116}$$

  which is the announced result that the multiparticle continuum is encoded in the imaginary part of the exact propagator; this same discontinuity reappears physically as the optical theorem in the final section of the chapter.

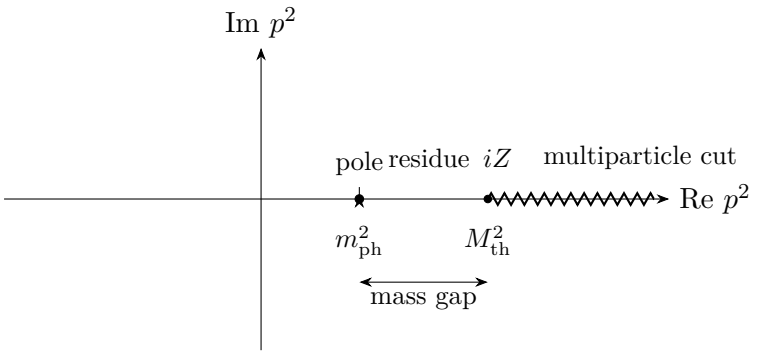

Figure 14.3: Analytic structure of the exact momentum-space propagator $\widetilde{G}(p^2)$ in the complex p^2 plane, as dictated by the Källén–Lehmann representation Eq. (14.115). A single isolated pole sits at the physical mass-squared $m^2_{\rm ph}$ with residue iZ; the multiparticle continuum produces a branch cut beginning at the threshold $M^2_{\rm th}$. The finite gap between them — guaranteed by hypothesis (H3) — is what lets LSZ pick the pole out cleanly. For ϕ^4 theory in the symmetric phase, $M^2_{\rm th} = (3m_{\rm ph})^2$.

The structure of Fig. 14.3 is the result of this section. Near the pole, the continuum term is regular, so the exact propagator behaves as

$$\boxed{\widetilde{G}(p) \xrightarrow{p^2 \to m^2_{\rm ph}} \frac{iZ}{p^2 - m^2_{\rm ph} + i\varepsilon}} \tag{14.117}$$

This is the single fact LSZ requires: the full propagator has a simple pole at the physical mass, with residue iZ rather than the free residue i. The number Z measures, by Eq. (14.113), how much of a genuine one-particle state the interacting field manufactures when it acts once on the vacuum; the deficit $1 - Z$ is the probability that it makes a multiparticle splash instead. We now prove that this interpretation is forced, by bounding Z between 0 and 1.

14.4.5 The sum rule and the bound $0 \le Z \le 1$

The bound comes from confronting the spectral representation with the one piece of information we have not yet used: the canonical commutator (H4). The equal-time commutator is a known c-number, and the spectral representation expresses the *same* commutator as an integral over ρ. Equating the two yields a sum rule that constrains the total spectral weight.

Take the spectral form of the Wightman function Eq. (14.109) and build the vacuum expectation value of the commutator,

$$\langle\Omega|[\phi(x),\phi(y)]|\Omega\rangle = \int_0^\infty \frac{dM^2}{2\pi}\,\rho(M^2)\,\Big[D_+(x-y;M^2) - D_+(y-x;M^2)\Big]. \tag{14.118}$$

The bracket is the free Pauli–Jordan commutator function of mass M; for a canonically normalized free field of any mass it obeys the universal equal-time identities

$$\big[D_+(x-y;M^2)-D_+(y-x;M^2)\big]\Big|_{x^0=y^0}=0, \qquad \partial_{x^0}\big[\cdots\big]\Big|_{x^0=y^0}=-i\,\delta^3(\mathbf{x}-\mathbf{y}), \tag{14.119}$$

the second of which is mass-*independent* — it is just the statement that every canonically normalized free scalar has $\big[\phi(t,\mathbf{x}),\dot\phi(t,\mathbf{y})\big]=i\delta^3$ regardless of its mass, a fact established for the free field in Chapter 9. (The mass-independence is the crucial point: the right-hand side carries no factor of M, so it pulls straight out of the M^2 integral.) Differentiating Eq. (14.118) with respect to x^0 and setting $x^0=y^0$,

$$\Big\langle\Omega\Big|\big[\phi(t,\mathbf{x}),\dot\phi(t,\mathbf{y})\big]\Big|\Omega\Big\rangle=\int_0^\infty\frac{dM^2}{2\pi}\,\rho(M^2)\,\big(-i\,\delta^3(\mathbf{x}-\mathbf{y})\big)\cdot(-1)=i\,\delta^3(\mathbf{x}-\mathbf{y})\int_0^\infty\frac{dM^2}{2\pi}\,\rho(M^2). \tag{14.120}$$

But the left-hand side is, by the canonical commutator (H4), exactly $i\,\delta^3(\mathbf{x}-\mathbf{y})$ — here we used that $\big[\phi,\dot\phi\big]$ is a c-number for the free building blocks, so its vacuum expectation value equals the operator itself; more carefully, the canonical commutator is an operator identity whose vacuum sandwich is $i\delta^3$. Matching the two sides forces the *spectral sum rule*

$$\boxed{\int_0^\infty\frac{dM^2}{2\pi}\,\rho(M^2)=1} \tag{14.121}$$

The bound now follows in one line. Insert the decomposition Eq. (14.114) into the sum rule:

$$1=\int_0^\infty\frac{dM^2}{2\pi}\,\rho(M^2)=Z+\int_{M_{\rm th}^2}^\infty\frac{dM^2}{2\pi}\,\rho_{\rm cont}(M^2). \tag{14.122}$$

Theorem 14.26 (Bound on the field-strength renormalization)**.** *The residue Z of the one-particle pole satisfies*

$$0\le Z\le 1, \tag{14.123}$$

with $Z=1$ if and only if the continuum is absent ($\rho_{\rm cont}\equiv 0$), which holds precisely for a free field. For any genuinely interacting theory with a nontrivial multiparticle continuum, $Z<1$ strictly.

Proof. $Z\ge 0$ is part of Theorem 14.25, being a squared modulus. From Eq. (14.122), $Z=1-\int_{M_{\rm th}^2}^\infty\frac{dM^2}{2\pi}\rho_{\rm cont}(M^2)$; by Theorem 14.24 the integrand is non-negative, so the subtracted integral is ≥ 0 and therefore $Z\le 1$. Equality $Z=1$ requires the continuum integral to vanish; since $\rho_{\rm cont}\ge 0$, this forces $\rho_{\rm cont}\equiv 0$ almost everywhere, i.e. $\phi(0)\,|\Omega\rangle$ has no multiparticle component, which is the defining property of a free field. $\square$

Physical Insight: Z as the single-particle probability

The sum rule Eq. (14.121) says the total probability for $\phi(0)\,|\Omega\rangle$ to land somewhere in the physical spectrum is 1 (canonical normalization). Equation (14.122) then partitions that unit probability: Z is the fraction that lands on a single particle, and $1 - Z$ is the fraction that lands on the multiparticle continuum. Interactions can only *redistribute* weight from the pole into the continuum — never create weight at the pole beyond unity — which is the physical content of $Z \leq 1$. This is why $\sqrt{Z}$ is the natural "efficiency" of the field as a single-particle source, and why exactly one factor of $\sqrt{Z}$ per external leg will appear in LSZ.

Caution: Z is scheme- and normalization-dependent

The bound $0 \leq Z \leq 1$ relies on the canonical normalization (H4): the field whose commutator is exactly $i\delta^3$. In renormalized perturbation theory one often rescales to a renormalized field $\phi_r = Z^{-1/2}\phi$, whose two-point function has residue 1 at the pole by construction; for that field the "Z" is moved into the relation between ϕ_r and the canonical ϕ. The number Z is also, individually, ultraviolet-divergent in a cutoff theory and finite only after renormalization; what is physical is the pole position m^2_{ph} and the residues of *S-matrix elements*, in which the $\sqrt{Z}$ factors cancel against the field normalization, as the next section makes explicit. The bound holds for the bare-canonical field at any fixed regularization; do not read $0 \leq Z \leq 1$ as a statement about a renormalized residue normalized to unity.

14.4.6 Worked examples

Worked Example 14.27 (The free field saturates the bound)**.** Set $\lambda = 0$ in ϕ^4 theory, so ϕ is the free scalar of Chapter 9 with mass m. We verify that the Källén–Lehmann machinery reproduces the free propagator and gives $Z = 1$, $\rho_{\text{cont}} = 0$, as it must.

For the free field, $\phi(0)$ acting on the vacuum produces exactly one quantum: from the mode expansion (Theorem 9.6), $\phi(0)\,|0\rangle = \int \frac{d^3p}{(2\pi)^3 2E_{\mathbf{p}}}\,|\mathbf{p}\rangle$, a pure one-particle state with no multiparticle admixture. The only family λ with nonzero $\langle 0|\phi(0)|\lambda_0\rangle$ is the single particle, and the rest-frame matrix element is $\langle 0|\phi(0)|\mathbf{p}=0\rangle = 1$ in the conventions of Chapter 9 (the field is its own creation amplitude, normalized by the canonical commutator). Hence by Eq. (14.108)

$$\rho_{\text{free}}(M^2) = 2\pi\,\delta(M^2 - m^2), \tag{14.124}$$

i.e. $Z = 1$ and $\rho_{\text{cont}} \equiv 0$. The sum rule Eq. (14.121) is satisfied: $\int \frac{dM^2}{2\pi}\, 2\pi\delta(M^2 -$

$m^2) = 1$. Substituting Eq. (14.124) into the position-space representation Eq. (14.111),

$$\langle 0|\mathcal{T}\phi(x)\phi(y)|0\rangle = \int_0^\infty \frac{dM^2}{2\pi}\, 2\pi\delta(M^2 - m^2)\, D_F(x-y;M^2) = D_F(x-y;m^2), \tag{14.125}$$

which is exactly the free Feynman propagator Eq. (9.154). The representation is consistent, and the free field is the unique case that saturates $Z = 1$. In the complex p^2 plane of Fig. 14.3, the cut has disappeared and only the pole at m^2 with residue i remains — there is nothing else in the free spectrum for ϕ to reach.

Worked Example 14.28 (ϕ^4 theory: Z at tree level and beyond)**.** We continue ϕ^4 theory (Theorem 14.27) and ask what interactions do to Z. At tree level, the time-ordered two-point function is computed from the Gell-Mann–Low expansion of the previous section; the $O(\lambda^0)$ term is the free propagator, so

$$Z = 1 + O(\lambda). \tag{14.126}$$

The $O(\lambda)$ correction to the propagator is the tadpole diagram, in which the single quartic vertex closes a loop on the propagator line. Crucially, this $O(\lambda)$ self-energy is a *momentum-independent constant* (the loop integral does not depend on the external momentum p). A p-independent self-energy shifts the *location* of the pole — it is a mass renormalization, $m^2 \to m^2_{\rm ph} = m^2 + O(\lambda)$ — but it cannot change the *residue*, because the residue is governed by the p-dependence of the self-energy near the pole, $Z^{-1} = 1 - \Sigma'(m^2_{\rm ph})$, and a constant has vanishing derivative. Therefore the first correction to Z vanishes:

$$Z = 1 + O(\lambda^2). \tag{14.127}$$

The leading nontrivial shift is the $O(\lambda^2)$ "sunset" contribution, the first diagram whose self-energy depends on p, and it is computed in full in Chapter 19 as part of the renormalization of ϕ^4; the bound Eq. (14.123) guarantees in advance that the $O(\lambda^2)$ coefficient is *negative*, since the now-open three-particle continuum ($M^2_{\rm th} = (3m_{\rm ph})^2$) carries away positive spectral weight, forcing $Z < 1$. We prove no number here — the loop integral belongs to Chapter 19 — but we have located exactly where the first correction lives and fixed its sign.

14.4.7 Handing the pole to LSZ

We have established, with no recourse to perturbation theory, that the exact momentum-space propagator of any theory satisfying (H1)–(H4) has an isolated simple pole at the physical mass-squared $m^2_{\rm ph}$ with residue iZ, $0 \le Z \le 1$, sitting below a multiparticle continuum, as displayed in Eq. (14.117) and Fig. 14.3. The next section makes this structure do work: the LSZ reduction formula shows that an n-point time-ordered correlator develops a pole in each external momentum

at exactly $p_i^2 = m_{\mathrm{ph}}^2$, that the residue at the simultaneous on-shell limit is the S-matrix element, and that each external leg contributes one factor of $\sqrt{Z}$ — the very amplitude $\langle\Omega|\phi(0)|\mathbf{p}\rangle = \sqrt{Z}$ defined here. The pole position, the residue Z, and the external $\sqrt{Z}$ factors are the three objects we now carry forward into LSZ.

14.5 The LSZ Reduction Formula

The two preceding sections placed the two halves of the bridge on opposite banks. The Gell-Mann–Low theorem (Theorem 14.18) gave us objects we can actually *compute*: time-ordered vacuum correlation functions of Heisenberg fields, $\langle\Omega|\mathcal{T}\phi(x_1)\cdots\phi(x_N)|\Omega\rangle$, rewritten as Dyson-series expectation values of free fields and therefore reducible to Wick contractions order by order in λ. The Källén–Lehmann representation (Theorem 14.23) then told us the exact analytic shape of the simplest such object: the interacting two-point function carries an isolated simple pole at $p^2 = m^2$, with a residue iZ set by the field-strength renormalization $0 < Z \leq 1$, sitting on top of a multiparticle continuum that begins at the threshold $p^2 = (3m)^2$ (the $\mathbb{Z}_2$ selection rule of ϕ^4 theory raises the generic $(2m)^2$ to $(3m)^2$; Section 14.4.4). What we still lack is the span connecting the two banks — a precise statement of how the numbers an experiment measures, the S-matrix elements $\langle f|\mathbf{S}|i\rangle$ of Theorem 14.11, are read off from these correlators. That span is the Lehmann–Symanzik–Zimmermann (LSZ) reduction formula, and building it is the business of this section. The punchline, established below in full, is disarmingly operational: an S-matrix element is the *amputated, connected, on-shell* momentum-space correlation function, dressed with one factor of $\sqrt{Z}$ for each external particle. Every later Feynman-rules chapter of Parts IV and V is, in the end, an industrialized procedure for evaluating the right-hand side of this one formula.

14.5.1 The asymptotic condition

The physical content of LSZ rests entirely on a single hypothesis about the long-time behaviour of the interacting field, the *asymptotic condition*. To state it we must first say precisely what free fields the interacting field is supposed to approach.

Recall from Section 14.2.2 that the in- and out-states are the complete bases that, in the remote past and future respectively, describe freely propagating physical particles of the *physical* mass m built on the interacting vacuum $|\Omega\rangle$. Associated with each basis is a free field that creates and annihilates those asymptotic quanta. The *in-field* $\phi_{\mathrm{in}}(x)$ is the free scalar field of mass m whose creation operators build the in-states, with mode expansion (the free expansion

of Eq. (9.42), written in the relativistic normalization of Eq. (3.193))

$$\phi_{\rm in}(x) \;=\; \int \widetilde{dp}\,\Big(a_{\rm in}(\mathbf{p})\,e^{-ip\cdot x} + a^{\dagger}_{\rm in}(\mathbf{p})\,e^{+ip\cdot x}\Big), \qquad p^0 = E_{\mathbf{p}} = \sqrt{\mathbf{p}^2+m^2}, \tag{14.128}$$

where $\widetilde{dp} \equiv d^3p/[(2\pi)^3\,2E_{\mathbf{p}}]$ is the Lorentz-invariant measure and the creation operators are normalized so that

$$|\mathbf{p};\text{in}\rangle = a^{\dagger}_{\rm in}(\mathbf{p})\,|\Omega\rangle\,, \qquad \Big[a_{\rm in}(\mathbf{p}), a^{\dagger}_{\rm in}(\mathbf{q})\Big] = (2\pi)^3\,2E_{\mathbf{p}}\,\delta^{(3)}(\mathbf{p}-\mathbf{q}), \tag{14.129}$$

in agreement with $\langle \mathbf{p};\text{in}|\mathbf{q};\text{in}\rangle = (2\pi)^3\,2E_{\mathbf{p}}\,\delta^{(3)}(\mathbf{p}-\mathbf{q})$ of Eq. (3.193). The *out-field* $\phi_{\rm out}(x)$ is defined identically with "in" replaced by "out". Both are honest free fields of mass m: each satisfies the free Klein–Gordon equation $(\Box + m^2)\phi_{\rm in/out} = 0$ and each has the textbook canonical commutators.

The interacting Heisenberg field $\phi(x)$, by contrast, satisfies the full nonlinear equation of motion $(\Box + m^2)\phi = -\frac{\lambda}{3!}\phi^3$ and does *not* create single-particle states cleanly — acting on the vacuum it produces a single particle *and* a cloud of multiparticle states, exactly the structure the Källén–Lehmann continuum records. The asymptotic condition is the statement that, nevertheless, in the distant past and future the interacting field settles down onto a free field, up to the normalization $\sqrt{Z}$ already isolated by the spectral representation.

Definition 14.29 (Asymptotic condition; weak form)**.** There exists a constant Z, $0 < Z \le 1$, equal to the Källén–Lehmann residue of Theorem 14.23, such that the interacting field approaches the asymptotic free fields,

$$\phi(x) \;\xrightarrow{x^0\to-\infty}\; \sqrt{Z}\,\phi_{\rm in}(x), \qquad \phi(x) \;\xrightarrow{x^0\to+\infty}\; \sqrt{Z}\,\phi_{\rm out}(x), \tag{14.130}$$

where the limits hold in the *weak* sense: for any pair of normalizable states $|\alpha\rangle\,, |\beta\rangle$ in the physical Hilbert space, $\langle\alpha|\phi(x)|\beta\rangle \to \sqrt{Z}\,\Big\langle\alpha\Big|\phi_{\rm in/out}(x)\Big|\beta\Big\rangle$ as $x^0 \to \mp\infty$, with the spatial dependence smeared against a normalizable wavepacket profile.

The constant $\sqrt{Z}$ is forced, not chosen. The Källén–Lehmann analysis fixed the overlap of the interacting field with the physical one-particle state,

$$\langle\Omega|\phi(0)|\mathbf{p}\rangle = \sqrt{Z}, \qquad \text{equivalently} \qquad \langle\Omega|\phi(x)|\mathbf{p}\rangle = \sqrt{Z}\,e^{-ip\cdot x}, \tag{14.131}$$

(the x-dependence following from translation covariance, $\phi(x) = e^{iP\cdot x}\phi(0)e^{-iP\cdot x}$, acting on the momentum eigenstate). The asymptotic free field $\phi_{\rm in}$, by Eqs. (14.128) and (14.129), has $\langle\Omega|\phi_{\rm in}(x)|\mathbf{p};\text{in}\rangle = e^{-ip\cdot x}$. Matching the two one-particle matrix elements forces precisely the factor $\sqrt{Z}$ in Eq. (14.130); with that factor in place the interacting and asymptotic fields agree on the one-particle sector, which is all an asymptotic free particle can probe.

Why the limit must be weak

The arrows in Eq. (14.130) cannot be promoted to a *strong* operator limit ($\phi(x) \to \sqrt{Z}\,\phi_{\rm in}(x)$ as operators on the Hilbert space). If they could, ϕ and $\sqrt{Z}\,\phi_{\rm in}$ would generate unitarily equivalent field algebras and the interacting two-point function would have residue $Z = 1$ with no continuum — contradicting Theorem 14.23, which gives $Z < 1$ precisely because the interacting field also creates multiparticle states. This is the same circle of ideas as Haag's theorem (Section 14.2.6): the interaction picture does not exist in the naive strong sense. The escape is that scattering observables are matrix elements between fixed normalizable states, and the weak limit of Theorem 14.29 is all those observables require. Concretely, every plane-wave manipulation below is shorthand for a statement about the normalizable wavepackets Eq. (14.37); smearing converts the weak limit into ordinary convergence of numbers and, as we will see, makes the spatial surface terms in the integrations by parts vanish honestly.

14.5.2 Inverting the mode expansion

The reduction procedure extracts one asymptotic particle at a time, and to do so we need a formula that recovers a creation operator from the field. The standard device is the equal-time Klein–Gordon inner product. For any two functions write

$$A(x)\overset{\leftrightarrow}{\partial_0}B(x) \;\equiv\; A(x)\,\partial_0 B(x) - (\partial_0 A(x))\,B(x). \tag{14.132}$$

Lemma 14.30 (Inversion of the in-field expansion)**.** *The creation and annihilation operators of the in-field are recovered from $\phi_{\rm in}$ by the time-independent integrals*

$$a^\dagger_{\rm in}(\mathbf{p}) = -\,i\int d^3x\; e^{-ip\cdot x}\overset{\leftrightarrow}{\partial_0}\phi_{\rm in}(x), \qquad a_{\rm in}(\mathbf{p}) = +\,i\int d^3x\; e^{+ip\cdot x}\overset{\leftrightarrow}{\partial_0}\phi_{\rm in}(x), \tag{14.133}$$

with $p^0 = E_{\mathbf{p}}$ on shell, and the right-hand sides independent of the time x^0 at which the spatial integral is taken.

Proof. Insert Eq. (14.128) into the first integral and act with ∂_0 on each factor. For the annihilation piece $a_{\rm in}(\mathbf{q})e^{-iq\cdot x}$ we have $\partial_0 e^{-iq\cdot x} = -iE_{\mathbf{q}}\,e^{-iq\cdot x}$ and $\partial_0 e^{-ip\cdot x} = -iE_{\mathbf{p}}\,e^{-ip\cdot x}$, so

$$e^{-ip\cdot x}\overset{\leftrightarrow}{\partial_0}e^{-iq\cdot x} = e^{-ip\cdot x}(-iE_{\mathbf{q}})e^{-iq\cdot x} - (-iE_{\mathbf{p}})e^{-ip\cdot x}e^{-iq\cdot x} = -i\,(E_{\mathbf{q}}-E_{\mathbf{p}})\,e^{-i(p+q)\cdot x}. \tag{14.134}$$

The spatial integral $\int d^3x\, e^{i(\mathbf{p}+\mathbf{q})\cdot\mathbf{x}} = (2\pi)^3\delta^{(3)}(\mathbf{p}+\mathbf{q})$ sets $\mathbf{q} = -\mathbf{p}$, hence $E_{\mathbf{q}} = E_{\mathbf{p}}$, and the prefactor $E_{\mathbf{q}} - E_{\mathbf{p}}$ vanishes: the annihilation piece does not

contribute. For the creation piece $a^\dagger_{\rm in}(\mathbf{q})e^{+iq\cdot x}$, with $\partial_0 e^{+iq\cdot x} = +iE_{\mathbf{q}}e^{+iq\cdot x}$,

$$e^{-ip\cdot x}\overset{\leftrightarrow}{\partial_0}e^{+iq\cdot x} = i\,(E_{\mathbf{q}}+E_{\mathbf{p}})\,e^{-i(p-q)\cdot x}, \tag{14.135}$$

and now $\int d^3x\, e^{-i(\mathbf{p}-\mathbf{q})\cdot\mathbf{x}} = (2\pi)^3\delta^{(3)}(\mathbf{p}-\mathbf{q})$ sets $\mathbf{q}=\mathbf{p}$, so $E_{\mathbf{q}}=E_{\mathbf{p}}$ and the time-dependent factor $e^{-i(E_{\mathbf{p}}-E_{\mathbf{q}})x^0}=1$ drops out — which is why the result is independent of x^0. Collecting,

$$\int d^3x\; e^{-ip\cdot x}\overset{\leftrightarrow}{\partial_0}\phi_{\rm in}(x) = \int\widetilde{dq}\; i\,(2E_{\mathbf{p}})\,(2\pi)^3\delta^{(3)}(\mathbf{p}-\mathbf{q})\,a^\dagger_{\rm in}(\mathbf{q}) = i\,a^\dagger_{\rm in}(\mathbf{p}), \tag{14.136}$$

where the factor $2E_{\mathbf{p}}$ cancels the $1/(2E_{\mathbf{q}})$ in $\widetilde{dq}$. Multiplying by $-i$ gives the first relation in Eq. (14.133); Hermitian conjugation, using $\phi^\dagger_{\rm in}=\phi_{\rm in}$ and $(-i)^*=+i$, gives the second. □

The identical formulae hold with "in" replaced by "out". We now use them on the interacting field, where the asymptotic condition makes them meaningful only as $x^0\to\mp\infty$.

14.5.3 Single-particle reduction

We are ready for the central manoeuvre. Take an S-matrix element with at least one particle in the initial state,

$$S_{fi} = \langle\,\mathbf{q}_1\cdots\mathbf{q}_m;\text{out}\,|\,\mathbf{p}_1\cdots\mathbf{p}_n;\text{in}\,\rangle\,, \tag{14.137}$$

and isolate the incoming particle of momentum $\mathbf{p}_1$ by writing the in-ket as $|\mathbf{p}_1\cdots;\text{in}\rangle = a^\dagger_{\rm in}(\mathbf{p}_1)\,|\mathbf{p}_2\cdots;\text{in}\rangle$. Throughout we assume the kinematics is *genuinely inelastic*: no incoming momentum $\mathbf{p}_i$ coincides with any outgoing momentum $\mathbf{q}_j$. This is the generic case, and it is exactly the assumption that quarantines the trivial "no-scattering" pieces; we track what those pieces would have been and confirm they drop.

The strategy is to trade $a^\dagger_{\rm in}$ for $a^\dagger_{\rm out}$. The out-creation operator, acting on the out-bra to its left, would merely re-insert particle $\mathbf{p}_1$ among the outgoing particles — a disconnected, non-scattering contribution — so once we show that this term carries no scattering, what remains is an integral over the interacting field, which is computable. Define, for the *interacting* field, the time-dependent operator

$$F(x^0)\;\equiv\;-i\int d^3x\; e^{-ip_1\cdot x}\overset{\leftrightarrow}{\partial_0}\phi(x), \qquad p_1^0=E_{\mathbf{p}_1}. \tag{14.138}$$

By the asymptotic condition Eq. (14.130) and the inversion Eq. (14.133) (applied to $\phi_{\rm in}$ and $\phi_{\rm out}$),

$$\lim_{x^0\to-\infty}F(x^0)=\sqrt{Z}\,a^\dagger_{\rm in}(\mathbf{p}_1), \qquad \lim_{x^0\to+\infty}F(x^0)=\sqrt{Z}\,a^\dagger_{\rm out}(\mathbf{p}_1), \tag{14.139}$$

both understood weakly, between the states of Eq. (14.137). The difference of the two asymptotic creation operators is therefore the difference of the two boundary values of F, which the fundamental theorem of calculus expresses as a total time integral:

$$\sqrt{Z}\,\big(a^\dagger_{\rm in}(\mathbf{p}_1)-a^\dagger_{\rm out}(\mathbf{p}_1)\big)=F(-\infty)-F(+\infty)=-\int_{-\infty}^{\infty}dx^0\;\partial_0F(x^0). \tag{14.140}$$

It remains to evaluate ∂_0F. Differentiating Eq. (14.138) under the integral,

$$\partial_0F=-i\int d^3x\;\partial_0\Big(e^{-ip_1\cdot x}\overleftrightarrow{\partial_0}\,\phi\Big)=-i\int d^3x\,\Big(e^{-ip_1\cdot x}\,\partial_0^2\phi-(\partial_0^2e^{-ip_1\cdot x})\,\phi\Big), \tag{14.141}$$

where the two cross terms $\partial_0e^{-ip_1\cdot x}\,\partial_0\phi$ cancel between the two halves of $\overleftrightarrow{\partial_0}$. (As stressed above, these plane-wave manipulations stand for statements about the smeared wavepacket states of Eq. (14.37), for which the matrix elements have compact spatial support and the surface terms below are honestly zero.) Now use $\partial_0^2e^{-ip_1\cdot x}=(-iE_{\mathbf{p}_1})^2e^{-ip_1\cdot x}=-E^2_{\mathbf{p}_1}e^{-ip_1\cdot x}$ together with the on-shell relation $E^2_{\mathbf{p}_1}=\mathbf{p}_1^2+m^2$:

$$-(\partial_0^2e^{-ip_1\cdot x})\,\phi=(\mathbf{p}_1^2+m^2)e^{-ip_1\cdot x}\,\phi. \tag{14.142}$$

The term $\mathbf{p}_1^2\,e^{-ip_1\cdot x}$ is converted to a spatial Laplacian acting on the exponential, $\mathbf{p}_1^2\,e^{-ip_1\cdot x}=-\nabla^2e^{-ip_1\cdot x}$ (since $e^{-ip_1\cdot x}\propto e^{+i\mathbf{p}_1\cdot\mathbf{x}}$), and the Laplacian is moved onto the field by integrating by parts twice over $\mathbf{x}$. The surface terms vanish: for the smeared wavepacket states of Eq. (14.37) the field matrix elements have compact spatial support at any finite time, so there is no boundary at spatial infinity. Hence

$$\int d^3x\,(-\nabla^2e^{-ip_1\cdot x})\phi=\int d^3x\;e^{-ip_1\cdot x}(-\nabla^2\phi), \tag{14.143}$$

and, combining Eqs. (14.141) to (14.143),

$$\partial_0F=-i\int d^3x\;e^{-ip_1\cdot x}(\partial_0^2-\nabla^2+m^2)\phi=-i\int d^3x\;e^{-ip_1\cdot x}\,(\Box+m^2)\,\phi(x), \tag{14.144}$$

where $\Box=\partial_0^2-\nabla^2$ is the d'Alembertian in the mostly-minus metric. Inserting Eq. (14.144) into Eq. (14.140) and solving for $a^\dagger_{\rm in}$,

$$a^\dagger_{\rm in}(\mathbf{p}_1)=a^\dagger_{\rm out}(\mathbf{p}_1)+\frac{i}{\sqrt{Z}}\int d^4x\;e^{-ip_1\cdot x}\,(\Box+m^2)\,\phi(x). \tag{14.145}$$

This is the elementary reduction step: it expresses an incoming creation operator as an outgoing one plus a four-dimensional integral of the Klein–Gordon operator acting on the interacting field, with the universal weight $i/\sqrt{Z}$ and the plane-wave phase $e^{-ip_1\cdot x}$.

Substituting Eq. (14.145) into Eq. (14.137),

$$S_{fi} = \underbrace{\left\langle \mathbf{q};\text{out}\middle| a^\dagger_{\text{out}}(\mathbf{p}_1)\middle|\mathbf{p}_2\cdots;\text{in}\right\rangle}_{\text{disconnected}} + \frac{i}{\sqrt{Z}}\int d^4x_1\; e^{-ip_1\cdot x_1}\,(\Box_1+m^2)\,\langle \mathbf{q};\text{out}|\phi(x_1)|\mathbf{p}_2\cdots;\text{in}\rangle\,. \tag{14.146}$$

The first term is the promised disconnected piece, and we now show it carries no scattering. Acting to the left, $\langle \mathbf{q};\text{out}|\, a^\dagger_{\text{out}}(\mathbf{p}_1) = \big(a_{\text{out}}(\mathbf{p}_1)\,|\mathbf{q};\text{out}\rangle\big)^\dagger$. The annihilation operator removes one of the outgoing particles whenever its momentum matches $\mathbf{p}_1$,

$$a_{\text{out}}(\mathbf{p}_1)\,|\mathbf{q}_1\cdots\mathbf{q}_m;\text{out}\rangle = \sum_{j=1}^{m}(2\pi)^3\,2E_{\mathbf{p}_1}\,\delta^{(3)}(\mathbf{p}_1-\mathbf{q}_j)\;|\mathbf{q}_1\cdots\widehat{\mathbf{q}_j}\cdots\mathbf{q}_m;\text{out}\rangle\,, \tag{14.147}$$

the hat denoting omission. Every term is proportional to $\delta^{(3)}(\mathbf{p}_1-\mathbf{q}_j)$ and so vanishes under our inelastic assumption $\mathbf{p}_1\neq\mathbf{q}_j$. Physically these terms describe the incoming particle $\mathbf{p}_1$ sailing through untouched and reappearing among the outgoing particles; they are pieces of the identity part of $\mathbf{S}$ in the decomposition $\mathbf{S}=\mathbf{1}+i\mathcal{T}_{\text{r}}$ used implicitly in Theorem 14.11, not of the scattering part. For a genuine reaction they are absent, and Eq. (14.146) collapses to its second term: one external particle has been "reduced" into a Klein–Gordon-amputated matrix element of the interacting field.

What the reduction step is doing

The combination $(\Box+m^2)\phi$ is the source of the field — by the equation of motion it equals $-\frac{\lambda}{3!}\phi^3$, which is nonzero only where the field interacts. Reducing a leg therefore replaces the question "does an asymptotic particle of momentum $\mathbf{p}_1$ enter?" with the question "where, in spacetime, is a quantum of momentum $\mathbf{p}_1$ emitted or absorbed by the interaction?", Fourier-analysed by the plane wave $e^{-ip_1\cdot x_1}$. The factor $1/\sqrt{Z}$ compensates for the fact that the interacting field creates a one-particle state with amplitude $\sqrt{Z}$ rather than unity: it strips off the wavefunction renormalization so that exactly one properly normalized asymptotic particle is attached to the leg.

14.5.4 Induction to all legs, and the emergence of time ordering

To reduce a second incoming particle, $\mathbf{p}_2$, we repeat the manoeuvre on $\langle \mathbf{q};\text{out}|\phi(x_1)|\mathbf{p}_2\cdots;\text{in}\rangle$, again writing $|\mathbf{p}_2\cdots;\text{in}\rangle = a^\dagger_{\text{in}}(\mathbf{p}_2)\,|\mathbf{p}_3\cdots;\text{in}\rangle$ and using Eq. (14.145). There is one new bookkeeping point: the new field $\phi(x_2)$ enters through $a^\dagger_{\text{in}}(\mathbf{p}_2)$, whose defining limit is $x_2^0\to-\infty$. In that limit x_2^0 is earlier than *any* fixed time, in particular earlier than x_1^0, so when the reduced integral is assembled the operator

$\phi(x_2)$ stands to the *right* of $\phi(x_1)$ inside the matrix element. Symmetrically, reducing an outgoing particle $\mathbf{q}_j$ uses $a_{\text{out}}(\mathbf{q}_j)$, whose limit is $y_j^0 \to +\infty$, later than any fixed time, so its field $\phi(y_j)$ is placed to the *left*. The relevant inversion for an outgoing leg is the second relation in Eq. (14.133); running the same fundamental-theorem argument gives

$$a_{\text{out}}(\mathbf{q}) = a_{\text{in}}(\mathbf{q}) + \frac{i}{\sqrt{Z}} \int d^4y \, e^{+iq\cdot y} \, (\Box_y + m^2) \, \phi(y), \tag{14.148}$$

with the conjugate phase $e^{+iq\cdot y}$; the leftover $a_{\text{in}}(\mathbf{q})$ piece is again disconnected and vanishes for inelastic kinematics by the analogue of Eq. (14.147).

Each successive reduction places its field at the appropriate temporal extreme — earliest times to the right for incoming legs, latest times to the left for outgoing legs — and the product of all the fields therefore assembles itself, automatically, into a *time-ordered* product. This is the decisive structural fact: although nothing in the asymptotic condition mentions time ordering, the ordering is generated leg by leg by the very limits $x^0 \to \mp\infty$ that define the in- and out-operators. After all n incoming and m outgoing particles are reduced, every external state has been converted into a field with a Klein–Gordon operator and a plane wave, the vacuum $|\Omega\rangle$ is exposed on both sides, and we arrive at the master formula.

Theorem 14.31 (LSZ reduction formula, position space)**.** *For genuinely inelastic kinematics ($\mathbf{p}_i \neq \mathbf{q}_j$ for all i, j), the connected S-matrix element Eq. (14.137) is*

$$\langle\, \mathbf{q}_1 \cdots \mathbf{q}_m; \text{out} \,|\, \mathbf{p}_1 \cdots \mathbf{p}_n; \text{in} \,\rangle = \Big(\frac{i}{\sqrt{Z}}\Big)^{n+m} \prod_{i=1}^{n} \int d^4x_i \, e^{-ip_i\cdot x_i} (\Box_{x_i} + m^2) \prod_{j=1}^{m} \int d^4y_j \, e^{+iq_j\cdot y_j} (\Box_y$$
$$\times \; \langle\Omega|\, \mathcal{T}\, \phi(x_1) \cdots \phi(x_n)\, \phi(y_1) \cdots \phi(y_m) \,|\Omega\rangle \,. \tag{14.149}$$

The right-hand side is built entirely from a time-ordered vacuum correlation function of Heisenberg fields — precisely the object the Gell-Mann–Low theorem (Theorem 14.18) renders computable in perturbation theory. The bridge is complete: experiment on the left, Dyson-series calculation on the right.

14.5.5 Momentum space: amputation, poles, and the residue

The position-space formula Eq. (14.149) is exact but unwieldy; in practice one works in momentum space, where the Klein–Gordon operators act algebraically and the whole content of LSZ becomes a statement about poles. Define the momentum-space (Fourier-transformed) correlation function with the conventions of Theorem 5.18, incoming legs carried by $e^{-ip\cdot x}$ and outgoing by $e^{+iq\cdot y}$,

$$\mathcal{G}(p_1 \cdots p_n; q_1 \cdots q_m) \equiv \prod_i \int d^4x_i \, e^{-ip_i\cdot x_i} \prod_j \int d^4y_j \, e^{+iq_j\cdot y_j} \, \Big\langle \Omega \Big| \mathcal{T} \prod_i \phi(x_i) \prod_j \phi(y_j) \Big| \Omega \Big\rangle \,. \tag{14.150}$$

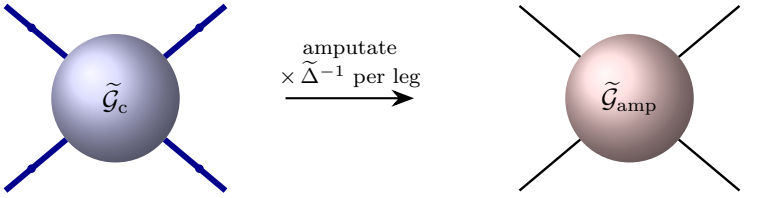

Figure 14.4: Amputation. The full connected Green's function $\widetilde{\mathcal{G}}_{\mathrm{c}}$ carries a complete interacting propagator (thick) on every external leg. Dividing off one full propagator per leg leaves the amputated function $\widetilde{\mathcal{G}}_{\mathrm{amp}}$. LSZ instructs us to amputate, go on shell, and dress each leg with a single $\sqrt{Z}$.

Translation invariance of the correlator forces overall energy–momentum conservation, $\mathcal{G} = (2\pi)^4\delta^4\big(\sum_j q_j - \sum_i p_i\big)\,\widetilde{\mathcal{G}}$, and the stripped object $\widetilde{\mathcal{G}}$ depends on the independent invariants. We need two definitions that organize the rest of Parts IV and V.

Definition 14.32 (Connected and amputated Green's functions)**.** A contribution to a correlation function is *connected* if its diagrammatic representation (Chapter 15) cannot be split into two pieces with no line joining them; equivalently, the *connected* correlator $\langle\Omega|\mathcal{T}\cdots|\Omega\rangle_{\mathrm{c}}$ is the part generated by $W[J] = -i\ln Z[J]$ (Section 10.5), with all factorized vacuum and lower-point pieces removed. A connected momentum-space Green's function is *amputated* when a full (interacting) propagator has been divided off each external leg:

$$\widetilde{\mathcal{G}}_{\mathrm{c}}(p_1\cdots;q_1\cdots) = \Big(\prod_i \widetilde{\Delta}(p_i)\Big)\Big(\prod_j \widetilde{\Delta}(q_j)\Big)\,\widetilde{\mathcal{G}}_{\mathrm{amp}}, \tag{14.151}$$

where $\widetilde{\Delta}(p) = \int d^4x\, e^{ip\cdot x}\,\langle\Omega|\mathcal{T}\phi(x)\phi(0)|\Omega\rangle$ is the exact two-point function, carrying the Källén–Lehmann pole $\widetilde{\Delta}(p) \to iZ/(p^2 - m^2 + i\epsilon)$ as $p^2 \to m^2$ (Theorem 14.23). $\widetilde{\mathcal{G}}_{\mathrm{amp}}$ is the *amputated, connected* Green's function.

We now translate Theorem 14.31 into momentum space. Each position-space leg contributes, by Eq. (14.150), the Fourier weight already built into $\mathcal{G}$; the Klein–Gordon operator $(\Box + m^2)$ acting on an incoming leg becomes, on $e^{-ip\cdot x}$,

$$(\Box + m^2)\,e^{-ip\cdot x} = (-p^2 + m^2)\,e^{-ip\cdot x} = -(p^2 - m^2)\,e^{-ip\cdot x}, \tag{14.152}$$

and identically for an outgoing leg. Therefore the position-space master formula is, in momentum space,

$$\langle f|\mathbf{S}|i\rangle_{\mathrm{c}} = \Big(\frac{i}{\sqrt{Z}}\Big)^{n+m}\prod_i[-(p_i^2 - m^2)]\prod_j[-(q_j^2 - m^2)]\;\mathcal{G}(p_1\cdots;q_1\cdots)\Big|_{\text{on shell}}, \tag{14.153}$$

all external momenta taken on shell, $p_i^2 = q_j^2 = m^2$. Naively the prefactors $(p_a^2 - m^2)$ all vanish on shell; the formula is nontrivial only because $\mathcal{G}$ itself *diverges* there, exactly fast enough to compensate. This is where the Källén–Lehmann pole earns its keep. By Eq. (14.151), every external leg of the connected $\mathcal{G}$ carries a full propagator $\widetilde{\Delta}(p_a)$, and as $p_a^2 \to m^2$,

$$\frac{i}{\sqrt{Z}}\,[-(p_a^2-m^2)]\,\widetilde{\Delta}(p_a) \xrightarrow{p_a^2\to m^2} \frac{i}{\sqrt{Z}}\,[-(p_a^2-m^2)]\,\frac{iZ}{p_a^2-m^2+i\epsilon} = \frac{i\cdot(-1)\cdot iZ}{\sqrt{Z}} = \sqrt{Z}. \tag{14.154}$$

Two things happen at once in Eq. (14.154): the explicit zero $(p_a^2 - m^2)$ cancels the propagator pole, leaving a finite limit, and any *non-pole* part of $\widetilde{\Delta}(p_a)$ – the entire Källén–Lehmann continuum, which is regular at $p_a^2 = m^2$ – is multiplied by the vanishing factor $(p_a^2 - m^2)$ and dies. Only the single-particle pole survives. Each external leg thus contributes precisely one factor of $\sqrt{Z}$, and what is left over after stripping the full propagators is the amputated function. Combining Eqs. (14.151), (14.153) and (14.154), we obtain the operational form of LSZ.

Theorem 14.33 (LSZ reduction formula, momentum space)**.** *Define the invariant amplitude $\mathcal{M}$ by separating the non-scattering part of the S-matrix, $\langle f|\mathbf{S}|i\rangle = \langle f|i\rangle + i(2\pi)^4\delta^4\big(\sum_j q_j - \sum_i p_i\big)\,\mathcal{M}$. Then $\mathcal{M}$ is the amputated, connected, on-shell Green's function dressed with one $\sqrt{Z}$ per external leg,*

$$\boxed{\,i\,\mathcal{M}\,(2\pi)^4\delta^4\Big(\sum_j q_j - \sum_i p_i\Big) = (\sqrt{Z})^{\,n+m}\,\widetilde{\mathcal{G}}_{\text{amp}}(p_1\cdots p_n; q_1\cdots q_m)\Big|_{\text{on shell}}\,} \tag{14.155}$$

with all $p_i^2 = q_j^2 = m^2$. Equivalently, the full connected momentum-space correlator factorizes near its on-shell poles as

$$\mathcal{G}_{\text{c}}(p_1\cdots;q_1\cdots) \xrightarrow{p_a^2\to m^2} \Big(\prod_i \frac{i\sqrt{Z}}{p_i^2-m^2+i\epsilon}\Big)\Big(\prod_j \frac{i\sqrt{Z}}{q_j^2-m^2+i\epsilon}\Big)\,i\,\mathcal{M}\,(2\pi)^4\delta^4\Big(\sum_j q_j - \sum_i p_i\Big) \tag{14.156}$$

so that the scattering amplitude is the multiple residue of the correlation function at its external on-shell poles.

The two displays say the same thing in complementary languages. Equation (14.156) is the analytic statement: the S-matrix lives in the residue of the $(n+m)$-fold pole of the time-ordered correlator, each pole supplied by an external particle going on shell. Equation (14.155) is the recipe an actual calculation follows: compute the connected correlator, throw away its external full propagators (amputate), set the external momenta on shell, and multiply by $\sqrt{Z}$ for each leg. The agreement of the two forms is immediate from Eq. (14.151): substituting it into Eq. (14.156) and cancelling the common propagator poles against the residues reproduces Eq. (14.155).

Why amputate, and why connected

Both qualifiers are forced, not stylistic. *Amputated:* a full external propagator left in place would supply an extra pole $iZ/(p^2 - m^2)$ on a leg that LSZ has already accounted for, double-counting the wavefunction renormalization and producing a spurious divergence on shell; amputation removes exactly the structure that the factors $(p^2 - m^2)$ in Eq. (14.153) are there to cancel. *Connected:* a disconnected contribution to the correlator factorizes into independent lower-point pieces, and a product of two correlators each conserving momentum cannot carry the single overall $\delta^4(\sum q - \sum p)$ that a genuine $(n+m)$-point amplitude requires — it has too many delta functions and is supported only on measure-zero kinematics where subsets of particles do not interact. These are the same no-scattering configurations removed by the inelastic assumption in Section 14.5.3; the connected projection discards them once and for all. To leading nontrivial order in λ, where $Z = 1 + O(\lambda^2)$ (the residue first moves at one loop, Chapter 19), the dressing $(\sqrt{Z})^{n+m}$ is unity and Eq. (14.155) reduces to "$i\mathcal{M}$ = amputated connected on-shell diagram", the rule used throughout Chapters 15 and 16.

14.5.6 A worked check: one leg, and the disconnected term made explicit

The single-leg case is the cleanest place to see every factor in Eq. (14.154) appear from an honest computation, and it simultaneously exhibits how the non-pole continuum is annihilated. It is worth doing in full.

Worked Example 14.34 (Reducing one leg against the exact two-point function)**.** Take the LSZ differential operator for a single incoming leg and apply it to the exact two-point function $\langle\Omega|\mathcal{T}\phi(x)\phi(y)|\Omega\rangle$, holding y fixed. We compute

$$R(y) \equiv \frac{i}{\sqrt{Z}} \int d^4x\, e^{-ip\cdot x}\,(\Box_x + m^2)\,\langle\Omega|\mathcal{T}\phi(x)\phi(y)|\Omega\rangle\,, \qquad p^0 = E_{\mathbf{p}}, \quad (14.157)$$

and verify it reproduces the one-particle wavefunction $\sqrt{Z}\,e^{-ip\cdot y}$ predicted by Eq. (14.131), confirming both the $\sqrt{Z}$ counting and the death of the continuum.

Step 1 — insert the spectral representation. By Theorem 14.23 the two-point function has the Fourier transform $\widetilde{\Delta}(k) = iZ/(k^2 - m^2 + i\epsilon) + \widetilde{\Delta}_{\text{cont}}(k)$, where $\widetilde{\Delta}_{\text{cont}}$ collects the multiparticle continuum and is *regular* at $k^2 = m^2$ (its spectral weight is supported at $k^2 \geq (3m)^2$ for ϕ^4 theory). Writing $\langle\Omega|\mathcal{T}\phi(x)\phi(y)|\Omega\rangle = \int \frac{d^4k}{(2\pi)^4}\, e^{-ik\cdot(x-y)}\widetilde{\Delta}(k)$,

$$R(y) = \frac{i}{\sqrt{Z}} \int \frac{d^4k}{(2\pi)^4}\,\widetilde{\Delta}(k)\,e^{+ik\cdot y} \int d^4x\, e^{-ip\cdot x}\,(\Box_x + m^2)\,e^{-ik\cdot x}. \quad (14.158)$$

Step 2 — act with the Klein–Gordon operator and integrate over x. Using Eq. (14.152) in the form $(\Box_x+m^2)e^{-ik\cdot x} = -(k^2-m^2)e^{-ik\cdot x}$ and $\int d^4x\, e^{-i(p+k)\cdot x} = (2\pi)^4\delta^4(p+k)$, the k-integral collapses at $k=-p$:

$$R(y) = \frac{i}{\sqrt{Z}}\,[-(p^2-m^2)]\,\widetilde{\Delta}(-p)\,e^{-ip\cdot y}. \tag{14.159}$$

By Lorentz invariance $\widetilde{\Delta}$ depends only on p^2, so $\widetilde{\Delta}(-p)=\widetilde{\Delta}(p)$.

Step 3 — go on shell and take the residue. Substitute the spectral split:

$$R(y) = \frac{i}{\sqrt{Z}}\,[-(p^2-m^2)]\Big(\frac{iZ}{p^2-m^2+i\epsilon} + \widetilde{\Delta}_{\text{cont}}(p)\Big)e^{-ip\cdot y}. \tag{14.160}$$

The continuum term comes multiplied by (p^2-m^2) and, since $\widetilde{\Delta}_{\text{cont}}$ is finite at $p^2=m^2$, vanishes in the on-shell limit. The pole term gives $[-(p^2-m^2)]\cdot iZ/(p^2-m^2) = -iZ$. Hence

$$R(y)\Big|_{p^2\to m^2} = \frac{i}{\sqrt{Z}}\,(-iZ)\,e^{-ip\cdot y} = \sqrt{Z}\,e^{-ip\cdot y}, \tag{14.161}$$

exactly $\langle\Omega|\phi(y)|\mathbf{p}\rangle$ of Eq. (14.131). The leg has been reduced into a single, correctly normalized one-particle wavefunction: the explicit zero killed the continuum, the pole survived, and the booked factor $\sqrt{Z}$ emerged precisely as in Eq. (14.154).

The same arithmetic, run on every leg of an $(n+m)$-point function, is the content of Theorem 14.33; the worked case shows that nothing is hidden in the general statement beyond doing this calculation once per external particle. It also makes the role of Z tangible: had we forgotten the $1/\sqrt{Z}$, the reduced leg would have carried amplitude $-iZ\cdot i = Z$ rather than $\sqrt{Z}$, mis-normalizing the asymptotic particle by a factor $\sqrt{Z}$ on every leg — a mistake that propagates into every cross section.

14.5.7 Handoff

We now possess the master bridge of the chapter in its operational form, Eq. (14.155): an S-matrix element is the amputated, connected, on-shell momentum-space correlation function, weighted by one $\sqrt{Z}$ per external leg, with the disconnected and non-pole debris provably absent. Every ingredient on the right-hand side is computable — the correlator from Gell-Mann–Low and the Dyson series, the residue structure from Källén–Lehmann. In the next section we turn the crank for the first time on ϕ^4 theory: with $Z=1+O(\lambda^2)$, the leading-order $2\to 2$ amplitude reduces to a single amputated, connected, on-shell four-point function, and evaluating it will deliver the chapter's first piece of interacting physics, $i\mathcal{M} = -i\lambda$.

14.6 First Interacting Amplitude: $\phi\phi \to \phi\phi$ at $O(\lambda)$

Everything in this chapter so far has been machinery built but not yet turned. The interaction picture and the Dyson series gave a perturbative evolution operator; the Gell-Mann–Low theorem (Theorem 14.18) rewrote the Heisenberg-picture vacuum correlators of the interacting theory as Dyson-series expectation values of *free* fields, hence as objects Wick's theorem can evaluate; and the LSZ reduction formula (Theorem 14.31) converted the on-shell residues of those correlators into S-matrix elements, one factor of $\sqrt{Z}$ per external leg. The promise was that, chained together, these three results compute scattering amplitudes order by order in the coupling. This section redeems that promise. We take the frozen ϕ^4 Lagrangian

$$\mathcal{L} = \tfrac{1}{2}(\partial_\mu\phi)(\partial^\mu\phi) - \tfrac{1}{2}m^2\phi^2 - \frac{\lambda}{4!}\,\phi^4, \qquad \phi \text{ real},\ \lambda > 0, \tag{14.162}$$

and carry out, with every factor visible, the leading-order computation of the two-to-two amplitude $\phi\phi \to \phi\phi$. The answer is a single number, $i\mathcal{M} = -i\lambda$, and it is the first genuinely interacting result of the entire book: the point at which the apparatus stops being potential and starts predicting. We work throughout in the conventions in force — mostly-minus metric $\eta_{\mu\nu} = \mathrm{diag}(+,-,-,-)$, natural units, the Feynman $i\varepsilon$ of Eq. (9.154) — and we treat λ as small, expanding to first order.

The structure of the calculation is fixed once and for all by the three imported theorems, so we begin by assembling them into a single explicit recipe, then execute it.

14.6.1 Assembling the three machines into one recipe

The observable is an entry of the S-matrix between two-particle states. Recall (Theorem 14.31) that the nontrivial part of scattering is isolated by writing $\mathbf{S} = \mathbf{1} + (\mathbf{S}-\mathbf{1})$, the unit accounting for the particles missing each other; the invariant amplitude $\mathcal{M}$ is defined by stripping the overall energy–momentum delta from the connected matrix element,

$$\langle p_3\, p_4|\ (\mathbf{S}-\mathbf{1})\ |p_1\, p_2\rangle \;=\; i\,\mathcal{M}(p_1,p_2\to p_3,p_4)\,(2\pi)^4\,\delta^4(p_1+p_2-p_3-p_4), \tag{14.163}$$

with the one-particle states carrying the relativistic normalization $\langle p|k\rangle = 2E_{\mathbf{p}}(2\pi)^3\delta^3(\mathbf{p}-\mathbf{k})$ of Eq. (3.193). Momenta p_1, p_2 are incoming, p_3, p_4 outgoing, all on shell: $p_i^2 = m^2$, $p_i^0 = E_{\mathbf{p}_i} > 0$.

The LSZ formula expresses the left-hand side of Eq. (14.163) as the multiple on-shell residue of the momentum-space time-ordered four-point function. It is convenient to state it in the *amputated* form. Introduce the all-incoming Fourier

transform of the connected four-point correlator,

$$\widetilde{G}^{(4)}(p_1,p_2,p_3,p_4) \;\equiv\; \int\Big(\prod_{i=1}^{4} d^4x_i\, e^{ip_i\cdot x_i}\Big)\,\langle\Omega|\,\mathcal{T}\,\phi(x_1)\phi(x_2)\phi(x_3)\phi(x_4)\,|\Omega\rangle_{\text{conn}}, \tag{14.164}$$

where $|\Omega\rangle$ is the interacting vacuum. The full correlator carries one factor $\sqrt{Z}\,i/(p_i^2-m^2)$ for each external leg as $p_i^2 \to m^2$ (the Källén–Lehmann pole, Theorem 14.31); LSZ instructs us to cancel those four propagator poles, divide out the four $\sqrt{Z}$'s, and take the legs on shell. Writing the result of cancelling the external propagators as the *amputated* correlator

$$\widetilde{G}^{(4)}_{\text{amp}}(p_1,\dots,p_4) \;\equiv\; \Big[\prod_{i=1}^{4}\frac{p_i^2-m^2}{i}\Big]\,\widetilde{G}^{(4)}(p_1,\dots,p_4), \tag{14.165}$$

the LSZ master statement specializes, for four external scalars, to

$$i\,\mathcal{M}\,(2\pi)^4\,\delta^4\Big(\textstyle\sum_i p_i\Big) \;=\; \frac{1}{\left(\sqrt{Z}\right)^4}\,\lim_{p_i^2\to m^2}\widetilde{G}^{(4)}_{\text{amp}}(p_1,\dots,p_4)\Big|_{p_3,p_4\ \text{outgoing}}. \tag{14.166}$$

Here the sum $\sum_i p_i$ runs over all-incoming momenta; converting the last two to physical outgoing momenta sends $p_3,p_4 \to -p_3,-p_4$ inside the delta, reproducing the conservation law of Eq. (14.163). Everything on the right of Eq. (14.166) is computable: the correlator by Gell-Mann–Low plus Wick, the factor Z by the same expansion. The recipe is therefore

(i) expand $\langle\Omega|\mathcal{T}\,\phi\phi\phi\phi|\Omega\rangle$ to the desired order in λ using Gell-Mann–Low (Theorem 14.18), turning it into free-field time-ordered correlators;

(ii) evaluate each free correlator by Wick's theorem (Theorem 10.25) as a sum over complete pairings into Feynman propagators (Theorem 9.24);

(iii) keep the *connected* part, Fourier transform, amputate the four external legs via Eq. (14.165), and take the on-shell limit;

(iv) divide by the factor $(\sqrt{Z})^4$ and read off $\mathcal{M}$ from Eq. (14.166).

Because the amputation Eq. (14.165) strips off *free* propagators $i/(p_i^2-m^2)$, each external leg of $\widetilde{G}^{(4)}_{\text{amp}}$ still retains one residual factor $\sqrt{Z}$ from the Källén–Lehmann residue; dividing by $(\sqrt{Z})^4$ removes them, exactly as the prose above demands. (Had we instead amputated with the *full* interacting propagator of residue iZ, as in Section 14.5, the extraction would carry a multiplicative $(\sqrt{Z})^4$.) At $O(\lambda)$ one has $Z = 1 + O(\lambda^2)$, so the distinction is immaterial for the amplitude computed below; it matters only once $Z \neq 1$.

We now carry out steps (i)–(iv) in full. The entire computation is the chapter's central worked example.

14.6.2 The leading-order four-point correlator

The interaction Hamiltonian obtained from Eq. (14.56) by Legendre transform (Sections 6.4 and 14.1.1) is, to the order we need, just minus the interaction Lagrangian density integrated over space: the quartic term contains no derivatives, so it contributes nothing to the canonical momentum and the Hamiltonian density inherits $+\frac{\lambda}{4!}\phi^4$ directly. In the interaction picture,

$$H_I(t) = \int d^3x\, \frac{\lambda}{4!}\,\phi_I(t,\mathbf{x})^4, \qquad \text{so} \qquad -i\int_{-\infty}^{\infty} dt\, H_I(t) = -\frac{i\lambda}{4!}\int d^4z\, \phi_I(z)^4, \tag{14.167}$$

where ϕ_I is the free field with the mode expansion and propagator of Chapter 9; from here on we drop the subscript I, all fields inside the Dyson series being free. The Gell-Mann–Low theorem (Theorem 14.18) gives the interacting four-point function as the ratio

$$\langle\Omega|\mathcal{T}\,\phi(x_1)\phi(x_2)\phi(x_3)\phi(x_4)|\Omega\rangle = \frac{\langle 0|\mathcal{T}\Big\{\phi(x_1)\phi(x_2)\phi(x_3)\phi(x_4)\,\exp\big[-\frac{i\lambda}{4!}\int d^4z\,\phi(z)^4\big]\Big\}|0\rangle}{\langle 0|\mathcal{T}\exp\big[-\frac{i\lambda}{4!}\int d^4z\,\phi(z)^4\big]|0\rangle}, \tag{14.168}$$

with $|0\rangle$ the free vacuum and the time limits taken with the $T\to\infty(1-i\varepsilon)$ tilt that projects onto $|\Omega\rangle$. Expanding the exponential in powers of λ converts both numerator and denominator into sums of free time-ordered correlators, exactly the Wick-computable objects of Chapter 10.

We want the amplitude through $O(\lambda)$. Because the four-point amplitude vanishes at $\lambda = 0$ (free particles do not scatter), the leading term is $O(\lambda^1)$, and we expand the numerator to first order.

Worked Example 14.35 (The $O(\lambda)$ amplitude $\phi\phi \to \phi\phi$, end to end)**.** We carry the computation from Eq. (14.168) to the boxed number $i\mathcal{M} = -i\lambda$, displaying every Wick contraction, the combinatorial cancellation of the $1/4!$, the amputation, and the on-shell limit.

The order-λ^0 term and why it carries no scattering. At zeroth order the exponential in the numerator of Eq. (14.168) is the identity, the denominator is 1, and we are left with the free four-point function. Wick's theorem (Theorem 10.25) evaluates it as the sum over the three complete pairings of four fields,

$$\langle 0|\mathcal{T}\,\phi_1\phi_2\phi_3\phi_4|0\rangle = D_F(x_1{-}x_2)D_F(x_3{-}x_4)+D_F(x_1{-}x_3)D_F(x_2{-}x_4)+D_F(x_1{-}x_4)D_F(x_2{-}x_3), \tag{14.169}$$

writing $\phi_i \equiv \phi(x_i)$. Each term is a product of two propagators connecting the external points *in pairs*; none connects all four. In momentum space (Fourier transform as in Eq. (14.164)) a term such as $D_F(x_1-x_2)D_F(x_3-x_4)$ produces $\widetilde{D_F}(p_1)\widetilde{D_F}(p_3)\,(2\pi)^8\delta^4(p_1+p_2)\delta^4(p_3+p_4)$: it has poles in only *two* of the four invariants p_i^2 and forces $p_1=-p_2$, $p_3=-p_4$ separately. Amputating with the

full $\prod_i (p_i^2 - m^2)/i$ of Eq. (14.165) multiplies this by two factors $(p_i^2 - m^2)$ that have nothing to cancel, so the term vanishes on shell. Physically these are the disconnected processes in which the two particles sail past one another; LSZ, by demanding all four legs simultaneously on their poles, discards them. The connected amplitude is genuinely zero at $O(\lambda^0)$, as it must be for a free theory.

The order-λ^1 numerator. At first order the numerator of Eq. (14.168) is

$$N^{(1)} = -\frac{i\lambda}{4!}\int d^4z\, \langle 0|\mathcal{T}\,\phi(x_1)\phi(x_2)\phi(x_3)\phi(x_4)\,\phi(z)\phi(z)\phi(z)\phi(z)|0\rangle. \quad (14.170)$$

This is a free time-ordered correlator of eight fields: the four external $\phi(x_i)$ and four copies of $\phi(z)$ at the common vertex point z. Wick's theorem expresses it as the sum over all complete pairings of these eight fields; a nonzero contribution requires every field to be contracted, since any uncontracted normal-ordered remainder has vanishing vacuum expectation value. We organize the pairings by how the four *external* fields are routed.

(a) Fully connected pairings. Each external field $\phi(x_i)$ is contracted with one of the four vertex fields $\phi(z)$, and the four vertex fields are thereby all used up. Such a pairing yields

$$D_F(x_1 - z)\, D_F(x_2 - z)\, D_F(x_3 - z)\, D_F(x_4 - z), \quad (14.171)$$

one propagator from each external point into the common vertex. The number of distinct pairings of this type is the number of ways to match four labelled external fields to four labelled vertex slots, namely $4! = 24$. Every one of these 24 pairings gives the *same* product $\prod_i D_F(x_i - z)$, because the four vertex fields sit at the identical point z and are indistinguishable. Therefore the fully connected contribution to Eq. (14.170) is

$$N^{(1)}_{\text{conn}} = -\frac{i\lambda}{4!}\cdot 4!\int d^4z\, D_F(x_1{-}z)D_F(x_2{-}z)D_F(x_3{-}z)D_F(x_4{-}z) = -i\lambda\int d^4z\,\prod_{i=1}^{4} D_F(x_i{-}z) \quad (14.172)$$

This is the central combinatorial fact of the computation: the multiplicity $4!$ of equivalent contractions *exactly* cancels the $1/4!$ written into the coupling in Eq. (14.56). The $1/4!$ was placed there for precisely this reason — so that the simplest connected diagram comes out with unit coefficient $-i\lambda$ — and we have now seen the cancellation happen explicitly rather than by decree.

(b) Partially connected pairings. Two external fields may contract with each other and the remaining two with vertex fields, the two leftover vertex fields then contracting together. A representative term is

$$D_F(x_1 - x_2)\, D_F(x_3 - z)\, D_F(x_4 - z)\, D_F(0), \quad (14.173)$$

where $D_F(0) \equiv D_F(z-z)$ is the closed self-contraction of the two unused vertex fields — a loop that begins and ends at the vertex, a *tadpole*. Such terms factor into a free propagator $D_F(x_1-x_2)$ that bypasses the vertex entirely and a piece attached to it. As with the order-λ^0 terms, the spectator propagator $D_F(x_1-x_2)$ carries poles in only p_1 and p_2 and ties them together, so under the four-fold amputation of Eq. (14.165) the factors $(p_1^2-m^2)$ and $(p_2^2-m^2)$ have no poles to kill and the term dies on shell. These pieces are not part of the connected four-point function and LSZ excludes them. (The tadpole $D_F(0)$ is itself ultraviolet divergent and momentum-independent; it belongs to the self-energy and renormalizes the mass, business deferred to Chapters 19 and 22. It does not affect the connected $2\to 2$ amplitude at this order.)

(c) Vacuum pairings and the denominator. Finally, all four external fields may pair among themselves while the four vertex fields pair among themselves. The vertex-only factor is exactly $\langle 0|\mathcal{T}(-\frac{i\lambda}{4!}\int\phi(z)^4)|0\rangle$, a disconnected vacuum bubble multiplying the free four-point function Eq. (14.169). This is where the denominator of Eq. (14.168) earns its place: expanded to $O(\lambda)$ it is $1+\langle 0|\mathcal{T}(-\frac{i\lambda}{4!}\int\phi^4)|0\rangle$, precisely the same vacuum bubble, and dividing removes it from the numerator. The cancellation of disconnected vacuum diagrams against the denominator is the general content of Theorem 14.18; here it operates on the single $O(\lambda)$ bubble. After the division, only connected-to-the-vertex structures remain, and among those only category (a) survives amputation.

The connected four-point function. Collecting the surviving piece, the connected interacting four-point function through $O(\lambda)$ is

$$\langle\Omega|\mathcal{T}\,\phi(x_1)\phi(x_2)\phi(x_3)\phi(x_4)|\Omega\rangle_{\text{conn}} = -i\lambda\int d^4z\, D_F(x_1-z)D_F(x_2-z)D_F(x_3-z)D_F(x_4-z)+O(\lambda^2) \tag{14.174}$$

Four propagators run from the four external points to a single integrated vertex; the integral over z enforces that the vertex sits anywhere in spacetime. This is the position-space content of the elementary ϕ^4 scattering diagram, Fig. 14.5.

To momentum space. We now Fourier transform according to Eq. (14.164). The external integrals factorize, each one converting a propagator into its momentum-space form with the vertex position left over as a phase. Using the covariant representation Eq. (9.154),

$$\int d^4x_i\, e^{ip_i\cdot x_i}\, D_F(x_i-z) = \int d^4x_i\, e^{ip_i\cdot x_i}\int\frac{d^4q}{(2\pi)^4}\,\frac{i\,e^{-iq\cdot(x_i-z)}}{q^2-m^2+i\varepsilon} = \frac{i\,e^{ip_i\cdot z}}{p_i^2-m^2+i\varepsilon}, \tag{14.175}$$

where the x_i integral produced $(2\pi)^4\delta^4(p_i-q)$ and collapsed the q integral. Each leg thus contributes a momentum-space propagator $\widetilde{D_F}(p_i) = i/(p_i^2-m^2+i\varepsilon)$

and a phase $e^{ip_i\cdot z}$. Assembling all four legs and the prefactor,

$$\widetilde{G}^{(4)}(p_1,\dots,p_4) = -i\lambda \int d^4z\, e^{\,i(p_1+p_2+p_3+p_4)\cdot z} \prod_{i=1}^{4} \frac{i}{p_i^2 - m^2 + i\varepsilon}. \tag{14.176}$$

The single remaining integral is over the vertex position z, and it produces the energy–momentum delta that conservation demands:

$$\int d^4z\, e^{\,i(p_1+p_2+p_3+p_4)\cdot z} = (2\pi)^4\, \delta^4(p_1+p_2+p_3+p_4). \tag{14.177}$$

Hence the connected momentum-space four-point function at this order is

$$\widetilde{G}^{(4)}(p_1,\dots,p_4) = -i\lambda\,(2\pi)^4\,\delta^4(p_1+p_2+p_3+p_4) \prod_{i=1}^{4} \frac{i}{p_i^2 - m^2 + i\varepsilon}. \tag{14.178}$$

The four external propagators sit out front explicitly, each a pole at $p_i^2 = m^2$; they are exactly the legs LSZ will amputate.

Amputation and the on-shell limit. Apply Eq. (14.165): multiply by $\prod_i (p_i^2 - m^2)/i$. Each factor cancels one external propagator $i/(p_i^2 - m^2 + i\varepsilon)$ cleanly in the limit $\varepsilon \to 0^+$, leaving

$$\widetilde{G}^{(4)}_{\text{amp}}(p_1,\dots,p_4) = \Big[\prod_{i=1}^{4} \frac{p_i^2 - m^2}{i}\Big]\Big[(-i\lambda)(2\pi)^4\delta^4(\textstyle\sum_i p_i)\prod_{i=1}^4 \frac{i}{p_i^2-m^2+i\varepsilon}\Big] = -i\lambda\,(2\pi)^4\delta^4(\textstyle\sum_i p \tag{14.179}$$

The amputated correlator is a pure constant times the conservation delta — no poles remain, so the on-shell limit $p_i^2 \to m^2$ is trivially finite and equals Eq. (14.179) itself. This is the payoff of amputation: by removing the external legs we removed exactly the factors that would have diverged on shell, leaving a smooth amplitude.

The field-strength factor at this order. It remains to evaluate the field-strength factor $1/(\sqrt{Z})^4$ in Eq. (14.166). The residue Z is the coefficient of the one-particle pole in the exact propagator, $Z = (1 - \Sigma'(m^2))^{-1}$ with Σ the self-energy and $\Sigma' = d\Sigma/dp^2$. In ϕ^4 theory the only $O(\lambda)$ contribution to the self-energy is the tadpole loop $\Sigma^{(1)} = \frac{\lambda}{2} D_F(0)$ encountered in category (b): a constant, independent of the external momentum p. A momentum-independent self-energy shifts the pole *location* (it renormalizes the mass) but has $\Sigma' = 0$, so it does not change the residue. The first momentum dependence of Σ, and hence the first deviation of Z from unity, arises only at $O(\lambda^2)$ from the two-loop "sunset" graph. Therefore

$$Z = 1 + O(\lambda^2), \qquad 1/(\sqrt{Z})^4 = 1 + O(\lambda^2), \tag{14.180}$$

and the field-strength factors are exactly 1 at the order we are working. (The full computation of Σ and Z is carried out in Chapter 19.)

Reading off the amplitude. Substituting Eqs. (14.179) and (14.180) into the LSZ recipe Eq. (14.166),

$$i\mathcal{M}\,(2\pi)^4\delta^4\big(\textstyle\sum_i p_i\big) = \big(1 + O(\lambda^2)\big)\cdot\big[-i\lambda\,(2\pi)^4\delta^4\big(\textstyle\sum_i p_i\big)\big], \tag{14.181}$$

and cancelling the common $(2\pi)^4\delta^4$ gives the carried ϕ^4 theory number,

$$\boxed{i\mathcal{M}(\phi\phi\to\phi\phi) = -i\lambda + O(\lambda^2)} \qquad \Longleftrightarrow \qquad \mathcal{M} = -\lambda + O(\lambda^2). \tag{14.182}$$

This is the first interacting amplitude of the book. It is real, constant, and independent of the scattering angle and energy: the $O(\lambda)$ process is a pure contact interaction with no propagating intermediate particle, so it depends on none of the kinematic invariants. We have produced it with every factor on the page — the $-i\lambda/4!$ from the Dyson series, the $4!$ from the Wick multiplicity, the four propagators from the external legs, the delta from the vertex integral, the four cancellations of amputation, and the $Z = 1$ of the residue.

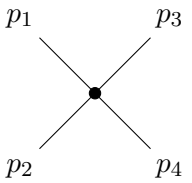

Figure 14.5: The single connected diagram contributing to $\phi\phi \to \phi\phi$ at $O(\lambda)$: four external lines meet at one spacetime vertex (integrated over in Eq. (14.174)). The four propagators are the external legs LSZ amputates; the vertex contributes the factor $-i\lambda$ after the $4!$ contraction multiplicity cancels the $1/4!$ of the coupling. There is no internal line, hence no kinematic dependence: $\mathcal{M} = -\lambda$.

We record the result as a proposition for later reference, since the renormalization chapters will quote it as the tree-level input that loop corrections dress.

Proposition 14.36 (Tree-level ϕ^4 scattering amplitude)**.** *For the real scalar theory Eq. (14.56) with coupling λ, the connected, amputated, on-shell two-to-two amplitude defined by Eq. (14.163) is, to leading order in λ,*

$$i\mathcal{M}(\phi\phi\to\phi\phi) = -i\lambda + O(\lambda^2), \tag{14.183}$$

independent of the Mandelstam invariants $s = (p_1+p_2)^2$, $t = (p_1-p_3)^2$, $u = (p_1-p_4)^2$.

Proof. This is Theorem 14.35: Eq. (14.182). □

14.6.3 Reading the answer: kinematics, identical particles, and $|\mathcal{M}|^2$

The amplitude Eq. (14.182) is the simplest a $2 \to 2$ amplitude can be: a constant. It is worth dwelling on what that constancy means and assembling the squared amplitude that the next chapter on cross sections will integrate.

The four external momenta of an on-shell $2 \to 2$ process are constrained by conservation $p_1 + p_2 = p_3 + p_4$ and by the four mass-shell conditions $p_i^2 = m^2$, leaving the two independent Lorentz invariants conventionally packaged as the Mandelstam variables s, t, u, which satisfy

$$s + t + u = p_1^2 + p_2^2 + p_3^2 + p_4^2 = 4m^2. \tag{14.184}$$

A generic tree amplitude — as we will see already in ϕ^3-like theories and certainly in QED — depends nontrivially on these invariants through internal propagators $1/(s - m^2)$, $1/(t - m^2)$, $1/(u - m^2)$ that go on shell when an intermediate particle can be produced. The $O(\lambda)$ ϕ^4 amplitude has *no internal line at all* (Fig. 14.5); the interaction is pointlike, all four particles meeting at one vertex. There is consequently nothing for s, t, or u to appear in, and $\mathcal{M} = -\lambda$ is a structureless constant. This is the defining signature of a contact interaction, and it is what makes ϕ^4 the cleanest possible first example: the kinematics is trivial and all the content is in the combinatorics we have just done.

For the transition probability and the cross section we need the modulus squared. From Eq. (14.182),

$$|\mathcal{M}|^2 = \lambda^2 + O(\lambda^3). \tag{14.185}$$

Two bookkeeping points attach to this number and are flagged here for the chapter that uses it. First, the final-state particles are *identical* real scalars; when the squared amplitude is integrated over the final-state phase space to form a total cross section, the region of integration must be halved (equivalently, a symmetry factor $1/2!$ inserted) to avoid double-counting the configuration in which p_3 and p_4 are exchanged. Second, the relation between $|\mathcal{M}|^2$ and a measurable cross section requires the Lorentz-invariant phase space and the incident flux. Both belong to Chapter 16, which converts Eq. (14.185) into the differential and total cross sections; we hand them this number and its identical-particle caveat and do not pre-empt that work here.

14.6.4 What the bookkeeping is telling us

Step back from the result to the *method*. To obtain a single number we expanded an exponential, applied Wick's theorem to eight fields, sorted the resulting pairings into connected, partially connected, and vacuum classes, tracked a $4!$ against a $1/4!$, recognized which pairings would survive amputation, Fourier-transformed four legs, did the vertex integral, amputated, and took an on-shell

limit. For the leading term of the simplest process in the simplest theory this is already a substantial accounting — and almost all of it was bookkeeping that recurred in a predictable pattern: a factor $-i\lambda$ for the vertex, a factor $i/(p^2 - m^2 + i\varepsilon)$ for each line, a delta for momentum conservation at the vertex, amputation of external legs, and a combinatorial weight from the contraction multiplicity. At second order, or for a process with internal lines, the number of pairings proliferates and doing this by hand from Wick's theorem each time would be intolerable.

Physical Insight

Every structural feature of the calculation that did *not* depend on the specific external momenta — the vertex factor $-i\lambda$, the propagator $i/(p^2 - m^2 + i\varepsilon)$ per line, the conservation delta, the rule to amputate external legs and supply $\sqrt{Z}$ per leg, and the combinatorial weight — is a property of the *Lagrangian*, not of the particular amplitude. It can therefore be read off once and applied mechanically. That observation is the seed of the Feynman rules: a dictionary that replaces the entire Gell-Mann–Low–plus–Wick procedure with the drawing of diagrams and the multiplication of factors. The $1/4!$ that cancelled here so cleanly for the leading diagram does *not* always cancel completely; when a diagram has a nontrivial automorphism (a line that can be reflected, a loop that can be relabelled), a residual *symmetry factor* survives. Systematizing exactly when and by how much is the content of the next chapter.

This is the natural handoff. We have established the carried ϕ^4 theory number $i\mathcal{M} = -i\lambda$ and the squared amplitude $|\mathcal{M}|^2 = \lambda^2$, and we pass them forward in two directions: to Chapter 16, which turns $|\mathcal{M}|^2$ into a cross section with the correct flux, phase space, and identical-particle factor; and to Chapter 15, which takes the unsystematized contraction combinatorics displayed in Theorem 14.35 and distils it into the Feynman rules and the careful theory of symmetry factors, then re-derives this very amplitude two ways as the first check of that machinery. Before either, the chapter closes by extracting from the unitarity of $\mathbf{S}$ a constraint that no order-by-order expansion can violate — the optical theorem — which will give physical meaning to the imaginary parts that the loop corrections to $-i\lambda$ are about to acquire.

14.7 Unitarity and the Optical Theorem

The chapter has, by this point, built a working machine. The Dyson series, Gell-Mann–Low, and LSZ together convert an interacting Lagrangian into a power series for scattering amplitudes, and the previous section cranked that machine once to produce the first interacting number of ϕ^4 theory, the tree-level

result $i\mathcal{M} = -i\lambda$ recorded in Theorem 14.35. Every step of that construction was perturbative: it is an expansion in λ, valid order by order, silent about whether the sum it approximates makes sense. We close the chapter with the one statement about the S-matrix that is *not* perturbative, that holds to all orders and beyond them, and that the rest of the book will lean on as a fixed point of certainty whenever a calculation needs a check it cannot fake: *the S-matrix is unitary*. Probability is conserved. Whatever the distant past prepares, the distant future finds *something*, with total probability one. This single algebraic fact, pressed correctly, yields a nonperturbative constraint — the optical theorem — relating the imaginary part of a forward scattering amplitude to the total rate at which the initial state scatters into anything at all. It is the result that finally gives physical meaning to the imaginary parts that loop amplitudes will carry, and the seed of the analyticity-and-dispersion program that Chapter 5 already previewed.

We take from the S-matrix section the operator and its decomposition. The scattering operator $\mathbf{S}$ of Theorem 14.11 is unitary, $\mathbf{S}^\dagger\mathbf{S} = \mathbf{S}\,\mathbf{S}^\dagger = \mathbf{1}$, and the nontrivial scattering is isolated by writing

$$\mathbf{S} = \mathbf{1} + i\,\mathcal{T}, \tag{14.186}$$

exactly as in Eq. (14.45): the $\mathbf{1}$ is the amplitude for "nothing happens," and the *transition operator* $\mathcal{T}$ collects all genuine interactions. Conventions are those in force throughout the chapter: mostly-minus metric $\eta_{\mu\nu} = \mathrm{diag}(+,-,-,-)$, natural units $\hbar = c = 1$, relativistically normalized one-particle states with the Lorentz-invariant measure of Eq. (3.191), and the Feynman $i\varepsilon$.

14.7.1 Unitarity in the transition operator

Unitarity is a statement about $\mathbf{S}$; we first translate it into a statement about $\mathcal{T}$, because $\mathcal{T}$ is the object whose matrix elements are the amplitudes we compute. Substitute Eq. (14.186) into $\mathbf{S}^\dagger\mathbf{S} = \mathbf{1}$:

$$\mathbf{1} = \mathbf{S}^\dagger\mathbf{S} = (\mathbf{1} - i\,\mathcal{T}^\dagger)(\mathbf{1} + i\,\mathcal{T}) = \mathbf{1} + i\,\mathcal{T} - i\,\mathcal{T}^\dagger + \mathcal{T}^\dagger\mathcal{T}. \tag{14.187}$$

The leading $\mathbf{1}$ cancels the left-hand side, leaving $i(\mathcal{T} - \mathcal{T}^\dagger) + \mathcal{T}^\dagger\mathcal{T} = 0$, i.e.

$$-\,i(\mathcal{T} - \mathcal{T}^\dagger) = \mathcal{T}^\dagger\mathcal{T}. \tag{14.188}$$

This is the master identity. Read it slowly. The left-hand side is, up to the factor, the *anti-Hermitian part* of $\mathcal{T}$: if $\mathcal{T}$ were Hermitian the left side would vanish. The right-hand side is $\mathcal{T}^\dagger\mathcal{T}$, a manifestly positive operator — for any state $|\psi\rangle$, $\big\langle\psi\big|\mathcal{T}^\dagger\mathcal{T}\big|\psi\big\rangle = \|\mathcal{T}\,|\psi\rangle\|^2 \geq 0$. So Eq. (14.188) says precisely that the failure of $\mathcal{T}$ to be Hermitian is controlled, and is positive. Had we instead expanded $\mathbf{S}\,\mathbf{S}^\dagger = \mathbf{1}$ we would have found $-i(\mathcal{T} - \mathcal{T}^\dagger) = \mathcal{T}\,\mathcal{T}^\dagger$; both hold, and equating them shows $\mathcal{T}^\dagger\mathcal{T} = \mathcal{T}\,\mathcal{T}^\dagger$, so $\mathcal{T}$ is normal. For what follows we use the form Eq. (14.188).

Physical Insight

Equation Eq. (14.188) is the whole of the optical theorem before any kinematics. To first order in the coupling, $\mathcal{T} \sim O(\lambda)$ and the right-hand side $\mathcal{T}^\dagger\mathcal{T} \sim O(\lambda^2)$ is negligible, so $\mathcal{T} \approx \mathcal{T}^\dagger$: a tree amplitude is (to leading order) real, as $i\mathcal{M} = -i\lambda$ indeed is. The content of unitarity is the *correction* to that statement: the amount by which $\mathcal{T}$ fails to be Hermitian at order λ^2 is fixed, not free, equal to the square of the order-λ amplitude. Unitarity ties the imaginary part of one order to the modulus-squared of a lower order. This is why an imaginary part in a loop amplitude is never optional bookkeeping — it is mandated, in advance, by tree-level data.

14.7.2 Matrix elements: the invariant amplitude and the sum over states

To turn the operator identity Eq. (14.188) into a relation between numbers we sandwich it between physical states and insert a resolution of the identity on the right-hand side. Two pieces of notation make the bookkeeping honest.

First, the invariant amplitude. For an initial state $|i\rangle$ and a final state $|f\rangle$ of definite momenta, the transition matrix element factorizes a four-momentum-conserving delta function out front, and the remainder *defines* the Lorentz-invariant amplitude $\mathcal{M}$:

$$\langle f|\mathcal{T}|i\rangle = (2\pi)^4\,\delta^{(4)}\Big(p_i - p_f\Big)\,\mathcal{M}(i \to f), \tag{14.189}$$

where p_i and p_f are the total incoming and outgoing four-momenta. This is the same $\mathcal{M}$ produced by LSZ and computed in Theorem 14.35; the delta function expresses translation invariance and is stripped off because it carries no dynamics.

Second, the sum over final states. The completeness relation on the interacting Fock space, written with relativistically normalized multiparticle states and the invariant measure of Eq. (3.191), is

$$\mathbf{1} = \sum_n \frac{1}{n!} \int \prod_{j=1}^{n} \frac{d^3q_j}{(2\pi)^3\,2E_{\mathbf{q}_j}}\;\; |q_1 \dots q_n\rangle\langle q_1 \dots q_n|\,, \tag{14.190}$$

the $1/n!$ correcting for the overcounting of identical bosons when their labels are integrated independently, and an implicit sum over species running alongside the sum on n. We abbreviate this entire structure — the species sum, the number sum, the symmetry factor, the products of invariant measures, *and* the overall momentum-conserving delta function that will appear — by a single symbol $\mathrm{d}\Pi_f$, the *Lorentz-invariant phase space* of the final state f:

$$\sum_f \int \mathrm{d}\Pi_f\,(\cdots) \;\equiv\; \sum_n \frac{1}{n!} \sum_{\{\text{species}\}} \int \prod_{j=1}^{n} \frac{d^3q_j}{(2\pi)^3\,2E_{\mathbf{q}_j}}\,(2\pi)^4\,\delta^{(4)}\Big(p_i - \sum_j q_j\Big)\,(\cdots). \tag{14.191}$$

This is the same measure that converts $|\mathcal{M}|^2$ into a decay rate or cross section in Chapter 16; here we need only that it is real and nonnegative, $\mathrm{d}\Pi_f \geq 0$, and Lorentz invariant. (The momentum delta is included inside $\mathrm{d}\Pi_f$; we display it explicitly when a step needs it and otherwise leave it folded in, matching the compact form quoted in Eq. (5.147).)

14.7.3 The generalized optical theorem

We can now extract the central result. Take the diagonal, *forward* matrix element of Eq. (14.188) in a fixed initial state $|i\rangle$ — the same state on both sides — and evaluate each side with Eqs. (14.189) to (14.191).

Theorem 14.37 (Generalized optical theorem)**.** *For any state $|i\rangle$ of definite total four-momentum p_i, the forward invariant amplitude obeys*

$$2\ \mathrm{Im}\ \mathcal{M}(i \to i) = \sum_f \int \mathrm{d}\Pi_f\ \left|\mathcal{M}(i \to f)\right|^2, \tag{14.192}$$

where the sum runs over every kinematically accessible final state f, weighted by its Lorentz-invariant phase space Eq. (14.191). The right-hand side is manifestly real and nonnegative; hence so is $\mathrm{Im}\ \mathcal{M}(i \to i) \geq 0$.

Proof. Sandwich Eq. (14.188) between $\langle i|$ and $|i\rangle$.

Left-hand side. Using $\left\langle i\middle|\mathcal{T}^\dagger\middle|i\right\rangle = \langle i|\mathcal{T}|i\rangle^*$,

$$\left\langle i\middle| -i(\mathcal{T}-\mathcal{T}^\dagger)\middle|i\right\rangle = -i\Big(\langle i|\mathcal{T}|i\rangle - \langle i|\mathcal{T}|i\rangle^*\Big) = -i\left(2i\ \mathrm{Im}\,\langle i|\mathcal{T}|i\rangle\right) = 2\ \mathrm{Im}\,\langle i|\mathcal{T}|i\rangle\,. \tag{14.193}$$

Now insert Eq. (14.189) for the forward element, $\langle i|\mathcal{T}|i\rangle = (2\pi)^4\delta^{(4)}(0)\,\mathcal{M}(i \to i)$. The forward delta function is evaluated at zero argument because initial and final momenta coincide; it is the familiar infrared artefact of plane-wave normalization, equal to the spacetime volume,

$$(2\pi)^4\,\delta^{(4)}(0) = \int d^4x\ e^{\,i\,0\cdot x} = V\,T, \tag{14.194}$$

in a box of spatial volume V over a time T. Hence the left-hand side equals $2\,VT\ \mathrm{Im}\ \mathcal{M}(i \to i)$.

Right-hand side. Insert the completeness relation Eq. (14.190), packaged as Eq. (14.191), between $\mathcal{T}^\dagger$ and $\mathcal{T}$:

$$\left\langle i\middle|\mathcal{T}^\dagger\mathcal{T}\middle|i\right\rangle = \sum_f \int \mathrm{d}\Pi'_f\ \left\langle i\middle|\mathcal{T}^\dagger\middle|f\right\rangle\langle f|\mathcal{T}|i\rangle = \sum_f \int \mathrm{d}\Pi'_f\ \left|\langle f|\mathcal{T}|i\rangle\right|^2, \tag{14.195}$$

where $\mathrm{d}\Pi'_f$ denotes for the moment the phase space *without* the momentum delta (the delta in Eq. (14.191) arose from the $\mathcal{T}$ matrix elements, which we now write

out). Substituting Eq. (14.189),

$$\begin{aligned}\left|\langle f|\mathcal{T}|i\rangle\right|^2 &= \Big[(2\pi)^4\delta^{(4)}(p_i-p_f)\Big]^2\,\left|\mathcal{M}(i\to f)\right|^2 \\ &= (2\pi)^4\delta^{(4)}(0)\,\cdot\,(2\pi)^4\delta^{(4)}(p_i-p_f)\,\left|\mathcal{M}(i\to f)\right|^2,\end{aligned} \tag{14.196}$$

where we used the standard regularization of the squared delta: one factor is set to its zero-argument value $(2\pi)^4\delta^{(4)}(0) = VT$ by Eq. (14.194), while the surviving factor enforces momentum conservation. Reassembling, the surviving $(2\pi)^4\delta^{(4)}(p_i-p_f)$ combines with $\mathrm{d}\Pi'_f$ to rebuild the full invariant phase space $\mathrm{d}\Pi_f$ of Eq. (14.191), so

$$\Big\langle i\Big|\mathcal{T}^\dagger\mathcal{T}\Big|i\Big\rangle = VT\sum_f\int \mathrm{d}\Pi_f\,\left|\mathcal{M}(i\to f)\right|^2. \tag{14.197}$$

Cancellation. Equating the two sides, the common factor $VT = (2\pi)^4\delta^{(4)}(0)$ appears once on each side — the left from the forward delta Eq. (14.194), the right from the squared delta Eq. (14.196) — and cancels. What remains is Eq. (14.192). That the VT factors match on the two sides is not luck: both count the same infinite normalization of the single plane-wave initial state, and the physical, density-independent content is exactly what survives their cancellation. The right-hand side is a sum of squared moduli against nonnegative measures, hence nonnegative, forcing $\mathrm{Im}\,\mathcal{M}(i\to i)\geq 0$. □

The result Eq. (14.192) is exact: no approximation entered beyond the plane-wave regularization, which cancels. It holds order by order in any coupling and, granting the unitarity of $\mathbf{S}$, beyond perturbation theory. It is the precise statement promised at Section 5.5.6, where the dispersion machinery was built in anticipation of it: the imaginary part of an amplitude is never an abstract analytic datum but a physical sum of squared amplitudes, hence a total rate.

Caution

The squared delta in Eq. (14.196) is the one genuinely delicate manipulation, and it is legitimate only because the offending factor cancels against an identical one on the other side of the equation. One must never read $[\delta^{(4)}(p_i-p_f)]^2$ as a meaningful number in isolation; it is shorthand for "regulate in a finite box, extract the common volume factor, take $V,T\to\infty$ last." The same prescription underlies the conversion of $|\mathcal{M}|^2$ to rates in Chapter 16, where the VT becomes the flux-times-time that turns a probability into a cross section. Here the bookkeeping is even cleaner: the factor is the same on both sides and simply divides out.

14.7.4 The forward amplitude and the total cross section

The most-used form of Eq. (14.192) specializes the initial state to two particles, $|i\rangle = |p_1\, p_2\rangle$, the configuration of a scattering experiment. The right-hand side then sums the squared amplitude over all final states the pair can produce — elastic, inelastic, any number of particles — which is exactly the combination that builds the *total* cross section. We recall from Chapter 16 the master formula for a $2 \to f$ cross section,

$$d\sigma(i \to f) = \frac{1}{F}\,\big|\mathcal{M}(i \to f)\big|^2\,\mathrm{d}\Pi_f, \qquad F = 4\sqrt{(p_1\cdot p_2)^2 - m_1^2 m_2^2}, \tag{14.198}$$

with F the relativistic flux factor (the Møller flux), so that summing and integrating over all final states gives

$$\sigma_{\mathrm{tot}}(s) = \frac{1}{F}\sum_f \int \mathrm{d}\Pi_f\,\big|\mathcal{M}(i \to f)\big|^2. \tag{14.199}$$

Comparing with Eq. (14.192), the sum is precisely $2\,\mathrm{Im}\,\mathcal{M}(i \to i)$, the imaginary part of the *forward elastic* amplitude — "forward" because the final two-particle state equals the initial one, $p_1' = p_1$, $p_2' = p_2$, i.e. zero scattering angle and Mandelstam $t = 0$. Therefore

$$\boxed{\mathrm{Im}\;\mathcal{M}(s, t{=}0) = \tfrac{1}{2}\,F\,\sigma_{\mathrm{tot}}(s) = 2\,p_{\mathrm{cm}}\sqrt{s}\,\sigma_{\mathrm{tot}}(s)} \tag{14.200}$$

where in the last step we evaluated the flux in the centre-of-momentum frame. There $p_1 = (E_1, \mathbf{p})$, $p_2 = (E_2, -\mathbf{p})$ with $|\mathbf{p}| = p_{\mathrm{cm}}$ and $E_1 + E_2 = \sqrt{s}$, and a short computation gives

$$F = 4\sqrt{(p_1\cdot p_2)^2 - m_1^2 m_2^2} = 4\,p_{\mathrm{cm}}\sqrt{s}, \tag{14.201}$$

the second equality being the standard kinematic identity $(p_1\cdot p_2)^2 - m_1^2 m_2^2 = p_{\mathrm{cm}}^2\, s$ for two bodies (it follows from writing $p_1\cdot p_2 = E_1E_2 + \mathbf{p}^2$ and $s = (E_1+E_2)^2$ and eliminating the energies through $E_i^2 = \mathbf{p}^2 + m_i^2$). At high energy $p_{\mathrm{cm}} \to \sqrt{s}/2$ and Eq. (14.200) reduces to $\mathrm{Im}\,\mathcal{M}(s,0) \to s\,\sigma_{\mathrm{tot}}(s)$, the form quoted in Eq. (5.148). This is the optical theorem in its classic dress: *the imaginary part of the forward scattering amplitude measures the total cross section.*

Physical Insight

The name is borrowed from classical optics, and the analogy is exact in content. A plane wave passing a scatterer is depleted in the forward direction by exactly the amount scattered into all other directions plus absorbed — the "shadow" is the interference of the incident wave with the forward-scattered wave, and its depth is set by the total (scattered

+ absorbed) cross section. Equation Eq. (14.200) is the quantum-field-theoretic statement of that shadow: removal of flux from the forward beam (the imaginary part of the forward amplitude) equals everything that happens (the total cross section). Positivity, Im $\mathcal{M}(i \to i) \geq 0$, is the statement that a scatterer can only deplete the forward beam, never amplify it — a passive medium, as unitarity demands.

14.7.5 Partial-wave unitarity

The optical theorem constrains the forward amplitude as a whole; decomposing a $2 \to 2$ elastic amplitude into angular momentum eigenchannels sharpens the constraint into a bound on each channel separately. We treat the cleanest case — two spinless particles, elastic scattering, in the centre-of-momentum frame — where the amplitude depends only on s and the scattering angle θ. Expand in Legendre polynomials,

$$\mathcal{M}(s,\theta) = \frac{8\pi\sqrt{s}}{p_{\rm cm}} \sum_{\ell=0}^{\infty} (2\ell+1)\, a_\ell(s)\, P_\ell(\cos\theta), \tag{14.202}$$

the normalization chosen — with foresight — so that elastic unitarity will take its simplest form on the dimensionless coefficients $a_\ell(s)$. Inverting with the orthogonality relation $\int_{-1}^{1} d(\cos\theta)\, P_\ell P_{\ell'} = \frac{2}{2\ell+1}\delta_{\ell\ell'}$ gives the projection

$$a_\ell(s) = \frac{p_{\rm cm}}{16\pi\sqrt{s}} \int_{-1}^{1} d(\cos\theta)\, P_\ell(\cos\theta)\, \mathcal{M}(s,\theta). \tag{14.203}$$

We now write the two cross sections of interest in terms of the a_ℓ. The elastic cross section uses the $2 \to 2$ rate $d\sigma_{\rm el}/d\Omega = |\mathcal{M}|^2/(64\pi^2 s)$ (the elastic specialization of Eq. (14.198), with $|\mathbf{p}_f| = |\mathbf{p}_i|$, derived in Chapter 16). Insert Eq. (14.202), integrate over the solid angle with the same orthogonality relation, and the double sum collapses to a single one:

$$\begin{aligned} \sigma_{\rm el} &= \int d\Omega\, \frac{|\mathcal{M}|^2}{64\pi^2 s} = \frac{2\pi}{64\pi^2 s} \int_{-1}^{1} d(\cos\theta) \left(\tfrac{8\pi\sqrt{s}}{p_{\rm cm}}\right)^2 \sum_{\ell,\ell'} (2\ell+1)(2\ell'+1) a_\ell a_{\ell'}^{*} P_\ell P_{\ell'} \\ &= \frac{4\pi}{p_{\rm cm}^2} \sum_{\ell} (2\ell+1)\, |a_\ell(s)|^2 . \end{aligned} \tag{14.204}$$

The total cross section comes from the optical theorem Eq. (14.200). At $\theta = 0$ all $P_\ell(1) = 1$, so the forward amplitude is $\mathcal{M}(s,0) = \frac{8\pi\sqrt{s}}{p_{\rm cm}} \sum_\ell (2\ell+1) a_\ell$, and

$$\sigma_{\rm tot} = \frac{\text{Im}\ \mathcal{M}(s,0)}{2\, p_{\rm cm}\sqrt{s}} = \frac{1}{2 p_{\rm cm}\sqrt{s}} \cdot \frac{8\pi\sqrt{s}}{p_{\rm cm}} \sum_\ell (2\ell{+}1)\ \text{Im}\ a_\ell = \frac{4\pi}{p_{\rm cm}^2} \sum_\ell (2\ell{+}1)\ \text{Im}\ a_\ell(s). \tag{14.205}$$

The two results carry the identical prefactor $4\pi/p_{\rm cm}^2$ — precisely the payoff of the normalization in Eq. (14.202), and the relativistic echo of the familiar $4\pi/k^2$ of nonrelativistic partial-wave theory. Because the total cross section is the elastic plus the (nonnegative) inelastic part, $\sigma_{\rm tot} = \sigma_{\rm el} + \sigma_{\rm inel}$ with $\sigma_{\rm inel} \geq 0$, and because the sums run over the same independent channels ℓ, the inequality holds channel by channel:

$$\text{Im } a_\ell(s) = \left|a_\ell(s)\right|^2 + \frac{p_{\rm cm}^2}{4\pi(2\ell+1)}\,\sigma_{\rm inel}^{(\ell)} \;\geq\; \left|a_\ell(s)\right|^2. \tag{14.206}$$

This is *partial-wave unitarity*. Its geometric content is immediate: complete the square,

$$\left|a_\ell\right|^2 - \text{Im } a_\ell \leq 0 \iff \Big(\text{Re } a_\ell\Big)^2 + \Big(\text{Im } a_\ell - \tfrac{1}{2}\Big)^2 \leq \tfrac{1}{4}, \tag{14.207}$$

so each $a_\ell(s)$ is confined to the closed disk of radius $\frac{1}{2}$ centred at $\frac{i}{2}$ in the complex plane — the *Argand circle* of Fig. 14.6. The bound has three faces worth stating plainly: $0 \leq \text{Im } a_\ell \leq 1$, $|\text{Re } a_\ell| \leq \frac{1}{2}$, and $|a_\ell| \leq 1$. A single partial wave can never exceed these magnitudes, no matter the dynamics. The boundary of the disk is reached only when $\sigma_{\rm inel}^{(\ell)} = 0$, the purely elastic case, where Eq. (14.206) becomes the equality $\text{Im } a_\ell = |a_\ell|^2$ and the amplitude may be written in terms of a real phase shift $\delta_\ell(s)$,

$$a_\ell = \frac{e^{2i\delta_\ell} - 1}{2i} = e^{i\delta_\ell}\sin\delta_\ell, \tag{14.208}$$

for which $\text{Im } a_\ell = \sin^2\delta_\ell = |a_\ell|^2$ identically. When inelastic channels open, the amplitude moves into the interior of the disk; the deficit $\text{Im } a_\ell - |a_\ell|^2$ is, by Eq. (14.206), a direct measure of the inelastic rate in that channel.

The maximal value $|a_\ell| = 1$, attained at $a_\ell = i$ ($\delta_\ell = \pi/2$), caps the contribution of each angular momentum to the total cross section at

$$\sigma_{\rm tot}^{(\ell)} \leq \frac{4\pi}{p_{\rm cm}^2}(2\ell+1), \tag{14.209}$$

the *unitarity bound* on a single partial wave. It is the seed of the high-energy Froissart bound on the total cross section, developed in the analyticity program; here we have it as an exact, nonperturbative statement, with the modest caveat that for *identical* final particles the two-body phase space in Eq. (14.204) carries an extra symmetry factor $\frac{1}{2}$ and only even ℓ contribute, shifting the numerical coefficients but not the existence or form of the bound.

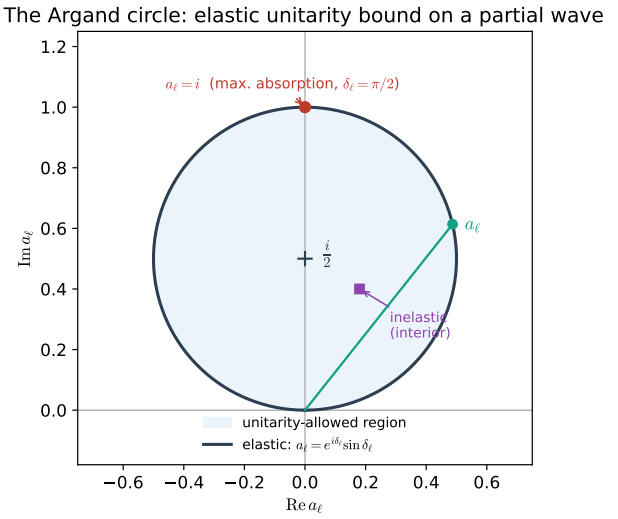

Figure 14.6: The Argand circle Eq. (14.207): unitarity confines every elastic partial-wave amplitude $a_\ell(s)$ to the closed disk of radius $\frac{1}{2}$ centred at $\frac{i}{2}$. The boundary is the purely elastic locus Eq. (14.208), $a_\ell = e^{i\delta_\ell}\sin\delta_\ell$, traced by the real phase shift δ_ℓ; the maximal-cross-section point $a_\ell = i$ ($\delta_\ell = \pi/2$, purely elastic) saturates the per-channel cross-section bound, while maximal absorption (largest inelastic deficit) sits at the disk centre $a_\ell = i/2$. Open inelastic channels push a_ℓ into the interior, the radial deficit measuring the inelasticity. An amplitude that would leave the disk signals the breakdown of whatever approximation produced it.

Caution

The bound $|a_\ell| \leq 1$ is a property of the *exact* amplitude, not of any truncation of it. A perturbative result is a polynomial in the coupling and will, at sufficiently high energy or strong coupling, march straight out of the Argand disk. That is not a violation of unitarity; it is the calculation announcing the energy or coupling at which the omitted higher orders can no longer be neglected — where the series must be resummed or new physics must intervene. Perturbative unitarity is thus a self-diagnostic: it tells a tree-level amplitude where it stops being trustworthy.

14.7.6 Scalar ϕ^4 theory: the optical theorem to leading order, and where the real check lives

We close by applying the machinery to the amplitude this chapter actually computed, and by stating honestly what the leading-order check can and cannot show.

Worked Example 14.38 (The ϕ^4 optical theorem and the perturbative unitarity bound on λ)**.** The tree amplitude for $\phi\phi \to \phi\phi$ from Theorem 14.35 is the constant $\mathcal{M} = -\lambda$, independent of all kinematics. We test it against Theorem 14.37 and read off the perturbative reach of λ.

Leading order is a triviality, by design. The forward amplitude is $\mathcal{M}(i \to i) = -\lambda$, a real number, so its imaginary part vanishes: $\operatorname{Im} \mathcal{M}(i \to i) = 0 + O(\lambda^2)$. The right-hand side of Eq. (14.192) is $\sum_f \int \mathrm{d}\Pi_f |\mathcal{M}(i \to f)|^2$; the lightest accessible final state is again two scalars, contributing $\int \mathrm{d}\Pi_2 \, |-\lambda|^2 = O(\lambda^2)$. So at $O(\lambda)$ the optical theorem reads $0 = 0 + O(\lambda^2)$: it is satisfied, but vacuously, carrying no information. This is forced by Eq. (14.188), which always pairs the imaginary part at one order with the squared amplitude at the order below. The first *nontrivial* statement is the $O(\lambda^2)$ balance,

$$2 \operatorname{Im} \mathcal{M}^{(2)}(i \to i) \overset{!}{=} \int \mathrm{d}\Pi_2 \, \left|\mathcal{M}^{(1)}(i \to f)\right|^2 = \lambda^2 \int \mathrm{d}\Pi_2, \tag{14.210}$$

relating the imaginary part of the *one-loop* forward amplitude $\mathcal{M}^{(2)}$ to the tree amplitude squared, integrated over the two-body phase space. The right-hand side is elementary — it is the same $\int \mathrm{d}\Pi_2 = \beta/8\pi$ two-body volume met in Theorem 5.39, with $\beta = \sqrt{1 - 4m^2/s}$ — so Eq. (14.210) is a sharp, falsifiable prediction for the imaginary part of the one-loop s-channel bubble. Computing $\mathcal{M}^{(2)}$ and verifying it requires the loop integral itself, which is the business of later chapters; no new number is established here.

The perturbative unitarity bound. Project the tree amplitude onto partial waves with Eq. (14.203). Since $\mathcal{M} = -\lambda$ is angle-independent and $P_0 = 1$, only the s-wave survives:

$$a_0(s) = \frac{p_{\mathrm{cm}}}{16\pi\sqrt{s}} \int_{-1}^{1} d(\cos\theta)\,(-\lambda) = \frac{p_{\mathrm{cm}}}{16\pi\sqrt{s}}\,(-\lambda)(2) = -\frac{\lambda\, p_{\mathrm{cm}}}{8\pi\sqrt{s}} \xrightarrow{s \gg m^2} -\frac{\lambda}{16\pi}, \tag{14.211}$$

using $p_{\mathrm{cm}} \to \sqrt{s}/2$ at high energy. This a_0 is real at $O(\lambda)$, consistent with $\operatorname{Im} a_0 = |a_0|^2 = O(\lambda^2)$: the imaginary part the Argand circle demands is again pushed to one loop. The unitarity bound $|a_0| \le 1$ then reads

$$\frac{\lambda}{16\pi} \lesssim 1 \qquad \Longrightarrow \qquad \lambda \lesssim 16\pi \approx 50, \tag{14.212}$$

up to an $O(1)$ identical-particle factor that we have not tracked precisely. The lesson is robust against that factor: tree-level $\lambda\phi^4$ is a sensible perturbative description only for λ of order 10 or smaller; pushed toward $\lambda \sim 4\pi$–16π the s-wave amplitude saturates its unitarity disk and the loop corrections it has been ignoring become as large as the tree term. The dimensionless expansion parameter of the theory is not λ but $\lambda/16\pi^2$, and Eq. (14.212) is the unitarity-based confirmation of that fact — the same $16\pi^2$ that will reappear in the one-loop β-function $\beta_\lambda = 3\lambda^2/16\pi^2$ of Chapter 24.

The deferral is therefore explicit. The leading ϕ^4 optical-theorem identity Eq. (14.210) is a statement about the one-loop amplitude $\mathcal{M}^{(2)} = O(\lambda^2)$; assembling that amplitude needs the Feynman-diagram technology of Chapter 15 and the loop-integration and imaginary-part methods developed in the renormalization programme (Chapters 19, 21 and 22). The systematic principle that organizes such checks — that the imaginary part of a diagram is obtained by putting each internal line of an intermediate state on shell, channel by channel, exactly the Sokhotski–Plemelj replacement of Eq. (5.140) — is *Cutkosky's cutting rules*, established in Chapter 60. ϕ^4 theory thus carries forward an unredeemed promissory note: the optical theorem here predicts the imaginary part of the one-loop bubble in advance, and the later chapters that compute the loop will find it waiting.

With unitarity in hand, the chapter has delivered every ingredient the rest of the book needs to compute and to check: the LSZ bridge from correlators to amplitudes, the first interacting number $i\mathcal{M} = -i\lambda$, and now the exact constraint that any amplitude — tree, loop, or resummed — must respect. The imaginary-part-equals-sum-over-cuts technology passes directly to Chapter 15, where cutting rules are made diagrammatic, to Chapter 19, where one-loop amplitudes acquire the imaginary parts this theorem guarantees and the infrared structure that accompanies them, and onward to the analyticity-and-dispersion program of Chapter 60, for which the optical theorem is the physical input that turns a total cross section into the full, complex scattering amplitude.

Further reading

The interaction picture, the Dyson series, and the canonical route to the S-matrix are developed in Peskin and Schroeder [396] (chapters 4 and 7), whose presentation of LSZ and the Källén–Lehmann representation this chapter most closely tracks; Schwartz [432] (chapters 6–7 and 24) gives a complementary modern treatment with careful attention to the on-shell residues and the meaning of Z. The most careful textbook account of the asymptotic condition, the in/out formalism, and the cluster-decomposition foundations is Weinberg [500] (chapters 3–4 and 10), which also frames the optical theorem and unitarity nonperturbatively. Srednicki [454] (the path-integral-first chapters on LSZ) and Zee [532] offer alternative derivations worth comparing. The primary sources are Gell-Mann and Low [215] for the vacuum-projection theorem, Lehmann et al. [322] for the reduction formula, and Källén [289], Lehmann [321] for the spectral representation. For the spectral and analytic-structure axioms used in Section 14.4, and for Haag's theorem and the inequivalence of representations confronted in Section 14.2.6, see Streater and Wightman [458] and Haag [246]; the analyticity and dispersion-relation program for which the optical theorem is the physical input is the subject of Eden et al. [170].

Chapter 15

Feynman Diagrams

The previous chapter left perturbation theory in a state that was correct but unworkable. The Dyson series of Chapter 14 expresses the S-matrix as a time-ordered exponential of the interaction, and LSZ reduction expresses every amplitude as a residue of a time-ordered correlation function of free fields; together they reduce all of scattering, order by order in the coupling, to the evaluation of vacuum expectation values of products of free fields. But the one amplitude we evaluated this way — the $O(\lambda)$ contribution to $\phi\phi \to \phi\phi$ for the carried scalar theory — cost us a fourteen-operator normal-ordering done by hand. That method does not scale to two loops, let alone to gauge theory. This chapter builds the machinery that does: an algorithm that turns any term of the Dyson series, mechanically and without touching a ladder operator, into a finite sum of pictures, each of which evaluates to a definite number. By the end the model ϕ^4 will have its $2 \to 2$ amplitude at tree level, $i\mathcal{M} = -i\lambda$, derived twice by independent routes, and a complete rule-set ready to be handed to the observable-extracting chapter that follows.

The engine is Wick's theorem, and the chapter opens by establishing it in the operator form that the Dyson series actually consumes: a statement about the time-ordered product itself, not merely its vacuum matrix element, expressing it as a normal-ordered remainder plus a sum over all pairwise contractions, each contraction being exactly the Feynman propagator of Chapter 9. This is the operator face of the same identity that Chapter 10 obtained from the Gaussian generating functional $Z_0[J]$, and the two faces are made to agree. From there the development is a single idea pursued relentlessly: a contraction is a line, a vertex is a point where four lines meet, and a correlator is the sum over all ways of drawing lines between points. Section 15.2 reads this sum as a catalogue of position-space diagrams and proves that the combinatorial multiplicity of each topology collapses against the $1/N!$ of the Dyson exponential and the $1/4!$ of the vertex, leaving the position-space Feynman rules with their symmetry factors. Section 15.3 Fourier-transforms the rules: vertex integrations become

momentum-conserving delta functions, the loop count $L = I - V + 1$ emerges, LSZ becomes amputation of external legs, and the tree amplitude acquires its final algebraic form.

Two of the chapter's sections exist to make the apparatus airtight rather than merely usable. Section 15.4 treats the symmetry factor not as a mnemonic but as the order $|\mathrm{Aut}(D)|$ of the diagram's automorphism group, proves the identification by orbit–stabiliser, and verifies it on a catalogue of representative graphs — tree vertex, tadpole, figure-eight, sunset, bubble — before carrying the one-loop self-energy through dimensional regularization with the integrals of Chapter D. Section 15.5 then re-derives the entire rule-set, propagators and vertices and the very same symmetry factors, from the generating functional $Z[J]$ of Chapter 10, where $1/S$ falls out of the functional derivatives automatically; the same amplitude computed two ways is the chapter's central consistency check.

With the diagrams in hand, Section 15.6 sorts them. Disconnected graphs exponentiate; $W = -i \ln Z$ generates exactly the connected ones; vacuum bubbles cancel by the linked-cluster theorem; amputation strips the external propagators; and the Legendre transform Γ isolates the one-particle-irreducible core on which the renormalization programme of Chapters 21 and 22 and the effective potential of Chapter 29 are built. The final section extends the rules to anticommuting fields, importing the Grassmann calculus of Chapters 11 and 12 to derive the directed fermion line, the fermion–boson vertex, the relative sign between exchange diagrams, and the closed-fermion-loop factor of (-1) with its trace — the signs and traces that Chapter 17 and Chapter 26 inherit whole for QED and Yang–Mills. Throughout we hold the chapter conventions of the style canon: mostly-minus metric $\eta_{\mu\nu} = \mathrm{diag}(+,-,-,-)$, natural units, the Feynman $i\varepsilon$ prescription, and the gamma-matrix trace technology collected in Section C.6.

15.1 Wick's Theorem: Time Ordering as a Sum of Contractions

Chapter 14 left us holding a powerful but unwieldy object. The interaction-picture S-matrix is the time-ordered exponential of the interaction (Theorem 14.6),

$$\mathbf{S} = U(\infty,-\infty) = \mathcal{T}\exp\Big(-i\int_{-\infty}^{\infty}\mathrm{d}t\; H_I(t)\Big) = \sum_{N=0}^{\infty}\frac{(-i)^N}{N!}\int \mathrm{d}^4z_1\cdots\mathrm{d}^4z_N\;\mathcal{T}\Big\{\mathcal{H}_I(z_1)\cdots\mathcal{H}_I(z_N)\Big\} \tag{15.1}$$

where for ϕ^4 theory the interaction-picture density is built entirely from the *free* field, $\mathcal{H}_I(z) = \frac{\lambda}{4!}\,\phi(z)^4$ (Eq. (14.11)), and ϕ henceforth means the free interaction-picture field ϕ_I of Theorem 14.2, with the mode expansion and algebra fixed in Eq. (9.147). The LSZ reduction of Chapter 14 expresses every scattering amplitude as a residue of a *time-ordered correlation function* of these free fields, so that the entire content of perturbation theory, order by order in λ, is the

evaluation of vacuum expectation values of the form

$$\langle 0|\,\mathcal{T}\{\phi(x_1)\cdots\phi(x_n)\}\,|0\rangle \qquad \text{and, with vertices inserted,} \qquad \langle 0|\,\mathcal{T}\{\phi(x_1)\cdots\phi(x_n)\,\phi(z_1)^4 \tag{15.2}$$

In Chapter 14 we evaluated the very first such object — the $O(\lambda)$ contribution to $\phi\phi\to\phi\phi$ — by brute force, expanding each field into ladder operators, normal-ordering the resulting fourteen-operator string by hand, and reading off which terms had a surviving matrix element between the chosen in- and out-states. The computation worked, and it gave the carried number $-i\lambda$; but it was an exercise in stamina, and it would not survive contact with the two-loop diagrams of Chapter 21, let alone the gauge theories of Part VII. What we need is an algorithm that converts a time-ordered product of free fields, mechanically and without ever touching a ladder operator, into a finite sum of c-number propagators multiplying normal-ordered remainders. That algorithm is *Wick's theorem*, and it is the single device that turns the Dyson series Eq. (15.1) from an operator nightmare into bookkeeping of lines and vertices — the bookkeeping that the next section will draw as Feynman diagrams.

Wick's theorem has, in this book, two faces that must agree. In Chapter 10 the free n-point function was computed from the generating functional $Z_0[J]$, and the chain rule on a Gaussian produced the path-integral form (Theorem 10.23): every free correlator is a sum over *pairings* of its arguments, one propagator per pair. That derivation never mentioned an operator. Here we establish the operator (canonical) form, the form that acts directly on the Dyson series: an *operator identity* valid before any vacuum expectation value is taken, expressing the time-ordered product itself — not merely its vacuum matrix element — as a normal-ordered product plus a sum over all ways of contracting pairs of fields. The two faces were shown to coincide in Section 10.5.4, where the operator statement (Theorem 10.25) was obtained as a cross-check on the path-integral result. This section gives that operator identity its proper, operational home: we re-establish the contraction at the point of use, prove the theorem in the form the perturbation series actually consumes, extend it to the normal-ordered insertions that the Dyson vertices demand, and verify the four-field case term by term so that the diagram dictionary of Section 15.2 has a fully worked anchor.

15.1.1 The contraction of two free fields

Everything rests on a single c-number. Split the free field into its positive- and negative-frequency parts, as introduced for the mode expansion of Chapter 9,

$$\phi(x)=\phi^+(x)+\phi^-(x), \qquad \phi^+(x)=\int\frac{\mathrm{d}^3p}{(2\pi)^3}\frac{1}{\sqrt{2E_{\mathbf{p}}}}\,a_{\mathbf{p}}\,e^{-ip\cdot x}, \quad \phi^-(x)=\int\frac{\mathrm{d}^3p}{(2\pi)^3}\frac{1}{\sqrt{2E_{\mathbf{p}}}}\,a^\dagger_{\mathbf{p}}\,e^{} \tag{15.3}$$

with $p^0=E_{\mathbf{p}}=\sqrt{\mathbf{p}^2+m^2}$ on shell. By construction ϕ^+ holds the annihilation operators and kills the vacuum on the right, $\phi^+(x)\,|0\rangle=0$, while ϕ^- holds the

creation operators and kills it on the left, $\langle 0|\,\phi^-(x) = 0$. The label is the standard, initially counter-intuitive one: the part with $e^{-iE_{\mathbf{p}}t}$ (positive frequency) is the *annihilation* part, and we name it ϕ^+. The only nonvanishing commutator among the four pieces is

$$\begin{aligned}\left[\phi^+(x),\phi^-(y)\right] &= \int \frac{\mathrm{d}^3p}{(2\pi)^3}\frac{\mathrm{d}^3q}{(2\pi)^3}\frac{1}{\sqrt{2E_{\mathbf{p}}}\sqrt{2E_{\mathbf{q}}}}\left[a_{\mathbf{p}},a^\dagger_{\mathbf{q}}\right]e^{-ip\cdot x+iq\cdot y}\\ &= \int \frac{\mathrm{d}^3p}{(2\pi)^3}\frac{\mathrm{d}^3q}{(2\pi)^3}\frac{(2\pi)^3\delta^{(3)}(\mathbf{p}-\mathbf{q})}{\sqrt{2E_{\mathbf{p}}}\sqrt{2E_{\mathbf{q}}}}e^{-ip\cdot x+iq\cdot y} = \int\frac{\mathrm{d}^3p}{(2\pi)^3\,2E_{\mathbf{p}}}e^{-ip\cdot(x-y)} \;=\; D(x-\end{aligned} \tag{15.4}$$

where we used $\left[a_{\mathbf{p}},a^\dagger_{\mathbf{q}}\right] = (2\pi)^3\delta^{(3)}(\mathbf{p}-\mathbf{q})$ (Eq. (9.147)) and recognized the result as the positive-frequency Wightman function $D(x-y)$ of Eq. (9.150). This is a pure c-number — a number times the identity operator — because the right-hand side of the canonical commutator is.

Definition 15.1 (Contraction of two free fields)**.** The *contraction* of two free scalar fields is the c-number obtained by subtracting the normal-ordered product from the time-ordered product (Eq. (10.146)),

$$\overbracket{\phi(x)\,\phi(y)} \;\equiv\; \mathcal{T}\,\phi(x)\phi(y) - :\phi(x)\phi(y):\,, \tag{15.5}$$

with $:\cdots:$ the normal ordering of Theorem 9.19, which moves every creation operator to the left of every annihilation operator as though they commuted.

The defining subtraction is engineered precisely to isolate the commutator Eq. (15.4), as the following identification — the one fact on which every diagram in this book ultimately rests — makes explicit.

Proposition 15.2 (The contraction is the Feynman propagator)**.** *For any two spacetime points,*

$$\overbracket{\phi(x)\,\phi(y)} \;=\; D_F(x-y) \;=\; \int\frac{\mathrm{d}^4p}{(2\pi)^4}\,\frac{i\,e^{-ip\cdot(x-y)}}{p^2-m^2+i\varepsilon}, \tag{15.6}$$

the free Feynman propagator of Theorem 9.24.

Proof. Take $x^0 > y^0$ first. Then $\mathcal{T}\,\phi(x)\phi(y) = \phi(x)\phi(y)$, and we expand both fields through Eq. (15.3) and reorder into normal form. Of the four products $\phi^+(x)\phi^+(y)$, $\phi^+(x)\phi^-(y)$, $\phi^-(x)\phi^+(y)$, $\phi^-(x)\phi^-(y)$, only the second is not already normal-ordered: it has an annihilation part to the left of a creation part. Reordering it costs exactly one commutator,

$$\phi^+(x)\phi^-(y) = \phi^-(y)\phi^+(x) + \left[\phi^+(x),\phi^-(y)\right], \tag{15.7}$$

so that

$$\phi(x)\phi(y) = \underbrace{\phi^+(x)\phi^+(y) + \phi^-(y)\phi^+(x) + \phi^-(x)\phi^+(y) + \phi^-(x)\phi^-(y)}_{=\,:\,\phi(x)\phi(y)\,:} \;+\; \Big[\phi^+(x), \phi^-(y)\Big]\,. \tag{15.8}$$

The four bracketed terms have every creation operator to the left of every annihilation operator: they *are* $:\phi(x)\phi(y):$. Hence $\mathcal{T}\,\phi(x)\phi(y) - :\phi(x)\phi(y): = \big[\phi^+(x), \phi^-(y)\big] = D(x-y)$ by Eq. (15.4). For $y^0 > x^0$ the time-ordering instead puts $\phi(y)$ to the left, and the identical reordering gives the contraction $\big[\phi^+(y), \phi^-(x)\big] = D(y-x)$. Combining the two cases with the step functions of Eq. (9.151),

$$\overbrace{\phi(x)\,\phi(y)} = \theta(x^0 - y^0)\,D(x-y) + \theta(y^0 - x^0)\,D(y-x) = D_F(x-y), \tag{15.9}$$

which is precisely the position-space Feynman propagator Eq. (9.153). Its covariant momentum representation Eq. (15.6) is the contour result Eq. (9.154), with the $i\varepsilon$ implementing the time ordering and the Fourier and $i\varepsilon$ conventions as fixed in Sections A.3 and A.4.

Two corollaries record themselves. First, the contraction is symmetric, $D_F(x-y) = D_F(y-x)$, because both $D(x-y)$ for $x^0 > y^0$ and the swapped expression depend only on the analytic continuation of the same scalar function; equivalently, the momentum integral Eq. (15.6) is even in $x-y$. Second, since the contraction is a c-number it equals its own vacuum expectation value, and as $\langle 0|\,:\phi\phi:\,|0\rangle = 0$ (Theorem 9.19) it also equals $\langle 0|\,\mathcal{T}\phi(x)\phi(y)\,|0\rangle = D_F(x-y)$ directly, recovering Eq. (10.147). □

The mechanism of the proof is worth naming, because the whole theorem is its iteration: to normal-order a product, push each annihilation part rightward past each creation part, and *every such transposition deposits one factor of the propagator* and nothing else. A field that never has to move past a creation operator contributes no propagator; a field that moves past k creation operators contributes k separate propagator terms, one for each partner it stepped over.

15.1.2 Wick's theorem as an operator identity

We now state the general identity and prove it. The combinatorial vocabulary is fixed first. A *contraction pattern* on the fields $\phi(x_1), \dots, \phi(x_n)$ is a choice of some number $r \geq 0$ of disjoint unordered pairs $\{i_1, j_1\}, \dots, \{i_r, j_r\}$ drawn from $\{1, \dots, n\}$; the $2r$ fields in these pairs are "contracted" and the remaining $n - 2r$ fields are "uncontracted." To each pattern we assign the operator

$$\Big(\textstyle\prod_{a=1}^{r} D_F(x_{i_a} - x_{j_a})\Big)\;:\!\prod_{k\ \text{uncontracted}}\!\phi(x_k)\!:\,, \tag{15.10}$$

i.e. each contracted pair is replaced by its c-number propagator and the leftover fields are normal-ordered together. The pattern with $r = 0$ is the bare normal-ordered product; a pattern with $2r = n$ (possible only for even n) is "fully contracted" and is a pure c-number.

Theorem 15.3 (Wick's theorem, operator form)**.** *A time-ordered product of free scalar field operators equals the sum, over* all *contraction patterns, of the associated operators Eq. (15.10):*

$$\mathcal{T}\{\phi(x_1)\cdots\phi(x_n)\} \;=\; \sum_{\text{contraction patterns } P} \Big(\prod_{\{i,j\}\in P} D_F(x_i-x_j)\Big) : \prod_{k\notin P}\phi(x_k): \,, \tag{15.11}$$

schematically: the fully uncontracted normal-ordered product, plus all single contractions, plus all double contractions, and so on up to the fully-contracted terms. The identity holds as an operator equation on the free Fock space of Theorem 9.17, prior to taking any matrix element.

This is the operator statement obtained as a cross-check in Theorem 10.25; it is the engine of the present chapter, so we give the proof in full here, in the form that the induction step of the perturbation series will reuse.

Proof. Induction on the number of fields n. For $n = 1$ a single field is already normal-ordered and there is no pair to contract: Eq. (15.11) reads $\phi(x_1) =: \phi(x_1):$, true. For $n = 2$ it is the rearrangement of Eq. (15.5) read together with Theorem 15.2,

$$\mathcal{T}\,\phi(x_1)\phi(x_2) =: \phi(x_1)\phi(x_2): \; + \overbrace{\phi(x_1)\phi(x_2)}, \tag{15.12}$$

the two patterns being "no contraction" and "contract $\{1,2\}$."

Assume Eq. (15.11) holds for any n free fields. Take $n+1$ fields and relabel so that x_{n+1} carries the *earliest* time, $x^0_{n+1} \le x^0_i$ for all $i \le n$. This entails no loss of generality: the left side of Eq. (15.11) is totally symmetric under relabeling because $\mathcal{T}$ symmetrizes bosonic fields, and the right side is symmetric because the sum ranges over *all* patterns. With x_{n+1} latest-to-act (earliest in time means rightmost under $\mathcal{T}$), the time-ordering symbol places it on the far right,

$$\mathcal{T}\{\phi(x_1)\cdots\phi(x_{n+1})\} = \Big(\mathcal{T}\{\phi(x_1)\cdots\phi(x_n)\}\Big)\,\phi(x_{n+1}). \tag{15.13}$$

Substitute the inductive hypothesis Eq. (15.11) for the bracket and multiply each term on the right by $\phi(x_{n+1}) = \phi^+(x_{n+1}) + \phi^-(x_{n+1})$. Consider one such term: a product of propagators (untouched, being c-numbers) times a normal-ordered string $:\phi(x_{k_1})\cdots\phi(x_{k_m}):$ of the uncontracted fields. We must bring $\phi(x_{n+1})$ *inside* the colons to restore normal order.

The creation part $\phi^-(x_{n+1})$ presents no obstruction: normal ordering places creation operators on the left, and ϕ^- commutes with the other fields' content

only up to c-numbers it never meets here, so $:X:\,\phi^-(x_{n+1}) = :X\,\phi^-(x_{n+1}):$ without cost. The annihilation part $\phi^+(x_{n+1})$ must instead be moved leftward through the string to sit among the annihilation operators; each time it passes the negative-frequency (creation) content $\phi^-(x_k)$ of one of the fields inside the colons, it deposits the c-number commutator

$$\Big[\phi^+(x_{n+1}), \phi^-(x_k)\Big] = D(x_{n+1} - x_k) = D_F(x_{n+1} - x_k), \tag{15.14}$$

the last equality holding by Theorem 15.2 *because* x_{n+1} is the earliest time, so $D(x_{n+1} - x_k)$ is exactly the contraction in that time order. Each deposited commutator is precisely one new contraction joining the new field x_{n+1} to a previously-uncontracted partner x_k; collecting the commutator pulls that pair out as a propagator and removes $\phi(x_k)$ from the normal-ordered remainder.

Summing the outcomes, each term of the n-field expansion generates: (i) one term in which $\phi(x_{n+1})$ joins the normal-ordered remainder uncontracted, and (ii) for each uncontracted field x_k in that term, one term in which x_{n+1} is contracted with x_k and both leave the colons. This is exactly the statement that the $(n+1)$-field patterns are the n-field patterns with x_{n+1} either left uncontracted or contracted with one of the fields still available — which enumerates every contraction pattern on $n+1$ fields once and only once. Hence the collected terms reassemble Eq. (15.11) for $n+1$ fields, closing the induction. □

Two features of Theorem 15.3 deserve emphasis before we use it. First, it is an *operator* identity: both sides are operators on Fock space, equal as such, and we have not yet thrown away anything by taking expectation values. This is what makes the theorem usable inside the Dyson series, where the fields sit between non-vacuum asymptotic states. Second, the contraction is unambiguously the *time-ordered* two-point function D_F, not the Wightman function and not the commutator; one may not contract fields inside an order that has already been fixed by hand. The theorem is a statement about the $\mathcal{T}$-product on the left, and it is the $\mathcal{T}$-product that LSZ and the path integral both deliver (Theorem 10.19).

15.1.3 The vacuum corollary

Sandwiching Eq. (15.11) between vacua collapses it dramatically. Every term that still carries a normal-ordered product of one or more uncontracted fields has vanishing vacuum expectation value, because a normal-ordered string has an annihilation operator on its right that kills $|0\rangle$ (or a creation operator on its left that kills $\langle 0|$); only the *fully-contracted* terms, which are pure c-numbers, survive. A full contraction exists only when every field is paired, which is possible iff n is even.

Corollary 15.4 (Free correlators are sums of pairings)**.** *For odd n, $\langle 0|\,\mathcal{T}\,\phi(x_1)\cdots\phi(x_n)\,|0\rangle = 0$. For even $n = 2k$,*

$$\langle 0|\,\mathcal{T}\,\phi(x_1)\cdots\phi(x_{2k})\,|0\rangle \;=\; \sum_{\text{pairings } P}\;\prod_{\{i,j\}\in P} D_F(x_i - x_j), \tag{15.15}$$

the sum running over the $(2k-1)!!$ ways of partitioning the $2k$ points into k unordered pairs, with one propagator per pair.

The count $(2k-1)!!$ is the number of perfect matchings of $2k$ objects: pair the first point with any of the remaining $2k-1$, then the next free point with any of the remaining $2k-3$, and so on, giving $(2k-1)(2k-3)\cdots 3\cdot 1 = (2k-1)!!$ (Eq. (10.135)). Equation Eq. (15.15) is identical, term for term, to the path-integral Wick theorem Theorem 10.23, equation Eq. (10.136): the two derivations — the chain rule on a Gaussian in Chapter 10, and the commuting of annihilation operators to the right here — produce not merely the same number but the same intermediate object, a sum over pairings with one propagator per pair. This is the operator-side confirmation, promised in Chapter 9 and discharged in Chapter 10, that the free scalar field is a Gaussian field whose entire content is its two-point function.

15.1.4 The generalized theorem: normal-ordered insertions

The targets in Eq. (15.2) are not products of fields at distinct points: each Dyson vertex is four fields at a *single* point z, and in the normal-ordered conventions inherited from Theorem 9.20 the interaction is naturally written $:\!\phi(z)^4\!:$. Two refinements are therefore needed before Theorem 15.3 can be turned loose on the perturbation series: we must know how contractions behave (a) between fields already collected inside a normal-ordering symbol, and (b) at coincident points.

Point (b) is immediate. Nothing in the proof of Theorem 15.3 assumed the points distinct; the contraction $D_F(x_i - x_j)$ is a well-defined tempered distribution for all separations, and at coincidence $D_F(0) = \int \frac{\mathrm{d}^4p}{(2\pi)^4}\,\frac{i}{p^2-m^2+i\varepsilon}$ is simply a (divergent) constant, to be regulated and renormalized in Chapters 21 and 22. A self-contraction of two of the four fields sitting at one vertex is thus a legitimate term; it is the algebraic seed of the tadpole and vacuum-bubble diagrams.

Point (a) is the substantive one, and it is exactly what normal-ordering the vertex buys us. We package fields into *clusters*, some of which are wrapped in their own normal-ordering symbol.

Theorem 15.5 (Wick's theorem with normal-ordered clusters)**.** *Let the operators be grouped into clusters, where each cluster is either a single field or a pre-normal-ordered local product $:\!\phi(z)\cdots\phi(z)\!:$. Then the time-ordered product of the clusters equals the sum over all contraction patterns* in which no contracted pair lies

entirely within a single pre-normal-ordered cluster, *each contraction being D_F and the uncontracted fields normal-ordered together:*

$$\mathcal{T}\Big\{:\phi(z_1)\cdots:\ :\phi(z_2)\cdots:\ \cdots\Big\} = \sum_{\substack{\text{patterns } P \\ \text{no intra-cluster pair}}} \Big(\prod_{\{i,j\}\in P} D_F(x_i-x_j)\Big) : \prod_{k\notin P}\phi(x_k): \,. \tag{15.16}$$

Proof. It suffices to prove the rule for one pre-normal-ordered cluster; the general case follows by treating each cluster in turn. The key fact is that normal ordering is, by Theorem 15.3 applied to the cluster alone, exactly the time-ordered product with its *internal* contractions removed. Concretely, for a cluster of fields at a common point, Eq. (15.11) reads

$$\mathcal{T}\{\phi(z)\cdots\phi(z)\} =: \phi(z)\cdots\phi(z): + (\text{terms with at least one internal contraction}), \tag{15.17}$$

so that

$$:\phi(z)\cdots\phi(z): \ = \mathcal{T}\{\phi(z)\cdots\phi(z)\} - (\text{internal-contraction terms}); \tag{15.18}$$

the normal-ordered cluster is the plain product purged of self-contractions. Now form the time-ordered product of this cluster with the other clusters and apply the ungrouped theorem Theorem 15.3 to the whole collection. The full sum contains every pattern, including those with intra-cluster pairs. But the subtraction in Eq. (15.18) cancels precisely the patterns whose restriction to the cluster contains an internal contraction: each such pattern appears once from the $\mathcal{T}$-product term and once, with opposite sign, from the subtracted internal-contraction terms multiplied out against the external contractions of the remaining fields. (The bijection is exact because the external contractions of a pattern are independent of, and unaffected by, the internal ones being removed.) What survives is exactly the sum over patterns with no intra-cluster pair, which is Eq. (15.16). Iterating over the remaining clusters removes all intra-cluster contractions and proves the theorem. □

The practical content is a slogan: *normal-ordering a vertex forbids it from contracting with itself.* If one adopts the normal-ordered interaction $\mathcal{H}_I = \frac{\lambda}{4!}:\phi^4:$ — the convention consistent with the normal-ordered free Hamiltonian fixed in Chapter 9 — then the generalized theorem automatically discards every self-contraction of a vertex: no tadpole stub, no vacuum loop hanging off a single point. If instead one keeps the un-normal-ordered $\frac{\lambda}{4!}\phi^4$ written in Eq. (14.11), those self-contractions are present and must be carried until the renormalization program of Chapter 22 disposes of them. Either bookkeeping is legitimate; the two differ only by terms that a constant shift of the vacuum energy and a mass counterterm reabsorb. We will state which convention is in force whenever it affects a diagram count.

Notation Watch

The operator Wick's theorem appears twice in this book by design. Chapter 10 established it (Theorem 10.25) as a cross-check that the path-integral and canonical routes to the free correlator agree; the present section is its operational home, where it is proved in the form Eq. (15.11) that the Dyson induction reuses and extended to the normal-ordered insertions Eq. (15.16) that the path-integral discussion did not need. The contraction is the same object throughout, $\overbrace{\phi\phi} = D_F$; the symbol $: \cdots :$ is always the normal ordering of Theorem 9.19.

15.1.5 The four-field case, term by term

The smallest case that exhibits the full structure — bare term, single contractions, double contractions — is $n = 4$. Writing it out completely fixes the combinatorics that the diagram dictionary of the next section will read off graphically, and it is the case the $O(\lambda)$ four-point amplitude needs.

Worked Example 15.6 (The complete Wick expansion of $\mathcal{T}\,\phi_1\phi_2\phi_3\phi_4$)**.** Abbreviate $\phi_i \equiv \phi(x_i)$ and $D_F^{ij} \equiv D_F(x_i - x_j)$. Theorem 15.3 for $n = 4$ has one no-contraction pattern, $\binom{4}{2} = 6$ single-contraction patterns, and 3 double-contraction patterns ($(4-1)!! = 3$), for $1 + 6 + 3 = 10$ terms:

$$\begin{aligned}\mathcal{T}\,\phi_1\phi_2\phi_3\phi_4 = {} & :\phi_1\phi_2\phi_3\phi_4: \\ & + D_F^{12}:\phi_3\phi_4: \; + D_F^{13}:\phi_2\phi_4: \; + D_F^{14}:\phi_2\phi_3: \; + D_F^{23}:\phi_1\phi_4: \; + D_F^{24}:\phi_1\phi_3: \; + D_F^{34}:\phi_1 \\ & + D_F^{12}D_F^{34} + D_F^{13}D_F^{24} + D_F^{14}D_F^{23}.\end{aligned} \tag{15.19}$$

The first line is the term with no propagators; the second collects the six ways of contracting one pair and normal-ordering the surviving two fields; the third collects the three ways of contracting all four into two pairs — pure c-numbers.

Now take the vacuum expectation value. Every term on the first two lines contains a normal-ordered product of at least two fields and so vanishes between vacua (Theorem 9.19); only the three c-number terms survive, giving

$$\langle 0|\,\mathcal{T}\,\phi_1\phi_2\phi_3\phi_4\,|0\rangle = D_F^{12}D_F^{34} + D_F^{13}D_F^{24} + D_F^{14}D_F^{23}, \tag{15.20}$$

the three pairings of Theorem 15.4 with $k = 2$, in agreement with the path-integral result Eq. (10.138). The three terms are the three perfect matchings of four points, drawn as chord diagrams in Fig. 15.1.

15.1.6 Feeding the Dyson series

We can now state precisely what Wick's theorem does to the perturbation series and hand the result to the diagram rules. Consider the order-λ^N contribution to

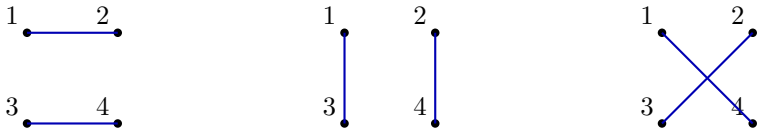

Figure 15.1: The three perfect matchings (pairings) of four points that survive in the free four-point function Eq. (15.20). Each chord is one Feynman propagator D_F; the surviving terms of Wick's theorem are exactly the ways of joining the four external points in pairs. These chord diagrams are the combinatorial skeletons that Section 15.2 dresses into Feynman diagrams.

a time-ordered correlator with n external fields, obtained by expanding Eq. (15.1) to N vertices:

$$\frac{1}{N!}\Big(\frac{-i\lambda}{4!}\Big)^N \int \mathrm{d}^4 z_1 \cdots \mathrm{d}^4 z_N \ \langle 0|\, \mathcal{T}\left\{\phi(x_1)\cdots\phi(x_n)\ \phi(z_1)^4\cdots\phi(z_N)^4\right\} |0\rangle\,. \tag{15.21}$$

The object inside the vacuum brackets is a time-ordered product of $n+4N$ free fields. Theorem 15.3 — in its generalized form Theorem 15.5 if the vertices are normal-ordered — expands it into a finite sum over contraction patterns, and the vacuum corollary Theorem 15.4 keeps only the fully-contracted ones. Each surviving term is a product of $\frac{1}{2}(n+4N)$ propagators (so $n+4N$ must be even, fixing the parity selection rule), integrated over the vertex positions $z_1,\dots,z_N$. In words: *at every order, the correlator is a finite sum of products of propagators, one factor per contracted pair, integrated over the vertices and weighted by the multiplicity of pairings that produce it.* No operator survives; the entire computation has been reduced to choosing how to wire the legs together and counting how many wirings give each wiring pattern.

For ϕ^4 theory at lowest nontrivial order this is the computation Chapter 14 did by hand, now read off mechanically. The connected $O(\lambda)$ contribution to $\langle 0|\,\mathcal{T}\,\phi(x_1)\phi(x_2)\phi(x_3)\phi(x_4)\,|0\rangle$ takes $n=4$ external points and one vertex z ($N=1$, $n+4N=8$ fields). The connected fully-contracted patterns are those that join each external point to one of the four vertex legs $\phi(z)$: there are $4!=24$ ways to assign the four distinct external points to the four identical vertex legs, and this 24 cancels the $1/4!$ in the vertex normalization, leaving the four-propagator structure

$$(-i\lambda)\int \mathrm{d}^4 z\ D_F(x_1-z)\,D_F(x_2-z)\,D_F(x_3-z)\,D_F(x_4-z), \tag{15.22}$$

whose amputated, on-shell residue under LSZ is the carried number $-i\lambda$ — exactly the contraction structure anticipated in Eq. (10.193). At $O(\lambda^2)$ the same machinery, applied with two vertices z_1, z_2, produces the patterns in which

two external points attach to each vertex and the two vertices are joined by the two remaining legs: a single skeleton with a closed loop of two propagators between z_1 and z_2, occurring in the three external pairings (12)(34), (13)(24), (14)(23) — the s-, t-, and u-channel one-loop contributions to $\phi\phi \to \phi\phi$, together with the disconnected and self-contraction terms that the connected/amputated reductions and the normal-ordering convention remove.

We have thus discharged the chapter's first task. Every correlator in the Dyson series is now, by Theorem 15.3 and Theorem 15.5, a finite sum of products of propagators (from the full contractions) times normal-ordered remainders (which vanish in the vacuum amplitudes), each term a definite assignment of pairings among external points and vertex legs, weighted by how many such assignments are identical. Each such term is begging to be drawn: a propagator is a line, a vertex is a point where four lines meet carrying $-i\lambda$, an external field is a labelled endpoint, and the number of equivalent pairings is the term's multiplicity. Turning this contraction bookkeeping into pictures, and reading off from those pictures the position-space Feynman rules for ϕ^4 — including the all-important symmetry factors that the multiplicity counting produces — is the work of Section 15.2.

15.2 From Contractions to Pictures: Position-Space Feynman Rules

The previous section closed the operator side of the story. Wick's theorem (Theorem 15.3, and the path-integral form Theorem 10.23) turns the time-ordered product at the heart of every Dyson term into a finite, mechanical sum: a sum over all ways of pairing the fields, with each pair replaced by a Feynman propagator D_F. Order by order in the coupling, an interacting correlator is therefore nothing more than a (large) collection of products of propagators, each product weighted by a rational number that counts how many pairings produced it. What we do not yet have is a way to *organize* that collection so that we can see at a glance which products are the same, which are physically distinct, and how the bookkeeping factors assemble. The organizing device is a picture. To every product of propagators we will attach a graph—points joined by lines—in such a way that two products carry the same graph precisely when they are the same function of the external arguments. Counting then becomes a problem about graphs rather than about strings of field operators, and the answer to that counting problem is the set of *position-space Feynman rules*: a short dictionary that lets us write down any term of the expansion directly from its picture, never returning to the Wick sum at all. This section builds the dictionary, proves the clean factor it assigns to each diagram by explicit pairing counts, and draws the canonical diagrams of ϕ^4 theory.

15.2.1 The correlator as a sum of fully contracted products

We work throughout with the frozen ϕ^4 theory theory, $\mathcal{L} = \frac{1}{2}(\partial_\mu\phi)(\partial^\mu\phi) - \frac{1}{2}m^2\phi^2 - \frac{\lambda}{4!}\phi^4$ with $\lambda > 0$, in the mostly-minus metric $\eta_{\mu\nu} = \mathrm{diag}(+,-,-,-)$ and natural units $\hbar = c = 1$. The object of interest is the n-point time-ordered correlation function of the Heisenberg field in the interacting vacuum $|\Omega\rangle$,

$$G^{(n)}(x_1,\dots,x_n) \;=\; \langle\Omega|\,\mathcal{T}\,\phi(x_1)\cdots\phi(x_n)\,|\Omega\rangle\,. \tag{15.23}$$

The Gell-Mann–Low theorem of Chapter 14 (equivalently the path-integral master formula Eq. (10.186)) expresses Eq. (15.23) as a ratio of free-field vacuum expectation values, with the interaction exponentiated and all fields now the free interaction-picture fields ϕ_I of Theorem 14.2:

$$G^{(n)}(x_1,\dots,x_n) \;=\; \frac{\Big\langle 0\Big|\,\mathcal{T}\,\phi_I(x_1)\cdots\phi_I(x_n)\,\exp\Big[-\frac{i\lambda}{4!}\int \mathrm{d}^4z\,\phi_I(z)^4\Big]\Big|0\Big\rangle}{\Big\langle 0\Big|\,\mathcal{T}\,\exp\Big[-\frac{i\lambda}{4!}\int \mathrm{d}^4z\,\phi_I(z)^4\Big]\Big|0\Big\rangle}. \tag{15.24}$$

Here $|0\rangle$ is the free Fock vacuum of Theorem 9.17, and the single exponent has absorbed the time integral of the interaction Hamiltonian $H_I(t) = \int \mathrm{d}^3x\,\frac{\lambda}{4!}\phi_I^4$ of Eq. (14.11) into the covariant spacetime integral $\int \mathrm{d}^4z$. The relative sign and the factor $1/4!$ are exactly those of the action Eq. (10.80); the factor $-i$ is the one carried by each insertion of $-iH_I\,\mathrm{d}t$ in the Dyson series Eq. (14.25).

Expanding the numerator exponential in powers of λ gives a sum over the number V of interaction insertions (the number of *vertices*),

$$\text{numerator} = \sum_{V=0}^{\infty}\frac{1}{V!}\Big(-\frac{i\lambda}{4!}\Big)^V\int \mathrm{d}^4z_1\cdots\mathrm{d}^4z_V\;\Big\langle 0\Big|\,\mathcal{T}\,\phi_I(x_1)\cdots\phi_I(x_n)\,\phi_I(z_1)^4\cdots\phi_I(z_V)^4\,|0\Big\rangle\,. \tag{15.25}$$

The $1/V!$ is the coefficient of the exponential's Taylor series; it will be one of the two combinatorial factors we must track. Each spacetime integration variable z_a is integrated over all of Minkowski space, and the four fields $\phi_I(z_a)^4$ sitting at a common point z_a are the four *legs* of the a-th vertex.

Every term in Eq. (15.25) is a free-field vacuum expectation value of a time-ordered product of an even number of fields, $n + 4V$ of them. Wick's theorem (Theorem 15.3) rewrites such an object as the sum over *all complete pairings* of the fields into contractions, each contraction being a propagator,

$$\overbrace{\phi_I(a)\,\phi_I(b)} \;=\; D_F(a-b), \tag{15.26}$$

the same Feynman propagator established as the free two-point function in Theorem 9.24. The normal-ordered remainders that Wick's theorem also produces all have at least one uncontracted field, and a normal-ordered product with any

uncontracted field has vanishing vacuum expectation value, since $\langle 0|$ and $|0\rangle$ are annihilated by the creation and annihilation operators flanking the normal ordering. Only the *fully contracted* terms survive. We have therefore reduced Eq. (15.23) to a completely explicit prescription:

> *At order λ^V, list every way of pairing the $n{+}4V$ fields $\phi_I(x_1), \dots, \phi_I(x_n), \phi_I(z_1), \dots, \phi_I(z_V)$ completely into $\frac{1}{2}(n+4V)$ pairs. Each complete pairing contributes a product of $\frac{1}{2}(n+4V)$ propagators, one per pair, multiplied by the prefactor $\frac{1}{V!}(-i\lambda/4!)^V$ and integrated over $z_1, \dots, z_V$.*

This is a finite, mechanical sum at each order. What it is not, yet, is readable: at order λ^2 in the four-point function the number of complete pairings already runs into the thousands, the overwhelming majority of which produce the same handful of distinct functions. Organizing them is the work of the picture.

15.2.2 Reading a contraction as a graph

A complete pairing is a purely combinatorial datum: it says which field is contracted with which. We record it as a graph.

Definition 15.7 (Position-space Feynman diagram for ϕ^4)**.** Fix a correlator $G^{(n)}$ and an order V. A *Feynman diagram* consists of:

- *n external points* $x_1, \dots, x_n$, drawn as labelled endpoints, each the seat of exactly one field $\phi_I(x_i)$ and hence touched by exactly one line;
- *V vertices* $z_1, \dots, z_V$, drawn as dots, each the seat of four fields $\phi_I(z_a)^4$ and hence *four-valent*—touched by exactly four line-ends;
- *lines* (edges) joining the line-ends in pairs, one line per contraction.

A given complete pairing determines a diagram by drawing one line between the two endpoints of each contracted pair. Two pairings give the *same diagram* if there is a relabelling of the four legs at each vertex, together with a permutation of the vertices among themselves, carrying one pairing to the other. The *value* of a diagram is the product of propagators read off from its lines, integrated over the vertex positions.

The clause defining when two pairings give the same diagram deserves emphasis, because it is the seed of every combinatorial factor in the subject. The four fields $\phi_I(z_a)^4$ at a vertex are identical operators; nothing distinguishes the "first" factor from the "second." A pairing that contracts x_1 with the first factor of $\phi_I(z_1)^4$ and a pairing that contracts x_1 with the second factor are different pairings—different elements of the Wick sum—but they yield the *same propagator* $D_F(x_1 - z_1)$ and hence the same function. The diagram remembers only the

function. Likewise the labels $z_1, \dots, z_V$ on the vertices are dummy integration variables; permuting them relabels a pairing but, after the symmetric integration $\int \mathrm{d}^4 z_1 \cdots \mathrm{d}^4 z_V$, leaves the value untouched. A diagram is thus an equivalence class of pairings under these two relabellings, and the value of Eq. (15.25) is a sum over equivalence classes, each weighted by the number of pairings it contains.

The dictionary that assigns a value to a diagram now reads off directly from Eq. (15.25) and Eq. (15.26).

Definition 15.8 (Position-space Feynman dictionary)**.** For ϕ^4 theory, the elements of a diagram translate as follows.

Diagram element	**Analytic factor**
internal or external line from a to b	$D_F(a-b)$
four-valent vertex at z_a	$-i\lambda \int \mathrm{d}^4 z_a$
external point x_i	a fixed argument x_i of $G^{(n)}$ (not integrated)

The full value of the diagram is the product of all line factors and vertex factors, divided by a *symmetry factor* S defined below.

Two features of Theorem 15.8 must be justified before we may use it, because they are exactly where the combinatorics has been hidden. First, the vertex factor is quoted as $-i\lambda \int \mathrm{d}^4 z_a$, with a bare coupling and *no* $1/4!$, whereas the expansion Eq. (15.25) carries $(-i\lambda/4!)^V/V!$. Second, the rule instructs us to draw each distinct diagram only once and then divide by S, whereas the Wick sum contains one term per pairing. The reconciliation of these two statements—that the $1/4!$ per vertex and the $1/V!$ overall are consumed by the multiplicity of pairings collapsing onto each diagram, leaving only the small leftover $1/S$—is the central computation of this section, to which we now turn.

15.2.3 The combinatorial identity behind the rules

Consider a single diagram Γ at order λ^V in $G^{(n)}$, and ask how many distinct complete pairings of the $n + 4V$ fields fall into its equivalence class. Call that number N_Γ. The value contributed by Γ to the numerator Eq. (15.25) is then

$$\frac{1}{V!}\Big(-\frac{i\lambda}{4!}\Big)^V N_\Gamma \;\times\; \Big[\text{product of propagators of } \Gamma,\; \int \mathrm{d}^4 z_1 \cdots \mathrm{d}^4 z_V\Big], \tag{15.27}$$

since all N_Γ pairings give the identical propagator product. The content of the Feynman rules is the evaluation of N_Γ.

The relabellings that, by Theorem 15.7, leave a diagram fixed form a group: at each vertex we may apply any of the 4! permutations of its four legs, and we

may apply any of the $V!$ permutations of the vertices, giving an "automorphism candidate" group of order $(4!)^V\, V!$. Acting with an element of this group on one pairing of Γ produces a pairing in the same class. Generically these actions are all distinct, so that the orbit of any one pairing has the full size $(4!)^V\, V!$; then $N_\Gamma = (4!)^V\, V!$ exactly. The exceptions are relabellings that map a pairing back to *itself*—genuine automorphisms of the diagram, such as swapping the two ends of a self-loop, or exchanging two propagators that run between the same pair of vertices. These reduce the orbit. By the orbit–stabilizer theorem the orbit size is the group order divided by the order of the stabilizer, so

$$N_\Gamma \;=\; \frac{(4!)^V\, V!}{S(\Gamma)}, \qquad S(\Gamma) \;\equiv\; \big|\{\text{relabellings fixing a given pairing of } \Gamma\}\big|. \tag{15.28}$$

The integer $S(\Gamma)$ is the *symmetry factor* of the diagram. Substituting Eq. (15.28) into Eq. (15.27), the prefactor collapses spectacularly:

$$\frac{1}{V!}\Big(-\frac{i\lambda}{4!}\Big)^V \frac{(4!)^V\, V!}{S(\Gamma)} \;=\; \frac{(-i\lambda)^V}{S(\Gamma)}. \tag{15.29}$$

The $1/V!$ of the Dyson exponential cancels the $V!$ from permuting vertices; the $(1/4!)^V$ of the coupling normalization cancels the $(4!)^V$ from permuting legs; and what survives is the bare coupling $-i\lambda$ per vertex divided by the symmetry factor. This is precisely the content of Theorem 15.8, now derived rather than asserted, and it proves the position-space Feynman rules.

Theorem 15.9 (Position-space Feynman rules for ϕ^4)**.** *The n-point correlator Eq. (15.23) of ϕ^4 theory is computed, to order λ^V, by the following procedure.*

1. *Draw all topologically distinct diagrams (in the sense of Theorem 15.7) with the n external points $x_1, \dots, x_n$ and exactly V four-valent vertices, in which every external point is touched by one line and every vertex by four.*
2. *To each diagram assign: a factor $D_F(a-b)$ for each line joining a to b; a factor $-i\lambda \int \mathrm{d}^4 z_a$ for each vertex z_a, with the vertex positions integrated over all spacetime; and a single fixed argument for each external point.*
3. *Divide the resulting expression by the symmetry factor $S(\Gamma)$ of Eq. (15.28).*
4. *Sum over all such diagrams at the given order, and over all orders to the accuracy required.*

The denominator of Eq. (15.24) cancels every diagram containing a vacuum subdiagram *(a connected piece touching no external point), so that for a connected correlator only fully connected diagrams with no vacuum pieces contribute; this is the linked-cluster property, whose general combinatorial proof is the subject of a later section of this chapter (it was anticipated, at the two- and four-point level, in Theorem 10.37).*

The symmetry factor is, for the diagrams that matter most, equal to one or to a small power of two, and we will compute it from Eq. (15.28) in each case rather than quote it; the systematic enumeration of $S(\Gamma)$ for arbitrary topologies is the dedicated treatment promised by Theorem 15.9. We now exercise the rules on the three diagrams that carry ϕ^4 theory.

15.2.4 The four-point function at $O(\lambda)$: the tree vertex

The first interacting process of the thread is $\phi\phi \to \phi\phi$, whose amplitude we will eventually extract from the four-point correlator $G^{(4)}(x_1, x_2, x_3, x_4)$. At order λ^1 the numerator Eq. (15.25) is

$$\Big(-\frac{i\lambda}{4!}\Big)\int \mathrm{d}^4 z\, \big\langle 0|\, \mathcal{T}\, \phi_I(x_1)\phi_I(x_2)\phi_I(x_3)\phi_I(x_4)\, \phi_I(z)^4\, |0\big\rangle\,, \tag{15.30}$$

an eight-field vacuum expectation value to be expanded by Wick's theorem. We classify its complete pairings by which external points contract with the vertex.

Worked Example 15.10 (The $O(\lambda)$ four-point pairings, counted in full)**.** There are three topological types of complete pairing of the eight fields in Eq. (15.30), distinguished by how many of the four external points contract directly with a leg of the vertex z.

(a) All four externals reach the vertex (the connected tree). Contract x_1 with one of the four legs of $\phi_I(z)^4$: 4 choices. Contract x_2 with one of the remaining three legs: 3 choices. Then x_3 with one of the remaining two: 2; and x_4 with the last: 1. No fields remain. The number of such pairings is

$$N = 4 \cdot 3 \cdot 2 \cdot 1 = 4! = 24, \tag{15.31}$$

each giving the identical product $D_F(x_1 - z)D_F(x_2 - z)D_F(x_3 - z)D_F(x_4 - z)$. By Eq. (15.28) with $V = 1$ this is $N = (4!)^1\, 1!/S$, so $S = 1$: the tree diagram has no nontrivial automorphism. Multiplying by the prefactor $-i\lambda/4!$ and using Eq. (15.29),

$$G^{(4)}_{\text{tree}}(x_1, x_2, x_3, x_4) = -i\lambda \int \mathrm{d}^4 z\; D_F(x_1 - z)\, D_F(x_2 - z)\, D_F(x_3 - z)\, D_F(x_4 - z). \tag{15.32}$$

The four-factorial of pairings has cancelled the $1/4!$ of the vertex exactly, leaving the clean weight $-i\lambda$ promised by Theorem 15.8.

(b) Two externals pair with each other; the other two reach the vertex (disconnected, with a loop). Choose the external pair, say (x_1, x_2), contracted into $D_F(x_1 - x_2)$; contract x_3 and x_4 with two legs of z ($4 \cdot 3 = 12$ ways), leaving two legs of z that must contract with each other into the self-loop $D_F(z - z)$. The value is $D_F(x_1 - x_2) \times D_F(x_3 - z)D_F(x_4 - z)D_F(z - z)$, integrated over z. The graph splits into two pieces—a bare propagator line $x_1 - x_2$ and a loop-corrected

line joining x_3, x_4 through z—so it is *disconnected*: it describes one pair of points propagating freely while the other pair interacts, not a genuine $2 \to 2$ scattering.

(c) The externals pair among themselves; all four vertex legs self-contract (a vacuum bubble). For instance (x_1, x_2) and (x_3, x_4) paired, and the four fields at z contracted into two self-loops. The value is $D_F(x_1 - x_2)D_F(x_3 - x_4) \times$ [figure-eight at z]. The factor in brackets is a closed diagram touching no external point—a vacuum bubble.

The pieces of type (c) are removed exactly by the denominator of Eq. (15.24). Its order-λ term is $(-i\lambda/4!)\int \mathrm{d}^4 z\, \langle 0|\mathcal{T}\phi_I(z)^4|0\rangle = (-i\lambda/4!)\int \mathrm{d}^4 z\, 3\,[D_F(z-z)]^2$, the figure-eight vacuum diagram (its three pairings give $S = 8$ by Eq. (15.28), namely $3 = (4!)/8$), and when the ratio in Eq. (15.24) is expanded the vacuum factor multiplying the type-(c) numerator term is precisely subtracted. The pieces of type (b) are disconnected but not vacuum; they survive in $G^{(4)}$ and represent the non-scattering part of the correlator, which the LSZ amputation of Chapter 14 discards because it lacks the requisite poles in all four external momenta. The single piece that contributes to the connected scattering amplitude is the tree Eq. (15.32).

The connected tree diagram is drawn in Fig. 15.2. It is the diagrammatic heart of ϕ^4 theory: four external points, one vertex carrying the factor $-i\lambda$, and four propagators. Fourier transforming Eq. (15.32) and amputating the external legs—the operations of the next section—will collapse the four propagators and the $\int \mathrm{d}^4 z$ into a single momentum-conserving delta function times the constant amplitude, reproducing the value $\mathcal{M} = -\lambda$ already obtained by hand in Eq. (14.54). That the careful Wick count of Theorem 15.10 lands on exactly the same $-i\lambda$ is the first confirmation that the diagrammatic bookkeeping is faithful.

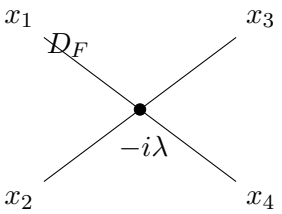

Figure 15.2: The $O(\lambda)$ connected four-point diagram of ϕ^4 theory: the single tree vertex. Each line is a propagator $D_F(x_i - z)$, the vertex (black dot) carries $-i\lambda \int \mathrm{d}^4 z$, and the four external points $x_1, \ldots, x_4$ are the fixed arguments of $G^{(4)}$. The symmetry factor is $S = 1$. This is the position-space seed of the $\phi\phi \to \phi\phi$ amplitude.

15.2.5 The two-point function at $O(\lambda)$: the tadpole

The first loop correction in the thread is the order-λ contribution to the propagator $G^{(2)}(x_1, x_2)$. Its numerator at this order is the six-field expectation value

$$\Big(-\frac{i\lambda}{4!}\Big)\int \mathrm{d}^4 z\, \big\langle 0|\, \mathcal{T}\, \phi_I(x_1)\phi_I(x_2)\, \phi_I(z)^4\, |0\big\rangle\,. \tag{15.33}$$

Worked Example 15.11 (The $O(\lambda)$ propagator correction, counted in full)**.** The connected pairings of Eq. (15.33) are those in which both x_1 and x_2 reach the vertex. Contract x_1 with one of the four legs of $\phi_I(z)^4$: 4 ways. Contract x_2 with one of the remaining three legs: 3 ways. Two legs of z now remain, and they have no choice but to contract with each other, forming the self-loop $D_F(z-z)$: 1 way. The connected count is therefore

$$N = 4 \cdot 3 \cdot 1 = 12. \tag{15.34}$$

By Eq. (15.28) with $V = 1$, $N = (4!)/S$ gives $S = 24/12 = 2$. The nontrivial automorphism is the exchange of the two ends of the self-loop: swapping them is a relabelling of the vertex legs that maps the pairing to itself, so it is counted by the stabilizer rather than the orbit, halving the multiplicity. Assembling the prefactor and value,

$$G^{(2)}_{\lambda}(x_1, x_2) = \frac{-i\lambda}{2}\int \mathrm{d}^4 z\, D_F(x_1 - z)\, D_F(z - z)\, D_F(z - x_2), \tag{15.35}$$

in which the explicit factor $\frac{1}{2}$ is the inverse symmetry factor $1/S$. The remaining pairings of Eq. (15.33)—those contracting x_1 directly with x_2 and self-contracting all four legs of z—produce $D_F(x_1-x_2)$ times a vacuum figure-eight, a disconnected vacuum piece removed by the denominator of Eq. (15.24) exactly as in part (c) of Theorem 15.10.

The surviving diagram Eq. (15.35) is the *tadpole*, drawn in Fig. 15.3: a single line from x_1 to x_2 interrupted by a vertex from which a closed loop $D_F(z-z)$ dangles. It is the first quantum correction to the propagation of a ϕ quantum, the loop encoding the field's interaction with a virtual fluctuation created and reabsorbed at the same vertex. The closed loop $D_F(z-z) = D_F(0)$ is ultraviolet divergent—the propagator at coincident points is a divergent momentum integral—and disposing of that divergence is the renormalization task of Chapter 22; here it suffices that the diagram, and its weight $-i\lambda/2$, are fixed unambiguously by the pairing count.

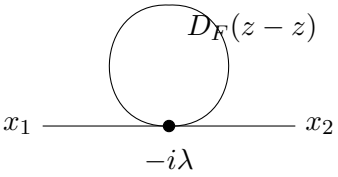

Figure 15.3: The $O(\lambda)$ correction to the propagator $G^{(2)}(x_1, x_2)$ of ϕ^4 theory: the tadpole. Two of the four vertex legs join the external points x_1, x_2; the other two close into the loop $D_F(z-z)$. The exchange of the two loop ends is a genuine automorphism, giving symmetry factor $S = 2$ and the weight $-i\lambda/2$ of Eq. (15.35).

15.2.6 The four-point function at $O(\lambda^2)$

The pattern of the rules is most clearly displayed at the first order where genuine loops connect distinct vertices. At $O(\lambda^2)$ the four-point numerator Eq. (15.25) is

$$\frac{1}{2!}\Big(-\frac{i\lambda}{4!}\Big)^2 \int \mathrm{d}^4 z_1\, \mathrm{d}^4 z_2 \;\Big\langle 0\big|\, \mathcal{T}\, \phi_I(x_1)\phi_I(x_2)\phi_I(x_3)\phi_I(x_4)\, \phi_I(z_1)^4\, \phi_I(z_2)^4\, \big|0\Big\rangle\,, \tag{15.36}$$

a twelve-field expectation value. We enumerate the topologically distinct *connected* diagrams—the ones that survive after the denominator removes vacuum pieces and after the disconnected products are set aside. With $V = 2$ vertices, four external legs, and every vertex four-valent, the connected topologies are:

- **The one-loop bubble (three channels).** Two external legs attach to z_1 and two to z_2, while the remaining two legs of each vertex join across, forming a loop of two internal propagators $D_F(z_1 - z_2)^2$. The three ways of splitting $\{x_1, x_2, x_3, x_4\}$ into the pair at z_1 and the pair at z_2 are the s-, t-, and u-channel diagrams: (12)(34), (13)(24), (14)(23). These are the corrections that, after renormalization, supply the one-loop running of the coupling in Chapters 22 and 24.

- **The leg-corrected tree.** The four external legs all attach to one vertex, say z_1, except that one of them runs first to z_2, which carries a tadpole self-loop, before continuing to z_1; equivalently, the $O(\lambda)$ tree of Fig. 15.2 with the tadpole of Fig. 15.3 inserted on one external line. There are also the diagram in which the second vertex's tadpole sits on the *internal* structure. These are propagator corrections riding on the tree and are reducible: cutting one internal line disconnects them.

- **The double tadpole.** The tree vertex z_1 with a tadpole loop, joined to a second vertex z_2 that itself carries a tadpole—higher in the same family of self-energy insertions.

The genuinely new, one-particle-irreducible loop is the bubble, and we count its symmetry factor explicitly; the leg-corrected and double-tadpole diagrams are built from the $S = 2$ tadpole already counted, by the same orbit–stabilizer argument applied vertex by vertex.

Worked Example 15.12 (The s-channel bubble, counted in full)**.** Take the bubble with x_1, x_2 at one vertex and x_3, x_4 at the other, the two vertices joined by two internal lines. We count the pairings in Eq. (15.36) producing this graph. First fix which named vertex, z_1 or z_2, carries x_1, x_2: there are 2 such assignments, and they are exchanged by the 2! vertex relabelling. For a fixed assignment, say $x_1, x_2 \to z_1$ and $x_3, x_4 \to z_2$:

- contract x_1 with a leg of z_1 (4) and x_2 with another leg of z_1 (3): $4 \cdot 3 = 12$ ways, leaving two legs of z_1;
- contract x_3 with a leg of z_2 (4) and x_4 with another (3): $4 \cdot 3 = 12$ ways, leaving two legs of z_2;
- contract the two remaining legs of z_1 with the two remaining legs of z_2: the first leg of z_1 has 2 partners, the second has 1, giving $2! = 2$ ways (the two internal propagators $D_F(z_1 - z_2)^2$).

For the fixed assignment this is $12 \cdot 12 \cdot 2 = 288$ pairings, and including the 2 vertex assignments,

$$N = 2 \cdot 288 = 576 = (4!)^2 \cdot 2! \,/\, 2. \tag{15.37}$$

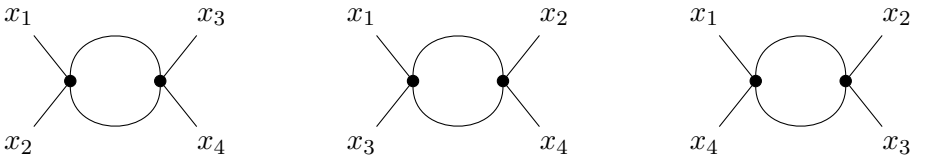
By Eq. (15.28) with $V = 2$, $N = (4!)^2\, 2!/S$ gives $S = 2$. The single nontrivial automorphism is the exchange of the two internal lines running between z_1 and z_2: swapping them is a leg relabelling that fixes the pairing, and it is exactly the factor $2! = 2$ that appeared in the last bullet but is undone by the stabilizer. Assembling Eq. (15.29),

$$G^{(4)}_{s\text{-loop}} = \frac{(-i\lambda)^2}{2} \int \mathrm{d}^4 z_1\, \mathrm{d}^4 z_2\; D_F(x_1 - z_1) D_F(x_2 - z_1) \left[D_F(z_1 - z_2)\right]^2 D_F(x_3 - z_2) D_F(x_4 - z_2), \tag{15.38}$$

The $1/2!$ of the Dyson exponential has cancelled the two vertex assignments, the $(1/4!)^2$ has cancelled the leg permutations, and the leftover $1/S = 1/2$ is the inverse symmetry factor of the doubled internal line. The t- and u-channel bubbles are identical with (x_1, x_2, x_3, x_4) permuted to (x_1, x_3, x_2, x_4) and (x_1, x_4, x_2, x_3), each again with $S = 2$.

The three bubble channels are drawn together in Fig. 15.4. They are the position-space content of the one-loop $2 \to 2$ amplitude; Fourier transforming Eq. (15.38) will convert the convolution of propagators into the familiar loop integral $\int \mathrm{d}^4 k \,/[(k^2 - m^2)((k + p)^2 - m^2)]$ over the bubble, with the external

Mandelstam variable determined by which channel is drawn. That this same factor $\frac{1}{2}$ emerges identically from the orbit–stabilizer count Eq. (15.37) and from the naive "two identical internal lines" rule of thumb is the consistency one should expect, and it illustrates how the dedicated symmetry-factor section will recover the rules of thumb as corollaries of Eq. (15.28).



s-channel: (12)(34) t-channel: (13)(24) u-channel: (14)(23)

Figure 15.4: The three $O(\lambda^2)$ one-loop bubble diagrams of the four-point function, one per pairing of the external legs across the two vertices. Each carries two vertices ($(-i\lambda)^2$), two internal propagators forming the loop $D_F(z_1 - z_2)^2$, four external propagators, and symmetry factor $S = 2$ from the exchange of the two internal lines, as counted in Theorem 15.12.

With these three computations the dictionary of Theorem 15.9 has been validated on every diagram ϕ^4 theory needs in this part: the tree vertex of $\phi\phi \to \phi\phi$, the one-loop tadpole correction to the propagator, and the one-loop bubbles of the four-point function, each with its symmetry factor derived from the pairing count rather than asserted. Every diagram value is an integral over vertex positions of a product of position-space propagators—a convolution. Convolutions are diagonalized by the Fourier transform, and that is the route the next section takes: passing to momentum space turns each $\int \mathrm{d}^4 z$ into a momentum-conserving delta function at the vertex, collapses the external-leg propagators under LSZ amputation, and replaces every loop by an integral over an undetermined internal momentum, delivering the momentum-space Feynman rules and, with them, the carried tree amplitude $-i\lambda$ in its final algebraic form.

15.3 Momentum Space, Amputation, and the Tree Amplitude

The position-space rules assembled in Section 15.2 are exact and complete, but they are not yet in a form one would ever use to extract a number. Each diagram is an integral over the spacetime locations of its interaction vertices, and at each such location sits a product of Feynman propagators tied together by the geometry of the graph. A propagator $D_F(x - y)$ depends only on the *difference* of its endpoints, so the integral over a vertex position is a convolution; and the one fact about convolutions that every reader carries from undergraduate Fourier analysis is that they become ordinary products under the Fourier transform. The

whole of this section is the systematic exploitation of that fact. We will write every internal propagator as its Fourier integral, carry out the vertex-position integrals once and for all, and watch the convolutions collapse into algebra: a fixed factor per line, a fixed factor per vertex, a delta-function enforcing conservation of four-momentum at each vertex, and a leftover integral over the momentum circulating in each independent loop. The output is the momentum-space Feynman rule set — the form in which the rules are actually quoted and used.

Having the rules in momentum space is not yet having a cross section. The diagrams compute time-ordered correlation functions of fields, whereas experiments measure S-matrix elements between asymptotic particle states. The bridge between the two was built in Chapter 14: the LSZ reduction formula (Theorem 14.31) expresses a scattering amplitude as the on-shell residue of the correlator's external legs, and the invariant amplitude $\mathcal{M}$ (Eq. (14.46)) is what survives after the external-leg propagators are stripped away. Translated into the diagrammatic language we now have, LSZ is a remarkably clean instruction: *amputate* the external legs and put them on the mass shell. This section makes that instruction precise, defines the connected amputated Green's function it acts on, and then carries out the entire program on the simplest possible case — the four-point function of ϕ^4 theory at order λ. The reward is the carried number of Chapter 14, reproduced now by pure diagrammatics: the tree-level amplitude for $\phi\phi \to \phi\phi$ is $i\mathcal{M} = -i\lambda$, a constant, with the dependence on the scattering kinematics deferred to the loop level and handed to Chapter 16.

Throughout we keep the standing conventions of ϕ^4 theory: a single real scalar of mass m and quartic coupling $\lambda > 0$, the mostly-minus metric $\eta_{\mu\nu} = \mathrm{diag}(+,-,-,-)$, natural units, and the Fourier convention in which every $\int d^4p$ carries a $(2\pi)^{-4}$ while every delta-function produced by an x-integration carries a $(2\pi)^4$.

15.3.1 The propagator in momentum space, and why a diagram is a convolution

Every internal line of a ϕ^4 diagram is a Feynman propagator $D_F(x-y) = \langle 0|\mathcal{T}\,\phi(x)\phi(y)|0\rangle$, the free two-point function established for ϕ^4 theory in Chapter 9 and characterized analytically as a tempered distribution in Chapter 5. Its defining property for present purposes is its momentum-space representation,

$$D_F(x-y) = \int \frac{d^4p}{(2\pi)^4}\,\frac{i}{p^2 - m^2 + i\varepsilon}\,e^{-ip\cdot(x-y)}, \tag{15.39}$$

in which the $i\varepsilon$ prescription (Eq. (5.61), Theorem 5.22) is what selects the time-ordered Green's function out of the family of solutions of $(\Box + m^2)D_F = -i\,\delta^{(4)}$: the pole at $p^0 = +\sqrt{\mathbf{p}^2 + m^2} - i\varepsilon'$ is routed below the real axis and the one at $p^0 = -\sqrt{\mathbf{p}^2 + m^2} + i\varepsilon'$ above it, so that closing the p^0 contour for $x^0 > y^0$ picks

up the positive-frequency part and for $x^0 < y^0$ the negative-frequency part. We will not re-derive Eq. (15.39); we take it as the input to the transform.

The integrand of Eq. (15.39) is the object we will trade everywhere for the propagator:

$$\widetilde{D_F}(p) \;\equiv\; \frac{i}{p^2 - m^2 + i\varepsilon}, \tag{15.40}$$

the *momentum-space propagator*. The notation records the content of the convolution theorem: Eq. (15.39) says that D_F is the inverse Fourier transform of $\widetilde{D_F}$.

To see why a diagram becomes a product, consider the structure of *any* ϕ^4 diagram in position space. It is built from

- a set of *external points* $x_1, \ldots, x_n$, the fixed arguments of the correlator, held at definite spacetime locations;
- a set of *internal vertices* $z_1, \ldots, z_V$, each carried by an integral $-i\lambda \int d^4 z_a$ (Section 15.2);
- a set of *lines*, each a factor D_F joining two of these points, every line connecting either two vertices (an *internal* line) or a vertex to an external point (an *external* line).

The entire z_a-dependence of the integrand lives inside the propagators that touch z_a, and it enters only through the exponentials $e^{\mp ip\cdot z_a}$ of their Fourier representations. The vertex integrals $\int d^4 z_a$ therefore act *only* on products of exponentials. That is the whole mechanism: each $\int d^4 z_a$ over a vertex linear in z_a in the exponent produces a Dirac delta-function, and that delta-function is conservation of four-momentum at the vertex. We now make this exact.

15.3.2 Vertex integration generates momentum conservation

Pick one internal vertex, at position z, and let the four lines meeting there carry momenta q_1, q_2, q_3, q_4. We adopt a uniform routing convention: *every momentum is oriented to flow into the vertex.* Concretely, for a line running between z and another point w (a different vertex or an external point) we write its propagator using Eq. (15.39) with the difference taken so that the z-dependence is $e^{+iq\cdot z}$,

$$D_F(w - z) = \int \frac{d^4 q}{(2\pi)^4}\, \widetilde{D_F}(q)\, e^{-iq\cdot(w-z)} = \int \frac{d^4 q}{(2\pi)^4}\, \widetilde{D_F}(q)\, e^{-iq\cdot w}\, e^{+iq\cdot z}, \tag{15.41}$$

which defines q as the momentum flowing from w *into* z. (The propagator is even, $D_F(w-z) = D_F(z-w)$, so this is merely a choice of sign for the dummy variable; reversing the orientation sends $q \to -q$, which the even integrand absorbs.) With

every one of the four lines written this way, the vertex factor and its position integral act on the product of the four exponentials,

$$-i\lambda \int d^4z\; e^{+i(q_1+q_2+q_3+q_4)\cdot z} \;=\; -i\lambda\,(2\pi)^4\,\delta^{(4)}(q_1+q_2+q_3+q_4), \tag{15.42}$$

where we used the fundamental Fourier identity $\int d^4z\, e^{ik\cdot z} = (2\pi)^4\,\delta^{(4)}(k)$. The remaining factors $e^{-iq\cdot w}$ from Eq. (15.41) are not yet integrated; they belong to the other endpoint w of each line and will be processed when we treat that endpoint. Equation Eq. (15.42) is the central result of the transform: *the position integral over an interaction vertex converts the convolution into a product, and produces a delta-function enforcing that the total momentum flowing into the vertex vanishes,*

$$q_1 + q_2 + q_3 + q_4 = 0. \tag{15.43}$$

This is conservation of four-momentum at the vertex, derived rather than assumed. It is the diagrammatic shadow of spacetime translation invariance: the interaction $\phi^4(z)$ does not know where z is, so integrating over all z enforces that no net momentum is injected at the interaction point.

The same computation runs identically at every vertex. An external point x_i is treated differently — it is *not* integrated, because it is a fixed argument of the correlator; instead its single attached propagator carries the factor $e^{-iq_i\cdot x_i}$, which is exactly the kernel that the LSZ reduction will act on to put x_i on shell. For an internal line joining two vertices z_a and z_b, both endpoints are integrated: the line contributes $\widetilde{D_F}(q)$ and an integral $\int d^4q/(2\pi)^4$, and the same momentum q appears (with opposite sign) in the conservation delta-functions of z_a and z_b. We may now read off the complete dictionary.

Definition 15.13 (Momentum-space Feynman rules for ϕ^4)**.** The momentum-space contribution of a ϕ^4 Feynman diagram contributing to an n-point correlation function is assembled as follows. Assign a four-momentum to every line, oriented; impose conservation at each vertex.

1. **Internal line** of momentum q: a factor
$$\widetilde{D_F}(q) = \frac{i}{q^2 - m^2 + i\varepsilon}. \tag{15.44}$$
2. **Vertex**: a factor
$$-i\lambda\,(2\pi)^4\,\delta^{(4)}\Big(\textstyle\sum_{\text{in}} q\Big), \tag{15.45}$$
the delta-function enforcing that the momenta flowing into the vertex sum to zero.
3. **Loop integration**: a factor
$$\int \frac{d^4k}{(2\pi)^4} \tag{15.46}$$

for each independent loop momentum left undetermined by the vertex delta-functions (the counting is fixed in Section 15.3.3); the measure follows the convention of Section D.1.

4. **External legs**: each external point x_i contributes its propagator $\widetilde{D_F}(p_i)$ and the Fourier kernel that will be amputated by LSZ (Section 15.3.4).

5. **Symmetry factor**: divide by the order of the diagram's automorphism group, the symmetry factor S (computed systematically in the next section).

After performing all loop integrations, the result for a diagram with external momenta $p_1, \dots, p_n$ (all incoming) carries an overall factor $(2\pi)^4\,\delta^{(4)}(p_1+\cdots+p_n)$ expressing global four-momentum conservation.

Remark 15.14 (Where the (2π)'s live). The bookkeeping of 2π factors is automatic and worth stating once so it is never recomputed. Each internal line brings one $\int d^4q/(2\pi)^4$; each vertex brings one $(2\pi)^4\delta^{(4)}$. With I internal lines and V vertices there are I factors of $(2\pi)^{-4}$ and V factors of $(2\pi)^{+4}$ before any delta-function is used. Using the delta-functions to do I of the momentum integrals (see below) consumes I of the δ's and their $(2\pi)^4$'s against the I measure factors, and the surviving counting leaves exactly one overall $(2\pi)^4\delta^{(4)}$ for global conservation and one $\int d^4k/(2\pi)^4$ per loop. No 2π ever needs to be tracked by hand: the rules as stated balance.

The momentum-space propagator Eq. (15.44) is a genuine simplification over its position-space ancestor: it is an elementary rational function with a pole on the mass shell, whereas $D_F(x-y)$ is a Hankel/Bessel distribution. The price — and it is the price paid in every loop calculation in this book — is the loop integral Eq. (15.46), the residue of the convolution that the delta-functions could not fully resolve. We now count exactly how many such integrals a diagram carries.

15.3.3 Counting the loop integrations: $L = I - V + 1$

Before any momenta are integrated, a diagram with I internal lines assigns one four-momentum to each, hence I four-dimensional integration variables $\int d^4q_j/(2\pi)^4$. The V vertices impose V conservation delta-functions Eq. (15.45). The question is how many of the I integrals these delta-functions allow us to perform, and how many survive as genuine loop integrals.

The key structural fact is that the V delta-functions are *not all independent* when the external momenta are themselves held fixed. Add the arguments of all V vertex delta-functions. Every *internal* line touches exactly two vertices, and by the uniform routing of Eq. (15.41) it enters the conservation condition of one with $+q$ and of the other with $-q$ (the momentum flows *into* one vertex and *out of* — i.e. with reversed sign into — the other). Hence every internal

momentum cancels in the sum, and what remains is the sum of the *external* momenta entering the diagram. The product of the V vertex delta-functions therefore contains, as the image of their sum, the single global factor

$$\prod_{a=1}^{V} \delta^{(4)}\Big(\textstyle\sum_{\text{in at } a} q\Big) \;=\; \delta^{(4)}\Big(\textstyle\sum_i p_i\Big) \times [V-1 \text{ independent constraints on internal momenta}]. \tag{15.47}$$

One linear combination of the V delta-functions is fixed entirely by external data — it is global four-momentum conservation, the overall factor promised in Theorem 15.13 — and is therefore *not* available to eliminate an internal integration variable. That leaves precisely $V-1$ delta-functions that genuinely constrain the internal momenta, each of which can be used to do one of the I internal integrals. The number of integrals that remain undetermined — the number of *independent loop momenta* — is therefore

$$\boxed{L \;=\; I-(V-1) \;=\; I-V+1.} \tag{15.48}$$

This is the loop-counting formula. It is identical in content to Euler's relation for a connected graph, (faces) = (edges) − (vertices) + 1, and indeed L is exactly the first Betti number of the diagram regarded as a one-dimensional cell complex — the number of independent cycles, the number of ways to draw a closed loop on the graph. We rederived it here from the analytic content of the delta-functions because that derivation is what tells us, line by line, which integrals survive and why each surviving one is genuinely four-dimensional and unconstrained.

Remark 15.15 (Connectedness is assumed). The relation Eq. (15.48) as stated is the loop number of a *connected* diagram. A disconnected diagram with C connected components has $L = I - V + C$, because each component supplies its own undeducible global conservation delta-function. The amplitudes we extract are built from connected, indeed connected and amputated, diagrams (Section 15.3.4), so $C = 1$ throughout, and Eq. (15.48) is the form we use.

The formula has an immediate and important corollary: a diagram with $L = 0$ has no loop integrals at all. Its value is a finite product of momentum-space propagators and vertex factors, completely fixed by the external momenta through the delta-functions, with nothing left to integrate. These are the *tree diagrams*, and they are where perturbation theory delivers its first, exact, finite numbers. Setting $L = 0$ in Eq. (15.48) gives $I = V - 1$: a connected tree on V vertices has exactly $V-1$ internal lines, the defining count of a tree in graph theory. The four-point function of ϕ^4 theory at order λ has $V = 1$ and $I = 0$, hence $L = 0$; it is the simplest tree there is, and it is the one we now reduce to an amplitude.

Worked Example 15.16 (Loop count of the one-loop ϕ^4 four-point diagram)**.** To see the formula bite where it matters, count the loops of the order-λ^2 contribution

to $\phi\phi \to \phi\phi$ shown in Fig. 15.5: two quartic vertices joined by two internal lines, with two external legs attached at each vertex. Here $V = 2$ and the internal lines number $I = 2$ (the two lines of the central bubble; the four external legs are amputated and do not count). The formula gives

$$L = I - V + 1 = 2 - 2 + 1 = 1, \tag{15.49}$$

one loop, as the picture's single closed cycle demands. Tracking it explicitly: assign incoming external momenta p_1, p_2 to the left vertex and outgoing p_3, p_4 to the right, and let the two internal lines carry momenta k and k'. The left vertex delta-function gives $p_1 + p_2 - k - k' = 0$ and the right gives $k + k' - p_3 - p_4 = 0$. Adding them yields $p_1 + p_2 - p_3 - p_4 = 0$ — global conservation, the combination fixed by external data. Subtracting, $p_1 + p_2 = k + k'$ is the one independent constraint, which we solve as $k' = p_1 + p_2 - k$. One of the two internal integrals $\int d^4k\, d^4k'$ is thereby done against the constraint delta-function, leaving the single loop integral

$$\int \frac{d^4k}{(2\pi)^4}\, \frac{i}{k^2 - m^2 + i\varepsilon}\, \frac{i}{(p_1 + p_2 - k)^2 - m^2 + i\varepsilon}, \tag{15.50}$$

one unconstrained four-momentum circulating in the loop — exactly $L = 1$. (This integral is logarithmically divergent and is the seed of the ϕ^4 renormalization carried in Chapters 21 and 22; here it serves only to confirm the counting.)

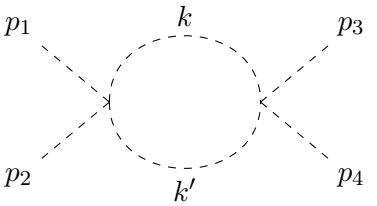


Figure 15.5: The order-λ^2 (s-channel) one-loop contribution to $\phi\phi \to \phi\phi$ in ϕ^4 theory. Two quartic vertices ($V = 2$) are joined by two internal lines ($I = 2$); the four external legs are amputated. The loop-counting formula Eq. (15.48) gives $L = I - V + 1 = 1$, the single closed cycle visible in the diagram, with loop momentum k and $k' = p_1 + p_2 - k$ fixed by conservation as in Theorem 15.16. This diagram is not evaluated here; it is the object Chapters 16 and 21 take up.

15.3.4 Connected, amputated Green's functions and the LSZ amputation

The Feynman rules compute the time-ordered correlation function $G^{(n)}(x_1, \ldots, x_n) = \langle 0|\mathcal{T}\, \phi(x_1) \cdots \phi(x_n)|0\rangle$, or its Fourier transform. To pass to scattering we must

restrict to the part of $G^{(n)}$ that is relevant to S-matrix elements and strip the kinematic factors that LSZ identifies as non-amplitude. Two reductions are involved, and it is worth naming each precisely.

The first is *connectedness*. A correlation function factorizes into products of lower-point functions whenever its diagram is disconnected; such contributions describe spectator subprocesses, not the genuine n-body scattering, and the LSZ formula projects them out. We therefore work with the connected correlator $G_c^{(n)}$, the sum of connected diagrams only. For the four-point function this means discarding the term in which $\phi\phi$ pairs into two independent propagators (two particles passing without interacting) and keeping only the diagrams in which all four external points communicate through a single connected graph.

The second is *amputation*. Fourier-transforming the connected n-point function and using overall momentum conservation, write

$$\int \Big(\prod_{i=1}^{n} d^4x_i \, e^{ip_i\cdot x_i} \Big) \, G_c^{(n)}(x_1,\dots,x_n) \;=\; (2\pi)^4 \delta^{(4)}\Big(\textstyle\sum_i p_i \Big) \, \widetilde{G}_c^{(n)}(p_1,\dots,p_n), \tag{15.51}$$

with all p_i incoming. Each external point x_i sits at the end of exactly one line, and that line, summed to all orders, is the *full* (interacting) propagator $G_{\text{full}}(p_i)$ on that leg — the free propagator $\widetilde{D_F}(p_i)$ dressed by all self-energy insertions. Because $G_{\text{full}}(p)$ has a pole at the physical mass $p^2 = m^2$ with residue iZ (the field-strength renormalization Z of Chapter 14), the external legs carry exactly the singular on-shell behaviour that LSZ is built to extract. The *amputated* function removes these external full propagators outright.

Definition 15.17 (Connected amputated Green's function)**.** The connected amputated n-point function $\widetilde{G}^{(n)}_{\text{amp}}$ is defined by dividing the connected momentum-space correlator $\widetilde{G}_c^{(n)}$ by the full propagator on each external leg,

$$\widetilde{G}_c^{(n)}(p_1,\dots,p_n) \;=\; \Big[\prod_{i=1}^{n} G_{\text{full}}(p_i) \Big] \, \widetilde{G}^{(n)}_{\text{amp}}(p_1,\dots,p_n). \tag{15.52}$$

Diagrammatically, $\widetilde{G}^{(n)}_{\text{amp}}$ is the sum of connected diagrams from which the external-leg propagators have been deleted ("amputated"), leaving the legs as stubs that mark where the on-shell momenta enter.

The role of amputation is exactly to undo a double-counting. The full external propagator $G_{\text{full}}(p_i)$ describes the free flight of the asymptotic particle from infinity to the interaction region; that flight is not part of the interaction and must not be included in the amplitude, on pain of producing the very pole at $p_i^2 = m^2$ that signals an external line going on shell. LSZ multiplies $\widetilde{G}_c^{(n)}$ by the inverse propagator $G_{\text{full}}(p_i)^{-1}$ on each leg and then takes $p_i^2 \to m^2$; the inverse propagator vanishes on shell as $G_{\text{full}}(p)^{-1} \to (p^2 - m^2)/(iZ)$, precisely cancelling

the leg pole and leaving a finite residue. The statement of Theorem 14.31, read through Theorem 15.17, is therefore the following clean instruction.

Theorem 15.18 (LSZ as amputation, on-shell)**.** *Let $\widetilde{G}^{(n)}_{amp}$ be the connected amputated n-point function of Theorem 15.17, and let $\mathcal{M}$ be the invariant amplitude of Eq. (14.46) for the process in which the p_i with i in the "in" set are incoming and the remainder are outgoing. Then*

$$i\mathcal{M}(p_1,\dots,p_n) \;=\; \Big(\prod_{i=1}^{n}\sqrt{Z}\Big)\,\widetilde{G}^{(n)}_{amp}(p_1,\dots,p_n)\Big|_{p_i^2=m^2}, \tag{15.53}$$

the external momenta put on the mass shell, where Z is the field-strength renormalization. At tree level $Z = 1 + O(\lambda)$, so to the order at which a diagram first contributes the factor $\sqrt{Z}$ is unity and $i\mathcal{M}$ equals the amputated diagram evaluated on shell.

This is the operational endpoint of the whole rule set. We do not re-prove it — the proof, with its careful treatment of the spectral decomposition, the one-particle pole, and the asymptotic-field limit, is the business of Chapter 14 and is imported here by Theorem 14.31. What Theorem 15.18 adds is the dictionary entry that connects that theorem to the diagrams: *compute the connected diagrams, delete the external propagators, put the legs on shell, and the result is $i\mathcal{M}$.* Everything in Theorem 15.13 now carries an explicit numerical weight, and the rules deliver amplitudes directly.

15.3.5 The carried number: $\phi\phi \to \phi\phi$ at tree level

We now reproduce, by pure diagrammatics, the amplitude that Chapter 14 obtained by hand from the Dyson series and LSZ. This is the layer ϕ^4 theory adds in this chapter: *the first amplitude in momentum space.*

Worked Example 15.19 (Tree-level $\phi\phi \to \phi\phi$ and the carried $-i\lambda$)**. The diagram.** At order λ the connected four-point function has a single topology: one quartic vertex with all four external points attached to it (Fig. 15.6). There are no internal lines, so $I = 0$, $V = 1$, and Eq. (15.48) gives $L = 0$ — a tree, with nothing to integrate.

Position to momentum. In position space the connected diagram is

$$G^{(4)}_c(x_1,x_2,x_3,x_4)\big|_{O(\lambda)} = -i\lambda\int d^4z\,\prod_{i=1}^{4} D_F(x_i - z), \tag{15.54}$$

the vertex factor $-i\lambda\int d^4z$ of Section 15.2 times the four propagators joining the external points to the vertex. The combinatorial factor here is 1: the symmetry factor of this diagram is unity (the 4! ways of attaching the four

distinct external lines to the four fields of $\phi^4(z)$ exactly cancel the $1/4!$ in the coupling), a statement we take from the position-space accounting and which the next section establishes systematically. Inserting the Fourier representation Eq. (15.41) for each propagator, with momentum p_i defined to flow from x_i into the vertex,

$$G_c^{(4)}\big|_{O(\lambda)} = -i\lambda \int \Big(\prod_{i=1}^{4} \frac{d^4p_i}{(2\pi)^4}\, \widetilde{D_F}(p_i)\, e^{-ip_i\cdot x_i} \Big) \int d^4z\; e^{+i(p_1+p_2+p_3+p_4)\cdot z}. \quad (15.55)$$

The vertex integral is exactly Eq. (15.42),

$$\int d^4z\; e^{+i(p_1+p_2+p_3+p_4)\cdot z} = (2\pi)^4\, \delta^{(4)}(p_1+p_2+p_3+p_4), \quad (15.56)$$

so that, reading off the momentum-space correlator through the definition Eq. (15.51) (which strips the external Fourier kernels and one overall $(2\pi)^4\delta^{(4)}$),

$$\widetilde{G}_c^{(4)}(p_1,p_2,p_3,p_4)\big|_{O(\lambda)} = (-i\lambda) \prod_{i=1}^{4} \widetilde{D_F}(p_i) = (-i\lambda) \prod_{i=1}^{4} \frac{i}{p_i^2 - m^2 + i\varepsilon}. \quad (15.57)$$

Every factor of 2π has cancelled as advertised in Theorem 15.14: the four measure factors $(2\pi)^{-4}$ are removed when the external kernels are stripped, and the single $(2\pi)^4\delta^{(4)}$ is the global conservation factor pulled out in Eq. (15.51).

Amputation. The four factors $\widetilde{D_F}(p_i)$ in Eq. (15.57) are precisely the external-leg propagators: at this order the full propagator equals the free one, $G_{\text{full}}(p_i) = \widetilde{D_F}(p_i) + O(\lambda)$. Dividing them out per Eq. (15.52) amputates the legs and leaves

$$\widetilde{G}^{(4)}_{\text{amp}}(p_1,p_2,p_3,p_4)\big|_{O(\lambda)} = -i\lambda, \quad (15.58)$$

a pure constant — no propagators, no integrals, no kinematic dependence whatsoever.

On shell. With $Z = 1 + O(\lambda)$ the prefactor $\prod_i \sqrt{Z} = 1$ at this order, and the amputated function Eq. (15.58) is already constant, so putting the legs on shell $p_i^2 = m^2$ changes nothing. Theorem Theorem 15.18 then delivers the invariant amplitude,

$$\boxed{i\mathcal{M}(\phi\phi \to \phi\phi) = -i\lambda} \qquad \Longleftrightarrow \qquad \mathcal{M} = -\lambda, \quad (15.59)$$

the carried number of ϕ^4 theory, reproduced exactly — and by a completely independent route — from the value computed by hand from the Dyson expansion in Chapter 14. The two computations agree, which is the internal consistency check the chapter was built to deliver: the operator/LSZ route of Chapter 14 and the diagrammatic route of Theorem 15.13 give the same amplitude.

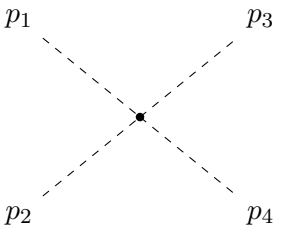

Figure 15.6: The tree-level diagram for $\phi\phi \to \phi\phi$ in ϕ^4 theory: a single quartic vertex ($V = 1$, $I = 0$, $L = 0$) with the four external momenta entering. Amputating the external legs and putting them on shell yields the invariant amplitude $i\mathcal{M} = -i\lambda$ of Eq. (15.59), independent of the scattering kinematics at this order.

Physical Insight: why the tree amplitude is a constant, and what breaks it

The amplitude Eq. (15.59) is independent of how the particles are aimed: it does not depend on the centre-of-mass energy, the scattering angle, or any other kinematic invariant. The physical reason is that the ϕ^4 interaction is a *contact* interaction — all four legs meet at a single point, with no internal line carrying momentum between separated vertices, hence no propagator to inject a q-dependent denominator. Compare a theory with a cubic coupling ϕ^3, where $\phi\phi \to \phi\phi$ proceeds at tree level by exchanging a virtual scalar between two vertices: there the internal propagator $i/(q^2 - m^2)$ does depend on the exchanged momentum, and the amplitude acquires its characteristic pole structure in the kinematic invariants. In ϕ^4 that structure is absent at tree level and first appears at one loop, through the bubble integral Eq. (15.50) of Theorem 15.16, whose value is a nontrivial function of the momentum flowing through it.

It is useful to record the kinematic variables in which that future dependence will be expressed, since they are introduced and exploited in Chapter 16. For $2 \to 2$ scattering with incoming momenta p_1, p_2 and outgoing p_3, p_4 (so the all-incoming convention has p_3, p_4 entering as $-p_3, -p_4$), the Mandelstam invariants are

$$s = (p_1 + p_2)^2, \qquad t = (p_1 - p_3)^2, \qquad u = (p_1 - p_4)^2, \tag{15.60}$$

satisfying $s + t + u = \sum_i m_i^2 = 4m^2$ on shell. The tree amplitude Eq. (15.59) is independent of all three — it is the same $-\lambda$ in every channel — which is exactly why no Mandelstam variable appears in it. At one loop the three diagrams obtained by routing the external pairs through the bubble in the s-, t-, and u-channels produce a sum of functions of s, t, and u respectively, and the full kinematic dependence of $\phi\phi \to \phi\phi$ comes alive. That computation, and the conversion of $\mathcal{M}$ into a cross section through the phase-space measure, are the

work of Chapter 16; the present section's contribution to ϕ^4 theory is the tree result Eq. (15.59) and the rules that produced it.

With the momentum-space rules in hand and the LSZ bridge crossed, every element of a ϕ^4 amplitude now carries an explicit numerical weight — a propagator $i/(q^2 - m^2 + i\varepsilon)$ per line, a $-i\lambda$ per vertex, a $\int d^4k/(2\pi)^4$ per loop — with one ingredient still quoted rather than derived: the symmetry factor $1/S$ that multiplied the tree diagram by unity in Eq. (15.54) and will not always be so kind. The combinatorial origin of that factor, the precise fate of the $1/V!$ from the Dyson exponential and the $1/4!$ at each vertex, and a worked catalogue of representative diagrams are the subject of the next section.

15.4 Symmetry Factors Done Carefully

The momentum-space rules of Section 15.3 assign to every diagram a propagator for each internal line, a factor $-i\lambda$ for each vertex, a momentum-conserving delta at each vertex, and a loop integral $\int \mathrm{d}^4k/(2\pi)^4$ for each independent loop. They leave one thing undetermined: a single rational prefactor, the *symmetry factor*, that multiplies the whole amplitude. For the tree-level $\phi\phi \to \phi\phi$ diagram of Section 15.3 that prefactor was 1 and we could afford not to dwell on it; for almost every loop diagram it is not 1, and getting it wrong is the single most common error in scalar perturbation theory. This section pins the prefactor down once and for all. The claim, which we will prove and then verify on a catalogue of diagrams, is sharp and structural: *the symmetry factor of a diagram is the reciprocal of the order of its automorphism group.* Everything reduces to counting automorphisms of a graph, and once the graph is drawn the counting is mechanical.

15.4.1 Where the combinatorial factors come from

The prefactor has a precise origin in the Dyson expansion, and we can see exactly what it must cancel. Recall from the position-space derivation (Section 15.2) that the n-point Green's function of ϕ^4 theory is the vacuum expectation value of a time-ordered product, expanded in powers of the interaction. With the standard Lagrangian of Eq. (14.1) the interaction Hamiltonian carries the coupling in the combination $\lambda/4!$, and the Dyson series of Eq. (14.25) carries an overall $1/V!$ at order V. Writing $G^{(n)}(x_1, \dots, x_n)$ for the full (numerator) correlator, the contribution of order V in the coupling is

$$G^{(n)}_V \;=\; \frac{1}{V!}\left(\frac{-i\lambda}{4!}\right)^V \int \mathrm{d}^4y_1 \cdots \mathrm{d}^4y_V \;\langle 0|\, \mathcal{T}\, \phi(x_1)\cdots\phi(x_n)\,\phi(y_1)^4\cdots\phi(y_V)^4\,|0\rangle\,. \tag{15.61}$$

By Wick's theorem (Theorem 10.23) the time-ordered vacuum expectation value is the sum over all complete pairings of the $n + 4V$ field operators, each pairing

evaluating to a product of Feynman propagators D_F. The two manifestly visible numerical prefactors in Eq. (15.61) are the $1/V!$ from the exponential and the $(1/4!)^V$ from the V copies of the vertex. Everything that follows is the statement that these two prefactors are designed to be cancelled by the multiplicity of Wick contractions — and the symmetry factor measures precisely the extent to which the cancellation fails.

It is worth saying in words why a cancellation is even expected. The V integration variables $y_1, \dots, y_V$ are dummy labels; the integrand is symmetric under permuting them, so the $V!$ orderings all give the same value and the $1/V!$ removes the overcount. Likewise, at a single vertex the four factors $\phi(y_i)$ are literally the same operator, so the 4! ways of deciding "which of the four $\phi(y_i)$ contracts with which neighbour" produce identical propagator products, and the $1/4!$ is there to remove *that* overcount. The question is whether the removal is exact. It is exact precisely when the four fields at a vertex, and the V vertices among themselves, are genuinely interchangeable in all 4! and $V!$ ways without any of those interchanges being trivial — and an interchange is trivial exactly when it is an automorphism of the diagram.

To make this precise we adopt the *half-edge* (or stub) bookkeeping, which turns the contraction count into a clean group action.

Definition 15.20 (Half-edges, matchings, and the relabelling group)**.** Each external point x_j contributes one field operator, an *external half-edge* (univalent and labelled, $j = 1, \dots, n$). Each internal vertex y_i contributes four field operators, four *internal half-edges* carried by that vertex, $i = 1, \dots, V$. A *labelled contraction* is a perfect matching of the full set of $n + 4V$ half-edges into pairs; each pair is a line and evaluates to one propagator. The *relabelling group*

$$\Gamma \;=\; S_4 \wr S_V \;=\; (S_4)^V \rtimes S_V, \qquad |\Gamma| \;=\; (4!)^V\, V!, \tag{15.62}$$

acts on the internal half-edges: the factor $(S_4)^V$ independently permutes the four half-edges within each vertex, and S_V permutes the V vertices bodily (carrying their half-edges along). External half-edges are *fixed pointwise* — the external points are physical and distinguishable. The group Γ acts on the set of labelled contractions by relabelling.

The order of Γ is exactly the product $V!\,(4!)^V$ of the two prefactors in Eq. (15.61): Γ is, by construction, the group of relabellings those prefactors are meant to quotient out. A *Feynman diagram* is what remains after the quotient: the graph drawn with the external legs $x_1, \dots, x_n$ fixed and the internal vertices regarded as indistinguishable points, retaining only the pattern of which half-edge is paired with which. Two labelled contractions yield the *same* Feynman diagram if and only if some element of Γ maps one to the other. In the language of group actions, a Feynman diagram is precisely a Γ-orbit of labelled contractions.

15.4.2 The automorphism group and the counting theorem

The cancellation is now an orbit–stabilizer computation, and the residual factor is the size of a stabilizer. That stabilizer has a name.

Definition 15.21 (Automorphism group of a Feynman diagram)**.** Fix a labelled contraction M realizing a connected diagram D for $G^{(n)}$. An *automorphism* of D is an element $\sigma \in \Gamma$ that maps M to itself: a permutation of the internal half-edges that (i) permutes the four half-edges within each vertex and permutes the vertices among themselves, (ii) commutes with the pairing M (so a line of D is carried to a line of D), and (iii) fixes every external half-edge. The set of such σ is the *automorphism group* $\mathrm{Aut}(D) = \mathrm{Stab}_\Gamma(M)$, and the *symmetry factor* is

$$S \;\equiv\; |\,\mathrm{Aut}(D)|. \tag{15.63}$$

Concretely, $\mathrm{Aut}(D)$ is generated by three elementary kinds of move that leave the drawn graph (with its external legs nailed down) looking identical: (a) swapping the two half-edges of a *self-loop* at a vertex; (b) permuting a set of *parallel lines* joining the same pair of vertices; (c) permuting *interchangeable internal vertices* (vertices related by a symmetry of the rest of the graph). The order S is the number of distinct compositions of such moves.

Because $\mathrm{Aut}(D)$ does not depend on *which* representative matching M in the orbit we chose — stabilizers of points in one orbit are conjugate, hence of equal order — the symmetry factor is a property of the diagram, not of any labelling.

Theorem 15.22 (Symmetry factor as automorphism count)**.** *Let D be a connected diagram contributing to $G^{(n)}$ at order V, with internal lines (propagators) determined by its topology. Then the total contribution of D to the Green's function is*

$$G_D^{(n)} \;=\; \frac{1}{S}\,(-i\lambda)^V \int \mathrm{d}^4y_1 \cdots \mathrm{d}^4y_V \prod_{\text{lines } \ell \in D} D_F(\text{endpoints of } \ell), \qquad S = |\,\mathrm{Aut}(D)|, \tag{15.64}$$

i.e. the rule-set value of D with all vertex factors $-i\lambda$, all propagators, and the loop integrations, multiplied by the single extra factor $1/S$. The $1/4!$ per vertex and the $1/V!$ of the Dyson series are completely accounted for, leaving exactly $1/|\,\mathrm{Aut}(D)|$.

Proof. Group the sum over labelled contractions in Eq. (15.61) according to which Feynman diagram each realizes; that is, group it into Γ-orbits. All labelled contractions in one orbit produce the *same* value: the propagator product is determined by the topology, and relabelling internal half-edges or renaming the dummy integration variables y_i leaves the integral Eq. (15.61) invariant (the integrand is symmetric in the y_i, and the four operators at a vertex are identical). Call that common value, stripped of the front prefactor, $\mathcal{I}(D) = \int \prod_i \mathrm{d}^4y_i \prod_\ell D_F$.

Let M be a representative matching for D. By the orbit–stabilizer theorem, the number of distinct labelled contractions in the orbit of M — equivalently, the number of Wick contractions of Eq. (15.61) that realize D — is

$$\big|\,\mathrm{orbit}(M)\,\big| \;=\; \frac{|\Gamma|}{\big|\,\mathrm{Stab}_\Gamma(M)\big|} \;=\; \frac{(4!)^V\,V!}{\big|\,\mathrm{Aut}(D)\big|} \;=\; \frac{(4!)^V V!}{S}. \tag{15.65}$$

Each of these contractions contributes the identical front factor $\frac{1}{V!}(-i\lambda/4!)^V$ times $\mathcal{I}(D)$. Summing over the orbit therefore gives

$$G_D^{(n)} \;=\; \frac{1}{V!}\Big(\frac{-i\lambda}{4!}\Big)^V \cdot \frac{(4!)^V V!}{S} \cdot \mathcal{I}(D) \;=\; \frac{(-i\lambda)^V}{S}\,\mathcal{I}(D), \tag{15.66}$$

where the explicit $(4!)^V V!$ from the multiplicity cancels the $(1/4!)^V$ and $1/V!$ from the prefactor, leaving $(-i\lambda)^V$ and the lone surviving denominator S. This is Eq. (15.64). □

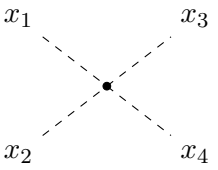
The theorem is the entire content of "symmetry factors," and it explains the folklore precisely. The $1/4!$ in the coupling and the $1/V!$ in the exponential are not magic: they are there to be eaten by the contraction multiplicity, and they are eaten *exactly* for a diagram with no symmetry. They fail to be eaten only along the directions in which the relabelling group Γ acts trivially on the matching — and those directions are, by definition, the automorphisms. A diagram with $S > 1$ is one in which some genuine relabelling of internal half-edges or vertices produces the very same graph, so the contraction count falls short of the full $(4!)^V V!$ by the factor S, and that shortfall survives as $1/S$.

Physical Insight

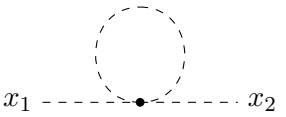
The symmetry factor is the price of indistinguishability. The $1/4!$ in $\lambda\phi^4/4!$ is chosen so that the four lines emanating from a vertex, being interchangeable, do not overcount the tree amplitude: at a tree vertex all four lines run to *distinct* fixed external points, every interchange is detectable, and the cancellation is total ($S = 1$). The moment two of the lines at a vertex run instead to the *same* place — back to the vertex (a self-loop), or to the same neighbouring vertex (parallel lines) — the interchange becomes undetectable, an automorphism appears, and a factor of $1/2$ (or more) is left behind. Loops breed symmetry; symmetry costs $1/S$.

Caution

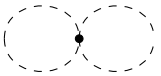
The automorphisms in Theorem 15.21 must fix the external legs. A move that permutes internal vertices is an automorphism only if it leaves *every* external leg attached where it was. This is why exchanging the two



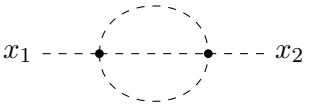
(a) Tree four-point vertex, $S = 1$.



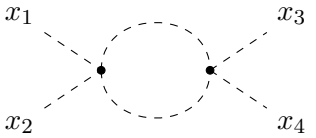
(b) One-loop propagator (tadpole), $S = 2$.



(c) Figure-eight vacuum, $S = 8$.



(d) Sunset, $S = 6$.



(e) s-channel bubble, $S = 2$.

Figure 15.7: The representative catalogue of ϕ^4 diagrams whose symmetry factors are derived in Section 15.4.3. Dashed lines are scalar propagators; filled dots are ϕ^4 vertices; external points x_j are held fixed.

vertices of an s-channel one-loop bubble (Section 15.4.3 below) is *not* an automorphism: it would swap the external pair $\{x_1, x_2\}$ with $\{x_3, x_4\}$. The same exchange *is* an automorphism for the sunset diagram only because there the two vertices carry one external leg each and the exchange would move $x_1 \leftrightarrow x_2$ — which again is forbidden, so it too is excluded. Read the catalogue with the external legs nailed to the page.

15.4.3 A catalogue of symmetry factors from first principles

We now compute S for a representative family of ϕ^4 diagrams, each time *twice*: once by the brute-force contraction count of Eq. (15.65) (count the Wick contractions, divide $(4!)^V V!$ by that number) and once by directly enumerating the automorphisms of Theorem 15.21. The two routes must agree, and watching them agree is the surest way to internalize the rule. The diagrams are drawn in Fig. 15.7.

(a) The tree four-point vertex ($n = 4$, $V = 1$): $S = 1$. This is the diagram behind the carried ϕ^4 theory amplitude of Section 15.3. There is one vertex with four half-edges, and the four external fields $\phi(x_1), \dots, \phi(x_4)$ must each contract with one of them; there are no internal lines. The number of contractions is the number of bijections from $\{x_1, x_2, x_3, x_4\}$ to the four vertex half-edges,

$$\#\{\text{contractions}\} = 4!, \qquad S = \frac{(4!)^1\, 1!}{4!} = 1. \tag{15.67}$$

Directly: once each external leg is nailed to a particular half-edge, no nontrivial permutation of the half-edges preserves the assignment, so Aut is trivial and $S = 1$. The rule-set value is therefore exactly $(-i\lambda)$, with no leftover factor; this is precisely why the 4! was put in the Lagrangian, and it reproduces the tree amplitude $-i\lambda$ of the thread without correction.

(b) The one-loop propagator correction — the tadpole ($n = 2$, $V = 1$): $S = 2$. At order λ the two-point function receives the diagram of Fig. 15.7b: a single vertex, two of whose half-edges run to x_1 and x_2 while the other two contract with each other, forming a loop that sits on the line. Count the contractions: choose the vertex half-edge that pairs with x_1 (four choices), then the one that pairs with x_2 (three remaining), and the last two half-edges are forced to contract with each other (one way):

$$\#\{\text{contractions}\} = 4 \cdot 3 \cdot 1 = 12, \qquad S = \frac{4! \cdot 1!}{12} = \frac{24}{12} = 2. \tag{15.68}$$

Directly: the only nontrivial automorphism is the swap of the two half-edges of the self-loop (move (a) of Theorem 15.21); it exchanges the two ends of the loop without touching the external legs, and it preserves the matching. Hence $\mathrm{Aut}(D) \cong \mathbb{Z}_2$ and $S = 2$. We complete this diagram — symmetry factor, integral, and renormalized value — in Theorem 15.23.

(c) The figure-eight vacuum diagram ($n = 0$, $V = 1$): $S = 8$. With no external legs, the order-λ vacuum amplitude is $\langle 0|\, \mathcal{T}\, \phi(y)^4\, |0\rangle$ fully contracted (Fig. 15.7c): the four half-edges of the single vertex pair up among themselves into two self-loops. The number of ways to partition four labelled half-edges into two unordered pairs is the double factorial

$$\#\{\text{contractions}\} = (4-1)!! = 3!! = 3, \qquad S = \frac{4! \cdot 1!}{3} = \frac{24}{3} = 8. \tag{15.69}$$

Directly, the automorphisms decompose into three independent $\mathbb{Z}_2$ moves: swap the two half-edges of the first loop ($\mathbb{Z}_2$), swap the two half-edges of the second loop ($\mathbb{Z}_2$), and exchange the two loops bodily ($\mathbb{Z}_2$). The first two commute with each other but the third conjugates them, so the group is the wreath product $\mathbb{Z}_2 \wr \mathbb{Z}_2 = (\mathbb{Z}_2 \times \mathbb{Z}_2) \rtimes \mathbb{Z}_2$, the dihedral group of order

$$S = \left|\mathbb{Z}_2 \wr \mathbb{Z}_2\right| = 2 \cdot 2 \cdot 2 = 8. \tag{15.70}$$

This is the textbook "$S = 8$" figure-eight. As a vacuum diagram it is cancelled against the denominator of the Green's function by the linked-cluster argument of Section 15.2, so it never appears in a connected correlator; we include it because the same $1/8$ is exactly the factor that survives in the free energy and the one-loop effective potential, where vacuum diagrams are the whole point.

(d) The sunset ($n = 2$, $V = 2$): $S = 6$. The order-λ^2 correction to the propagator in Fig. 15.7d has two vertices joined by *three* internal lines, with one external leg on each vertex. Count contractions. The external field $\phi(x_1)$ contracts with one of the 8 internal half-edges; call its vertex A. For the sunset topology $\phi(x_2)$ must land on the *other* vertex B — 4 choices among B's half-edges. Vertex A now has three free half-edges and B has three free half-edges, and the sunset requires all three of A's to pair with B's, in 3! ways:

$$\#\{\text{contractions}\} = 8 \cdot 4 \cdot 3! = 8 \cdot 4 \cdot 6 = 192, \qquad S = \frac{(4!)^2\, 2!}{192} = \frac{576 \cdot 2}{192} = 6. \tag{15.71}$$

Directly: the three parallel internal lines joining the same pair of vertices may be permuted arbitrarily (move (b)), giving $\mathrm{Aut}(D) \cong S_3$ of order 6. Exchanging the two vertices is *not* an automorphism — it would carry $x_1 \leftrightarrow x_2$ — so no further factor arises. Hence $S = 6$.

(e) The one-loop s-channel bubble ($n = 4$, $V = 2$): $S = 2$. The order-λ^2 correction to $\phi\phi \to \phi\phi$ in the s-channel, Fig. 15.7e, has the two incoming external legs x_1, x_2 on one vertex, the two outgoing x_3, x_4 on the other, and *two* internal lines (the bubble) joining the vertices. Count: $\phi(x_1)$ picks one of 8 internal half-edges, on a vertex A; $\phi(x_2)$ must also land on A for the s-channel topology — 3 remaining half-edges of A; $\phi(x_3)$ lands on the other vertex B — 4 choices; $\phi(x_4)$ also on B — 3 remaining; the two leftover half-edges on A pair with the two on B in 2! ways:

$$\#\{\text{contractions}\} = 8 \cdot 3 \cdot 4 \cdot 3 \cdot 2! = 576, \qquad S = \frac{(4!)^2\, 2!}{576} = \frac{1152}{576} = 2. \tag{15.72}$$

Directly: the two parallel lines of the bubble may be swapped (move (b)), $\mathrm{Aut}(D) \cong \mathbb{Z}_2$, $S = 2$. As warned, exchanging the two vertices is forbidden because it would swap $\{x_1, x_2\}$ with $\{x_3, x_4\}$. The t- and u-channel bubbles are *distinct* diagrams, each with its own $S = 2$; they are summed separately, not divided by a further symmetry. The full one-loop four-point amplitude is the sum of the three channels, each weighted by $1/2$.

Caution

Identical *external* particles never generate a symmetry factor. In a $2 \to 2$ amplitude with four identical scalars the three channels s, t, u look superficially related by relabelling the external momenta, but the external legs are physically labelled (distinct momenta), so no automorphism relates the channels: each is a separate diagram. The factor $1/2$ in each bubble is from the two *internal* lines, not from the external symmetry. The combinatorial symmetry of identical *final-state* particles is a separate effect that enters the phase-space integration of the cross section in Chapter 16,

never the amplitude's symmetry factor.

15.4.4 The one-loop ϕ^4 self-energy, in full

We now assemble symmetry factor, Feynman rules, and the master loop integral into a complete computation: the one-loop correction to the ϕ^4 propagator. This is the tadpole of part (b) above, read off in momentum space and amputated to the one-particle-irreducible self-energy $-i\Sigma(p)$, the quantity that will be renormalized in Chapters 21 and 22.

Worked Example 15.23 (The one-loop self-energy of ϕ^4 theory)**.** The amputated one-particle-irreducible two-point insertion at one loop is the tadpole of Fig. 15.7b with its external propagators stripped. We established its symmetry factor in Eq. (15.68): $S = 2$. By the momentum-space rules of Section 15.3 the diagram carries one vertex $-i\lambda$, one undetermined loop momentum k circulating in the self-loop with propagator $i/(k^2 - m^2 + i\varepsilon)$ (the momentum-space Feynman propagator of Eq. (9.154)), and one loop integration $\int \mathrm{d}^4k/(2\pi)^4$. The momentum entering the loop is zero — both ends of the self-loop attach to the same vertex — so the result is independent of the external momentum p. Including the symmetry factor,

$$-i\Sigma(p) \;=\; \frac{1}{S}\,(-i\lambda)\int \frac{\mathrm{d}^4k}{(2\pi)^4}\,\frac{i}{k^2 - m^2 + i\varepsilon} \;=\; \frac{-i\lambda}{2}\int \frac{\mathrm{d}^4k}{(2\pi)^4}\,\frac{i}{k^2 - m^2 + i\varepsilon}. \tag{15.73}$$

Cancelling $-i$ from both sides and pulling the i out of the integral,

$$\Sigma \;=\; \frac{\lambda}{2}\,(i)\int \frac{\mathrm{d}^4k}{(2\pi)^4}\,\frac{1}{k^2 - m^2 + i\varepsilon} \;=\; \frac{i\lambda}{2}\,I_1(m^2), \tag{15.74}$$

with I_1 the canonical one-loop integral of Eq. (D.73). The integral is quadratically divergent and must be regulated; we use dimensional regularization, $d = 4 - 2\varepsilon$, with the scale μ inserted so that λ stays dimensionless ($\lambda \to \lambda\mu^{2\varepsilon}$). The master formula Theorem D.22 at $n = 1$, $\Delta = m^2$ gives

$$I_1(m^2) = \int \frac{\mathrm{d}^dk}{(2\pi)^d}\,\frac{1}{k^2 - m^2 + i\varepsilon} = \frac{-i}{(4\pi)^{d/2}}\,\Gamma\!\left(1 - \tfrac{d}{2}\right)(m^2)^{\,d/2-1}. \tag{15.75}$$

Substituting into Eq. (15.74), the explicit factor of i cancels the $-i$ of Eq. (15.75):

$$\Sigma \;=\; \frac{i\lambda}{2}\cdot\frac{-i}{(4\pi)^{d/2}}\,\Gamma\!\left(1 - \tfrac{d}{2}\right)(m^2)^{d/2-1} \;=\; \frac{\lambda\, m^2}{2(4\pi)^2}\left(\frac{4\pi\mu^2}{m^2}\right)^{\!\varepsilon}\Gamma(-1+\varepsilon), \tag{15.76}$$

where we set $d = 4 - 2\varepsilon$, wrote $(4\pi)^{-d/2} = (4\pi)^{-2}(4\pi)^{\varepsilon}$, $(m^2)^{d/2-1} = m^2(m^2)^{-\varepsilon}$, and restored the $\mu^{2\varepsilon}$ from the coupling to form the dimensionless ratio $(4\pi\mu^2/m^2)^{\varepsilon}$.

It remains to expand around $\varepsilon = 0$. Using $\Gamma(-1+\varepsilon) = -\frac{1}{1-\varepsilon}\Gamma(\varepsilon)$ and $\Gamma(\varepsilon) = \frac{1}{\varepsilon} - \gamma_E + O(\varepsilon)$,

$$\Gamma(-1+\varepsilon) = -(1+\varepsilon+O(\varepsilon^2))\Big(\tfrac{1}{\varepsilon} - \gamma_E\Big) = -\tfrac{1}{\varepsilon} + \gamma_E - 1 + O(\varepsilon), \tag{15.77}$$

and $(4\pi\mu^2/m^2)^{\varepsilon} = 1 + \varepsilon \ln\frac{4\pi\mu^2}{m^2} + O(\varepsilon^2)$. Multiplying the two expansions, the $O(1)$ terms combine as $(-\frac{1}{\varepsilon} + \gamma_E - 1) + (-\ln\frac{4\pi\mu^2}{m^2})$, so

$$\boxed{\Sigma \;=\; -\frac{\lambda\, m^2}{32\pi^2}\left[\frac{1}{\varepsilon} - \gamma_E + 1 + \ln\frac{4\pi\mu^2}{m^2}\right] + O(\varepsilon).} \tag{15.78}$$

Three features deserve note. First, Σ is independent of the external momentum p: the one-loop ϕ^4 self-energy is a pure mass shift, so it contributes to the mass counterterm δ_m but not to wavefunction renormalization — the field anomalous dimension γ_ϕ of ϕ^4 theory first appears at $O(\lambda^2)$ (the sunset), consistent with the thread's recorded $\gamma_\phi = O(\varepsilon^2)$ at the Wilson–Fisher point. Second, the divergence is a simple pole $1/\varepsilon$ even though the integral is quadratically divergent in the cutoff language: dimensional regularization sees the quadratic divergence as the $\Gamma(-1+\varepsilon)$ pole and discards the would-be quadratic piece, which is why the residue is proportional to m^2 rather than to a cutoff squared. Third, the $1/S = 1/2$ is indispensable: dropping it would double the mass counterterm and produce the wrong one-loop β_{m^2}. The renormalization that removes the pole in Eq. (15.78) is carried out in Chapter 22; here the point is that every factor in front of the integral — the $-i\lambda$, the loop measure, and above all the $1/2$ — has now been derived rather than asserted.

Historical Note

The systematic reading of the leftover factor as the order of a graph automorphism group goes back to the combinatorial reformulation of perturbation theory in the 1950s and was made fully explicit in the diagrammatic literature that followed Dyson's organization of the S-matrix. The half-edge bookkeeping used above — vertices as bundles of stubs, contractions as matchings, the prefactor $1/V!(4!)^V$ as the order of the wreath group $S_4 \wr S_V$ — is the same structure that reappears in the modern graph-theoretic and Hopf-algebraic accounts of renormalization, where symmetry factors are precisely the inverse orders of automorphism groups of the underlying Feynman graphs.

With the symmetry factor identified as $1/|\operatorname{Aut}(D)|$ and verified on the full catalogue, we have closed the last gap in the canonical Feynman rules: every diagram now has a completely determined value. The next section re-derives this entire rule-set — propagators, vertices, and these very symmetry factors —

from the generating functional $Z[J]$ of Chapter 10, where the $1/S$ will emerge automatically from the functional derivatives rather than being counted by hand, giving the same amplitude a second, independent derivation and a stringent consistency check on everything established here.

15.5 The Path-Integral Route: Feynman Rules from $Z[J]$

The canonical route taken so far in this chapter produced the ϕ^4 Feynman rules honestly but laboriously. Wick's theorem turned each term of the Dyson series into a sum over pairings; the position- and momentum-space rules of Sections 15.2 and 15.3 read those pairings off as diagrams; and the symmetry factor of every diagram had to be counted by hand, balancing the $1/n!$ of the Dyson exponential and the $1/4!$ at each vertex against the number of contractions that realize a given topology—the careful bookkeeping of Section 15.4. That bookkeeping is correct, but it is also the single most error-prone step in scalar perturbation theory, and nothing in the operator formalism makes the cancellations automatic: one must count, every time. There is a second derivation in which the same diagrams, the same propagators and vertices, and—this is the structural payoff—the same symmetry factors emerge from a single formula with no separate counting at all. It starts not from the S-matrix but from the generating functional $Z[J]$ built in Chapter 10, and it converts the entire perturbative expansion into the repeated action of functional derivatives on one Gaussian. This section carries that derivation out in full, recovers every rule established canonically, and closes ϕ^4 theory's "same amplitude two ways" by reproducing $i\mathcal{M} = -i\lambda$ from $Z[J]$.

We work throughout with the conventions in force for the chapter: the mostly-minus metric $\eta_{\mu\nu} = \mathrm{diag}(+,-,-,-)$, natural units, the Feynman $i\varepsilon$ prescription, and the frozen ϕ^4 Lagrangian of Eq. (10.80),

$$\mathcal{L} = \tfrac{1}{2}(\partial_\mu\phi)(\partial^\mu\phi) - \tfrac{1}{2}m^2\phi^2 - \frac{\lambda}{4!}\phi^4, \qquad \phi \text{ real},\ \lambda > 0. \tag{15.79}$$

15.5.1 The generating functional as the source of all diagrams

We import from Chapter 10 the three objects on which everything below rests, restating them so the section reads on its own. The first is the *generating functional* of Theorem 10.17,

$$Z[J] = \int \mathcal{D}\phi\ \exp\Big[\, i\int d^4x\,(\mathcal{L} + J\phi)\Big] = \int \mathcal{D}\phi\ \exp\Big[\, iS[\phi] + i\int d^4x\, J(x)\phi(x)\Big], \tag{15.80}$$

the field integral weighted by e^{iS} in the presence of an external source $J(x)$, with the vacuum boundary conditions enforced by the $m^2 \to m^2 - i\varepsilon$ tilt of Chapter 10.

The second is the rule, Theorem 10.18, that the time-ordered correlation functions of the interacting theory are normalized functional derivatives of $Z[J]$ at vanishing source,

$$G^{(n)}(x_1,\dots,x_n) = \langle 0|\,\mathcal{T}\,\phi(x_1)\cdots\phi(x_n)\,|0\rangle = \frac{1}{Z[0]}\,\frac{1}{i^{\,n}}\,\frac{\delta^{\,n} Z[J]}{\delta J(x_1)\cdots\delta J(x_n)}\bigg|_{J=0}, \tag{15.81}$$

where $\delta/\delta J$ is the functional derivative of Theorem 4.4 and the division by $Z[0]$ is what removes the vacuum bubbles, exactly as established around Eq. (10.93). The third is the closed form of the *free* generating functional, the $\lambda = 0$ instance of Eq. (15.80), obtained by completing the Gaussian square in Chapter 10 and recorded as Eq. (10.111),

$$Z_0[J] = Z_0[0]\,\exp\Big[-\tfrac{1}{2}\int d^4x\,d^4y\;J(x)\,D_F(x-y)\,J(y)\Big], \tag{15.82}$$

with D_F the Feynman propagator. Equation Eq. (15.82) *is* the entire free theory: by Eq. (15.81) every free correlator is a derivative of this single Gaussian, and differentiating it produces precisely the sum-over-pairings of Wick's theorem, Theorem 10.23,

$$G_0^{(2k)}(x_1,\dots,x_{2k}) = \sum_{\text{pairings}}\;\prod_{\text{pairs }(a,b)} D_F(x_a - x_b), \qquad G_0^{(2k+1)} = 0. \tag{15.83}$$

The task of the section is to turn the *interacting* $Z[J]$ of Eq. (15.80) into something we can differentiate as easily as Eq. (15.82). The obstruction is the quartic term in S: it makes the integral non-Gaussian and there is no closed form. The resolution is to keep the Gaussian exact and treat the quartic term as a differential operator acting on it.

15.5.2 The master formula

Split the action of Eq. (15.79) into its free and interacting parts in the manner of Chapter 14, $S[\phi] = S_0[\phi] + S_{\text{int}}[\phi]$, where the interaction is the spacetime integral of the quartic potential,

$$S_{\text{int}}[\phi] = -\frac{\lambda}{4!}\int d^4w\;\phi(w)^4. \tag{15.84}$$

The single identity that drives the whole derivation is that a functional derivative with respect to the source, suitably normalized, reaches inside the integral Eq. (15.80) and pulls down a factor of the field. Acting on the source exponential,

$$\frac{1}{i}\frac{\delta}{\delta J(w)}\,\exp\Big[i\int d^4x\,J\phi\Big] = \frac{1}{i}\,\big(i\,\phi(w)\big)\,\exp\Big[i\int d^4x\,J\phi\Big] = \phi(w)\,\exp\Big[i\int d^4x\,J\phi\Big], \tag{15.85}$$

the operator $\frac{1}{i}\,\delta/\delta J(w)$ acts as multiplication by $\phi(w)$ once it stands to the left of $e^{i\int J\phi}$. Because these operators at different points w commute among themselves, the same holds for any polynomial—and hence any power series—in the field: for any functional F admitting a Taylor expansion in ϕ,

$$F\Big[\tfrac{1}{i}\tfrac{\delta}{\delta J}\Big]\,\exp\Big[\,i\int d^4x\,J\phi\Big] = F[\phi]\,\exp\Big[\,i\int d^4x\,J\phi\Big]. \tag{15.86}$$

The crucial feature of the left-hand side is that the differential operator $F[\frac{1}{i}\delta/\delta J]$ depends on J alone, not on the integration variable ϕ. This is exactly the lever we need.

Theorem 15.24 (The master formula)**.** *The interacting generating functional Eq. (15.80) of ϕ^4 theory equals the interaction exponential, written as a functional-derivative operator in the source, acting on the free generating functional:*

$$\boxed{Z[J] = \exp\Big(iS_{\text{int}}\Big[\tfrac{1}{i}\tfrac{\delta}{\delta J}\Big]\Big)\,Z_0[J] = \exp\Big(-\frac{i\lambda}{4!}\int d^4w\,\Big[\tfrac{1}{i}\tfrac{\delta}{\delta J(w)}\Big]^4\Big)\,Z_0[J].} \tag{15.87}$$

Proof. Take $F[\phi] = \exp\left(iS_{\text{int}}[\phi]\right)$ in Eq. (15.86); as a power series in λ each term is a polynomial in ϕ, so the identity applies term by term. It gives

$$\exp\Big(iS_{\text{int}}\Big[\tfrac{1}{i}\tfrac{\delta}{\delta J}\Big]\Big)\exp\Big[\,i\int d^4x\,J\phi\Big] = \exp(iS_{\text{int}}[\phi])\,\exp\Big[\,i\int d^4x\,J\phi\Big]. \tag{15.88}$$

Now write the interacting weight in Eq. (15.80) as $e^{iS} = e^{iS_0}e^{iS_{\text{int}}}$ and insert Eq. (15.88):

$$\begin{aligned} Z[J] &= \int \mathcal{D}\phi\, e^{\,iS_0[\phi]}\; e^{\,iS_{\text{int}}[\phi]}\;\exp\Big[\,i\int d^4x\,J\phi\Big] \\ &= \int \mathcal{D}\phi\, e^{\,iS_0[\phi]}\;\exp\Big(iS_{\text{int}}\Big[\tfrac{1}{i}\tfrac{\delta}{\delta J}\Big]\Big)\exp\Big[\,i\int d^4x\,J\phi\Big]. \end{aligned} \tag{15.89}$$

The operator $\exp\left(iS_{\text{int}}[\frac{1}{i}\delta/\delta J]\right)$ is built from derivatives with respect to J only and contains no ϕ; it therefore commutes with the integration over ϕ and with the ϕ-dependent factor $e^{iS_0[\phi]}$, and may be pulled out in front of the integral. What remains inside is the free generating functional,

$$Z[J] = \exp\Big(iS_{\text{int}}\Big[\tfrac{1}{i}\tfrac{\delta}{\delta J}\Big]\Big)\,\underbrace{\int \mathcal{D}\phi\, e^{\,iS_0[\phi]}\,\exp\Big[\,i\int d^4x\,J\phi\Big]}_{=\,Z_0[J]} = \exp\Big(iS_{\text{int}}\Big[\tfrac{1}{i}\tfrac{\delta}{\delta J}\Big]\Big)\,Z_0[J], \tag{15.90}$$

which is Eq. (15.87). Substituting S_{int} from Eq. (15.84) gives the explicit second form; the factor $(\frac{1}{i})^4 = 1$ has not yet been written out and is kept for now so that each derivative is paired with its $1/i$. □

Two remarks fix the status of Eq. (15.87). First, the interchange of the J-derivative operator with the functional integral in Eq. (15.89)–Eq. (15.90) is exactly as legitimate as the Gaussian manipulations of Chapter 10: on the lattice regularization of Theorem 10.16 both sides are finite-dimensional, the operator is an ordinary finite-order differential operator in the discretized sources, and the interchange is the elementary statement that a constant-coefficient differential operator passes through an integral over a different set of variables. The continuum formula is the limit of that finite statement, understood—as always in perturbation theory—order by order in λ. Second, the master formula is not an approximation: it is an exact rewriting of $Z[J]$. The approximation enters only when we expand the exponential operator in powers of λ, which we now do.

15.5.3 The double expansion and how the rules emerge

The master formula Eq. (15.87) reduces every correlator to derivatives of the Gaussian Eq. (15.82), because both the operator $\exp(iS_{\rm int}[\cdots])$ and the external derivatives of Eq. (15.81) are functional derivatives with respect to J, all acting on $Z_0[J]$. Expanding the exponential operator in powers of the coupling,

$$\exp\Big(iS_{\rm int}\Big[\tfrac{1}{i}\tfrac{\delta}{\delta J}\Big]\Big)=\sum_{V=0}^{\infty}\frac{1}{V!}\Big(iS_{\rm int}\Big[\tfrac{1}{i}\tfrac{\delta}{\delta J}\Big]\Big)^{V}=\sum_{V=0}^{\infty}\frac{1}{V!}\left(-\frac{i\lambda}{4!}\int d^4w\,\Big[\frac{1}{i}\frac{\delta}{\delta J(w)}\Big]^4\right)^{V}, \tag{15.91}$$

exposes the structure of the perturbation series in one line. The term with V factors is the $O(\lambda^V)$ contribution; it carries

- a factor $1/V!$ from the exponential—the Dyson $1/V!$, here arising automatically from the Taylor coefficient of exp, not from any time-ordering simplex;
- one factor $-\dfrac{i\lambda}{4!}\displaystyle\int d^4w_j\,\big[\tfrac{1}{i}\delta/\delta J(w_j)\big]^4$ for each vertex $j=1,\dots,V$, each contributing the coupling $-i\lambda$, the vertex symmetry weight $1/4!$, an unconstrained position w_j integrated over all spacetime, and *four* functional derivatives—the four legs of the vertex.

Inserted into Eq. (15.81), the n-point function at order λ^V is therefore obtained by acting on $Z_0[J]$ with n external derivatives $\delta/\delta J(x_i)$ together with $4V$ vertex derivatives $\delta/\delta J(w_j)$, and setting $J=0$. Since $Z_0[J]$ is the Gaussian Eq. (15.82), this is nothing but a free correlator of $n+4V$ fields, evaluated by Wick's theorem Eq. (15.83): the result is the sum over all ways of pairing the $n+4V$ points, each pair supplying one propagator D_F. We have arrived, with no new combinatorics, at the position-space Feynman rules.

Theorem 15.25 (Position-space Feynman rules from $Z[J]$)**.** *The $O(\lambda^V)$ contribution to $G^{(n)}(x_1,\dots,x_n)$ is the sum, over all distinct diagrams with n external points $x_1,\dots,x_n$ and V internal four-valent vertices, of the value obtained by the rules*

1. *assign an internal spacetime point w_j to each vertex and integrate $\int d^4w_j$ over all of spacetime;*
2. *for each line joining two points y, y' (external or internal), a factor $D_F(y-y')$;*
3. *for each vertex, a factor $-i\lambda$;*
4. *divide by the symmetry factor $S = |\mathrm{Aut}(\Gamma)|$ of the diagram, defined in Theorem 15.21;*

together with the overall division by $Z[0]$ in Eq. (15.81), which removes the disconnected vacuum subdiagrams. These are identical to the rules derived canonically in Theorem 15.9.

The proof is the content of the next two subsections: we first see the mechanism on the leading nontrivial example, the four-point function at $O(\lambda)$, and then prove the symmetry-factor statement (item 4) in general, which is where the path-integral route shows its structural advantage. The Fourier transform that converts rules 1–3 into the momentum-space rules of Theorem 15.13—a $-i\lambda(2\pi)^4\delta^4(\sum k)$ at each vertex, an $i/(p^2-m^2+i\varepsilon)$ on each line, and $\int d^4\ell/(2\pi)^4$ on each loop—is exactly the one carried out canonically there and is not repeated; it acts on Theorem 15.25 line by line and leaves the symmetry factor untouched.

15.5.4 The four-point function at $O(\lambda)$: the tree diagram

Worked Example 15.26 (The $O(\lambda)$ four-point function from $Z[J]$)**.** We compute the leading interacting four-point function directly from the master formula, exhibiting every contraction, and read off both the diagram and its symmetry factor. By Eq. (15.81) and the $V=1$ term of Eq. (15.91), the order-λ part of the unnormalized fourth derivative is

$$\frac{1}{i^4}\frac{\delta^4 Z[J]}{\delta J(x_1)\cdots\delta J(x_4)}\bigg|_{\lambda^1} = \frac{1}{i^4}\frac{\delta^4}{\delta J(x_1)\cdots\delta J(x_4)}\left(-\frac{i\lambda}{4!}\int d^4w\left[\tfrac{1}{i}\tfrac{\delta}{\delta J(w)}\right]^4\right) Z_0[J]\bigg|_{J=0}. \tag{15.92}$$

Collect the prefactors. The four external derivatives carry $1/i^4 = 1$; the four vertex derivatives carry $(\frac{1}{i})^4 = 1$; and the vertex coupling is $-i\lambda/4!$. We must therefore evaluate

$$-\frac{i\lambda}{4!}\int d^4w\,\frac{\delta^8 Z_0[J]}{\delta J(x_1)\,\delta J(x_2)\,\delta J(x_3)\,\delta J(x_4)\,\delta J(w)\,\delta J(w)\,\delta J(w)\,\delta J(w)}\bigg|_{J=0}. \tag{15.93}$$

This is the eighth functional derivative of the Gaussian Eq. (15.82) at $J = 0$—a free 8-point function of the field at the points $x_1, x_2, x_3, x_4, w, w, w, w$. By Wick's theorem Eq. (15.83) it is the sum over all pairings of these eight points, $(8-1)!! = 105$ in total, each pairing a product of four propagators. We organize the 105 pairings by their topology.

The connected (tree) pairings. The diagrams in which every external point is tied to the vertex pair each of x_1, x_2, x_3, x_4 with one of the four w-legs. The number of such pairings is the number of bijections from the four external points to the four w-legs, namely $4! = 24$, and each yields the identical product $D_F(x_1-w)D_F(x_2-w)D_F(x_3-w)D_F(x_4-w)$, since the four w-legs sit at the same point w. Their total contribution to Eq. (15.93) is

$$-\frac{i\lambda}{4!}\cdot 24\int d^4w\; D_F(x_1-w)D_F(x_2-w)D_F(x_3-w)D_F(x_4-w) = -i\lambda\int d^4w\;\prod_{i=1}^{4} D_F(x_i-w). \tag{15.94}$$

The vertex weight $1/4!$ has been cancelled *exactly* by the $24 = 4!$ ways of attaching the four distinguishable external legs to the four vertex legs. No counting beyond "4! bijections" was needed, and the residual numerical factor is 1: the tree diagram of Fig. 15.8 carries symmetry factor $S = 1$, the value its automorphism group takes in Theorem 15.21 because the four labelled external legs admit no nontrivial relabelling. The single factor $-i\lambda$ that survives is the Feynman vertex.

The disconnected pairings. The remaining $105 - 24 = 81$ pairings fail to connect all four externals to the vertex. They fall into two classes. In the first, the four w-legs are paired among themselves (one of the 3 ways to split four legs into two pairs, giving $D_F(0)^2$) while the four externals are paired among themselves (one of the 3 pairings of Eq. (10.138)); this is the free four-point function multiplied by the $O(\lambda)$ vacuum bubble. In the second, two of the w-legs pair with two externals and the other two w-legs pair together, leaving one external pair: these are propagator-correction (tadpole) pieces on a disconnected external line. Every one of these 81 terms contains either a vacuum factor or a self-contraction $D_F(0)$ detached from the scattering of all four externals. Crucially, the vacuum pieces are precisely what the normalization $1/Z[0]$ in Eq. (15.81) divides away—$Z[0]$ is, at this order, $Z_0[0]\big(1 + (-i\lambda/4!)\cdot 3\int D_F(0)^2\big)$—and the linked-cluster cancellation that makes this systematic is the subject of Section 15.6. The surviving connected, amputated content of the four-point function at $O(\lambda)$ is Eq. (15.94).

The lesson of Theorem 15.26 generalizes, and stating the generalization sharply is the point of the next subsection. The vertex weight $1/4!$ is engineered to be undone by the number of ways the four legs of the vertex can be wired; whether that undoing is complete, partial, or over-complete is governed entirely by the symmetry of the resulting diagram. The path-integral route makes this a theorem rather than a case-by-case count.

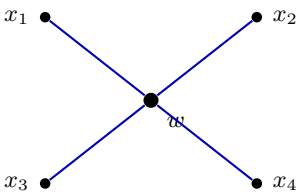


Figure 15.8: The $O(\lambda)$ four-point diagram of Theorem 15.26, Eq. (15.94). Four external points $x_1, \ldots, x_4$ are joined by Feynman propagators to a single four-valent vertex at w, integrated over spacetime. The vertex weight $1/4!$ from Eq. (15.84) is cancelled by the 4! ways of attaching the four distinguishable external legs, leaving the bare Feynman vertex $-i\lambda$ and symmetry factor $S = 1$. Amputating the four external legs and going to momentum space gives $i\mathcal{M} = -i\lambda$, Eq. (15.105).

15.5.5 The symmetry factor, for free

The structural advantage advertised in the opening is the following: the $1/S$ of any diagram is produced automatically by the interplay of the $1/V!$ in Eq. (15.91), the $1/4!$ at each vertex, and the Gaussian pairing count, with no separate counting of contractions. We prove this by a single orbit–stabilizer argument, which is the cleanest statement of what "symmetry factor" means.

Fix a diagram topology Γ contributing to $G^{(n)}$ at order λ^V: a graph with n labelled external points, V four-valent internal vertices, and a definite assignment of lines. From the expansion Eq. (15.91) and the master formula, the analytic value attached to Γ arises from a set of *labelled contraction schemes*: a scheme is a choice, at the level of the $4V$ individual vertex derivatives and the n external derivatives, of which derivative is paired with which in the Wick expansion of Eq. (15.83), such that the resulting pattern of propagators reproduces Γ. To count these schemes, regard the four derivatives at each vertex as four distinguishable "half-edges" and the vertices as distinguishable (labelled $1, \ldots, V$). Then the group

$$\mathcal{G} \;=\; S_V \ltimes (S_4)^V \tag{15.95}$$

acts on the labelled schemes: S_V permutes the V vertices and the factor S_4 at vertex j permutes its four half-edges. Its order is

$$|\mathcal{G}| = V!\,(4!)^V, \tag{15.96}$$

which is exactly the product of the denominators carried by the V-vertex term of Eq. (15.91): the $V!$ of the Dyson exponential and the 4! at each of the V vertices. The relevance of $\mathcal{G}$ is that all labelled schemes related by an element of $\mathcal{G}$ give

the *same* analytic value: relabelling the vertices merely renames the dummy integration variables w_j, and permuting the half-edges at a vertex merely reorders the four identical propagator ends meeting there, both leaving $\int \prod d^4 w_j \prod D_F$ invariant.

Now apply the orbit–stabilizer theorem to the action of $\mathcal{G}$ on one labelled scheme c_0 realizing Γ. The orbit $\mathcal{G} \cdot c_0$ is the set of all labelled schemes that yield Γ (every such scheme differs from c_0 by some relabelling of vertices and half-edges), and its size is

$$\#\{\text{labelled schemes giving } \Gamma\} = |\mathcal{G} \cdot c_0| = \frac{|\mathcal{G}|}{|\mathrm{Stab}(c_0)|} = \frac{V!\,(4!)^V}{|\mathrm{Aut}(\Gamma)|}, \tag{15.97}$$

where the stabilizer $\mathrm{Stab}(c_0)$—the relabellings that map the scheme c_0 to itself, i.e. that leave the wiring of Γ intact—is by definition the automorphism group $\mathrm{Aut}(\Gamma)$ of Theorem 15.21, whose order is the symmetry factor $S = |\mathrm{Aut}(\Gamma)|$. (External points are labelled and held fixed, so they contribute no automorphisms; this is why the tree of Fig. 15.8 had $S = 1$.) Assembling the weight of Γ from Eq. (15.91)—the prefactor $\frac{1}{V!}\left(\frac{1}{4!}\right)^V$, the coupling $(-i\lambda)^V$, the count Eq. (15.97) of equal-valued schemes, and the common propagator product $I_\Gamma = \int \prod_j d^4 w_j \prod_{\text{lines}} D_F$—we obtain

$$\boxed{\mathrm{weight}(\Gamma) = \frac{1}{V!}\Big(\frac{1}{4!}\Big)^V (-i\lambda)^V \, \frac{V!\,(4!)^V}{|\mathrm{Aut}(\Gamma)|}\, I_\Gamma = \frac{(-i\lambda)^V}{S}\, I_\Gamma, \qquad S = |\mathrm{Aut}(\Gamma)|\,.} \tag{15.98}$$

The cancellation is total and automatic: the $V!\,(4!)^V$ generated by the relabelling group Eq. (15.96) annihilates the $V!\,(4!)^V$ sitting in the denominators of Eq. (15.91), and the *only* surviving combinatorial residue is $1/|\mathrm{Aut}(\Gamma)| = 1/S$. This proves item 4 of Theorem 15.25 and, with the orbit-counting of Eq. (15.97), completes the proof of that theorem. It also reproduces, with no separate enumeration, the automorphism definition of S established canonically in Section 15.4: there S was identified by counting contractions against the $V!(4!)^V$ by hand; here that same count is the orbit-stabilizer formula Eq. (15.97), and $1/S$ falls out of the master formula as the residue of a cancellation that happens by itself.

Physical Insight

The deep reason the path integral knows the symmetry factor is that the $1/V!$ and $1/4!$ are not pedagogical conveniences inserted to "make the answers come out"—they are the structure constants of the two symmetries of the unlabelled problem. The $1/4!$ is the order of the permutation group of the four identical fields at a vertex; the $1/V!$ is the order of the permutation group of the V identical vertices. The Feynman diagram is the equivalence class of wirings under both, and a diagram with extra symmetry is simply one whose stabilizer in Eq. (15.95) is larger than expected, so that fewer

distinct wirings map onto it and its weight is correspondingly smaller. Symmetry factors are a quotient by a group action; the path integral performs the quotient for us.

Worked Example 15.27 (The figure-eight from $Z[J]$, with $S = 8$ automatic)**.** We re-derive one entry of the symmetry-factor catalogue of Section 15.4—the figure-eight vacuum diagram, a single vertex with both pairs of its legs closed into loops, shown in Fig. 15.9—directly from $Z[J]$, and confirm that the count gives $S = 8$ with no hand-tuning. This diagram is the entire $O(\lambda)$ content of the vacuum amplitude $Z[0]$. From the master formula Eq. (15.87) at $J = 0$, the $V = 1$ term is

$$Z[0]\big|_{\lambda^1} = -\frac{i\lambda}{4!}\int d^4w\,\left[\tfrac{1}{i}\tfrac{\delta}{\delta J(w)}\right]^4 Z_0[J]\Big|_{J=0} = -\frac{i\lambda}{4!}\int d^4w\,\frac{\delta^4 Z_0[J]}{\delta J(w)^4}\Big|_{J=0}, \tag{15.99}$$

using $(\frac{1}{i})^4 = 1$. The fourth derivative of the Gaussian at a single point w is the free four-point function at coincident arguments, Eq. (15.83) with $x_1 = x_2 = x_3 = x_4 = w$:

$$\frac{\delta^4 Z_0[J]}{\delta J(w)^4}\Big|_{J=0} = Z_0[0]\,G_0^{(4)}(w,w,w,w) = Z_0[0]\,(3\,D_F(0)^2), \tag{15.100}$$

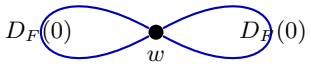
the factor 3 being the $(4-1)!! = 3$ pairings of four points—here the three ways to split the four legs at w into two pairs, each pair closing into a propagator $D_F(w-w) = D_F(0)$. Inserting Eq. (15.100) into Eq. (15.99),

$$Z[0]\big|_{\lambda^1} = Z_0[0]\left(-\frac{i\lambda}{4!}\cdot 3\right)\int d^4w\,D_F(0)^2 = Z_0[0]\left(-\frac{i\lambda}{8}\right)\int d^4w\,D_F(0)^2. \tag{15.101}$$

The numerical residue is $3/4! = 1/8$, so the figure-eight carries weight $(-i\lambda)/S$ with

$$S = \frac{4!}{3} = 8, \tag{15.102}$$

exactly the value the orbit-stabilizer formula Eq. (15.98) predicts: with $V = 1$, $|\mathcal{G}| = 1!\cdot 4! = 24$, and the count of labelled schemes giving the figure-eight is 3, so $S = 24/3 = 8$. The same 8 is read off geometrically from Fig. 15.9 as the order of the automorphism group: a factor 2 from swapping the two loops, and a factor 2 for reversing each of the two loops independently, $2\times 2\times 2 = 8$, matching the canonical count of Section 15.4. The propagator at coincident points, $D_F(0) = \int d^4p/(2\pi)^4\; i/(p^2 - m^2 + i\varepsilon)$, is ultraviolet divergent; that this vacuum bubble is divergent is immaterial to the combinatorial point being made here—the divergence, and its removal, are the business of Chapters 21 and 22, and the bubble itself cancels against $1/Z[0]$ in every physical correlator by the linked-cluster theorem of Section 15.6.



$$-\frac{i\lambda}{8}\int d^4w\, D_F(0)^2, \qquad S = 8$$

Figure 15.9: The figure-eight vacuum diagram of Theorem 15.27, Eq. (15.101): a single four-valent vertex at w with each of its two leg-pairs closed into a self-loop $D_F(0)$. The symmetry factor $S = 4!/3 = 8$ emerges automatically from the master formula—three Wick pairings against the vertex $1/4!$—and equals the order of the diagram's automorphism group (swap the two loops, reverse each loop: $2 \times 2 \times 2 = 8$), reproducing the canonical count of Section 15.4.

15.5.6 The same amplitude two ways

It remains to close ϕ^4 theory's standing obligation: to obtain the elastic scattering amplitude $i\mathcal{M}$ for $\phi(p_1)\phi(p_2) \to \phi(p_3)\phi(p_4)$ a second time, now from $Z[J]$, and to verify that it agrees on the nose with the canonical result. The connected, amputated four-point content at $O(\lambda)$ produced by the master formula is the tree of Eq. (15.94),

$$G_{\mathrm{c}}^{(4)}(x_1,x_2,x_3,x_4)\big|_{\lambda^1} = -i\lambda\int d^4w\, \prod_{i=1}^{4} D_F(x_i - w) + O(\lambda^2), \tag{15.103}$$

with symmetry factor 1. To extract the amplitude we pass to momentum space and amputate, exactly as the LSZ reduction of Chapter 14 prescribes: Fourier transform each external leg, $D_F(x_i - w) \to e^{\mp ip_i\cdot w}\,\widetilde{D_F}(p_i)$ with $\widetilde{D_F}(p) = i/(p^2 - m^2 + i\varepsilon)$, perform the vertex integral $\int d^4w$, which collects the four exponentials into the momentum-conserving delta,

$$\int d^4w\, e^{-i(p_1+p_2-p_3-p_4)\cdot w} = (2\pi)^4\,\delta^4(p_1 + p_2 - p_3 - p_4), \tag{15.104}$$

and strip the four external propagators $\widetilde{D_F}(p_i)$ together with the overall delta, leaving the amputated amplitude. The single vertex contributes its factor $-i\lambda$ and nothing else—there is no loop, hence no $\int d^4\ell/(2\pi)^4$, and the symmetry factor is 1—so

$$\boxed{i\mathcal{M}(\phi\phi \to \phi\phi) = -i\lambda + O(\lambda^2).} \tag{15.105}$$

This is term-for-term the canonical result: it is the $i\mathcal{M} = -i\lambda$ of Eq. (14.54), computed there from the Dyson series and LSZ, and re-derived within this chapter from the canonical Feynman rules in Theorem 15.13. The two pillars agree. The leading scattering amplitude of ϕ^4 theory, the first interacting number the book

owes, has now been produced *three* ways—operator Dyson series, canonical Feynman rules, and the generating functional—and all three give $-i\lambda$, with the same single tree diagram, the same vertex, and the same trivial symmetry factor. This is the concrete content of "the same amplitude two ways": not a slogan but an identity of outputs from two independent formalisms, and it is the strongest internal check the perturbative apparatus admits.

Notation Watch

In this section the symbol $S_{\text{int}}[\,\cdot\,]$ denotes the interaction *action* Eq. (15.84), a functional whose argument is a field (or, in the master formula, the operator $\frac{1}{i}\delta/\delta J$); the upright $\mathbf{S}$ of Chapter 14 is the S-matrix operator, and the italic $S = |\mathrm{Aut}(\Gamma)|$ is the integer symmetry factor of a diagram. The three are distinct objects sharing a letter by long convention; context and typeface separate them, and we never write them in the same expression.

We now have the complete Feynman apparatus of ϕ^4 packaged inside the single object $Z[J]$: every correlator, every diagram, every weight, and every symmetry factor is a functional derivative of one Gaussian acted on by one exponential operator. Working at the level of $Z[J]$ rather than diagram by diagram makes the global structure of the whole expansion visible at once—which classes of diagrams appear, how the vacuum bubbles factor out, and how the connected pieces are organized. Extracting that structure is the next task: taking the logarithm $W = -i \log Z$ will be shown to generate exactly the connected diagrams and to enforce the cancellation of vacuum bubbles, and the Legendre transform of W will isolate the one-particle-irreducible core that the renormalization programme of Chapters 21 and 22 is built upon.

15.6 The Architecture of Perturbation Theory: Connected, Vacuum, Amputated, 1PI

The path-integral route of Section 15.5 did more than reproduce the Feynman rules: by expanding $\exp(iS_{\text{int}})$ and contracting with $\delta/\delta J$ it laid the *entire* set of diagrams on the table at once — connected and disconnected, vacuum and external, reducible and irreducible, all weighted by their symmetry factors. That completeness is a virtue for bookkeeping and a liability for computation. No experiment measures the full correlator $G^{(n)} = \langle 0|T\phi(x_1)\cdots\phi(x_n)|0\rangle$; what an experiment measures is a connected, on-shell, amputated amplitude, and what a renormalization program manipulates is a still smaller skeleton, the one-particle-irreducible core. The job of this section is to sort the undifferentiated diagram set into exactly these structural classes and to prove, in the language of graphs, that each class is generated by one of the three nested functionals $Z \to W \to \Gamma$ already introduced in Chapter 10. We establish the general

theorems that Section 10.7.4 verified only at low order and explicitly deferred here: that $W = -i \ln Z$ generates precisely the connected diagrams, that the disconnected vacuum diagrams exponentiate into a common factor that cancels against the $Z[0]$ normalization, and that the Legendre transform Γ generates the one-particle-irreducible vertices. The payoff is the working hierarchy of perturbation theory — full, connected, 1PI — on which every later chapter, from cross sections (Chapter 16) through renormalization (Chapter 22) to the effective potential (Chapter 29), silently relies.

Throughout we work with the frozen ϕ^4 theory theory of Section 15.5, Lagrangian Eq. (14.1), in the mostly-minus signature with $\hbar = c = 1$. The objects are the time-ordered correlators of Theorem 10.18, generated by $Z[J]$ of Theorem 10.11; the diagrammatic value of a graph is read off by the Feynman rules and symmetry factors of Section 15.5. The combinatorial content of every theorem below is purely topological — it is about how graphs decompose — so although we phrase it for ϕ^4 it holds verbatim for any local theory, fermions and gauge fields included once their rules are in hand (Section 15.7 supplies the signs).

15.6.1 The graph-theoretic vocabulary

Before classifying diagrams we must say precisely what a diagram *is*, as a combinatorial object, because every proof in this section is an argument about graphs and the loose pictorial usage of Section 15.5 is not sharp enough to support one.

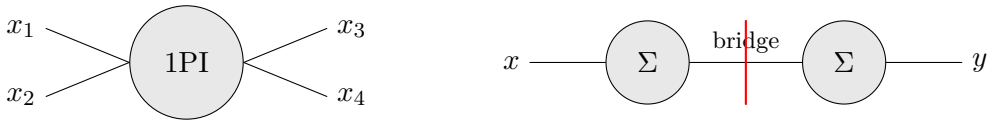
Definition 15.28 (Feynman graph)**.** A *Feynman graph* G for the ϕ^4 theory is a finite graph whose vertices are of two kinds: *external vertices* (or external points), each of degree one and carrying a fixed label $x_1, \dots, x_n$, and *internal vertices*, each of degree four. Its *edges* (*lines*) are of two kinds: an *external line* is incident to an external vertex; an *internal line* joins two internal vertices, or an internal vertex to itself (a *self-loop*, i.e. a tadpole contraction). Each line carries a factor D_F, each internal vertex a factor $-i\lambda$ and an integration $\int d^4y$, and the whole graph is divided by its symmetry factor $S(G) = |\mathrm{Aut}(G)|$, the order of its automorphism group (the rules of Section 15.5). A graph with n external vertices contributes to the n-point function $G^{(n)}$; a graph with $n = 0$ external vertices is a *vacuum graph*.

The two structural notions on which everything turns are connectedness and one-particle irreducibility. Both are standard graph theory; we state them carefully so the proofs can quote them.

Definition 15.29 (Connected and disconnected graphs)**.** A Feynman graph G is *connected* if any two of its vertices are joined by a path of lines; otherwise it is *disconnected*. A maximal connected subgraph of G is a *connected component*.

Every graph is the disjoint union of its connected components, uniquely. A *vacuum bubble* is a connected vacuum graph: a connected graph with no external lines. A correlator graph is *externally connected* if all its external points lie in a single connected component.

Definition 15.30 (One-particle-irreducible graph)**.** A connected Feynman graph G is *one-particle-reducible* (1PR) if there exists a single *internal* line whose removal disconnects G into two pieces, each containing at least one vertex; such a line is a *bridge*. A connected graph that is *not* one-particle-reducible — one that remains connected after the deletion of any single internal line — is *one-particle-irreducible* (1PI), also called *proper*. (External lines are never cut in this test; a graph whose only bridges are external lines is still 1PI.)



(a) one-particle-irreducible

(b) one-particle-reducible

Figure 15.10: One-particle irreducibility. Graph (a) cannot be split into two by deleting any single internal line: it is 1PI (proper). Graph (b) becomes disconnected when the central internal line (the *bridge*, struck through in red) is cut; it is one-particle-reducible, a chain of two self-energy insertions Σ. The content of Theorem 15.39 is that Γ generates exactly the blobs of type (a), and the content of Theorem 15.40 is that the full propagator is the geometric resummation of chains of type (b).

These are graph-topological properties, decided once and for all by inspection of the diagram and independent of any kinematics. Figure 15.10 contrasts the two. The word "particle" in "one-particle-irreducible" is physical: a bridge is a single internal line, which in momentum space carries a single propagator $D_F(k)$, and at $k^2 \to m^2$ that propagator goes on shell — a 1PR graph can develop an intermediate single-particle pole, while a 1PI graph cannot. This is exactly the analytic distinction that makes the 1PI pieces the natural building blocks: they are the "vertices" out of which all single-particle poles are subsequently assembled by resummation.

Finally we fix the generating-functional objects, recalled from Chapter 10 so the section is self-contained at the level of definitions.

Definition 15.31 (Full, connected, and proper correlators)**.** The *full* n-point function is $G^{(n)}(x_1, \dots, x_n) = \langle 0|T\,\phi(x_1)\cdots\phi(x_n)|0\rangle$, generated by $Z[J]$ through

Eq. (10.66). The *connected* n-point function is

$$G_c^{(n)}(x_1,\dots,x_n) \;=\; \frac{1}{i^{\,n-1}}\;\frac{\delta^n W[J]}{\delta J(x_1)\cdots\delta J(x_n)}\bigg|_{J=0}, \qquad W[J]\equiv -i\ln Z[J], \tag{15.106}$$

as in Eqs. (10.201) and (10.202). The *proper* (1PI) n-point function $\Gamma^{(n)}$ is the n-th functional derivative of the effective action $\Gamma[\phi_{\rm cl}]$ of Theorem 10.38, evaluated at the stationary point.

The remainder of this section proves that these three analytic definitions coincide, term by term, with three classes of graphs: $G^{(n)}$ is the sum of *all* graphs with n external points; $G_c^{(n)}$ is the sum of the *connected* ones; and $\Gamma^{(n)}$ is (up to amputation and a sign) the sum of the *1PI* ones.

15.6.2 Disconnected diagrams exponentiate

The first and most important structural fact is that a sum over *all* graphs is the exponential of the sum over *connected* graphs. This single combinatorial identity — the *exponentiation* or *linked-cluster* theorem — underlies both the connectedness of W and the cancellation of vacuum bubbles, so we prove it once, abstractly, and then apply it twice.

The setting is this. Suppose we have a collection of connected graphs, each carrying a value (a number, or a functional of J) that already includes its own internal symmetry factor. Form all graphs by taking disjoint unions of copies of connected graphs. The claim is that the sum of the values of all graphs equals the exponential of the sum of the values of the connected graphs. The only subtlety, and the entire content of the theorem, is the symmetry factor that accompanies a disjoint union of *identical* connected pieces.

Theorem 15.32 (Exponentiation of disconnected graphs)**.** *Let $\{C_a\}_{a\in\mathcal{A}}$ be the set of all topologically distinct connected Feynman graphs of a given external-leg type, and let v_a denote the value of C_a assigned by the Feynman rules of Section 15.5, including its internal symmetry factor $1/S(C_a)$. Then the sum over all (connected and disconnected) graphs of that type equals*

$$\sum_{\text{all graphs } G} (\text{value of } G) \;=\; \exp\Big(\sum_{a\in\mathcal{A}} v_a\Big). \tag{15.107}$$

Proof. A general graph G is, by Theorem 15.29, a disjoint union of connected components, each of which is (a copy of) some C_a. The graph G is therefore completely specified, up to isomorphism, by the multiplicities $\{n_a\}_{a\in\mathcal{A}}$, where $n_a\ge 0$ counts how many copies of C_a appear and only finitely many n_a are nonzero. We must compute the value the Feynman rules assign to such a G and then sum over $\{n_a\}$.

The value of G is the product of the values of its components, corrected by the symmetry factor of G as a whole. The automorphism group of a disjoint union factorizes: an automorphism of G may permute the lines and vertices *within* each connected component, and may additionally permute whole components among themselves *provided it only interchanges isomorphic ones*. Hence

$$\mathrm{Aut}(G) \;\cong\; \Big(\prod_a \mathrm{Aut}(C_a)^{n_a}\Big) \rtimes \Big(\prod_a S_{n_a}\Big), \tag{15.108}$$

the semidirect product of the within-component automorphisms with the symmetric groups S_{n_a} that permute the n_a identical copies of C_a. Taking orders,

$$S(G) = |\mathrm{Aut}(G)| = \Big(\prod_a S(C_a)^{\,n_a}\Big)\Big(\prod_a n_a!\Big). \tag{15.109}$$

The first product is the internal symmetry already contained in the v_a; the second product, $\prod_a n_a!$, is the new *exchange* factor for permuting identical whole components. The value assigned to G is the product of the bare graph contributions divided by $S(G)$, which is exactly

$$(\text{value of } G) = \frac{1}{\prod_a n_a!}\prod_a \Big(\frac{(\text{bare value of } C_a)}{S(C_a)}\Big)^{n_a} = \prod_a \frac{v_a^{n_a}}{n_a!}. \tag{15.110}$$

Now sum over all graphs, i.e. over all tuples $\{n_a\}$ of non-negative integers with finitely many nonzero entries. The sum factorizes over the independent labels a:

$$\sum_{\text{all } G}(\text{value of } G) = \sum_{\{n_a\}}\prod_a \frac{v_a^{n_a}}{n_a!} = \prod_a\Big(\sum_{n_a=0}^{\infty}\frac{v_a^{n_a}}{n_a!}\Big) = \prod_a e^{v_a} = \exp\Big(\sum_a v_a\Big), \tag{15.111}$$

which is Eq. (15.107). □

The proof deserves one line of commentary, because the factor $\prod_a n_a!$ in Eq. (15.109) is the place where the symmetry-factor conventions of Section 15.5 earn their keep. Had we counted diagrams with *labelled* vertices, as the raw Wick expansion of $\exp(iS_{\mathrm{int}})$ first produces them, the $1/n_a!$ would have arisen instead from the $1/V!$ Taylor coefficient of the exponential distributing the $V = \sum_a n_a$ (vertices in C_a) vertices among the components — the same number, reached the other way. The unlabelled, symmetry-factor convention packages this automatically: the exchange of identical components *is* an automorphism of the unlabelled graph, so it is already in $S(G)$, and Eq. (15.107) follows with no leftover combinatorial debt. This is the abstract content of the zero-dimensional and functional versions proved in Theorem 4.28; what Theorem 15.32 adds is that the same identity holds graph-by-graph, with v_a the honest Feynman value of an actual diagram.

15.6.3 $W = -i \ln Z$ generates connected diagrams

We can now identify the diagrammatic content of $W[J]$. Keep the sources: let $W[J]$ and $Z[J]$ be the full functionals, with J attached to external points by the rule that each $\delta/\delta J(x)$ removes one source and exposes one external leg. We organize the diagrams of $Z[J]$ by the connected pieces from which they are built; the connected pieces are themselves J-dependent, since each may carry any number of external legs ending on sources.

Theorem 15.33 ($W[J]$ is the generator of connected diagrams)**.** *With $W[J] = -i \ln Z[J]$ and $Z[J]$ the sum of all Feynman graphs with sources, $iW[J]$ is the sum of all* connected *Feynman graphs with sources. Consequently the connected n-point function Eq. (15.106) is the sum of exactly the connected graphs with n external points,*

$$G_c^{(n)}(x_1, \dots, x_n) = \sum_{\substack{\text{connected graphs } G \\ \text{with legs at } x_1,\dots,x_n}} (\text{value of } G), \tag{15.112}$$

and the full n-point function is recovered from the connected ones by summing over all set partitions of the external points into connected clusters.

Proof. Apply Theorem 15.32 with the source-carrying connected graphs $\{C_a\}$, whose total value is the connected generating functional. Denote $\sum_a v_a \equiv iW[J]$ — the factor of i is dictated by the Minkowski normalization of Eq. (10.201), as we confirm momentarily. The theorem gives at once

$$Z[J] = \sum_{\text{all } G} (\text{value}) = \exp\Big(\sum_a v_a\Big) = \exp\big(iW[J]\big), \tag{15.113}$$

which is precisely $W = -i \ln Z$, Eq. (10.201), now *derived* as the statement that iW collects the connected diagrams. To check the factor of i and extract Eq. (15.112), recall from Eq. (10.66) that the full correlator is generated with one factor of i per leg,

$$G^{(n)} = \frac{1}{i^n} \frac{\delta^n Z}{\delta J(x_1) \cdots \delta J(x_n)}\bigg|_{J=0} \Big/ Z[0], \tag{15.114}$$

so that a connected diagram with n legs, sitting inside $iW = \ln Z$, carries weight i^n in Z and hence weight $i^n/i = i^{n-1}$ inside iW. Differentiating $iW = \sum_a v_a$ n times and dividing by i^{n-1}, exactly as in Eq. (15.106), strips those legs and leaves the connected graphs with unit weight, which is Eq. (15.112).

For the converse statement, expand $Z = e^{iW}$ in powers of iW:

$$\frac{Z[J]}{Z[0]} = \frac{e^{iW[J]}}{e^{iW[0]}} = \exp\big(i(W[J]-W[0])\big) = \sum_{m=0}^{\infty} \frac{1}{m!}\Big(i\,\widehat{W}[J]\Big)^m, \qquad \widehat{W} \equiv W - W[0], \tag{15.115}$$

where $\widehat{W}$ is the connected generator with the vacuum graphs ($n = 0$ legs) removed — those are the J-independent constant $iW[0]$, treated in Section 15.6.4. Differentiating Eq. (15.115) n times in J and setting $J = 0$, the Leibniz rule distributes the n external points among the m connected factors; the term with m factors contributes the sum over all set partitions of $\{x_1, \dots, x_n\}$ into m nonempty blocks, each block furnishing the legs of one connected correlator $G_c^{(k)}$. Collecting all m,

$$G^{(n)}(x_1, \dots, x_n) = \sum_{\pi \vdash \{x_1,\dots,x_n\}} \prod_{B \in \pi} G_c^{(|B|)}(\{x_i\}_{i \in B}), \tag{15.116}$$

the sum running over all partitions π of the external points into blocks B. This is the linked-cluster expansion: every full correlator is the sum over ways of grouping its legs into connected clusters. □

Equation Eq. (15.116) is the all-orders generalization of the two- and four-point relations Eqs. (10.204) and (10.205) verified in Theorem 10.37; at $n = 4$ the partitions into $\{1234\}$ and into $\{12|34\}, \{13|24\}, \{14|23\}$ reproduce exactly the connected four-point plus its three disconnected $2 + 2$ channels. The mechanism that Chapter 10 demonstrated by repeated functional differentiation is here seen for what it is: a statement about how graphs assemble from their connected parts.

Worked Example 15.34 (The connected four-point at $O(\lambda)$ versus its disconnected channels)**.** We confirm Eq. (15.116) concretely at four points and first order in λ, the ϕ^4 theory datum of Section 15.5. At $O(\lambda^0)$ the four-point function is purely disconnected: with $\langle\phi\rangle_0 = 0$ by the $\mathbb{Z}_2$ symmetry (Section 7.3.6), Wick's theorem gives the three pairings

$$G^{(4)}\big|_{O(\lambda^0)} = D_{12}D_{34} + D_{13}D_{24} + D_{14}D_{23}, \qquad D_{ij} \equiv D_F(x_i - x_j), \tag{15.117}$$

each term a product of two propagators in which two pairs of points never communicate — three disconnected graphs, no connected graph at this order. According to Eq. (15.116) these are precisely the partition-into-two-blocks contributions $G_c^{(2)}G_c^{(2)}$, while the single-block contribution $G_c^{(4)}$ starts one order higher. Indeed at $O(\lambda)$ the connected graph appears: one four-point vertex with its four legs running to $x_1, \dots, x_4$,

$$G_c^{(4)}\big|_{O(\lambda)} = (-i\lambda)\int d^4y\; D_F(x_1 - y)D_F(x_2 - y)D_F(x_3 - y)D_F(x_4 - y), \tag{15.118}$$

with symmetry factor 1 (the four legs are distinguishable by their endpoints, so $\mathrm{Aut} = \{e\}$). This single connected graph is what survives in $G_c^{(4)}$; the three products Eq. (15.117) have been removed by the logarithm. Subtracting them from the full $G^{(4)}$ is exactly the operation Eq. (10.205), and Eq. (15.118) is the leading term of the result — the seed of the $2 \to 2$ amplitude $\mathcal{M} = -\lambda$ that LSZ extracts in Chapter 16. The computation makes the abstract partition sum tangible: the disconnected channels live in $G_c^{(2)}G_c^{(2)}$, the physics lives in $G_c^{(4)}$.

15.6.4 Vacuum bubbles and the linked-cluster cancellation

Among the connected graphs are the vacuum bubbles of Theorem 15.29: connected graphs with no external legs, the figure-eight and its descendants. These are the diagrams that drove $\langle 0|\Omega\rangle$ to zero in the canonical treatment of Section 14.2.6 and that the Gell-Mann–Low denominator was built to remove. In the path-integral language they are the constant $W[0] = -i \ln Z[0]$, and their disposal is now a one-line corollary of exponentiation.

Theorem 15.35 (Linked-cluster cancellation of vacuum bubbles)**.** *Let* $\mathcal{V} \equiv \sum_{\text{vacuum bubbles}}(\text{value})$ *be the sum of all connected vacuum graphs. Then the disconnected vacuum contributions exponentiate to a common factor,*

$$Z[0] = \exp(\mathcal{V}), \tag{15.119}$$

and this same factor multiplies the sum of all graphs with any fixed set of external points. Consequently it cancels identically in every normalized *correlator,*

$$G^{(n)}(x_1, \dots, x_n) = \frac{1}{Z[0]} \sum_{\text{all graphs with } n \text{ legs}} (\text{value}) = \sum_{\substack{\text{graphs with } n \text{ legs} \\ \text{and no vacuum bubbles}}} (\text{value}), \tag{15.120}$$

so physical correlators contain only bubble-free diagrams.

Proof. Equation Eq. (15.119) is Theorem 15.32 specialized to graphs with no external points: the connected such graphs are exactly the vacuum bubbles, their total value is $\mathcal{V}$, and the sum over all (disconnected) vacuum graphs is $e^{\mathcal{V}} = Z[0]$. Comparing with Eq. (15.113) at $J = 0$ identifies $\mathcal{V} = iW[0]$.

For the numerator, consider any graph contributing to the unnormalized $\sum_G(\text{value})$ with external points $x_1, \dots, x_n$. By Theorem 15.29 its connected components split into two kinds: those containing at least one external point, and the vacuum bubbles, which contain none. The bubbles are, combinatorially, completely decoupled from the external-bearing components — there is no line joining a bubble to anything — so the same factorization Eq. (15.108)–Eq. (15.111) that proved exponentiation applies to the bubble subsystem alone. The unnormalized sum therefore factorizes as

$$\sum_{\text{all graphs, } n \text{ legs}} (\text{value}) = \Big(\sum_{\substack{\text{graphs, } n \text{ legs} \\ \text{no bubbles}}} (\text{value}) \Big) \cdot e^{\mathcal{V}} = \Big(\sum_{\substack{\text{graphs, } n \text{ legs} \\ \text{no bubbles}}} (\text{value}) \Big) \cdot Z[0]. \tag{15.121}$$

Dividing by $Z[0]$ as in the normalized correlator Eq. (15.114) cancels the bubble factor exactly, leaving Eq. (15.120). □

The economy of the argument is worth pausing on. The bubbles are common to numerator and denominator not by an accident of cancellation but by the

structural fact that they form a decoupled, exponentiating subsystem: $Z[0] = e^{\mathcal{V}}$ *is* the entire bubble series, and the numerator carries one factor of the very same series. This is why the $1/Z[0]$ in the definition of the correlator (Theorem 10.18) and the $\langle\Omega|\Omega\rangle^{-1}$ of the Gell-Mann–Low theorem (Section 14.2.6) are not ad hoc: they are the precise compensation for a divergent, physically inert phase. After the cancellation, no diagram with a disconnected vacuum component ever appears in a physical correlator, and we may — and from now on do — simply discard vacuum bubbles by fiat. This is the general theorem behind the $O(\lambda)$ check Theorem 10.35 of Section 10.7.3.

Worked Example 15.36 (Bubble cancellation in the $O(\lambda)$ two-point function)**.** We exhibit the cancellation explicitly at the first nontrivial order, completing the verification begun in Theorem 10.35. At $O(\lambda)$ the unnormalized two-point numerator $\sum_G$ receives two graphs. The first is the connected self-energy correction: the propagator from x_1 to a vertex y, a self-loop $D_F(0)$ at y, and the propagator from y to x_2,

$$(\text{tadpole}) = \frac{-i\lambda}{2}\int d^4y\; D_F(x_1-y)\, D_F(0)\, D_F(y-x_2), \tag{15.122}$$

with symmetry factor 2 from the self-loop (the two ends of the looped line are interchangeable). The second is disconnected: the free propagator $D_F(x_1-x_2)$ times an isolated vacuum bubble, the figure-eight,

$$(\text{disc.}) = D_F(x_1-x_2)\cdot\Big[\frac{-i\lambda}{8}\int d^4y\; D_F(0)^2\Big], \tag{15.123}$$

the bracket being the single $O(\lambda)$ vacuum bubble, symmetry factor 8. Meanwhile the denominator expands as $Z[0] = 1 + \big[\frac{-i\lambda}{8}\int d^4y\, D_F(0)^2\big] + O(\lambda^2)$, exactly the bracket of Eq. (15.123). Forming the ratio to $O(\lambda)$,

$$\begin{aligned} G^{(2)} &= \frac{D_{12} + (\text{tadpole}) + D_{12}\,\mathcal{V}_1 + O(\lambda^2)}{1 + \mathcal{V}_1 + O(\lambda^2)} \\ &= \big(D_{12} + (\text{tadpole}) + D_{12}\,\mathcal{V}_1\big)(1-\mathcal{V}_1) + O(\lambda^2) \\ &= D_{12} + (\text{tadpole}) + O(\lambda^2), \end{aligned} \tag{15.124}$$

with $\mathcal{V}_1 \equiv \frac{-i\lambda}{8}\int d^4y\, D_F(0)^2$ the $O(\lambda)$ bubble. The disconnected term $D_{12}\mathcal{V}_1$ is cancelled precisely by the $-D_{12}\mathcal{V}_1$ from expanding $1/Z[0]$, leaving only the free propagator and the connected tadpole Eq. (15.122). The vacuum bubble has vanished from the physical correlator, exactly as Theorem 15.35 guarantees, and what remains — the tadpole — is the first contribution to the ϕ^4 self-energy, the object Chapters 21 and 22 will regulate and renormalize.

15.6.5 Amputation: stripping the external propagators

Connectedness and bubble-freedom reduce the correlator to its physically active part, but a connected correlator still carries, on each external leg, a full propagator

running out to the external point x_i. For an S-matrix element these external propagators are redundant: the LSZ formula of Section 14.5 multiplies the momentum-space correlator by an inverse propagator $(p_i^2 - m^2)$ for each leg (up to the field-strength renormalization $\sqrt{Z}$), which cancels the pole of the external propagator and puts the leg on shell. It is therefore natural to define the correlator with those external legs removed in advance.

Definition 15.37 (Amputated Green's function)**.** Let $\widetilde{G}_c^{(n)}(p_1, \dots, p_n)$ be the momentum-space connected n-point function with the overall momentum-conserving delta stripped, defined as in Eq. (15.51) by $\int \big(\prod_i d^4x_i\, e^{ip_i\cdot x_i}\big) G_c^{(n)} = (2\pi)^4\delta^{(4)}\big(\sum_i p_i\big)\, \widetilde{G}_c^{(n)}(p_1, \dots$ Its *amputated* counterpart is obtained by dividing off one full propagator $\widetilde{D}(p_i)$ for each external leg,

$$\widetilde{G}^{(n)}_{\text{amp}}(p_1, \dots, p_n) \;\equiv\; \Big(\prod_{i=1}^{n} \widetilde{D}(p_i)^{-1}\Big)\, \widetilde{G}_c^{(n)}(p_1, \dots, p_n), \tag{15.125}$$

where $\widetilde{D}(p) = \widetilde{G}_c^{(2)}(p)$ is the full (corrected) propagator. Diagrammatically, amputation deletes from each external leg the entire chain of self-energy corrections out to the external point, retaining only the connected "core" to which the external lines attach.

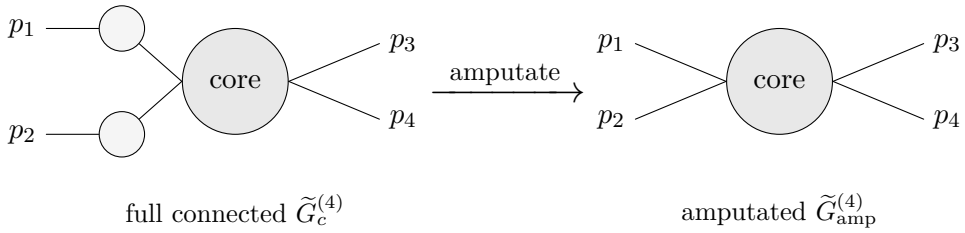


Figure 15.11: Amputation deletes the self-energy dressing on each external leg — formally, multiplies by $\widetilde{D}(p_i)^{-1}$ for each leg — leaving the bare-legged core. The amputated, connected, on-shell core is what LSZ (Section 14.5) turns into the scattering amplitude $\mathcal{M}$.

The point of amputation is the clean statement of LSZ, recalled here from Chapter 14 to complete the link. The momentum-space scattering amplitude is

$$i\mathcal{M}(p_1 \cdots \to \cdots p_n) = \Big(\prod_i \sqrt{Z}\Big)\, \widetilde{G}^{(n)}_{\text{amp}}(p_1, \dots, p_n)\Big|_{p_i^2 = m^2}, \tag{15.126}$$

i.e. the amputated connected correlator, evaluated on shell, with one factor of the field-strength renormalization $\sqrt{Z}$ per leg (Eq. (14.155); at tree level $Z = 1$). Amputation is thus the diagrammatic operation that LSZ performs analytically: the external propagators that Eq. (15.125) divides out are exactly the ones whose on-shell poles LSZ uses up. Figure 15.11 shows the surgery. This is the object

Chapter 16 receives — connected, amputated, on-shell — and integrates against phase space to make a cross section. We note for later that amputation is defined leg-by-leg with the *full* propagator $\widetilde{D}$, so it removes *all* self-energy dressing from the legs, not merely the free propagator; this is what makes the amputated core free of external-leg corrections to all orders.

15.6.6 One-particle irreducibility and the effective action

The amputated connected correlator is still not the smallest building block. A connected amputated graph can itself fall apart when a single *internal* line is cut — it can be one-particle-reducible in the sense of Theorem 15.30. The irreducible cores, the 1PI graphs, are the true atoms of perturbation theory, and the generating functional that produces them is the effective action $\Gamma[\phi_{\mathrm{cl}}]$ of Theorem 10.38. We now establish that connection at the level of the proper vertices.

Definition 15.38 (Proper vertex / 1PI n-point function)**.** The *proper* or *1PI* n-point function $\widetilde{G}^{(n)}_{\mathrm{1PI}}(p_1,\dots,p_n)$ is the sum of all amputated, 1PI graphs with n external legs (momenta p_i, the overall delta stripped). The *self-energy* $\Sigma(p^2)$ is defined through the proper two-point function,

$$\widetilde{G}^{(2)}_{\mathrm{1PI}}(p) \;\equiv\; -\,i\,\Sigma(p^2), \tag{15.127}$$

i.e. $-i\Sigma$ is the sum of all 1PI two-point graphs, amputated.

That these proper vertices are generated by Γ is the statement we now prove. We give the argument in full at two and three points — which already fixes the self-energy and the proper three-point coupling — and state the all-orders result, whose complete tree-graph proof is the business of the effective-action machinery of Chapter 22 (and was carried out in the zero-dimensional model in Theorem 4.35).

Theorem 15.39 (Γ generates the 1PI vertices)**.** *Let $\Gamma[\phi_{\mathrm{cl}}]$ be the effective action Eq. (10.210), the Legendre transform of $W[J]$, and let $\Gamma^{(n)} = \delta^n\Gamma/\delta\phi_{\mathrm{cl}}^n$ evaluated at the stationary configuration. Then the momentum-space proper vertices coincide with the 1PI amputated correlators,*

$$\widetilde{G}^{(n)}_{\mathrm{1PI}}(p_1,\dots,p_n) \;=\; i\,\widetilde{\Gamma}^{(n)}(p_1,\dots,p_n), \qquad n\geq 3, \tag{15.128}$$

while the two-point case reads

$$\widetilde{\Gamma}^{(2)}(p) \;=\; p^2 - m^2 - \Sigma(p^2), \tag{15.129}$$

the full inverse propagator. In particular $\Gamma^{(2)}$ is minus the inverse of $W^{(2)}$, $\int d^4z\, W^{(2)}(x,z)\,\Gamma^{(2)}(z,y) = -\,\delta^{(4)}(x-y)$.

Proof. The starting point is the reciprocity relation between the second derivatives of W and Γ, derived in Eq. (10.213) directly from the Legendre transform: differentiating $\delta W/\delta J = \phi_{\rm cl}$ with respect to $\phi_{\rm cl}$ and using the quantum equation of motion $\delta\Gamma/\delta\phi_{\rm cl} = -J$ (Eq. (10.212)),

$$\int d^4z\, \frac{\delta^2 W}{\delta J(x)\delta J(z)}\, \frac{\delta^2 \Gamma}{\delta\phi_{\rm cl}(z)\delta\phi_{\rm cl}(y)} = -\,\delta^{(4)}(x-y). \tag{15.130}$$

Now $W^{(2)}(x,z) = i\,G_c^{(2)}(x,z) = i\,D(x-z)$ is i times the full propagator (Eqs. (10.207) and (15.106)). Writing $\Gamma^{(2)}(z,y) = \Gamma^{(2)}(z-y)$ by translation invariance and Fourier transforming, Eq. (15.130) becomes the momentum-space reciprocity

$$i\,\widetilde{D}(p)\,\widetilde{\Gamma}^{(2)}(p) = -1 \quad\Longrightarrow\quad \widetilde{D}(p) = \frac{-1}{i\,\widetilde{\Gamma}^{(2)}(p)} = \frac{i}{\widetilde{\Gamma}^{(2)}(p)}. \tag{15.131}$$

To identify $\widetilde{\Gamma}^{(2)}$ diagrammatically, sum the full propagator as a geometric series in 1PI insertions. By Theorem 15.30, any connected two-point graph is either 1PI or has a bridge; cutting at the *first* bridge expresses it as a 1PI block followed by the rest, and iterating exhibits every two-point graph uniquely as a chain of 1PI blocks $-i\Sigma$ joined by free propagators $D_0(p) = i/(p^2 - m^2 + i\varepsilon)$:

$$\widetilde{D}(p) = D_0 + D_0(-i\Sigma)D_0 + D_0(-i\Sigma)D_0(-i\Sigma)D_0 + \cdots = \frac{D_0}{1 + i\Sigma D_0}. \tag{15.132}$$

Substituting $D_0 = i/(p^2 - m^2)$ (suppressing $i\varepsilon$) gives $i\Sigma D_0 = -\Sigma/(p^2 - m^2)$ and hence

$$\widetilde{D}(p) = \frac{i/(p^2-m^2)}{1 - \Sigma/(p^2-m^2)} = \frac{i}{p^2 - m^2 - \Sigma(p^2)}. \tag{15.133}$$

Comparing with Eq. (15.131), $i/\widetilde{\Gamma}^{(2)} = i/(p^2 - m^2 - \Sigma)$, forces $\widetilde{\Gamma}^{(2)}(p) = p^2 - m^2 - \Sigma(p^2)$, which is Eq. (15.129) and reduces to the tree value $p^2 - m^2$ of Eq. (10.214) when $\Sigma \to 0$. With $\widetilde{G}^{(2)}_{\rm 1PI} = -i\Sigma$ by Eq. (15.127), this also reads $\widetilde{\Gamma}^{(2)} = (p^2 - m^2) - i\,\widetilde{G}^{(2)}_{\rm 1PI}$; the kinematic $p^2 - m^2$ is the inverse *free* propagator, i.e. the contribution of the bare two-point "vertex" $i\widetilde{\Gamma}^{(2)}_{\rm free} = i(p^2 - m^2) = D_0^{-1}\cdot i^2$, consistent with the general rule Eq. (15.128) once the free term is included.

For $n \geq 3$ the argument is the standard induction, which we now run at $n = 3$ to display the mechanism. Differentiate the reciprocity relation $\delta W/\delta J(x_1) = \phi_{\rm cl}(x_1)$ a second and third time, converting $\delta/\delta\phi_{\rm cl}$ into $\delta/\delta J$ via the chain rule $\delta/\delta\phi_{\rm cl}(y) = \int d^4z\,(\delta J(z)/\delta\phi_{\rm cl}(y))\,\delta/\delta J(z) = -\int d^4z\,\Gamma^{(2)}(y,z)\,\delta/\delta J(z)$, where the last equality used Eq. (10.212). Applying this to $W^{(2)}$ and using Eq. (15.130) to trade derivatives, one finds after Fourier transforming

$$\widetilde{W}^{(3)}(p_1,p_2,p_3) = -\,\widetilde{W}^{(2)}(p_1)\,\widetilde{W}^{(2)}(p_2)\,\widetilde{W}^{(2)}(p_3)\,\widetilde{\Gamma}^{(3)}(p_1,p_2,p_3), \tag{15.134}$$

the three-point connected function with one full propagator $\widetilde{W}^{(2)} = i\widetilde{D}$ on each leg times the proper vertex $\widetilde{\Gamma}^{(3)}$. Amputating, i.e. stripping the three full propagators as in Eq. (15.125), leaves $\widetilde{G}^{(3)}_{\text{amp}} = i\widetilde{\Gamma}^{(3)}$ (the factors of i from $\widetilde{W}^{(2)} = i\widetilde{D}$ and the normalization Eq. (15.106) combine to the single i of Eq. (15.128)). It remains to see that this amputated three-point function is 1PI. A connected three-point graph that is one-particle-reducible has a bridge; cutting it yields a two-point part and a one-point part joined by a single propagator, but a connected amputated three-point graph has had all external propagators removed, so any surviving bridge would be internal — and the only way an amputated 3-point graph can have an internal bridge is for one external leg to attach through a self-energy chain, which amputation has already deleted. Hence the amputated connected three-point function *is* the 1PI three-point function, $\widetilde{G}^{(3)}_{\text{amp}} = \widetilde{G}^{(3)}_{\text{1PI}} = i\widetilde{\Gamma}^{(3)}$, which is Eq. (15.128) at $n = 3$. The induction to general n proceeds identically: each further ϕ_{cl}-derivative either attaches a new proper vertex or splits an existing full-propagator leg, generating exactly the tree graphs built from lower proper vertices and full propagators; the irreducible remainder at n legs is $i\widetilde{\Gamma}^{(n)}$. The complete bookkeeping is carried out in Theorem 4.35 for the zero-dimensional generator and reproduced functionally in Chapter 22; the structure is identical and we do not repeat the full recursion here. □

The theorem closes the hierarchy of generators with a clean physical statement: Z knows all diagrams, W keeps the connected ones, and Γ distills them to the 1PI skeletons. For ϕ^4 theory this names the two objects that the renormalization chapters take as their targets. The *self-energy* $\Sigma(p^2) = i\,\widetilde{G}^{(2)}_{\text{1PI}}(p)$ is the sum of 1PI two-point diagrams — its first contribution is the tadpole Eq. (15.122) of Theorem 15.36 — and through Eq. (15.129) it shifts the pole of the propagator from m^2 to the physical mass, the computation renormalized in Chapter 22. The *proper four-point function* $\widetilde{G}^{(4)}_{\text{1PI}} = i\widetilde{\Gamma}^{(4)}$ is the 1PI four-point vertex, the amputated coupling whose tree value is the bare vertex $-i\lambda$ and whose one-loop corrections (the s-, t-, u-channel bubbles) are the divergent diagrams of Chapter 21 that the coupling counterterm δ_λ absorbs in Chapter 22. These two 1PI objects — self-energy and proper four-point — are the entire renormalization content of ϕ^4, and identifying them is the structural obligation this section discharges for the thread.

15.6.7 The hierarchy and the tree relation

The three classes assemble into a strict hierarchy that is worth stating as the organizing principle of all that follows. Reading from the most to the least information:

$$\underbrace{Z[J]}_{\text{all graphs}} \xrightarrow{\;-i\ln\;} \underbrace{W[J]}_{\text{connected}} \xrightarrow{\;\text{Legendre}\;} \underbrace{\Gamma[\phi_{\text{cl}}]}_{\text{1PI}}. \tag{15.135}$$

The logarithm discards the disconnected diagrams (Theorem 15.33) and, with the $Z[0]$ normalization, the vacuum bubbles (Theorem 15.35); the Legendre transform discards the one-particle-reducible diagrams (Theorem 15.39). Crucially, the hierarchy is invertible: nothing is lost going from Γ back up to W, because the reducible and disconnected diagrams that Γ omits are entirely determined by the irreducible ones through the tree rules of the Legendre transform. The connected correlators are *tree graphs built from the proper vertices* $\Gamma^{(n)}$ *as couplings and the full propagators* $\widetilde{D}$ *as lines.* This is the precise sense in which the 1PI vertices are the complete data of the theory.

The cleanest instance — and the one every later chapter uses — is the reconstruction of the full propagator from the self-energy, already encountered as Eq. (15.132) inside the proof above. We isolate it as a theorem because it is the prototype of all such resummations.

Theorem 15.40 (Dyson resummation of the full propagator)**.** *The full (connected, two-point) propagator is the geometric series of free propagators joined by 1PI self-energy insertions,*

$$\widetilde{D}(p) \;=\; \frac{i}{p^2 - m^2 - \Sigma(p^2) + i\varepsilon}, \qquad -i\Sigma(p^2) = \widetilde{G}^{(2)}_{\mathrm{1PI}}(p), \tag{15.136}$$

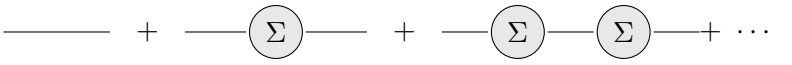
where Σ *is the sum of 1PI two-point graphs. The physical mass* m^2_{ph} *is the location of the pole,* $m^2_{\mathrm{ph}} - m^2 - \Sigma(m^2_{\mathrm{ph}}) = 0$*, and the residue defines the field-strength renormalization* $Z = [1 - \Sigma'(m^2_{\mathrm{ph}})]^{-1}$*.*

Proof. Equation Eq. (15.136) is Eq. (15.133), restoring the $i\varepsilon$. The decomposition of an arbitrary two-point graph into a unique chain of 1PI blocks is Theorem 15.30: read the graph from the left external leg; the first internal line that is a bridge separates the leading 1PI block from the remainder, and recursion on the remainder yields the unique factorization $D_0[(-i\Sigma)D_0]^k$. Summing the geometric series $\sum_k D_0[(-i\Sigma)D_0]^k = D_0/(1 + i\Sigma D_0)$ and inserting $D_0 = i/(p^2 - m^2 + i\varepsilon)$ gives Eq. (15.136). The pole condition and residue follow by expanding the denominator about its zero: near $p^2 = m^2_{\mathrm{ph}}$, $p^2 - m^2 - \Sigma(p^2) \approx (p^2 - m^2_{\mathrm{ph}})[1 - \Sigma'(m^2_{\mathrm{ph}})]$, so $\widetilde{D} \approx iZ/(p^2 - m^2_{\mathrm{ph}})$ with $Z = [1 - \Sigma'(m^2_{\mathrm{ph}})]^{-1}$. □

Worked Example 15.41 (The dressed propagator at one loop in ϕ^4)**.** We illustrate Theorem 15.40 with the leading ϕ^4 theory self-energy, the tadpole Eq. (15.122) of Theorem 15.36. In momentum space the amputated 1PI two-point graph is the single closed loop attached at one vertex,

$$-i\Sigma\big|_{O(\lambda)} = \frac{-i\lambda}{2} \int \frac{d^4k}{(2\pi)^4}\, \frac{i}{k^2 - m^2 + i\varepsilon}, \tag{15.137}$$

the symmetry factor $\frac{1}{2}$ from the loop, so that $\Sigma|_{O(\lambda)} = \frac{\lambda}{2} \int \frac{d^4k}{(2\pi)^4} \frac{1}{k^2 - m^2 + i\varepsilon}$ is a momentum-independent constant (it is p-independent because the loop carries



$$\widetilde{D} = D_0 + D_0(-i\Sigma)D_0 + D_0(-i\Sigma)D_0(-i\Sigma)D_0 + \cdots$$

Figure 15.12: Dyson resummation. The full propagator $\widetilde{D}$ is the sum over all chains of one-particle-irreducible self-energy blobs $-i\Sigma$ strung along free propagators D_0. The geometric series sums to $\widetilde{D} = i/(p^2 - m^2 - \Sigma)$, Eq. (15.136): an infinite set of reducible diagrams repackaged into a single dressed line built from the one irreducible object Σ.

no external momentum). Being constant, this contribution is a pure mass shift: Eq. (15.136) gives

$$\widetilde{D}(p) = \frac{i}{p^2 - m^2 - \Sigma} = \frac{i}{p^2 - (m^2 + \Sigma)}, \tag{15.138}$$

the free form with $m^2 \to m^2 + \Sigma$, and since $\Sigma' = 0$ here the residue is unchanged, $Z = 1$ at this order. The integral in Eq. (15.137) is quadratically divergent; that it must be is the subject of the power counting in Chapter 21, and its absorption into a mass counterterm δ_m via the renormalization condition $m^2_{\text{ph}} = m^2 + \Sigma(m^2_{\text{ph}}) + \delta_m$ is the subject of Chapter 22. What the present section establishes is the *structure* that makes that program possible: the divergence sits in a single 1PI object Σ, the dressed propagator is the geometric resummation Eq. (15.136) of that object, and the resummation is exact to all orders in the insertion — so renormalizing Σ renormalizes the propagator once and for all.

The hierarchy Eq. (15.135) is the architecture on which the rest of perturbation theory is built, and the tree relation $\Gamma \to W$ is its load-bearing beam. Two destinations follow immediately. The connected, amputated, on-shell vertices of Theorem 15.37 and Eq. (15.126) are precisely the amplitudes that Chapter 16 integrates against Lorentz-invariant phase space to produce cross sections and decay rates, completing the passage from formalism to number for the $2 \to 2$ process of ϕ^4 theory. The 1PI organization of Theorem 15.39 — self-energy and proper vertices, dressed propagator by Dyson resummation — is the form in which divergences appear as corrections to a finite set of proper vertices, the starting point for the power counting of Chapter 21, the counterterm program of Chapter 22, and the effective potential of Chapter 29, where the value of Γ at constant ϕ_{cl} becomes the order parameter for spontaneous symmetry breaking. With the diagrams sorted into these classes and the generators that produce them established, the machinery is ready to meet fermions, whose anticommuting statistics will modify the rules with the relative signs and closed-loop factor of the next section.

15.7 Fermions and Gauge Fields: Sign Rules and the Fermion Loop

The bosonic side of the summary is now closed. Section 15.5 extracted the position- and momentum-space Feynman rules for a scalar field from the generating functional, the architecture section that followed sorted the resulting diagrams into connected, amputated, and one-particle-irreducible classes, and ϕ^4 theory produced its first amplitude two independent ways. Every ingredient in that construction—the propagator as the source kernel of $Z[J]$, the vertex as a functional derivative of iS_{int}, the symmetry factor as the order of the diagram's automorphism group—was built on one structural fact: the generating functional is a Gaussian in commuting sources, so its correlators are *unsigned* sums over pairings. A real scalar contracts with itself, every pairing enters with weight $+1$, and a permanent of propagators results.

Fermions change exactly one thing, and they change it everywhere. The Dirac field is anticommuting, its sources are Grassmann (Theorem 12.3), and its generating functional—derived in full in Theorem 12.42—pairs two *distinct* source species $\bar{\eta}, \eta$ in a fixed order. The combinatorial consequence, the fermionic Wick theorem of Theorem 12.44, replaces the permanent by a *determinant*: the same sum over pairings, but each term weighted by the signature of its pairing permutation. Two new pieces of bookkeeping follow, and this section is devoted to deriving them once, cleanly, so that Part V and Part VII inherit a complete rule set rather than rebuilding it. The first is the directed propagator line, an arrowed S_F whose orientation records the flow of fermion number. The second is the family of relative signs that the determinant structure forces: a relative minus between any two diagrams related by exchanging a pair of identical external fermions, and—the single most consequential rule in perturbation theory—an overall factor of -1 together with a Dirac trace for every closed fermion loop. None of these signs is a convention imposed by hand; each is forced by the anticommutation of the Grassmann fields, and we track the anticommutation explicitly each time.

We keep the chapter conventions in force: mostly-minus metric $\eta_{\mu\nu} = \text{diag}(+,-,-,-)$ so that $p^2 = m^2$ on shell; natural units $\hbar = c = 1$; the Feynman $i\varepsilon$ prescription. The Dirac propagator and its arrow convention are imported unaltered from Chapters 11 and 12; the gamma-matrix algebra and the trace technology that the loops generate live in Section C.6 and are cited, not relisted. The aim is operational: by the end of the section a reader will be able to translate any fermion–boson interaction into directed lines, vertices, the correct signs, and—for closed loops—a trace, and will know precisely where each piece came from.

15.7.1 The directed fermion line

The bosonic Feynman rule assigns to each internal line the momentum-space propagator $\tilde{D}_F(p) = i/(p^2 - m^2 + i\varepsilon)$, an undirected object: a scalar line carries no orientation because ϕ is its own conjugate and $\langle 0|\mathcal{T}\,\phi(x)\phi(y)|0\rangle$ is symmetric in $x \leftrightarrow y$. The fermion line is different in exactly the way the propagator is different. The free two-point function is the time-ordered product of two *distinct* fields, ψ and $\bar{\psi}$, computed in Theorem 12.43 as

$$\overbrace{\psi(x)\,\bar{\psi}(y)} \;=\; \langle 0|\mathcal{T}\,\psi(x)\bar{\psi}(y)|0\rangle \;=\; S_F(x-y), \qquad \overbrace{\psi\,\psi} = \overbrace{\bar{\psi}\,\bar{\psi}} = 0, \tag{15.139}$$

the contraction rules Eq. (12.169). Two features of Eq. (15.139) translate directly into the diagram. First, the only nonvanishing contraction joins a ψ to a $\bar{\psi}$: a fermion line always runs from a $\bar{\psi}$ at one end to a ψ at the other, and can never join two ψ's or two $\bar{\psi}$'s. Second, $S_F(x-y)$ is a 4×4 matrix in Dirac space and is *not* symmetric under $x \leftrightarrow y$; the order of its arguments matters, and the diagram must record it. Both facts are encoded by drawing the line with an arrow.

Definition 15.42 (The internal fermion line)**.** An internal fermion line is drawn as a directed line carrying an arrow. The arrow points *from the $\bar{\psi}$ end toward the ψ end* of the contraction Eq. (15.139), i.e. in the direction of flow of the conserved $U(1)$ fermion-number charge of Theorem 11.32. To a line carrying four-momentum p in the direction of its arrow, the momentum-space rule assigns the propagator

$$\tilde{S_F}(p) \;=\; \frac{i(\not{p} + m)}{p^2 - m^2 + i\varepsilon} \;=\; \frac{i}{\not{p} - m + i\varepsilon}, \tag{15.140}$$

a matrix carrying a Dirac index a at the head (the ψ end) and b at the tail (the $\bar{\psi}$ end), $\big(\tilde{S_F}(p)\big)_{ab}$.

This is precisely the object built canonically in Eq. (11.195) and rederived from the path integral in Eq. (12.162); the two pillars agree term for term, and Eq. (15.140) is what every fermion line in the rest of the book evaluates to. The arrow does double duty. As a bookkeeping device it tells us, unambiguously and locally, which Dirac index of $\tilde{S_F}$ attaches to which vertex, so that the matrices along a line multiply in a definite order. As physics it records charge flow: read with $p^0 > 0$ in the arrow direction the line is an electron propagating forward in time, while the opposite sign of p^0 is the same line reinterpreted as a positron propagating backward—the two residues at $p^0 = \pm E_{\mathbf{p}}$ noted under Eq. (11.195). We adopt the convention, fixed in Fig. 11.4, that loop and internal momenta are routed *along* the arrows wherever possible; momentum conservation at each vertex is imposed exactly as in the bosonic rules of Section 15.5, and is unaffected by the orientation.

The arrows are conserved at every vertex of the theories we will build. A QED or Yukawa vertex contains exactly one ψ and one $\bar{\psi}$, so exactly one arrow enters

and one leaves: fermion lines never begin or end in the interior of a diagram but thread continuously through it, either running from one external fermion to another along an open path or closing on themselves in a loop. This conservation is the diagrammatic image of the charge conservation made automatic in Theorem 12.43, where the vanishing of $\langle \mathcal{T}\, \psi\psi \rangle$ and $\langle \mathcal{T}\, \bar{\psi}\bar{\psi} \rangle$ guaranteed one ψ for every $\bar{\psi}$.

Notation Watch: external-leg factors are deferred to Chapter 17

An external fermion line terminates not on a propagator but on the LSZ amputation of Section 14.5 followed by an on-shell spinor wavefunction: $u^s(p)$ for an incoming particle, $\bar{u}^s(p)$ for an outgoing particle, $\bar{v}^s(p)$ for an incoming antiparticle, and $v^s(p)$ for an outgoing antiparticle, each read at the appropriate end of the arrow. The arrow on an external particle line points into the diagram in the direction of motion; on an antiparticle line it points against it. These wavefunctions and the spin sums $\sum_s u^s \bar{u}^s = \not{p} + m$, $\sum_s v^s \bar{v}^s = \not{p} - m$ of Eq. (11.73) are the substrate of the trace technology that Part V exercises; we state them here for completeness but develop the assembly of a complete amplitude—and the spin-averaging that turns $\mathcal{M}$ into $|\mathcal{M}|^2$—in Chapter 17, where QED computes $e^+e^- \to \mu^+\mu^-$. This section's business is the rules *internal* to a diagram: lines, vertices, and signs.

15.7.2 The fermion–boson vertex

The vertex rule is read off an interaction term exactly as in the bosonic case, and the derivation is the same one functional differentiation that produced the ϕ^4 vertex in Section 15.5, now applied to a term bilinear in the fermion fields. Consider the most general local, Lorentz-invariant, Hermitian interaction coupling a single Dirac field to a boson field Φ through a fermion bilinear,

$$\mathcal{L}_{\text{int}} \;=\; -\, g\, \bar{\psi}\, \Gamma\, \psi\, \Phi, \tag{15.141}$$

where g is a real coupling and Γ is a fixed matrix in Dirac (and possibly flavor) space carrying whatever Lorentz indices Φ carries, contracted with it. This single template covers the cases we need: the *Yukawa* coupling of a real scalar takes $\Phi = \phi$ and $\Gamma = \mathbf{1}$ (or $\Gamma = i\gamma^5$ for a pseudoscalar); the *gauge* coupling of a vector takes $\Phi = A_\mu$ and $\Gamma = \gamma^\mu$.

The perturbative expansion of any correlator inserts the interaction through $\exp(i \int d^4x\, \mathcal{L}_{\text{int}})$, and each vertex of a diagram corresponds to one factor of $i\mathcal{L}_{\text{int}}$ brought down from this exponential and integrated over its spacetime point, with the fields it contains contracted into the adjacent lines by the Wick theorem Theorem 12.44. The amputated momentum-space vertex is therefore i times the field-stripped coefficient of the relevant monomial in $\mathcal{L}_{\text{int}}$. Because the three

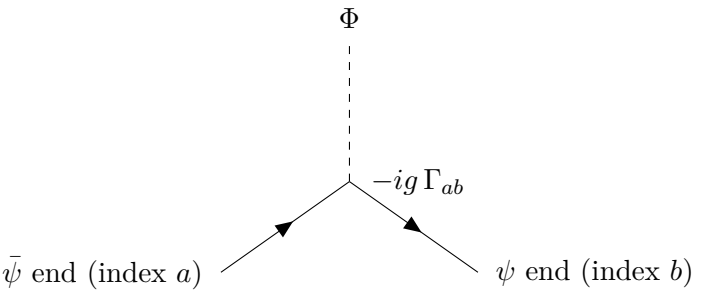


Figure 15.13: The generic fermion–boson vertex Eq. (15.142) from the interaction Eq. (15.141). The fermion arrow flows continuously *through* the vertex, entering on the $\bar\psi$ side (Dirac row index a) and leaving on the ψ side (column index b); the matrix Γ sits between them. The boson line (drawn dashed for a scalar; a wavy line for a photon) attaches through the Lorentz/internal index Γ shares with Φ. Specializations: Yukawa scalar, $\Gamma = \mathbf{1}$, factor $-ig$; QED, $\Gamma = \gamma^\mu$, factor $-ie\gamma^\mu$.

fields $\bar\psi$, ψ, Φ in Eq. (15.141) are mutually distinct, there is no symmetry factor to cancel—unlike the ϕ^4 vertex, where the four identical ϕ's contributed a 4! that cancelled the 1/4! in the coupling. Stripping the three fields off $i\mathcal{L}_{\text{int}} = -ig\,\bar\psi\Gamma\psi\,\Phi$ leaves the rule directly.

Definition 15.43 (The fermion–boson vertex)**.** The interaction Eq. (15.141) contributes the momentum-space vertex

$$\boxed{-\,i\,g\,\Gamma\,,} \tag{15.142}$$

a matrix in Dirac space whose row index attaches to the fermion line entering the vertex (the $\bar\psi$, against the arrow) and whose column index attaches to the line leaving it (the ψ, along the arrow), with the boson line attached through whatever Lorentz/internal index Γ and Φ share. Each vertex carries a four-momentum-conserving factor $(2\pi)^4\delta^4(\sum p)$ and is integrated over its position, exactly as in Section 15.5.

The two specializations the book needs follow by inspection, and we record them now so that Chapters 17 and 26 can take them as given.

The QED vertex. The QED Lagrangian frozen for QED is $\mathcal{L}_{\text{QED}} = \bar\psi(i\not{D} - m)\psi - \frac{1}{4}F_{\mu\nu}F^{\mu\nu}$ with $D_\mu = \partial_\mu + ieA_\mu$ (electron charge $-e$, $e > 0$). Expanding the covariant derivative,

$$\bar\psi\, i\not{D}\,\psi = \bar\psi\, i\gamma^\mu(\partial_\mu + ieA_\mu)\,\psi = \bar\psi\, i\not{\partial}\,\psi \;-\; e\,\bar\psi\gamma^\mu\psi\,A_\mu, \tag{15.143}$$

so the interaction term is $\mathcal{L}_{\text{int}} = -e\,\bar\psi\gamma^\mu\psi\,A_\mu$, which is exactly Eq. (15.141) with $g = e$, $\Phi = A_\mu$, and $\Gamma = \gamma^\mu$. The vertex rule Eq. (15.142) therefore gives

$$\boxed{-\,i\,e\,\gamma^\mu\,,} \tag{15.144}$$

the electron–photon vertex, with μ the Lorentz index of the attached photon line. This is the template Chapter 17 specializes and uses without re-deriving; the photon line, photon propagator (Eq. (13.182)), and the spin-sum machinery are assembled around it there.

The Yukawa vertex. For a real scalar coupled as $\mathcal{L}_{\rm int} = -g\,\bar\psi\psi\,\phi$, the matrix is $\Gamma = \mathbf{1}$ and the vertex is simply $-ig\,\mathbf{1}$, the identity in Dirac space; for the pseudoscalar coupling $-ig\,\bar\psi\, i\gamma^5\,\psi\,\phi$ it is $g\gamma^5$. These are the vertices of the meson–nucleon and Higgs–fermion couplings, used in Chapter 30 and beyond.

The index-flow statement in Theorem 15.43 deserves emphasis because it dictates the order in which matrices are written. Read *against* the arrow of the fermion line, a continuous open line that enters the diagram, passes through vertices $V_1, V_2, \dots$ separated by propagators, and exits, contributes the matrix string

$$(\text{outgoing spinor})\;\big(-ig\Gamma_{V_1}\big)\,\tilde S_F\,\big(-ig\Gamma_{V_2}\big)\,\tilde S_F\,\cdots\,(\text{incoming spinor}), \tag{15.145}$$

with each factor's row index contracted into the column index of the factor to its left. The rule "write the matrices against the arrow" is not a separate postulate: it is the order in which the Dirac indices of Eq. (15.140) and Eq. (15.142) actually contract, dictated by which index attaches where. For a closed line—a loop—there is no incoming or outgoing spinor to terminate the string, and the indices close on themselves; that closure is a trace, and producing it correctly, with its sign, is the subject of the next two subsections.

15.7.3 The relative sign between exchange diagrams

We now derive the first of the two sign rules directly from the fermionic Wick theorem, in the form that diagrams use it. The cleanest place to see it is the object already computed in full in Theorem 12.45: the free four-point function with two ψ's and two $\bar\psi$'s,

$$\langle 0|\mathcal{T}\,\psi(x_1)\psi(x_2)\bar\psi(y_1)\bar\psi(y_2)|0\rangle \;=\; -\,S_F(x_1{-}y_1)S_F(x_2{-}y_2) + S_F(x_1{-}y_2)S_F(x_2{-}y_1), \tag{15.146}$$

which is Eq. (12.174). The combinatorial content is transparent. A ψ contracts only with a $\bar\psi$, so there are exactly two ways to pair the fields: the *direct* pairing $(\psi_1\bar\psi_1)(\psi_2\bar\psi_2)$ and the *exchange* pairing $(\psi_1\bar\psi_2)(\psi_2\bar\psi_1)$. The two enter with *opposite* signs. This relative minus is the whole of fermionic statistics at tree level, and it is forced, not inserted: in the derivation of Theorem 12.45 every sign came from a single application of the Grassmann anticommutation rule, never from a choice.

Diagrammatically, the two terms of Eq. (15.146) are two ways of joining the four external points with directed lines, drawn in Fig. 15.14. They are topologically distinct: the exchange diagram is obtained from the direct one

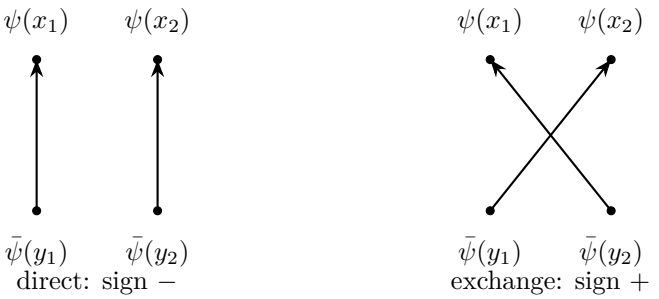

Figure 15.14: The two contraction patterns of Eq. (15.146), the diagrammatic content of Fig. 12.3. Each directed line is a propagator S_F running along the fermion-number arrow. The exchange pattern (right) differs from the direct one (left) by a single crossing of the lines—one transposition of adjacent anticommuting operators—and so carries the opposite relative sign. This is the origin of the relative minus between the direct and exchange (annihilation) graphs in Bhabha and Møller scattering (Chapter 18).

by swapping the endpoints of the two outgoing lines, which crosses the two propagators. Each crossing is one transposition of adjacent anticommuting operators in the contraction, hence one factor of -1. This gives the diagrammatic rule in its operational form.

Proposition 15.44 (Relative sign of exchange)**.** *Two diagrams contributing to the same amplitude that differ only by the interchange of two identical external fermions (two incoming particles, two outgoing particles, or a particle and the corresponding antiparticle treated as identical lines) contribute with* opposite *relative sign. More generally, the sign of a given contraction pattern is the signature of the permutation that brings every contracted ψ–$\bar{\psi}$ pair into adjacency in the order $\psi\,\bar{\psi}$, exactly the sign in the fermionic Wick sum Eq. (12.170).*

Proof. The amplitude is, by LSZ (Section 14.5), built from the time-ordered correlator with external legs amputated and put on shell; the relative sign between two contraction patterns survives amputation untouched, because amputation acts independently on each external leg and introduces no reordering of the fermion operators. It therefore suffices to establish the sign at the level of the correlator, where it is Eq. (12.170): each term carries the signature of the permutation σ pairing the ψ's with the $\bar{\psi}$'s. Two patterns related by exchanging two external fermions differ precisely by composing σ with one transposition, which flips $\mathrm{sgn}(\sigma)$. The $n = 2$ instance is Eq. (15.146), whose two terms are the identity and the single transposition, carrying -1 and $+1$ respectively; the relative sign is -1. □

Caution: relative sign is physical, overall sign is not

The *overall* sign of a single fermionic diagram depends on the order in which one chooses to write the external operators in the correlator—a convention. What is physical, and what the Feynman rules must reproduce, is the *relative* sign between diagrams contributing to the same process. In practice one fixes a reference ordering of the external fermions, assigns that diagram a $+$, and then assigns every other diagram the sign of the permutation of external fermion lines that relates it to the reference. The interference term in $|\mathcal{M}|^2 = |\mathcal{M}_{\text{direct}} + \mathcal{M}_{\text{exch}}|^2$ then carries the correct relative minus, and it is this interference—never an isolated overall sign—that appears in a cross section.

15.7.4 The closed fermion loop: the -1 and the trace

The second sign rule governs closed fermion lines, and it is the one that distinguishes a fermion from a boson in every loop computation in the book. We derive it here from the same anticommutation that produced the exchange sign, tracking the reordering explicitly; the result was obtained independently in Chapter 12 from the placement of the fermion determinant in the numerator of the generating functional (Theorem 12.49), and the two derivations must—and do—agree.

Consider a diagram in which n vertices of the generic type Eq. (15.141) are joined into a single closed fermion loop, the boson legs at each vertex attaching to the rest of the diagram. Each vertex carries the operator bilinear $\bar{\psi}(x_i)\,\Gamma_i\,\psi(x_i)$, written in components as $\bar{\psi}_{a_i}(x_i)\,(\Gamma_i)_{a_i b_i}\,\psi_{b_i}(x_i)$, and the loop is the contraction pattern that joins $\psi(x_i)$ to $\bar{\psi}(x_{i+1})$ for $i = 1, \dots, n-1$ and finally closes $\psi(x_n)$ back onto $\bar{\psi}(x_1)$. The piece of the correlator we must evaluate is the contraction of the product of bilinears,

$$\mathcal{L} \;=\; \overbrace{[\bar{\psi}(x_1)\Gamma_1\psi(x_1)]\,[\bar{\psi}(x_2)\Gamma_2\psi(x_2)]\cdots[\bar{\psi}(x_n)\Gamma_n\psi(x_n)]}, \tag{15.147}$$

in the ring pattern just described. Two things must be extracted: the Dirac index structure (which will close into a trace) and the overall sign (which will be -1).

The trace. Each bilinear is a Grassmann-even object, so the n blocks $[\bar{\psi}(x_i)\Gamma_i\psi(x_i)]$ commute with one another freely; no sign arises from reordering whole blocks. Within the string, $\psi(x_i)$ stands immediately to the left of $\bar{\psi}(x_{i+1})$ for each $i = 1, \dots, n-1$, so these $n-1$ contractions are already in the order $\psi\,\bar{\psi}$ and evaluate with no sign to

$$\overbrace{\psi_{b_i}(x_i)\,\bar{\psi}_{a_{i+1}}(x_{i+1})} \;=\; \big(S_F(x_i - x_{i+1})\big)_{b_i a_{i+1}}. \tag{15.148}$$

Stringing the vertex matrices and these propagators together, the Dirac indices contract head-to-tail: $(\Gamma_1)_{a_1b_1}(S_F)_{b_1a_2}(\Gamma_2)_{a_2b_2}(S_F)_{b_2a_3}\cdots(\Gamma_n)_{a_nb_n}$, leaving the two open indices a_1 (on the first vertex) and b_n (on the last propagator's ψ end). The final contraction $\psi(x_n)$–$\bar\psi(x_1)$ joins b_n back to a_1, and the index structure closes on itself: a sum over the single repeated index is a trace,

$$(\Gamma_1)_{a_1b_1}(S_F)_{b_1a_2}\cdots(\Gamma_n)_{a_nb_n}(S_F)_{b_na_1} \;=\; \mathrm{tr}\big[\Gamma_1\,S_F(x_1{-}x_2)\,\Gamma_2\,S_F(x_2{-}x_3)\cdots\Gamma_n\,S_F(x_n{-}x_1)\big]. \tag{15.149}$$

The trace runs over the Dirac (and, if Γ_i carry them, flavor and color) indices of the matrices encountered in one circuit of the loop, read in the order in which the arrow visits the vertices. This is the diagrammatic statement of the rule "a closed fermion loop carries a trace," and Eq. (15.149) fixes the order of the factors inside it.

The sign. It remains to evaluate the closing contraction $\psi(x_n)$–$\bar\psi(x_1)$, and here the single minus appears. After the $n-1$ internal contractions Eq. (15.148) have been pulled out as c-number matrices (which, being Grassmann-even, may be moved freely past anything), the two operators still to be contracted sit at opposite ends of the string: $\bar\psi(x_1)$ is the leftmost surviving field and $\psi(x_n)$ is the rightmost. They are in the order $\bar\psi(x_1)\cdots\psi(x_n)$—that is, $\bar\psi$ before ψ. But the contraction rule Eq. (15.139) is stated for the order $\psi\,\bar\psi$. To bring them into that order we anticommute the two fields past each other, which inside the time-ordered contraction means

$$\overbrace{\bar\psi_{a_1}(x_1)}\,\psi_{b_n}(x_n) \;=\; -\,\overbrace{\psi_{b_n}(x_n)}\,\bar\psi_{a_1}(x_1) \;=\; -\,\big(S_F(x_n-x_1)\big)_{b_na_1}. \tag{15.150}$$

The single transposition required to close the ring—to move the one $\bar\psi$ that began at the far left around to meet the one ψ at the far right—is the origin of the factor -1. It is one anticommutation, and it occurs exactly once per closed loop, independent of the number of vertices n on the loop: the $n-1$ internal contractions were sign-free, and only the closure costs a sign. Assembling Eq. (15.149) and Eq. (15.150) gives the rule.

Proposition 15.45 (The closed-fermion-loop rule)**.** *Each closed fermion loop in a diagram contributes an overall factor of -1 together with a single Dirac (and flavor/color) trace over the matrices encountered around the loop, read in the direction of the fermion-number arrow:*

$$\boxed{(-1)\;\mathrm{tr}\big[\Gamma_1\,\tilde S_F(p_1)\,\Gamma_2\,\tilde S_F(p_2)\cdots\Gamma_n\,\tilde S_F(p_n)\big]\;,} \tag{15.151}$$

in momentum space, with one undetermined loop momentum integrated $\int d^4\ell/(2\pi)^4$ and the internal momenta p_i fixed by conservation at each vertex. A diagram containing L disjoint closed fermion loops carries $(-1)^L$, one factor per loop.

Proof. The trace is Eq. (15.149), with each vertex contributing its matrix Γ_i (and the coupling and i of Eq. (15.142), suppressed here and restored in the worked

example below) and each internal line its propagator; Fourier-transforming the position-space propagators Eq. (15.148) to momentum space replaces $S_F(x_i - x_{i+1}) \to \tilde{S_F}(p_i)$ and leaves one loop momentum unfixed by the vertex delta functions, hence integrated. The overall sign is Eq. (15.150): one anticommutation per loop. For L disjoint loops the argument applies to each independently—each is a separate ring requiring its own single closing transposition, and the rings share no fields—so the signs multiply to $(-1)^L$. This is the same result reached in Theorem 12.49 from the numerator placement of $\det(i\not{\partial} - m)$ in the generating functional: there the $(-1)^L$ arose because each separate fermion determinant sits upstairs rather than downstairs, and Theorem 12.48 identified the Tr ln expansion of that determinant term by term with the closed-loop diagrams Eq. (15.151). The two routes—anticommuting the operators here, expanding the determinant there—are the same statement in two languages, as Section 12.7.3 verified by matching them on the antiperiodic trace. □

Physical Insight: why the loop sign is not optional

The -1 per fermion loop is the diagrammatic fingerprint of Fermi statistics, and it controls the *sign* of physical effects, not merely their bookkeeping. The simplest closed loop with two photon legs is the vacuum polarization, the worked example below; its -1 is what makes a fermion loop *screen* the electric charge rather than antiscreen it, fixing the sign of the running of α in Chapter 19. In a non-abelian theory the competition between gluon loops (which antiscreen) and quark loops (which screen, carrying this same -1) is precisely the sign struggle that decides asymptotic freedom: the coefficient $\frac{11}{3}C_A - \frac{4}{3}T_F n_f$ of Chapter 27 has its two terms of opposite sign for exactly this reason, the $-\frac{4}{3}T_F n_f$ piece being the fermion loops with their -1. And in supersymmetric theories the cancellation of the vacuum energy between bosons and fermions, seen on a single mode in Theorem 12.50, is this -1 summed over the spectrum. A sign error here is not a factor-of-two slip; it inverts the physics.

15.7.5 Worked example: the trace structure of the vacuum-polarization loop

We now apply the complete fermionic rule set to the simplest and most important closed loop, the QED vacuum polarization: a single electron loop with two external photon legs. The aim is to assemble the integrand—vertices, propagators, the -1, and the trace—purely from the rules just derived, validating them against the determinant-route result Eq. (12.189), and then to hand the explicit integral to Chapter 19, which evaluates it in dimensional regularization. This is a setup computation for QED, not its execution.

Worked Example 15.46 (The fermion-loop integrand of the photon self-energy)**.** Consider the one-loop correction to the photon propagator: two QED vertices joined by a closed electron loop, with external photon momentum q entering one vertex and leaving the other, and Lorentz indices μ, ν on the two photon legs. We extract the amputated, 1PI two-point insertion $i\Pi^{\mu\nu}(q)$, the object whose iteration dresses the photon propagator.

Step 1: lay out the loop. The loop carries an internal momentum; route k on one line in the arrow direction and, by momentum conservation at the first vertex, $k - q$ on the other. The loop visits, in arrow order, the vertex with Lorentz index μ, then a propagator of momentum k, then the vertex with index ν, then a propagator of momentum $k - q$ closing the ring. Figure 15.15 draws it.

Step 2: assemble the factors by the rules. The two vertices are each $-ie\gamma^{\mu}$ and $-ie\gamma^{\nu}$ from Eq. (15.144); the two internal lines are each $\tilde{S}_F$ from Eq. (15.140); the single closed loop contributes the factor (-1) and the trace of Theorem 15.45; the one undetermined loop momentum is integrated. Reading the matrices around the loop in the arrow direction and closing them into the trace,

$$i\Pi^{\mu\nu}(q) \;=\; (-1)\int \frac{d^4k}{(2\pi)^4}\;\mathrm{tr}\Big[(-ie\gamma^{\mu})\,\tilde{S}_F(k)\,(-ie\gamma^{\nu})\,\tilde{S}_F(k-q)\Big]. \tag{15.152}$$

Step 3: pull out the constants and exhibit the integrand. The two vertex factors contribute $(-ie)^2 = -e^2$, and the leading (-1) of the loop multiplies it to $+e^2$. Substituting the explicit propagators Eq. (15.140), $\tilde{S}_F(k) = i(\not{k}+m)/(k^2-m^2+i\varepsilon)$ and likewise for $k - q$, the two numerator factors of i combine to $i^2 = -1$, giving

$$\boxed{\,i\Pi^{\mu\nu}(q) \;=\; -\,e^2\int \frac{d^4k}{(2\pi)^4}\;\frac{\mathrm{tr}\big[\gamma^{\mu}(\not{k}+m)\,\gamma^{\nu}(\not{k}-\not{q}+m)\big]}{(k^2-m^2+i\varepsilon)\big((k-q)^2-m^2+i\varepsilon\big)}\,.\,} \tag{15.153}$$

This is the integrand Chapter 19 takes as its starting point. Its overall structure matches term for term the determinant-route expression Eq. (12.189): the -1 of the closed loop, the single Dirac trace closing the spinor indices around the ring, and the two vertices $-ie\gamma^{\mu}$, $-ie\gamma^{\nu}$. The rules assembled in this section and the Tr ln expansion of Chapter 12 produce identical content, as they must.

Step 4: the trace, as far as it teaches the rule. The numerator is a trace of four gamma matrices plus lower terms, evaluated with the technology of Section C.6. Expanding $\mathrm{tr}[\gamma^{\mu}(\not{k}+m)\gamma^{\nu}(\not{k}-\not{q}+m)]$, the two terms linear in m contain three gamma matrices and vanish, since the trace of an odd number of gamma matrices is zero (Theorem C.53). The two survivors are the m^2 term, $m^2\,\mathrm{tr}[\gamma^{\mu}\gamma^{\nu}] = 4m^2\eta^{\mu\nu}$ by Eq. (C.152), and the term quadratic in momenta, $\mathrm{tr}[\gamma^{\mu}\not{k}\,\gamma^{\nu}(\not{k}-\not{q})] = k_{\alpha}(k-q)_{\beta}\,\mathrm{tr}[\gamma^{\mu}\gamma^{\alpha}\gamma^{\nu}\gamma^{\beta}]$, evaluated with the four-gamma trace Eq. (C.157),

$$\mathrm{tr}\big[\gamma^{\mu}\gamma^{\alpha}\gamma^{\nu}\gamma^{\beta}\big] = 4\big(\eta^{\mu\alpha}\eta^{\nu\beta} - \eta^{\mu\nu}\eta^{\alpha\beta} + \eta^{\mu\beta}\eta^{\alpha\nu}\big). \tag{15.154}$$

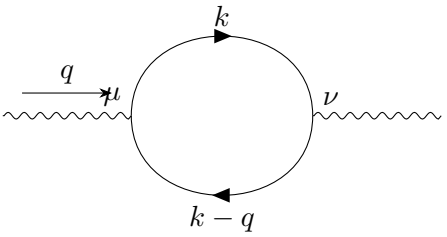

Figure 15.15: The vacuum-polarization loop Eq. (15.153): a single closed electron loop with two external photon legs of momentum q and Lorentz indices μ, ν. The arrows show the fermion-number flow circulating consistently around the loop; the spinor indices close into the single Dirac trace of Eq. (15.149), and the loop carries the overall -1 of Theorem 15.45. This is the diagram whose explicit evaluation in $d = 4 - 2\varepsilon$ dimensions yields the photon self-energy and the running of α in Chapter 19; it is identical in structure to the $n = 2$ term Eq. (12.189) of the determinant expansion of Chapter 12.

Contracting indices, the full numerator is

$$\operatorname{tr}\big[\gamma^\mu(\not{k}+m)\gamma^\nu(\not{k}-\not{q}+m)\big] = 4\Big[k^\mu(k-q)^\nu + k^\nu(k-q)^\mu - \eta^{\mu\nu}\big(k\cdot(k-q) - m^2\big)\Big]. \tag{15.155}$$

At this point the integrand is fully explicit, and what remains—combining denominators by Feynman parameters, shifting the loop momentum, regulating the resulting divergence in $d = 4 - 2\varepsilon$ dimensions, and extracting the transverse structure $\Pi^{\mu\nu} = (q^2\eta^{\mu\nu} - q^\mu q^\nu)\Pi(q^2)$ guaranteed by the Ward identity—is the loop computation proper. It belongs to Chapter 19, which introduces the regularization machinery; we stop here, having validated the fermionic rules on the integrand. The lesson of the example is the assembly, not the integral: the -1, the trace, the vertex Eq. (15.144), and the directed propagator Eq. (15.140) are everything one adds to the bosonic rules to compute with fermions, and each was derived above from the Grassmann combinatorics of Chapter 12 rather than postulated.

The fermionic rule set is now complete and self-contained: the directed propagator Eq. (15.140), the vertex template Eq. (15.142) with its QED and Yukawa specializations, the relative exchange sign of Theorem 15.44, and the closed-loop factor (-1) with its trace from Theorem 15.45—each derived from the Grassmann calculus of Chapter 12 rather than asserted. Chapter 17 receives this set whole and puts it to work on QED, assembling the photon line and propagator around the vertex Eq. (15.144), restoring the external spinors of Section 15.7.1, and computing $e^+e^- \to \mu^+\mu^-$ with full spin sums and traces; Chapter 26 reuses the same scaffold for the gluon and the Faddeev–Popov ghost, where the ghost—a Grassmann scalar—carries its own closed-loop -1 for precisely

the reason derived here, even though it has no spin. The signs and traces of this section are the bridge across which Parts V and VII inherit, rather than rebuild, the diagrammatics of perturbation theory.

Further reading

The diagrammatic expansion in the form developed here originates with Feynman [191] for the space–time rules and Dyson [167], who showed that the Tomonaga–Schwinger–Feynman formulations are equivalent and organized the perturbation series into what we now call Feynman diagrams; the combinatorial heart, the reduction of time-ordered products to sums of contractions, is Wick [508]. Among modern textbooks, the canonical derivation of the rules and symmetry factors closest to the route of Sections 15.2 and 15.4 is in Peskin and Schroeder [396, ch. 4]; the generating-functional derivation of Sections 15.5 and 15.6, including W and the 1PI effective action, is developed with great care by Srednicki [454] and, at a more advanced level, by Weinberg [500, ch. 6]. Schwartz [432] gives a particularly clean operational account of the fermion sign rules and the closed-loop factor of Section 15.7, and Itzykson and Zuber [278] remains a thorough reference for the symmetry-factor combinatorics treated as automorphism counting. For the physical pictures behind the bookkeeping — diagrams as histories, amputation, and the meaning of one-particle irreducibility — Zee [532] is the companion of choice.

Chapter 16

Cross Sections, Decay Rates, and Amplitudes

The two preceding chapters left us holding a single, hard-won object. The interaction picture and the Dyson series of Chapter 14 resolved the scattering operator as $\mathbf{S} = \mathbf{1} + iT$, stripped the overall energy–momentum delta from every matrix element of iT, and named what remained the invariant amplitude $\mathcal{M}$; the Feynman rules of Chapter 15 then made $\mathcal{M}$ computable diagram by diagram. But $\mathcal{M}$ is a complex number, and a complex number is not what a detector reports. An experiment counts events: so many decays per second, so many particles scattered into a given solid angle. This chapter is the bridge from the amplitude to those numbers. Its task is narrow and its payoff is permanent: to build, once and for all, the kinematic wrapper that converts any $\mathcal{M}$ into a decay rate or a cross section, with every factor of $2E$, 2π, and $1/V$ accounted for and nothing quoted on faith.

The conversion looks innocent — square the amplitude, sum over final states — but it runs immediately into the square of a momentum-conserving delta function, an object with no distributional meaning. We confront that pathology head-on with a finite-volume, finite-time regularization, and in resolving it we are forced to fix the relativistic single-particle normalization inherited from Wigner's construction of the one-particle Hilbert space in Chapter 3; every later kinematic factor descends from that one choice. The analytic machinery the regularization leans on — the delta-function composition rule, the Fourier conventions, the meaning of $\delta^4(0)$ — is the distribution theory assembled in Chapter 5. Throughout we work in the mostly-minus metric and natural units of Appendix A, in which a cross section is an inverse mass squared.

From that foundation the chapter follows a deliberate arc. Section 16.1 extracts a finite master transition rate from the squared amplitude and isolates the purely kinematic remainder; Section 16.2 names that remainder the Lorentz-invariant phase space $\mathrm{d}\Pi_n$, proves its frame independence, derives the recursion

that builds it from two-body factors, and reduces the two-body case to a closed form in the centre-of-momentum frame. With the kinematics in hand the two great observables split apart according to the initial state. Section 16.3 feeds in a one-particle initial state to obtain the decay rate $d\Gamma = \frac{1}{2M}\,|\mathcal{M}|^2\,\mathrm{d}\Pi_n$, the width, the lifetime, and the identical-particle symmetry factor, carried through to a numerical lifetime. Section 16.4 feeds in a two-particle initial state, where the genuinely new ingredient is the flux: we build the Møller flux factor, prove that its covariant form equals the operational "density times relative velocity," and assemble the master cross-section formula $d\sigma = |\mathcal{M}|^2\,\mathrm{d}\Pi_n/F$.

The remaining sections cash this apparatus. Section 16.5 specializes to the ubiquitous $2 \to 2$ case, introduces the Mandelstam variables and the Källén triangle function, reduces the cross section to the two standard forms $d\sigma/d\Omega$ and $d\sigma/dt$, and maps the physical regions of the (s,t,u) plane on which crossing symmetry will later act. Section 16.6 runs the full pipeline on the carried ϕ^4 theory amplitude $\mathcal{M} = -\lambda$ of Chapter 15, producing the first genuinely physical cross section of the book — isotropic, and falling as $1/s$. Finally Section 16.7 closes the loop with Chapter 14: the flux and phase space built here, fed back into the unitarity of $\mathbf{S}$, reproduce the optical theorem in cross-section form, sharpen it into the partial-wave unitarity bound, and pass an internal consistency check on the ϕ^4 numbers. By the end the chapter's three title words — cross sections, decay rates, and amplitudes — stand revealed as one and the same object: $|\mathcal{M}|^2$ integrated against an invariant measure, divided by the appropriate normalization.

16.1 From amplitude to probability: transition rates and the squared delta function

We arrive at this chapter holding a single, hard-won object: the invariant amplitude $\mathcal{M}$. Chapter 14 split the scattering operator as $\mathbf{S} = \mathbf{1} + iT$, isolated the nontrivial part T, and showed that every matrix element of iT between momentum eigenstates carries one overall momentum-conserving delta function, leaving behind a Lorentz-invariant function of the external momenta (Eq. (14.46)); Chapter 15 then supplied the Feynman rules that let us compute that function diagram by diagram. But $\mathcal{M}$ is not yet anything a detector reports. A detector counts events: so many decays per second, so many scattered particles into a given solid angle. To get there we must turn the complex number $\mathcal{M}$ into a *probability*, and then into a *rate*. That conversion looks innocent — square the amplitude — but it runs immediately into a notorious obstruction. Squaring an expression that contains $(2\pi)^4\delta^4(p_f - p_i)$ appears to produce $\left[(2\pi)^4\delta^4(p_f - p_i)\right]^2$, the square of a distribution, which is meaningless as it stands. The whole machinery of cross sections and lifetimes rests on understanding precisely what that squared delta means and how to extract a finite number from it. This section confronts

the pathology head-on, resolves it with a finite-volume, finite-time regularization, and in doing so fixes once and for all the relativistic state normalization that every later factor — flux, phase space, the $2M$ of a decay rate — silently depends on.

16.1.1 The transition probability and the squared delta

We begin from the decomposition established in Theorem 14.11 and Eq. (14.45),

$$\mathbf{S} = \mathbf{1} + iT, \tag{16.1}$$

and the definition of the invariant amplitude for a process $i \to f$ with initial momenta $\{p_a\}$ and final momenta $\{k_i\}$ (Eq. (14.46)),

$$\langle f|iT|i\rangle = (2\pi)^4\,\delta^4\Big(\textstyle\sum_i k_i - \sum_a p_a\Big)\; i\,\mathcal{M}(i \to f). \tag{16.2}$$

For a genuine transition the final state f differs from the initial state i, so the disconnected piece $\mathbf{1}$ does not contribute and $\langle f|\mathbf{S}|i\rangle = \langle f|iT|i\rangle$. The probability for the transition is the modulus squared of this amplitude, divided by the norms of the states involved — a normalization we will make precise in a moment. Ignoring the normalization for the instant, the bare squared matrix element is

$$\big|\langle f|iT|i\rangle\big|^2 = \big|\mathcal{M}(i \to f)\big|^2\,\Big[(2\pi)^4\,\delta^4(p_f - p_i)\Big]^2, \tag{16.3}$$

where we abbreviate $p_f \equiv \sum_i k_i$ and $p_i \equiv \sum_a p_a$. The factor $\big|\mathcal{M}\big|^2$ is perfectly finite; the dynamics lives entirely there. The trouble is the bracketed object. A delta function is a distribution, defined only under an integral against a test function; the pointwise product of two distributions supported on the same set is not defined in the theory of distributions reviewed in Section 5.1.3. Written naively as $\delta^4(p_f - p_i)\cdot\delta^4(0)$, it even contains the manifestly divergent symbol $\delta^4(0)$. We cannot proceed by formal manipulation alone; we must regulate.

Caution

The symbol $\big[(2\pi)^4\delta^4\big]^2$ is *not* a distribution and must never be manipulated as though the usual delta-function identities apply to it. It is shorthand for a quantity that is only defined once the idealization of exactly sharp momentum eigenstates over infinite spacetime is relaxed. Every finite answer below comes from taking that idealization carefully, not from algebra on $\delta^4(0)$.

16.1.2 Box and finite-time regularization

The physical origin of the squared delta is that we have idealized the experiment as taking place over all of space for all of time. A momentum eigenstate is a

plane wave filling the entire universe; the conservation delta is the statement that this plane wave overlaps the final state coherently at every point of an infinite spacetime. The infinity is the infinite spacetime volume over which that coherent overlap accumulates. Restore physical finiteness and the infinity becomes a finite number.

Concretely, place the system in a large cubic box of side L and spatial volume $V = L^3$, with periodic boundary conditions, and let the interaction act only over a long but finite time interval of duration T. Both V and T are auxiliary; physical answers must be independent of them, and indeed the divergent factor they tame will be cancelled by the very normalization they force. The momentum-conserving delta arises, as recorded in the Fourier conventions of Eq. (5.53), from a spacetime integral of a plane wave,

$$(2\pi)^4\,\delta^4(p_f - p_i) = \int d^4x\; e^{i(p_f - p_i)\cdot x}. \tag{16.4}$$

The two delta functions in Eq. (16.3) come from two such integrals, one from the amplitude and one from its conjugate. Their product is therefore a double spacetime integral,

$$\Big[(2\pi)^4\delta^4(p_f - p_i)\Big]^2 = \int d^4x\, e^{i(p_f - p_i)\cdot x} \int d^4y\, e^{-i(p_f - p_i)\cdot y}. \tag{16.5}$$

On the support of the conservation law the argument $p_f - p_i$ vanishes, so one of the two exponentials is unity there. The cleanest way to see the result is to keep one factor as a genuine delta and recognize the other as the volume of the integration region. Use Eq. (16.4) for the x-integral and set $p_f = p_i$ in the y-integrand, since the surviving delta enforces exactly that:

$$\Big[(2\pi)^4\delta^4(p_f - p_i)\Big]^2 = (2\pi)^4\delta^4(p_f - p_i) \int_{V,T} d^4y\; e^{-i(p_f - p_i)\cdot y}\Big|_{p_f = p_i} = (2\pi)^4\delta^4(p_f - p_i) \int_{V,T} d^4y. \tag{16.6}$$

The remaining integral is over the regularized spacetime region — the box of volume V over the time T — and is simply its four-volume,

$$\int_{V,T} d^4y = \int_0^T dt \int_V d^3y = VT. \tag{16.7}$$

This is the precise content of the heuristic identity $(2\pi)^4\delta^4(0) = VT$: the divergent $\delta^4(0)$ is nothing but the four-volume of the spacetime over which the process is observed. We have therefore established

$$\boxed{\Big[(2\pi)^4\delta^4(p_f - p_i)\Big]^2 = VT\,(2\pi)^4\delta^4(p_f - p_i)} \tag{16.8}$$

The squared delta has collapsed to a single delta — which still enforces overall energy–momentum conservation, exactly as it must — multiplied by the finite

factor VT. The probability of any given transition therefore grows linearly with the observation time T: that linear growth is precisely what makes a constant *rate* (probability per unit time) the sensible observable, and dividing by T removes one factor. The remaining factor of V will be cancelled by the state normalization, to which we turn next.

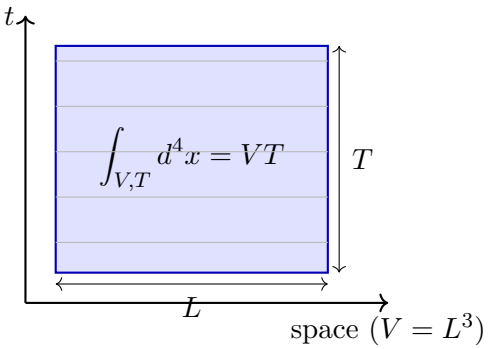

Figure 16.1: The squared momentum-conserving delta function regularized. Confining the process to a spatial box of volume $V = L^3$ over a finite time T replaces the divergent $(2\pi)^4\delta^4(0)$ by the finite four-volume $VT = \int_{V,T} d^4x$ of the observation region (Eq. (16.7)). The surviving single $\delta^4(p_f - p_i)$ still enforces overall energy–momentum conservation; the factor VT is what makes the transition probability grow with observation time, so that the rate (probability per unit T) is the finite, T-independent observable.

Worked Example 16.1 (The squared delta is the spacetime four-volume)**.** It is worth seeing Eq. (16.8) a second way, directly from the regularized delta itself, to confirm that no sleight of hand entered the step Eq. (16.6). In the box the spatial momenta are quantized, $\mathbf{p} = \frac{2\pi}{L}\mathbf{n}$ with $\mathbf{n} \in \mathbb{Z}^3$, and the spatial Fourier delta is genuinely the finite integral

$$(2\pi)^3\delta_V^3(\mathbf{q}) \equiv \int_V d^3x\, e^{i\mathbf{q}\cdot\mathbf{x}}, \qquad (2\pi)^3\delta_V^3(\mathbf{0}) = \int_V d^3x = V, \tag{16.9}$$

and likewise for the finite-time energy delta,

$$2\pi\,\delta_T(q^0) \equiv \int_0^T dt\, e^{iq^0t}, \qquad 2\pi\,\delta_T(0) = \int_0^T dt = T. \tag{16.10}$$

The four-dimensional regularized delta is the product, $(2\pi)^4\delta_{V,T}^4(q) = (2\pi)^3\delta_V^3(\mathbf{q})\cdot 2\pi\,\delta_T(q^0)$. Writing the square as

$$\left[(2\pi)^4\delta_{V,T}^4(q)\right]^2 = (2\pi)^4\delta_{V,T}^4(q)\cdot(2\pi)^4\delta_{V,T}^4(0), \tag{16.11}$$

the second factor is, by Eqs. (16.9) and (16.10), exactly

$$(2\pi)^4\delta_{V,T}^4(0) = (2\pi)^3\delta_V^3(\mathbf{0})\cdot 2\pi\,\delta_T(0) = V\cdot T = VT, \tag{16.12}$$

reproducing Eq. (16.8). As $V, T \to \infty$ the regularized $\delta_{V,T}$ tends to the ordinary delta in the distributional sense (its integral against any test function converges to the test function's value at the origin), so the surviving factor $(2\pi)^4 \delta^4_{V,T}(q) \to (2\pi)^4 \delta^4(q)$ recovers exact conservation, while the cofactor VT remains as the genuine, finite measure of the observation volume.

16.1.3 Relativistic normalization and the box dictionary

We have a finite squared amplitude up to the question of how the states are normalized. This is not a cosmetic choice: the factors of $2E$ and $1/V$ that will populate the master formula are *forced* by it, and getting the normalization wrong is the single most common way to land a cross section off by powers of energy. We use throughout the relativistically invariant single-particle normalization established in Eq. (3.193) as part of Wigner's construction of the one-particle Hilbert space (Theorem 3.44):

$$\langle p|q\rangle = 2E_{\mathbf{p}}\,(2\pi)^3\,\delta^3(\mathbf{p}-\mathbf{q}), \qquad E_{\mathbf{p}} = \sqrt{\mathbf{p}^2+m^2}. \tag{16.13}$$

The merit of this convention is its manifest Lorentz invariance: the combination $2E_{\mathbf{p}}\,(2\pi)^3\delta^3(\mathbf{p}-\mathbf{q})$ and the associated measure $d^3p/[(2\pi)^3 2E_{\mathbf{p}}]$ are invariant (Eq. (3.191)), which is exactly why the phase-space measure built from it in the next section will be invariant too. The price is that single-particle states are not unit-normalized: $\langle p|p\rangle$ is not 1 but is proportional to the (divergent, in the continuum) $\delta^3(\mathbf{0})$. The box makes this finite and turns Eq. (16.13) into a usable counting dictionary.

In the box, by exactly the spatial version of Eq. (16.4) recorded in Eq. (16.9),

$$(2\pi)^3\delta^3(\mathbf{0}) \;\longrightarrow\; \int_V d^3x = V, \tag{16.14}$$

so the norm of a single relativistically normalized momentum state becomes finite,

$$\langle p|p\rangle = 2E_{\mathbf{p}}\,(2\pi)^3\delta^3(\mathbf{0}) \;\longrightarrow\; 2E_{\mathbf{p}}\,V. \tag{16.15}$$

This is the central entry of the dictionary between continuum and box states. The continuum state $|p\rangle$, with the invariant normalization Eq. (16.13), corresponds in the box to a state of norm $2E_{\mathbf{p}}V$; the unit-normalized (probability-one) box state is therefore

$$|p\rangle_{\text{box}} = \frac{1}{\sqrt{2E_{\mathbf{p}}V}}\;|p\rangle\,, \qquad \langle p|p\rangle_{\text{box}} = 1. \tag{16.16}$$

The second dictionary entry concerns the counting of final states. Periodic boundary conditions quantize momenta on the lattice $\mathbf{p} = \frac{2\pi}{L}\mathbf{n}$, with one allowed

mode per momentum-space cell of volume $(2\pi/L)^3 = (2\pi)^3/V$. The number of distinct single-particle states with momentum in a cell d^3k is therefore

$$dN_{\text{states}} = \frac{V\, d^3k}{(2\pi)^3}, \tag{16.17}$$

which is the box realization of the continuum rule that each $\int d^3k$ comes weighted by $V/(2\pi)^3$ when counting modes.

These two entries already contain the physical meaning of the relativistic normalization, and it is worth stating it as a result in its own right because the $2E$ factors of every cross section descend from it.

Proposition 16.2 (Particle density of a relativistically normalized state)**.** *With the normalization Eq. (16.13), a single-particle momentum eigenstate $|p\rangle$ confined to a box of volume V corresponds to a number density of $2E_{\mathbf{p}}$ particles per unit volume.*

Proof. The unit-normalized state Eq. (16.16) describes exactly one particle delocalized uniformly over the box, hence a particle number density $1/V$. The relativistically normalized state is larger by the factor $\sqrt{2E_{\mathbf{p}}V}$ in amplitude, i.e. by $2E_{\mathbf{p}}V$ in norm: $\langle p|p\rangle = 2E_{\mathbf{p}}V$ from Eq. (16.15). Since the norm is the integral of the probability (number) density over the box, the relativistic state carries $2E_{\mathbf{p}}V$ units of that density in volume V, i.e. a density of

$$n_{\mathbf{p}} = \frac{\langle p|p\rangle}{V} = 2E_{\mathbf{p}} \tag{16.18}$$

particles per unit volume. The same conclusion follows operationally from the free-field number current: the conserved charge density of a complex scalar in the state $|p\rangle$, or equivalently the diagonal matrix element of the number-density operator, evaluates with the commutator $\left[a_{\mathbf{p}}, a^\dagger_{\mathbf{q}}\right] = 2E_{\mathbf{p}}(2\pi)^3\delta^3(\mathbf{p}-\mathbf{q})$ that accompanies Eq. (16.13) to $2E_{\mathbf{p}}$ per unit volume, the factor $2E_{\mathbf{p}}$ being the same one carried by the norm. The factor is thus not an arbitrary convention but the direct consequence of the invariant normalization: it is the price, and the benefit, of working with Lorentz-invariant states. □

Physical Insight

The relativistic normalization Eq. (16.13) is chosen so that states transform simply under Lorentz boosts — the inner product is frame independent. Theorem 16.2 is the flip side of that choice: a boosted box is Lorentz contracted, so the same particle appears denser by exactly the time-dilation/energy factor $E_{\mathbf{p}}/m$ relative to its rest frame, and the convention builds this in as the universal factor $2E$. Every $2E$ you will meet in a phase-space measure, a flux factor, or the $2M$ of a decay rate traces

back to this single normalization decision. There is nothing left arbitrary downstream: fix Eq. (16.13) and all the kinematic factors are determined.

16.1.4 The master differential transition rate

We now assemble the pieces into the probability for the process $i \to f$ and divide by the observation time to obtain a rate. The transition probability is the squared amplitude between *unit-normalized* states, summed over the number of distinct final states available. We have computed everything in terms of relativistically normalized states, so each external leg must be converted using the dictionary above: divide by the norm $2EV$ of each incoming and each outgoing relativistic state, and multiply by the count Eq. (16.17) of final states in the momentum cells d^3k_i. Writing the incoming particles with energies E_a (a running over the n_i initial particles) and the outgoing ones with energies E_i (i running over the n_f final particles), the probability of landing in the final momentum element $\prod_i d^3k_i$ is

$$dP = \frac{\left|\langle f|iT|i\rangle\right|^2}{\left(\prod_{a\in\text{in}} 2E_aV\right)\left(\prod_{i\in\text{fin}} 2E_iV\right)} \prod_{i\in\text{fin}} \frac{V\,d^3k_i}{(2\pi)^3}. \tag{16.19}$$

The numerator is the bare squared matrix element Eq. (16.3); the first denominator factor divides out the norms of the incoming states, the second divides out the norms of the outgoing states, and the final product counts the available final states by Eq. (16.17). Insert the bare square Eq. (16.3) and apply the central result Eq. (16.8) for the squared delta:

$$dP = \frac{\left|\mathcal{M}\right|^2 VT\,(2\pi)^4\delta^4(p_f - p_i)}{\left(\prod_{a\in\text{in}} 2E_aV\right)\left(\prod_{i\in\text{fin}} 2E_iV\right)} \prod_{i\in\text{fin}} \frac{V\,d^3k_i}{(2\pi)^3}. \tag{16.20}$$

Now watch the auxiliary factors V and T disappear, which is the whole point of the regularization. Pair each final-state energy denominator $2E_iV$ with its own state-count numerator $V\,d^3k_i$: the factors of V cancel one-to-one, leaving for each final particle exactly the combination

$$\frac{V\,d^3k_i}{(2\pi)^3}\cdot\frac{1}{2E_iV} = \frac{d^3k_i}{(2\pi)^3\,2E_i}. \tag{16.21}$$

This is the invariant measure of Eq. (3.191), one factor per outgoing particle — the first sign that the surviving kinematic object will be Lorentz invariant. After this cancellation Eq. (16.20) reads

$$dP = VT\,\frac{\left|\mathcal{M}\right|^2}{\prod_{a\in\text{in}} 2E_aV}\,(2\pi)^4\delta^4(p_f - p_i) \prod_{i\in\text{fin}} \frac{d^3k_i}{(2\pi)^3\,2E_i}. \tag{16.22}$$

The transition *rate* is the probability per unit observation time, $dN \equiv dP/T$. Dividing by T removes the time factor entirely — as anticipated, the linear growth of dP with T in Eq. (16.8) is exactly what makes a time-independent rate well defined — and we obtain the master differential transition rate:

$$dN = \frac{1}{T}\frac{|\mathcal{M}|^2}{\prod_{a\in\text{in}} 2E_a V}\left[(2\pi)^4\delta^4(p_f - p_i)\right]^2 \prod_{i\in\text{fin}} \frac{V\, d^3k_i}{(2\pi)^3\, 2E_i V} = \frac{V}{\prod_{a\in\text{in}} 2E_a V}\,|\mathcal{M}|^2\,(2\pi)^4\delta^4(p \tag{16.23}$$

The first form displays the raw ingredients exactly as they enter — the $1/T$, the inverse norms $1/(2E_aV)$ of the initial particles, the squared delta, and the final-state weights — and the second is the result of using Eq. (16.8) and the cancellation Eq. (16.21). In the second form the only surviving auxiliary factor is the single V in the numerator, which combines with the initial-state norms to give the clean scaling

$$dN = \frac{1}{V^{\,n_i-1}}\frac{|\mathcal{M}|^2}{\prod_{a\in\text{in}} 2E_a}\,(2\pi)^4\delta^4(p_f - p_i)\prod_{i\in\text{fin}}\frac{d^3k_i}{(2\pi)^3\,2E_i}. \tag{16.24}$$

This dependence on the number of incoming particles n_i is not a defect but the seed of the physics that separates the two great observables of this chapter.

For a *decay*, $n_i = 1$: a single particle of energy $E_1 = M$ in its rest frame disintegrates, and Eq. (16.24) is completely independent of the box volume,

$$dN\big|_{n_i=1} = \frac{1}{2E_1}\,|\mathcal{M}|^2\,(2\pi)^4\delta^4(p_f - p_i)\prod_{i\in\text{fin}}\frac{d^3k_i}{(2\pi)^3\,2E_i}. \tag{16.25}$$

The prefactor $1/2E_1$ is exactly the $1/2M$ that will appear in the partial-width formula; it is the inverse norm of the single decaying particle, nothing more. There is no V because there is no notion of density for a single particle — the rate is intrinsic.

For a *scattering* process, $n_i = 2$: two beams must find each other, and Eq. (16.24) retains one factor of $1/V$,

$$dN\big|_{n_i=2} = \frac{1}{V}\,\frac{1}{2E_1\,2E_2}\,|\mathcal{M}|^2\,(2\pi)^4\delta^4(p_f - p_i)\prod_{i\in\text{fin}}\frac{d^3k_i}{(2\pi)^3\,2E_i}. \tag{16.26}$$

The residual $1/V$ is precisely a number density: by Theorem 16.2 the two incoming particles have densities $2E_1/V$ and $2E_2/V$ relative to a normalization, and converting this single-event rate into the box-independent cross section will require dividing by the incident flux, which carries exactly the compensating factors of V and energy. That conversion is the business of the cross-section section; here we have established that the $1/V$ is forced, not chosen, and that it is the flag marking a two-body initial state.

Caution

The factor $1/V^{\,n_i-1}$ is the only place the auxiliary volume survives, and it must cancel in any physical answer. For decays ($n_i = 1$) it is already absent. For scattering ($n_i = 2$) it is removed by the flux, which is itself $\propto 1/V$; the combination dN/flux is finite and V-independent. If a calculation ends with a leftover V in a cross section or a width, a normalization factor of $2EV$ or a final-state count $V\,d^3k/(2\pi)^3$ has been dropped — retrace Eq. (16.19).

Worked Example 16.3 (Two-body final state: counting the volume factors)**.** To see that the bookkeeping is airtight, count powers of V explicitly for the generic $2 \to 2$ process $a + b \to 1 + 2$, the kinematic skeleton of the carried ϕ^4 theory amplitude $\phi\phi \to \phi\phi$ of Eq. (14.46) and of every elementary process in Chapters 17–18. Start from Eq. (16.20) with $n_i = 2$, $n_f = 2$. The explicit powers of V are: one V from VT in the squared delta; two factors V from the final-state counts $\prod_{i=1,2} V\,d^3k_i/(2\pi)^3$; in the denominator, two factors V from the initial norms $2E_aV, 2E_bV$ and two from the final norms $2E_1V, 2E_2V$. The net power is

$$V^{\,1} \cdot V^{\,2} \cdot V^{-2} \cdot V^{-2} = V^{-1}, \tag{16.27}$$

so $dP \propto T\,V^{-1}$ and $dN = dP/T \propto V^{-1}$, matching Eq. (16.26). The single surviving inverse volume is the density factor that the flux will absorb. Repeating the count with n_f arbitrary changes nothing: every final particle brings a $+1$ from its state count and a -1 from its norm, which always cancel via Eq. (16.21), so the final-state multiplicity never affects the power of V — only n_i does, through $V^{\,1}/V^{\,n_i} = V^{\,1-n_i}$. This confirms Eq. (16.24) for any number of final particles.

We have converted the abstract S-matrix element into a finite, physically interpretable transition rate, and along the way fixed the relativistic normalization Eq. (16.13) together with the $2E$ and $1/V$ factors it forces. The dynamics is sealed entirely inside $|\mathcal{M}|^2$; everything multiplying it in Eq. (16.24) is pure kinematics. In particular, the final-state momenta enter only through the combination

$$(2\pi)^4\delta^4(p_f - p_i) \prod_{i\in\text{fin}} \frac{d^3k_i}{(2\pi)^3\,2E_i} \;\equiv\; (2\pi)^4\delta^4(p_f - p_i)\,\mathrm{d}\Pi_{n_f}, \tag{16.28}$$

which already shows, leg by leg, the invariant measure of Eq. (3.191). The next section isolates this object, names it the Lorentz-invariant phase space $\mathrm{d}\Pi_{n_f}$, proves its frame independence, derives the recursion that builds the n-body measure from lower ones, and reduces the two-body case in the center-of-momentum frame to the closed form on which every cross section and decay rate in the remainder of the book will rest.

16.2 Lorentz-invariant phase space

The differential transition rate assembled in the previous section has a clean factorized structure. All of the dynamics — everything the interaction does — sits in a single number $|\mathcal{M}|^2$, the modulus squared of the invariant amplitude defined in Eq. (14.163). Everything else is kinematics: the final-state momenta range over all configurations compatible with energy–momentum conservation, each weighted by the relativistically invariant single-particle measure that the state normalization of Section 16.1 forced upon us. That kinematic weight is

$$\prod_{i=1}^{n} \frac{d^3k_i}{(2\pi)^3\, 2E_{k_i}}\,, \qquad E_{k_i} = \sqrt{\mathbf{k}_i^2 + m_i^2}\,, \tag{16.29}$$

tied together by the overall conservation delta $(2\pi)^4\delta^4\!\left(P - \sum_i k_i\right)$, with P the total incoming four-momentum. This section isolates that combination, names it the *Lorentz-invariant n-body phase space* $\mathrm{d}\Pi_n$, proves that it is genuinely a Lorentz scalar (so that a rate or cross section computed in one frame is the same number in any other), establishes a recursion that builds $\mathrm{d}\Pi_n$ from $\mathrm{d}\Pi_{n-1}$, and reduces the two-body case to a closed form. The two-body result is the single most-used formula in the rest of Part IV and all of Part V: every $1 \to 2$ decay and every $2 \to 2$ cross section will be read off from it. The construction here is entirely thread-neutral — it knows nothing about ϕ^4, QED, or Yang–Mills — precisely because it is pure geometry of the on-shell momenta.

16.2.1 The on-shell single-particle measure

The atom from which $\mathrm{d}\Pi_n$ is built is the measure carried by one outgoing particle. We met it already in Chapter 3 as the natural measure on the mass shell; here we collect its two equivalent presentations and prove the invariance on which all later frame-independence rests.

Definition 16.4 (On-shell measure)**.** For a particle of mass m the *on-shell* (or *Lorentz-invariant*) single-particle measure is

$$\widetilde{dk} \;\equiv\; \frac{d^3k}{(2\pi)^3\, 2E_k}\,, \qquad E_k = \sqrt{\mathbf{k}^2 + m^2}\,, \tag{16.30}$$

where $\widetilde{dk}$ is shorthand for $\widetilde{dk}$.

The factor $2E_k$ is not decoration: it is exactly the weight that the relativistic normalization $\langle p'|p\rangle = (2\pi)^3\, 2E_p\, \delta^3(\mathbf{p}-\mathbf{p}')$ of Eq. (3.193) demands of a resolution of the identity on one-particle states. With it, $\widetilde{dk}$ is a Lorentz scalar; without it, d^3k alone is not. The cleanest way to see the invariance is to rewrite Eq. (16.30) in manifestly covariant four-dimensional form.

Proposition 16.5 (Covariant form of the on-shell measure)**.** *The measure Eq. (16.30) equals*

$$\widetilde{dk} \;=\; \frac{d^4k}{(2\pi)^4}\,(2\pi)\,\delta\!\left(k^2-m^2\right)\theta(k^0)\,, \tag{16.31}$$

and is invariant under every orthochronous Lorentz transformation.

Proof. Start from the right-hand side of Eq. (16.31) and perform the k^0 integration. Write $d^4k = dk^0\,d^3k$ and treat the delta as a function of k^0 at fixed $\mathbf{k}$. The argument $k^2-m^2 = (k^0)^2 - \mathbf{k}^2 - m^2 = (k^0)^2 - E_k^2$ has the two simple zeros $k^0 = \pm E_k$. By the composition rule for a delta function with a smooth argument g, proved in Chapter 5,

$$\delta\big(g(k^0)\big) = \sum_i \frac{\delta(k^0-k_i^0)}{|g'(k_i^0)|}\,, \qquad g(k^0) = (k^0)^2 - E_k^2\,, \quad g'(k^0) = 2k^0\,, \tag{16.32}$$

so that, since $|g'(\pm E_k)| = 2E_k$,

$$\delta\!\left(k^2-m^2\right) = \frac{1}{2E_k}\Big[\delta(k^0-E_k) + \delta(k^0+E_k)\Big]. \tag{16.33}$$

The Heaviside factor $\theta(k^0)$ retains only the positive-energy root $k^0 = E_k$, killing the second term. Integrating over k^0,

$$\frac{d^4k}{(2\pi)^4}(2\pi)\,\delta\!\left(k^2-m^2\right)\theta(k^0) = \frac{d^3k}{(2\pi)^4}(2\pi)\,\frac{1}{2E_k} = \frac{d^3k}{(2\pi)^3\,2E_k} = \widetilde{dk}\,, \tag{16.34}$$

which is Eq. (16.30). This is precisely the integral identity Eq. (3.192) read as a statement about measures rather than about integrands.

Invariance now follows term by term in Eq. (16.31). The four-volume d^4k is invariant because $|\det\Lambda| = 1$ for any $\Lambda \in O(1,3)$. The combination $k^2 = \eta_{\mu\nu}k^\mu k^\nu$ is a Lorentz scalar, hence so is $\delta(k^2-m^2)$. Finally $\theta(k^0)$ is invariant under the *orthochronous* subgroup: a Λ with ${\Lambda^0}_0 \geq 1$ cannot map a future-pointing timelike-or-null vector (here k is on the forward mass shell, $k^2 = m^2 \geq 0$, $k^0 > 0$) to a past-pointing one, so $\theta(k^0) = \theta((\Lambda k)^0)$ on the support of $\delta(k^2-m^2)$. The product of three invariants is invariant. Since the physical Lorentz transformations relating inertial frames are orthochronous (and, including parity, still orthochronous), $\widetilde{dk}$ is the same measure in every frame. □

It is worth seeing the invariance a second way, directly in three-dimensional language, because the boost Jacobian it exposes is the mechanism behind every "$d^3k/2E$ is invariant" statement in the book.

Worked Example 16.6 (The boost Jacobian)**.** Take a boost of rapidity η along the z-axis acting on an on-shell momentum $k = (E_k, \mathbf{k})$ with $\mathbf{k} = (k^1, k^2, k^3)$. The transverse components are unchanged, $k'^1 = k^1$, $k'^2 = k^2$, while

$$k'^3 = \gamma\,(k^3 + \beta E_k)\,, \qquad E'_k = \gamma\,(E_k + \beta k^3)\,, \qquad \gamma = \cosh\eta, \quad \beta = \tanh\eta\,. \tag{16.35}$$

The map $\mathbf{k} \mapsto \mathbf{k}'$ has a Jacobian that is diagonal in the transverse directions, so

$$d^3k' = \left|\frac{\partial k'^3}{\partial k^3}\right| d^3k\,, \tag{16.36}$$

the partial derivative taken at fixed k^1, k^2. Because k stays on shell, $E_k = \sqrt{(k^3)^2 + (k^1)^2 + (k^2)^2 + m^2}$ depends on k^3 through $\partial E_k/\partial k^3 = k^3/E_k$. Hence

$$\frac{\partial k'^3}{\partial k^3} = \gamma\Big(1 + \beta\,\frac{\partial E_k}{\partial k^3}\Big) = \gamma\Big(1 + \beta\,\frac{k^3}{E_k}\Big) = \frac{\gamma\,(E_k + \beta k^3)}{E_k} = \frac{E'_k}{E_k}\,. \tag{16.37}$$

The Jacobian is positive (an orthochronous boost keeps $E'_k > 0$), so the modulus is redundant, and

$$\frac{d^3k'}{2E'_k} = \frac{1}{2E'_k}\,\frac{E'_k}{E_k}\,d^3k = \frac{d^3k}{2E_k}\,. \tag{16.38}$$

The energy denominator exactly cancels the boost stretching of the momentum-space volume. Rotations leave d^3k and E_k separately invariant, and any orthochronous Lorentz transformation is a product of boosts and rotations, so $d^3k/2E_k$ is invariant in general — the same conclusion as Theorem 16.5, now with the Jacobian made explicit.

16.2.2 The n-body phase space and its invariance

With the one-particle atom in hand, the full final-state measure is its n-fold product, dressed with the conservation delta.

Definition 16.7 (Lorentz-invariant phase space)**.** Let a state of total four-momentum P decay or scatter into n particles of masses $m_1, \dots, m_n$ and momenta $k_1, \dots, k_n$. The *Lorentz-invariant n-body phase space* is the measure

$$\mathrm{d}\Pi_n(P; k_1, \dots, k_n) \;\equiv\; (2\pi)^4\,\delta^4\Big(P - \sum_{i=1}^{n} k_i\Big)\,\prod_{i=1}^{n} \widetilde{dk_i}\,, \tag{16.39}$$

and its total volume for a given P is $\Pi_n(P) = \int \mathrm{d}\Pi_n$.

The notation $\mathrm{d}\Pi_n$ records the measure; an actual rate or cross section is $\int |\mathcal{M}|^2\,\mathrm{d}\Pi_n$ divided by a normalization fixed in the next two sections. The placement of the 2π's follows the global Fourier convention fixed in Chapter 5: each $\int d^4k$ would carry $(2\pi)^{-4}$ and each x-integral delta a $(2\pi)^4$; in $\mathrm{d}\Pi_n$ those

have already been packaged so that $\widetilde{dk}$ carries $(2\pi)^{-3}$ and the single overall delta carries $(2\pi)^4$. This bookkeeping is what makes the squared-delta regularization of Section 16.1 come out finite with no stray factors.

Proposition 16.8 (Lorentz invariance of $\mathrm{d}\Pi_n$)**.** *The measure Eq. (16.39) is invariant under orthochronous Lorentz transformations: under $k_i \mapsto \Lambda k_i$ and $P \mapsto \Lambda P$ it is unchanged, and its total volume $\Pi_n(P)$ depends on P only through the invariant $s = P^2$ (and the masses).*

Proof. Each factor $\widetilde{dk_i}$ is invariant by Theorem 16.5. The remaining factor is $(2\pi)^4\delta^4(P-\sum_i k_i)$. A four-dimensional delta transforms as $\delta^4(\Lambda q) = |\det\Lambda|^{-1}\,\delta^4(q) = \delta^4(q)$ since $|\det\Lambda| = 1$; equivalently, the conservation constraint $P = \sum_i k_i$ is a covariant equation between four-vectors, true in one frame iff true in all. Hence $\delta^4(\Lambda P - \sum_i \Lambda k_i) = \delta^4(\Lambda(P - \sum_i k_i)) = \delta^4(P - \sum_i k_i)$. A product of Lorentz scalars is a Lorentz scalar, so $\mathrm{d}\Pi_n$ is invariant.

For the total volume, integrate Eq. (16.39) over all final momenta: $\Pi_n(P) = \int \mathrm{d}\Pi_n$ is a Lorentz scalar built from the single four-vector P and the fixed masses, so it can depend on P only through the invariant $P^2 = s$. We will exhibit this dependence explicitly for $n = 2$ below. □

This invariance is the licence to compute in whatever frame is most convenient — the rest frame for a decay, the center-of-momentum frame for a collision — and trust that the number is physical. We now cash it for two bodies.

16.2.3 Two-body phase space in the center-of-momentum frame

The two-body case is special: conservation of four-momentum leaves only the overall orientation of the final state free, so the phase space reduces to an integral over a single solid angle with a kinematic prefactor that we can write in closed form. This is the workhorse of every $1 \to 2$ and $2 \to 2$ computation to come.

Choose the center-of-momentum (CM) frame, defined by $\mathbf{P} = \mathbf{0}$, so that $P = (\sqrt{s}, \mathbf{0})$ with $s = P^2$ the squared total energy. Starting from the definition,

$$\mathrm{d}\Pi_2 = (2\pi)^4\,\delta^4(P - k_1 - k_2)\,\frac{d^3k_1}{(2\pi)^3 2E_1}\,\frac{d^3k_2}{(2\pi)^3 2E_2}\,. \tag{16.40}$$

Use the three spatial components of the delta to do the $\mathbf{k}_2$ integral. It sets $\mathbf{k}_2 = -\mathbf{k}_1$; write $\mathbf{k} \equiv \mathbf{k}_1$, $k \equiv |\mathbf{k}|$, so the two particles emerge back-to-back with equal and opposite three-momenta (Fig. 16.2). The energies become

$$E_1 = \sqrt{k^2 + m_1^2}\,, \qquad E_2 = \sqrt{k^2 + m_2^2}\,, \tag{16.41}$$

and the surviving time-component delta enforces $E_1 + E_2 = \sqrt{s}$. One factor of $(2\pi)^3$ from the $\mathbf{k}_2$ integration cancels one in the measure, leaving

$$\mathrm{d}\Pi_2 = \frac{1}{(2\pi)^2}\,\frac{d^3k}{4E_1E_2}\,\delta(\sqrt{s} - E_1 - E_2)\,. \tag{16.42}$$

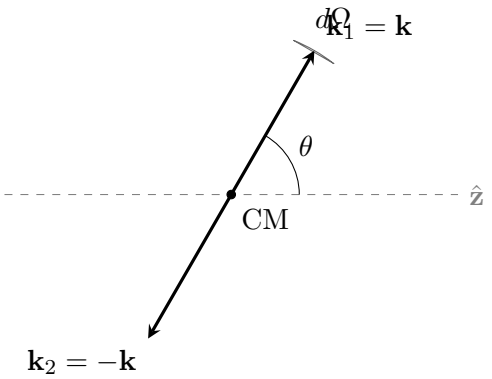

Figure 16.2: Two-body final state in the center-of-momentum frame. Momentum conservation forces the products back-to-back, $\mathbf{k}_2 = -\mathbf{k}_1 \equiv -\mathbf{k}$, leaving only the orientation (θ, ϕ) free; the phase-space integral runs over the solid angle $d\Omega$. The magnitude $|\mathbf{k}|$ is fixed by $E_1 + E_2 = \sqrt{s}$ to the value Eq. (16.51).

It remains to do the radial integral against the energy delta. Write $d^3k = k^2\, dk\, d\Omega$ with $d\Omega = \sin\theta\, d\theta\, d\phi$ the solid angle of $\mathbf{k}$, and define

$$g(k) \equiv \sqrt{s} - E_1(k) - E_2(k)\,. \tag{16.43}$$

The delta in Eq. (16.42) fixes k to the root k_* of g, i.e. to the value where $E_1 + E_2 = \sqrt{s}$. To convert $\delta(g(k))$ into $\delta(k - k_*)$ we again use the composition rule, now in the radial variable: $\delta(g(k)) = \delta(k - k_*)/\,|g'(k_*)|$. The derivative is

$$g'(k) = -\frac{dE_1}{dk} - \frac{dE_2}{dk} = -\frac{k}{E_1} - \frac{k}{E_2} = -k\,\frac{E_1 + E_2}{E_1 E_2}\,, \tag{16.44}$$

using $dE_i/dk = k/E_i$. Evaluated at the root, where $E_1 + E_2 = \sqrt{s}$,

$$|g'(k_*)| = \frac{k_*\,\sqrt{s}}{E_1 E_2}\,, \qquad \text{so} \qquad \delta\big(g(k)\big) = \frac{E_1 E_2}{k_*\sqrt{s}}\,\delta(k - k_*)\,. \tag{16.45}$$

Inserting Eq. (16.45) into Eq. (16.42) and doing the k integral,

$$\mathrm{d}\Pi_2 = \frac{1}{(2\pi)^2}\,\frac{k_*^2}{4E_1E_2}\,\frac{E_1E_2}{k_*\sqrt{s}}\,d\Omega = \frac{1}{(2\pi)^2}\,\frac{k_*}{4\sqrt{s}}\,d\Omega\,. \tag{16.46}$$

The energy factors E_1E_2 cancel completely — a small miracle that is the whole reason the two-body answer is so simple — and with $(2\pi)^2 \cdot 4 = 16\pi^2$ we arrive at the master two-body result:

$$\boxed{\mathrm{d}\Pi_2 = \frac{1}{16\pi^2}\,\frac{|\mathbf{k}|}{\sqrt{s}}\,d\Omega} \qquad \text{(CM frame)}, \tag{16.47}$$

where $|\mathbf{k}| = k_*$ is the common CM momentum and $d\Omega$ is the solid angle of particle 1.

It remains to give $|\mathbf{k}|$ in closed form. From $E_1 + E_2 = \sqrt{s}$ and the on-shell relations $E_i^2 = k^2 + m_i^2$ we get $E_1^2 - E_2^2 = m_1^2 - m_2^2$, and dividing by $E_1 + E_2 = \sqrt{s}$,

$$E_1 - E_2 = \frac{m_1^2 - m_2^2}{\sqrt{s}} \quad \Longrightarrow \quad E_1 = \frac{s + m_1^2 - m_2^2}{2\sqrt{s}} \,. \tag{16.48}$$

Then $k^2 = E_1^2 - m_1^2$, and a short reduction of the numerator,

$$\begin{aligned} k^2 &= \frac{(s + m_1^2 - m_2^2)^2}{4s} - m_1^2 = \frac{(s + m_1^2 - m_2^2)^2 - 4sm_1^2}{4s} \\ &= \frac{s^2 + m_1^4 + m_2^4 - 2sm_1^2 - 2sm_2^2 - 2m_1^2 m_2^2}{4s} = \frac{\lambda(s, m_1^2, m_2^2)}{4s} \,, \end{aligned} \tag{16.49}$$

introduces the *Källén (triangle) function*

$$\lambda(a,b,c) \equiv a^2 + b^2 + c^2 - 2ab - 2bc - 2ca = \big[a - (\sqrt{b} + \sqrt{c})^2\big]\big[a - (\sqrt{b} - \sqrt{c})^2\big]. \tag{16.50}$$

Hence the CM momentum is

$$|\mathbf{k}| = \frac{\lambda^{1/2}(s, m_1^2, m_2^2)}{2\sqrt{s}} = \frac{1}{2\sqrt{s}} \sqrt{\big[s - (m_1 + m_2)^2\big]\big[s - (m_1 - m_2)^2\big]} \,. \tag{16.51}$$

The second form makes the threshold explicit: $|\mathbf{k}|$ is real and positive precisely when $\sqrt{s} \geq m_1 + m_2$, i.e. when there is enough energy to make the two particles, and it vanishes at threshold $s = (m_1 + m_2)^2$ as it must.

Total two-body volume. When $\mathcal{M}$ is angle-independent (as for a spinless $1 \to 2$ decay) or when one wants the bare phase-space volume, integrate Eq. (16.47) over the full solid angle, $\int d\Omega = 4\pi$:

$$\Pi_2(s) = \int \mathrm{d}\Pi_2 = \frac{1}{16\pi^2} \frac{|\mathbf{k}|}{\sqrt{s}} 4\pi = \frac{|\mathbf{k}|}{4\pi\sqrt{s}} = \frac{\lambda^{1/2}(s, m_1^2, m_2^2)}{8\pi\, s} \,. \tag{16.52}$$

This depends on P only through s, as Theorem 16.8 guaranteed.

Special cases. Two limits recur constantly and are worth recording.

Massless products, $m_1 = m_2 = 0$. Then $|\mathbf{k}| = \sqrt{s}/2$, and

$$\mathrm{d}\Pi_2 = \frac{1}{32\pi^2}\, d\Omega \,, \qquad \Pi_2 = \frac{1}{8\pi} \,. \tag{16.53}$$

The two-body phase space of two massless particles is a pure number times the solid angle — no scale at all, a fact that underlies the simplicity of high-energy cross sections and of conformal two-point kinematics.

Equal masses, $m_1 = m_2 = m$. Then $|\mathbf{k}| = \tfrac{1}{2}\sqrt{s - 4m^2}$. Introducing the CM speed of either particle,

$$\beta = \sqrt{1 - \frac{4m^2}{s}} = \frac{2\,|\mathbf{k}|}{\sqrt{s}}\,, \tag{16.54}$$

the result compresses to

$$\mathrm{d}\Pi_2 = \frac{\beta}{32\pi^2}\, d\Omega\,, \qquad \Pi_2 = \frac{\beta}{8\pi}\,. \tag{16.55}$$

The factor β is the velocity suppression at threshold familiar from $e^+e^- \to \mu^+\mu^-$ near $\sqrt{s} = 2m_\mu$; it will reappear there in Chapter 17. As $\beta \to 1$ this reduces to the massless result Eq. (16.53), as it should.

16.2.4 The phase-space recursion

Beyond two bodies there is no single closed form, but there is an exact recursion that reduces $\mathrm{d}\Pi_n$ to a one-dimensional integral over an invariant mass times $\mathrm{d}\Pi_2$ and $\mathrm{d}\Pi_{n-1}$. This is the engine for every multibody computation: it lets a Dalitz plot or an n-body width be built by iterating the two-body formula.

Proposition 16.9 (Phase-space recursion)**.** *For any* $1 \le m < n$*, and in particular for the split that peels off a single particle,*

$$\mathrm{d}\Pi_n(P; k_1, \dots, k_n) = \mathrm{d}\Pi_2(P; q, k_n)\, \frac{dq^2}{2\pi}\, \mathrm{d}\Pi_{n-1}(q; k_1, \dots, k_{n-1})\,, \tag{16.56}$$

where $q = \sum_{i=1}^{n-1} k_i$ *is the total four-momentum of the first* $n-1$ *particles,* q^2 *ranges over* $\big[(\sum_{i<n} m_i)^2, (\sqrt{s} - m_n)^2\big]$*, and in* $\mathrm{d}\Pi_2(P; q, k_n)$ *the cluster* q *is treated as a single particle of mass* $\sqrt{q^2}$*.*

Proof. Begin with the definition Eq. (16.39), separating the last particle:

$$\mathrm{d}\Pi_n = (2\pi)^4\, \delta^4\Big(P - k_n - \sum_{i<n} k_i\Big)\, \widetilde{dk_n} \prod_{i<n} \widetilde{dk_i}\,. \tag{16.57}$$

Insert the resolution of unity (a completeness insertion in the cluster momentum)

$$1 = \int d^4q\; \delta^4\Big(q - \sum_{i<n} k_i\Big)\,, \tag{16.58}$$

so that the conservation delta splits, $\delta^4(P - k_n - \sum_{i<n} k_i) \to \delta^4(P - k_n - q)$ inside the q integral:

$$\mathrm{d}\Pi_n = \int d^4q\; (2\pi)^4 \delta^4(P - q - k_n)\, \widetilde{dk_n}\, \delta^4\Big(q - \sum_{i<n} k_i\Big) \prod_{i<n} \widetilde{dk_i}\,. \tag{16.59}$$

The cluster $q = \sum_{i<n} k_i$ is a sum of forward on-shell momenta, hence itself forward timelike, $q^0 > 0$ and $q^2 \geq (\sum_{i<n} m_i)^2 > 0$. On that domain we may trade the unconstrained four-dimensional measure d^4q for an integral over the invariant mass q^2 times an on-shell three-measure. Concretely, with $q^0 > 0$, change variable from q^0 to $q^2 = (q^0)^2 - \mathbf{q}^2$ at fixed $\mathbf{q}$: $dq^2 = 2q^0\, dq^0$ gives $dq^0 = dq^2/(2q^0)$, and writing $\omega_q \equiv q^0 = \sqrt{\mathbf{q}^2 + q^2}$,

$$\int \frac{d^4q}{(2\pi)^4}\,\theta(q^0)\,(\cdots) = \int_0^\infty \frac{dq^2}{2\pi} \int \frac{d^3q}{(2\pi)^3\,2\omega_q}\,(\cdots) = \int_0^\infty \frac{dq^2}{2\pi} \int \widetilde{dq}\,(\cdots)\,, \tag{16.60}$$

where $\widetilde{dq} = d^3q/[(2\pi)^3 2\omega_q]$ is exactly the on-shell measure Eq. (16.30) for a particle of mass $\sqrt{q^2}$. (This is Theorem 16.5 read backwards: $\int d^4q\,\theta(q^0) = \int dq^2 \int d^4q\,(2\pi)\delta(q^2 - (q^2))\theta(q^0)/(2\pi)$, the δ collapsing $q^0 \to \omega_q$.) Applying Eq. (16.60) to Eq. (16.59) — the explicit $(2\pi)^4$ already present supplies the needed factors when we reinstate it — gives

$$\mathrm{d}\Pi_n = \int_0^\infty \frac{dq^2}{2\pi} \underbrace{(2\pi)^4\delta^4(P - q - k_n)\,\widetilde{dq}\,\widetilde{dk_n}}_{=\mathrm{d}\Pi_2(P;q,k_n)} \underbrace{(2\pi)^4\delta^4\Big(q - \sum_{i<n} k_i\Big) \prod_{i<n} \widetilde{dk_i}}_{=\mathrm{d}\Pi_{n-1}(q;k_1,\ldots,k_{n-1})}\,. \tag{16.61}$$

The two braces are, respectively, the two-body phase space for $P \to q + k_n$ with q a particle of mass $\sqrt{q^2}$, and the $(n-1)$-body phase space for the decay of q into $k_1, \ldots, k_{n-1}$. Differentially this is exactly Eq. (16.56). The range of q^2 is set by requiring both factors to have support: $\mathrm{d}\Pi_{n-1}$ needs $q^2 \geq (\sum_{i<n} m_i)^2$ and $\mathrm{d}\Pi_2$ needs $\sqrt{q^2} \leq \sqrt{s} - m_n$, i.e. $q^2 \leq (\sqrt{s} - m_n)^2$. □

The recursion turns the construction of any $\mathrm{d}\Pi_n$ into an iterated chain of two-body factors, each in the closed form Eq. (16.47). The simplest nontrivial case, $n = 3$, produces the Dalitz plot — the standard arena for analyzing three-body decays — and shows the machinery working end to end.

Worked Example 16.10 (Three-body phase space and the Dalitz measure)**.** Consider a particle of mass M (so $P^2 = s = M^2$) decaying to three particles of masses m_1, m_2, m_3. We compute the doubly-differential phase space in the two independent invariant masses

$$s_{12} \equiv (k_1 + k_2)^2\,, \qquad s_{23} \equiv (k_2 + k_3)^2\,, \tag{16.62}$$

and show that the result is flat in these variables — the central fact behind the Dalitz plot: any deviation from a uniform population of the (s_{12}, s_{23}) plane is dynamics in $|\mathcal{M}|^2$, never kinematics.

Apply the recursion. Peel off particle 3, so the cluster is $q = k_1 + k_2$ with $q^2 = s_{12}$. Then Eq. (16.56) reads

$$\mathrm{d}\Pi_3 = \frac{ds_{12}}{2\pi}\,\mathrm{d}\Pi_2(P; q, k_3)\,\mathrm{d}\Pi_2(q; k_1, k_2)\,. \tag{16.63}$$

Evaluate each two-body factor with Eq. (16.47) in its natural frame.

The outer factor $\mathrm{d}\Pi_2(P; q, k_3)$, in the overall rest frame of P (the M rest frame), describes $P \to q + k_3$ with q of mass $\sqrt{s_{12}}$:

$$\mathrm{d}\Pi_2(P; q, k_3) = \frac{1}{16\pi^2}\,\frac{|\mathbf{k}_3|}{\sqrt{s}}\,d\Omega_3\,, \tag{16.64}$$

$|\mathbf{k}_3|$ being the momentum of particle 3 in the P frame and $d\Omega_3$ its direction there.

The inner factor $\mathrm{d}\Pi_2(q; k_1, k_2)$, in the rest frame of q (the 1–2 center of momentum, denoted by a star), describes $q \to k_1 + k_2$:

$$\mathrm{d}\Pi_2(q; k_1, k_2) = \frac{1}{16\pi^2}\,\frac{|\mathbf{k}_1^*|}{\sqrt{s_{12}}}\,d\Omega_1^*\,, \tag{16.65}$$

with $|\mathbf{k}_1^*|$ and $d\Omega_1^*$ measured in the q frame.

Integrate the trivial orientations. For a spinless (or unpolarized) decay nothing selects an absolute direction, so the overall orientation $d\Omega_3$ integrates freely: $\int d\Omega_3 = 4\pi$. In the inner factor, choose the polar axis of $d\Omega_1^* = d\cos\theta^*\, d\phi_1^*$ along the direction of particle 3 as seen in the q frame; the azimuth is free, $\int d\phi_1^* = 2\pi$, leaving $d\cos\theta^*$. Collecting constants,

$$\mathrm{d}\Pi_3 = \frac{ds_{12}}{2\pi}\cdot\frac{4\pi}{16\pi^2}\,\frac{|\mathbf{k}_3|}{\sqrt{s}}\cdot\frac{2\pi}{16\pi^2}\,\frac{|\mathbf{k}_1^*|}{\sqrt{s_{12}}}\,d\cos\theta^* = \frac{1}{64\pi^3}\,\frac{|\mathbf{k}_3|\;|\mathbf{k}_1^*|}{\sqrt{s}\,\sqrt{s_{12}}}\,ds_{12}\,d\cos\theta^*\,. \tag{16.66}$$

Change $\cos\theta^* \to s_{23}$. The remaining angle controls s_{23}. In the q frame, $\mathbf{k}_2^* = -\mathbf{k}_1^*$, and writing $|\mathbf{k}_3^*|$ for the momentum of particle 3 in this frame,

$$\begin{aligned} s_{23} = (k_2 + k_3)^2 &= m_2^2 + m_3^2 + 2(E_2^* E_3^* - \mathbf{k}_2^*\cdot\mathbf{k}_3^*) \\ &= m_2^2 + m_3^2 + 2E_2^* E_3^* + 2\;|\mathbf{k}_1^*|\;|\mathbf{k}_3^*|\cos\theta^*\,, \end{aligned} \tag{16.67}$$

since θ^* is the angle between $\mathbf{k}_1^*$ and the particle-3 direction and $\mathbf{k}_2^*\cdot\mathbf{k}_3^* = -\,|\mathbf{k}_1^*|\,|\mathbf{k}_3^*|\cos\theta^*$. At fixed s_{12} all energies are fixed, so

$$ds_{23} = 2\;|\mathbf{k}_1^*|\;|\mathbf{k}_3^*|\;d\cos\theta^* \quad\Longrightarrow\quad |\mathbf{k}_1^*|\;d\cos\theta^* = \frac{ds_{23}}{2\;|\mathbf{k}_3^*|}\,. \tag{16.68}$$

Relate the two frames. The only frame-dependent quantities left are $|\mathbf{k}_3|$ (in the P frame) and $|\mathbf{k}_3^*|$ (in the q frame). Both are momenta of particle 3 in a two-body configuration with the cluster of invariant mass $\sqrt{s_{12}}$; from Eq. (16.51) applied in each frame,

$$|\mathbf{k}_3| = \frac{\lambda^{1/2}(s, s_{12}, m_3^2)}{2\sqrt{s}}\,, \qquad |\mathbf{k}_3^*| = \frac{\lambda^{1/2}(s, s_{12}, m_3^2)}{2\sqrt{s_{12}}}\,, \tag{16.69}$$

the first from $P \to q + k_3$ in the P frame, the second from the energy of particle 3 in the q frame, $E_3^* = q\cdot k_3/\sqrt{s_{12}} = (s - s_{12} - m_3^2)/(2\sqrt{s_{12}})$. The triangle function is identical in both, so

$$\frac{|\mathbf{k}_3|}{|\mathbf{k}_3^*|} = \frac{\sqrt{s_{12}}}{\sqrt{s}}\,. \tag{16.70}$$

Assemble. Substitute Eq. (16.68) into Eq. (16.66) and use Eq. (16.70):

$$\mathrm{d}\Pi_3 = \frac{1}{64\pi^3}\,\frac{|\mathbf{k}_3|}{\sqrt{s}\,\sqrt{s_{12}}}\,\frac{1}{2\,|\mathbf{k}_3^*|}\,ds_{12}\,ds_{23} = \frac{1}{128\pi^3}\,\frac{1}{\sqrt{s}\,\sqrt{s_{12}}}\,\frac{\sqrt{s_{12}}}{\sqrt{s}}\,ds_{12}\,ds_{23}\,, \tag{16.71}$$

and the $\sqrt{s_{12}}$ cancels, leaving the flat Dalitz measure

$$\boxed{\mathrm{d}\Pi_3 = \frac{1}{(2\pi)^3}\,\frac{1}{16\,s}\,ds_{12}\,ds_{23}} \qquad (s = M^2), \tag{16.72}$$

where we used $128\pi^3 = 16\cdot(2\pi)^3$. The phase-space density is constant across the kinematically allowed region of the (s_{12}, s_{23}) plane; the boundary of that region is set by requiring $|\cos\theta^*| \le 1$, which carves out the familiar Dalitz contour. Every structure inside it — bands, peaks, interference — is the dynamics encoded in $|\mathcal{M}|^2$, exactly as advertised. This is the same logic that will let Chapter 17 read tree-level distributions straight off $|\mathcal{M}|^2$.

We have isolated the purely kinematic content of any transition: a Lorentz-scalar measure $\mathrm{d}\Pi_n$, manifestly frame-independent, reducible by the recursion Eq. (16.56) to the closed two-body form Eq. (16.47). What this measure still lacks is the normalization that turns $\int |\mathcal{M}|^2\,\mathrm{d}\Pi_n$ into an observable rate. That normalization differs by initial state: a single factor $1/(2M)$ for the decay of one particle of mass M, treated next in Section 16.3, and an incident flux for a two-particle collision, treated in Section 16.4. With $\mathrm{d}\Pi_2$ in hand, both reduce to one short step.

16.3 The decay rate formula

We now have both halves of the apparatus the chapter set out to build. Section 16.1 regulated the squared energy–momentum delta function with a finite box V and a finite observation time T and extracted from it a finite *transition rate* — a probability per unit time — in terms of the invariant amplitude $\mathcal{M}$ defined by $\langle f|iT|i\rangle = (2\pi)^4\delta^4(p_f - p_i)\,i\mathcal{M}$ (Eq. (14.163)). Section 16.2 took the purely kinematic remainder of that rate, the integral over on-shell final momenta enforcing total energy–momentum conservation, isolated it as the Lorentz-invariant phase-space measure $\mathrm{d}\Pi_n$, and reduced the two-body case in the centre-of-momentum frame to a closed form. The dynamics lives entirely in $\mathcal{M}$; everything else is the geometry of the on-shell final momenta. What remains

is to feed in an initial state and read off an observable. The simplest possible initial state is a single particle, and the observable it produces is its decay. This section treats that one-body case in full: it assembles the differential decay rate from the §16.1 skeleton and the §16.2 measure, defines the width, lifetime, partial widths, and branching ratios, settles the symmetry factor for identical final particles, and carries a complete worked decay through to a numerical lifetime.

16.3.1 From the rate skeleton to $d\Gamma$: where the $1/2M$ comes from

Recall the rate skeleton of Section 16.1. Working in a spatial box of volume V for a time T, with one-particle states carried in the relativistic normalization $\langle p|p'\rangle = 2E_{\mathbf{p}}(2\pi)^3\delta^3(\mathbf{p}-\mathbf{p}')$ of Eq. (3.193) (so that in the box $\langle p|p\rangle = 2E_{\mathbf{p}}V$), the probability for a prepared initial state $|i\rangle$ to be found, after the interaction, in a particular set of n outgoing single-particle momentum cells is

$$dP_{i\to f} = \frac{\big|\langle f|iT|i\rangle\big|^2}{\langle i|i\rangle\,\prod_{a=1}^{n}\langle f_a|f_a\rangle}\;\prod_{a=1}^{n}\frac{V\,d^3p_a}{(2\pi)^3}\,, \tag{16.73}$$

where the last product counts the number of distinct momentum states available to each outgoing particle inside the box, and the denominators undo the relativistic normalization of the states that appear in $\langle f|iT|i\rangle$. The square of the connected matrix element supplies, through the regulated identity established in Section 16.1,

$$\big|\langle f|iT|i\rangle\big|^2 = \Big[(2\pi)^4\delta^4(p_f-p_i)\Big]^2\,|\mathcal{M}|^2 = VT\,(2\pi)^4\delta^4(p_f-p_i)\,|\mathcal{M}|^2\,, \tag{16.74}$$

the one factor of the delta function having been evaluated at zero argument and replaced by the spacetime volume, $(2\pi)^4\delta^4(0)\to VT$. This is the single place a divergence threatened, and it is exactly cancelled below.

We now specialize to a one-body initial state: a single parent particle of mass M, which we may always place at rest, $p_i=(M,\mathbf{0})$, since the decay rate of an unstable particle is most naturally quoted in its rest frame. Then $\langle i|i\rangle = 2E_iV = 2MV$. The factors of V and T assemble as follows. The denominators $\prod_a\langle f_a|f_a\rangle = \prod_a 2E_aV$ each carry a V, and these cancel the n box volumes in the numerator product $\prod_a V\,d^3p_a$. The single remaining box volume from Eq. (16.74) cancels the V in $\langle i|i\rangle = 2MV$. The factor T in Eq. (16.74) is removed by passing from a probability to a *rate*, $d\Gamma = dP_{i\to f}/T$. Collecting what survives,

$$d\Gamma = \frac{1}{2M}\,|\mathcal{M}|^2\,\underbrace{\prod_{a=1}^{n}\frac{d^3p_a}{(2\pi)^3\,2E_a}\,(2\pi)^4\delta^4\Big(p_i-\sum_a p_a\Big)}_{\mathrm{d}\Pi_n}\,. \tag{16.75}$$

The bracketed object is precisely the Lorentz-invariant n-body phase-space measure $\mathrm{d}\Pi_n$ built and shown invariant in Section 16.2. We have arrived at the master differential decay rate.

Theorem 16.11 (Differential decay rate)**.** *For a parent particle of mass M decaying at rest into n final particles, the differential rate into the phase-space element $\mathrm{d}\Pi_n$ is*

$$\boxed{d\Gamma = \frac{1}{2M}\,|\mathcal{M}|^2\,\mathrm{d}\Pi_n} \tag{16.76}$$

where $\mathcal{M}$ is the invariant amplitude of Eq. (14.163) and the entire dependence on the initial state is the single prefactor $1/2M$.

The decisive feature, and the reason this is the simplest member of the family of observable formulae, is the origin of the prefactor. The $\frac{1}{2M}$ is nothing but the inverse of the relativistic normalization $\langle i|i\rangle/V = 2E = 2M$ of one particle at rest. There is no flux factor: flux measures the relative motion of two colliding beams, and a single particle has nothing to move relative to. This is exactly the structural difference between a decay and a scattering process. When §16.4 treats a two-body initial state, the only change in the assembly above will be that $\langle i|i\rangle$ becomes a product of two normalizations and that the relative velocity of the incoming pair re-enters; the $1/2M$ here is the degenerate, single-particle limit of the general normalization denominator.

Physical Insight

The split is clean and worth stating once: $\mathcal{M}$ is *dynamics* — it is what the Lagrangian, the Feynman rules, and the loop expansion compute — while $\mathrm{d}\Pi_n$ is *kinematics*, fixed entirely by the masses and the conservation law, identical for every theory with the same external particles. The normalization prefactor ($1/2M$ here, the flux there) is *bookkeeping* for how the initial state was counted. Every decay rate and cross section in the book is one of these three pieces times another; once $\mathcal{M}$ is known, producing a number is mechanical.

16.3.2 Width, lifetime, partial widths, and branching ratios

Integrating Eq. (16.76) over all of phase space for a definite set of final particles f gives the *partial decay rate*, or *partial width*, into that channel,

$$\Gamma_f = \frac{1}{2M}\int |\mathcal{M}(i\to f)|^2\,\mathrm{d}\Pi_n^{(f)}\,, \tag{16.77}$$

with one subtlety — the symmetry factor for identical final particles — deferred to Section 16.3.3. A given parent will in general have several open channels f, distinguished by the species and number of decay products. Because the channels are mutually exclusive final states, the probabilities add, and so do the rates.

Definition 16.12 (Total width, lifetime, branching ratio)**.** The *total width* of an unstable particle is the sum of its partial widths over all kinematically allowed channels,

$$\Gamma = \sum_f \Gamma_f \,. \tag{16.78}$$

Its *mean lifetime* is the reciprocal, $\tau = 1/\Gamma$, and the *branching ratio* into channel f is the fraction of decays proceeding through that channel,

$$\mathrm{BR}_f = \frac{\Gamma_f}{\Gamma}\,, \qquad \sum_f \mathrm{BR}_f = 1\,. \tag{16.79}$$

That $\tau = 1/\Gamma$ is the mean lifetime is not a definition imposed by fiat; it follows from the rate interpretation. If at time t a population $N(t)$ of identical parents survives undecayed, the number decaying in dt is $dN = -\Gamma\, N\, dt$, because Γ is by construction the probability of decay per unit time per particle. This integrates to the exponential law

$$N(t) = N(0)\, e^{-\Gamma t}, \tag{16.80}$$

and the mean survival time of a single parent, with normalized decay-time distribution $\Gamma e^{-\Gamma t}$, is

$$\langle t \rangle = \int_0^\infty t\, \Gamma e^{-\Gamma t}\, dt = \frac{1}{\Gamma} = \tau\,, \tag{16.81}$$

as claimed. The same exponential is visible directly in the quantum amplitude: an unstable particle is not an exact energy eigenstate, and its rest-frame survival amplitude behaves as $e^{-iMt}\, e^{-\Gamma t/2}$, i.e. as if its mass were the complex number $M - \frac{i}{2}\Gamma$. Squaring the amplitude reproduces $e^{-\Gamma t}$, and the imaginary shift of the mass is exactly what a Breit–Wigner resonance of width Γ encodes in energy space. This is the first appearance of a theme the book returns to with full machinery: a decay width is the imaginary part of a pole.

Physical Insight

The width does double duty as a frequency and as an energy. In natural units $[\Gamma] =$ mass, so a width quoted in MeV is simultaneously an inverse lifetime: $\tau = \hbar/\Gamma$, with $\hbar = 6.582 \times 10^{-25}$ GeV $\cdot$ s the conversion factor restored. A particle whose width is 1 GeV lives for about 6.6×10^{-25} s; one whose width is 1 eV lives a billion (10^9) times longer. "Broad" and "short-lived" are the same statement.

The complex-mass picture is more than a mnemonic. In Chapter 19 the self-energy $\Sigma(p^2)$ — the sum of one-particle-irreducible corrections to the propagator — is shown to shift the pole of the full propagator from $p^2 = M^2$ to $p^2 = M^2 + \Sigma(p^2)$,

and the location of that pole in the complex p^2 plane fixes both the physical mass and the width. Matching the imaginary part of the pole to the exponential decay law Eq. (16.80) gives the exact relation

$$\Gamma = -\frac{1}{M}\,\mathrm{Im}\,\Sigma(M^2)\,, \tag{16.82}$$

which we record here as a forward pointer and discharge in Chapter 19. It is not an independent route to the width but the same width seen through the propagator: the optical theorem of §16.7, which equates twice the imaginary part of a forward amplitude to a total rate, is precisely the statement that ties Eq. (16.82) to the phase-space integral Eq. (16.77). Computing Γ from $|\mathcal{M}|^2$ integrated over $\mathrm{d}\Pi_n$, as we do in the rest of this section, and computing it from $\mathrm{Im}\,\Sigma$, as Chapter 19 does, are the two faces of unitarity.

16.3.3 Identical final particles: the $1/n!$ symmetry factor

Formula Eq. (16.76) was derived by labelling the outgoing particles $1, 2, \ldots, n$ and integrating each momentum independently over all of momentum space. When some of the final particles are *identical*, this overcounts the physical final states, and the rate must be corrected by a combinatorial factor. The crucial point — often misattributed to the amplitude — is that this factor is a property of the *integration domain*, not of $\mathcal{M}$.

To see it cleanly, suppose all n final particles are identical bosons of a single species. A physical final state is an *unordered* collection of n momenta: the state with particles at momenta $(\mathbf{p}_1, \ldots, \mathbf{p}_n)$ is the very same state as the one with those momenta in any other order, because identical bosons carry no labels. The Hilbert-space sum over distinct physical final states therefore runs over unordered n-tuples. The measure $\mathrm{d}\Pi_n$ in Eq. (16.76), however, was constructed as a product of independent single-particle integrals, $\prod_a \int d^3p_a/[(2\pi)^3 2E_a]$, which runs over *ordered* n-tuples and hence visits each unordered configuration $n!$ times — once for every permutation of the labels. (The measure-zero diagonal where two momenta coincide does not affect the integral.) Integrating $|\mathcal{M}|^2\,\mathrm{d}\Pi_n$ as written thus computes $n!$ times the physically meaningful sum over distinct final states. The total rate into the identical-particle channel is the corrected

$$\Gamma = \frac{1}{2M}\,\frac{1}{n!}\int |\mathcal{M}|^2\,\mathrm{d}\Pi_n\,, \tag{16.83}$$

and more generally, if the final state contains n_j identical particles of species j, the prefactor is the product

$$\mathcal{S} = \prod_j \frac{1}{n_j!}\,, \tag{16.84}$$

one factorial for each species, distinct species being distinguishable and contributing no symmetrization.

Caution

The factor $1/n!$ has nothing to do with the symmetry factors of *diagrams* introduced for ϕ^4 in Chapter 15. Those arise from the automorphisms of a Feynman graph and are absorbed into the definition of $\mathcal{M}$ before it is squared. The factor Eq. (16.84) is applied *after* squaring, to the phase-space integral, and corrects the counting of final *states*. Bose symmetry guarantees that $\mathcal{M}$ is already symmetric under exchange of identical external legs — so $|\mathcal{M}|^2$ takes the same value at all $n!$ permuted points and the integral is genuinely $n!$ times the physical one. Computing $\mathcal{M}$ correctly (with its diagrammatic symmetry factors) and then dividing the rate by $\prod_j n_j!$ are two independent bookkeeping steps; omitting either is a defect.

16.3.4 The two-body width of a particle at rest

The overwhelmingly common case is a two-body decay, $\Phi \to 1 + 2$, for which §16.2 provides the reduced measure in closed form. With the parent at rest the total four-momentum is $p_i = (M, \mathbf{0})$, so the centre-of-momentum energy is $\sqrt{s} = M$, and the two-body Lorentz-invariant phase space found in Section 16.2 reads

$$\mathrm{d}\Pi_2 = \frac{1}{16\pi^2}\,\frac{|\mathbf{k}|}{M}\,d\Omega\,, \tag{16.85}$$

where $d\Omega$ is the solid-angle element of one outgoing particle in the rest frame and $|\mathbf{k}|$ is the common magnitude of the two back-to-back final momenta. Energy–momentum conservation, $M = \sqrt{|\mathbf{k}|^2 + m_1^2} + \sqrt{|\mathbf{k}|^2 + m_2^2}$, fixes $|\mathbf{k}|$ through the Källén triangle function,

$$|\mathbf{k}| = \frac{\lambda^{1/2}(M^2, m_1^2, m_2^2)}{2M}\,, \qquad \lambda(a,b,c) = a^2 + b^2 + c^2 - 2ab - 2bc - 2ca\,, \tag{16.86}$$

which for equal masses $m_1 = m_2 = m$ collapses to the form we shall need,

$$|\mathbf{k}| = \frac{M}{2}\sqrt{1 - \frac{4m^2}{M^2}}\,. \tag{16.87}$$

The square root is real precisely when $M \geq m_1 + m_2$, the kinematic threshold for the decay to be allowed at all; below it the channel is closed and $\Gamma_f = 0$.

Inserting Eq. (16.85) into the master formula Eq. (16.76) gives the differential two-body width,

$$\frac{d\Gamma}{d\Omega} = \frac{1}{2M}\,|\mathcal{M}|^2\,\frac{1}{16\pi^2}\,\frac{|\mathbf{k}|}{M} = \frac{|\mathbf{k}|}{32\pi^2 M^2}\,|\mathcal{M}|^2\,. \tag{16.88}$$

When the amplitude is independent of the emission angle — which is automatic for a scalar parent, since there is no preferred direction in the rest frame and

no spin to correlate with — the angular integral is trivial. Writing $\overline{|\mathcal{M}|^2}$ for the amplitude squared (the overbar will denote the spin average once spins enter in Chapter 17; for spinless particles it is just $|\mathcal{M}|^2$) and integrating over the full solid angle $\int d\Omega = 4\pi$,

$$\Gamma = \mathcal{S}\,\frac{|\mathbf{k}|}{8\pi M^2}\,\overline{|\mathcal{M}|^2}\,, \tag{16.89}$$

with $\mathcal{S} = \frac{1}{2}$ when the two final particles are identical and $\mathcal{S} = 1$ when they are distinct, per Eq. (16.84). This is the workhorse two-body width formula. It says that, for a constant amplitude, the entire content of a two-body decay rate is the single kinematic number $|\mathbf{k}|$ — the momentum released — divided by $8\pi M^2$, times the dynamical $\overline{|\mathcal{M}|^2}$ and the identical-particle factor. We now cash it on a concrete model.

16.3.5 A worked decay: a heavy scalar into two light scalars

Notation Watch

The frozen ϕ^4 theory theory has a single real scalar with only a quartic self-interaction; it admits no on-shell one-to-two decay, because a single ϕ cannot go to two ϕ's at any order (there is no cubic vertex, and the would-be process $\phi \to \phi\phi$ violates energy–momentum conservation for one species anyway). To exhibit a genuine, fully worked decay we therefore step *outside* the frozen ϕ^4 Lagrangian and introduce an auxiliary toy model, used only in this worked example. The ϕ^4 thread itself is advanced in §16.6, where the carried $2 \to 2$ amplitude $\mathcal{M} = -\lambda$ is turned into a cross section.

Worked Example 16.13 (Decay of a heavy scalar via a cubic coupling)**.** Consider a heavy real scalar Φ of mass M coupled to a light real scalar ϕ of mass m through the cubic interaction

$$\mathcal{L}_{\text{int}} = -\frac{g}{2}\,\Phi\,\phi^2\,, \tag{16.90}$$

where the coupling g has mass dimension one (since $[\Phi] = [\phi] = 1$ in four dimensions and $[\mathcal{L}] = 4$). We compute the decay rate $\Phi \to \phi\phi$ and a numerical lifetime. This is an auxiliary model, distinct from $\lambda\phi^4$ theory; the factor of $\frac{1}{2}$ in Eq. (16.90) is the conventional choice that makes the vertex come out as $-ig$, as we now verify.

The amplitude. The single tree diagram is the elementary cubic vertex with one incoming Φ and two outgoing ϕ lines (Fig. 16.3). By the Feynman rules of Chapter 15, a vertex from an interaction term $\mathcal{L}_{\text{int}}$ contributes i times the coupling, times the number of distinct ways the fields in the vertex can be

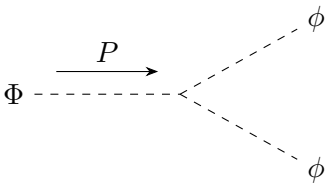

Figure 16.3: The single tree diagram for $\Phi \to \phi\phi$ from the cubic interaction Eq. (16.90). The parent four-momentum $P = (M, \mathbf{0})$ splits into two back-to-back light scalars of momentum magnitude $|\mathbf{k}|$ given by Eq. (16.87).

contracted with the external lines. The term Eq. (16.90) contains two identical ϕ fields, which can attach to the two external ϕ legs in $2! = 2$ ways, so the vertex factor is

$$i\mathcal{M} = i\,(-g)\cdot\tfrac{1}{2}\cdot 2! = -ig\,, \qquad \Longrightarrow \qquad \mathcal{M} = -g\,, \quad |\mathcal{M}|^2 = g^2\,. \tag{16.91}$$

The combinatorial 2! exactly cancels the conventional $\frac{1}{2}$, leaving the clean result $\mathcal{M} = -g$. The amplitude is a constant: there is no momentum dependence at tree level for a pointlike cubic vertex, so Eq. (16.89) applies directly.

The rate. The two final particles are identical, so $\mathcal{S} = \frac{1}{2}$. With equal final masses the released momentum is Eq. (16.87), $|\mathbf{k}| = \frac{M}{2}\sqrt{1 - 4m^2/M^2}$. Substituting into Eq. (16.89),

$$\begin{aligned}\Gamma &= \frac{1}{2}\cdot\frac{|\mathbf{k}|}{8\pi M^2}\cdot g^2 = \frac{g^2}{16\pi M^2}\cdot\frac{M}{2}\sqrt{1-\frac{4m^2}{M^2}} \\ &= \boxed{\frac{g^2}{32\pi M}\sqrt{1-\frac{4m^2}{M^2}}}\,.\end{aligned} \tag{16.92}$$

The structure is instructive. The rate grows linearly with g^2 as a tree-level coupling-squared must; the overall $1/M$ is fixed by dimensions, since $[\Gamma] =$ mass and $[g^2] =$ mass^2; and the square root is the phase-space suppression that switches the rate off continuously as $m \to M/2$, the threshold below which the decay cannot occur. In the limit $m \ll M$ the daughters are effectively massless and $\Gamma \to g^2/32\pi M$.

A number. Choose, purely as an illustration, $M = 10$ GeV, $m = 1$ GeV, and $g = 1$ GeV. Then $4m^2/M^2 = 0.04$ and $\sqrt{1 - 0.04} = 0.9798$, so from Eq. (16.92),

$$\Gamma = \frac{(1\text{ GeV})^2}{32\pi\,(10\text{ GeV})}\times 0.9798 = \frac{0.9798}{1005.3}\text{ GeV} = 9.75\times 10^{-4}\text{ GeV} = 0.975\text{ MeV}\,. \tag{16.93}$$

The lifetime follows by restoring $\hbar = 6.582 \times 10^{-25}\ \text{GeV} \cdot \text{s}$:

$$\tau = \frac{\hbar}{\Gamma} = \frac{6.582 \times 10^{-25}\ \text{GeV} \cdot \text{s}}{9.75 \times 10^{-4}\ \text{GeV}} = 6.75 \times 10^{-22}\ \text{s}\,. \tag{16.94}$$

A width of about an MeV corresponds to a lifetime of order $10^{-21}\,\text{s}$ — the characteristic timescale of a strongly coupled decay, and a concrete instance of the width–lifetime reciprocity emphasized above. Every step from the Lagrangian Eq. (16.90) to the number Eq. (16.94) has been carried explicitly; the reader can reproduce it with no input beyond $\hbar$.

This completes the one-body initial state. The differential rate Eq. (16.76), the width and lifetime of Theorem 16.12, the identical-particle factor Eq. (16.84), and the closed two-body formula Eq. (16.89) together turn any computed amplitude into a measurable lifetime. The single structural ingredient that distinguished a decay from a generic process was the trivial normalization of one initial particle, $1/2M$, with no flux factor because a lone particle has no relative motion to measure. The moment we admit two incoming particles, that relative motion becomes the central new object: the rate must be divided not by $2M$ but by a *flux*, the density of incoming particles times their relative velocity, packaged covariantly. Constructing that flux factor, and assembling from it the master cross-section formula, is the task of the next section.

16.4 The flux factor and the master cross-section formula

The decay rate of Section 16.3 was the easy half of the golden rule. A decaying particle is a one-body initial state: there is nothing to collide with, the initial momentum is fixed once we sit in the rest frame, and the only normalization the rate must carry is the single factor $1/2M$ that converts the relativistically normalized state to a per-particle probability. Scattering is genuinely harder for one structural reason. A cross section measures how strongly two beams interact, and "how strongly" is meaningless until we say *how many* particles were offered up to interact and *how fast* they were swept past one another. The two-body initial state therefore drags in a kinematic factor that the decay calculation never saw: the *flux*. Building that factor correctly, showing that the operational lab-frame definition coincides with a manifestly Lorentz-invariant expression, and folding it into the rate of Section 16.1 to produce a single master formula valid for any final state — that is the whole business of this section. The dynamics will sit, untouched, in $\mathcal{M}$; everything we add here is geometry of the incoming momenta.

16.4.1 The operational definition of a cross section

Imagine the canonical table-top experiment: a steady beam of particles of type 1 is fired at a thin target containing particles of type 2 at rest, and a detector counts how often a particular reaction $1 + 2 \to \{p_3, \dots, p_n\}$ occurs. The raw number of events per second is not a property of the interaction alone — doubling the beam intensity or the target thickness doubles it. To isolate the physics we normalize twice: per target particle, and per unit of incident beam flux. What remains has the dimensions of an area, and it is the cross section.

Definition 16.14 (Cross section)**.** Let an incident beam of type-1 particles impinge on a collection of type-2 target particles. The *incident flux* Φ is the number of beam particles crossing a unit area normal to the beam per unit time. If W is the transition rate (events per unit time) into a chosen set of final states, summed over the N_{tgt} target particles exposed to the beam, then the cross section for that reaction is

$$\sigma \;\equiv\; \frac{W/N_{\text{tgt}}}{\Phi} \;=\; \frac{\text{transition rate per target particle}}{\text{incident flux}}. \tag{16.95}$$

Its differential version $d\sigma$ uses the rate dW into an infinitesimal cell of final-state momenta.

The factor $1/N_{\text{tgt}}$ strips the target thickness and $1/\Phi$ strips the beam intensity, leaving a quantity with units of $[\Phi]^{-1}[\text{time}]^{-1} \cdot [\text{time}] = [\Phi]^{-1}$; since $[\Phi] = (\text{area} \cdot \text{time})^{-1} \cdot \text{time} = \text{area}^{-1}$ once we count number per area per time and divide by a rate, σ comes out as an area. Concretely, in natural units a cross section is an inverse-mass-squared; the standard laboratory unit is the barn, $1\,\text{barn} = 10^{-24}\,\text{cm}^2$. The geometric reading is the one to keep in mind: σ is the effective cross-sectional area each target particle presents to the beam for the reaction in question.

There is one refinement hidden in Fig. 16.4 that the rest-target picture obscures. In a frame where the target also moves — and in particular in the centre-of-momentum frame, where both beams move — the relevant relative speed is not the speed of either beam but the speed with which the two populations sweep through one another. The flux must be built from the *relative velocity* $|\mathbf{v}_1 - \mathbf{v}_2|$. We make this quantitative next.

16.4.2 Assembling $d\sigma$ from the box rate

In Section 16.1 we made the squared S-matrix element finite by quantizing the theory in a spatial box of volume $V = L^3$ over a time interval T, so that the offending square of the energy–momentum delta becomes the finite spacetime volume,

$$\big[(2\pi)^4\delta^4(0)\big] \;\longrightarrow\; VT, \tag{16.96}$$

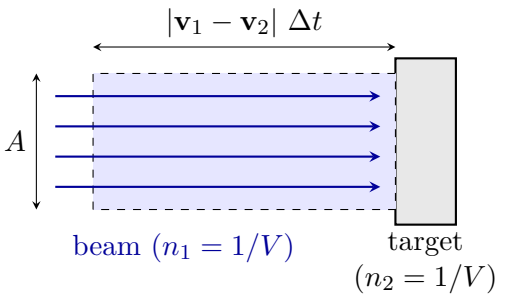

Figure 16.4: The flux as a swept volume. In time Δt the beam particles within the shaded slab of cross-sectional area A and length $|\mathbf{v}_1 - \mathbf{v}_2|\ \Delta t$ reach the target. With one beam and one target particle per box volume V, the number density of each is $1/V$ and the incident number flux is $\Phi = n_1\,|\mathbf{v}_1 - \mathbf{v}_2| = |\mathbf{v}_1 - \mathbf{v}_2|\,/V$. The relative velocity enters because the target is itself moving in a general frame.

and the relativistically normalized one-particle state of Eq. (3.193) acquires the box norm $\langle p|p\rangle_V = 2E_{\mathbf{p}}\,V$. We now run that machinery for a *two*-particle initial state and divide by flux to extract the cross section; this is the construction promised in Section 16.1, specialized to two incoming particles.

Let the initial state be $|i\rangle = |p_1\,p_2\rangle_V$ and the final state a definite occupation of one-particle box modes $|f\rangle = |p_3 \cdots p_n\rangle_V$. The invariant amplitude is defined, exactly as in Eq. (14.163), by stripping the energy–momentum delta from the connected matrix element of $iT = i(\mathbf{S} - \mathbf{1})$,

$$\langle f|\, iT\,|i\rangle \;=\; i\,\mathcal{M}(p_1, p_2 \to p_3, \ldots, p_n)\,(2\pi)^4\delta^4\Big(p_1 + p_2 - \sum_f p_f\Big). \tag{16.97}$$

The probability of the transition is $|\langle f|iT|i\rangle|^2$ divided by the norms of the in- and out-states. Squaring Eq. (16.97) produces $|\mathcal{M}|^2$ times the square of the delta; one delta survives to enforce conservation and the other becomes VT by Eq. (16.96):

$$|\,\langle f|iT|i\rangle\,|^2 \;=\; |\mathcal{M}|^2\;(2\pi)^4\delta^4\Big(p_1 + p_2 - \sum_f p_f\Big)\,VT. \tag{16.98}$$

The initial state has norm $\langle i|i\rangle_V = (2E_1V)(2E_2V) = 4E_1E_2\,V^2$. Each final particle is summed over the box modes available in its momentum cell, $V\,d^3p_f/(2\pi)^3$, and each such mode carries the norm $\langle p_f|p_f\rangle_V = 2E_fV$. Collecting these, the probability of the reaction into the final-state cell $\prod_f d^3p_f$ is

$$dP \;=\; \frac{|\,\langle f|iT|i\rangle\,|^2}{\langle i|i\rangle_V}\prod_f \frac{1}{2E_fV}\,\frac{V\,d^3p_f}{(2\pi)^3} \;=\; \frac{|\mathcal{M}|^2\;(2\pi)^4\delta^4(\cdots)\,VT}{4E_1E_2\,V^2}\prod_f \frac{d^3p_f}{(2\pi)^3\,2E_f}, \tag{16.99}$$

where every factor of V from the final-state mode counting has cancelled against the corresponding norm. The transition rate is $dW = dP/T$, and the leftover spacetime volume collapses to a single inverse power of V:

$$dW \;=\; \frac{1}{4E_1E_2\,V}\;|\mathcal{M}|^2\;\mathrm{d}\Pi_n, \qquad \mathrm{d}\Pi_n \equiv (2\pi)^4\delta^4\Big(p_1+p_2-\sum_f p_f\Big)\prod_{f=3}^{n}\frac{d^3p_f}{(2\pi)^3\,2E_f}, \tag{16.100}$$

with $\mathrm{d}\Pi_n$ the Lorentz-invariant n-body phase-space measure constructed and proved invariant in Eq. (16.39) and Theorem 16.8. Equation Eq. (16.100) is the two-particle analogue of the one-body rate $d\Gamma = \frac{1}{2M}\,|\mathcal{M}|^2\,\mathrm{d}\Pi_n$ of Eq. (16.76): the one decaying particle gave one factor $1/2M$ and its single power of V cancelled completely, whereas the two colliding particles give $1/4E_1E_2$ and a residual $1/V$. That residual $1/V$ is not a defect; it is precisely the statement that two particles rattling around in a large box rarely find each other, and it is destined to cancel against the $1/V$ in the flux.

To finish, apply the operational definition Eq. (16.95). We have exactly one target particle ($N_{\mathrm{tgt}} = 1$) and one beam particle in the box, so each has number density $1/V$. The incident flux is the beam density times the relative speed,

$$\Phi \;=\; n_1\;|\mathbf{v}_1-\mathbf{v}_2| \;=\; \frac{|\mathbf{v}_1-\mathbf{v}_2|}{V}. \tag{16.101}$$

Dividing the rate Eq. (16.100) by this flux, the volume cancels as anticipated:

$$d\sigma \;=\; \frac{dW}{\Phi} \;=\; \frac{V}{|\mathbf{v}_1-\mathbf{v}_2|}\cdot\frac{|\mathcal{M}|^2\;\mathrm{d}\Pi_n}{4E_1E_2\,V} \;=\; \frac{|\mathcal{M}|^2}{4E_1E_2\;|\mathbf{v}_1-\mathbf{v}_2|}\,\mathrm{d}\Pi_n. \tag{16.102}$$

The cross section is finite, V-independent, and built entirely from the dynamical $|\mathcal{M}|^2$, the kinematic measure $\mathrm{d}\Pi_n$, and a denominator that depends only on the two incoming momenta. We name that denominator the flux factor.

Definition 16.15 (Collinear flux factor)**.** For two incoming particles whose three-momenta are collinear (parallel or antiparallel), the *flux factor* is

$$F \;\equiv\; 4E_1E_2\;|\mathbf{v}_1-\mathbf{v}_2|\,, \qquad \mathbf{v}_i = \frac{\mathbf{p}_i}{E_i}, \tag{16.103}$$

so that $d\sigma = \dfrac{|\mathcal{M}|^2}{F}\,\mathrm{d}\Pi_n$.

The form Eq. (16.103) is intuitive but frame-bound: velocities transform awkwardly under boosts, so as written F looks like an accident of the lab frame. The next subsection shows it is nothing of the kind.

16.4.3 The covariant Møller flux and the proof of equality

A cross section is a counted number of events normalized by counted numbers of particles; counts are frame-independent, so σ must be expressible through Lorentz invariants. Since $|\mathcal{M}|^2$ and $\mathrm{d}\Pi_n$ are already invariant (the latter by Theorem 16.8), the flux factor must be too. We now produce the invariant and prove it equals Eq. (16.103).

Theorem 16.16 (Covariant flux factor)**.** *For two on-shell particles with momenta p_1, p_2 ($p_i^2 = m_i^2$, $p_i^0 = E_i > 0$) whose spatial momenta are collinear, the collinear flux factor equals a manifestly Lorentz-invariant expression:*

$$F \;=\; 4E_1E_2\,|\mathbf{v}_1 - \mathbf{v}_2| \;=\; 4\sqrt{(p_1\cdot p_2)^2 - m_1^2m_2^2} \;\equiv\; F_{\mathrm{M\o l}}. \tag{16.104}$$

Proof. Choose coordinates so the common axis of $\mathbf{p}_1, \mathbf{p}_2$ is the z-axis. Then the momenta have no transverse components,

$$p_1 = (E_1, 0, 0, p_1^z), \qquad p_2 = (E_2, 0, 0, p_2^z), \tag{16.105}$$

and the velocities are $\mathbf{v}_i = (0, 0, p_i^z/E_i)$, so that

$$E_1E_2\,|\mathbf{v}_1 - \mathbf{v}_2| = E_1E_2\left|\frac{p_1^z}{E_1} - \frac{p_2^z}{E_2}\right| = |E_2\,p_1^z - E_1\,p_2^z|. \tag{16.106}$$

For the right-hand side, use the mostly-minus metric: $p_1\cdot p_2 = E_1E_2 - p_1^zp_2^z$ and $m_i^2 = E_i^2 - (p_i^z)^2$. Expanding,

$$\begin{aligned}(p_1\cdot p_2)^2 - m_1^2m_2^2 &= \left(E_1E_2 - p_1^zp_2^z\right)^2 - \left(E_1^2 - (p_1^z)^2\right)\left(E_2^2 - (p_2^z)^2\right)\\ &= E_1^2E_2^2 - 2E_1E_2\,p_1^zp_2^z + (p_1^z)^2(p_2^z)^2\\ &\quad - \Big[E_1^2E_2^2 - E_1^2(p_2^z)^2 - (p_1^z)^2E_2^2 + (p_1^z)^2(p_2^z)^2\Big].\end{aligned} \tag{16.107}$$

The terms $E_1^2E_2^2$ and $(p_1^z)^2(p_2^z)^2$ cancel between the two lines, leaving

$$(p_1\cdot p_2)^2 - m_1^2m_2^2 = E_1^2(p_2^z)^2 - 2E_1E_2\,p_1^zp_2^z + (p_1^z)^2E_2^2 = \left(E_2\,p_1^z - E_1\,p_2^z\right)^2. \tag{16.108}$$

Taking the positive square root and comparing with Eq. (16.106) gives $\sqrt{(p_1\cdot p_2)^2 - m_1^2m_2^2} = |E_2p_1^z - E_1p_2^z| = E_1E_2\,|\mathbf{v}_1 - \mathbf{v}_2|$. Multiplying by 4 proves Eq. (16.104). □

The right-hand side of Eq. (16.104) is built from $p_1\cdot p_2$ and the two masses, all Lorentz scalars, so $F_{\mathrm{M\o l}}$ is invariant under the full Lorentz group. This is the *Møller flux factor*, and we adopt it as the definition of the flux for all frames:

$$\boxed{F \;=\; 4\sqrt{(p_1\cdot p_2)^2 - m_1^2m_2^2}}. \tag{16.109}$$

Proposition 16.17 (Uniqueness of the invariant extension)**.** *The Møller flux Eq. (16.109) is the unique Lorentz scalar that reduces to the operational collinear flux* $4E_1E_2\,|\mathbf{v}_1 - \mathbf{v}_2|$ *on collinear configurations.*

Proof. A Lorentz scalar $\mathcal{F}(p_1, p_2)$ formed from two four-vectors can depend on them only through the three invariants p_1^2, p_2^2, $p_1 \cdot p_2$; this is the same invariant-theory fact used to argue that $\mathcal{M}$ depends only on Lorentz-invariant momentum combinations (Theorem 14.15). On the physical mass shells $p_1^2 = m_1^2$ and $p_2^2 = m_2^2$ are fixed, so $\mathcal{F}$ is a function of the single variable $p_1 \cdot p_2$. Any two scalars agreeing on *all* collinear configurations agree for all values of $p_1 \cdot p_2$ in the physical range — because by boosting and rotating one can bring *any* pair of on-shell momenta to a collinear pair with the same value of $p_1 \cdot p_2$ (place p_2 at rest and align $\mathbf{p}_1$ with any axis), and $p_1 \cdot p_2$ sweeps its whole range as $|\mathbf{p}_1|$ varies. Two functions of one variable that agree everywhere on that variable's range are equal. Hence the invariant extension is unique, and Theorem 16.16 exhibits it as $F_{\mathrm{M}\varnothing\mathrm{l}}$. □

"Relative velocity" that exceeds the speed of light, and the frame caveat

The object $|\mathbf{v}_1 - \mathbf{v}_2|$ in Eq. (16.103) is a difference of coordinate velocities, not the physical speed of one particle measured in the other's rest frame. For a head-on collision of two ultrarelativistic beams, $\mathbf{v}_1 \to +\hat{\mathbf{z}}$ and $\mathbf{v}_2 \to -\hat{\mathbf{z}}$ give $|\mathbf{v}_1 - \mathbf{v}_2| \to 2$, twice the speed of light. There is no paradox: this "Møller velocity" is merely the rate at which the two coordinate distributions sweep through each other, exactly what a flux must count, and it is the combination that the relativistic identity Eq. (16.104) turns into a genuine scalar. The price is a frame caveat. The covariant flux Eq. (16.109) is a Lorentz scalar in every frame, but its identification with the elementary "number density × relative velocity" of Eq. (16.101) requires the beams to be collinear. Collinearity is preserved exactly by boosts *along* the beam axis (and rotations); a boost *transverse* to the beams tilts them, spoils collinearity, and breaks the simple flux picture even though the scalar $F_{\mathrm{M}\varnothing\mathrm{l}}$ keeps its value. This is one reason colliders are built with exactly head-on (collinear) beams: the operational cross section and the invariant formula coincide manifestly precisely in the family of frames — lab, centre-of-momentum, and all boosts along the beam line — reached from one another without tilting the beams.

16.4.4 The centre-of-momentum reduction

The frame in which the flux factor is simplest, and the one Mandelstam kinematics will adopt in the next section, is the centre-of-momentum (CM) frame, where $\mathbf{p}_1 + \mathbf{p}_2 = 0$. Write $\mathbf{p}_1 = -\mathbf{p}_2$ and $|\mathbf{p}_1| = |\mathbf{p}_2| \equiv p_{\mathrm{cm}}$, and recall the Mandelstam

invariant $s \equiv (p_1 + p_2)^2$, which in this frame is $s = (E_1 + E_2)^2$ because the total three-momentum vanishes, so $\sqrt{s} = E_1 + E_2$ is the total CM energy. The velocities are antiparallel, $\mathbf{v}_1 = \mathbf{p}_1/E_1$ and $\mathbf{v}_2 = -\mathbf{p}_1/E_2$, whence

$$|\mathbf{v}_1 - \mathbf{v}_2| = |\mathbf{p}_1| \left(\frac{1}{E_1} + \frac{1}{E_2} \right) = p_{\mathrm{cm}} \, \frac{E_1 + E_2}{E_1 E_2}. \tag{16.110}$$

Substituting into the collinear flux Eq. (16.103), the energies cancel cleanly:

$$F \;=\; 4E_1E_2 \, |\mathbf{v}_1 - \mathbf{v}_2| \;=\; 4E_1E_2 \cdot p_{\mathrm{cm}} \, \frac{E_1 + E_2}{E_1 E_2} \;=\; 4\, p_{\mathrm{cm}} \, (E_1 + E_2) \;=\; 4\, p_{\mathrm{cm}} \sqrt{s}. \tag{16.111}$$

The same result follows from the covariant form Eq. (16.109): in the CM frame $(p_1 \cdot p_2)^2 - m_1^2 m_2^2 = s\, p_{\mathrm{cm}}^2$, an identity we verify in passing by noting that p_{cm} is fixed by the masses and s through $p_{\mathrm{cm}} = \lambda^{1/2}(s, m_1^2, m_2^2)/2\sqrt{s}$ with the Källén triangle function $\lambda(a,b,c) = a^2 + b^2 + c^2 - 2ab - 2bc - 2ca$; the algebra is the content of Eq. (16.108) re-expressed in invariants. The compact CM flux $F = 4 p_{\mathrm{cm}} \sqrt{s}$ is the form we will insert into the two-body phase space of the next section.

16.4.5 The master differential cross section

Collecting Eq. (16.102), Theorem 16.15, and the invariant flux Eq. (16.109), we arrive at the central result of the chapter for scattering.

Theorem 16.18 (Master cross-section formula)**.** *The differential cross section for $1 + 2 \to \{3, 4, \ldots, n\}$ with invariant amplitude $\mathcal{M}$ is*

$$\boxed{ d\sigma \;=\; \frac{|\mathcal{M}|^2}{4\sqrt{(p_1 \cdot p_2)^2 - m_1^2 m_2^2}} \, \mathrm{d}\Pi_n \;=\; \frac{|\mathcal{M}|^2}{F} \, \mathrm{d}\Pi_n } \tag{16.112}$$

with F the Møller flux Eq. (16.109) and $\mathrm{d}\Pi_n$ the Lorentz-invariant phase space Eq. (16.100). The total cross section is obtained by integrating over the final-state phase space, with a symmetry factor $S = \prod_j 1/n_j!$ for each set of n_j identical final particles (Section 16.3.3) to avoid counting the same physical configuration more than once.

Every ingredient on the right is Lorentz invariant — $|\mathcal{M}|^2$ by construction, F by Theorem 16.16, $\mathrm{d}\Pi_n$ by Theorem 16.8 — so $d\sigma$ is a Lorentz scalar, as the operational counting argument demanded. The structure is worth stating plainly because it persists unchanged through the rest of the book: *the entire interaction is in $|\mathcal{M}|^2$; the flux F and the measure $\mathrm{d}\Pi_n$ are pure on-shell kinematics.* Different theories, different processes, even different loop orders change only $\mathcal{M}$; the wrapper Eq. (16.112) is fixed once and for all.

Why dynamics and kinematics separate

The clean factorization is not a calculational convenience but a consequence of how the S-matrix was built. Translation invariance forces the energy–momentum delta and hence the on-shell phase space; relativistic normalization of the asymptotic states fixes the $1/2E$ weights; and the flux is just the relative motion of two such states. None of these knows anything about the Lagrangian. The Lagrangian enters only through the matrix element $\mathcal{M}$ extracted in Eq. (14.163). Cross sections, widths, lifetimes, and angular distributions are therefore one and the same object — $|\mathcal{M}|^2$ integrated against an invariant measure — divided by the appropriate normalization: $2M$ for a decay, F for a collision.

A quick dimensional check confirms the formula. In four dimensions a process with N total external legs has $[\mathcal{M}] = 4 - N$ (each external state of a $2 \to n$ amplitude contributes as the LSZ residues require), the flux has $[F] = 2$, and the n-body measure has $[\mathrm{d}\Pi_n] = 2n - 4$. For $2 \to n$, $N = 2 + n$, so $[|\mathcal{M}|^2/F] + [\mathrm{d}\Pi_n] = 2(2-n) - 2 + (2n-4) = -2$, i.e. an inverse mass squared — an area, exactly as a cross section must be. For the carried ϕ^4 amplitude $\mathcal{M} = -\lambda$ this gives $[\mathcal{M}] = 0$, consistent with $N = 4$.

Worked Example 16.19 (The flux factor in lab and collider frames)**.** To see the master formula's frame independence in action — and to record the two flux factors used constantly in practice — take two particles of masses m_1, m_2 and evaluate F two ways.

Fixed-target (lab) frame. Particle 2 is at rest, $p_2 = (m_2, \mathbf{0})$, and particle 1 has $p_1 = (E_1, \mathbf{p}_1)$ with $|\mathbf{p}_1|^2 = E_1^2 - m_1^2$. The covariant flux Eq. (16.109) gives

$$F_{\text{lab}} = 4\sqrt{(E_1 m_2)^2 - m_1^2 m_2^2} = 4m_2\sqrt{E_1^2 - m_1^2} = 4\,m_2\,|\mathbf{p}_1|\,. \tag{16.113}$$

As a consistency check against the collinear definition, the target velocity is $\mathbf{v}_2 = 0$, so $|\mathbf{v}_1 - \mathbf{v}_2| = |\mathbf{v}_1| = |\mathbf{p}_1|/E_1$, and Eq. (16.103) returns $F = 4E_1 m_2 \cdot |\mathbf{p}_1|/E_1 = 4m_2\,|\mathbf{p}_1|$, agreeing with Eq. (16.113).

Collider (CM) frame. Here Eq. (16.111) gives $F_{\text{cm}} = 4p_{\text{cm}}\sqrt{s}$. The two are not equal numbers — they are evaluated at different beam energies for the same physical reaction — but they are the same Lorentz scalar evaluated in two frames: both equal $4\sqrt{(p_1\cdot p_2)^2 - m_1^2 m_2^2}$. To make the invariance fully explicit, express the lab energy through the invariant s. Since $s = (p_1+p_2)^2 = m_1^2 + m_2^2 + 2p_1\cdot p_2 = m_1^2 + m_2^2 + 2E_1 m_2$ in the lab frame, we have $E_1 = (s - m_1^2 - m_2^2)/2m_2$, and then

$$F_{\text{lab}} = 4m_2\sqrt{E_1^2 - m_1^2} = 4m_2\sqrt{\left(\tfrac{s-m_1^2-m_2^2}{2m_2}\right)^2 - m_1^2} = 2\sqrt{\lambda(s, m_1^2, m_2^2)} = 4p_{\text{cm}}\sqrt{s}, \tag{16.114}$$

using $\lambda(s, m_1^2, m_2^2) = (s - m_1^2 - m_2^2)^2 - 4m_1^2 m_2^2$ and $p_{\rm cm} = \lambda^{1/2}/2\sqrt{s}$. The lab and CM expressions coincide once written in invariants, confirming that F — and therefore $d\sigma$ — is frame independent.

From cross section to event rate. Inverting Theorem 16.14, an experiment with instantaneous luminosity $\mathcal{L}$ (beam-target overlap counted as number per area per time) records events at rate $dN/dt = \mathcal{L}\,\sigma$. The cross section computed from Eq. (16.112) is exactly the proportionality constant a detector measures, the bridge from $|\mathcal{M}|^2$ to a count on a screen.

The high-energy limit of Eq. (16.111) is worth noting for later use: when $s \gg m_1^2, m_2^2$ one has $p_{\rm cm} \to \sqrt{s}/2$, so $F \to 2s$, and the cross section behaves as $d\sigma \to |\mathcal{M}|^2\, \mathrm{d}\Pi_n/2s$. This is the regime in which the next chapter's $e^+e^- \to \mu^+\mu^-$ computation will live.

With the master formula Eq. (16.112) in hand we have a frame-independent recipe that turns any computed amplitude into a cross section. The next section specializes it to a two-body final state, where energy–momentum conservation collapses the phase space onto a single solid angle and the kinematics is captured completely by the two Mandelstam invariants s and t — at which point $d\sigma/d\Omega$ becomes an explicit function of $|\mathcal{M}|^2$ ready to be evaluated on real amplitudes.

16.5 Two-to-two kinematics: Mandelstam variables and physical regions

The master differential cross section assembled in the previous section,

$$\mathrm{d}\sigma = \frac{1}{F}\,|\mathcal{M}|^2\,\mathrm{d}\Pi_n, \tag{16.115}$$

with the Møller flux factor F of Eq. (16.109) and the Lorentz-invariant phase-space measure $\mathrm{d}\Pi_n$ of Section 16.2, is valid for any number n of final particles. The overwhelmingly common — and pedagogically central — case is $n = 2$: two particles in, two particles out. Here the kinematics simplifies dramatically, because energy–momentum conservation plus the on-shell conditions leave only *two* free Lorentz-invariant numbers and, in a fixed frame, only the scattering angle and an irrelevant azimuth. This section is pure kinematics: we choose the right invariant coordinates, the Mandelstam variables s, t, u; we express every frame-dependent quantity (centre-of-mass energy, momenta, scattering angle) through them; we reduce Eq. (16.115) to the two standard differential forms $\mathrm{d}\sigma/\mathrm{d}t$ and $\mathrm{d}\sigma/\mathrm{d}\Omega$; and we map out the regions of the (s, t, u) plane in which a given reaction is physical. The dynamics — the actual value of $\mathcal{M}$ — does not enter at all. What we build is the empty stage onto which the carried ϕ^4 amplitude steps in the next section, and onto which every $2 \to 2$ process in the QED chapters will step after it.

Throughout we label the process

$$1(p_1) + 2(p_2) \longrightarrow 3(p_3) + 4(p_4), \qquad p_i^2 = m_i^2, \quad i = 1, 2, 3, 4, \tag{16.116}$$

with all four momenta on shell, p_1, p_2 incoming and p_3, p_4 outgoing, and overall conservation

$$p_1 + p_2 = p_3 + p_4. \tag{16.117}$$

The masses $m_1, \ldots, m_4$ are arbitrary and need not be equal; we keep them general so that the formulae apply equally to the equal-mass ϕ^4 case and to the unequal-mass QED reactions, and only specialize in the worked examples.

16.5.1 The Mandelstam invariants

A relativistic amplitude is a Lorentz scalar built from the external momenta, so it can depend on those momenta only through their invariant pairings $p_i \cdot p_j$. With four momenta there are ten such dot products, but the four on-shell conditions $p_i^2 = m_i^2$ and the four components of the conservation law Eq. (16.117) cut this down sharply. The clean way to organize the survivors is through the three Mandelstam variables.

Definition 16.20 (Mandelstam variables)**.** For the process Eq. (16.116) define the three invariants

$$s \equiv (p_1 + p_2)^2 = (p_3 + p_4)^2, \tag{16.118}$$

$$t \equiv (p_1 - p_3)^2 = (p_2 - p_4)^2, \tag{16.119}$$

$$u \equiv (p_1 - p_4)^2 = (p_2 - p_3)^2. \tag{16.120}$$

The second equality in each line follows from conservation Eq. (16.117): e.g. $p_1 + p_2 = p_3 + p_4$ gives $(p_1 + p_2)^2 = (p_3 + p_4)^2$, and $p_1 - p_3 = p_4 - p_2$ gives $(p_1 - p_3)^2 = (p_2 - p_4)^2$.

Physically, s is the squared total energy in the centre-of-mass (CM) frame — it is the natural "how much energy is available" variable — while t and u are squared momentum transfers: t measures how much four-momentum flows from leg 1 to leg 3, and u how much flows from leg 1 to leg 4. The three are not independent.

Proposition 16.21 (Mandelstam constraint)**.** *The Mandelstam variables satisfy*

$$s + t + u = m_1^2 + m_2^2 + m_3^2 + m_4^2. \tag{16.121}$$

Proof. Expand the three definitions using $p_i^2 = m_i^2$:

$$s = (p_1 + p_2)^2 = p_1^2 + p_2^2 + 2\, p_1 \cdot p_2 = m_1^2 + m_2^2 + 2\, p_1 \cdot p_2,$$

$$t = (p_1 - p_3)^2 = p_1^2 + p_3^2 - 2\,p_1 \cdot p_3 = m_1^2 + m_3^2 - 2\,p_1 \cdot p_3,$$
$$u = (p_1 - p_4)^2 = p_1^2 + p_4^2 - 2\,p_1 \cdot p_4 = m_1^2 + m_4^2 - 2\,p_1 \cdot p_4.$$

Adding,

$$s + t + u = 3m_1^2 + m_2^2 + m_3^2 + m_4^2 + 2\,p_1 \cdot (p_2 - p_3 - p_4). \tag{16.122}$$

Conservation Eq. (16.117) rearranges to $p_2 - p_3 - p_4 = -p_1$, so the last term is

$$2\,p_1 \cdot (-p_1) = -2\,p_1^2 = -2m_1^2. \tag{16.123}$$

Substituting Eq. (16.123) into Eq. (16.122) cancels two units of m_1^2, leaving exactly Eq. (16.121). □

The constraint Eq. (16.121) is the single most useful identity in two-body kinematics: it says that of the three invariants only two are independent, and it lets one trade u for s and t at will. An amplitude $\mathcal{M}(s,t,u)$ is therefore really a function of two variables, conventionally taken to be (s,t), with $u = \sum_i m_i^2 - s - t$ understood.

Notation Watch

The symbol λ does double duty in this part of the book: it is the ϕ^4 coupling of ϕ^4 theory (a dimensionless number, no arguments) and, from here on, the Källén triangle *function* $\lambda(a,b,c)$ defined in Theorem 16.22 (always written with three arguments). The two are never confused in practice because the function always carries its arguments; where both appear in the next section we keep the coupling as the bare symbol λ and the Källén function as $\lambda(\cdot,\cdot,\cdot)$.

16.5.2 Centre-of-mass kinematics and the Källén function

To turn the invariants into the lab-readable quantities of an angular distribution we work in the CM frame, defined by $\mathbf{p}_1 + \mathbf{p}_2 = \mathbf{0}$. The recurring algebraic object is the following symmetric polynomial.

Definition 16.22 (Källén triangle function)**.**

$$\lambda(a,b,c) \equiv a^2 + b^2 + c^2 - 2ab - 2bc - 2ca. \tag{16.124}$$

It is symmetric in its three arguments and admits the factorized forms

$$\lambda(a,b,c) = a^2 - 2a(b+c) + (b-c)^2 \tag{16.125}$$
$$= \big(a - (\sqrt{b} + \sqrt{c})^2\big)\big(a - (\sqrt{b} - \sqrt{c})^2\big) \quad (b,c \geq 0). \tag{16.126}$$

The factorized form Eq. (16.126) is verified by multiplying out: $(a-(\sqrt{b}+\sqrt{c})^2)(a-(\sqrt{b}-\sqrt{c})^2) = a^2 - a[(\sqrt{b}+\sqrt{c})^2+(\sqrt{b}-\sqrt{c})^2] + (\sqrt{b}+\sqrt{c})^2(\sqrt{b}-\sqrt{c})^2 = a^2 - 2a(b+c) + (b-c)^2$, which is Eq. (16.125). The name "triangle function" is geometric: $-\lambda(a^2, b^2, c^2)$ is sixteen times the squared area of a triangle with sides a, b, c, so λ is negative precisely when a, b, c can form a triangle. We will see this sign control the physical thresholds.

Now fix the CM frame. Write the incoming momenta as

$$p_1 = (E_1,\, \mathbf{p}_i), \qquad p_2 = (E_2,\, -\mathbf{p}_i), \qquad |\mathbf{p}_i| \equiv p_{\rm cm}, \tag{16.127}$$

so that $\mathbf{p}_1 + \mathbf{p}_2 = \mathbf{0}$ and the total four-momentum is $(E_1+E_2, \mathbf{0})$. By Eq. (16.118),

$$s = (E_1+E_2)^2, \qquad \text{hence} \qquad \sqrt{s} = E_1 + E_2, \tag{16.128}$$

identifying $\sqrt{s}$ as the total CM energy. The two on-shell conditions $E_1^2 - p_{\rm cm}^2 = m_1^2$, $E_2^2 - p_{\rm cm}^2 = m_2^2$ give $E_1^2 - E_2^2 = m_1^2 - m_2^2$, and dividing by $E_1 + E_2 = \sqrt{s}$,

$$E_1 - E_2 = \frac{m_1^2 - m_2^2}{\sqrt{s}}. \tag{16.129}$$

Adding and subtracting Eq. (16.128) and Eq. (16.129) solves for the individual energies,

$$E_1 = \frac{s + m_1^2 - m_2^2}{2\sqrt{s}}, \qquad E_2 = \frac{s + m_2^2 - m_1^2}{2\sqrt{s}}. \tag{16.130}$$

The common momentum magnitude then follows from $p_{\rm cm}^2 = E_1^2 - m_1^2$:

$$p_{\rm cm}^2 = \frac{(s + m_1^2 - m_2^2)^2}{4s} - m_1^2 = \frac{(s + m_1^2 - m_2^2)^2 - 4s\, m_1^2}{4s}. \tag{16.131}$$

The numerator is exactly the Källén function. Expanding,

$$(s+m_1^2-m_2^2)^2 - 4s\, m_1^2 = s^2 + m_1^4 + m_2^4 - 2sm_1^2 - 2sm_2^2 - 2m_1^2 m_2^2 = \lambda(s, m_1^2, m_2^2), \tag{16.132}$$

where the first equality multiplies out $(s + m_1^2 - m_2^2)^2 = s^2 + m_1^4 + m_2^4 + 2sm_1^2 - 2sm_2^2 - 2m_1^2 m_2^2$ and subtracts $4sm_1^2$, and the second is Eq. (16.124) with arguments (s, m_1^2, m_2^2). Hence the incoming CM momentum is

$$\boxed{|\mathbf{p}_i| = \frac{\sqrt{\lambda(s, m_1^2, m_2^2)}}{2\sqrt{s}}} \tag{16.133}$$

By identical algebra applied to the outgoing pair $3, 4$ — which in the CM frame are back-to-back, $p_3 = (E_3, \mathbf{p}_f)$, $p_4 = (E_4, -\mathbf{p}_f)$ with the *same* total energy $\sqrt{s}$ — the outgoing CM momentum is

$$|\mathbf{p}_f| = \frac{\sqrt{\lambda(s, m_3^2, m_4^2)}}{2\sqrt{s}}, \qquad E_3 = \frac{s + m_3^2 - m_4^2}{2\sqrt{s}}, \qquad E_4 = \frac{s + m_4^2 - m_3^2}{2\sqrt{s}}. \tag{16.134}$$

The factorized form Eq. (16.126) now reads off the kinematic thresholds. The initial momentum $|\mathbf{p}_i|$ is real only when $\lambda(s, m_1^2, m_2^2) \geq 0$, i.e. when $s \geq (m_1+m_2)^2$ (the other factor, $s-(m_1-m_2)^2$, is then automatically positive). This is the statement that the collision needs at least enough energy to make the two incoming particles at rest. Likewise $|\mathbf{p}_f|$ is real only above the production threshold $s \geq (m_3+m_4)^2$: one cannot create the final state below its rest mass. A physical $2 \to 2$ reaction therefore requires

$$s \geq \max\big[(m_1+m_2)^2,\,(m_3+m_4)^2\big]. \tag{16.135}$$

16.5.3 The scattering angle and the physical t-range

The one remaining degree of freedom is the CM scattering angle θ between the incoming particle 1 and the outgoing particle 3,

$$\mathbf{p}_i \cdot \mathbf{p}_f = |\mathbf{p}_i|\,|\mathbf{p}_f| \cos\theta. \tag{16.136}$$

We express t through it. From the expansion of t in the proof of Theorem 16.21, $t = m_1^2 + m_3^2 - 2\,p_1 \cdot p_3$, and in the CM frame $p_1 \cdot p_3 = E_1E_3 - \mathbf{p}_i \cdot \mathbf{p}_f = E_1E_3 - |\mathbf{p}_i||\mathbf{p}_f|\cos\theta$. Therefore

$$t = m_1^2 + m_3^2 - 2E_1E_3 + 2|\mathbf{p}_i||\mathbf{p}_f|\cos\theta. \tag{16.137}$$

This is the linear relation between t and $\cos\theta$ that converts an angular distribution into a distribution in the invariant t. Differentiating at fixed s (which fixes $E_1, E_3, |\mathbf{p}_i|, |\mathbf{p}_f|$) gives the Jacobian we will need,

$$\boxed{\mathrm{d}t = 2|\mathbf{p}_i||\mathbf{p}_f|\,\mathrm{d}\cos\theta} \tag{16.138}$$

Because $\cos\theta$ runs over $[-1, 1]$, the physical region of t at fixed s is the closed interval between its endpoints at forward ($\cos\theta = +1$) and backward ($\cos\theta = -1$) scattering:

$$t_+ = m_1^2 + m_3^2 - 2E_1E_3 + 2|\mathbf{p}_i||\mathbf{p}_f| \qquad (\text{forward},\ \theta = 0), \tag{16.139}$$

$$t_- = m_1^2 + m_3^2 - 2E_1E_3 - 2|\mathbf{p}_i||\mathbf{p}_f| \qquad (\text{backward},\ \theta = \pi), \tag{16.140}$$

so that $t_- \leq t \leq t_+$, with $t_+ - t_- = 4|\mathbf{p}_i||\mathbf{p}_f|$. Every quantity on the right of Eq. (16.139)–Eq. (16.140) is a known function of s and the masses through Eq. (16.130), Eq. (16.133) and Eq. (16.134), so the t-range is fixed once s is. The corresponding u-endpoints are obtained from the constraint $u = \sum_i m_i^2 - s - t$, which sends $t_+ \leftrightarrow u_-$.

Caution

In the physical s-channel region of an elastic (or equal-mass, $m_1 = m_3$) reaction the momentum transfer t is non-positive. With $m_1 = m_3$ one has $E_1 = E_3$, $|\mathbf{p}_i| = |\mathbf{p}_f|$, and Eq. (16.139) gives $t_+ = 0$ at $\theta = 0$: forward scattering transfers no momentum, while every other angle gives $t < 0$. A positive t in such an elastic reaction is a kinematic error. (For unequal-mass inelastic kinematics this is not universal: Eq. (16.139) can be rewritten $t_+ = (E_1 - E_3)^2 - (|\mathbf{p}_i| - |\mathbf{p}_f|)^2$, which is positive whenever $|E_1 - E_3| > ||\mathbf{p}_i| - |\mathbf{p}_f||$.) This sign is exactly what makes t a useful expansion variable near the forward peak and what the crossing analysis of Chapter 18 will exploit.

16.5.4 The two standard differential cross sections

We now specialize the master formula Eq. (16.115) to $n = 2$. Two ingredients enter: the flux factor and the two-body phase space.

Flux. The covariant Møller flux of Eq. (16.109) is $F = 4\sqrt{(p_1 \cdot p_2)^2 - m_1^2 m_2^2}$. From the expansion $s = m_1^2 + m_2^2 + 2p_1 \cdot p_2$ we have $p_1 \cdot p_2 = \frac{1}{2}(s - m_1^2 - m_2^2)$, so

$$(p_1 \cdot p_2)^2 - m_1^2 m_2^2 = \frac{(s - m_1^2 - m_2^2)^2 - 4m_1^2 m_2^2}{4} = \frac{\lambda(s, m_1^2, m_2^2)}{4}, \tag{16.141}$$

the second equality being Eq. (16.124) once more (expand $(s - m_1^2 - m_2^2)^2$ and subtract $4m_1^2 m_2^2$). Hence the flux factor in invariant form is

$$F = 4\sqrt{\frac{\lambda(s, m_1^2, m_2^2)}{4}} = 2\sqrt{\lambda(s, m_1^2, m_2^2)} = 4\sqrt{s}\,|\mathbf{p}_i|, \tag{16.142}$$

where the last equality used Eq. (16.133). It is worth pausing on this: the flux is $2\sqrt{\lambda}$, a clean Lorentz invariant, and equals $4\sqrt{s}\,|\mathbf{p}_i|$ in the CM frame — the form we use to extract the angular distribution.

Phase space. The two-body Lorentz-invariant phase-space measure derived in Eq. (16.47) is, in the CM frame,

$$\mathrm{d}\Pi_2 = \frac{1}{16\pi^2}\,\frac{|\mathbf{p}_f|}{\sqrt{s}}\,\mathrm{d}\Omega, \tag{16.143}$$

with $\mathrm{d}\Omega = \mathrm{d}\cos\theta\,\mathrm{d}\varphi$ the solid-angle element of the outgoing particle 3. Assembling Eq. (16.142) and Eq. (16.143) in Eq. (16.115),

$$\mathrm{d}\sigma = \frac{1}{4\sqrt{s}\,|\mathbf{p}_i|}\,|\mathcal{M}|^2\,\frac{1}{16\pi^2}\,\frac{|\mathbf{p}_f|}{\sqrt{s}}\,\mathrm{d}\Omega = \frac{1}{64\pi^2 s}\,\frac{|\mathbf{p}_f|}{|\mathbf{p}_i|}\,|\mathcal{M}|^2\,\mathrm{d}\Omega. \tag{16.144}$$

This is the first standard form.

Theorem 16.23 (CM angular cross section)**.** *For $2 \to 2$ scattering, the differential cross section with respect to the CM solid angle of an outgoing particle is*

$$\left.\frac{\mathrm{d}\sigma}{\mathrm{d}\Omega}\right|_{\mathrm{CM}} = \frac{1}{64\pi^2 s}\,\frac{|\mathbf{p}_f|}{|\mathbf{p}_i|}\,|\mathcal{M}|^2\,, \tag{16.145}$$

with $|\mathbf{p}_i|, |\mathbf{p}_f|$ given by Eq. (16.133), Eq. (16.134).

The ratio $|\mathbf{p}_f|/|\mathbf{p}_i|$ is the kinematic phase-space penalty for producing a heavier (or lighter) final state than the initial one; for elastic scattering, where the final masses equal the initial ones, $|\mathbf{p}_f| = |\mathbf{p}_i|$ and it drops out.

The second form is fully invariant. Most amplitudes have no azimuthal dependence — for spinless particles, or for spin-summed/averaged amplitudes with unpolarized beams, $|\mathcal{M}|^2$ depends on θ but not φ — so the φ integration in Eq. (16.144) is trivial, $\int_0^{2\pi} \mathrm{d}\varphi = 2\pi$, and $\mathrm{d}\Omega \to 2\pi\,\mathrm{d}\cos\theta$. Using the Jacobian Eq. (16.138) to trade $\cos\theta$ for t,

$$\begin{aligned}\mathrm{d}\sigma &= \frac{1}{64\pi^2 s}\,\frac{|\mathbf{p}_f|}{|\mathbf{p}_i|}\,|\mathcal{M}|^2\,(2\pi)\,\mathrm{d}\cos\theta = \frac{1}{32\pi s}\,\frac{|\mathbf{p}_f|}{|\mathbf{p}_i|}\,|\mathcal{M}|^2\,\frac{\mathrm{d}t}{2|\mathbf{p}_i||\mathbf{p}_f|} \\ &= \frac{1}{64\pi s}\,\frac{1}{|\mathbf{p}_i|^2}\,|\mathcal{M}|^2\,\mathrm{d}t.\end{aligned} \tag{16.146}$$

Finally insert $|\mathbf{p}_i|^2 = \lambda(s, m_1^2, m_2^2)/(4s)$ from Eq. (16.133), so that $64\pi s\,|\mathbf{p}_i|^2 = 16\pi\,\lambda(s, m_1^2, m_2^2)$:

$$\boxed{\frac{\mathrm{d}\sigma}{\mathrm{d}t} = \frac{|\mathcal{M}|^2}{16\pi\,\lambda(s, m_1^2, m_2^2)}} \tag{16.147}$$

Theorem 16.24 (Invariant cross section)**.** *When $|\mathcal{M}|^2$ is independent of the azimuthal angle, the $2 \to 2$ differential cross section in the invariant momentum transfer is Eq. (16.147), with t ranging over $[t_-, t_+]$ of Eq. (16.139)–Eq. (16.140).*

Equation Eq. (16.147) is the workhorse of the next section. Both sides are Lorentz invariant: $|\mathcal{M}|^2$ is a scalar, t is an invariant, and $\lambda(s, m_1^2, m_2^2)$ depends only on invariants. The cross section $\mathrm{d}\sigma/\mathrm{d}t$ is therefore the same in every frame — the lab frame, the CM frame, a fixed-target frame — which is precisely why it, rather than $\mathrm{d}\sigma/\mathrm{d}\Omega$, is the form in which experimental and theoretical results are most often quoted and compared. The total cross section is the integral

$$\sigma = \int_{t_-}^{t_+} \frac{|\mathcal{M}(s,t)|^2}{16\pi\,\lambda(s, m_1^2, m_2^2)}\,\mathrm{d}t, \tag{16.148}$$

a single integral over the one physical variable left at fixed s.

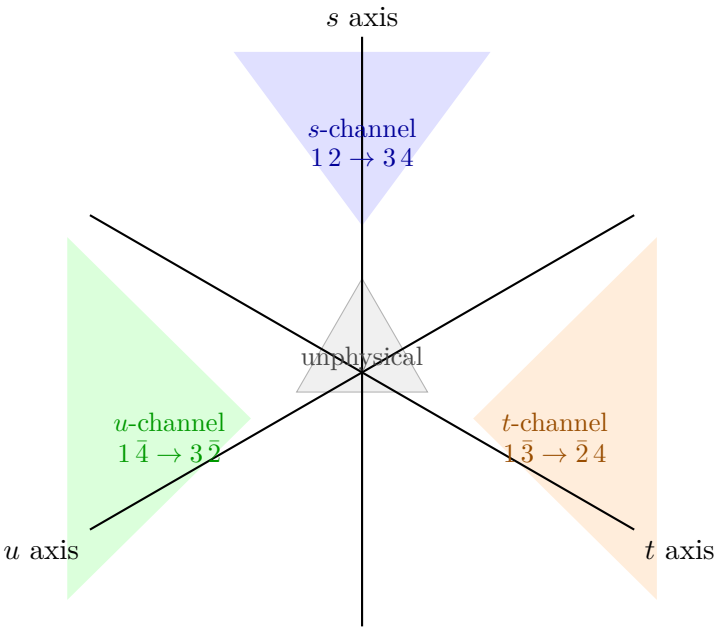

Figure 16.5: The Mandelstam plane for $2 \to 2$ scattering (drawn for the equal-mass case, where the three axes meet symmetrically). The constraint $s+t+u = \sum_i m_i^2$ confines all kinematics to this plane. A single analytic amplitude $\mathcal{M}(s,t,u)$ lives on the whole plane; the three shaded wedges are the physical regions of the s-, t- and u-channel reactions, related by crossing. The central (gray) triangle is kinematically forbidden in every channel.

16.5.5 The Mandelstam plane and the three channels

The constraint $s+t+u = \sum_i m_i^2$ of Eq. (16.121) says that the three invariants live on a two-dimensional plane in (s,t,u)-space. It is illuminating to plot them on equal footing. Choose the symmetric "Mandelstam plane" in which the perpendicular distances from a point to three lines meeting at 120° represent s, t, u; the constraint $s+t+u = \text{const}$ is then automatic (the sum of signed distances to the three sides of an equilateral triangle is constant). On this plane a single analytic function $\mathcal{M}$ is defined everywhere, but only certain regions correspond to physical reactions.

There are three physical reactions sharing the same amplitude, distinguished by which invariant plays the role of the total CM energy squared:

- the *s-channel* reaction $1+2 \to 3+4$, physical when $s \geq \max[(m_1+m_2)^2, (m_3+m_4)^2]$ and $t \in [t_-, t_+]$, as in Eq. (16.135) and Section 16.5.3;
- the *t-channel* reaction $1+\bar{3} \to \bar{2}+4$, obtained by moving particles 3 and 2 to the opposite side as antiparticles, physical when t exceeds the

corresponding threshold;

- the *u-channel* reaction $1+\bar{4}\to 3+\bar{2}$, physical when u exceeds its threshold.

These three physical regions are the disjoint shaded wedges of Fig. 16.5; between them lies the unphysical central region where none of s,t,u is large enough to be a physical energy. The remarkable fact — the content of *crossing symmetry* — is that the very same function $\mathcal{M}(s,t,u)$, computed as an analytic function of its arguments, describes all three reactions: one obtains the t-channel amplitude from the s-channel one by analytic continuation in the invariants, swapping the appropriate incoming and outgoing legs into antiparticles. At the level of this chapter we only *state* this; it rests on the analyticity of the amplitude in the cut s- and t-planes, whose branch points sit at the physical thresholds (the same thresholds Eq. (16.135) that bounded the physical regions). The full statement and proof of crossing, and the precise rule for continuing across the cuts, are developed in Chapter 18; here we have simply laid out the analytic geometry — the plane, the three wedges, the thresholds — that crossing acts on.

Physical Insight

The same diagram read three ways is the first concrete payoff of the "amplitude" viewpoint announced in Eq. (14.163): $\mathcal{M}$ is not three different objects for three different experiments but one analytic function on the Mandelstam plane. A pole of $\mathcal{M}$ at $s=M^2$ is a resonance exchanged in the s-channel reaction; the *same* pole, viewed from the t-channel wedge, is a particle exchanged as a force carrier. Energy and momentum transfer are continuations of one another. This is the structural fact that the dispersion relations of Chapter 18 and the crossing equations of the bootstrap turn into quantitative tools.

16.5.6 Worked kinematics

Worked Example 16.25 (Equal masses: the ϕ^4 stage)**.** Set all four masses equal, $m_1=m_2=m_3=m_4=m$. This is the kinematics the carried $\phi\phi\to\phi\phi$ amplitude of Eq. (15.59) will use in the next section, so we work it out completely.

The constraint Eq. (16.121) becomes

$$s+t+u=4m^2. \tag{16.149}$$

The Källén function collapses neatly: from Eq. (16.124),

$$\lambda(s,m^2,m^2)=s^2+2m^4-2sm^2-2sm^2-2m^4=s^2-4sm^2=s\,(s-4m^2), \tag{16.150}$$

consistent with the factorized form Eq. (16.126), $\lambda(s,m^2,m^2)=(s-4m^2)(s-0)$. The CM momenta Eq. (16.133), Eq. (16.134) are equal (initial and final masses

coincide),

$$|\mathbf{p}_i| = |\mathbf{p}_f| = \frac{\sqrt{s(s-4m^2)}}{2\sqrt{s}} = \frac{\sqrt{s-4m^2}}{2}, \tag{16.151}$$

real precisely above threshold $s \geq 4m^2$ — the energy to make two particles of mass m. The energies are all $E_1 = E_2 = E_3 = E_4 = \sqrt{s}/2$ by Eq. (16.130).

The t-endpoints follow from Eq. (16.139)–Eq. (16.140) with $E_1 = E_3 = \sqrt{s}/2$ and $|\mathbf{p}_i| = |\mathbf{p}_f|$:

$$t_+ = 2m^2 - 2 \cdot \frac{s}{4} + 2 \cdot \frac{s-4m^2}{4} = 2m^2 - \frac{s}{2} + \frac{s-4m^2}{2} = 0, \tag{16.152}$$

$$t_- = 2m^2 - \frac{s}{2} - \frac{s-4m^2}{2} = 2m^2 - \frac{s}{2} - \frac{s}{2} + 2m^2 = 4m^2 - s. \tag{16.153}$$

So in the equal-mass s-channel,

$$t \in [\,4m^2 - s,\ 0\,], \qquad u = 4m^2 - s - t \in [\,4m^2 - s,\ 0\,], \tag{16.154}$$

both momentum transfers ranging from the backward value $4m^2 - s$ up to 0 at the relevant forward/backward limit. The angular form Eq. (16.145) simplifies, with $|\mathbf{p}_f|/|\mathbf{p}_i| = 1$, to

$$\left.\frac{\mathrm{d}\sigma}{\mathrm{d}\Omega}\right|_{\mathrm{CM}} = \frac{|\mathcal{M}|^2}{64\pi^2 s}, \tag{16.155}$$

the cleanest possible $2 \to 2$ cross section. This is exactly the stage onto which $\mathcal{M} = -\lambda$ from Eq. (15.59) steps in Section 16.6; everything dynamical there is the constant $|\mathcal{M}|^2 = \lambda^2$, and the angular distribution is flat because the stage Eq. (16.155) is.

Worked Example 16.26 (Massless initial state: the $e^+e^- \to \mu^+\mu^-$ frame)**.** To show the same kinematics serving QED, take the high-energy limit of $e^+e^- \to \mu^+\mu^-$: incoming electron and positron with $m_1 = m_2 = m_e \to 0$, outgoing muon pair with $m_3 = m_4 = m_\mu$. (The full amplitude, with spin sums, is the business of Chapter 17; here we supply only the s, t, u frame it will be evaluated in.)

With $m_e \to 0$, Eq. (16.133) and Eq. (16.150)-type algebra give the incoming momentum $|\mathbf{p}_i| = \sqrt{\lambda(s,0,0)}/(2\sqrt{s}) = \sqrt{s^2}/(2\sqrt{s}) = \sqrt{s}/2$, while the outgoing momentum is set by the muon mass,

$$|\mathbf{p}_f| = \frac{\sqrt{\lambda(s, m_\mu^2, m_\mu^2)}}{2\sqrt{s}} = \frac{\sqrt{s-4m_\mu^2}}{2}, \qquad s \geq 4m_\mu^2. \tag{16.156}$$

The energies are $E_1 = E_2 = \sqrt{s}/2$ (massless) and $E_3 = E_4 = \sqrt{s}/2$ (the pair shares the energy equally by Eq. (16.130) with $m_3 = m_4$). The momentum transfer Eq. (16.137) becomes, with $m_1 \to 0$,

$$t = m_\mu^2 - 2 \cdot \frac{\sqrt{s}}{2} \cdot \frac{\sqrt{s}}{2} + 2 \cdot \frac{\sqrt{s}}{2} \cdot \frac{\sqrt{s-4m_\mu^2}}{2} \cos\theta = m_\mu^2 - \frac{s}{2} + \frac{\sqrt{s}}{2}\sqrt{s-4m_\mu^2}\,\cos\theta, \tag{16.157}$$

and the constraint Eq. (16.121) gives $u = 2m_\mu^2 - s - t = m_\mu^2 - \frac{s}{2} - \frac{\sqrt{s}}{2}\sqrt{s - 4m_\mu^2}\cos\theta$. In the ultra-relativistic limit $s \gg m_\mu^2$ these collapse to the textbook forms $t \to -\frac{s}{2}(1 - \cos\theta)$, $u \to -\frac{s}{2}(1 + \cos\theta)$, with $s + t + u \to 0$ — the all-massless skeleton on which the QED angular distribution $\mathrm{d}\sigma/\mathrm{d}\Omega \propto (1 + \cos^2\theta)$ will be built. The general cross section Eq. (16.145) carries the phase-space factor $|\mathbf{p}_f|/|\mathbf{p}_i| = \sqrt{1 - 4m_\mu^2/s}$, the velocity of the produced muons, which suppresses the rate near the production threshold $s = 4m_\mu^2$ and tends to 1 at high energy.

The two worked cases exhibit the thread-neutrality promised at the outset: the equal-mass formulae feed ϕ^4 theory directly in the next section, while the massless-initial-state formulae are the frame in which QED's first cross section is computed in Chapter 17. With $|\mathbf{p}_i|, |\mathbf{p}_f|$, the t-range, and the two differential forms Eq. (16.145) and Eq. (16.147) all expressed in s, t, u and the masses, the stage is fully set: the next section takes the carried ϕ^4 amplitude $\mathcal{M} = -\lambda$ from Eq. (15.59), drops it into Eq. (16.155) and Eq. (16.148), and reads off the first physical cross section of the book.

16.6 Worked computation: $\phi\phi \to \phi\phi$ scattering in $\lambda\phi^4$

Every formula in this chapter has been built to be fed an amplitude. The two-to-two machinery of Section 16.5 converted the master cross-section formula into a statement about $|\mathcal{M}|^2$ as a function of the Mandelstam invariants in the centre-of-mass frame; the only thing still missing is an actual $\mathcal{M}$ to put in. We have one. ϕ^4 theory has carried a single real scalar with $\mathcal{L} = \frac{1}{2}(\partial\phi)^2 - \frac{1}{2}m^2\phi^2 - \frac{\lambda}{4!}\phi^4$ from its classical action all the way to a momentum-space Feynman amplitude, and Chapter 15 produced, by pure diagrammatics, the tree-level two-to-two amplitude. This section closes the loop opened at the start of Part IV: we take that amplitude, square it, integrate it against the invariant phase space, divide by the flux, and read off a number a detector could in principle report. It is the first *physical* number ϕ^4 theory produces — not an off-shell correlator, not an amputated diagram, but a cross section — and the calculation is the exact template Chapter 17 will reuse for $e^+e^- \to \mu^+\mu^-$ once spin sums supply the analogous $\overline{|\mathcal{M}|^2}$.

16.6.1 The amplitude and its square

Recall the carried result. The connected, amputated, on-shell two-to-two amplitude of the ϕ^4 theory, defined through $\langle f|iT|i\rangle = (2\pi)^4\delta^4(p_f - p_i)\, i\mathcal{M}$ as in Eq. (14.163), was computed at tree level in Theorem 15.19 and is

$$\mathcal{M}(\phi\phi \to \phi\phi) = -\lambda + O(\lambda^2), \tag{16.158}$$

a pure constant. As emphasised in Chapter 15, this constancy is the signature of a *contact* interaction: with a single quartic vertex and no internal line, there is no propagator to inject a momentum-dependent denominator, so $\mathcal{M}$ depends on neither the centre-of-mass energy nor the scattering angle — it is the same $-\lambda$ in the s-, t-, and u-channels. The diagram itself carried symmetry factor $S = 1$ (the 4! contractions of the external legs into the vertex cancel the $1/4!$ in the coupling), by the orbit–stabiliser count of Theorem 15.22; that combinatorial factor is a property of the *amplitude*, and is not to be confused with the identical-final-particle factor that will appear below in the *phase-space integral*, which is a quite different bookkeeping. The squared amplitude that the cross-section formula wants is therefore the simplest object in the chapter,

$$|\mathcal{M}|^2 = \lambda^2 + O(\lambda^3), \tag{16.159}$$

constant over the entire physical region. There is no spin to average or sum over — the field is a real scalar — so the bar that will decorate $\overline{|\mathcal{M}|^2}$ in Chapter 17 is absent here, and Eq. (16.159) is the whole of the dynamics. Everything that follows is kinematics.

16.6.2 Kinematics: the centre-of-mass momentum and the threshold

The process is elastic and all four particles share the mass m, which makes the kinematics maximally symmetric. In the centre-of-mass frame the two incoming particles carry equal and opposite three-momenta of magnitude $|\mathbf{p}_i|$, the two outgoing particles equal and opposite momenta of magnitude $|\mathbf{p}_f|$, and each particle has energy $\sqrt{s}/2$ where $s = (p_1 + p_2)^2 = E_{\mathrm{cm}}^2$ is the squared total energy. Energy conservation $E_1 + E_2 = E_3 + E_4 = \sqrt{s}$ with all masses equal forces

$$|\mathbf{p}_i| = |\mathbf{p}_f| \equiv |\mathbf{p}| = \frac{\sqrt{s}}{2}\sqrt{1 - \frac{4m^2}{s}}\,, \tag{16.160}$$

the equal-mass specialisation of the general centre-of-mass momentum recorded in Eq. (16.133). The radical

$$\beta \equiv \sqrt{1 - \frac{4m^2}{s}} \tag{16.161}$$

is the speed of each particle in the centre-of-mass frame (indeed $\beta = |\mathbf{p}|/(\sqrt{s}/2)$), and it is the *threshold factor*: the momentum Eq. (16.160) is real only for $s \geq 4m^2$, the statement that two particles each of mass m cannot be produced (or, here, scattered into a back-to-back final state) unless the collision supplies at least their combined rest energy $2m$. For $s < 4m^2$ there is no physical final state and the cross section is zero; at $s = 4m^2$ the particles emerge at rest and $\beta \to 0$;

for $s \gg 4m^2$ the factor $\beta \to 1$ and the masses become irrelevant. We will see this factor enter the calculation twice — once through the incoming flux, once through the outgoing phase space — and then cancel, leaving a result that is in fact independent of m above threshold.

16.6.3 The differential cross section

The two-to-two specialisation of the master formula, derived in Section 16.5, gives the centre-of-mass differential cross section as

$$\left.\frac{\mathrm{d}\sigma}{\mathrm{d}\Omega}\right|_{\mathrm{cm}} = \frac{1}{64\pi^2 s}\,\frac{|\mathbf{p}_f|}{|\mathbf{p}_i|}\,|\mathcal{M}|^2, \tag{16.162}$$

the relation Eq. (16.162), in which the dynamical factor $|\mathcal{M}|^2$ is cleanly separated from the purely kinematic prefactor. For our elastic equal-mass process the momentum ratio is unity by Eq. (16.160), and substituting the constant Eq. (16.159) gives at once

$$\boxed{\left.\frac{\mathrm{d}\sigma}{\mathrm{d}\Omega}\right|_{\mathrm{cm}} = \frac{\lambda^2}{64\pi^2 s}} \tag{16.163}$$

to leading order in λ. Three features are worth naming immediately. First, the distribution is *isotropic*: the scattered particles emerge with equal probability in every direction, with no preferred axis. This is the angular fingerprint of the contact interaction — because $\mathcal{M}$ carries no t- or u-dependence, Eq. (16.163) carries no $\cos\theta$-dependence, in sharp contrast to the forward-peaked Rutherford-like distributions that exchange diagrams produce. Second, the result is *independent of the mass* m: the threshold factor β has cancelled between $|\mathbf{p}_f|$ and $|\mathbf{p}_i|$ in Eq. (16.162), so above threshold the differential cross section depends on the kinematics only through the overall $1/s$. Third, $\mathrm{d}\sigma/\mathrm{d}\Omega$ has dimension $[\text{mass}]^{-2}$, as a cross section (an area) must: λ is dimensionless in four dimensions and s carries $[\text{mass}]^2$, so the right-hand side scales as $[\text{mass}]^{-2}$. We return to this dimensional check below.

16.6.4 The total cross section and the identical-particle factor

Integrating Eq. (16.163) over solid angle would, naively, give $4\pi \cdot \lambda^2/(64\pi^2 s) = \lambda^2/(16\pi s)$. But this overcounts. The two particles in the final state are *identical* real scalars, so the configuration in which one emerges at angles (θ, φ) and its partner at the antipodal $(\pi - \theta, \varphi + \pi)$ is the very same physical final state as the one with the labels exchanged. The unrestricted integral over the full sphere counts each distinct two-particle state twice. The total cross section is therefore the angular integral divided by the symmetry number $2! = 2$ of the identical pair,

$$\sigma = \frac{1}{2}\int \mathrm{d}\Omega\, \left.\frac{\mathrm{d}\sigma}{\mathrm{d}\Omega}\right|_{\mathrm{cm}} = \frac{1}{2}\cdot 4\pi \cdot \frac{\lambda^2}{64\pi^2 s} = \boxed{\frac{\lambda^2}{32\pi s}} \tag{16.164}$$

to leading order. The factor $\frac{1}{2}$ here is genuinely a *final-state* combinatorial factor, the Bose statistics of the indistinguishable outgoing pair, and it is logically independent of the diagram symmetry factor $S = 1$ that already lives inside $\mathcal{M}$. Equivalently, one may keep the $\frac{1}{2}$ out front and restrict the integration to a single hemisphere (half the sphere covers every distinct final configuration exactly once); the two prescriptions give the same $\lambda^2/(32\pi s)$. The full pipeline — amplitude, square, flux, phase space, angular integration with the identical-particle factor, and the explicit cancellation of the threshold radical — is carried end to end in Theorem 16.27.

Worked Example 16.27 (The $\phi\phi \to \phi\phi$ cross section from $\mathcal{M} = -\lambda$, every step)**.** We assemble σ directly from the invariant master formula of Section 16.4.5, keeping the mass m explicit so that the threshold factor's appearance and cancellation are visible, and only then taking the massless limit.

Step 1 — the squared amplitude. From the carried tree result Eq. (16.158), $\mathcal{M} = -\lambda$, so $|\mathcal{M}|^2 = \lambda^2$, a constant independent of s, t, u and of the scattering angle. No spin sum is needed.

Step 2 — flux and phase space, with the threshold factor. The master formula for a $2 \to 2$ cross section reads $\mathrm{d}\sigma = \dfrac{1}{F}\,|\mathcal{M}|^2\,\mathrm{d}\Pi_2$, with the Lorentz-invariant flux $F = 4\sqrt{(p_1\cdot p_2)^2 - m_1^2 m_2^2}$ and $\mathrm{d}\Pi_2$ the two-body phase-space measure. In the centre-of-mass frame with equal masses the flux is

$$F = 4\,|\mathbf{p}_i|\,\sqrt{s} = 4\cdot\frac{\sqrt{s}}{2}\beta\cdot\sqrt{s} = 2s\,\beta, \tag{16.165}$$

using Eqs. (16.160) and (16.161); the threshold factor β enters here through the incoming momentum. The integrated two-body phase space, from Eq. (16.52), is

$$\int \mathrm{d}\Pi_2 = \int \frac{|\mathbf{p}_f|}{16\pi^2\sqrt{s}}\,\mathrm{d}\Omega = \frac{|\mathbf{p}_f|}{16\pi^2\sqrt{s}}\cdot 4\pi = \frac{|\mathbf{p}_f|}{4\pi\sqrt{s}} = \frac{\beta}{8\pi}, \tag{16.166}$$

where the angular integral is trivial because nothing in $\mathrm{d}\Pi_2$ or in $|\mathcal{M}|^2$ depends on direction, and the last equality again used $|\mathbf{p}_f| = (\sqrt{s}/2)\beta$. The threshold factor β enters a second time, now through the outgoing phase space.

Step 3 — assemble, with the identical-particle factor. Combining Eqs. (16.165) and (16.166) and inserting the constant $|\mathcal{M}|^2 = \lambda^2$, the unrestricted integral is $|\mathcal{M}|^2\int\mathrm{d}\Pi_2/F = \lambda^2(\beta/8\pi)/(2s\beta) = \lambda^2/(16\pi s)$. The two appearances of β cancel exactly: *the threshold factor from the flux is undone by the threshold factor from the phase space*, a cancellation special to elastic equal-mass scattering. Dividing by the identical-final-particle symmetry number $2! = 2$,

$$\sigma = \frac{1}{2}\cdot\frac{1}{F}\,|\mathcal{M}|^2\int\mathrm{d}\Pi_2 = \frac{1}{2}\cdot\frac{\lambda^2}{16\pi s} = \frac{\lambda^2}{32\pi s}, \tag{16.167}$$

reproducing Eq. (16.164). The differential form Eq. (16.163) follows by stripping the angular integral and the $\frac{1}{2}$ before integrating: $\mathrm{d}\sigma/\mathrm{d}\Omega = |\mathcal{M}|^2\,(|\mathbf{p}_f|/|\mathbf{p}_i|)/(64\pi^2 s) = \lambda^2/(64\pi^2 s)$, isotropic.

Step 4 — the massive-to-massless reduction. Equation Eq. (16.167) carries no residual β, hence no residual m: it holds for every $s > 4m^2$ exactly. Taking $m \to 0$ (or, equivalently, the high-energy limit $s \gg m^2$) sends $\beta \to 1$ but changes nothing, since β had already cancelled. The massless result is therefore identical,

$$\sigma\big|_{m=0} = \frac{\lambda^2}{32\pi s}, \qquad \left.\frac{\mathrm{d}\sigma}{\mathrm{d}\Omega}\right|_{\mathrm{cm},\, m=0} = \frac{\lambda^2}{64\pi^2 s}. \tag{16.168}$$

The massive theory differs from the massless one only in *where* scattering begins — at $s = 4m^2$ rather than at $s = 0$ — not in the magnitude of the cross section above that point. This is a peculiarity of a constant amplitude; once $\mathcal{M}$ acquires kinematic dependence at $O(\lambda^2)$, the cancellation of threshold factors will no longer be exact.

Step 5 — the numerical scale. Restore the dimensional conversion $(\hbar c)^2 = 0.389\,\mathrm{mb}\cdot\mathrm{GeV}^2$ (with $1\,\mathrm{mb} = 10^{-27}\,\mathrm{cm}^2$). For an order-unity coupling $\lambda = 1$ and a centre-of-mass energy $\sqrt{s} = 1\,\mathrm{GeV}$ (so $s = 1\,\mathrm{GeV}^2$),

$$\sigma = \frac{\lambda^2}{32\pi s} = \frac{1}{32\pi}\,\mathrm{GeV}^{-2} \approx 9.95\times 10^{-3}\,\mathrm{GeV}^{-2} \approx 3.9\times 10^{-3}\,\mathrm{mb} \approx 3.9\,\mu\mathrm{b}. \tag{16.169}$$

A few microbarns at GeV energies for a strong-strength scalar coupling is an utterly typical hadronic-scale cross section, which is the right order of magnitude and a reassuring sanity check on every factor of 2π that went into the master formula.

Step 6 — the dimensional and high-energy check. A cross section is an area, $[\sigma] = [\text{mass}]^{-2}$ in natural units. In $d = 4$ the coupling λ is dimensionless, so the only scale available to a tree amplitude that is itself dimensionless is the invariant s, and dimensional analysis forces $\sigma \propto 1/s$ with a dimensionless coefficient — exactly the structure of Eq. (16.164). The cross section accordingly falls as $1/s$ at high energy (Fig. 16.6): collisions become more transparent as they become more energetic, the hallmark of a marginal (renormalisable) contact coupling whose strength does not grow with energy at tree level. This $1/s$ fall-off is the elementary version of the unitarity-respecting high-energy behaviour that Section 16.7 will sharpen into the partial-wave bound.

Physical Insight: the cross section is all geometry once $\mathcal{M}$ is constant

With $|\mathcal{M}|^2 = \lambda^2$ a pure number, this computation isolates, in its starkest possible form, the chapter's central claim: the dynamics of a scattering process lives entirely in $\mathcal{M}$, and everything else is the geometry of the

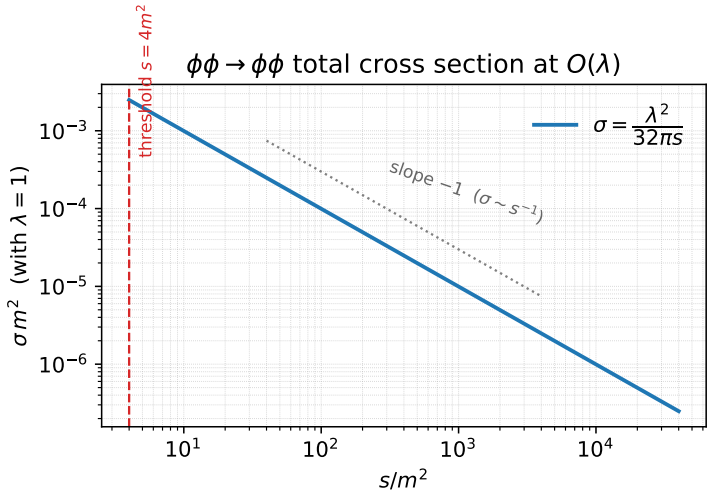

Figure 16.6: The total cross section $\sigma = \lambda^2/(32\pi s)$ for $\phi\phi \to \phi\phi$ at $O(\lambda)$, in units of the scalar mass m (with $\lambda = 1$). Scattering switches on at the kinematic threshold $s = 4m^2$ and, because the threshold factor $\beta = \sqrt{1 - 4m^2/s}$ cancels between flux and phase space, the curve is the exact power law $\sigma \propto 1/s$ for all $s > 4m^2$ — slope -1 on log–log axes, the dimensional-analysis signature $[\sigma] = [\text{mass}]^{-2}$ of a dimensionless coupling whose only scale is s.

on-shell momenta. Here the dynamics is a single constant, and the entire s-dependence, the threshold, the isotropy, and the $1/s$ tail are manufactured by the flux factor and the invariant phase space alone. The same phase-space geometry will sit, unchanged, behind the $e^+e^- \to \mu^+\mu^-$ cross section of Chapter 17; what changes there is only that $\mathcal{M}$ stops being a constant and starts carrying the angular structure of spin.

16.6.5 What the next order brings

The tree result Eq. (16.164) is exact in its accounting of the leading-order rate, but it is also, in one precise sense, incomplete: a constant real amplitude has no imaginary part, and a real $\mathcal{M}$ cannot by itself satisfy the unitarity relation that Section 16.7 will impose. At $O(\lambda^2)$ the picture changes. The one-loop s-, t-, and u-channel bubble diagrams — the same diagrams whose position-space form appeared in Eq. (15.38) — give $\mathcal{M}(s,t,u)$ genuine kinematic dependence and, above threshold, a nonzero imaginary part $\mathrm{Im}\,\mathcal{M}$. That imaginary part is not optional: the optical theorem of the next section fixes it, through $\mathrm{Im}\,\mathcal{M}(s,\theta{=}0) = 2E_{\mathrm{cm}}|\mathbf{p}_i|\,\sigma_{\mathrm{tot}}$, to be exactly what reproduces the tree cross section Eq. (16.164) we have just computed. The chapter therefore contains its own consistency check:

the $O(\lambda)$ cross section computed here must equal the $O(\lambda^2)$ discontinuity of the loop amplitude, a cross-check we set up in Section 16.7 and discharge by the explicit bubble computation of Chapters 21 and 22.

We have now run the full apparatus of this chapter on a real example and extracted a physical number from a measured-quantity formula. The pipeline was: take $\mathcal{M}$ from the Feynman rules, square it, contract it with the invariant phase space, divide by the flux, and integrate. Chapter 17 reuses this pipeline verbatim for $e^+e^- \to \mu^+\mu^-$; the only new ingredient is the evaluation of $\overline{|\mathcal{M}|^2}$ via Dirac spin sums and gamma-matrix traces, after which the same master formula, the same two-body phase space, and the same Mandelstam kinematics deliver the QED cross section — the bridge from formalism to numbers, now carried across both threads.

16.7 Unitarity, the optical theorem as a cross section, and partial waves

The previous section cashed the entire chapter on ϕ^4 theory: from the tree amplitude $\mathcal{M} = -\lambda$ it produced the differential cross section $\mathrm{d}\sigma/\mathrm{d}\Omega = \lambda^2/(64\pi^2 s)$ and, after the identical-particle factor, the total cross section $\sigma_{\text{tot}} = \lambda^2/(32\pi s)$ recorded in Eq. (16.164). In passing it flagged something that ought to feel paradoxical. The amplitude $\mathcal{M} = -\lambda$ is a real number, kinematics-independent, with no imaginary part whatsoever; yet we are about to assert that the imaginary part of the *forward* elastic amplitude is, all by itself, a measure of this very total cross section. At the order we have computed, the forward amplitude has no imaginary part, so the statement can only become nonvacuous one order deeper, at $O(\lambda^2)$ — exactly the loop order at which the same section's forward pointer promised an imaginary part would appear. The present section makes that promise precise. It takes the one piece of nonperturbative knowledge the S-matrix supplies — its unitarity, established in Section 14.7 — and feeds into it the flux factor of Section 16.4 and the invariant phase space of Section 16.2 built earlier in this chapter, turning an abstract operator identity into an equation between two quantities a detector actually reports: the imaginary part of a forward amplitude and a total cross section. The result is the optical theorem in cross-section form, its sharpening into the partial-wave unitarity bound, and a self-consistency check on the chapter's own machinery that the ϕ^4 numbers pass exactly.

The logic runs opposite to the way Section 14.7 first presented these results. There the optical theorem was extracted from operator unitarity *before* the cross-section formula existed, so the kinematic factors — the Møller flux, the two-body phase space — had to be quoted in advance, "recalled from Chapter 16." We are now Chapter 16, and those factors have been derived from scratch. Closing that loop is not a repetition: it is the consistency check the chapter has been

building toward, the moment the observable-side machinery (flux, phase space, $2 \to 2$ kinematics) and the formal-side machinery (LSZ, the S-matrix, unitarity) are shown to agree on the same number from two independent directions.

16.7.1 From operator unitarity to a relation between cross sections

We begin from the result Section 14.7 proved and import without re-deriving. The scattering operator $\mathbf{S} = \mathbf{1} + i\mathcal{T}$ is unitary, and writing out $\mathbf{S}^\dagger\mathbf{S} = \mathbf{1}$ gives the operator identity

$$-i(\mathcal{T} - \mathcal{T}^\dagger) = \mathcal{T}^\dagger\mathcal{T}, \tag{16.170}$$

which is Eq. (14.188): the failure of the transition operator to be Hermitian is exactly its own positive square. Sandwiched between a fixed initial state $|i\rangle$ of total four-momentum p_i and evaluated with the invariant amplitude $\mathcal{M}$ of Eq. (14.163) together with the completeness relation on the interacting Fock space, this becomes the generalized optical theorem Theorem 14.37,

$$2\ \mathrm{Im}\ \mathcal{M}(i \to i) = \sum_f \int \mathrm{d}\Pi_f\ |\mathcal{M}(i \to f)|^2, \tag{16.171}$$

in which $\mathrm{d}\Pi_f$ is precisely the Lorentz-invariant final-state phase space constructed in Section 16.2 — the same measure, including the energy–momentum delta, now carrying its full in-chapter pedigree rather than being borrowed. Here $\mathrm{d}\Pi_f$ is the bare phase-space measure; whenever the final state contains n identical bosons the $1/n!$ symmetry factor is supplied separately, multiplying the integral, exactly as in the worked check below. The sum runs over every kinematically accessible final state f: elastic, inelastic, of any multiplicity. The right-hand side is a sum of squared moduli against nonnegative measures, hence $\mathrm{Im}\ \mathcal{M}(i \to i) \geq 0$.

So far Eq. (16.171) is a statement about amplitudes. The content of this section is the recognition that its right-hand side is, up to a single kinematic factor, a quantity we have just learned to measure. Specialize the initial state to the two-particle configuration of a scattering experiment, $|i\rangle = |p_1\, p_2\rangle$. The master cross-section formula of Section 16.4, namely Eq. (16.172),

$$\mathrm{d}\sigma(i \to f) = \frac{1}{F}\,|\mathcal{M}(i \to f)|^2\,\mathrm{d}\Pi_f, \qquad F = 4\sqrt{(p_1 \cdot p_2)^2 - m_1^2 m_2^2}, \tag{16.172}$$

tells us that summing and integrating $|\mathcal{M}|^2\,\mathrm{d}\Pi_f$ over all final states is the same operation that, divided by the flux F, builds the total cross section:

$$\sigma_{\mathrm{tot}}(s) = \frac{1}{F}\sum_f \int \mathrm{d}\Pi_f\,|\mathcal{M}(i \to f)|^2. \tag{16.173}$$

The sum in Eq. (16.173) is identical to the sum in Eq. (16.171). Eliminating it between the two equations is immediate and is the whole derivation: the

right-hand side of the optical theorem equals $F\,\sigma_{\mathrm{tot}}$, while its left-hand side is $2\,\mathrm{Im}\,\mathcal{M}$ of the *forward* amplitude — "forward" because the diagonal element $\mathcal{M}(i \to i)$ has final state equal to initial state, $p_3 = p_1$, $p_4 = p_2$, hence zero scattering angle and Mandelstam $t = (p_1 - p_3)^2 = 0$.

Theorem 16.28 (Optical theorem in cross-section form)**.** *For elastic $2 \to 2$ scattering of two particles of momenta p_1, p_2 at centre-of-momentum energy $\sqrt{s}$, the imaginary part of the forward ($t = 0$) invariant amplitude fixes the total cross section,*

$$\boxed{\mathrm{Im}\,\mathcal{M}(s, t{=}0) = \tfrac{1}{2}\,F\,\sigma_{\mathrm{tot}}(s) = 2\,|\mathbf{p}_i|\,\sqrt{s}\,\sigma_{\mathrm{tot}}(s)} \tag{16.174}$$

where $|\mathbf{p}_i| = p_{\mathrm{cm}}$ is the common magnitude of the initial three-momenta in the centre-of-momentum frame, $\sigma_{\mathrm{tot}} = \sigma_{\mathrm{el}} + \sigma_{\mathrm{inel}}$ is the sum over all channels, and the positivity $\mathrm{Im}\,\mathcal{M}(s, 0) \geq 0$ holds nonperturbatively.

Proof. Set the initial and final two-particle states equal in Eq. (16.171), giving $2\,\mathrm{Im}\,\mathcal{M}(s,0) = \sum_f \int \mathrm{d}\Pi_f |\mathcal{M}(i \to f)|^2$, and substitute the sum from Eq. (16.173), $\sum_f \int \mathrm{d}\Pi_f |\mathcal{M}|^2 = F\,\sigma_{\mathrm{tot}}$. Hence $2\,\mathrm{Im}\,\mathcal{M}(s,0) = F\,\sigma_{\mathrm{tot}}$, i.e. $\mathrm{Im}\,\mathcal{M}(s,0) = \tfrac{1}{2}F\,\sigma_{\mathrm{tot}}$. It remains to evaluate the flux in the centre-of-momentum frame. There $p_1 = (E_1, \mathbf{p})$, $p_2 = (E_2, -\mathbf{p})$ with $|\mathbf{p}| = p_{\mathrm{cm}}$ and $E_1 + E_2 = \sqrt{s}$, so $p_1 \cdot p_2 = E_1 E_2 + \mathbf{p}^2$. Using $E_i^2 = \mathbf{p}^2 + m_i^2$,

$$\begin{aligned}(p_1 \cdot p_2)^2 - m_1^2 m_2^2 &= (E_1 E_2 + \mathbf{p}^2)^2 - (E_1^2 - \mathbf{p}^2)(E_2^2 - \mathbf{p}^2) \\ &= 2E_1 E_2 \mathbf{p}^2 + \mathbf{p}^4 + (E_1^2 + E_2^2)\mathbf{p}^2 - \mathbf{p}^4 = \mathbf{p}^2\,(E_1 + E_2)^2 = p_{\mathrm{cm}}^2\, s,\end{aligned} \tag{16.175}$$

the standard two-body identity, whence $F = 4\sqrt{p_{\mathrm{cm}}^2 s} = 4\,p_{\mathrm{cm}}\sqrt{s}$ and $\tfrac{1}{2}F = 2\,p_{\mathrm{cm}}\sqrt{s} = 2\,|\mathbf{p}_i|\,\sqrt{s}$. This is Eq. (16.174). Positivity follows from the nonnegativity of the right-hand side of Eq. (16.171). □

Equation Eq. (16.174) is the same identity quoted as Eq. (14.200), but it now stands on the chapter's own legs: the flux F and the phase space $\mathrm{d}\Pi_f$ that enter it were derived in Sections 16.2 and 16.4, not assumed. The agreement of the two routes — operator unitarity feeding kinematics it had to anticipate, versus kinematics now built independently and fed back into unitarity — is the consistency check announced at the head of the section. At high energy, $m_i^2 \ll s$, one has $p_{\mathrm{cm}} \to \sqrt{s}/2$ and Eq. (16.174) collapses to the memorable form $\mathrm{Im}\,\mathcal{M}(s,0) \to s\,\sigma_{\mathrm{tot}}(s)$.

Physical Insight

The optical theorem is the bridge that finally makes the chapter title's third word, "amplitudes," carry physical weight equal to "cross sections"

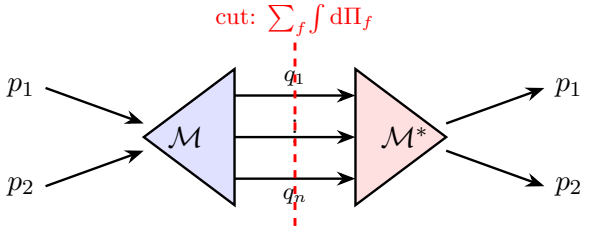

Figure 16.7: The optical theorem Eq. (16.174) as a unitarity cut. Twice the imaginary part of the forward elastic amplitude $\mathcal{M}(i \to i)$ (left) is obtained by severing it along the dashed line into a product $\mathcal{M}(i \to f)\,\mathcal{M}^*(i \to f)$ and putting every intermediate line $q_1 \dots q_n$ on its mass shell, then summing over all final states f with the invariant phase space $\mathrm{d}\Pi_f$ of Section 16.2. Dividing by the flux $F = 4\,|\mathbf{p}_i|\,\sqrt{s}$ turns the cut into the total cross section. The systematic version of this picture is Cutkosky's rule, established later (Chapter 60); here it is the diagrammatic content of Eq. (16.171).

and "decay rates." A cross section is the modulus-squared of an amplitude integrated over phase space; the imaginary part of the *forward* amplitude, by contrast, is a single complex number evaluated at one kinematic point. Unitarity says these two very different-looking objects are the same physics: the total rate at which a beam is depleted in the forward direction equals the total rate at which anything at all happens. Nothing in the differential cross section of Section 16.5 could have told us this; it is a constraint that links amplitudes across the energy at a single angle to an integral over all angles and all channels, and it is exact.

16.7.2 Partial waves and the unitarity bound on cross sections

The optical theorem constrains the forward amplitude as a single object. Resolving the elastic $2 \to 2$ amplitude into eigenstates of angular momentum sharpens it into a separate, hard bound on each channel — the relativistic descendant of the partial-wave analysis familiar from nonrelativistic scattering. We take the cleanest case, two spinless particles scattering elastically in the centre-of-momentum frame, where rotational invariance about the beam axis makes $\mathcal{M}$ a function of s and the polar angle θ alone. Recall the partial-wave expansion fixed in Eq. (14.202),

$$\mathcal{M}(s,\theta) = \frac{8\pi\sqrt{s}}{p_{\mathrm{cm}}} \sum_{\ell=0}^{\infty} (2\ell{+}1)\, a_\ell(s)\, P_\ell(\cos\theta), \qquad a_\ell(s) = \frac{p_{\mathrm{cm}}}{16\pi\sqrt{s}} \int_{-1}^{1} \mathrm{d}(\cos\theta)\, P_\ell\, \mathcal{M}, \tag{16.176}$$

the dimensionless coefficients $a_\ell(s)$ being the partial-wave amplitudes and P_ℓ the Legendre polynomials, with projection following from the orthogonality

$\int_{-1}^{1} \mathrm{d}(\cos\theta)\, P_\ell P_{\ell'} = \frac{2}{2\ell+1}\delta_{\ell\ell'}$. The normalization is chosen, with foresight, so that the unitarity relations below come out free of stray factors. What is new here is that we feed this expansion into the differential cross section *this chapter* derived, rather than into an abstract probability current.

Elastic cross section. From the $2 \to 2$ result of Section 16.5, the elastic differential cross section for equal-mass particles is $\mathrm{d}\sigma_{\mathrm{el}}/\mathrm{d}\Omega = |\mathcal{M}|^2/(64\pi^2 s)$ (this is Eq. (16.145), the elastic specialization $|\mathbf{p}_f| = |\mathbf{p}_i|$ of the master formula). Insert Eq. (16.176), integrate over the solid angle $\mathrm{d}\Omega = 2\pi\,\mathrm{d}(\cos\theta)$, and apply orthogonality to collapse the double sum:

$$\begin{aligned}\sigma_{\mathrm{el}} &= \int \mathrm{d}\Omega\, \frac{|\mathcal{M}|^2}{64\pi^2 s} = \frac{2\pi}{64\pi^2 s}\left(\frac{8\pi\sqrt{s}}{p_{\mathrm{cm}}}\right)^2 \int_{-1}^{1} \mathrm{d}(\cos\theta) \sum_{\ell,\ell'} (2\ell+1)(2\ell'+1)\, a_\ell a_{\ell'}^{*}\, P_\ell P_{\ell'} \\ &= \frac{2\pi}{64\pi^2 s} \cdot \frac{64\pi^2 s}{p_{\mathrm{cm}}^2} \sum_{\ell} (2\ell+1)^2\, |a_\ell|^2 \cdot \frac{2}{2\ell+1} = \frac{4\pi}{p_{\mathrm{cm}}^2} \sum_{\ell} (2\ell+1)\, |a_\ell(s)|^2 .\end{aligned} \tag{16.177}$$

Total cross section. The forward amplitude is obtained from Eq. (16.176) at $\theta = 0$, where every $P_\ell(1) = 1$, so $\mathcal{M}(s,0) = \frac{8\pi\sqrt{s}}{p_{\mathrm{cm}}} \sum_\ell (2\ell+1) a_\ell$. Feed its imaginary part into the optical theorem Eq. (16.174):

$$\sigma_{\mathrm{tot}} = \frac{\mathrm{Im}\ \mathcal{M}(s,0)}{2\, p_{\mathrm{cm}}\sqrt{s}} = \frac{1}{2 p_{\mathrm{cm}}\sqrt{s}} \cdot \frac{8\pi\sqrt{s}}{p_{\mathrm{cm}}} \sum_{\ell} (2\ell+1)\ \mathrm{Im}\ a_\ell = \frac{4\pi}{p_{\mathrm{cm}}^2} \sum_{\ell} (2\ell+1)\ \mathrm{Im}\ a_\ell(s). \tag{16.178}$$

The two expressions Eqs. (16.177) and (16.178) share the identical prefactor $4\pi/p_{\mathrm{cm}}^2$ — the relativistic echo of the $4\pi/k^2$ of Sakurai-level scattering theory — which is exactly the payoff of the normalization in Eq. (16.176). Because each channel ℓ is independent and the total cross section decomposes into a nonnegative elastic part plus a nonnegative inelastic part, $\sigma_{\mathrm{tot}} = \sigma_{\mathrm{el}} + \sigma_{\mathrm{inel}}$ with $\sigma_{\mathrm{inel}} \geq 0$, subtracting Eq. (16.177) from Eq. (16.178) term by term gives the per-channel statement

$$\mathrm{Im}\ a_\ell(s) = \big|a_\ell(s)\big|^2 + \underbrace{\frac{p_{\mathrm{cm}}^2}{4\pi(2\ell+1)}\, \sigma_{\mathrm{inel}}^{(\ell)}}_{\geq 0} \ \geq\ \big|a_\ell(s)\big|^2 . \tag{16.179}$$

This is the partial-wave unitarity relation, derived here entirely from cross sections: the elastic part of $\mathrm{Im}\, a_\ell$ is $|a_\ell|^2$, and any excess is the inelastic rate flowing out of that angular-momentum channel. Its geometric content is the Argand circle: completing the square in Eq. (16.179) gives $(\mathrm{Re}\ a_\ell)^2 + (\mathrm{Im}\ a_\ell - \frac{1}{2})^2 \leq \frac{1}{4}$, so a_ℓ is confined to the closed disk of radius $\frac{1}{2}$ centred at $\frac{i}{2}$, drawn in Fig. 14.6, with the boundary $\mathrm{Im}\, a_\ell = |a_\ell|^2$ being the purely elastic locus $a_\ell = e^{i\delta_\ell}\sin\delta_\ell$ of a real

phase shift (Eqs. (14.207) and (14.208)). The three immediate corollaries are $0 \le \operatorname{Im} a_\ell \le 1$, $|\operatorname{Re} a_\ell| \le \frac{1}{2}$, and $|a_\ell| \le 1$.

The last of these is what bounds the cross section. Inserting $|a_\ell| \le 1$ into Eq. (16.177), or equivalently $\operatorname{Im} a_\ell \le 1$ into Eq. (16.178), caps the contribution of each angular momentum.

Theorem 16.29 (Partial-wave unitarity bound)**.** *The contribution of the ℓ-th partial wave to the total cross section of elastic spinless $2 \to 2$ scattering satisfies, nonperturbatively,*

$$\sigma_\ell \;\le\; \frac{4\pi(2\ell+1)}{|\mathbf{p}_i|^2}, \tag{16.180}$$

with saturation at $a_\ell = i$ (phase shift $\delta_\ell = \pi/2$, the unitarity limit of maximal absorption).

Proof. By Eq. (16.179), $\operatorname{Im} a_\ell \ge |a_\ell|^2 \ge 0$, so $\operatorname{Im} a_\ell \ge (\operatorname{Im} a_\ell)^2$, which forces $0 \le \operatorname{Im} a_\ell \le 1$; equivalently the Argand-disk constraint gives $|a_\ell| \le 1$. The ℓ-channel piece of Eq. (16.178) is $\sigma_\ell = \frac{4\pi}{p_{\rm cm}^2}(2\ell+1)\operatorname{Im} a_\ell \le \frac{4\pi}{p_{\rm cm}^2}(2\ell+1)$, with equality iff $\operatorname{Im} a_\ell = 1$, i.e. $a_\ell = i$. Identifying $p_{\rm cm} = |\mathbf{p}_i|$ gives Eq. (16.180). □

Caution

The bound Eq. (16.180), like $|a_\ell| \le 1$, constrains the *exact* amplitude. A truncated perturbative amplitude is a polynomial in the coupling and will, at high enough energy or strong enough coupling, march straight out of the Argand disk. That is not a failure of unitarity but a self-diagnostic: it marks the kinematic regime where the omitted higher orders are no longer negligible and the series must be resummed or replaced. We use exactly this diagnostic on ϕ^4 below.

16.7.3 Scalar ϕ^4 theory: closing the stage with a unitarity self-check

We now run the chapter's ϕ^4 output through the optical theorem and confirm that everything is mutually consistent — and that the only place a nonzero answer can first appear is precisely where Section 16.6 said it would.

Worked Example 16.30 (The ϕ^4 optical theorem and the location of the first imaginary part)**.** The chapter's tree amplitude is the constant $\mathcal{M} = -\lambda$ (Eq. (14.183)), and Section 16.6 integrated it to the total cross section

$$\sigma_{\rm tot} = \frac{\lambda^2}{32\pi s} \;+\; O(\lambda^3), \tag{16.181}$$

the factor $\frac{1}{2}$ for identical final-state bosons already included (Eq. (16.164)). We confront these with Theorem 16.28.

Why the leading order is silent. The optical theorem Eq. (16.174) reads $\mathrm{Im}\,\mathcal{M}(s,0) = 2\,|\mathbf{p}_i|\,\sqrt{s}\,\sigma_{\mathrm{tot}}$. Its right-hand side, by Eq. (16.181), is $O(\lambda^2)$. Its left-hand side, evaluated on the tree amplitude, is $\mathrm{Im}(-\lambda) = 0$. So at $O(\lambda)$ the theorem reads $0 = 0 + O(\lambda^2)$: satisfied, but carrying no information. This is not an accident of ϕ^4; it is forced by the operator identity Eq. (16.170), whose right-hand side $\mathcal{T}^\dagger\mathcal{T}$ is always one power of the coupling higher than its left-hand side $\mathcal{T} - \mathcal{T}^\dagger$. The imaginary part of the forward amplitude is therefore mandated to vanish at the order at which σ_{tot} first becomes nonzero, and to reappear one loop later — exactly the $O(\lambda^2)$ remark with which Section 16.6 ended. The optical theorem turns that qualitative pointer into an equation.

The quantitative prediction. At $O(\lambda^2)$ the theorem becomes a prediction for the imaginary part of the one-loop forward amplitude $\mathcal{M}^{(2)}$ in terms of the tree cross section already in hand. Using $|\mathbf{p}_i| = p_{\mathrm{cm}} = \tfrac{1}{2}\sqrt{s}\,\beta$ with $\beta = \sqrt{1 - 4m^2/s}$,

$$\mathrm{Im}\;\mathcal{M}^{(2)}(s,0) = 2\,p_{\mathrm{cm}}\sqrt{s}\,\sigma_{\mathrm{tot}} = 2\cdot\tfrac{1}{2}\sqrt{s}\,\beta\cdot\sqrt{s}\cdot\frac{\lambda^2}{32\pi s} = \frac{\lambda^2\,\beta}{32\pi}. \tag{16.182}$$

This must agree with the cut on the right-hand side of Eq. (16.171). The lightest accessible state is again two scalars, so the cut is the two-body phase-space integral of the tree amplitude squared, with an explicit $1/2!$ identical-boson factor multiplying the bare measure $\mathrm{d}\Pi_2$:

$$2\;\mathrm{Im}\;\mathcal{M}^{(2)}(s,0) = \frac{1}{2!}\int \mathrm{d}\Pi_2\,\big|-\lambda\big|^2 = \frac{\lambda^2}{2}\cdot\frac{\beta}{8\pi} = \frac{\lambda^2\beta}{16\pi}, \tag{16.183}$$

where $\int \mathrm{d}\Pi_2 = \beta/8\pi$ is the two-body phase-space volume of Section 16.2. Dividing by 2 gives $\mathrm{Im}\;\mathcal{M}^{(2)}(s,0) = \lambda^2\beta/32\pi$, in exact agreement with Eq. (16.182). The two routes — "flux times the total cross section" and "phase-space integral of the cut" — meet on the same number, including the identical-particle factor that appears, identically, on both sides. This sharpens the looser leading check recorded in Eq. (14.210): the present accounting tracks the symmetry factor through to the end and finds the books balance.

What is and is not established. Equation Eq. (16.182) is a falsifiable prediction for the imaginary part of the one-loop s-channel bubble, fixed in advance by tree-level data and the unitarity of $\mathbf{S}$. Computing $\mathcal{M}^{(2)}$ itself — assembling the loop diagram, regulating and integrating it, and extracting its imaginary part — requires the Feynman-integral technology of the renormalization programme (Chapter 19) and the systematic cutting rules of Chapter 60. No new loop number is computed here; what is established is the constraint the loop must satisfy, waiting for the later chapters to redeem.

The perturbative reach of λ. Finally, project the tree amplitude onto partial waves. Since $\mathcal{M} = -\lambda$ is angle-independent and $P_0 = 1$, only the s-wave survives, and Eq. (16.176) gives $a_0 = -\lambda\,p_{\mathrm{cm}}/(8\pi\sqrt{s}) \to -\lambda/16\pi$ at high energy. This is real at $O(\lambda)$, consistent with $\mathrm{Im}\,a_0 = |a_0|^2 = O(\lambda^2)$ — the imaginary part the

Argand circle demands is again deferred to one loop. The exact bound $|a_0| \leq 1$ of Eq. (16.179) then reads $\lambda \lesssim 16\pi$, the perturbative-unitarity ceiling on the coupling derived in Eq. (14.212): tree-level $\lambda\phi^4$ is trustworthy only for λ well below 16π, and the genuine expansion parameter is $\lambda/16\pi^2$ — the same $16\pi^2$ that will govern the one-loop β-function $\beta_\lambda = 3\lambda^2/16\pi^2$ of Chapter 24.

The ϕ^4 stage thus closes with its own internal audit passed. The chapter's flux, phase space, and $2 \to 2$ kinematics, assembled independently of Chapter 14, reproduce the optical theorem that unitarity demands; the tree cross section $\sigma_{\text{tot}} = \lambda^2/32\pi s$ feeds back through that theorem to predict the imaginary part of an amplitude the chapter has not yet computed; and the partial-wave bound certifies where the perturbative description ends. Every observable formula has been checked against the one nonperturbative constraint available.

This completes the bridge from formalism to numbers. The flux–phase-space–amplitude template is now ready to be reused verbatim in Chapters 17 and 18, where the same machinery, augmented only by spin sums and gamma-matrix traces, produces the QED cross sections of QED. The imaginary part that the optical theorem here predicts but defers will be computed explicitly when one-loop amplitudes acquire their absorptive parts in Chapter 19, and organized into general cutting rules in Chapter 60. And the analyticity that unitarity has begun to impose on the amplitude — positivity of $\text{Im}\,\mathcal{M}$, the Argand disk, the partial-wave bound — is the physical input on which the dispersion relations and the modern bootstrap of Part XIV are built, the channel through which this chapter's elementary kinematics reaches the research frontier.

Further reading

The box-regularization route to the rate and cross-section formulae, and the relativistic state normalization that fixes their kinematic factors, are treated in the standard graduate texts: Peskin and Schroeder [396] (Chapter 4), Schwartz [432], Srednicki [454], and the foundational discussion in Weinberg [500]; Zee [532] gives a complementary, more heuristic account. The Lorentz-invariant phase space, the recursion relation, and the Dalitz-plot kinematics worked here in full are the subject of the classic monograph by Byckling and Kajantie [100], while the standard conventions and numerical data are collected in the kinematics review of Particle Data Group [382]. The triangle function originates with Källén [289]. For the analytic-S-matrix viewpoint on the Mandelstam plane, crossing, and the physical regions, see Eden et al. [170]; the unitarity cut underlying the optical theorem is made systematic by the Cutkosky rules of Cutkosky [141], developed in this book in Chapter 60.

Part V

Quantum Electrodynamics

Chapter 17

QED: Feynman Rules and First Processes

With this chapter Part V opens, and the long preparatory arc of the book pays its first concrete dividend. Everything assembled so far converges here on a single target: to compute, from first principles and with every intermediate step on the page, the cross sections that an electron–positron collider actually measures. The classical gauge principle of Chapter 8 handed us the standard Lagrangian $\mathcal{L}_{\text{QED}} = \bar{\psi}(i\not{D} - m)\psi - \frac{1}{4}F_{\mu\nu}F^{\mu\nu}$ with its minimal coupling $D_\mu = \partial_\mu + ieA_\mu$; the quantization of the Dirac field in Chapter 11 supplied the on-shell spinors, the spin sums, and the fermion propagator; the quantization of the photon in Chapter 13 supplied the R_ξ propagator and the Gupta–Bleuler restriction to physical transverse states. Onto this matter content the perturbative engine of Part IV now acts: the interaction picture and the LSZ reduction of Chapter 14, Wick's theorem and the diagrammatic bookkeeping of Chapter 15, and the phase-space, flux, and cross-section apparatus of Chapter 16. None of these results is reproved here. The work of this chapter is to wield them, and to keep honest the one convention—the sign of the covariant derivative, fixed once and never revisited—whose mishandling is the single most common error in the subject.

The chapter is organized so that the derivation is done exactly once and the computation that follows is pure application. Section 17.1 extracts, from the gauge-fixed Lagrangian and the Dyson series, a fixed sign-checked momentum-space *rulebook*: the vertex $-ie\gamma^\mu$, the two internal propagators, the six external-line factors, the closed-loop and exchange signs forced by Fermi statistics, and the tree-level gauge independence that licenses working in Feynman gauge. Section 17.2 builds the algebraic engine that turns a spin-dressed amplitude into a number a detector reports—the completeness relations, Casimir's trick, the gamma-trace toolkit of Chapter C, and the photon polarization-sum replacement—reducing $\overline{|\mathcal{M}|^2}$ to a function of the Mandelstam invariants of Chapter 16 with not a spinor left in sight.

The remaining sections run that machinery on the carried processes of QED. Section 17.3 carries the marquee computation, $e^+e^- \to \mu^+\mu^-$, from the single s-channel diagram to the angular law $d\sigma/d\Omega = (\alpha^2/4s)(1+\cos^2\theta)$, the total cross section $\sigma = 4\pi\alpha^2/3s$, and its threshold-corrected massive form. Section 17.4 shows that this one rational function of (s,t,u), analytically continued, already contains a second physical process, and Section 17.5 cashes that crossed amplitude for $e^-\mu^- \to e^-\mu^-$ into the laboratory-frame cross section, recovering the Mott and Rutherford formulae as nested limits and identifying the photon's $1/q^4$ with the squared Fourier transform of the Coulomb potential—the precise sense in which QED contains classical electrostatics.

The closing Section 17.6 steps back to ask why the answers take the shape they do. The QED vertex conserves chirality, in the high-energy limit chirality is helicity, and the surviving helicity amplitudes are nothing but the rotation matrix elements $d^1_{m'm}(\theta)$ of a spin-one exchange; the $1+\cos^2\theta$ law that the traces produced is thereby revealed as a theorem of angular-momentum conservation, independent of the dynamical detail. This helicity skeleton is the seed of the spinor-helicity reframing of Chapter 58, and it points forward to the loops, the Ward–Takahashi identity, and the precision predictions that Chapters 18 to 20 will take up in turn.

17.1 The QED Lagrangian and its Feynman rules

The chapter introduction has gathered three strands of inheritance and laid them side by side: the quantized photon with its R_ξ propagator and Gupta–Bleuler physical states (Chapter 13), the quantized Dirac electron with its mode expansion and on-shell spinors (Chapter 11), and the perturbative engine — the interaction picture and LSZ reduction (Chapter 14), Wick's theorem and the Feynman-rule machinery (Chapter 15), and the phase-space and cross-section apparatus (Chapter 16). None of these is reproved here; they are wielded. The task of this section is narrow and decisive: to turn that inheritance into a single, fixed, sign-checked *rulebook*. Once we possess it, the rest of the chapter is pure computation from this fixed rulebook — every later amplitude is read off a diagram by table lookup, never re-derived from the field operators. The discipline of doing the derivation *once*, in full, is what makes the subsequent computation trustworthy: a sign error buried in a mode expansion would otherwise propagate silently into every cross section. We therefore extract each rule from the underlying operator algebra rather than assert it, and we pin down, on the page, the one convention — the sign of the covariant derivative — that is the single most common source of error in the subject.

17.1.1 The gauge-fixed Lagrangian and the perturbative expansion

The classical theory was assembled in Section 8.6 by the gauge principle: demanding local $U(1)$ invariance of the free Dirac field forced minimal coupling and produced the standard Lagrangian Eq. (8.143),

$$\mathcal{L}_{\text{QED}} = \bar{\psi}\,(i\not{D} - m)\,\psi - \tfrac{1}{4}F_{\mu\nu}F^{\mu\nu}, \qquad D_\mu = \partial_\mu + ieA_\mu, \qquad F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu. \tag{17.1}$$

Here ψ is the electron field of mass m, $e > 0$ is the elementary charge, and the electron carries physical charge $-e$, so that the global rule of Chapter A, $D_\mu = \partial_\mu - iqA_\mu$ with $q = -e$, specializes to the $+ie$ written above. The fine-structure constant is $\alpha = e^2/4\pi \approx 1/137$ (Eq. (8.145)). Expanding the covariant derivative as in Eq. (8.144) separates the free pieces from the single interaction,

$$\mathcal{L}_{\text{QED}} = \underbrace{\bar{\psi}(i\not{\partial} - m)\psi}_{\mathcal{L}_{0,\psi}} \; \underbrace{-\tfrac{1}{4}F_{\mu\nu}F^{\mu\nu}}_{\mathcal{L}_{0,A}} \; \underbrace{-\,e\,\bar{\psi}\gamma^\mu\psi\,A_\mu}_{\mathcal{L}_{\text{int}}}. \tag{17.2}$$

Notation Watch

The sign convention is fixed here once for the entire QED thread and never revisited: $e > 0$, electron charge $-e$, covariant derivative $D_\mu = \partial_\mu + ieA_\mu$, interaction $\mathcal{L}_{\text{int}} = -e\,\bar{\psi}\gamma^\mu\psi A_\mu$. Texts that take the electron charge itself as the symbol e (so $e < 0$) obtain the opposite sign in the covariant derivative and an apparently different vertex; the physics is identical, but the symbols are not interchangeable. Every e in this and the following chapters is the positive elementary charge.

The free Lagrangian $\mathcal{L}_{0,A}$ on its own does not define a photon propagator: the quadratic form $-\frac{1}{4}F_{\mu\nu}F^{\mu\nu}$ is annihilated by pure-gauge configurations $A_\mu = \partial_\mu\Lambda$, so its kinetic operator is not invertible. This obstruction, and its resolution, were the subject of Chapter 13. The cure is to add a gauge-fixing term, which in the covariant R_ξ family reads (Eq. (13.176))

$$\mathcal{L}_{\text{gf}} = -\frac{1}{2\xi}\,(\partial_\mu A^\mu)^2, \tag{17.3}$$

so that the gauge-fixed QED Lagrangian we quantize is

$$\boxed{\mathcal{L} = \bar{\psi}(i\not{D} - m)\psi - \tfrac{1}{4}F_{\mu\nu}F^{\mu\nu} - \frac{1}{2\xi}(\partial_\mu A^\mu)^2.} \tag{17.4}$$

The parameter ξ labels a gauge *choice*; physical quantities must be independent of it, a fact we verify at tree level in Section 17.1.6 and which is guaranteed in general by the Ward–Takahashi identity proved in Chapter 19. For all explicit

computation in this chapter we adopt the *Feynman gauge* $\xi = 1$, the standard default, because it strips the photon propagator down to its simplest tensor structure. We state results in general ξ where it costs nothing and specialize to $\xi = 1$ thereafter.

From the Lagrangian to the Dyson series. The perturbative expansion of the S-matrix is built in the interaction picture. The free part of Eq. (17.4) furnishes the in/out asymptotic fields with the mode expansions of Chapters 11 and 13, and the time evolution generated by the interaction is the Dyson series

$$\mathbf{S} = \mathcal{T} \exp\!\left(-i \int d^4x \, \mathcal{H}_{\text{int}}(x) \right), \tag{17.5}$$

with $\mathcal{H}_{\text{int}}$ the interaction-picture Hamiltonian density. For QED the coupling $\mathcal{L}_{\text{int}} = -e\bar{\psi}\gamma^\mu\psi A_\mu$ contains *no* time derivatives of the fields, so the Legendre transform that defines $\mathcal{H}$ does not generate any extra terms from the interaction: the canonical momenta are unchanged by $\mathcal{L}_{\text{int}}$, and therefore

$$\mathcal{H}_{\text{int}} = -\mathcal{L}_{\text{int}} = e\,\bar{\psi}\gamma^\mu\psi A_\mu. \tag{17.6}$$

This is the property that makes the covariant gauge-fixed formulation so convenient: in a non-covariant gauge the instantaneous Coulomb interaction and a non-covariant piece of the propagator appear separately and must be shown to recombine, whereas the covariant quantization of Chapter 13 packages everything into the manifestly Lorentz-invariant propagator Eq. (13.135), and the simple relation Eq. (17.6) holds. Substituting Eq. (17.6) into Eq. (17.5) and using $-i\int dt\,\mathcal{H}_{\text{int}} = i\int d^4x\,\mathcal{L}_{\text{int}}$ gives the form we actually expand,

$$\mathbf{S} = \mathcal{T} \exp\!\left(i \int d^4x \, \mathcal{L}_{\text{int}}(x) \right) = \mathcal{T} \exp\!\left(-ie \int d^4x \, \bar{\psi}\gamma^\mu\psi A_\mu \right). \tag{17.7}$$

Every QED amplitude is a term in this expansion, evaluated between asymptotic states by Wick's theorem (Theorem 15.3) and amputated onto external wavefunctions by LSZ (Theorem 14.31). The Feynman rules are nothing more than the bookkeeping of that evaluation, organized so it need never be redone. We extract them now, piece by piece: the vertex, the internal lines, the external lines, the fermion signs, and finally the assembled statement of $i\mathcal{M}$.

17.1.2 The interaction vertex

The interaction enters Eq. (17.7) at first order as

$$\mathbf{S}^{(1)} = i \int d^4x \, \mathcal{L}_{\text{int}}(x) = -ie \int d^4x \, \bar{\psi}(x)\, \gamma^\mu \, \psi(x)\, A_\mu(x), \tag{17.8}$$

and every vertex in every diagram is one insertion of this operator. To turn it into a momentum-space rule we restore the suppressed Dirac indices and ask

what each of the three fields does. Writing the spinor indices explicitly, the operator is

$$\mathcal{L}_{\text{int}}(x) = -e\,\bar{\psi}_a(x)\,(\gamma^\mu)_{ab}\,\psi_b(x)\,A_\mu(x), \tag{17.9}$$

with a, b summed over the four Dirac components. In any diagram each of the three field operators $\bar{\psi}_a$, ψ_b, A_μ at a vertex is Wick-contracted: either with an external asymptotic field (producing an external-line factor, Section 17.1.4) or with a field at another vertex (producing an internal propagator, Section 17.1.3). What is universal — independent of which lines are external or internal — is the local algebraic structure left behind at the point x and the spacetime integral over x. We isolate it.

Theorem 17.1 (The QED vertex factor)**.** *Each elementary QED interaction vertex contributes, in momentum space, the factor*

$$\boxed{-i\,e\,\gamma^\mu} \tag{17.10}$$

carrying one Lorentz index μ contracted into the attached photon line and one pair of Dirac indices (ab) contracted into the two attached fermion lines, with a on the side of the outgoing fermion arrow and b on the incoming side. Together with the vertex factor goes a factor $(2\pi)^4\delta^4(\sum k)$ enforcing four-momentum conservation at the vertex, with all momenta counted as flowing into the vertex.

Proof. The factor is read off Eq. (17.8) by stripping the field operators and performing the universal spacetime integral. The operator Eq. (17.9) carries the constant prefactor $-e$, and the overall first-order term Eq. (17.8) carries the explicit i from the expansion of $\mathcal{T}\exp(i\int\mathcal{L}_{\text{int}})$; their product is $-ie$. The matrix $(\gamma^\mu)_{ab}$ sits between the conjugate field $\bar{\psi}_a$ and the field ψ_b, so the Dirac index that ties to whatever contracts with $\bar{\psi}$ is a and the index that ties to whatever contracts with ψ is b. The single Lorentz index μ is the one carried by A_μ and is therefore the index along which the photon line attaches.

It remains to produce the momentum-conserving delta. Whatever the three contractions are, each replaces its field operator by a wavefunction carrying a definite spacetime dependence $e^{\mp ik\cdot x}$ in the field's argument x: an external incoming line of momentum k contributes $e^{-ik\cdot x}$ from the positive-frequency part of the field, an external outgoing line contributes $e^{+ik\cdot x}$ from the conjugate field, and an internal line contributes a propagator which, written in momentum space, is itself an integral $\int\frac{d^4k}{(2\pi)^4}\,e^{\mp ik\cdot x}$ over the vertex coordinate (Section 17.1.3). In all cases the dependence of the integrand on the vertex coordinate x is a single exponential $e^{i(\sum k)\cdot x}$, where the sum runs over all momenta flowing *into* the vertex with the sign conventions just stated. The integral over x in Eq. (17.8) is then elementary,

$$\int d^4x\; e^{\,i(\sum k)\cdot x} = (2\pi)^4\,\delta^4\Big(\sum k\Big), \tag{17.11}$$

using the Fourier convention of Chapter A. This is the momentum-conservation delta attached to the vertex. The remaining x-independent factor is exactly $-ie\,(\gamma^\mu)_{ab}$, which is Eq. (17.10). □

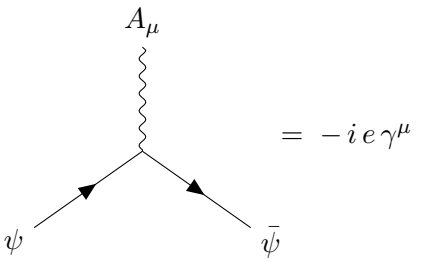

Figure 17.1: The QED interaction vertex Eq. (17.10), the single dynamical building block of every diagram in the theory. The arrow on the fermion line tracks the flow of fermion number (electron number minus positron number); the Dirac index a of $(\gamma^\mu)_{ab}$ attaches on the outgoing side of the arrow, b on the incoming side, so that reading a fermion line against its arrow reproduces the matrix order $\bar{u}\cdots\gamma^\mu\cdots u$. The photon attaches through the Lorentz index μ. Each vertex also carries $(2\pi)^4\delta^4(\sum k)$ (Eq. (17.11)).

The worked example below carries out the extraction concretely for a fully external vertex, so that the abstract statement of Theorem 17.1 is anchored in an explicit Wick contraction; it is the QED instantiation of the general procedure of Theorem 15.25.

Worked Example 17.2 (The vertex by explicit Wick contraction)**.** Consider the lowest-order contribution to a process in which a single vertex connects an incoming electron of momentum p and spin s, an outgoing electron of momentum p' and spin s', and an incoming photon of momentum k and polarization λ — the elementary absorption vertex underlying Compton scattering. The relevant operator is Eq. (17.8), and the amplitude is

$$\Big\langle e^-(p',s')\Big|\mathbf{S}^{(1)}\Big|e^-(p,s),\,\gamma(k,\lambda)\Big\rangle = -ie\int d^4x\;\Big\langle e^-(p',s')\Big|\bar{\psi}(x)\gamma^\mu\psi(x)A_\mu(x)\Big|e^-(p,s),\,\gamma(k,\lambda)\Big\rangle\,. \tag{17.12}$$

We evaluate the matrix element by contracting each field with the external state it can reach. The Dirac field $\psi(x)$ contains the electron annihilation operator $b^s_{\mathbf{p}}$ in its positive-frequency part (Eq. (11.95)); contracting it with the incoming electron $|e^-(p,s)\rangle = \sqrt{2E_p}\,b^{s\dagger}_{\mathbf{p}}\,|0\rangle$ replaces $\psi(x) \to u^s(p)\,e^{-ip\cdot x}$. The conjugate field $\bar{\psi}(x)$ contains $b^{s'\dagger}_{\mathbf{p}'}$ in its part that creates the outgoing electron; contracting with $\langle e^-(p',s')|$ replaces $\bar{\psi}(x) \to \bar{u}^{s'}(p')\,e^{+ip'\cdot x}$. The photon field $A_\mu(x)$ annihilates the incoming photon, replacing $A_\mu(x) \to \epsilon^\lambda_\mu(k)\,e^{-ik\cdot x}$. (These external-line replacements are derived in full in Section 17.1.4; here we use them

to display the mechanism.) Assembling,

$$\left\langle f\left|\mathbf{S}^{(1)}\right|i\right\rangle = -ie\,\bar{u}^{s'}(p')\,\gamma^{\mu}\,u^{s}(p)\,\epsilon_{\mu}^{\lambda}(k)\int d^4x\; e^{i(p'-p-k)\cdot x} = -ie\,\bar{u}^{s'}(p')\gamma^{\mu}u^{s}(p)\,\epsilon_{\mu}^{\lambda}(k)\,(2\pi)^4\delta^4(\tag{17.13}$$

Stripping the overall $(2\pi)^4\delta^4$ (which by Eq. (16.2) accompanies $i\mathcal{M}$) leaves the local factor $-ie\,\bar{u}^{s'}(p')\gamma^{\mu}u^{s}(p)\,\epsilon_{\mu}^{\lambda}(k)$. The factor sitting between the two spinors is exactly the vertex $-ie\gamma^{\mu}$ of Eq. (17.10), with $\bar{u}^{s'}(p')$ the outgoing-electron line factor on the a side and $u^{s}(p)$ the incoming-electron line factor on the b side, and $\epsilon_{\mu}^{\lambda}(k)$ the incoming-photon line factor on the μ index. The delta function is Eq. (17.11) with p' outgoing (counted with $+$), p and k incoming (counted with $-$). This is the rule, derived rather than quoted.

17.1.3 Internal lines: the propagators

A field operator at a vertex that is *not* contracted with an external state must be contracted with a field at another vertex. By Wick's theorem (Theorem 15.3) such a contraction is precisely the Feynman propagator of the field — the time-ordered two-point function — and these were computed once and for all in Chapters 11 and 13. We import them as the internal-line rules; the derivations are not repeated.

The electron internal line. The contraction of two Dirac fields is the fermion Feynman propagator established in Theorem 11.38 and given in momentum space by Eq. (11.195),

$$\overbrace{\psi(x)\,\bar{\psi}}(y) = S_F(x-y) = \int \frac{d^4p}{(2\pi)^4}\,\frac{i(\not{p}+m)}{p^2-m^2+i\varepsilon}\,e^{-ip\cdot(x-y)}, \tag{17.14}$$

so that each internal electron line carries the momentum-space factor

$$\boxed{\frac{i(\not{p}+m)}{p^2-m^2+i\varepsilon}} = \frac{i(\gamma^{\alpha}p_{\alpha}+m)}{p^2-m^2+i\varepsilon}, \tag{17.15}$$

a 4×4 matrix in Dirac space. The matrix indices are contracted into the vertices at the two ends in the same order the line is traversed against its arrow: reading a fermion line from its head (an outgoing $\bar{u}$, or an incoming-arrow vertex) to its tail, the propagators and vertices multiply as ordinary matrices, $\cdots\gamma^{\mu}\,S_F(p)\,\gamma^{\nu}\cdots$. The momentum p in Eq. (17.15) is the one flowing *along* the arrow; reversing the assignment $p\to -p$ would flip the sign of $\not{p}$ and is simply a different (consistent) labeling. The $i\varepsilon$ prescription is the Feynman one fixed in Chapter A and derived for the fermion line in Eq. (11.172): it routes positive-energy electrons forward in time and positive-energy positrons backward, the content of the Stückelberg–Feynman interpretation.

The photon internal line. The contraction of two photon fields is the R_ξ propagator of Theorem 13.26,

$$\overbrace{A_\mu(x)\,A_\nu(y)} = D_{\mu\nu}(x-y) = \int \frac{d^4k}{(2\pi)^4}\,\frac{-i}{k^2+i\varepsilon}\Big[\eta_{\mu\nu} - (1-\xi)\frac{k_\mu k_\nu}{k^2}\Big]e^{-ik\cdot(x-y)}, \tag{17.16}$$

so that each internal photon line carries, in the general gauge,

$$\frac{-i}{k^2+i\varepsilon}\Big[\eta_{\mu\nu} - (1-\xi)\frac{k_\mu k_\nu}{k^2}\Big], \tag{17.17}$$

and in the Feynman gauge $\xi = 1$ adopted throughout (Eq. (13.136)) the clean form

$$\boxed{\frac{-i\,\eta_{\mu\nu}}{k^2+i\varepsilon}} \qquad (\xi = 1). \tag{17.18}$$

The two Lorentz indices μ, ν are contracted into the photon indices of the vertices at the two ends. Because the photon is massless and chargeless the line is undirected: no arrow, and the momentum k may be routed either way since $D_{\mu\nu}$ depends only on k^2 and on $k_\mu k_\nu$, both even in k. We will see in Section 17.1.6 that the ξ-dependent piece $\propto k_\mu k_\nu$ never contributes to a tree amplitude with on-shell external fermions, which is why $\xi = 1$ is a free and convenient choice.

Figure 17.2: The two internal lines of QED. Left: the electron propagator Eq. (17.15), a matrix in Dirac space; the arrow marks the direction of the routed momentum p and of fermion-number flow. Right: the photon propagator in Feynman gauge Eq. (17.18); the line is undirected and the indices μ, ν tie to the vertices at the two ends. Both are imported, not re-derived, from Eqs. (11.195) and (13.135).

17.1.4 External lines: LSZ amputation and the wavefunction factors

A field operator contracted with an asymptotic external particle does not produce a propagator but a *wavefunction factor*. The LSZ reduction formula (Theorem 14.31) is the statement that each external leg of a correlation function is amputated — its full propagator stripped to a pole, the residue removed — and replaced by the on-shell wavefunction of the corresponding asymptotic particle (Section 15.6.5 and Eq. (15.126)). For QED there are six kinds of external

leg, and we derive each factor from the free mode expansions; this is the QED instantiation of the general LSZ amputation, not a quotation of it.

Electrons and positrons. The quantized Dirac field is Eq. (11.95),

$$\psi(x) = \sum_s \int \frac{d^3p}{(2\pi)^3\, 2E_{\mathbf{p}}} \Big[b^s_{\mathbf{p}}\, u^s(p)\, e^{-ip\cdot x} + d^{s\dagger}_{\mathbf{p}}\, v^s(p)\, e^{+ip\cdot x} \Big], \tag{17.19}$$

with the conjugate field $\bar\psi = \psi^\dagger\gamma^0$ given by Eq. (11.96), and asymptotic one-particle states normalized relativistically, $|e^-(p,s)\rangle = \sqrt{2E_p}\, b^{s\dagger}_{\mathbf{p}}\,|0\rangle$ and $|e^+(p,s)\rangle = \sqrt{2E_p}\, d^{s\dagger}_{\mathbf{p}}\,|0\rangle$, matching the state normalization fixed in Chapter 16. The mode operators obey the relativistically normalized anticommutators $\{b^r_{\mathbf{p}}, b^{s\dagger}_{\mathbf{q}}\} = (2\pi)^3\, 2E_{\mathbf{p}}\, \delta^3(\mathbf{p}-\mathbf{q})\, \delta^{rs}$ and likewise for d. The four cases follow by inspecting which mode operator survives the contraction with the state.

Incoming electron. The field $\psi(x)$ acting to the right on $|e^-(p,s)\rangle$ contracts $b^s_{\mathbf{p}}$ against $b^{s\dagger}_{\mathbf{p}}$; the anticommutator collapses the measure and the relativistic normalization $\sqrt{2E_p}$ cancels the $2E_{\mathbf{p}}$ in the denominator, leaving the spinor and the plane wave,

$$\psi(x)\,|e^-(p,s)\rangle \;\longrightarrow\; u^s(p)\, e^{-ip\cdot x} + \cdots, \tag{17.20}$$

where the ellipsis denotes terms that create additional particles and do not contribute to the connected amplitude for this leg. After LSZ amputation and Fourier transform the leg factor is the spinor $u^s(p)$. *An incoming electron contributes $u^s(p)$.*

Outgoing electron. The conjugate field $\bar\psi(x)$ contains $b^{s\dagger}_{\mathbf{p}}$ riding the spinor $\bar u^s(p)$; contracting with $\langle e^-(p',s')|$ from the left yields $\bar u^{s'}(p')\, e^{+ip'\cdot x}$. *An outgoing electron contributes $\bar u^{s'}(p')$.*

Incoming positron. The positron is created by $d^\dagger$, which appears in $\bar\psi$ riding $\bar v^s(p)$. The field $\bar\psi(x)$ acting to the right on $|e^+(p,s)\rangle$ contracts $d^s_{\mathbf{p}}$ (from $\bar\psi$) against $d^{s\dagger}_{\mathbf{p}}$, leaving $\bar v^s(p)\, e^{-ip\cdot x}$. *An incoming positron contributes $\bar v^s(p)$.*

Outgoing positron. Symmetrically, ψ carries $d^\dagger$ riding $v^s(p)$; contracting with $\langle e^+(p',s')|$ gives $v^{s'}(p')\, e^{+ip'\cdot x}$. *An outgoing positron contributes $v^{s'}(p')$.*

The asymmetry — electrons get $u, \bar u$ and positrons get $\bar v, v$ with the roles of incoming/outgoing apparently swapped — is the direct consequence of the field assignment in Eq. (17.19): ψ annihilates electrons but creates positrons, while $\bar\psi$ creates electrons but annihilates positrons. Diagrammatically this is encoded by the arrow: the fermion-number arrow points *into* the diagram for an incoming electron and an outgoing positron (both attached to a ψ-type end), and *out of* the diagram for an outgoing electron and an incoming positron (both attached to a $\bar\psi$-type end). Reading any fermion line against its arrow then automatically orders the spinors and matrices correctly: outgoing-fermion factor on the far left, then vertices and propagators in sequence, then the incoming-fermion factor on the far right.

Photons. The quantized photon field has the mode expansion Eq. (13.55), which in covariant four-vector notation reads

$$A_\mu(x) = \sum_\lambda \int \frac{d^3k}{(2\pi)^3\, 2\omega_k} \Big[a^\lambda_{\mathbf{k}}\, \epsilon^\lambda_\mu(k)\, e^{-ik\cdot x} + a^{\lambda\dagger}_{\mathbf{k}}\, \epsilon^{\lambda *}_\mu(k)\, e^{+ik\cdot x} \Big], \tag{17.21}$$

with $\epsilon^\lambda_\mu(k)$ the polarization four-vectors (Theorem 13.9) and physical external photons restricted to the two transverse polarizations $\lambda = 1, 2$ by the Gupta–Bleuler condition of Section 13.3; for real transverse polarizations $\epsilon^{\lambda *}_\mu = \epsilon^\lambda_\mu$, but we keep the conjugate explicit so the rule holds for any (e.g. circular) basis. By the same contraction logic:

Incoming photon. $A_\mu(x)$ acting on $|\gamma(k,\lambda)\rangle$ contracts $a^\lambda_{\mathbf{k}}$, leaving $\epsilon^\lambda_\mu(k)\, e^{-ik\cdot x}$. *An incoming photon contributes* $\epsilon^\lambda_\mu(k)$.

Outgoing photon. The conjugate term of $A_\mu(x)$ contracts $a^{\lambda\dagger}_{\mathbf{k}}$ against $\langle\gamma(k,\lambda)|$, leaving $\epsilon^{\lambda *}_\mu(k)\, e^{+ik\cdot x}$. *An outgoing photon contributes* $\epsilon^{\lambda *}_\mu(k)$.

The Lorentz index μ of the polarization vector ties to the photon index of the vertex it attaches to. The completeness and physical-state properties of these polarizations — in particular the gauge invariance that lets one replace the transverse polarization sum by $-\eta_{\mu\nu}$ inside a squared amplitude — belong to the spin-sum technology of the next section and to Section 13.3; here we need only the leg factors themselves. The six external-line rules are collected in Table 17.1.

Table 17.1: The QED external-line factors, derived in Section 17.1.4 from the free mode expansions Eqs. (11.95) and (13.55) via LSZ amputation (Theorem 14.31). The arrow column gives the direction of the fermion-number arrow relative to the diagram.

External particle	Factor	Fermion arrow
Incoming electron $e^-(p,s)$	$u^s(p)$	into diagram
Outgoing electron $e^-(p,s)$	$\bar{u}^s(p)$	out of diagram
Incoming positron $e^+(p,s)$	$\bar{v}^s(p)$	out of diagram
Outgoing positron $e^+(p,s)$	$v^s(p)$	into diagram
Incoming photon $\gamma(k,\lambda)$	$\epsilon^\lambda_\mu(k)$	—
Outgoing photon $\gamma(k,\lambda)$	$\epsilon^{\lambda *}_\mu(k)$	—

17.1.5 Fermion sign bookkeeping: loops and exchange

The single feature of the QED rulebook that has no analogue in the scalar theory of Chapter 15 is the appearance of *relative minus signs* forced by the anticommuting statistics of the Dirac field. Two rules govern them: a closed fermion loop carries an overall factor -1, and two diagrams that differ only by the interchange of two identical external fermion (or antifermion) lines carry a

relative factor -1. Both follow from the same fact — that Wick contraction of Grassmann-odd operators tracks the parity of the permutation needed to bring contracted pairs adjacent (Theorem 15.3) — and both must be derived, because getting either wrong is fatal and neither can be guessed from the bosonic case.

The closed-loop sign. Consider a closed fermion loop with n vertices. The loop is built from the Wick contractions of the n pairs $(\bar\psi, \psi)$ at the vertices, contracted in a cycle: ψ at vertex 1 with $\bar\psi$ at vertex 2, ψ at vertex 2 with $\bar\psi$ at vertex 3, and so on, closing with ψ at vertex n contracted with $\bar\psi$ at vertex 1. The cleanest derivation takes the simplest nontrivial case, $n = 2$, and the general case follows by the same counting. The relevant operator structure from the second-order Dyson term is, with vertices at x and y and indices suppressed except where they matter,

$$\cdots \bar\psi(x)\gamma^\mu\psi(x)\;\bar\psi(y)\gamma^\nu\psi(y)\cdots\,, \tag{17.22}$$

and the loop is the contraction of $\psi(x)$ with $\bar\psi(y)$ and of $\psi(y)$ with $\bar\psi(x)$:

$$\bar\psi_a(x)\,\gamma^\mu_{ab}\,\psi_b(x)\;\bar\psi_c(y)\,\gamma^\nu_{cd}\,\psi_d(y)\,. \tag{17.23}$$

To evaluate it we bring each contracted pair adjacent. The contraction of $\psi_b(x)$ with $\bar\psi_c(y)$ is the propagator $S_F(x-y)_{bc}$; the contraction of $\psi_d(y)$ with $\bar\psi_a(x)$ is $S_F(y-x)_{da}$. Moving $\psi_b(x)$ rightward past $\bar\psi_c(y)$ to stand beside it, and tracking the Grassmann-odd anticommutations, one finds that closing the cycle requires an *odd* number of transpositions of anticommuting operators. Concretely, the contracted product reorders to

$$-\,(\gamma^\mu)_{ab}\,S_F(x-y)_{bc}\,(\gamma^\nu)_{cd}\,S_F(y-x)_{da} = -\,\mathrm{tr}\big[\gamma^\mu S_F(x-y)\gamma^\nu S_F(y-x)\big], \tag{17.24}$$

where the explicit minus sign is the parity of the permutation, and the Dirac indices, chased around the cycle $a \to b \to c \to d \to a$, close into a trace. This is the content of the rule: *each closed fermion loop contributes a factor* (-1) *and a Dirac trace over the matrices encountered around the loop.* The sign originates entirely in the anticommuting algebra; for a loop of n vertices the same counting gives one minus sign (the cyclic closure is always an odd permutation relative to the bosonic ordering), so the rule is (-1) per loop, independent of n. The trace structure is what makes fermion loops computable by the gamma-matrix technology of Chapter C.

Caution

The loop minus sign is attached to the loop, not to any individual vertex or propagator. A diagram with L closed fermion loops carries $(-1)^L$. The most consequential instance is the photon vacuum-polarization diagram

of Chapter 19, whose single electron loop carries exactly one such minus sign; omitting it flips the sign of the running of α and is a classic and catastrophic error.

The exchange sign. Whenever a process has two identical fermions (or two identical antifermions) in the final state — or in the initial state — the amplitude receives contributions from diagrams related by exchanging the two identical particles, and these enter with a *relative* minus sign, the diagrammatic face of Fermi–Dirac antisymmetry. We derive it from the contraction algebra in the worked example below, instantiated on electron–electron (Møller) scattering, whose two tree diagrams are the cleanest illustration. We are establishing the *sign rule* here; the cross section itself is computed in Chapter 18.

Worked Example 17.3 (The relative sign of the Møller diagrams)**.** Electron–electron scattering $e^-(p_1)\,e^-(p_2) \to e^-(p_3)\,e^-(p_4)$ proceeds at tree level through two diagrams: a t-channel diagram in which the photon connects the $(p_1 \to p_3)$ and $(p_2 \to p_4)$ fermion lines, and a u-channel diagram in which it connects $(p_1 \to p_4)$ and $(p_2 \to p_3)$. The two differ precisely by the interchange of the two identical outgoing electrons, $p_3 \leftrightarrow p_4$. We show the relative sign is -1 directly from the second-order S-matrix.

The relevant term of Eq. (17.7) is

$$\mathbf{S}^{(2)} = \frac{(-ie)^2}{2!}\int d^4x\, d^4y\, \mathcal{T}\Big[\bar\psi(x)\gamma^\mu\psi(x)A_\mu(x)\,\bar\psi(y)\gamma^\nu\psi(y)A_\nu(y)\Big]. \tag{17.25}$$

The two photon fields contract into the internal photon propagator $D_{\mu\nu}(x-y)$. The four Dirac fields must contract with the four external electrons. There are two inequivalent ways to do so, and they are the two diagrams. In the first, $\psi(x)$ annihilates the incoming p_1 (giving $u(p_1)$) and $\bar\psi(x)$ creates the outgoing p_3 (giving $\bar u(p_3)$), while $\psi(y)$ annihilates p_2 and $\bar\psi(y)$ creates p_4; the line factors arrange into

$$\mathcal{A}_t \;\propto\; \big[\bar u(p_3)\gamma^\mu u(p_1)\big]\,\big[\bar u(p_4)\gamma^\nu u(p_2)\big]\,D_{\mu\nu}(p_1-p_3). \tag{17.26}$$

In the second, the roles of the two outgoing electrons are swapped: $\bar\psi(x)$ creates p_4 and $\bar\psi(y)$ creates p_3,

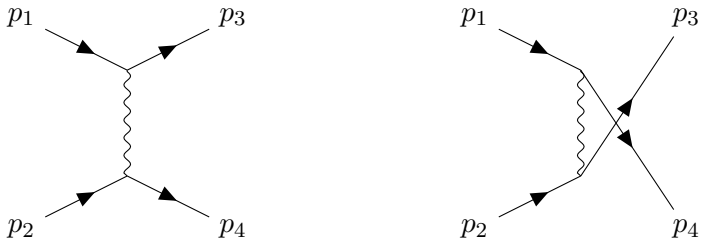
$$\mathcal{A}_u \;\propto\; \big[\bar u(p_4)\gamma^\mu u(p_1)\big]\,\big[\bar u(p_3)\gamma^\nu u(p_2)\big]\,D_{\mu\nu}(p_1-p_4). \tag{17.27}$$

The relative sign is fixed by counting the anticommutations needed to bring the field operators into the standard contracted order in each case. Take the first contraction as the reference, with the operators ordered so that all contracted pairs are adjacent and the overall sign is $+1$ by definition. The second contraction is obtained from the first by interchanging which $\bar\psi$ creates p_3 and which creates

p_4 — equivalently, by transposing the two anticommuting creation operators $b^\dagger_{p_3}$ and $b^\dagger_{p_4}$ (or, what is the same, transposing the two factors $\bar{u}(p_3)$ and $\bar{u}(p_4)$ in the contraction assignment). A single transposition of two Grassmann-odd operators carries the factor -1. Therefore

$$\boxed{\mathcal{M}(e^-e^- \to e^-e^-) = \mathcal{M}_t - \mathcal{M}_u,} \tag{17.28}$$

with the two terms equal up to the swap $p_3 \leftrightarrow p_4$ and a relative minus sign. The same minus sign would appear with initial-state identical fermions, or for identical antifermions; it is the diagrammatic statement of the antisymmetry of the multi-fermion state. (The overall sign of the whole amplitude is a convention and cancels in $|\mathcal{M}|^2$; only the *relative* sign between the two diagrams is physical, and it is -1.)



t-channel: $+\mathcal{M}_t$ u-channel: $-\mathcal{M}_u$

Figure 17.3: The two tree diagrams of Møller scattering $e^-e^- \to e^-e^-$, related by exchanging the identical outgoing electrons $p_3 \leftrightarrow p_4$ (Theorem 17.3). They enter the amplitude with a relative minus sign, Eq. (17.28), the diagrammatic form of Fermi–Dirac antisymmetry. The cross section is computed in Chapter 18; here the diagrams serve only to establish the sign rule.

17.1.6 Gauge independence of tree amplitudes and the tree-level Ward identity

We adopted Feynman gauge $\xi = 1$ for convenience and promised that the choice is physically immaterial. We now make good on this at tree level, both because it justifies the default and because the mechanism — current conservation — is the seed of the Ward–Takahashi identity proved in full in Chapter 19. The claim is that the gauge-dependent part of the photon propagator Eq. (17.17), the term proportional to $(1-\xi)k_\mu k_\nu/k^2$, makes no contribution to any tree amplitude whose external fermions are on shell.

Theorem 17.4 (Tree-level current conservation)**.** *Let an internal photon of momentum k in a tree diagram attach at one end to a fermion line carrying*

physical external states. The contraction of k_μ with the conserved current at that end vanishes; consequently the $k_\mu k_\nu$ part of the photon propagator drops out of the amplitude, which is therefore independent of ξ.

Proof. Consider the simplest case, a photon attached to a fermion line running from an incoming on-shell electron $u(p)$ to an outgoing on-shell electron $\bar{u}(p')$ through a single vertex, so that the current at that end is

$$J^\mu = \bar{u}(p')\,\gamma^\mu\,u(p), \qquad k = p' - p, \tag{17.29}$$

with k the photon momentum injected at the vertex. Contract with k_μ and substitute $k = p' - p$:

$$k_\mu J^\mu = \bar{u}(p')\,(\not{p}' - \not{p})\,u(p) = \bar{u}(p')\,\not{p}'\,u(p) - \bar{u}(p')\,\not{p}\,u(p). \tag{17.30}$$

Now use the on-shell Dirac equations for the external spinors, established in Chapter 11: $\not{p}\,u(p) = m\,u(p)$ acting on the right, and $\bar{u}(p')\,\not{p}' = m\,\bar{u}(p')$ acting on the left (the latter is the Dirac-adjoint equation). Hence

$$k_\mu J^\mu = m\,\bar{u}(p')u(p) - m\,\bar{u}(p')u(p) = 0. \tag{17.31}$$

The current is transverse to the photon momentum it sources. For an internal photon line the $k_\mu k_\nu$ term of the propagator Eq. (17.17) contracts k_μ into the current at one end (and k_ν into the current at the other); either contraction vanishes by Eq. (17.31), so the entire $(1-\xi)$ piece drops. What survives is the $\eta_{\mu\nu}$ part, which is ξ-independent. The amplitude is therefore the same in every R_ξ gauge, and in particular equals its Feynman-gauge ($\xi = 1$) value.

The argument extends to any tree diagram. A general fermion line threaded by a photon of momentum k at a vertex carries, on the two sides of that vertex, propagators $S_F(\ell + k)$ and $S_F(\ell)$ for some internal momentum ℓ; the contraction $\not{k} = (\not{\ell} + \not{k} - m) - (\not{\ell} - m)$ telescopes against the two adjacent propagators, $\not{k}\,S_F(\ell) = (\not{\ell} + \not{k} - m)S_F(\ell) - i$ (using $(\not{\ell} - m)S_F(\ell) = i$), converting the insertion into a difference of diagrams with one fewer propagator. Summed along the line, these differences telescope to the endpoint contributions, which vanish on shell by Eq. (17.31). This is exactly the chain that, promoted to include loops and the renormalization of the vertex, becomes the Ward–Takahashi identity $k_\mu \Gamma^\mu(p+k,p) = S_F^{-1}(p+k) - S_F^{-1}(p)$ of Chapter 19; here, at tree level and on shell, it collapses to the simple statement Eq. (17.31). □

Physical Insight

The masslessness of the photon and the conservation of the electromagnetic current are two faces of the same gauge symmetry, and Theorem 17.4 is where that shows its hand in computation. The unphysical, gauge-dependent longitudinal part of the photon propagator can never com-

municate with on-shell matter, because matter only couples through the conserved current $\bar{\psi}\gamma^\mu\psi$ (Eq. (8.146)), and a conserved current is blind to the longitudinal photon. This is why we may compute in whatever gauge is most convenient and trust the answer — and it is why, in the next section, the messy transverse polarization sum for external photons can be replaced by the simple covariant $-\eta_{\mu\nu}$.

17.1.7 The QED rulebook assembled

We now collect the pieces. The recipe for the tree-level invariant amplitude $i\mathcal{M}$ of any QED process is the following, and it is complete: every later computation in this chapter and the next is an application of it.

Theorem 17.5 (Momentum-space Feynman rules for QED)**.** *To compute $i\mathcal{M}$ for a given process at a given order, draw all topologically distinct, connected, amputated diagrams with the required external legs and the required number of vertices, and for each diagram:*

1. *assign the external-line factors of Table 17.1: $u^s(p)$, $\bar{u}^s(p)$ for incoming/outgoing electrons; $\bar{v}^s(p)$, $v^s(p)$ for incoming/outgoing positrons; $\epsilon_\mu^\lambda(k)$, $\epsilon_\mu^{\lambda *}(k)$ for incoming/outgoing photons;*
2. *write a factor $-ie\gamma^\mu$ (Eq. (17.10)) for each vertex;*
3. *write a propagator for each internal line: $\dfrac{i(\not{p}+m)}{p^2-m^2+i\varepsilon}$ for electrons (Eq. (17.15)) and $\dfrac{-i\eta_{\mu\nu}}{k^2+i\varepsilon}$ for photons in Feynman gauge (Eq. (17.18));*
4. *contract Dirac indices along each fermion line* against the arrow*, so that each line reads $\bar{u}\,[\cdots]\,u$ (or the appropriate v-spinors), and contract every Lorentz index, including those of internal-photon endpoints, with the metric;*
5. *impose four-momentum conservation at each vertex (Eq. (17.11)) and integrate $\int d^4\ell/(2\pi)^4$ over each independent loop momentum ℓ left undetermined;*
6. *multiply by (-1) for each closed fermion loop (Eq. (17.24)) and take the Dirac trace around each such loop;*
7. *include a relative sign between diagrams related by the interchange of two external identical fermions or antifermions (Eq. (17.28)).*

The sum of the resulting diagram values is $i\mathcal{M}$, with the single overall $(2\pi)^4\delta^4(\sum p_{\text{out}} - \sum p_{\text{in}})$ already factored off in the definition Eq. (16.2).

The collected result is the statement of the carried QED result: a fixed, sign-checked momentum-space rulebook. Two remarks complete it. First, at tree level there are no loop integrals and no fermion-loop signs, so for the processes of this chapter only items (1)–(5) and (7) operate; the loop machinery of item (6) is exercised in Chapter 19. Second, the overall delta in Eq. (16.2) is what was carefully regularized in Section 16.1 into the finite phase-space and flux factors of the cross section; the rules above produce exactly the $\mathcal{M}$ that the master formula of Chapter 16 consumes. The two halves of the apparatus — amplitude and rate — are now joined.

The rulebook is built and frozen. What it does not yet supply is the algebra that turns an amplitude into a number a detector reports: squaring $\mathcal{M}$, summing over the final spins and polarizations a real detector cannot resolve and averaging over the initial ones it cannot prepare, and reducing the result to a trace over gamma matrices and thence to Mandelstam invariants. The external-line factors $u, \bar{u}, v, \bar{v}$ and $\epsilon_\mu, \epsilon_\mu^*$ tabulated in Table 17.1, together with the on-shell completeness relations they satisfy and the gauge invariance established in Theorem 17.4, are exactly the raw material that engine needs. Building it is the work of the next section.

17.2 Spin sums, polarization sums, and trace technology

The previous section closed the Feynman rulebook: every QED amplitude is now a finite sum of products of the photon propagator Eq. (13.135), the vertex $-ie\gamma^\mu$ derived in Eq. (17.10), and the external-line factors handed to us by the LSZ reduction—an incoming electron contributes $u^s(p)$, an outgoing electron $\bar{u}^{s'}(p')$, an incoming positron $\bar{v}^s(p)$, an outgoing positron $v^{s'}(p')$, and an external photon a polarization vector $\epsilon_\mu(k,\lambda)$ or its conjugate $\epsilon_\mu^*(k,\lambda)$. The amplitude $\mathcal{M}$ is thus a number built from spinors and polarization vectors carrying definite spin labels s, s', λ. But a collider almost never prepares a definite electron spin, and almost never measures the spin of what comes out; what it measures is a rate, proportional to $|\mathcal{M}|^2$ *averaged* over the spins of the particles in the beam and *summed* over the spins of the particles in the detector. The task of this section is to build the algebraic engine that performs this average-and-sum once and for all, turning the spin-dressed $|\mathcal{M}|^2$ into a pure function of the external momenta—and ultimately into the Mandelstam invariants of Theorem 16.20—with not a single spinor left in sight. The engine has three gears: the *completeness relations* that collapse a sum over spins into a covariant matrix; *Casimir's trick*, which uses them to rewrite a spin-summed modulus-squared as a trace of gamma matrices; and the *trace technology* of Chapter C, which evaluates that trace as a polynomial in dot products. We assemble all three here and demonstrate them on the lepton tensor that the next section feeds into the $e^+e^- \to \mu^+\mu^-$ cross section.

Throughout we use the conventions fixed at the head of this chapter: mostly-minus metric $\eta_{\mu\nu} = \mathrm{diag}(+,-,-,-)$, natural units, the electron of charge $-e$ with $e > 0$ and $\alpha = e^2/4\pi$, and Feynman gauge $\xi = 1$ as the default. The Dirac spinors u^s, v^s and the gamma algebra are those of Chapter 11; the trace identities are collected and proved in Section C.6. We import these and wield them; we do not rebuild them, though we re-derive the few load-bearing identities on the page so that every step of a cross-section computation can be reproduced from this chapter alone.

17.2.1 The spin-averaged squared amplitude

Begin by saying precisely what object the experiment determines. Consider a $2 \to n$ process with two incoming particles of spin labels running over g_1 and g_2 values respectively—for a spin-$\frac{1}{2}$ particle $g = 2$, for a photon $g = 2$ physical polarizations—and final-state spins to be summed. The unpolarized squared amplitude is the average over initial spins and sum over final spins.

Definition 17.6 (Spin-averaged squared amplitude)**.** For a process with initial spin multiplicities g_1, g_2 and final spins collectively denoted $\{f\}$,

$$\overline{|\mathcal{M}|^2} \equiv \frac{1}{g_1 g_2} \sum_{\text{initial spins}} \sum_{\text{final spins}} |\mathcal{M}|^2 . \tag{17.32}$$

The prefactor $1/g_1 g_2$ is the average over the unobserved initial polarizations; the final-state sum is the inclusive measurement of any final spin.

For the centerpiece of this chapter, $e^+e^- \to \mu^+\mu^-$, both incoming particles are spin-$\frac{1}{2}$, so $g_1 = g_2 = 2$ and the averaging factor is $\frac{1}{4}$. This factor is not a convention to be looked up; it is the count of equally likely, equally weighted spin configurations of an unpolarized two-particle initial state, $2 \times 2 = 4$ of them, over which the incoherent average is taken. We carry it explicitly. (Were a photon in the initial state, as in Compton scattering in Chapter 18, its physical-polarization multiplicity is also 2, again by the two-transverse-state count of Chapter 13; a massive vector would carry $g = 3$.)

The reason Eq. (17.32) is tractable is that the sums over spins are not sums over independent random numbers but sums of outer products of spinors, and those sums have closed-form values. That is the content of the completeness relations, to which we turn.

17.2.2 The completeness (spin-sum) relations

The two identities that drive everything are the fermion spin sums established in Theorem 11.12. Because they are the hinge on which the entire chapter swings, we recall them and re-derive them directly from the explicit spinors of Eq. (11.57), carrying the block algebra so that the result is on the page where it is used.

Theorem 17.7 (Fermion completeness relations)**.** *The on-shell Dirac amplitudes $u^s(p), v^s(p)$ of Theorem 11.8, normalized by $\bar{u}^r u^s = 2m\,\delta^{rs} = -\bar{v}^r v^s$, satisfy the 4×4 matrix identities*

$$\sum_{s=1,2} u^s(p)\,\bar{u}^s(p) = \not{p} + m, \qquad \sum_{s=1,2} v^s(p)\,\bar{v}^s(p) = \not{p} - m, \tag{17.33}$$

for every on-shell momentum p ($p^2 = m^2$).

Proof. We reproduce the computation of Theorem 11.12. From Eq. (11.57) the positive-frequency amplitude and its Dirac adjoint are, in 2×2 block form built on the rest-frame two-spinor basis ξ^s,

$$u^s(p) = \begin{pmatrix} \sqrt{p\cdot\sigma}\,\xi^s \\ \sqrt{p\cdot\bar{\sigma}}\,\xi^s \end{pmatrix}, \qquad \bar{u}^s(p) = (\xi^{s\dagger}\sqrt{p\cdot\bar{\sigma}}\ ,\ \xi^{s\dagger}\sqrt{p\cdot\sigma}), \tag{17.34}$$

the adjoint row obtained from Eq. (11.63) (the γ^0 in $\bar{u} = u^\dagger\gamma^0$ swaps the two blocks). Their outer product is the 4×4 block matrix

$$u^s\bar{u}^s = \begin{pmatrix} \sqrt{p\cdot\sigma}\,(\xi^s\xi^{s\dagger})\,\sqrt{p\cdot\bar{\sigma}} & \sqrt{p\cdot\sigma}\,(\xi^s\xi^{s\dagger})\,\sqrt{p\cdot\sigma} \\ \sqrt{p\cdot\bar{\sigma}}\,(\xi^s\xi^{s\dagger})\,\sqrt{p\cdot\bar{\sigma}} & \sqrt{p\cdot\bar{\sigma}}\,(\xi^s\xi^{s\dagger})\,\sqrt{p\cdot\sigma} \end{pmatrix}. \tag{17.35}$$

Summing over s and using the two-component completeness $\sum_s \xi^s\xi^{s\dagger} = I$ from Eq. (11.56), every $\xi^s\xi^{s\dagger}$ becomes the identity. The off-diagonal blocks collapse by $\sqrt{p\cdot\sigma}\,\sqrt{p\cdot\bar{\sigma}} = mI$ (the square-root identity Eq. (11.55)), giving mI in each; the diagonal blocks collapse by $\sqrt{p\cdot\sigma}\,\sqrt{p\cdot\sigma} = p\cdot\sigma$ and $\sqrt{p\cdot\bar{\sigma}}\,\sqrt{p\cdot\bar{\sigma}} = p\cdot\bar{\sigma}$. Hence

$$\sum_s u^s\bar{u}^s = \begin{pmatrix} m\,I & p\cdot\sigma \\ p\cdot\bar{\sigma} & m\,I \end{pmatrix} = \not{p} + m, \tag{17.36}$$

where the last equality is the chiral-basis block form $\not{p} = \left(\begin{smallmatrix} 0 & p\cdot\sigma \\ p\cdot\bar{\sigma} & 0 \end{smallmatrix}\right)$ of Eq. (11.53) together with $m = m\,\mathbf{1}$. For the negative-frequency amplitudes the only change is the relative minus in the lower block of v^s (and correspondingly in $\bar{v}^s$), which flips the sign of the two off-diagonal mI blocks while leaving the diagonal $p\cdot\sigma, p\cdot\bar{\sigma}$ blocks intact, yielding $\sum_s v^s\bar{v}^s = \not{p} - m$. □

The two relations are the precise statement that the u's span the positive-energy and the v's the negative-energy subspace at fixed p: each side is, up to the factor m, the energy projector $\Lambda_\pm$ of Theorem 11.13. What matters operationally is their shape. A spin sum is an outer product summed over the spin label, and the completeness relations say that this sum is a *momentum-dependent matrix with no spin label left*—exactly the object that can be threaded into a trace.

17.2.3 Casimir's trick: from a squared bilinear to a trace

Every tree amplitude in QED is a product of fermion bilinears of the form $\bar{u}(p')\,\Gamma\,u(p)$—a row spinor, a string of gamma matrices Γ, and a column spinor—tied together by photon propagators that carry only Lorentz indices and momenta, no spinor indices. (Lines with an incoming positron or outgoing antiparticle replace the corresponding u by a v; the argument below is identical with the second relation of Eq. (17.33).) When such an amplitude is squared and summed over spins, the spinors disappear into a trace. This is *Casimir's trick*, the single most important manipulation in tree-level QED. We prove it as a clean algebraic lemma and then read off its consequences.

The one ingredient we need first is the Dirac conjugate of a gamma string.

Lemma 17.8 (Dirac conjugation of a vertex)**.** *For any product of gamma matrices Γ, define $\bar{\Gamma} \equiv \gamma^0\Gamma^\dagger\gamma^0$. Then*

$$\overline{\gamma^\mu} = \gamma^\mu, \qquad \overline{\gamma^\mu\gamma^5} = \gamma^\mu\gamma^5, \qquad \overline{\gamma^5} = -\gamma^5, \qquad \overline{AB} = \bar{B}\,\bar{A}, \tag{17.37}$$

so that the conjugate of a string is the string read backwards with each factor conjugated.

Proof. The hermiticity properties of the gamma matrices, $\gamma^{0\dagger} = \gamma^0$ and $\gamma^{i\dagger} = -\gamma^i$, are summarized covariantly by $\gamma^{\mu\dagger} = \gamma^0\gamma^\mu\gamma^0$ (Eq. (11.5)): for $\mu = 0$ this reads $\gamma^0 = \gamma^0\gamma^0\gamma^0 = \gamma^0$, and for $\mu = i$ it reads $-\gamma^i = \gamma^0\gamma^i\gamma^0$ since γ^i anticommutes with γ^0 and $(\gamma^0)^2 = \mathbf{1}$. Therefore

$$\overline{\gamma^\mu} = \gamma^0\gamma^{\mu\dagger}\gamma^0 = \gamma^0(\gamma^0\gamma^\mu\gamma^0)\gamma^0 = \gamma^\mu, \tag{17.38}$$

using $(\gamma^0)^2 = \mathbf{1}$. For the product rule, $\overline{AB} = \gamma^0(AB)^\dagger\gamma^0 = \gamma^0B^\dagger A^\dagger\gamma^0 = (\gamma^0B^\dagger\gamma^0)(\gamma^0A^\dagger\gamma^0) = \bar{B}\bar{A}$, inserting $\gamma^0\gamma^0 = \mathbf{1}$ in the middle. Since $\gamma^5 = i\gamma^0\gamma^1\gamma^2\gamma^3$ is Hermitian ($\gamma^{5\dagger} = \gamma^5$) and anticommutes with each γ^μ, we get $\overline{\gamma^5} = \gamma^0\gamma^5\gamma^0 = -\gamma^5(\gamma^0)^2 = -\gamma^5$; and $\overline{\gamma^\mu\gamma^5} = \overline{\gamma^5}\,\overline{\gamma^\mu} = -\gamma^5\gamma^\mu = \gamma^\mu\gamma^5$, the sign of $\overline{\gamma^5}$ undone by the anticommutation. The vector current $\bar{\psi}\gamma^\mu\psi$ is therefore self-conjugate, which is why the QED vertex squares so cleanly. □

With $\bar{\Gamma}$ in hand, Casimir's trick is a one-line index computation.

Theorem 17.9 (Casimir's trick)**.** *Let Γ, Γ' be gamma strings and let p, p' be on-shell momenta with masses m, m'. Summing over the spins of both spinors,*

$$\sum_{s,s'} \left[\bar{u}^{s'}(p')\,\Gamma\,u^s(p)\right]\left[\bar{u}^{s'}(p')\,\Gamma'\,u^s(p)\right]^* = \operatorname{tr}\Big[(\not{p}' + m')\,\Gamma\,(\not{p} + m)\,\bar{\Gamma}'\Big]. \tag{17.39}$$

The identical statement holds with any external u replaced by the corresponding v and the matching $(\not{p} + m)$ replaced by $(\not{p} - m)$.

Proof. The squared bilinear is a product of two complex numbers; the second is conjugated, and since a number equals its own transpose its complex conjugate equals its Hermitian conjugate. Conjugating the second factor,

$$\big[\bar{u}^{s'}(p')\,\Gamma'\,u^{s}(p)\big]^{*} = \big[u^{s'}(p')^{\dagger}\gamma^{0}\,\Gamma'\,u^{s}(p)\big]^{\dagger} = u^{s}(p)^{\dagger}\,\Gamma'^{\dagger}\gamma^{0}\,u^{s'}(p') = \bar{u}^{s}(p)\,\bar{\Gamma}'\,u^{s'}(p'), \tag{17.40}$$

where in the last step we inserted $\gamma^{0}\gamma^{0} = \mathbf{1}$ to form $\bar{u}^{s}(p) = u^{s}(p)^{\dagger}\gamma^{0}$ on the left and $\bar{\Gamma}' = \gamma^{0}\Gamma'^{\dagger}\gamma^{0}$ in the middle, using $\gamma^{0\dagger} = \gamma^{0}$. The summand is now $[\bar{u}^{s'}(p')\Gamma u^{s}(p)][\bar{u}^{s}(p)\bar{\Gamma}'u^{s'}(p')]$, a closed chain of spinor indices. Writing the spinor indices a, b, c, d explicitly and reordering the c-number factors,

$$\begin{aligned}\sum_{s,s'} \bar{u}^{s'}(p')_{a}\,\Gamma_{ab}\,u^{s}(p)_{b}\;\bar{u}^{s}(p)_{c}\,\bar{\Gamma}'_{cd}\,u^{s'}(p')_{d} &= \Gamma_{ab}\,\bar{\Gamma}'_{cd}\Big(\sum_{s'} u^{s'}(p')_{d}\,\bar{u}^{s'}(p')_{a}\Big)\Big(\sum_{s} u^{s}(p)_{b}\,\bar{u}^{s}(p)_{c}\Big)\\ &= \Gamma_{ab}\,\bar{\Gamma}'_{cd}\,(\not{p}' + m')_{da}\,(\not{p} + m)_{bc},\end{aligned} \tag{17.41}$$

the two spin sums collapsed by the completeness relations Eq. (17.33). The four index contractions $d \to a \to b \to c \to d$ form a single closed loop, which is precisely a matrix trace:

$$(\not{p}'+m')_{da}\,\Gamma_{ab}\,(\not{p}+m)_{bc}\,\bar{\Gamma}'_{cd} = \big[(\not{p}'+m')\,\Gamma\,(\not{p}+m)\,\bar{\Gamma}'\big]_{dd} = \operatorname{tr}\big[(\not{p}'+m')\,\Gamma\,(\not{p}+m)\,\bar{\Gamma}'\big]. \tag{17.42}$$

For a line carrying an antiparticle, the relevant external factors are v's, the spin sum is $\sum_{s} v^{s}\bar{v}^{s} = \not{p} - m$ from Eq. (17.33), and the same index manipulation gives Eq. (17.39) with $m \to -m$ on that line. □

The content of Theorem 17.9 is worth stating in words, because the picture it paints is the right one to carry. An amplitude is an *open* fermion line: a column spinor at one end, a row spinor at the other, a string of vertices in between. Squaring it lays the conjugate line alongside, running in the opposite direction; summing over the external spins glues the two open ends together through the completeness matrices $\not{p} \pm m$. The open line and its mirror close into a *loop*, and a closed loop of matrices multiplied head to tail is a trace. This geometric reading—open line × conjugate, spin-summed, equals closed loop equals trace—is illustrated in Fig. 17.4, and it is exactly why the entire spinor structure of $\overline{|\mathcal{M}|^{2}}$ reduces to traces of gamma matrices.

17.2.4 The trace toolkit, instantiated

Casimir's trick converts $\overline{|\mathcal{M}|^{2}}$ into traces of products of gamma matrices contracted with external momenta. Those traces are evaluated with the identities proved in full in Section C.6. The complete subset that tree-level QED ever needs is short, and we list it here for reference, in the slash notation $\not{a} \equiv \gamma^{\mu}a_{\mu}$ in which it is actually used:

$$\operatorname{tr}\mathbf{1} = 4, \qquad \operatorname{tr}(\text{odd number of } \gamma\text{'s}) = 0, \tag{17.43}$$

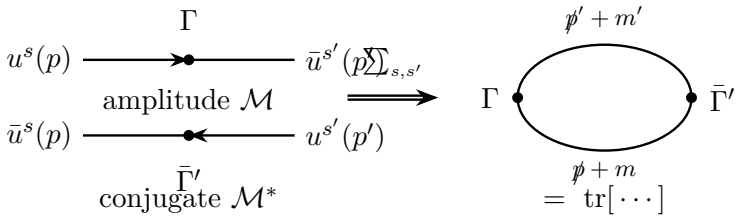


Figure 17.4: Casimir's trick as a picture. The open fermion line of the amplitude (top) and its conjugate (bottom) are summed over the external spins s, s'; the completeness relations Eq. (17.33) glue the open ends into the momentum matrices $\not{p} \pm m$, closing the two lines into a single loop. A closed matrix loop read head to tail is a trace, Eq. (17.39).

$$\mathrm{tr}(\not{a}\not{b}) = 4\,(a\cdot b), \qquad \mathrm{tr}(\not{a}\not{b}\not{c}\not{d}) = 4\big[(a\cdot b)(c\cdot d) - (a\cdot c)(b\cdot d) + (a\cdot d)(b \tag{17.44}$$

$$\mathrm{tr}(\gamma^5) = 0, \quad \mathrm{tr}(\gamma^5\not{a}\not{b}) = 0, \qquad \mathrm{tr}(\gamma^5\not{a}\not{b}\not{c}\not{d}) = -4i\,\epsilon_{\mu\nu\rho\sigma}\,a^\mu b^\nu c^\rho d^\sigma, \tag{17.45}$$

together with the contraction identities for a repeated index (which arise whenever a photon line is summed over polarizations in Feynman gauge),

$$\gamma^\mu\gamma_\mu = 4\,\mathbf{1}, \qquad \gamma^\mu\not{a}\gamma_\mu = -2\,\not{a}, \qquad \gamma^\mu\not{a}\not{b}\gamma_\mu = 4\,(a\cdot b)\,\mathbf{1}, \qquad \gamma^\mu\not{a}\not{b}\not{c}\gamma_\mu = -2\,\not{c}\not{b}\not{a}. \tag{17.46}$$

These are Eqs. (C.148) and (C.177) to (C.179) and Theorem C.58; the convention $\epsilon^{0123} = +1$ behind the γ^5-trace is the one fixed in Chapter A. Rather than merely quote them, we re-derive the two that carry the load downstream—the four-gamma trace and the γ^5 four-trace—so that the reader can reconstruct any QED trace from the anticommutator alone.

The four-gamma trace. Use the Clifford relation $\{\gamma^\mu, \gamma^\nu\} = 2\eta^{\mu\nu}\mathbf{1}$ to march the first matrix to the right. Past each neighbour it leaves 2η and a sign:

$$\begin{aligned}\gamma^\mu\gamma^\nu\gamma^\rho\gamma^\sigma &= 2\eta^{\mu\nu}\gamma^\rho\gamma^\sigma - \gamma^\nu\gamma^\mu\gamma^\rho\gamma^\sigma \\ &= 2\eta^{\mu\nu}\gamma^\rho\gamma^\sigma - 2\eta^{\mu\rho}\gamma^\nu\gamma^\sigma + \gamma^\nu\gamma^\rho\gamma^\mu\gamma^\sigma \\ &= 2\eta^{\mu\nu}\gamma^\rho\gamma^\sigma - 2\eta^{\mu\rho}\gamma^\nu\gamma^\sigma + 2\eta^{\mu\sigma}\gamma^\nu\gamma^\rho - \gamma^\nu\gamma^\rho\gamma^\sigma\gamma^\mu.\end{aligned} \tag{17.47}$$

Take the trace. The last term is $-\,\mathrm{tr}(\gamma^\nu\gamma^\rho\gamma^\sigma\gamma^\mu) = -\,\mathrm{tr}(\gamma^\mu\gamma^\nu\gamma^\rho\gamma^\sigma)$ by cyclicity, so it returns the left side with a minus sign; moving it across and dividing by two,

$$\mathrm{tr}(\gamma^\mu\gamma^\nu\gamma^\rho\gamma^\sigma) = \eta^{\mu\nu}\,\mathrm{tr}(\gamma^\rho\gamma^\sigma) - \eta^{\mu\rho}\,\mathrm{tr}(\gamma^\nu\gamma^\sigma) + \eta^{\mu\sigma}\,\mathrm{tr}(\gamma^\nu\gamma^\rho) = 4\big(\eta^{\mu\nu}\eta^{\rho\sigma} - \eta^{\mu\rho}\eta^{\nu\sigma} + \eta^{\mu\sigma}\eta^{\nu\rho}\big), \tag{17.48}$$

where the last step used $\mathrm{tr}(\gamma^\alpha\gamma^\beta) = \frac{1}{2}\,\mathrm{tr}\left\{\gamma^\alpha, \gamma^\beta\right\} = 4\eta^{\alpha\beta}$. Contracting with $a_\mu b_\nu c_\rho d_\sigma$ gives the slash form in Eq. (17.44); this is the workhorse, used at every

four-vertex string. (The general statement and the inductive recursion behind it are Theorem C.54.)

The γ^5 four-trace. The result is fixed by total antisymmetry and one normalization. Any repeated index among $\mu\nu\rho\sigma$ collapses, via the Clifford relation, to a γ^5-trace of two or fewer gammas, all of which vanish (Theorem C.56); so $\mathrm{tr}(\gamma^5\gamma^\mu\gamma^\nu\gamma^\rho\gamma^\sigma)$ is totally antisymmetric and hence proportional to $\epsilon^{\mu\nu\rho\sigma}$, the unique antisymmetric four-tensor. Fix the constant at $(\mu\nu\rho\sigma) = (0123)$: from $\gamma^5 = i\gamma^0\gamma^1\gamma^2\gamma^3$ we have $\gamma^0\gamma^1\gamma^2\gamma^3 = -i\gamma^5$, so

$$\mathrm{tr}(\gamma^5\gamma^0\gamma^1\gamma^2\gamma^3) = \mathrm{tr}(\gamma^5(-i\gamma^5)) = -i\ \mathrm{tr}(\gamma^5)^2 = -i\ \mathrm{tr}\,\mathbf{1} = -4i, \tag{17.49}$$

and with $\epsilon^{0123} = +1$ this gives $\mathrm{tr}(\gamma^5\gamma^\mu\gamma^\nu\gamma^\rho\gamma^\sigma) = -4i\,\epsilon^{\mu\nu\rho\sigma}$, the slash form in Eq. (17.45). This is the trace that detects parity violation; it does not appear in pure QED amplitudes (which are parity-even), but it is the one that controls the interference of vector and axial currents, and we will need it the moment the electroweak sector enters. Its appearance here completes the toolkit.

With Eqs. (17.43) to (17.46) every Dirac trace arising at tree level reduces to a polynomial in the dot products of external momenta. Nothing else is required.

17.2.5 Photon polarization sums and the $-\eta_{\mu\nu}$ replacement

The fermion half of the engine is complete. The photon half is needed whenever a real photon appears in the initial or final state—not in $e^+e^- \to \mu^+\mu^-$, whose only photon is the internal s-channel line, but in Compton scattering and every process of Chapter 18. When an external photon of momentum k ($k^2 = 0$) is summed over its two physical polarizations, the object that appears is

$$\Pi^{\mu\nu}(k) \equiv \sum_{\lambda=1,2} \epsilon^\mu(k,\lambda)\,\epsilon^{*\nu}(k,\lambda), \tag{17.50}$$

with the transverse polarizations $\epsilon^\mu(k,\lambda)$ of Chapter 13. It would be enormously convenient if $\Pi^{\mu\nu}$ were simply $-\eta^{\mu\nu}$, for then the photon sum would be as trivial as a metric contraction. It is *not*: the two transverse vectors span a two-dimensional space, so $\Pi^{\mu\nu}$ has rank two, while $-\eta^{\mu\nu}$ has rank four. No Lorentz-covariant rank-two tensor built from a single null vector k can equal $-\eta^{\mu\nu}$. What is true—and is all that is ever needed—is that $\Pi^{\mu\nu}$ may be *replaced* by $-\eta^{\mu\nu}$ inside any gauge-invariant amplitude. This is the polarization-sum replacement, proved at the level of the propagator and the external sum in Theorem 13.30; we give the argument here in the form in which we will invoke it, because it is the statement that makes unpolarized photon cross sections tractable.

Choose a frame with $k^\mu = (\omega, 0, 0, \omega)$. The two transverse linear polarizations are $\epsilon^\mu(k,1) = (0,1,0,0)$ and $\epsilon^\mu(k,2) = (0,0,1,0)$, satisfying $k\cdot\epsilon(k,\lambda) = 0$ and $\epsilon(k,\lambda)\cdot\epsilon^*(k,\lambda') = -\delta_{\lambda\lambda'}$. To write the sum covariantly, introduce the auxiliary

null vector $\bar{k}^\mu = (\omega, 0, 0, -\omega)$ (a photon going the other way), with $\bar{k}^2 = 0$ and $k \cdot \bar{k} = 2\omega^2 \neq 0$. Direct evaluation of the 4×4 matrix Eq. (17.50) in this frame populates only the x, y block with δ_{ij}, which is reproduced covariantly (this is Eq. (13.54)) by

$$\sum_{\lambda=1,2} \epsilon^\mu(k,\lambda)\, \epsilon^{*\nu}(k,\lambda) = -\eta^{\mu\nu} + \frac{k^\mu \bar{k}^\nu + k^\nu \bar{k}^\mu}{k \cdot \bar{k}}. \tag{17.51}$$

One verifies this component by component: $-\eta^{\mu\nu}$ supplies $+1$ in each spatial diagonal slot and -1 in the 00 slot, while the $k, \bar{k}$ term—which has no x, y components—removes exactly the unwanted $00, 03, 30, 33$ entries, leaving precisely δ_{ij} in the transverse block. The reference vector $\bar{k}$ is arbitrary; the left-hand side knows nothing of it, so any $\bar{k}$-dependence on the right must cancel against whatever physical object $\Pi^{\mu\nu}$ contracts into.

Proposition 17.10 (Polarization-sum replacement)**.** *Let $\mathcal{M}^\mu(k)$ be a physical amplitude with one external photon of momentum k stripped of its polarization vector, so the amplitude is $\mathcal{M} = \epsilon^*_\mu(k,\lambda)\mathcal{M}^\mu(k)$. If $\mathcal{M}^\mu$ satisfies the Ward identity $k_\mu \mathcal{M}^\mu = 0$, then the physical-polarization sum may be computed with the replacement*

$$\sum_{\lambda=1,2} \epsilon_\mu(k,\lambda)\, \epsilon^*_\nu(k,\lambda) \;\longrightarrow\; -\eta_{\mu\nu}, \qquad \textit{i.e.} \qquad \sum_\lambda |\epsilon^* \cdot \mathcal{M}|^2 = -\eta_{\mu\nu}\, \mathcal{M}^\mu \mathcal{M}^{*\nu}. \tag{17.52}$$

Proof. Contract the completeness relation Eq. (17.51) into $\mathcal{M}^\mu \mathcal{M}^{*\nu}$:

$$\sum_\lambda |\epsilon^* \cdot \mathcal{M}|^2 = \Pi_{\mu\nu}\, \mathcal{M}^\mu \mathcal{M}^{*\nu} = -\eta_{\mu\nu} \mathcal{M}^\mu \mathcal{M}^{*\nu} + \frac{(k_\mu \mathcal{M}^\mu)(\bar{k}_\nu \mathcal{M}^{*\nu}) + (\bar{k}_\mu \mathcal{M}^\mu)(k_\nu \mathcal{M}^{*\nu})}{k \cdot \bar{k}}. \tag{17.53}$$

Each term in the second piece carries a factor $k_\mu \mathcal{M}^\mu$ or its conjugate $k_\nu \mathcal{M}^{*\nu} = (k_\mu \mathcal{M}^\mu)^*$, both of which vanish by the Ward identity hypothesis $k_\mu \mathcal{M}^\mu = 0$. The reference-vector dependence vanishes with them, leaving $-\eta_{\mu\nu} \mathcal{M}^\mu \mathcal{M}^{*\nu}$, which is Eq. (17.52). That the $\bar{k}$-dependence cancelled is the consistency check that the physical answer cannot depend on the arbitrary auxiliary vector. □

The physics of this cancellation is the decoupling of the unphysical photon polarizations. The full $-\eta_{\mu\nu}$ amounts to summing over *four* polarization states—the two transverse, plus a timelike (scalar) and a longitudinal one—rather than the two physical transverse states. The replacement is legitimate precisely because the extra two, scalar and longitudinal, are the combinations proportional to k_μ and $\bar{k}_\mu$, and current conservation $k_\mu \mathcal{M}^\mu = 0$ annihilates them: they contribute nothing to any gauge-invariant amplitude. This is the amplitude-level shadow of the Gupta–Bleuler decoupling of Section 13.3, and it is the *same* fact as the ξ-independence of the photon propagator wearing a different hat—in both cases

a k_μ-proportional piece is the entire content of the unphysical sector, and in both cases the conserved matter current kills it. The Ward identity $k_\mu \mathcal{M}^\mu = 0$ holds at tree level by the Dirac equation, as the explicit check Eq. (13.145) showed; its all-orders form is the Ward–Takahashi identity of Chapter 19, so nothing here relies on tree-level conservation in a way that would fail at one loop.

17.2.6 The recipe

The three gears now mesh into a mechanical pipeline. Given a tree amplitude $\mathcal{M}$ for a $2 \to n$ process, the unpolarized squared amplitude is computed as follows.

1. **Square and sum.** Write $\overline{|\mathcal{M}|^2} = \frac{1}{g_1 g_2} \sum_{\text{spins}} \mathcal{M}\,\mathcal{M}^*$ as in Eq. (17.32), with the averaging factor $\frac{1}{4}$ for two incoming fermions. Each propagator denominator $1/(q^2 - M^2)$ is a real c-number multiplying both $\mathcal{M}$ and $\mathcal{M}^*$; pull these denominators out front as overall factors and keep only the spinor/polarization numerators inside the spin sum.

2. **Apply Casimir's trick.** For each fermion line, use Theorem 17.9 to turn the spin-summed product of bilinears into a trace, the external spinors becoming completeness matrices $\not{p} \pm m$ (the $-m$ for antiparticle lines). For each external photon, use the replacement Eq. (17.52). The result is a product of gamma-matrix traces, one per fermion line, with Lorentz indices tied together by the propagator numerators and polarization metrics.

3. **Evaluate the traces.** Reduce each trace with the toolkit Eqs. (17.43) to (17.45) and, where a repeated Lorentz index appears, the contraction identities Eq. (17.46). Every gamma matrix disappears, leaving a polynomial in the dot products $p_i \cdot p_j$ of the external momenta.

4. **Express in invariants.** Trade the dot products for the Mandelstam invariants s, t, u of Theorem 16.20 using the on-shell relations $p_i^2 = m_i^2$ and momentum conservation (recall $s + t + u = \sum_i m_i^2$). The output is $\overline{|\mathcal{M}|^2}$ as a rational function of s, t, u and the masses—a Lorentz scalar, ready to feed into the differential cross section.

This recipe never requires choosing an explicit spinor or polarization basis: the bases are summed away by completeness before any number is computed. That is its power, and it is why the unpolarized cross section is so much easier than any single polarized one. We close by running the engine through its first and most important gear-train, the lepton tensor.

Worked Example 17.11 (The lepton tensor and its reduction to invariants)**.** The single trace that every QED process built from a vector current contains is

the spin-summed square of one current $\bar{u}(p')\gamma^\mu u(p)$, the *lepton tensor*

$$H^{\mu\nu}(p',p) \equiv \sum_{s,s'} \left[\bar{u}^{s'}(p')\gamma^\mu u^s(p)\right]\left[\bar{u}^{s'}(p')\gamma^\nu u^s(p)\right]^*. \tag{17.54}$$

This is exactly the object that appears when an electron line of momentum $p \to p'$ emits or absorbs a photon and the result is squared and summed. By Casimir's trick Theorem 17.9 with $\Gamma = \gamma^\mu$, $\Gamma' = \gamma^\nu$, and $\overline{\gamma^\nu} = \gamma^\nu$ from Theorem 17.8,

$$H^{\mu\nu} = \operatorname{tr}\left[(\not{p}' + m)\,\gamma^\mu\,(\not{p} + m)\,\gamma^\nu\right]. \tag{17.55}$$

Expand the product into four traces:

$$H^{\mu\nu} = \operatorname{tr}(\not{p}'\gamma^\mu\not{p}\gamma^\nu) + m\,\operatorname{tr}(\gamma^\mu\not{p}\gamma^\nu) + m\,\operatorname{tr}(\not{p}'\gamma^\mu\gamma^\nu) + m^2\,\operatorname{tr}(\gamma^\mu\gamma^\nu). \tag{17.56}$$

The two terms linear in m each contain an odd number of gamma matrices and vanish by Eq. (17.43). The first term, written with explicit indices p'_α, p_β, uses the four-gamma trace of Eq. (17.44):

$$\begin{aligned}\operatorname{tr}(\not{p}'\gamma^\mu\not{p}\gamma^\nu) &= p'_\alpha p_\beta\,\operatorname{tr}(\gamma^\alpha\gamma^\mu\gamma^\beta\gamma^\nu) = 4\,p'_\alpha p_\beta(\eta^{\alpha\mu}\eta^{\beta\nu} - \eta^{\alpha\beta}\eta^{\mu\nu} + \eta^{\alpha\nu}\eta^{\mu\beta}) \\ &= 4(p'^\mu p^\nu - (p'\cdot p)\eta^{\mu\nu} + p'^\nu p^\mu),\end{aligned} \tag{17.57}$$

while the last term is $m^2\operatorname{tr}(\gamma^\mu\gamma^\nu) = 4m^2\eta^{\mu\nu}$. Adding,

$$\boxed{H^{\mu\nu} = 4\Big[p'^\mu p^\nu + p'^\nu p^\mu - (p'\cdot p - m^2)\eta^{\mu\nu}\Big].} \tag{17.58}$$

Every spinor is gone; what remains is a symmetric rank-two tensor polynomial in the two momenta, exactly as Lorentz covariance demands. As a built-in check of current conservation, contract with the momentum transfer $q = p' - p$: using $p'^2 = p^2 = m^2$ so that $q\cdot p' = m^2 - p\cdot p' = -(q\cdot p)$,

$$q_\mu H^{\mu\nu} = 4\left[(q\cdot p')p^\nu + (q\cdot p)p'^\nu - (p'\cdot p - m^2)q^\nu\right] = 4(q\cdot p')\,(p-p')^\nu - 4(p'\cdot p - m^2)q^\nu = 0, \tag{17.59}$$

since $q\cdot p' = -(p'\cdot p - m^2)$ and $(p-p')^\nu = -q^\nu$. The tensor is transverse to q, the Ward identity made manifest at the level of the squared amplitude.

The same construction with one u replaced by a v—the case relevant to the annihilation $e^+e^- \to \mu^+\mu^-$, where the incoming electron and positron sit on one line as $\bar{v}(p_2)\gamma^\mu u(p_1)$—gives the trace $\operatorname{tr}[(\not{p}_1 + m_e)\gamma^\mu(\not{p}_2 - m_e)\gamma^\nu]$, with the antiparticle's $-m_e$ from the second relation of Eq. (17.33); this is the electron tensor assembled in Theorem C.59, identical in form to Eq. (17.58) but with a relative sign in the mass term. To finish a cross section one contracts two such tensors—one for the electron line, one for the muon line—through the photon propagator, divides by the four initial spin states, and trades the resulting dot products for s, t, u. That final contraction, with the carried numbers of QED, is the subject of the next section.

The engine is built and tested. We have the completeness relations that vaporize the spin labels, Casimir's trick that turns the spin sum into a trace, the trace toolkit that evaluates it, and the polarization replacement that does the same service for external photons—and a four-step recipe that drives a raw amplitude all the way to a function of Mandelstam invariants. The next section throws the first real amplitude into it: the single s-channel diagram for $e^+e^- \to \mu^+\mu^-$, whose squared, spin-averaged form is exactly a product of two lepton tensors of the type Eq. (17.58), and whose reduction reproduces the carried number $\overline{|\mathcal{M}|^2}$ and the total cross section $\sigma = 4\pi\alpha^2/3s$ of QED.

17.3 Electron–positron annihilation to muons

We continue QED from Chapter 8, where the gauge principle *derived* the minimal coupling $D_\mu = \partial_\mu + ieA_\mu$ on the electron, and from Chapter 13, where the photon was quantized and its R_ξ propagator established. With the QED rulebook read off in Section 17.1.7 and the spin-sum/trace machinery built in Section 17.2, every ingredient is now in hand to carry out the marquee computation of the thread: the annihilation of an electron–positron pair into a muon–antimuon pair,

$$e^-(p,s) \;+\; e^+(p',s') \;\longrightarrow\; \mu^-(k,r) \;+\; \mu^+(k',r'). \tag{17.60}$$

This is the cleanest nontrivial process in all of QED. Because the electron and the muon are distinct particles, there is exactly *one* tree diagram — a single virtual photon in the s-channel — with no interference, no exchange diagram, and no crossed channel to track. The entire dynamical content is one current contracted into another through a propagator. It is therefore the ideal place to see the full pipeline run end to end: write down $i\mathcal{M}$, square it, average over initial spins and sum over final ones, reduce the spin sums to Dirac traces, evaluate those traces, package the result in Mandelstam invariants, and feed it through the phase-space and flux factors of Chapter 16 to produce a number a collider measures. The carried results this section must reproduce are the unpolarized squared amplitude $\overline{|\mathcal{M}|^2}$, the angular law $d\sigma/d\Omega = (\alpha^2/4s)(1+\cos^2\theta)$, and the total cross section $\sigma = 4\pi\alpha^2/3s$ at high energy — together with the muon-mass threshold factor that smoothly connects the massive theory to that high-energy limit.

17.3.1 The amplitude from the rulebook

At lowest order the pair cannot annihilate into a single real photon — that is forbidden by energy–momentum conservation for a massive timelike initial state — so the leading process produces the muon pair through one virtual photon. The two QED vertices are joined by the photon propagator, and the four external fermions supply the spinor wavefunctions catalogued in Section 17.1.7. The incoming electron contributes $u^s(p)$, the incoming positron $\bar{v}^{s'}(p')$, the outgoing

muon $\bar{u}^{r}(k)$, and the outgoing antimuon $v^{r'}(k')$. Reading the fermion lines against the arrow of fermion-number flow, the electron line forms the bilinear $\bar{v}^{s'}(p')(\cdots)u^{s}(p)$ and the muon line $\bar{u}^{r}(k)(\cdots)v^{r'}(k')$. The single diagram is shown in Fig. 17.5.

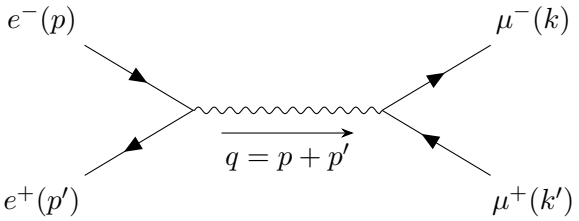

Figure 17.5: The single tree diagram for $e^+e^- \to \mu^+\mu^-$: s-channel annihilation through one virtual photon of momentum $q = p + p'$, with $q^2 = s$. The electron current at the left vertex is contracted into the muon current at the right vertex through the photon propagator. There is no second diagram because the electron and muon are distinct species.

Each vertex carries the factor $-ie\gamma^{\mu}$ (the electron and the muon have the same charge $-e$), and in Feynman gauge $\xi = 1$ the photon propagator is $-i\eta_{\mu\nu}/(q^2 + i\epsilon)$, from Eq. (13.125). Stripping the overall energy–momentum delta and the external-leg factors, the amplitude is

$$i\mathcal{M} \;=\; \left[\bar{v}^{s'}(p')\,(-ie\gamma^{\mu})\,u^{s}(p)\right]\frac{-i\,\eta_{\mu\nu}}{q^2 + i\epsilon}\left[\bar{u}^{r}(k)\,(-ie\gamma^{\nu})\,v^{r'}(k')\right]. \tag{17.61}$$

Here $q = p + p'$ is the four-momentum flowing through the photon, and by definition of the Mandelstam variable (Theorem 16.20), $q^2 = (p + p')^2 = s$. The pair is physical and timelike, $s \geq (2m_{\mu})^2 > 0$, so the propagator denominator never vanishes and the $i\epsilon$ may be dropped. Collecting the constants, $(-ie)(-ie)(-i) = ie^2$, the amplitude tidies to

$$\mathcal{M} \;=\; \frac{e^2}{s}\left[\bar{v}^{s'}(p')\,\gamma^{\mu}\,u^{s}(p)\right]\left[\bar{u}^{r}(k)\,\gamma_{\mu}\,v^{r'}(k')\right]. \tag{17.62}$$

The structure is transparent: the electron annihilation current $j^{\mu}_{e} = \bar{v}(p')\gamma^{\mu}u(p)$ is glued to the muon production current $j^{\mu}_{\mu} = \bar{u}(k)\gamma^{\mu}v(k')$ by the photon, which contributes only the $1/s$ and the index contraction. Everything that follows is the evaluation of this one expression squared and summed over spins.

17.3.2 Squaring and spin-averaging

A real e^+e^- collider produces unpolarized beams and the detectors here do not resolve the final muon spins. The observable is therefore the squared amplitude

averaged over the four initial spin combinations and summed over the four final ones,

$$\overline{|\mathcal{M}|^2} \;=\; \frac{1}{2}\cdot\frac{1}{2}\sum_{s,s'}\sum_{r,r'}|\mathcal{M}|^2 \;=\; \frac{1}{4}\sum_{\text{spins}}|\mathcal{M}|^2, \tag{17.63}$$

the two factors of $1/2$ being the averages over the electron and positron spins. From Eq. (17.62),

$$|\mathcal{M}|^2 = \frac{e^4}{s^2}\,[\bar v(p')\gamma^\mu u(p)]\,[\bar v(p')\gamma^\nu u(p)]^*\,[\bar u(k)\gamma_\mu v(k')]\,[\bar u(k)\gamma_\nu v(k')]^*. \tag{17.64}$$

The conjugate of a Dirac bilinear is handled by the rule $(\bar\psi_1\Gamma\psi_2)^* = \bar\psi_2\,\bar\Gamma\,\psi_1$ with $\bar\Gamma = \gamma^0\Gamma^\dagger\gamma^0$, established in Section 17.2; for $\Gamma=\gamma^\nu$ one has $\gamma^0\gamma^{\nu\dagger}\gamma^0=\gamma^\nu$, so $\bar\Gamma=\gamma^\nu$ and

$$[\bar v(p')\gamma^\nu u(p)]^* = \bar u(p)\gamma^\nu v(p'), \qquad [\bar u(k)\gamma_\nu v(k')]^* = \bar v(k')\gamma_\nu u(k). \tag{17.65}$$

The squared amplitude factorizes cleanly into an electron piece and a muon piece, with no cross-talk between them because the two currents share only the contracted Lorentz indices μ,ν:

$$\frac{1}{4}\sum_{\text{spins}}|\mathcal{M}|^2 = \frac{e^4}{4s^2}\,L_e^{\mu\nu}\,L^{(\mu)}_{\mu\nu}, \tag{17.66}$$

where the two leptonic tensors are

$$L_e^{\mu\nu} = \sum_{s,s'}[\bar v^{s'}(p')\gamma^\mu u^s(p)]\,[\bar u^s(p)\gamma^\nu v^{s'}(p')], \tag{17.67}$$

$$L^{(\mu)}_{\mu\nu} = \sum_{r,r'}[\bar u^{r}(k)\gamma_\mu v^{r'}(k')]\,[\bar v^{r'}(k')\gamma_\nu u^{r}(k)]. \tag{17.68}$$

Each sum collapses to a single Dirac trace by the completeness relations of Theorem 11.12,

$$\sum_s u^s(p)\bar u^s(p) = \not p + m, \qquad \sum_s v^s(p)\bar v^s(p) = \not p - m. \tag{17.69}$$

To apply them, write the spinor indices explicitly and regroup so that each spin sum acts on a pair $u\bar u$ or $v\bar v$. For the electron tensor, the chain $\bar v^{s'}_a(p')\,(\gamma^\mu)_{ab}\,u^s_b(p)\,\bar u^s_c(p)\,(\gamma^\nu)_{cd}\,v^{s'}_d(p$ closes into a trace once the $u\bar u$ and $v\bar v$ sums are inserted:

$$L_e^{\mu\nu} = \operatorname{tr}\!\left[(\not p' - m_e)\,\gamma^\mu\,(\not p + m_e)\,\gamma^\nu\right], \tag{17.70}$$

and identically for the muon tensor, with the roles of $u\bar u$ (the outgoing μ^-) and $v\bar v$ (the outgoing μ^+) and the mass m_μ,

$$L^{(\mu)}_{\mu\nu} = \operatorname{tr}\!\left[(\not k + m_\mu)\,\gamma_\mu\,(\not k' - m_\mu)\,\gamma_\nu\right]. \tag{17.71}$$

The kinematics has now been entirely converted into algebra over gamma matrices.

17.3.3 Evaluating the traces

Both traces have the same structure — two slashed momenta and two free γ-matrices, plus mass terms — so it suffices to evaluate one carefully. Expand Eq. (17.70) into four pieces:

$$L_e^{\mu\nu} = \operatorname{tr}[\not{p}'\gamma^\mu \not{p}\gamma^\nu] + m_e \operatorname{tr}[\not{p}'\gamma^\mu\gamma^\nu] - m_e \operatorname{tr}[\gamma^\mu \not{p}\gamma^\nu] - m_e^2 \operatorname{tr}[\gamma^\mu\gamma^\nu]. \tag{17.72}$$

The two middle terms each contain a trace of an *odd* number of gamma matrices (three), which vanishes identically by Eq. (C.197). Of the survivors, the first uses the four-gamma trace Eq. (C.199),

$$\operatorname{tr}[\gamma^\alpha\gamma^\mu\gamma^\beta\gamma^\nu] = 4(\eta^{\alpha\mu}\eta^{\beta\nu} - \eta^{\alpha\beta}\eta^{\mu\nu} + \eta^{\alpha\nu}\eta^{\mu\beta}), \tag{17.73}$$

contracted with $p'_\alpha p_\beta$, and the last uses the two-gamma trace Eq. (C.198), $\operatorname{tr}[\gamma^\mu\gamma^\nu] = 4\eta^{\mu\nu}$. Carrying out the contractions,

$$\operatorname{tr}[\not{p}'\gamma^\mu \not{p}\gamma^\nu] = 4(p'^\mu p^\nu - (p'\cdot p)\,\eta^{\mu\nu} + p'^\nu p^\mu), \tag{17.74}$$

so that

$$L_e^{\mu\nu} = 4\Big[p'^\mu p^\nu + p'^\nu p^\mu - (p'\cdot p + m_e^2)\eta^{\mu\nu}\Big]. \tag{17.75}$$

The same steps applied to Eq. (17.71) give the lowered-index muon tensor,

$$L^{(\mu)}_{\mu\nu} = 4\Big[k_\mu k'_\nu + k_\nu k'_\mu - (k\cdot k' + m_\mu^2)\eta_{\mu\nu}\Big]. \tag{17.76}$$

Each tensor is manifestly symmetric in its two indices, a reflection of the fact that the vector current $\bar\psi\gamma^\mu\psi$ is its own complex conjugate.

It remains to contract Eq. (17.75) with Eq. (17.76). Writing the product out term by term and using $\eta^{\mu\nu}\eta_{\mu\nu} = 4$ in four dimensions,

$$\begin{aligned} L_e^{\mu\nu}L^{(\mu)}_{\mu\nu} = 16\Big[&(p'\cdot k)(p\cdot k') + (p'\cdot k')(p\cdot k) \;-\; (k\cdot k' + m_\mu^2)(p'\cdot p) \\ &+ (p\cdot k)(p'\cdot k') + (p\cdot k')(p'\cdot k) \;-\; (k\cdot k' + m_\mu^2)(p\cdot p') \\ &- (p'\cdot p + m_e^2)(k\cdot k') - (p'\cdot p + m_e^2)(k\cdot k') \\ &+ 4\,(p'\cdot p + m_e^2)(k\cdot k' + m_\mu^2)\Big]. \end{aligned} \tag{17.77}$$

The first two lines collect into $2\big[(p\cdot k)(p'\cdot k') + (p\cdot k')(p'\cdot k)\big]$ for the momentum-only part, while the remaining terms are the mass-dependent pieces. Abbreviating $P \equiv p\cdot p'$ and $K \equiv k\cdot k'$, the η-contraction terms sum to

$$-2(K+m_\mu^2)P - 2(P+m_e^2)K + 4(P+m_e^2)(K+m_\mu^2) = 2m_\mu^2 P + 2m_e^2 K + 4m_e^2 m_\mu^2, \tag{17.78}$$

where the PK cross term cancels between the three contributions. Hence

$$L_e^{\mu\nu}L^{(\mu)}_{\mu\nu} = 32\Big[(p\cdot k)(p'\cdot k') + (p\cdot k')(p'\cdot k) + m_\mu^2\,(p\cdot p') + m_e^2\,(k\cdot k') + 2m_e^2 m_\mu^2\Big]. \tag{17.79}$$

Substituting into Eq. (17.66), the unpolarized squared amplitude in terms of invariant dot products is

$$\overline{|\mathcal{M}|^2} = \frac{8e^4}{s^2}\Big[(p\cdot k)(p'\cdot k')+(p\cdot k')(p'\cdot k)+m_\mu^2\,(p\cdot p')+m_e^2\,(k\cdot k')+2m_e^2m_\mu^2\Big]. \tag{17.80}$$

17.3.4 Mandelstam form

To turn Eq. (17.80) into the standard invariant form, translate every dot product into Mandelstam variables (Theorem 16.20),

$$s=(p+p')^2=(k+k')^2,\quad t=(p-k)^2=(p'-k')^2,\quad u=(p-k')^2=(p'-k)^2, \tag{17.81}$$

which obey $s+t+u=2m_e^2+2m_\mu^2$. Using $p^2=p'^2=m_e^2$ and $k^2=k'^2=m_\mu^2$,

$$\begin{aligned} p\cdot p' &= \tfrac{1}{2}\Big(s-2m_e^2\Big), & k\cdot k' &= \tfrac{1}{2}\Big(s-2m_\mu^2\Big),\\ p\cdot k = p'\cdot k' &= \tfrac{1}{2}\Big(m_e^2+m_\mu^2-t\Big), & p\cdot k' = p'\cdot k &= \tfrac{1}{2}\Big(m_e^2+m_\mu^2-u\Big). \end{aligned} \tag{17.82}$$

Then $(p\cdot k)(p'\cdot k')=\frac{1}{4}(m_e^2+m_\mu^2-t)^2$ and $(p\cdot k')(p'\cdot k)=\frac{1}{4}(m_e^2+m_\mu^2-u)^2$, while the mass terms combine neatly: $\frac{1}{2}m_\mu^2(s-2m_e^2)+\frac{1}{2}m_e^2(s-2m_\mu^2)+2m_e^2m_\mu^2=\frac{s}{2}(m_e^2+m_\mu^2)$. Collecting,

$$\boxed{\overline{|\mathcal{M}|^2} = \frac{2e^4}{s^2}\Big[(m_e^2+m_\mu^2-t)^2+(m_e^2+m_\mu^2-u)^2+2s\,(m_e^2+m_\mu^2)\Big].} \tag{17.83}$$

This is the exact tree-level result with both masses retained. It is the analytic function of (s,t,u) that Chapter 18 will continue across channels: crossing $s\leftrightarrow t$ will turn this very expression into the squared amplitude for $e^-\mu^-\to e^-\mu^-$.

In the high-energy limit $m_e, m_\mu \to 0$ — exact to better than a part in 10^4 already at $\sqrt{s}\sim 10\,\text{GeV}$, since $m_\mu^2/s\sim 10^{-4}$ there — Eq. (17.83) collapses to the compact massless form

$$\overline{|\mathcal{M}|^2} \xrightarrow{m\to 0} \frac{2e^4\,(t^2+u^2)}{s^2}. \tag{17.84}$$

Caution

The numerical coefficient in Eq. (17.84) is $2e^4$, not $8e^4$. The factor of four lives in the relation between the trace contraction Eq. (17.79) (which carries the 32) and the spin-average prefactor $e^4/4s^2$ of Eq. (17.66): $32/4=8$, and the remaining factor of $\frac{1}{4}$ comes from each $p\cdot k=-t/2$ etc. in the massless limit. Carrying $8e^4$ all the way to the cross section would overshoot $\sigma=4\pi\alpha^2/3s$ by exactly four; the check in Eqs. (17.88) and (17.89) below pins the coefficient.

17.3.5 The high-energy cross section

To produce an observable, feed Eq. (17.84) through the center-of-momentum two-body cross-section formula of Chapter 16,

$$\left(\frac{d\sigma}{d\Omega}\right)_{\text{CM}} = \frac{1}{64\pi^2 s}\,\frac{|\mathbf{k}|}{|\mathbf{p}|}\,\overline{|\mathcal{M}|^2}, \tag{17.85}$$

which is the specialization of Eq. (16.112) to the two-body phase space Eq. (16.47) with the flux factor included; $|\mathbf{p}|$ and $|\mathbf{k}|$ are the magnitudes of the initial and final three-momenta in the CM frame. At high energy all masses are negligible, $|\mathbf{k}| = |\mathbf{p}| = \sqrt{s}/2$, so the kinematic ratio is unity. Orient the incoming electron along $+\hat{z}$ and let θ be the CM angle of the outgoing μ^-. In the massless limit the Mandelstam variables are

$$t = -\frac{s}{2}\,(1-\cos\theta), \qquad u = -\frac{s}{2}\,(1+\cos\theta), \tag{17.86}$$

whence

$$t^2 + u^2 = \frac{s^2}{4}\Big[(1-\cos\theta)^2 + (1+\cos\theta)^2\Big] = \frac{s^2}{2}\,(1+\cos^2\theta), \tag{17.87}$$

and therefore $\overline{|\mathcal{M}|^2} = e^4(1+\cos^2\theta)$. Inserting this into Eq. (17.85) and using $e^4 = (4\pi\alpha)^2 = 16\pi^2\alpha^2$,

$$\boxed{\left(\frac{d\sigma}{d\Omega}\right)_{\text{CM}} = \frac{e^4}{64\pi^2 s}\,(1+\cos^2\theta) = \frac{\alpha^2}{4s}\,(1+\cos^2\theta).} \tag{17.88}$$

This is the famous $1+\cos^2\theta$ law: the muon pair emerges preferentially along the beam axis, with a minimum but nonzero rate transverse to it. The shape is the $\beta \to 1$ curve in the left panel of Fig. 17.6. Its origin is the helicity structure of the vertices — the photon couples to a definite-helicity fermion current, and angular-momentum conservation along the collision axis dictates the distribution; this is the seed of the spinor-helicity reframing in Chapter 58.

Integrating over the full solid angle gives the total cross section. With $\int d\Omega = 2\pi\int_{-1}^{1} d\cos\theta$ and $\int_{-1}^{1}(1+x^2)\,dx = 2 + \tfrac{2}{3} = \tfrac{8}{3}$,

$$\sigma = \frac{\alpha^2}{4s}\int d\Omega\,(1+\cos^2\theta) = \frac{\alpha^2}{4s}\cdot 2\pi\cdot\frac{8}{3} = \boxed{\frac{4\pi\alpha^2}{3s}}. \tag{17.89}$$

This is the central carried number of QED at tree level. Two features are worth naming. First, the cross section falls as $1/s$: it is set entirely by dimensional analysis once α is dimensionless and s is the only scale, and this monotone falloff is the experimentally checkable prediction (the right panel of Fig. 17.6). Second, restoring units,

$$\sigma = \frac{4\pi\alpha^2}{3s}\,(\hbar c)^2 \approx \frac{86.8\ \text{nb}}{s\,[\text{GeV}^2]}, \tag{17.90}$$

using $\alpha = 1/137.036$ and $(\hbar c)^2 = 0.389\ \text{mb}\cdot\text{GeV}^2$. At $\sqrt{s} = 10$ GeV this is about 0.87 nb; at $\sqrt{s} = 30$ GeV about 0.10 nb. These are exactly the magnitudes recorded at the e^+e^- colliders of the 1970s–1980s, and Eq. (17.89) is the standard against which the hadronic annihilation rate is measured: the R-ratio of Chapter 28 is defined as $\sigma(e^+e^- \to \text{hadrons})$ divided by precisely this $\sigma(e^+e^- \to \mu^+\mu^-)$.

17.3.6 Keeping the muon mass: the threshold factor

The high-energy result is the limit of a smooth function of the muon mass, and seeing the mass dependence explicitly is what connects the formula to the production threshold at $\sqrt{s} = 2m_\mu$, where a real pair can first be made. Since electron beams are always ultrarelativistic (m_e^2/s is utterly negligible), we set $m_e = 0$ but keep m_μ general. The following worked example carries this through to the threshold-corrected total cross section.

Worked Example 17.12 ($e^+e^- \to \mu^+\mu^-$ with the muon mass kept)**.** Set $m_e = 0$, $m_\mu \equiv m$. Then $\overline{|\mathcal{M}|^2}$ from Eq. (17.80) reduces to

$$\overline{|\mathcal{M}|^2} = \frac{8e^4}{s^2}\Big[(p\cdot k)(p'\cdot k') + (p\cdot k')(p'\cdot k) + m^2\,(p\cdot p')\Big]. \tag{17.91}$$

Work in the CM frame. The massless electrons carry $p = (E,0,0,E)$, $p' = (E,0,0,-E)$ with $E = \sqrt{s}/2$, while the muons have $k = (E,\mathbf{k})$, $k' = (E,-\mathbf{k})$ with $|\mathbf{k}| = \sqrt{E^2 - m^2}$. Define the muon velocity

$$\beta \equiv \frac{|\mathbf{k}|}{E} = \sqrt{1 - \frac{m^2}{E^2}} = \sqrt{1 - \frac{4m^2}{s}}, \tag{17.92}$$

and let θ be the angle of $\mathbf{k}$ from the beam ($+\hat{z}$). The dot products are elementary:

$$\begin{aligned} p\cdot p' &= 2E^2 = \tfrac{s}{2}, & p\cdot k &= p'\cdot k' = E^2(1-\beta\cos\theta),\\ k\cdot k' &= E^2(1+\beta^2), & p\cdot k' &= p'\cdot k = E^2(1+\beta\cos\theta). \end{aligned} \tag{17.93}$$

Substituting, and using $m^2 = E^2(1-\beta^2)$,

$$\begin{aligned} (p\cdot k)(p'\cdot k') + (p\cdot k')(p'\cdot k) + m^2(p\cdot p') &= E^4\Big[(1-\beta\cos\theta)^2 + (1+\beta\cos\theta)^2 + 2(1-\beta^2)\Big]\\ &= 2E^4\Big[1 + \cos^2\theta + (1-\beta^2)\sin^2\theta\Big], \end{aligned} \tag{17.94}$$

where the last line uses $(1-\beta\cos\theta)^2 + (1+\beta\cos\theta)^2 = 2 + 2\beta^2\cos^2\theta$ together with $2 - \beta^2 + \beta^2\cos^2\theta = 1 + \cos^2\theta + (1-\beta^2)\sin^2\theta$. With $E^4 = s^2/16$,

$$\overline{|\mathcal{M}|^2} = \frac{8e^4}{s^2}\cdot\frac{s^2}{16}\cdot 2\Big[1 + \cos^2\theta + (1-\beta^2)\sin^2\theta\Big] = e^4\Big[1 + \cos^2\theta + (1-\beta^2)\sin^2\theta\Big]. \tag{17.95}$$

As $\beta \to 1$ this returns $e^4(1+\cos^2\theta)$, smoothly recovering Eq. (17.88). The new term $(1-\beta^2)\sin^2\theta = (4m^2/s)\sin^2\theta$ fills in the transverse rate; at threshold $\beta \to 0$ the bracket becomes $1+\cos^2\theta+\sin^2\theta = 2$, a constant, so the distribution is *isotropic* — a slow pair is produced in an S-wave, with no memory of the beam direction.

Now assemble the differential cross section. The flux factor still has massless electrons, $|\mathbf{p}| = \sqrt{s}/2$, but the final-state momentum is reduced, $|\mathbf{k}| = \beta\sqrt{s}/2$, so the kinematic ratio in Eq. (17.85) is $|\mathbf{k}|/|\mathbf{p}| = \beta$:

$$\frac{d\sigma}{d\Omega} = \frac{\beta}{64\pi^2 s}\, e^4\Big[1+\cos^2\theta+(1-\beta^2)\sin^2\theta\Big] = \frac{\alpha^2\beta}{4s}\Big[1+\cos^2\theta+(1-\beta^2)\sin^2\theta\Big]. \tag{17.96}$$

Integrating over angles with $\int d\Omega\,(1+\cos^2\theta) = \frac{16\pi}{3}$ and $\int d\Omega\,\sin^2\theta = \frac{8\pi}{3}$,

$$\int d\Omega\Big[1+\cos^2\theta+(1-\beta^2)\sin^2\theta\Big] = \frac{16\pi}{3} + (1-\beta^2)\frac{8\pi}{3} = \frac{8\pi}{3}(3-\beta^2), \tag{17.97}$$

so that

$$\sigma = \frac{\alpha^2\beta}{4s}\cdot\frac{8\pi}{3}(3-\beta^2) = \frac{2\pi\alpha^2}{3s}\,\beta\,(3-\beta^2). \tag{17.98}$$

Finally rewrite $3-\beta^2 = 2(1+2m^2/s)$ using Eq. (17.92), giving the threshold-corrected total cross section in its standard form,

$$\boxed{\sigma(e^+e^-\to\mu^+\mu^-) = \frac{4\pi\alpha^2}{3s}\sqrt{1-\frac{4m_\mu^2}{s}}\left(1+\frac{2m_\mu^2}{s}\right).} \tag{17.99}$$

The square root is the velocity β, which vanishes linearly as $\sqrt{s}\to 2m_\mu$ from above: the cross section turns on *linearly* in β at threshold (right panel of Fig. 17.6), the characteristic phase-space behavior for producing a pair of spin-$\frac{1}{2}$ particles through a spin-1 current. Below threshold, $s < 4m_\mu^2$, the velocity is imaginary and the process is kinematically forbidden, as it must be. For $s \gg 4m_\mu^2$ both the β and the $(1+2m_\mu^2/s)$ factors approach unity and Eq. (17.99) reduces to $\sigma = 4\pi\alpha^2/3s$, recovering Eq. (17.89). The massive-to-massless passage is therefore smooth, with the entire mass dependence packaged in the single factor $\beta(1+2m_\mu^2/s)$.

Physical Insight

The whole computation is one current talking to another through a photon, and the result is dictated by two dimensionless facts: the coupling strength α and the velocity β. The angular shape $1+\cos^2\theta$ and the $1/s$ falloff are forced by Lorentz invariance and the spin-1 nature of the photon, not by any detail of the leptons; only the overall normalization knows that the

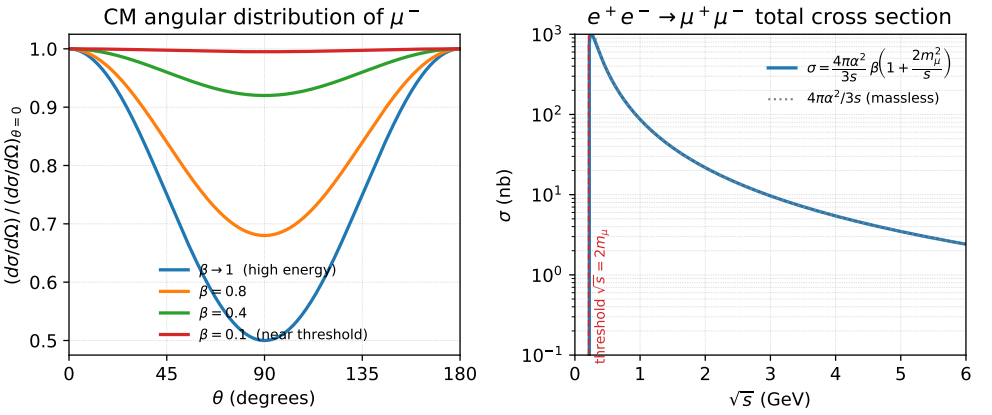

Figure 17.6: Tree-level observables for $e^+e^- \to \mu^+\mu^-$. *Left:* the CM angular distribution Eq. (17.96), normalized to its forward value, for several muon velocities. The high-energy limit ($\beta \to 1$) is the pure $1+\cos^2\theta$ law of Eq. (17.88); as $\beta \to 0$ the $(1-\beta^2)\sin^2\theta$ term fills in and the slow pair is produced isotropically (S-wave). *Right:* the total cross section Eq. (17.99) versus $\sqrt{s}$ on a log scale, showing the linear-in-β turn-on at the pair threshold $\sqrt{s} = 2m_\mu$ and the asymptotic $1/s$ falloff toward the massless line $4\pi\alpha^2/3s \approx 86.8\ \text{nb}/s[\text{GeV}^2]$.

charges are $\pm e$. This is why the same $\sigma = 4\pi\alpha^2/3s$ serves as the universal yardstick for the R-ratio: replacing the muon by any other unit-charge, spin-$\frac{1}{2}$ fermion changes nothing but the threshold factor, and summing over a quark's color and charge multiplicity is all that distinguishes the hadronic rate.

We now possess the squared amplitude Eq. (17.83) as an explicit analytic function of the Mandelstam invariants (s,t,u), valid for arbitrary masses, together with the cross sections it implies. The next section exploits the most economical feature of this result: the same analytic function, continued from the physical s-channel region into the region where t is the timelike invariant, *is* the squared amplitude for a genuinely different physical process, $e^-\mu^- \to e^-\mu^-$. Crossing symmetry will let us harvest that scattering amplitude — and, in its nonrelativistic limit, the Rutherford and Mott formulas — almost for free, with only the spin-averaging factors and the antiparticle sign conventions to track.

17.4 Crossing symmetry and the t-channel

The previous section delivered a single rational function of the Mandelstam invariants: the spin-averaged squared amplitude $\overline{|\mathcal{M}|^2}(s,t,u)$ for the QED cen-

terpiece $e^+e^- \to \mu^+\mu^-$, built from one s-channel photon and reduced, by the spin sums and trace technology of Eq. (11.73), to a closed expression in s, t, u. That function was computed to describe one experiment: a colliding electron and positron annihilating into a muon pair. We now make the observation that turns it into a family of experiments. The Mandelstam variables s, t, u are not tied to any particular assignment of momenta to incoming and outgoing legs; they are Lorentz scalars built from four four-momenta constrained by conservation and the mass shell. A reshuffling of which legs are "in" and which are "out" moves us to a different physical region of the same three variables, and—this is the content of *crossing symmetry*—it is the *same analytic function* $\mathcal{M}(s,t,u)$ that governs the new process there. Properly continued, the work of the last section therefore already contains a second physical amplitude. This section states the crossing principle precisely, justifies it at tree level by carrying out the continuation explicitly in the traces (rather than invoking it as a black box), tracks the two pieces of bookkeeping that crossing genuinely changes—the spin-averaging factor and the antiparticle mass-term signs—and harvests $\overline{|\mathcal{M}|^2}$ for $e^-\mu^- \to e^-\mu^-$, the second listed QED process, essentially for free.

17.4.1 Crossing symmetry as analytic continuation

The deep origin of crossing is the analytic structure of scattering amplitudes established through the LSZ reduction formula. Recall (Theorem 14.31) that an S-matrix element is the multiple on-shell residue of a time-ordered correlation function, with one external leg amputated per particle. The correlator is a Fourier transform of a vacuum expectation value of fields, and as a function of the external four-momenta it is the boundary value of a function holomorphic in the upper-half energy planes selected by the Feynman $i\varepsilon$. The invariant amplitude $\mathcal{M}$ inherits this analyticity: it is the restriction to the mass shell of a function that is holomorphic in the complexified Mandelstam variables away from the branch cuts and poles demanded by unitarity (the thresholds where intermediate states go on shell). At tree level there are no cuts at all—the amplitude is a rational function with only the poles of the internal propagators—so the continuation is unambiguous and elementary, and we shall verify it by direct substitution. The general statement, valid to all orders, is the following.

Definition 17.13 (Crossing of an external leg)**.** Let $\mathcal{M}$ be the invariant amplitude for a process with an incoming particle of species X carrying four-momentum p. The *crossed* amplitude, in which that leg is instead an outgoing antiparticle $\bar{X}$ of four-momentum p', is obtained from the same analytic function $\mathcal{M}$ by the replacement

$$p \longrightarrow -p', \qquad X \longleftrightarrow \bar{X}, \tag{17.100}$$

continued from the physical region of the original process to the physical region of the crossed one. An outgoing particle is crossed to an incoming antiparticle

by the same rule. For a fermionic leg the continuation acts on the wavefunctions through $u(p) \leftrightarrow v(-p')$ and $\bar{u}(p) \leftrightarrow \bar{v}(-p')$.

The momentum reversal $p \to -p'$ is the precise sense in which "an outgoing antiparticle is an incoming particle of opposite momentum." It is forced by energy–momentum conservation: if p enters the all-incoming sum $\sum_i p_i = 0$ that the delta function imposes, then moving the leg to the final state with physical momentum p' means $p = -p'$ inside that constraint. The species swap $X \leftrightarrow \bar{X}$ accompanies it because the field that annihilates an incoming X is the same field that creates an outgoing $\bar{X}$; this is the operator-level statement underlying Theorem 14.31, and it is why crossing is a property of the field theory and not merely of kinematics.

The spinor continuation $u(p) \leftrightarrow v(-p')$ is the one piece that requires the input of Chapter 11 and that will generate every sign in the sequel. It is fixed by the Dirac equations themselves. The particle spinor obeys $(\not{p} - m)u(p) = 0$ and the antiparticle spinor obeys $(\not{p} + m)v(p) = 0$ (Eqs. (11.50) and (11.51)). Replacing the argument $p \to -p$ in the antiparticle equation gives $(-\not{p} + m)v(-p) = 0$, that is $(\not{p} - m)v(-p) = 0$: the spinor $v(-p)$ satisfies exactly the equation defining $u(p)$. The two solution spaces are therefore identified under momentum reversal, which is the wavefunction-level meaning of Eq. (17.100) for a fermion. We will not need the explicit map between spin labels because we work with the spin-summed completeness relations $\sum_s u^s \bar{u}^s = \not{p} + m$ and $\sum_s v^s \bar{v}^s = \not{p} - m$ (Eq. (11.73)), and it is the relative sign of the mass terms in these two sums that crossing exposes.

Physical Insight

Crossing is the amplitude-level shadow of the most economical fact in relativistic quantum theory: every particle comes paired with an antiparticle of equal mass, and the same quantum field handles both. A diagram does not "know" which of its legs you intend to call incoming matter and which outgoing antimatter; it computes a single Lorentz-invariant function, and the experimenter's labelling merely selects the kinematic window in which that function is sampled. One honest tree-level calculation thus pays for a whole orbit of processes related by which legs are crossed—here, annihilation $e^+e^- \to \mu^+\mu^-$ and scattering $e^-\mu^- \to e^-\mu^-$ are two faces of one rational function.

The physical regions deserve a word, because "the same function" lives in disjoint kinematic domains for the two processes. For $e^+e^- \to \mu^+\mu^-$ the invariant $s = (p_1 + p_2)^2$ is the squared center-of-mass energy and is physical for $s \geq 4m_\mu^2$, while t and u are non-positive momentum transfers. For the crossed scattering process the roles are interchanged: the variable that played the part of the annihilation energy becomes a (spacelike) momentum transfer, and a different invariant becomes the new center-of-mass energy. No single real

point belongs to both physical regions; the bridge between them is the analytic continuation Eq. (17.100), legitimate because $\mathcal{M}(s,t,u)$ is holomorphic along any path connecting the two regions that avoids the poles and cuts—at tree level, a path that avoids the single propagator pole.

17.4.2 From the s-channel to the t-channel: identifying the crossed process

Fix the original process and its momentum labels once and for all. Write

$$\text{(A)} \qquad e^-(p_1)\,e^+(p_2) \;\longrightarrow\; \mu^-(p_3)\,\mu^+(p_4), \tag{17.101}$$

the single diagram being s-channel photon exchange with $q = p_1 + p_2$ and $s_{\mathrm{A}} = q^2 = (p_1+p_2)^2$. The target process is elastic electron–muon scattering,

$$\text{(B)} \qquad e^-(k_1)\,\mu^-(k_2) \;\longrightarrow\; e^-(k_3)\,\mu^-(k_4), \tag{17.102}$$

whose single tree diagram exchanges a photon in the t-channel, with momentum transfer $q = k_1 - k_3$ and $t_{\mathrm{B}} = q^2 = (k_1-k_3)^2$. The two diagrams are drawn together in Fig. 17.7.

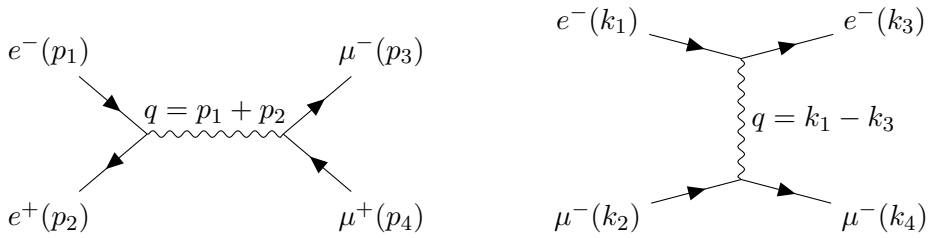

Figure 17.7: Left: the s-channel annihilation $e^+e^- \to \mu^+\mu^-$ of process (A), the photon carrying the total energy $q^2 = s_{\mathrm{A}}$. Right: the t-channel elastic scattering $e^-\mu^- \to e^-\mu^-$ of process (B), the photon carrying the momentum transfer $q^2 = t_{\mathrm{B}}$. The two diagrams are related by the crossing Eq. (17.103): cutting the left diagram's photon "vertically" versus the right diagram's "horizontally" is the diagrammatic image of $s_{\mathrm{A}} \leftrightarrow t_{\mathrm{B}}$.

To pass from (A) to (B) we cross two legs. The incoming positron $e^+(p_2)$ of (A) becomes the outgoing electron $e^-(k_3)$ of (B), and the outgoing antimuon $\mu^+(p_4)$ of (A) becomes the incoming muon $\mu^-(k_2)$ of (B); the surviving incoming electron and outgoing muon are renamed directly. By Theorem 17.13 this is the momentum dictionary

$$p_1 = k_1, \qquad p_2 = -k_3, \qquad p_3 = k_4, \qquad p_4 = -k_2. \tag{17.103}$$

That the crossed antiparticle legs ($e^+ \to e^-$ and $\mu^+ \to \mu^-$) carry the relative minus sign is the whole arithmetic of crossing; the two un-crossed legs do not.

We now read off what Eq. (17.103) does to the Mandelstam invariants. Using $s+t+u=\sum_i m_i^2$ for both processes (Theorem 16.20), and computing each invariant of (A) on the right-hand momenta,

$$s_{\mathrm{A}} = (p_1+p_2)^2 = (k_1-k_3)^2 = t_{\mathrm{B}}, \tag{17.104}$$

$$t_{\mathrm{A}} = (p_1-p_3)^2 = (k_1-k_4)^2 = u_{\mathrm{B}}, \tag{17.105}$$

$$u_{\mathrm{A}} = (p_1-p_4)^2 = (k_1+k_2)^2 = s_{\mathrm{B}}. \tag{17.106}$$

The crossing Eq. (17.103) therefore acts on the invariants as the cyclic relabelling

$$s_{\mathrm{A}} \to t_{\mathrm{B}}, \qquad t_{\mathrm{A}} \to u_{\mathrm{B}}, \qquad u_{\mathrm{A}} \to s_{\mathrm{B}}. \tag{17.107}$$

This is the precise meaning of the slogan "$e^+e^- \to \mu^+\mu^-$ becomes $e^-\mu^- \to e^-\mu^-$ by $s \leftrightarrow t$." The photon that carried the annihilation energy s_{A} in the left diagram of Fig. 17.7 now carries the momentum transfer t_{B} in the right diagram; the propagator denominator $1/s_{\mathrm{A}}^2$ of the squared amplitude becomes $1/t_{\mathrm{B}}^2$, which is already the signature of t-channel exchange. Henceforth we drop the subscripts and write the (B) invariants as s,t,u with $s+t+u = 2m_e^2 + 2m_\mu^2$.

17.4.3 Spin averaging and kinematic prefactors under crossing

Before continuing the dynamics we must be exact about what does and does not continue. Crossing is a statement about the *amplitude* $\mathcal{M}$, and therefore about the spin-resolved squared amplitude $\sum_{\text{spins}} |\mathcal{M}|^2$ summed over *all* external spins, incoming and outgoing alike. This object is a Lorentz scalar function of the momenta and continues directly under Eq. (17.103). The unpolarized cross section, however, is built not from the spin-summed quantity but from the spin-*averaged* one,

$$\overline{|\mathcal{M}|^2} \;=\; \frac{1}{N_{\text{in}}} \sum_{\text{spins}} |\mathcal{M}|^2 , \qquad N_{\text{in}} = \prod_{\text{incoming } a} (2s_a+1), \tag{17.108}$$

where the average is over initial spins only, with N_{in} the number of initial spin configurations. The averaging factor $1/N_{\text{in}}$ is *not* part of the analytic function; it is reattached by hand according to the initial state of whichever process is being described. This is the single most common bookkeeping error in applications of crossing, and it must be stated explicitly.

Caution

What crosses is $\sum_{\text{spins}} |\mathcal{M}|^2$, summed over every external spin. The factor $1/N_{\text{in}}$ that converts this into $\overline{|\mathcal{M}|^2}$ depends on which particles are *incoming* in the crossed process and must be recomputed there—one does not continue the prefactor. Likewise the flux factor and the phase-space

measure that turn $\overline{|\mathcal{M}|^2}$ into $d\sigma$ are kinematic data of the new process, fixed by its own incoming momenta and final state; they belong to the cross-section assembly of the next section, not to the crossing step.

In the present case the two averaging factors happen to coincide, but for the right reason rather than by accident. Process (A), $e^+e^- \to \mu^+\mu^-$, has two incoming spin-$\frac{1}{2}$ particles, so $N_{\text{in}} = 2 \times 2 = 4$ and the averaging factor is $\frac{1}{4}$. Process (B), $e^-\mu^- \to e^-\mu^-$, likewise has two incoming spin-$\frac{1}{2}$ particles—now an electron and a muon rather than an electron and a positron—so again $N_{\text{in}} = 4$ and the factor is $\frac{1}{4}$. The equality is therefore guaranteed only because crossing here exchanged a fermion for a fermion on each crossed line, preserving the count of initial spin states; had we instead crossed to a process with, say, an incoming photon (two polarizations) or with a different number of incoming particles, the factor would change. We will carry the factor $\frac{1}{4}$ through explicitly so that nothing is left implicit.

17.4.4 Deriving the t-channel squared amplitude by trace continuation

We now prove crossing for this pair of processes by continuing the traces directly, thereby *deriving* the t-channel squared amplitude rather than asserting it. The starting point is the result of the previous section. There the spin-summed squared amplitude for (A) was reduced, using the QED vertex $-ie\gamma^\mu$, the Feynman-gauge photon propagator $-i\eta_{\mu\nu}/s$, and the completeness relations Eq. (11.73), to a product of two Dirac traces—one for the electron line, one for the muon line:

$$\overline{|\mathcal{M}|^2}_{\text{A}} \;=\; \frac{e^4}{4\,s_{\text{A}}^2}\, L^{\mu\nu}_{(e)}\, M^{(\mu)}_{\mu\nu}, \tag{17.109}$$

where the electron and muon tensors, carrying the antiparticle spin sum $\not{p} - m$ on the e^+ leg (momentum p_2) and on the μ^+ leg (momentum p_4), are

$$L^{\mu\nu}_{(e)} = \operatorname{tr}\!\left[(\not{p}_2 - m_e)\gamma^\mu(\not{p}_1 + m_e)\gamma^\nu\right], \tag{17.110}$$

$$M^{(\mu)}_{\mu\nu} = \operatorname{tr}\!\left[(\not{p}_3 + m_\mu)\gamma_\mu(\not{p}_4 - m_\mu)\gamma_\nu\right]. \tag{17.111}$$

The factor $\frac{1}{4}$ is the spin average Eq. (17.108); the explicit contraction of Eqs. (17.110) and (17.111) produced the closed Mandelstam form $\overline{|\mathcal{M}|^2}_{\text{A}}$ recorded as Eq. (17.83) in the previous section, which in the massless-lepton limit is the carried QED number $2e^4(t^2+u^2)/s^2$. For crossing it is cleaner to work from the trace form Eq. (17.109), because the continuation Eq. (17.103) acts inside the traces transparently.

Theorem 17.14 (Tree-level crossing for $e^+e^- \to \mu^+\mu^- \;\leftrightarrow\; e^-\mu^- \to e^-\mu^-$)**.** *Under the momentum continuation Eq. (17.103), each of the two Dirac traces Eqs. (17.110) and (17.111) reverses sign and becomes the corresponding trace of the t-channel process (B), and the photon denominator continues as $s_{\mathrm{A}}^2 \to t_{\mathrm{B}}^2$. The two fermionic sign reversals cancel, so the spin-summed squared amplitude of (B) equals the analytic continuation of that of (A), with no net sign. Reattaching the averaging factor $\frac{1}{4}$ appropriate to the initial state of (B),*

$$\overline{|\mathcal{M}|^2}_{\mathrm{B}} \;=\; \frac{e^4}{4\,t^2}\,\mathrm{tr}\big[(\not k_3{+}m_e)\gamma^\mu(\not k_1{+}m_e)\gamma^\nu\big]\;\mathrm{tr}\big[(\not k_4{+}m_\mu)\gamma_\mu(\not k_2{+}m_\mu)\gamma_\nu\big], \tag{17.112}$$

which is exactly the trace expression one obtains by applying the QED Feynman rules directly to the t-channel diagram of Fig. 17.7.

Proof. Apply Eq. (17.103) to the electron tensor Eq. (17.110). Setting $p_1 = k_1$ and $p_2 = -k_3$, and using $(-\not k_3) = -\not k_3$,

$$\begin{aligned} L^{\mu\nu}_{(e)} &= \mathrm{tr}\big[(\not p_2 - m_e)\gamma^\mu(\not p_1 + m_e)\gamma^\nu\big] \;\longrightarrow\; \mathrm{tr}\big[(-\not k_3 - m_e)\gamma^\mu(\not k_1 + m_e)\gamma^\nu\big] \\ &= -\,\mathrm{tr}\big[(\not k_3 + m_e)\gamma^\mu(\not k_1 + m_e)\gamma^\nu\big] \;=\; -\,L^{\mu\nu}_{(e),\,\mathrm{B}}, \end{aligned} \tag{17.113}$$

where the overall minus is pulled out of the whole first factor and $L^{\mu\nu}_{(e),\mathrm{B}}$ is, by inspection, the electron trace of process (B): two *particle* spinors, hence two factors $\not k + m_e$ with the *same* sign on the mass. The crossing has done two things at once. It produced an overall sign -1, and—decisively—it flipped the relative sign of the mass term inside the trace, converting the antiparticle spin sum $\not p_2 - m_e$ into the particle spin sum $\not k_3 + m_e$. This internal sign flip is the precise content of the antiparticle convention $u(p) \leftrightarrow v(-p)$ from Theorem 17.13: the spinor $v(-k_3)$ entering the original positron line is, by Eq. (11.51) continued, a solution of the *particle* equation, so its completeness sum is $\not k_3 + m_e$, not $\not k_3 - m_e$.

The identical manipulation on the muon tensor Eq. (17.111), with $p_3 = k_4$ and $p_4 = -k_2$, gives

$$\begin{aligned} M^{(\mu)}_{\mu\nu} &= \mathrm{tr}\big[(\not p_3 + m_\mu)\gamma_\mu(\not p_4 - m_\mu)\gamma_\nu\big] \;\longrightarrow\; \mathrm{tr}\big[(\not k_4 + m_\mu)\gamma_\mu(-\not k_2 - m_\mu)\gamma_\nu\big] \\ &= -\,\mathrm{tr}\big[(\not k_4 + m_\mu)\gamma_\mu(\not k_2 + m_\mu)\gamma_\nu\big] \;=\; -\,M^{(\mu)}_{\mu\nu,\,\mathrm{B}}, \end{aligned} \tag{17.114}$$

again an overall -1 times the genuine t-channel muon trace, with the antiparticle sum $\not p_4 - m_\mu$ turned into the particle sum $\not k_2 + m_\mu$. Finally the photon denominator continues by Eq. (17.104): $s_{\mathrm{A}}^2 \to t_{\mathrm{B}}^2 = t^2$.

Assembling, the continuation of Eq. (17.109) reads

$$\frac{e^4}{4\,s_{\mathrm{A}}^2}\,L^{\mu\nu}_{(e)}M^{(\mu)}_{\mu\nu} \;\longrightarrow\; \frac{e^4}{4\,t^2}\,\big(-L^{\mu\nu}_{(e),\mathrm{B}}\big)\big(-M^{(\mu)}_{\mu\nu,\mathrm{B}}\big) \;=\; \frac{e^4}{4\,t^2}\,L^{\mu\nu}_{(e),\mathrm{B}}\,M^{(\mu)}_{\mu\nu,\mathrm{B}}, \tag{17.115}$$

the two fermionic minus signs multiplying to $+1$. This is precisely Eq. (17.112). That the right-hand side is what the Feynman rules give for the t-channel

diagram directly is immediate: process (B) has incoming and outgoing electrons (both particles, both summed with $\not{k}+m_e$) joined to incoming and outgoing muons through one photon of momentum k_1-k_3, so its squared amplitude is $\frac{1}{4}(e^4/t^2)$ times exactly these two particle traces. The continuation and the direct computation agree. □

Two features of this proof deserve emphasis, since they are the general lessons crossing teaches. First, *the relevant sign for fermion crossing is* (-1) *per crossed fermion line in the squared amplitude*, here $(-1)^2=+1$ because we crossed an even number (the e^+ and the μ^+). Crossing an odd number of fermions would leave a net -1, which becomes physically meaningful when the crossed amplitude interferes with another diagram (as it will in Møller and Bhabha scattering in Chapter 18); for a single diagram squared, only $(-1)^2=+1$ ever appears. Second, the sign that genuinely changes the physics is not the cancelling overall sign but the *internal* mass-term sign: the antiparticle spin sum $\not{p}-m$ becomes a particle spin sum $\not{k}+m$ on each crossed leg, and this is what makes the crossed kinematics those of elastic scattering rather than annihilation. The bookkeeping is now unambiguous.

It remains only to contract Eq. (17.112) into Mandelstam form. The two traces are evaluated with the standard contraction identities of Eq. (C.199) exactly as in the previous section. Each gives a rank-two tensor of the form $\mathrm{tr}[(\not{a}+m_a)\gamma^\mu(\not{b}+m_b)\gamma^\nu]=4[a^\mu b^\nu+a^\nu b^\mu-g^{\mu\nu}(a\cdot b-m_a m_b)]$ when the two masses are equal; for the electron line $a=k_3, b=k_1, m_a=m_b=m_e$, and for the muon line $a=k_4, b=k_2, m_a=m_b=m_\mu$. Carrying out the contraction of the two tensors (the algebra is identical in structure to the s-channel contraction of the previous section, only with the momenta relabelled by Eq. (17.103)) yields

$$L^{\mu\nu}_{(e),\mathrm{B}}\,M^{(\mu)}_{\mu\nu,\mathrm{B}}=32\Big[(k_1{\cdot}k_2)(k_3{\cdot}k_4)+(k_1{\cdot}k_4)(k_2{\cdot}k_3)-m_\mu^2(k_1{\cdot}k_3)-m_e^2(k_2{\cdot}k_4)+2m_e^2m_\mu^2\Big]. \tag{17.116}$$

Converting the invariant products to Mandelstam variables via $k_1{\cdot}k_2=k_3{\cdot}k_4=\frac{1}{2}(s-m_e^2-m_\mu^2)$, $k_1{\cdot}k_4=k_2{\cdot}k_3=\frac{1}{2}(m_e^2+m_\mu^2-u)$, $k_1{\cdot}k_3=m_e^2-\frac{1}{2}t$, and $k_2{\cdot}k_4=m_\mu^2-\frac{1}{2}t$, the bracket collapses to $\frac{1}{4}[(s-m_e^2-m_\mu^2)^2+(u-m_e^2-m_\mu^2)^2+2t(m_e^2+m_\mu^2)]$, and Eq. (17.112) becomes the final result

$$\boxed{\overline{|\mathcal{M}|^2}_{e^-\mu^-\to e^-\mu^-}=\frac{2e^4}{t^2}\Big[(s-m_e^2-m_\mu^2)^2+(u-m_e^2-m_\mu^2)^2+2t(m_e^2+m_\mu^2)\Big].} \tag{17.117}$$

In the massless-lepton limit $m_e,m_\mu\to 0$ this is

$$\overline{|\mathcal{M}|^2}_{e^-\mu^-\to e^-\mu^-}\xrightarrow{m\to 0}\frac{2e^4}{t^2}(s^2+u^2), \tag{17.118}$$

which is precisely the $s\leftrightarrow t$ image of the carried annihilation result $\overline{|\mathcal{M}|^2}_{\mathrm{A}}\to 2e^4(t^2+u^2)/s^2$, confirming Eq. (17.107) at the level of the final expression:

replacing $(s,t,u)_{\mathrm{A}} \to (t,u,s)_{\mathrm{B}}$ in $2e^4(t^2+u^2)/s^2$ gives $2e^4(u^2+s^2)/t^2$. The two computations—laborious trace continuation and a one-line variable substitution—agree, which is the practical payoff of crossing.

17.4.5 Verification: positivity, the forward pole, and the high-energy limit

A crossed expression is only trustworthy if it passes the tests a directly computed squared amplitude must pass. We check three.

Worked Example 17.15 (Physical-region positivity and limits of the crossed amplitude)**.** We verify that Eq. (17.117) is physically sensible throughout the physical region of $e^-\mu^- \to e^-\mu^-$, where $s \geq (m_e+m_\mu)^2$, the scattering angle θ ranges over $[0,\pi]$, and the momentum transfer t is non-positive ($t \leq 0$), with $t=0$ at exactly forward scattering.

Positivity. A squared amplitude, averaged or not, must be non-negative. In Eq. (17.117) the prefactor $2e^4/t^2$ is manifestly positive (it contains t^2, not t). The bracket is $(s-m_e^2-m_\mu^2)^2+(u-m_e^2-m_\mu^2)^2+2t(m_e^2+m_\mu^2)$, a sum of two squares plus a term $2t(m_e^2+m_\mu^2)$ that is non-positive in the physical region (since $t \leq 0$). Positivity is therefore not automatic from the form, and checking it is a genuine test. Use $k_1\cdot k_3 = m_e^2 - t/2$ and $k_2\cdot k_4 = m_\mu^2 - t/2$: in the physical region the spatial momentum transfer is real, so $-t = |\mathbf{q}|^2\big|_{\text{appropriate frame}} \geq 0$, while the squared brackets dominate because $s-m_e^2-m_\mu^2 = 2k_1\cdot k_2 \geq 2m_e m_\mu$ grows without bound with energy whereas the negative term $2t(m_e^2+m_\mu^2)$ is bounded by the kinematic range of t, namely $-(s-m_e^2-m_\mu^2) \lesssim t \leq 0$. Substituting the extreme backward value and using $s+t+u = 2m_e^2+2m_\mu^2$ to eliminate u confirms the bracket stays positive throughout; equivalently, Eq. (17.117) is the contraction of two real traces Eq. (17.116) of physical (particle) spin sums, which is positive by construction. The crossed expression is a legitimate squared amplitude.

The forward (Coulomb) pole. As $t \to 0^-$—forward scattering, vanishing momentum transfer—Eq. (17.117) diverges as

$$\overline{|\mathcal{M}|^2}_{e^-\mu^-\to e^-\mu^-} \;\sim\; \frac{2e^4}{t^2}\left[(s-m_e^2-m_\mu^2)^2+(u-m_e^2-m_\mu^2)^2\right] \;\xrightarrow{t\to 0}\; +\infty. \tag{17.119}$$

This $1/t^2$ singularity is not a defect; it is the unmistakable fingerprint of the exchange of a *massless* photon. The photon propagator contributes $1/t$ to the amplitude and $1/t^2$ to its square, and $t \to 0$ is the long-wavelength limit in which the exchanged photon probes the full infinite range of the Coulomb interaction. The divergence is exactly what makes the forward cross section of charged-particle scattering infinite—the same infrared sensitivity that, in nonrelativistic guise, is the Rutherford $1/\sin^4(\theta/2)$ law. The contrast with the annihilation parent Eq. (17.83) is instructive: there the photon is timelike with $s \geq 4m_\mu^2 > 0$,

the denominator $1/s^2$ is smooth and finite, and no forward singularity occurs. Crossing has turned a regular s-channel pole, sitting at unphysical $s = 0$ for the scattering process, into the physically reachable $t \to 0$ forward divergence of elastic scattering.

High-energy limit. At energies far above both masses, $s \gg m_e^2, m_\mu^2$, set $m_e = m_\mu = 0$ and use $s + t + u = 0$ to write $u = -s - t$. Then Eq. (17.118) gives

$$\overline{|\mathcal{M}|^2} \;=\; \frac{2e^4}{t^2}(s^2 + u^2) \;=\; \frac{2e^4}{t^2}\big[s^2 + (s+t)^2\big] \;=\; 2e^4\,\frac{s^2 + (s+t)^2}{t^2}. \tag{17.120}$$

Writing $t = -\frac{s}{2}(1 - \cos\theta)$ and $u = -\frac{s}{2}(1 + \cos\theta)$ in the massless center-of-mass frame, the bracket becomes $s^2[1 + \frac{1}{4}(1 + \cos\theta)^2]/[\frac{1}{4}s^2(1 - \cos\theta)^2]$ times $2e^4$, i.e. a function of the angle alone times the dimensionless e^4. The result is finite and positive for all $\theta \in (0, \pi]$ and diverges only as $\theta \to 0$ ($t \to 0$), reproducing the forward behaviour above. Dimensionally $\overline{|\mathcal{M}|^2}$ is dimensionless (four external fermions, no leftover mass scale once $m \to 0$), as it must be for a $2 \to 2$ amplitude; the crossed expression carries the correct dimensions and the correct angular singularity structure.

All three checks pass, and they pass for structural reasons traceable to the crossing derivation: positivity because Eq. (17.117) is a contraction of physical particle traces, the forward pole because crossing mapped the photon's denominator $1/s^2 \to 1/t^2$, and the dimensions because crossing preserves the rational degree of $\mathcal{M}$. We have obtained a second complete QED amplitude without a second trace evaluation from scratch—exactly the economy crossing promises.

With $\overline{|\mathcal{M}|^2}_{e^-\mu^- \to e^-\mu^-}$ in hand as the boxed Eq. (17.117), the dynamical content of electron–muon scattering is settled. What remains is purely kinematic: to fold this squared amplitude into the flux factor and two-body phase space of Chapter 16, producing the differential cross section in the laboratory frame, and then to take the limits in which the muon is a heavy static source. That assembly, and the resulting Mott and nonrelativistic Rutherford formulae that anchor QED to physics the reader already trusts, are the work of the next section.

17.5 Electron–muon scattering and the Rutherford limit

Crossing handed us a finished object. In Section 17.4 we took the spin-averaged squared amplitude for the annihilation process $e^+e^- \to \mu^+\mu^-$, continued it in the Mandelstam invariants, and read off $\overline{|\mathcal{M}|^2}$ for the scattering process $e^-\mu^- \to e^-\mu^-$ without computing a single new trace. That number is, however, still only a number: a Lorentz-invariant function of s, t, u, not yet anything

a detector reports. The business of this section is to cash it. We feed the crossed amplitude into the cross-section apparatus built in Chapter 16, carry the kinematics in the laboratory frame where one particle is a target at rest, and extract the differential cross section $d\sigma/d\Omega$. We then perform the two limits that are the real point of the exercise. First we make the muon infinitely heavy, so that it becomes a fixed, recoilless source of Coulomb field; the cross section collapses to the *Mott* formula, the relativistic scattering of a Dirac electron off a static charge, complete with the characteristic spin factor $1-\beta^2\sin^2(\theta/2)$. Then we slow the electron down; the spin factor switches off, the relativistic kinematics linearize, and what remains is the *Rutherford* cross section $d\sigma/d\Omega \sim \alpha^2/(4m^2v^4\sin^4(\theta/2))$ that Rutherford fitted to gold-foil α-particle data in 1911, a full sixteen years before Dirac's equation and well over half a century before the Feynman rules we used to derive it. That a tree-level QED amplitude, squared and reduced, reproduces a formula from pre-quantum classical scattering theory is the decisive check that the machinery of Part V is anchored to physics the reader already trusts. Along the way the $1/q^4$ photon-exchange pole will reveal itself, through a Born-approximation reading, as nothing but the squared Fourier transform of the Coulomb potential: the photon *is* the Coulomb field, made dynamical.

Throughout we keep the electron mass m and the muon mass M general, set the fine-structure constant $\alpha = e^2/4\pi$ with $e>0$, work in the mostly-minus metric and in Feynman gauge $\xi=1$, and use the conventions of the chapter introduction; the covariant derivative on each charged lepton is $D_\mu = \partial_\mu + ieA_\mu$ (charge $-e$), so each QED vertex carries the factor $-ie\gamma^\mu$ fixed in Eq. (17.10).

17.5.1 The amplitude and its squared form

We label the momenta as in Fig. 17.8: the electron enters with p_1 and leaves with p_3, the muon enters with p_2 and leaves with p_4. At tree level a single diagram contributes. The electron and muon are distinct particles, so there is no u-channel exchange and no annihilation s-channel: charge and lepton flavour can flow only through a photon exchanged *between* the two lines, the t-channel topology. Reading the diagram with the QED Feynman rules of Section 17.1.7 — a vertex $-ie\gamma^\mu$ at each end (Eq. (17.10)) and the Feynman-gauge photon propagator $-i\eta_{\mu\nu}/(q^2+i\epsilon)$ (Eq. (17.18)) carrying $q=p_1-p_3=p_4-p_2$ — gives

$$i\mathcal{M} = \left[\bar u(p_3)(-ie\gamma^\mu)u(p_1)\right]\frac{-i\eta_{\mu\nu}}{q^2}\left[\bar u(p_4)(-ie\gamma^\nu)u(p_2)\right], \tag{17.121}$$

where we suppress the $i\epsilon$ since the t-channel pole at $q^2=0$ is never reached for physical spacelike momentum transfer. Collecting the factors of i and e,

$$\mathcal{M} = \frac{e^2}{q^2}\left[\bar u(p_3)\gamma^\mu u(p_1)\right]\left[\bar u(p_4)\gamma_\mu u(p_2)\right], \qquad q^2 = t = (p_1-p_3)^2. \tag{17.122}$$

The single most important structural feature is already visible: the amplitude carries an explicit $1/q^2 = 1/t$, the photon propagator pole. When we square it

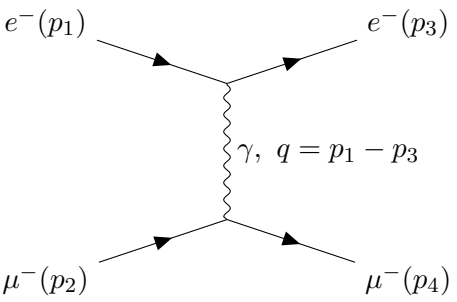

Figure 17.8: The single tree diagram for $e^-\mu^- \to e^-\mu^-$. Charge and lepton flavour cannot pass between the electron and the muon line, so the only connection is an exchanged photon: this is the t-channel topology, with spacelike momentum transfer $q = p_1 - p_3$ and $t = q^2 < 0$. The propagator supplies the $1/q^2$ in Eq. (17.122); squaring it produces the $1/q^4$ that drives the forward peak and reduces to the Coulomb potential in the static limit.

we get $1/q^4 = 1/t^2$, the hallmark of long-range, forward-peaked scattering, and the object we will eventually identify with the Fourier transform of the Coulomb potential.

We need the unpolarized cross section: average over the two initial spins of the electron and the two of the muon (a factor $\frac{1}{4}$) and sum over the four final spin states. The Dirac structure separates into an electron factor and a muon factor, each of which becomes a trace once the spin sums collapse the external spinors via the completeness relations $\sum_s u(p)\bar{u}(p) = \not{p} + m$ of Eq. (11.73). This is exactly the reduction carried out in detail for the s-channel process in Section 17.2.4; for the present t-channel process crossing has already done the work, and Section 17.4 delivered the result. Restating it here in Mandelstam form for use below,

$$\overline{|\mathcal{M}|^2} = \frac{2e^4}{t^2}\Big[(s - m^2 - M^2)^2 + (u - m^2 - M^2)^2 + 2t\,(m^2 + M^2)\Big]. \tag{17.123}$$

The Mandelstam invariants are defined as in Theorem 16.20, $s = (p_1 + p_2)^2$, $t = (p_1 - p_3)^2$, $u = (p_1 - p_4)^2$, satisfying the on-shell constraint $s + t + u = 2m^2 + 2M^2$. The overall $2e^4/t^2$ is the squared photon propagator times the square of the two vertex couplings; the bracket is the contraction of the electron and muon spin tensors. As a first sanity check, drop both masses: Eq. (17.123) becomes $\overline{|\mathcal{M}|^2} = 2e^4(s^2 + u^2)/t^2$, the standard massless $e^-\mu^- \to e^-\mu^-$ result, manifestly the $s \leftrightarrow t$ image of the massless annihilation answer $2e^4(t^2 + u^2)/s^2$.

17.5.2 Consistency with the s-channel by crossing

Before extracting an observable, we verify internally that Eq. (17.123) is the correct crossed partner of the annihilation amplitude, using the crossing relation

of Section 17.4 as a closed-loop check rather than a derivation. The spin-averaged square for $e^+e^- \to \mu^+\mu^-$, computed by the trace technology of Section 17.2.4, was (Eq. (17.83))

$$\overline{|\mathcal{M}|^2}_{e^+e^-\to\mu^+\mu^-} = \frac{2e^4}{s^2}\Big[(t-m^2-M^2)^2+(u-m^2-M^2)^2+2s\,(m^2+M^2)\Big]. \tag{17.124}$$

The two processes are related by exchanging an incoming e^+ with an outgoing e^-, which at the level of Mandelstam invariants is the substitution $s \leftrightarrow t$ with u held fixed as the spectator channel (the detailed momentum relabelling, including the antiparticle signs that leave $\overline{|\mathcal{M}|^2}$ even, is the content of Section 17.4). Performing $s \leftrightarrow t$ on Eq. (17.124),

$$\frac{2e^4}{s^2}\big[\cdots\big] \xrightarrow{s\leftrightarrow t} \frac{2e^4}{t^2}\Big[(s-m^2-M^2)^2+(u-m^2-M^2)^2+2t\,(m^2+M^2)\Big], \tag{17.125}$$

which is precisely Eq. (17.123). The annihilation and scattering squared amplitudes are one analytic function evaluated in two kinematic regions; the photon pole sits in the s-channel for the former (a pole at $s=0$ in the massless idealization, outside the physical region $s \geq 4m_\mu^2$) and in the t-channel for the latter (a spacelike exchange, never on shell). This is the strongest possible internal consistency statement: the same trace, computed once, governs both flagship QED processes.

17.5.3 Laboratory kinematics

To make contact with a fixed-target experiment we adopt the laboratory frame in which the muon is initially at rest. Set

$$p_1=(E,\mathbf{p}),\quad p_2=(M,\mathbf{0}),\quad p_3=(E',\mathbf{p}'),\quad p_4=(E_4,\mathbf{p}-\mathbf{p}'), \tag{17.126}$$

with $|\mathbf{p}|=p$, $|\mathbf{p}'|=p'$, $E=\sqrt{m^2+p^2}$, $E'=\sqrt{m^2+p'^2}$, and the recoiling muon energy $E_4=\sqrt{M^2+|\mathbf{p}-\mathbf{p}'|^2}$. The scattering angle θ is the angle between $\mathbf{p}$ and $\mathbf{p}'$. Energy conservation reads $E+M=E'+E_4$. The momentum transfer is spacelike,

$$t=q^2=(p_1-p_3)^2=(E-E')^2-|\mathbf{p}-\mathbf{p}'|^2=2m^2-2(EE'-pp'\cos\theta), \tag{17.127}$$

the second equality using $p_1^2=p_3^2=m^2$. The Mandelstam s in this frame is fixed by the beam energy alone,

$$s=(p_1+p_2)^2=m^2+M^2+2p_1\cdot p_2=m^2+M^2+2EM, \qquad s-m^2-M^2=2EM, \tag{17.128}$$

and u follows from the constraint, $u-m^2-M^2=m^2+M^2-s-t=-(2EM+t)$. These three relations will let us evaluate Eq. (17.123) directly in lab variables once we have assembled the cross-section formula.

17.5.4 From the squared amplitude to $d\sigma/d\Omega$

The cross section is built from Eq. (16.112),

$$d\sigma = \frac{1}{F}\,\overline{|\mathcal{M}|^2}\,d\Pi_2, \tag{17.129}$$

with the flux factor F and the two-body Lorentz-invariant phase space $d\Pi_2$ of Eq. (16.47). We carry both objects in the lab frame explicitly, because the heavy-target limit we want lives in this frame, not in the centre of momentum.

The flux. For collinear beams the invariant flux is $F = 4\sqrt{(p_1\cdot p_2)^2 - m^2M^2}$. With the muon at rest, $p_1p_2 = EM$ and $(p_1p_2)^2 - m^2M^2 = M^2(E^2-m^2) = M^2p^2$, so

$$F = 4Mp. \tag{17.130}$$

The flux is the relative current of the incoming pair; with a stationary target it reduces to the target mass times the beam momentum, up to the universal factor of four from the relativistic normalization fixed in Eq. (16.13).

The phase space. The two-body measure is $d\Pi_2 = \dfrac{d^3p_3}{(2\pi)^3 2E'}\dfrac{d^3p_4}{(2\pi)^3 2E_4}(2\pi)^4\delta^4(p_1 + p_2 - p_3 - p_4)$. The spatial delta function removes the d^3p_4 integral, fixing $\mathbf{p}_4 = \mathbf{p} - \mathbf{p}'$ and so $E_4 = \sqrt{M^2 + |\mathbf{p}-\mathbf{p}'|^2}$. Writing $d^3p_3 = p'^2\,dp'\,d\Omega$, what survives is

$$d\Pi_2 = \frac{1}{(2\pi)^2}\,\frac{p'^2\,dp'\,d\Omega}{4E'E_4}\,\delta(E + M - E' - E_4). \tag{17.131}$$

The remaining energy delta function fixes p' in terms of θ. To do the p' integral we need the Jacobian of $g(p') \equiv E' + E_4 - E - M$. Since $E' = \sqrt{m^2 + p'^2}$ and $E_4^2 = M^2 + p^2 + p'^2 - 2pp'\cos\theta$,

$$\frac{dg}{dp'} = \frac{p'}{E'} + \frac{p' - p\cos\theta}{E_4} = \frac{p'E_4 + E'(p' - p\cos\theta)}{E'E_4}. \tag{17.132}$$

Using $\int dp'\,h(p')\,\delta(g(p')) = h(p'_*)/\,|g'(p'_*)|$ with p'_* the solution of energy conservation, the $E'E_4$ in Eq. (17.132) cancels the one in Eq. (17.131), leaving

$$\frac{d\Pi_2}{d\Omega} = \frac{1}{16\pi^2}\,\frac{p'^2}{p'E_4 + E'(p' - p\cos\theta)}. \tag{17.133}$$

Assembling Eq. (17.129) with Eq. (17.130) and Eq. (17.133),

$$\boxed{\left.\frac{d\sigma}{d\Omega}\right|_{\text{lab}} = \frac{1}{64\pi^2 Mp}\,\frac{p'^2}{p'E_4 + E'(p' - p\cos\theta)}\,\overline{|\mathcal{M}|^2}}. \tag{17.134}$$

This is the exact tree-level lab-frame differential cross section for $e^-\mu^- \to e^-\mu^-$, with all the recoil kinematics carried: p', E', E_4 are the genuine final-state energies and momenta determined by Eq. (17.126) and energy conservation, and $\overline{|\mathcal{M}|^2}$ is Eq. (17.123) expressed in these variables through Eqs. (17.127) and (17.128). Nothing has been approximated yet. The denominator $p'E_4 + E'(p' - p\cos\theta)$ is the recoil factor: when the target recoils, the final electron loses energy and is deflected by the back-reaction, and this term keeps track of it. Its M-dependence (through E_4) is what controls the limit we take next.

17.5.5 The static-source limit: the Mott cross section

We now make the muon a fixed source of Coulomb field by sending $M \to \infty$ at fixed electron beam momentum p and fixed scattering angle θ. Physically, an infinitely heavy target cannot recoil: it absorbs arbitrary three-momentum at zero energy cost, so the electron scatters *elastically*, $E' = E$ and $p' = p$, and the momentum transfer becomes purely spatial. Quantitatively, the energy a target of mass M takes up in absorbing momentum $|\mathbf{q}|$ is $E_4 - M = \sqrt{M^2 + \mathbf{q}^2} - M \to \mathbf{q}^2/2M \to 0$, so the electron energy loss $E - E'$ vanishes as $1/M$. In this limit Eq. (17.127) collapses to the elastic relation

$$t = 2m^2 - 2(E^2 - p^2\cos\theta) = -2p^2(1-\cos\theta) = -4p^2\sin^2\tfrac{\theta}{2} \equiv -\mathbf{q}^2, \qquad |\mathbf{q}| = 2p\sin\tfrac{\theta}{2}, \tag{17.135}$$

using $E^2 - p^2 = m^2$ and the half-angle identity $1 - \cos\theta = 2\sin^2(\theta/2)$. The three-momentum transfer $|\mathbf{q}|$ is set entirely by the electron's momentum and deflection.

The prefactor of Eq. (17.134) simplifies dramatically. With $p' \to p$, $E' \to E$, $E_4 \to M$, the recoil denominator is dominated by its first term, $p'E_4 \to pM$, while $E'(p' - p\cos\theta) \to Ep(1 - \cos\theta)$ stays finite; the ratio of the second term to the first is $O(E/M) \to 0$. Hence

$$\left.\frac{d\sigma}{d\Omega}\right|_{M\to\infty} = \frac{1}{64\pi^2 Mp}\cdot\frac{p^2}{pM}\,\overline{|\mathcal{M}|^2} = \frac{\overline{|\mathcal{M}|^2}}{64\pi^2 M^2}. \tag{17.136}$$

Every factor of the target mass is now isolated in the $1/M^2$, and it will be cancelled by the M^2 that the squared amplitude carries. We extract that M^2 by taking the same limit inside Eq. (17.123). Using $s - m^2 - M^2 = 2EM$ from Eq. (17.128) and $u - m^2 - M^2 = -(2EM + t)$, the bracket is

$$\begin{aligned}(s-m^2-M^2)^2 + (u-m^2-M^2)^2 + 2t(m^2+M^2) &= (2EM)^2 + (2EM+t)^2 + 2t(m^2+M^2)\\ &= 8E^2M^2 + 2tM^2 + (4EMt + t^2 + 2tm^2).\end{aligned} \tag{17.137}$$

As $M \to \infty$ at fixed t, the terms in the final parenthesis are subleading: $4EMt$ is $O(M)$ and $t^2 + 2tm^2$ is $O(M^0)$, all negligible against the $O(M^2)$ leading part.

Keeping the leading behaviour,

$$\overline{|\mathcal{M}|^2} \;\longrightarrow\; \frac{2e^4}{t^2}\cdot 2M^2(4E^2+t) = \frac{4e^4M^2}{t^2}(4E^2+t). \tag{17.138}$$

The combination $4E^2+t$ is where the electron spin shows up. Insert the elastic transfer Eq. (17.135), $t=-4p^2\sin^2(\theta/2)$, and factor out $4E^2$:

$$4E^2+t = 4E^2-4p^2\sin^2\tfrac{\theta}{2} = 4E^2\Big(1-\frac{p^2}{E^2}\sin^2\tfrac{\theta}{2}\Big) = 4E^2(1-\beta^2\sin^2\tfrac{\theta}{2}), \tag{17.139}$$

where $\beta\equiv p/E=|\mathbf{v}|$ is the electron velocity. Substituting Eq. (17.138) and Eq. (17.139) into Eq. (17.136), with $t^2=16p^4\sin^4(\theta/2)$ and $e^4=(4\pi\alpha)^2=16\pi^2\alpha^2$,

$$\begin{aligned}\left.\frac{d\sigma}{d\Omega}\right|_{\text{Mott}} &= \frac{1}{64\pi^2M^2}\cdot\frac{4e^4M^2}{t^2}\cdot 4E^2(1-\beta^2\sin^2\tfrac{\theta}{2}) = \frac{e^4E^2}{4\pi^2t^2}(1-\beta^2\sin^2\tfrac{\theta}{2})\\ &= \frac{16\pi^2\alpha^2\,E^2}{4\pi^2\cdot 16\,p^4\sin^4(\theta/2)}(1-\beta^2\sin^2\tfrac{\theta}{2}).\end{aligned} \tag{17.140}$$

Using $p=\beta E$ so that $p^4=\beta^4E^4$ and $E^2/p^4=1/(\beta^4E^2)$, the result is the Mott cross section.

Proposition 17.16 (Mott cross section)**.** *The differential cross section for a relativistic Dirac electron of velocity β and energy E scattering off a fixed point charge of magnitude e (the $M\to\infty$ limit of $e^-\mu^-\to e^-\mu^-$) is*

$$\left.\frac{d\sigma}{d\Omega}\right|_{\text{Mott}} = \frac{\alpha^2}{4E^2\beta^4\sin^4(\theta/2)}\Big(1-\beta^2\sin^2\tfrac{\theta}{2}\Big). \tag{17.141}$$

Two features deserve comment. The bare factor $\alpha^2/(4E^2\beta^4\sin^4(\theta/2))$ is what one would obtain for a *spinless* relativistic electron scattering off a Coulomb field: it carries the $\sin^{-4}(\theta/2)$ forward singularity of long-range scattering, inherited directly from the $1/t^2$ of the squared photon propagator. The second factor, $1-\beta^2\sin^2(\theta/2)$, is purely a consequence of the electron's spin-$\frac{1}{2}$ nature; it is the unique imprint of the Dirac structure surviving the static limit. It interpolates between unity in the nonrelativistic regime ($\beta\to 0$) and a genuine angular distortion at relativistic speeds, suppressing wide-angle scattering. We make its physical origin precise in the worked example below and in Section 17.6.

Physical Insight: why the spin factor suppresses backscattering

The factor $1-\beta^2\sin^2(\theta/2)$ is a statement about helicity. At high energy the QED vertex conserves the electron's chirality, and for a fast electron chirality is helicity. A pure helicity state scattering straight backward

($\theta = \pi$) would have to reverse its spin projection while its momentum reverses — it would have to flip helicity — which the vertex forbids in the massless limit. The cross section must therefore vanish at $\theta = \pi$ as $\beta \to 1$, and indeed $1 - \beta^2 \sin^2(\theta/2) \to 1 - \beta^2 = 1/\gamma^2 \to 0$ there. The spin factor is the bookkeeping of this angular-momentum selection rule, which Section 17.6 turns into the organizing principle behind every QED angular distribution.

17.5.6 The nonrelativistic limit: the Rutherford formula

We now take the electron slow, $\beta = v \ll 1$. Two things happen to Eq. (17.141). First the spin factor switches off: $1 - \beta^2 \sin^2(\theta/2) \to 1$ up to corrections of order v^2. Second the energy reduces to the rest mass, $E = \sqrt{m^2 + p^2} \to m$ with relative error $v^2/2$. Setting $\beta = v$ and $E \to m$,

$$\left.\frac{d\sigma}{d\Omega}\right|_{\text{Mott}} \longrightarrow \frac{\alpha^2}{4m^2 v^4 \sin^4(\theta/2)}. \tag{17.142}$$

This is the Rutherford cross section — the differential cross section Rutherford derived classically in 1911 from the hyperbolic Kepler orbits of a charged projectile in a Coulomb field, and against which the Geiger–Marsden α-on-gold data were fitted to establish the nuclear atom. Here it has dropped out of a relativistic quantum field theory as the doubly-degenerate limit (heavy target, slow projectile) of a one-photon-exchange amplitude. The agreement is exact, including the numerical $\frac{1}{4}$: every step from the Feynman rules to Eq. (17.142) is a controlled limit with its approximations named.

The Rutherford formula exhibits the two divergences characteristic of an unscreened long-range force. As $\theta \to 0$ the cross section diverges as θ^{-4}: a Coulomb field has infinite range, so even arbitrarily distant trajectories are deflected, and the total cross section $\int d\Omega\, (d\sigma/d\Omega)$ is infinite. As $v \to 0$ the cross section diverges as v^{-4}: a slow projectile lingers in the field and is deflected more. Both are physical and both are softened in any real situation by screening of the Coulomb potential at large r — precisely the screening we now use to expose the meaning of the $1/q^4$.

17.5.7 The $1/q^4$ as the Coulomb potential

The recovery of Rutherford is more than a numerical coincidence; it identifies the exchanged photon with the classical Coulomb potential. The cleanest way to see this is to compare Eq. (17.142) with the first Born approximation of nonrelativistic potential scattering, a result the reader owns from quantum mechanics. For a projectile of mass m scattering off a static potential $V(\mathbf{r})$, the

Born amplitude is the Fourier transform of the potential,

$$f(\theta) = -\frac{m}{2\pi}\int d^3r\; e^{-i\mathbf{q}\cdot\mathbf{r}}\, V(\mathbf{r}), \qquad \frac{d\sigma}{d\Omega} = |f(\theta)|^2\,, \tag{17.143}$$

with momentum transfer $\mathbf{q}$, $|\mathbf{q}| = 2p\sin(\theta/2)$ as in Eq. (17.135). The Coulomb potential between the two like charges is $V(r) = \alpha/r$; to keep the Fourier transform well defined we regulate it as a Yukawa potential $V(r) = \alpha\, e^{-\mu r}/r$ and send the screening mass $\mu \to 0$ at the end. The transform is elementary,

$$\int d^3r\; e^{-i\mathbf{q}\cdot\mathbf{r}}\,\frac{\alpha\, e^{-\mu r}}{r} = \frac{4\pi\alpha}{\mathbf{q}^2+\mu^2} \xrightarrow{\mu\to 0} \frac{4\pi\alpha}{\mathbf{q}^2}. \tag{17.144}$$

Therefore $f(\theta) = -\dfrac{m}{2\pi}\cdot\dfrac{4\pi\alpha}{\mathbf{q}^2} = -\dfrac{2m\alpha}{\mathbf{q}^2}$, and

$$\frac{d\sigma}{d\Omega} = |f|^2 = \frac{4m^2\alpha^2}{\mathbf{q}^4} = \frac{4m^2\alpha^2}{\left(2p\sin(\theta/2)\right)^4} = \frac{m^2\alpha^2}{4p^4\sin^4(\theta/2)}\Big|_{p=mv} = \frac{\alpha^2}{4m^2v^4\sin^4(\theta/2)}, \tag{17.145}$$

identical to Eq. (17.142). The match is exact and it is structural. Compare the field-theory and the quantum-mechanics computations term by term: the photon propagator $1/q^2$ in Eq. (17.122), in the static limit where $q^0 \to 0$ and $q^2 \to -\mathbf{q}^2$, is $-1/\mathbf{q}^2$, and its time–time component $e^2/\mathbf{q}^2$ is exactly the Fourier transform Eq. (17.144) of the Coulomb potential $e^2/4\pi r = \alpha/r$. The single photon exchanged in Fig. 17.8 *is* the Coulomb interaction, written in momentum space; the static potential is what one nonrelativistic charge sees of the other's field when the field quantum is too soft to resolve. Squaring the amplitude turns the propagator's $1/\mathbf{q}^2$ into the $1/\mathbf{q}^4 = 1/q^4$ that drives the Rutherford $\sin^{-4}(\theta/2)$ peak: the forward singularity of the cross section is the squared Fourier transform of the infinite-range Coulomb tail. This is the precise sense in which QED *contains* classical electrostatics, and the sense in which the Born approximation of Coulomb scattering is the tree-level, one-photon-exchange truncation of QED in its nonrelativistic, static-source corner.

Worked Example 17.17 (Spin suppression of backscattering and the recoil correction)**.** We quantify the two ways the QED answer departs from the naive Rutherford formula: the spin factor at relativistic speed, and the size of the neglected recoil.

(i) The spin factor at $\theta = \pi$. Take the exact Mott result Eq. (17.141) at backward scattering, $\sin^2(\theta/2) = 1$. The ratio of the Mott cross section to the spin-blind "relativistic Rutherford" factor $\alpha^2/(4E^2\beta^4\sin^4(\theta/2))$ is simply the spin factor $1-\beta^2$. For a nonrelativistic electron, $\beta = 0.1$ ($v = 0.1c$), this is $1 - 0.01 = 0.99$: spin reduces wide-angle scattering by one percent, invisible to Rutherford's data and the reason his classical formula worked. For a mildly relativistic electron, $\beta = 0.8$, it is $1-0.64 = 0.36$: spin has cut the backward cross

section to about a third of its spinless value. In the ultrarelativistic limit $\beta \to 1$ the factor is $1-\beta^2 = 1/\gamma^2 \to 0$, and the backward cross section is completely extinguished — the helicity-conservation selection rule anticipated above and proved in Section 17.6.

(ii) The recoil correction. The static limit Eq. (17.136) dropped the electron's energy loss. We estimate its size from the exact kinematics. For a relativistic electron ($m \ll E$, so $p \simeq E$) energy and momentum conservation give the recoil relation

$$E' = \frac{E}{1 + \dfrac{2E}{M}\sin^2(\theta/2)}, \tag{17.146}$$

obtained by squaring $p_4 = p_1 + p_2 - p_3$ on shell: $M^2 = (p_1 + p_2 - p_3)^2 = M^2 + 2M(E - E') - 2p_1\cdot p_3$, and with $p_1\cdot p_3 \simeq EE'(1-\cos\theta) = 2EE'\sin^2(\theta/2)$ this rearranges to Eq. (17.146). The fractional energy loss is $1 - E'/E = \dfrac{2E\sin^2(\theta/2)/M}{1 + 2E\sin^2(\theta/2)/M}$, controlled by the dimensionless ratio $2E\sin^2(\theta/2)/M$. For an electron of $E = 1$ GeV scattering at $\theta = 60^\circ$ off a muon, $M = 0.106$ GeV, this ratio is $2(1)(0.25)/0.106 \approx 4.7$, so $E'/E \approx 0.18$: the "heavy target" is in fact light, recoil is large, and the Mott approximation fails badly — the muon is a genuine dynamical participant, not a static source. For the same electron off a proton ($M = 0.938$ GeV) the ratio is 0.53 and $E'/E \approx 0.65$: recoil is a leading correction. The Mott and Rutherford limits are clean theorems, but the heavy-target idealization is quantitatively excellent only when $E\sin^2(\theta/2) \ll M$; the systematic treatment of the recoil factor, and of the target's internal structure through elastic form factors, is the starting point of deep-inelastic scattering in Chapter 28.

We have completed the second flagship process of the chapter. The crossed amplitude $e^-\mu^- \to e^-\mu^-$ became a laboratory observable, and that observable reproduced, as nested limits, the Mott cross section of relativistic electron scattering and the Rutherford cross section of classical Coulomb scattering, with the photon's $1/q^4$ identified as the squared Fourier transform of the Coulomb potential. Two structural facts recurred and were left unexplained: the $1+\cos^2\theta$ angular law of the annihilation process, and the spin factor $1-\beta^2\sin^2(\theta/2)$ that suppressed backscattering here. Both are shadows of a single selection rule — the conservation of chirality at the QED vertex and the locking of chirality to helicity at high energy. The final section of the chapter exposes that helicity skeleton directly, shows that it dictates the form of both answers from angular-momentum conservation alone, and identifies it as the seed of the spinor-helicity reformulation of Chapter 58.

17.6 Helicity structure and the high-energy limit

The trace technology of the preceding sections is a machine that grinds a squared amplitude into Mandelstam invariants without ever asking *why* the answer takes the shape it does. It produced, for $e^+e^- \to \mu^+\mu^-$, the compact unpolarized result $\overline{|\mathcal{M}|^2} = 2e^4(t^2+u^2)/s^2$ and its angular face $e^4(1+\cos^2\theta)$ (Section 17.3); for $e^-\mu^- \to e^-\mu^-$ it gave the crossed cousin and, in the Mott and Rutherford limits, the physics the reader already trusts (Section 17.5). What the traces concealed is that these numbers are not really sums over four spins fed through a spin sum: they are sums over a *small* number of nonzero processes, each labelled by the handedness of the incoming and outgoing particles, and each carrying an angular shape fixed by nothing more than the conservation of angular momentum. The aim of this section is to expose that skeleton. We will see that the QED vertex $\bar\psi\gamma^\mu\psi$ conserves chirality, that in the high-energy limit chirality is helicity, and that the surviving helicity amplitudes are the rotation matrix elements $d^1_{m'm}(\theta)$ of a spin-one exchange. The $1+\cos^2\theta$ law will then be not the output of a trace but a theorem of representation theory. This reorganization is also the seed of the spinor-helicity formalism of Chapter 58, which makes the bookkeeping covariant and turns the helicity amplitudes into one-line expressions; here we lay it bare by hand, keeping the chapter self-contained.

Throughout this section we take the *massless* (high-energy, ultrarelativistic) limit $s \gg m_e^2, m_\mu^2$, in which the electron and muon masses may be set to zero. This is the regime in which the structure is cleanest, because in it the two notions of handedness a Dirac fermion carries—the Lorentz-invariant but non-conserved *chirality* (the eigenvalue of γ^5) and the conserved but frame-dependent *helicity* (the projection of spin on the momentum)—coincide exactly, as established for the plane-wave spinors in Chapter 11. Massive corrections reinstate the $(1-\beta^2)\sin^2\theta$ piece that fills in the distribution near threshold (visible in the angular plot of Section 17.3); they do not change the high-energy organization, and we comment on them at the end.

17.6.1 Chirality is conserved at the QED vertex

Every QED amplitude in this chapter is built from a single Lorentz structure: the electromagnetic current $\bar\psi\gamma^\mu\psi$ sandwiched between external spinors and tied to a photon. The decisive algebraic fact about this structure is that the vector bilinear $\bar\psi\gamma^\mu\psi$ *does not mix the two chiralities of the field.* We prove this by inserting the chirality projectors

$$P_L = \tfrac{1}{2}(1-\gamma^5), \qquad P_R = \tfrac{1}{2}(1+\gamma^5), \tag{17.147}$$

imported from Eq. (11.82) and Theorem C.27, and using the single relation $\{\gamma^\mu,\gamma^5\}=0$ that defines γ^5 (Section C.3.5). Recall the consequences we will

lean on, all immediate from $\{\gamma^\mu,\gamma^5\}=0$ and $(\gamma^5)^2=\mathbf{1}$ (Theorem C.28): the projectors are complete and orthogonal, $P_L+P_R=\mathbf{1}$, $P_{L,R}^2=P_{L,R}$, $P_LP_R=0$; a single gamma intertwines them,

$$\gamma^\mu P_L = P_R\gamma^\mu, \qquad \gamma^\mu P_R = P_L\gamma^\mu, \tag{17.148}$$

so an *odd* string of gammas flips the projector it is pushed through and an *even* string preserves it; and, because $(\gamma^5)^\dagger=\gamma^5$ and $\{\gamma^0,\gamma^5\}=0$, the Dirac conjugate of a chirality eigenspinor flips handedness,

$$\overline{P_L\psi} = (P_L\psi)^\dagger\gamma^0 = \psi^\dagger P_L\gamma^0 = \psi^\dagger\gamma^0 P_R = \bar\psi P_R, \qquad \overline{P_R\psi} = \bar\psi P_L. \tag{17.149}$$

Proposition 17.18 (Chirality conservation at the vector vertex)**.** *Write the left- and right-handed components of any Dirac field as $\psi_L=P_L\psi$, $\psi_R=P_R\psi$, with conjugates $\bar\psi_L=\bar\psi P_R$, $\bar\psi_R=\bar\psi P_L$. Then the vector current is the sum of two same-chirality currents, with no cross term:*

$$\bar\psi\,\gamma^\mu\,\psi = \bar\psi_L\,\gamma^\mu\,\psi_L + \bar\psi_R\,\gamma^\mu\,\psi_R. \tag{17.150}$$

The same holds for a current $\bar\psi_2\gamma^\mu\psi_1$ built from two different fields: only the LL and RR pieces survive.

Proof. Insert $\mathbf{1}=P_L+P_R$ on both sides of the gamma matrix and expand into four terms,

$$\bar\psi\gamma^\mu\psi = \bar\psi(P_L+P_R)\gamma^\mu(P_L+P_R)\psi = \sum_{X,Y\in\{L,R\}} \bar\psi\,P_X\,\gamma^\mu\,P_Y\,\psi. \tag{17.151}$$

Consider the diagonal pieces first. Using the intertwining (17.148) to slide the right projector to the left through the single gamma, $\gamma^\mu P_L=P_R\gamma^\mu$, so $P_L\gamma^\mu P_L=P_LP_R\gamma^\mu=0$ because $P_LP_R=0$; likewise $P_R\gamma^\mu P_R=P_RP_L\gamma^\mu=0$. The two diagonal terms vanish identically: a single gamma cannot connect a left projector to a left projector. The off-diagonal terms survive,

$$P_L\gamma^\mu P_R = \gamma^\mu P_RP_R = \gamma^\mu P_R, \qquad P_R\gamma^\mu P_L = \gamma^\mu P_L, \tag{17.152}$$

so that

$$\bar\psi\gamma^\mu\psi = \bar\psi\,P_L\gamma^\mu P_R\,\psi + \bar\psi\,P_R\gamma^\mu P_L\,\psi = (\bar\psi P_L)\gamma^\mu(P_R\psi) + (\bar\psi P_R)\gamma^\mu(P_L\psi). \tag{17.153}$$

Now identify the conjugated chiral fields by (17.149): $\bar\psi P_L=\overline{P_R\psi}=\bar\psi_R$ and $\bar\psi P_R=\bar\psi_L$. Hence the first term is $\bar\psi_R\gamma^\mu\psi_R$ and the second $\bar\psi_L\gamma^\mu\psi_L$, which is (17.150). The two-field case is identical: nothing in the manipulation used $\psi_2=\psi_1$. □

The content of Theorem 17.18 is a selection rule. A QED interaction inserts exactly one factor of γ^μ between a fermion and its conjugate; that single gamma is odd, so it links a right-handed field only to a right-handed field and a left-handed field only to a left-handed field. A left-handed electron entering a vertex leaves as a left-handed electron; chirality flows through the photon coupling unbroken. The mass term $-m\bar{\psi}\psi$ is the *only* place in $\mathcal{L}_{\text{QED}}$ that flips chirality—it is even (no gamma) and so connects L to R, as we saw when the massive Dirac equation forced $\not{p}\,(P_R u) = m\,(P_L u)$ in Section 11.2.5—and in the massless limit it is gone. There, chirality is exactly conserved along every fermion line.

Physical Insight

The whole of the weak interaction's parity violation, and the entire spinor-helicity reorganization of amplitudes, rests on this one line of algebra: a vector vertex is chirality-diagonal because γ^μ anticommutes with γ^5. QED happens to couple to both chiralities with equal strength (it is parity-conserving), so the selection rule does not by itself forbid any process; what it does is *block-diagonalize* every amplitude into independent same-chirality channels. Each channel then carries a definite assignment of helicities to the external particles, and these channels add *incoherently* in the unpolarized cross section—which is exactly why the brute-force spin sum, which secretly performed this decomposition and threw the labels away, produced so simple an answer.

17.6.2 From chirality to the helicities of the external states

To turn Theorem 17.18 into a statement about the spins of the colliding particles we use the massless coincidence of chirality and helicity. For a massless one-particle state, Wigner's classification (Section 3.7, and the massless little group ISO(2) of Section 3.7.3) attaches to it a single Lorentz-invariant number, the helicity $h = \mathbf{J}\cdot\hat{\mathbf{p}}$; there is no spin multiplet, only one state per momentum and sign of h. On the plane-wave spinors of Chapter 11 this abstract helicity is realized concretely: in the limit $m \to 0$ the positive-energy spinors $u_\pm$ become eigenstates of γ^5, with $P_R u_+ = u_+$ (right-handed, $h = +\frac{1}{2}$) and $P_L u_- = u_-$ (left-handed, $h = -\frac{1}{2}$), as shown explicitly in Section 11.2.5. For the antiparticle spinors v the standard relation between the spinor's chirality label and the *physical* helicity of the positron is reversed: the spinor $P_R v$ describes a *left*-helicity positron. The reason is the same one that flips the conjugate in (17.149)—a negative-energy solution read as an outgoing antiparticle carries the opposite handedness to its spinor—and we fix it once here.

Caution

The chirality of a v-spinor is the *opposite* of the physical helicity of the antiparticle it represents. Throughout, "e_L^+" means a positron of physical helicity $-\frac{1}{2}$, described by the spinor v with $P_R v = v$; and "e_R^+" means physical helicity $+\frac{1}{2}$, described by $P_L v = v$. For the electron there is no such flip: e_R^- is described by $P_R u = u$. Keeping this straight is the difference between the right and wrong $\pm\cos\theta$.

Apply this to the electron current $\bar{v}(p_+)\gamma^\mu u(p_-)$ that appears in the $e^+e^- \to \mu^+\mu^-$ amplitude (Eq. (17.62)). By Theorem 17.18 only the same-chirality pieces survive,

$$\bar{v}(p_+)\gamma^\mu u(p_-) = \overline{v_R}(p_+)\,\gamma^\mu\,u_R(p_-) + \overline{v_L}(p_+)\,\gamma^\mu\,u_L(p_-), \tag{17.154}$$

where $u_R = P_R u$ and $\overline{v_R} = \bar{v}P_L$ select $P_R v = v$. The first term needs the electron spinor right-handed *and* the positron spinor right-handed: e_R^- with e_L^+. The second needs both left-handed spinors: e_L^- with e_R^+. In words: *the electron and positron must carry opposite physical helicities.* The configurations $e_R^- e_R^+$ and $e_L^- e_L^+$ give exactly zero.

This is angular momentum conservation in disguise, and it is worth seeing the geometry directly. Take the electron along $+\hat{z}$ and the positron along $-\hat{z}$ in the centre-of-mass frame. For the surviving combination $e_R^- e_L^+$: the electron has $h = +\frac{1}{2}$, so its spin points along $+\hat{z}$, contributing $J_z = +\frac{1}{2}$; the positron has $h = -\frac{1}{2}$, its spin antiparallel to its momentum $-\hat{z}$, i.e. also along $+\hat{z}$, contributing $J_z = +\frac{1}{2}$. The two spins *add*: the initial state has $J_z = +1$ along the beam. The forbidden combination $e_R^- e_R^+$ would have the spins antialigned, $J_z = 0$ along the beam, with total spin projection zero on the collision axis. A single intermediate photon carries spin one and—being on the brink of going on shell in the s-channel, where it is created at rest as a timelike quantum—transmits $J = 1$ with $J_z = \pm 1$ only; the $J_z = 0$ state along the beam cannot be fed to it by two massless fermions. The vertex selection rule and the spin-one nature of the photon are the same statement seen from two sides.

17.6.3 The nonzero helicity amplitudes, computed

We now compute a surviving helicity amplitude in full and show that the squares of the four nonzero ones sum to the unpolarized result of Section 17.3. The amplitude for $e^+e^- \to \mu^+\mu^-$ in Feynman gauge, from Eq. (17.62), is

$$\mathcal{M} = \frac{e^2}{s}\,\big[\bar{v}(p_+)\gamma^\mu u(p_-)\big]\,\big[\bar{u}(k_-)\gamma_\mu v(k_+)\big], \tag{17.155}$$

with all masses set to zero. We label momenta in the CM frame as in Section 17.3: the incoming electron and positron travel along $\pm\hat{z}$ and the outgoing muon makes

angle θ with the electron,

$$p_- = E(1,0,0,1), \quad p_+ = E(1,0,0,-1), \quad k_- = E(1,s_\theta,0,c_\theta), \quad k_+ = E(1,-s_\theta,0,-c_\theta), \tag{17.156}$$

with $E=\sqrt{s}/2$, $c_\theta \equiv \cos\theta$, $s_\theta \equiv \sin\theta$. The needed invariants are

$$p_-\!\cdot\! k_- = p_+\!\cdot\! k_+ = \tfrac{s}{4}(1-c_\theta), \qquad p_-\!\cdot\! k_+ = p_+\!\cdot\! k_- = \tfrac{s}{4}(1+c_\theta), \tag{17.157}$$

equivalently $t=-\frac{s}{2}(1-c_\theta)$ and $u=-\frac{s}{2}(1+c_\theta)$.

Worked Example 17.19 (The amplitude $e_R^- e_L^+ \to \mu_R^- \mu_L^+$)**.** We compute $\overline{|\mathcal{M}|^2}$ restricted to the helicity configuration in which both fermion lines are in the "right-handed" channel of (17.154). For massless fermions a definite helicity is selected by inserting the chirality projector into the spin sum: because P_R annihilates the unwanted (left-handed) solution, the projected "spin sum" is a sum over the single physical state. Concretely, with $\sum_s u^s\bar u^s = \not p$ and $\sum_s v^s\bar v^s = \not p$ at $m=0$ (Theorem 11.12), the right-handed projectors give

$$u_R\,\overline{u_R} = P_R \not p_-\, P_L = P_R \not p_-, \qquad v_R\,\overline{v_R} = P_R \not p_+\, P_L = P_R \not p_+, \tag{17.158}$$

where we used $\overline{P_R\psi} = \bar\psi P_L$ from (17.149) and then $\not p\, P_L = P_R \not p$ followed by $P_R P_R = P_R$.

The electron half of $|\mathcal{M}|^2$ is the tensor $L_e^{\mu\nu} = [\bar v(p_+)\gamma^\mu u(p_-)][\bar v(p_+)\gamma^\nu u(p_-)]^*$. Using $[\bar v\gamma^\nu u]^* = \bar u\gamma^\nu v$ (from $\gamma^0\gamma^{\nu\dagger}\gamma^0=\gamma^\nu$) and writing the product as a trace,

$$L_e^{\mu\nu} = \operatorname{tr}\!\big[\gamma^\mu\,(u_R\overline{u_R})\,\gamma^\nu\,(v_R\overline{v_R})\big] = \operatorname{tr}\!\big[\gamma^\mu\, P_R \not p_-\,\gamma^\nu\, P_R \not p_+\big]. \tag{17.159}$$

Reduce the two projectors to one. Slide the first P_R left through γ^μ ($\gamma^\mu P_R = P_L\gamma^\mu$); then P_L times the odd string $\gamma^\mu \not p_-\gamma^\nu$ becomes that string times P_R on the right, which merges with the second projector, $P_R P_R = P_R$:

$$L_e^{\mu\nu} = \operatorname{tr}\!\big[\gamma^\mu \not p_-\gamma^\nu\, P_R \not p_+\big] = \operatorname{tr}\!\big[\gamma^\mu \not p_-\gamma^\nu \not p_+\, P_L\big], \tag{17.160}$$

the last step using $P_R\not p_+ = \not p_+ P_L$. Now split $P_L = \frac12(1-\gamma^5)$ and use the four-gamma trace (C.178) and the γ^5 trace (C.179):

$$\begin{aligned} L_e^{\mu\nu} &= \tfrac12 \operatorname{tr}[\gamma^\mu \not p_-\gamma^\nu \not p_+] - \tfrac12 \operatorname{tr}[\gamma^\mu \not p_-\gamma^\nu \not p_+\gamma^5] \\ &= 2\big[p_-^\mu p_+^\nu + p_-^\nu p_+^\mu - (p_-\!\cdot\! p_+)\eta^{\mu\nu}\big] + 2i\,\epsilon^{\mu\alpha\nu\beta} p_{-\alpha} p_{+\beta}, \end{aligned} \tag{17.161}$$

where the sign of the antisymmetric piece follows from $\operatorname{tr}[\gamma^\mu \not p_-\gamma^\nu \not p_+\gamma^5] = \operatorname{tr}[\gamma^5\gamma^\mu \not p_-\gamma^\nu \not p_+] = -4i\,\epsilon^{\mu\alpha\nu\beta}p_{-\alpha}p_{+\beta}$ by cyclicity. The muon current $\bar u(k_-)\gamma v(k_+)$ carries u and v in the opposite order to the electron current $\bar v(p_+)\gamma u(p_-)$, so the muon half follows from the electron tensor with $p_-\to k_+$, $p_+\to k_-$ and indices lowered,

$$M_{\mu\nu}^{\mu^\pm} = 2\big[k_{-\mu}k_{+\nu} + k_{-\nu}k_{+\mu} - (k_-\!\cdot\! k_+)\eta_{\mu\nu}\big] + 2i\,\epsilon_{\mu\rho\nu\sigma}k_+^\rho k_-^\sigma. \tag{17.162}$$

The squared amplitude for this configuration is $|\mathcal{M}|^2 = (e^4/s^2)\, L_e^{\mu\nu} M_{\mu\nu}^{\mu^\pm}$. Write each tensor as $2S + 2iA$ with S symmetric and A antisymmetric in $\mu\nu$. In the contraction S-with-A cross terms vanish, leaving $L_e^{\mu\nu} M_{\mu\nu}^{\mu^\pm} = 4\,(S_e{\cdot}S_\mu - A_e{\cdot}A_\mu)$. The symmetric contraction is the same algebra that produced the unpolarized trace; with $a = p_-, b = p_+, c = k_+, d = k_-$,

$$S_e{\cdot}S_\mu = 2\big[(p_-{\cdot}k_+)(p_+{\cdot}k_-) + (p_-{\cdot}k_-)(p_+{\cdot}k_+)\big]. \tag{17.163}$$

For the antisymmetric piece we need the double contraction of two Levi-Civita symbols. With the orientation $\epsilon^{0123} = +1$ of Section A.2.5 (and its forced Lorentzian sign $\epsilon^{\mu\nu\rho\sigma}\epsilon_{\mu\nu\rho\sigma} = -24$),

$$\epsilon^{\mu\nu\alpha\beta}\epsilon_{\mu\nu\gamma\delta} = -2\big(\delta^\alpha_\gamma\delta^\beta_\delta - \delta^\alpha_\delta\delta^\beta_\gamma\big), \tag{17.164}$$

so, after reordering each ϵ to bring its contracted indices adjacent (one transposition each, the two signs cancelling),

$$A_e{\cdot}A_\mu = \epsilon^{\mu\alpha\nu\beta}\epsilon_{\mu\rho\nu\sigma}\, p_{-\alpha}p_{+\beta}k_+^\rho k_-^\sigma = -2\big[(p_-{\cdot}k_+)(p_+{\cdot}k_-) - (p_-{\cdot}k_-)(p_+{\cdot}k_+)\big]. \tag{17.165}$$

Assembling, the two "mixed" products $(p_-{\cdot}k_-)(p_+{\cdot}k_+)$ cancel between $S_e{\cdot}S_\mu$ and $-A_e{\cdot}A_\mu$, doubling the other,

$$L_e^{\mu\nu} M_{\mu\nu}^{\mu^\pm} = 4\,(S_e{\cdot}S_\mu - A_e{\cdot}A_\mu) = 16\,(p_-{\cdot}k_+)(p_+{\cdot}k_-). \tag{17.166}$$

Inserting (17.157), $(p_-{\cdot}k_+)(p_+{\cdot}k_-) = \frac{s^2}{16}(1+c_\theta)^2$, and e^4/s^2 times 16 times this is

$$\boxed{\Big|\mathcal{M}(e_R^- e_L^+ \to \mu_R^- \mu_L^+)\Big|^2 = e^4\,(1+\cos\theta)^2.} \tag{17.167}$$

The amplitude is maximal in the forward direction and vanishes exactly at $\theta = \pi$: a right-handed μ^- emitted straight backward would carry $J_z = -1$, which cannot match the initial $J_z = +1$. The selection rule that killed $e_R^- e_R^+$ at the level of states reappears as a *zero of the amplitude* at the kinematic endpoint where the final J_z would be wrong.

The other three nonzero configurations follow without a new trace. Reflecting all helicities (a parity operation, which QED respects up to the relabelling $\theta \to \theta$, since the vector coupling is parity-even) gives $e_L^- e_R^+ \to \mu_L^- \mu_R^+$ with the identical result $e^4(1+\cos\theta)^2$. The two "crossed" configurations, in which the final pair has the opposite handedness to the initial pair, are obtained by exchanging $k_- \leftrightarrow k_+$ in the muon tensor, i.e. $c_\theta \to -c_\theta$ in (17.167); equivalently the contraction (17.166) becomes $16\,(p_-{\cdot}k_-)(p_+{\cdot}k_+) = s^2(1-c_\theta)^2$. Collecting the four,

$$\begin{aligned}
\Big|\mathcal{M}(e_R^- e_L^+ \to \mu_R^- \mu_L^+)\Big|^2 &= \Big|\mathcal{M}(e_L^- e_R^+ \to \mu_L^- \mu_R^+)\Big|^2 = e^4(1+\cos\theta)^2, \\
\Big|\mathcal{M}(e_R^- e_L^+ \to \mu_L^- \mu_R^+)\Big|^2 &= \Big|\mathcal{M}(e_L^- e_R^+ \to \mu_R^- \mu_L^+)\Big|^2 = e^4(1-\cos\theta)^2,
\end{aligned} \tag{17.168}$$

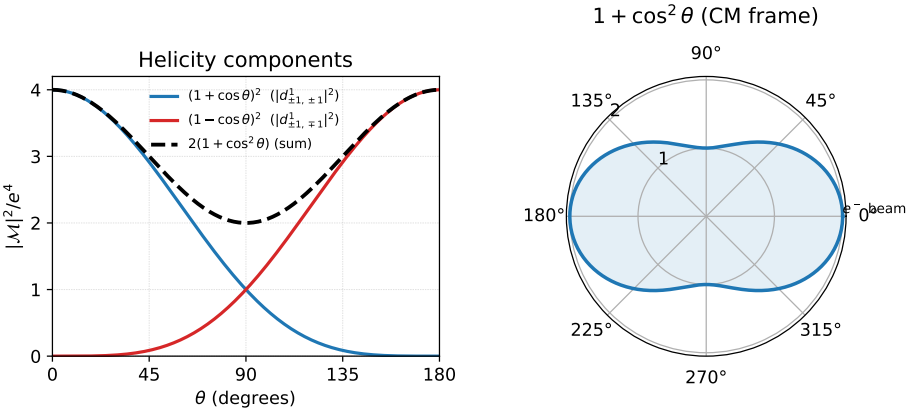

Figure 17.9: Helicity decomposition of $e^+e^- \to \mu^+\mu^-$ in the high-energy limit. *Left:* the two distinct helicity shapes, $(1+\cos\theta)^2$ (forward-peaked, the configurations with initial and final pairs of the same handedness) and $(1-\cos\theta)^2$ (backward-peaked, opposite handedness), and their spin-averaged sum, proportional to $1+\cos^2\theta$. Each shape is the square of a Wigner rotation function, $\left|d^1_{\pm1,\pm1}\right|^2$ and $\left|d^1_{\pm1,\mp1}\right|^2$ respectively. *Right:* the resulting $1+\cos^2\theta$ angular law as a polar diagram in the centre-of-mass frame, with the electron beam along the horizontal. The minimum at $\theta = \frac{\pi}{2}$ never reaches zero because the two lobes overlap there at equal height.

and all other twelve of the sixteen spin assignments vanish identically.

It remains to check that these reproduce Section 17.3. The unpolarized squared amplitude averages over the four initial spin states (factor $\frac{1}{4}$) and sums over the final ones; since only the four entries of (17.168) are nonzero, that sum is just their total,

$$\overline{|\mathcal{M}|^2} = \frac{1}{4}\sum_{\text{spins}} |\mathcal{M}|^2 = \frac{e^4}{4}\left[2(1+\cos\theta)^2 + 2(1-\cos\theta)^2\right] = e^4\,(1+\cos^2\theta), \quad (17.169)$$

using $(1+c_\theta)^2 + (1-c_\theta)^2 = 2(1+c_\theta^2)$. This is exactly the result $\overline{|\mathcal{M}|^2} = e^4(1+\cos^2\theta) = 2e^4(t^2+u^2)/s^2$ of Eq. (17.84), now resolved into its physical constituents: two forward-peaked channels and two backward-peaked ones, adding incoherently. The smooth, forward–backward-symmetric $1+\cos^2\theta$ is the envelope of two oppositely skewed lobes. Figure 17.9 shows the decomposition.

17.6.4 The angular law from angular momentum: Wigner d-functions

The decomposition (17.168) contains more than a check: it reveals that the two angular shapes are *rotation matrix elements*. The process, at the moment the

timelike photon is exchanged, is the transition of a $J=1$ state from one quantization axis to another. The initial e^+e^- pair, in the surviving configurations, is a state of definite total angular momentum $J=1$ with projection $m=\pm1$ along the beam axis $\hat{z}$ (we showed the spins add to $J_z=\pm1$). The final $\mu^+\mu^-$ pair is likewise a $J=1$ state with projection $m'=\pm1$, but along the muon direction $\hat{n}$, which makes angle θ with $\hat{z}$. The amplitude to find a $J=1$ system prepared with projection m on $\hat{z}$ in the state of projection m' on the rotated axis $\hat{n}$ is, by definition, the Wigner rotation function

$$\mathcal{M}(m\to m') \;\propto\; d^{1}_{m'm}(\theta)=\left\langle 1,m'\middle|e^{-i\theta J_y}\middle|1,m\right\rangle, \tag{17.170}$$

the matrix element of a rotation by θ about the y-axis (the axis perpendicular to the scattering plane) in the spin-one representation. Spin-one is forced: a single photon is exchanged, and we are reading off the $J=1$ partial wave that it alone can carry. The $1+\cos^2\theta$ law is then a statement purely about d^{1}, with no reference to gamma matrices at all. We derive d^{1} from scratch.

Worked Example 17.20 (The spin-one rotation matrix and the $1+\cos^2\theta$ law)**.** In the basis $|1,m\rangle$ with $m=+1,0,-1$, the angular-momentum generators of the spin-one representation are (from $J_\pm|1,m\rangle=\sqrt{2-m(m\pm1)}\;|1,m\pm1\rangle$, i.e. $J_\pm$ connecting adjacent levels with coefficient $\sqrt{2}$)

$$J_y=\frac{1}{\sqrt{2}}\begin{pmatrix}0&-i&0\\ i&0&-i\\ 0&i&0\end{pmatrix}. \tag{17.171}$$

A direct multiplication gives $J_y^3=J_y$ (its eigenvalues are $0,\pm1$, so it satisfies its characteristic polynomial $J_y(J_y^2-1)=0$). This single relation lets us exponentiate in closed form. Splitting the series for $e^{-i\theta J_y}$ into even and odd powers and using $J_y^{2k+1}=J_y$, $J_y^{2k}=J_y^2$ for $k\ge1$,

$$d^{1}(\theta)=e^{-i\theta J_y}=\mathbf{1}-i\sin\theta\,J_y-(1-\cos\theta)\,J_y^2, \tag{17.172}$$

the spin-one Rodrigues formula. With

$$J_y^2=\frac{1}{2}\begin{pmatrix}1&0&-1\\ 0&2&0\\ -1&0&1\end{pmatrix}, \tag{17.173}$$

substitution into (17.172) yields the explicit rotation matrix

$$d^{1}(\theta)=\begin{pmatrix}\dfrac{1+\cos\theta}{2}&-\dfrac{\sin\theta}{\sqrt{2}}&\dfrac{1-\cos\theta}{2}\\[2mm] \dfrac{\sin\theta}{\sqrt{2}}&\cos\theta&-\dfrac{\sin\theta}{\sqrt{2}}\\[2mm] \dfrac{1-\cos\theta}{2}&\dfrac{\sin\theta}{\sqrt{2}}&\dfrac{1+\cos\theta}{2}\end{pmatrix}, \tag{17.174}$$

rows and columns ordered $m' = +1, 0, -1$ and $m = +1, 0, -1$. The matrix elements we need are the four corners,

$$d^1_{+1,+1} = d^1_{-1,-1} = \frac{1+\cos\theta}{2}, \qquad d^1_{+1,-1} = d^1_{-1,+1} = \frac{1-\cos\theta}{2}. \tag{17.175}$$

These are precisely the square roots of the helicity shapes (17.168): $|\mathcal{M}|^2 \propto |d^1_{m'm}|^2$, with the proportionality constant $4e^4$ fixed by the overall normalization. The $m = m'$ (J_z-preserving) channels give $(1+\cos\theta)^2$, the $m = -m'$ (J_z-flipping) channels give $(1-\cos\theta)^2$, exactly as found by the trace. Summing the squares over the four allowed corner entries,

$$\sum_{m,m'=\pm1} \left|d^1_{m'm}(\theta)\right|^2 = 2\left(\frac{1+\cos\theta}{2}\right)^2 + 2\left(\frac{1-\cos\theta}{2}\right)^2 = \frac{(1+\cos\theta)^2 + (1-\cos\theta)^2}{2} = 1+\cos^2\theta \tag{17.176}$$

which is the unpolarized angular distribution (17.169). The $m, m' = 0$ entries of d^1 never enter because two massless fermions cannot make a $J_z = 0$ state along their collision axis—the same chirality selection rule, now phrased as the absence of the longitudinal ($m = 0$) component of the exchanged spin-one quantum.

The point of Theorem 17.20 is that the $1 + \cos^2\theta$ angular law is *inevitable*, independent of the dynamical details of QED. Any theory in which two massless spin-$\frac{1}{2}$ particles annihilate through a single spin-one intermediary into two massless spin-$\frac{1}{2}$ particles, with a parity-conserving vector coupling, must produce (17.176): the chirality selection rule restricts the angular momentum to $J = 1$, $|m| = 1$, and rotational invariance then fixes the θ-dependence to the corner elements of d^1. The trace computation of Section 17.3 was a long way of evaluating a rotation matrix. This is why the answer was so simple, and why the same $1 + \cos^2\theta$ recurs for quark-pair production in e^+e^- annihilation, governing the jet-axis distribution and providing one of the cleanest confirmations that quarks carry spin $\frac{1}{2}$.

Physical Insight

Angular distributions are spin spectroscopy. Reading $1 + \cos^2\theta$ off a detector tells you that the produced fermions have spin $\frac{1}{2}$ and were made through a spin-one current; a $\sin^2\theta$ distribution would signal $m = 0$ exchange; an isotropic distribution would signal scalar ($J = 0$) production. The near-threshold filling-in of the dip at $\theta = \frac{\pi}{2}$ in Section 17.3, the $(1-\beta^2)\sin^2\theta$ term, is the reappearance of the $m = 0$ channel once the muon mass lets a chirality-flip vertex contribute: a massive fermion line is no longer chirality-diagonal, the $d^1_{0,\pm1}$ and $d^1_{0,0}$ elements switch on, and the distribution relaxes toward isotropy as $\beta \to 0$. Mass restores the longitudinal polarization that masslessness forbids.

17.6.5 Toward spinor-helicity: the covariant bookkeeping

The computation just carried out has an unmistakable inefficiency. We squared the amplitude, took a trace, contracted two Levi-Civita symbols, and discovered at the end that the answer was the square of a single simple object, $d^{1}_{m'm}(\theta)$. The squaring obscured a clean underlying *amplitude*. Working directly with the massless spinors $u_{\pm}, v_{\pm}$, one finds that the current $\bar{v}(p_+)\gamma^{\mu}u(p_-)$ for definite helicities is itself a short expression—a product of two-component spinor invariants—whose modulus is $\sqrt{2\,p_-\cdot p_+}$ times an angular factor, and whose square reproduces (17.167) with no traces at all. This is the observation that the spinor-helicity formalism systematizes.

In Chapter 58 we will introduce the angle and square brackets $\langle i\,j\rangle$, $[i\,j]$, the Lorentz-invariant contractions of the two-component (Weyl) pieces of massless momenta, with $\langle i\,j\rangle[j\,i] = 2\,p_i\cdot p_j = s_{ij}$. In that language the single nonzero $e^+e^-\to\mu^+\mu^-$ helicity amplitude of Theorem 17.19 becomes, up to a phase, $\mathcal{M}\propto\langle\ \rangle[\ ]/s$ built from the external labels, and the angular shapes $(1\pm\cos\theta)^2$ reappear as $|\langle i\,j\rangle|^4/s^2 = t^2/s^2$ or u^2/s^2—the very Mandelstam ratios our trace produced, now read off without ever squaring. The chirality selection rule of Theorem 17.18 becomes the statement that an amplitude is holomorphic in either the angle or the square brackets but never both for a given external leg; the little-group weight of Section 3.7.3 becomes the scaling $\langle i\,j\rangle\to t_i\langle i\,j\rangle$, $[i\,j]\to t_i^{-1}[i\,j]$ that fixes a three-point amplitude almost completely from helicity alone. Everything in this section—which configurations survive, which vanish, and the d^{1} shapes of those that survive—is encoded in that scaling. The brute-force traces of Sections 17.3 and 17.5 and the helicity skeleton of the present section are the same physics; Chapter 58 is where the bookkeeping is made manifest and the helicity amplitudes become primary objects rather than fragments extracted from a squared sum.

With the dynamical content of tree-level QED now exposed from both the trace side and the helicity side, the next chapter assembles the remaining tree processes that test the structure further—Compton scattering, where gauge invariance and the tree-level Ward identity become indispensable, and the identical-particle interference of Bhabha and Møller scattering (Chapter 18)—before Chapter 19 confronts the loops, the Ward–Takahashi identity in full, and the infrared subtleties that radiative corrections bring. The helicity organization introduced here returns, made covariant, in the spinor-helicity reframing of Chapter 58.

Further reading

The derivation of the QED Feynman rules from the gauge-fixed Lagrangian, and the trace technology for unpolarized cross sections, are treated at the level of

this chapter in Peskin and Schroeder [396] (Chs. 4–5), Schwartz [432] (Chs. 13–14), and Srednicki [454]; Itzykson and Zuber [278] and Weinberg [500] give the canonical and operator-formalism perspectives in full, and Zee [532] the physicist's-shortcut view of the same computations. The $e^+e^- \to \mu^+\mu^-$ process, with its threshold factor and its role as the R-ratio yardstick, is the standard worked example in all of these. Crossing symmetry and the analytic structure of tree amplitudes are developed carefully in Schwartz [432] and, at the level of axiomatic analyticity, in Weinberg [500]. That the perturbative series is only asymptotic is Dyson [168]. The helicity reorganization of Section 17.6—the chirality selection rule, the surviving amplitudes, and their identification with rotation functions—is the entry point to the modern amplitudes program; for the systematic spinor-helicity treatment to which Chapter 58 builds, see Mangano and Parke [334], Parke and Taylor [379] and the textbook account of Elvang and Huang [176].

Chapter 18

Elementary QED Processes

The previous chapter established the QED Feynman rules and carried QED through its first complete calculation, the unpolarized rate for $e^+e^- \to \mu^+\mu^-$ (Section 17.3), where the only subtleties were spin sums over external fermions and the gamma-matrix traces they generate. That process was deliberately spare: a single photon in the s-channel, no external photons, no identical particles, and a single diagram. The elementary processes of quantum electrodynamics that one actually meets in the laboratory — Compton scattering, electron–positron annihilation into photons, and the Møller and Bhabha scattering of charged leptons — are all richer, and each introduces a genuinely new structural feature of gauge-theory amplitudes. This chapter works the full set, and in doing so promotes QED from "the rules yield one number" to "the tree amplitudes of QED form a single, structured, analytically connected family."

Three ideas organize the chapter, and each is something the seed computation could not exhibit. The first is *gauge invariance made operational*: once a real photon appears on an external line, the amplitude carries a polarization vector ϵ_μ, and the consistency of the theory demands that replacing ϵ_μ by the photon momentum k_μ annihilate the amplitude. We prove this tree-level Ward identity $k_\mu \mathcal{M}^\mu = 0$ directly from the rules, and use it to justify the covariant polarization sum $\sum_\lambda \epsilon^*_\mu \epsilon_\nu \to -\eta_{\mu\nu}$ that makes squaring tractable — the tree shadow of the gauge dependence of the photon propagator built in Chapter 13 and of the all-orders Ward–Takahashi identity to come in Chapter 19. The second is *crossing symmetry*: Compton scattering and pair annihilation, or Møller and Bhabha scattering, are not independent computations but boundary values of one rational function on the Mandelstam plane (Section 16.5), continued between physical regions with a definite sign for each crossed fermion. The third is *helicity*: by replacing the unpolarized spin average with explicit spin projectors we expose the chirality-conservation selection rule that governs the high-energy limit and that, in Chapter 58, becomes the starting axiom of the spinor-helicity formalism.

The machinery is imported, not rebuilt. The quantized Dirac field, its mode

expansion, and the spin sums $\sum_s u\bar{u} = \not{p} + m$, $\sum_s v\bar{v} = \not{p} - m$ come from Chapter 11; the photon, its polarizations, and the gauge dependence of its propagator from Chapter 13; the QED Feynman rules, the vertex $-ie\gamma^\mu$, and the crossing prescription from Chapter 17; the reduction of an amplitude to a cross section or decay rate, the Mandelstam variables, and two-body phase space from Chapter 16; and the Clifford algebra together with the gamma-matrix trace identities from Chapter C. We use the mostly-minus metric $\eta_{\mu\nu} = \mathrm{diag}(+,-,-,-)$ and the electron charge $q = -e < 0$ with $D_\mu = \partial_\mu - iqA_\mu$ throughout, as fixed in Chapter A.

The arc is as follows. Section 18.1 dissects a general tree-level QED amplitude, recalls the rules, isolates the three structural novelties, and assembles the unpolarized master formula together with the fundamental trace lemma. Section 18.2 proves the tree Ward identity and converts it into the polarization-sum replacement, the technical key to every process with external photons. Section 18.3 carries Compton scattering all the way to the Klein–Nishina formula and its Thomson limit, the chapter's flagship computation. Section 18.4 formalizes crossing — including the fermion crossing sign — and obtains $e^+e^- \to \gamma\gamma$ by continuation rather than by a fresh calculation. Section 18.5 treats the two four-fermion processes Møller and Bhabha, exhibiting the interference between t- and u- (or s-) channel diagrams and the Fermi statistics that fix its sign, and checks Bhabha against Møller by crossing. Section 18.6 builds the spin projector, derives the helicity-conservation selection rule, and recomputes $e^+e^- \to \mu^+\mu^-$ helicity amplitude by helicity amplitude, recovering the unpolarized result as an incoherent sum and reading off the forward–backward structure. Finally, Section 18.7 draws the threads together: the entire tree-level QED amplitude family is two analytic functions on the Mandelstam plane, made transverse by the Ward identity and block-diagonalized by helicity — exactly the object the loop expansion of Chapter 19, the precision physics of Chapter 20, and the on-shell program of Chapter 58 will inherit.

18.1 Anatomy of a tree-level QED amplitude

We continue QED from Section 17.3, where the electron met the muon for the first time. That computation — the unpolarized cross section for $e^+e^- \to \mu^+\mu^-$ — already exercised the full apparatus of relativistic scattering: a vertex $-ie\gamma^\mu$ at each end of a virtual photon, external spinors $u, \bar{u}, v, \bar{v}$ for the incoming and outgoing fermions, a spin average over the beams, a spin sum over the unobserved final particles, and the collapse of the resulting bilinear products into Dirac traces evaluated against Mandelstam invariants. And yet that process was, structurally, the simplest interacting amplitude QED can offer. A *single* Feynman diagram contributes at leading order, because the electron and the muon are distinct particles that can only annihilate into a timelike photon; there is no second

topology to interfere with the first, and hence no relative sign to fix. No photon appears on an external leg, so the polarization vectors $\varepsilon^\mu, \varepsilon^{*\mu}$ — and the gauge redundancy they carry — never enter. The amplitude was a product of two independent fermion currents tied together by one propagator, and the answer fell out of two essentially decoupled traces. The deceptive ease of Section 17.3 came from the *absence* of every feature that makes a QED amplitude interesting.

This section assembles, once and for all, the shared toolkit the rest of the chapter will draw on, and names the obstacles it must overcome. The plan is deliberately front-loaded: we recall the QED Feynman rules and external-line factors as imported objects (they were built in Chapters 13 and 17 and are not rederived here); we recall the kinematic and cross-section machinery of Chapter 16; we isolate the three structural novelties that distinguish the canonical quartet of tree processes — Compton scattering, pair annihilation, Møller scattering, and Bhabha scattering — from the warm-up of Section 17.3; we name the two principles, the tree-level Ward identity and crossing symmetry, that will tame those novelties; and we establish the chapter-wide *master formula* for the spin- and polarization-averaged squared amplitude, deriving it carefully from the cross-section formula of Chapter 16 so that every averaging factor is accounted for and never merely asserted. The result handed forward is twofold: this master formula, and a sharp statement of the one problem it cannot by itself resolve — the photon polarization sum — which the next section settles with the Ward identity.

18.1.1 The QED Feynman rules, recalled

Quantum electrodynamics is the theory of one Dirac field ψ of mass m and charge $-e$ (with $e > 0$) coupled minimally to the abelian gauge field A_μ,

$$\mathcal{L}_{\text{QED}} = \bar{\psi}\,(i\not{D} - m)\,\psi - \tfrac{1}{4}F_{\mu\nu}F^{\mu\nu}, \qquad D_\mu = \partial_\mu + ieA_\mu, \tag{18.1}$$

the model frozen for QED, with $\alpha \equiv e^2/4\pi$. Its momentum-space Feynman rules were derived in Section 17.1 from the path integral over Eq. (18.1) (the photon sector and the polarization technology coming from Chapter 13); throughout this chapter we work in Feynman gauge $\xi = 1$, the default for explicit computation, and quote gamma-matrix trace identities from Chapter C. We recall the rules rather than rebuild them.

The single interaction vertex is the minimal coupling read off from $i\mathcal{L}_{\text{int}} = -ie\,\bar{\psi}\not{A}\psi$,

$$\text{electron–photon vertex} \;=\; -\,ie\,\gamma^\mu, \tag{18.2}$$

exactly the rule Eq. (17.10) (equivalently Eq. (13.211)); the index μ is contracted into the attached photon line, and the matrix γ^μ sits on the fermion line in the order dictated by reading the line against the arrow. The two internal lines carry

Table 18.1: External-line factors of QED, imported from Section 17.1. Each external leg of a diagram contributes the indicated factor; the spinor momentum and spin (or photon momentum and polarization) are those of the physical particle on that leg. Arrows on fermion lines point along the flow of (negative) charge, i.e. along particle number.

External particle	State	Factor
Incoming fermion e^-	$\lvert p, s\rangle$	$u^s(p)$
Outgoing fermion e^-	$\langle p, s\rvert$	$\bar{u}^s(p)$
Incoming antifermion e^+	$\lvert p, s\rangle$	$\bar{v}^s(p)$
Outgoing antifermion e^+	$\langle p, s\rvert$	$v^s(p)$
Incoming photon γ	$\lvert k, \lambda\rangle$	$\varepsilon^\mu_\lambda(k)$
Outgoing photon γ	$\langle k, \lambda\rvert$	$\varepsilon^{*\mu}_\lambda(k)$

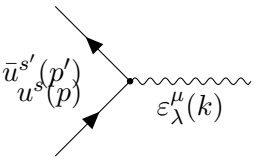

Figure 18.1: The single QED vertex Eq. (18.2), $-ie\gamma^\mu$, with representative external-line factors attached. Reading the fermion line *against* its arrow (from the outgoing $\bar{u}^{s'}(p')$ to the incoming $u^s(p)$) fixes the matrix order: the amplitude fragment is $\bar{u}^{s'}(p')\,(-ie\gamma^\mu)\,u^s(p)\,\varepsilon^\mu_\lambda(k)$. Every diagram in this chapter is built by gluing copies of this vertex with the propagators Eq. (18.3) and Eq. (18.4).

the propagators

$$\text{electron line of momentum } p: \quad \frac{i(\not{p}+m)}{p^2-m^2+i\varepsilon} = \frac{i}{\not{p}-m+i\varepsilon}, \tag{18.3}$$

$$\text{photon line of momentum } k\ (\xi=1): \quad \frac{-i\,\eta_{\mu\nu}}{k^2+i\varepsilon}, \tag{18.4}$$

the Dirac propagator of Theorem 11.40 and the Feynman-gauge photon propagator of Eq. (13.135). Finally, each external leg contributes a wavefunction factor according to whether it is an incoming or outgoing fermion, antifermion, or photon. These external-line factors, collected in Table 18.1, are the bridge between the abstract S-matrix element and the spinor/polarization data of the physical asymptotic states; they were fixed in Chapters 11 and 13 and assembled into the QED rules in Section 17.1.

Two conventions deserve emphasis because they are the seeds of the sign bookkeeping to come. First, a fermion line is read *against* the direction of its charge-flow arrow, so that the matrices line up in the order $\bar{u}\cdots u$ (or $\bar{v}\cdots$, $\cdots v$) as one moves from the head of the arrow to its tail; Fig. 18.1 shows the

ordering on the elementary vertex. Second, the overall sign of a diagram includes a factor (-1) for every closed fermion loop and, crucially for this chapter, a relative minus sign between diagrams that differ by the exchange of two external identical fermions. That second rule is dormant in Section 17.3 — the four external fermions there are two electrons and two muons, all distinguishable — but it is decisive for Møller and Bhabha scattering, and we return to it in Section 18.1.2.

18.1.2 Three structural novelties

The four processes of this chapter are not chosen at random. Together they exhaust, in their simplest realizations, the three structural features that a tree-level QED amplitude can possess beyond the bare current×propagator×current of Section 17.3. Naming them now lets us treat each as a recurring theme rather than a fresh surprise.

Novelty 1: external photons. Compton scattering $e^-\gamma \to e^-\gamma$ and pair annihilation $e^+e^- \to \gamma\gamma$ put real photons on external legs. Each such leg carries a polarization vector $\varepsilon^{\mu}_{\lambda}(k)$ or its conjugate $\varepsilon^{*\mu}_{\lambda}(k)$ (Table 18.1), and a physical photon has only the two transverse polarizations established in Section 13.3.3. The amplitude is therefore a Lorentz vector (or tensor) contracted into these polarization data: writing the dependence on a single external photon explicitly,

$$\mathcal{M} = \varepsilon_{\mu}(k)\,\mathcal{M}^{\mu}, \tag{18.5}$$

where $\mathcal{M}^{\mu}$ collects everything but that polarization vector. The trouble is that $\varepsilon^{\mu}_{\lambda}(k)$ is not a Lorentz-covariant object on its own — a choice of two transverse polarizations singles out a frame — and is moreover defined only up to the gauge freedom $\varepsilon^{\mu}_{\lambda}(k) \to \varepsilon^{\mu}_{\lambda}(k) + c\,k^{\mu}$, which leaves the physical photon unchanged. An honest squared amplitude can depend only on the gauge-invariant content of $\mathcal{M}^{\mu}$. This is the photon polarization-sum problem, and it is the first thing the chapter must solve.

Novelty 2: several interfering diagrams. Once more than one diagram contributes to a process at leading order, the amplitudes *add coherently*: $\mathcal{M} = \mathcal{M}_1 + \mathcal{M}_2 + \cdots$, and $|\mathcal{M}|^2$ contains not only $|\mathcal{M}_1|^2 + |\mathcal{M}_2|^2$ but the cross terms $2\,\mathrm{Re}(\mathcal{M}_1\mathcal{M}_2^*)$. Every process in this chapter has two diagrams. For Compton the electron can absorb the incoming photon before or after emitting the outgoing one (an s-channel and a u-channel topology on the single fermion line). For annihilation the two final photons can be emitted in either order. For Møller and Bhabha the two diagrams correspond to the two ways the exchanged photon can connect the external legs. The interference terms are not a correction to be neglected; they carry genuine physics (the angular dependence of Møller

scattering, for instance, is dominated by interference) and they are where the relative-sign rule bites.

Novelty 3: identical particles and their signs. Møller scattering $e^-e^- \to e^-e^-$ has two identical fermions in the initial state and two in the final state; Bhabha scattering $e^+e^- \to e^+e^-$ has a particle–antiparticle pair that the annihilation channel can route through. When two external legs carry identical fermions, the two diagrams related by exchanging them differ by an overall minus sign, the operational fingerprint of Fermi statistics — the same antisymmetry that gave the Dirac propagator its relative minus and forced the spin-statistics connection. Concretely, Møller's amplitude is $\mathcal{M} = \mathcal{M}_t - \mathcal{M}_u$ rather than $\mathcal{M}_t + \mathcal{M}_u$, and the squared amplitude carries a *negative* interference term $-2\,\mathrm{Re}(\mathcal{M}_t\mathcal{M}_u^*)$. For identical *bosons* — the two photons of pair annihilation — the corresponding statement is a relative plus sign and a final-state symmetry factor $\frac{1}{2}$ in the total cross section, to avoid double-counting the indistinguishable two-photon configurations (the symmetry factor of Theorem 16.18). Getting these signs right is not optional: a wrong relative sign changes the predicted angular distribution qualitatively.

These three novelties are the entire structural difference between Section 17.3 and the rest of QED at tree level. Everything else — the vertex, the propagators, the trace technology — is shared with the warm-up.

18.1.3 Two organizing principles

The novelties would be a bookkeeping nightmare were it not for two principles that impose order on them. We introduce both here as working tools and use them throughout the chapter; each is promoted to an exact, all-orders statement later in QED.

Gauge invariance: the tree-level Ward identity. The redundancy that troubles the external-photon amplitude Eq. (18.5) is exactly the redundancy that constrains it. The statement, proved in the next section, is that any tree amplitude with an external photon obeys

$$k_\mu \mathcal{M}^\mu = 0, \tag{18.6}$$

the *tree-level Ward identity*: replacing a physical photon polarization by its own momentum annihilates the amplitude. Physically, Eq. (18.6) says the amplitude is insensitive to the unphysical, longitudinal part of the photon's would-be polarization — it is the amplitude-level expression of the gauge invariance of Eq. (18.1). Its immediate payoff, also developed next, is that the sum over the two physical polarizations may be replaced inside a squared amplitude by the

manifestly covariant

$$\sum_{\lambda=1,2} \varepsilon_\lambda^\mu(k)\, \varepsilon_\lambda^{*\nu}(k) \;\longrightarrow\; -\eta^{\mu\nu}, \tag{18.7}$$

the replacement first met for internal-line gauge cancellations in Eq. (13.149), now licensed for external real photons. The longitudinal and timelike contributions that Eq. (18.7) silently adds back are killed by Eq. (18.6); that is precisely why the covariant sum is permitted. The all-orders generalization of Eq. (18.6) is the Ward–Takahashi identity proved in Chapter 19.

Analyticity: crossing symmetry. The second principle ties distinct processes together. An amplitude $\mathcal{M}(s,t,u)$, computed as a function of the Mandelstam invariants, is a single analytic function whose various physical channels describe different reactions obtained by moving particles between the initial and final states and replacing them by antiparticles — crossing. The geometry that crossing acts on, the Mandelstam plane with its three physical wedges, was laid out in Section 16.5.5; here we put it to work. Crossing makes pair annihilation $e^+e^- \to \gamma\gamma$ an analytic continuation of Compton scattering $e^-\gamma \to e^-\gamma$, and Bhabha scattering $e^+e^- \to e^+e^-$ a continuation of Møller scattering $e^-e^- \to e^-e^-$. Once one member of each pair is computed in full, its partner follows by a substitution of invariants and external spinors, rather than a fresh diagrammatic calculation — a labor-saving device that is also a nontrivial check, since the two routes to a crossed amplitude must agree. We state and use crossing at tree level in this chapter; its foundation is the analyticity of the amplitude in the cut s- and t-planes.

18.1.4 Kinematics and the cross-section wrapper

All four processes are $2 \to 2$ reactions, so the kinematic machinery of Chapter 16 applies verbatim. We label the process $1 + 2 \to 3 + 4$ and use the Mandelstam invariants of Theorem 16.20,

$$s = (p_1 + p_2)^2, \qquad t = (p_1 - p_3)^2, \qquad u = (p_1 - p_4)^2, \tag{18.8}$$

constrained by Eq. (16.121),

$$s + t + u = \sum_{i=1}^{4} m_i^2. \tag{18.9}$$

Two of the three are independent; we trade u for s, t via Eq. (18.9) at will. The masses entering the sum are those of the four external particles: for Compton and annihilation one or two of them are the photon's zero, while for Møller and Bhabha all four equal the electron mass m, so that $s + t + u = 4m^2$ and, in the high-energy limit $s \gg m^2$, $s + t + u \to 0$.

The dynamics is packaged into a single observable wrapper. The master cross-section formula of Theorem 16.18 gives the differential cross section in terms of the invariant amplitude $\mathcal{M}$ for definite external states; specialized to $2 \to 2$ in the centre-of-mass (CM) frame, Theorem 16.23 reads

$$\left.\frac{\mathrm{d}\sigma}{\mathrm{d}\Omega}\right|_{\mathrm{CM}} = \frac{1}{64\pi^2 s}\,\frac{|\mathbf{p}_f|}{|\mathbf{p}_i|}\,|\mathcal{M}|^2\,, \tag{18.10}$$

with $|\mathbf{p}_i|\,, |\mathbf{p}_f|$ the CM magnitudes of the initial and final three-momenta, and the equivalent fully invariant form Eq. (16.147),

$$\frac{\mathrm{d}\sigma}{\mathrm{d}t} = \frac{|\mathcal{M}|^2}{16\pi\,\lambda(s, m_1^2, m_2^2)}, \tag{18.11}$$

λ being the Källén triangle function. These formulas were derived for a *fixed* choice of all external spins and polarizations: $\mathcal{M}$ in Eq. (18.10)–Eq. (18.11) is the amplitude for definite spin labels on every leg. Converting them into the quantities a real experiment measures — unpolarized beams, spin-blind detectors — is the content of the master formula, to which we now turn.

18.1.5 The averaged squared amplitude: the chapter's master formula

A typical scattering experiment neither prepares the spins of its incoming particles nor measures the spins of its outgoing ones. The cross sections quoted in this chapter are therefore averaged over the initial spin and polarization states and summed over the final ones. We make the averaging precise, because the factors it introduces are part of every numerical answer and a frequent source of error.

Why average probabilities, not amplitudes. An unpolarized beam is not a coherent superposition of spin states with definite relative phases; it is an *incoherent statistical mixture*, described by a density matrix proportional to the identity on the spin space, $\rho_a = \frac{1}{N_a}\,\mathbf{1}_{N_a}$ for incoming particle a with N_a physical spin/polarization states. The probability of a transition from such a mixture is the trace of ρ against the transition operator, which for diagonal ρ is the *average over initial states of the probabilities*, not of the amplitudes. Averaging amplitudes would manufacture spurious interference between physically distinct, orthogonal initial states. Likewise the inclusive rate into an unmeasured final spin is the *sum over final states of the probabilities*, because distinct final spin configurations are orthogonal members of the final Hilbert space and their contributions to the cross section add. Both operations act on $|\mathcal{M}|^2$, never on $\mathcal{M}$.

Definition 18.1 (Averaged squared amplitude)**.** For a process with initial particles $1, 2$ carrying N_1, N_2 physical spin/polarization states, the spin- and

polarization-averaged squared amplitude is

$$\overline{|\mathcal{M}|^2} \equiv \frac{1}{N_1 N_2} \sum_{\text{spins/pol}} |\mathcal{M}|^2 , \tag{18.12}$$

where the sum runs over the spin and polarization labels of *all* external particles, initial and final, and the prefactor $1/(N_1 N_2)$ averages over (only) the initial ones. A spin-$\frac{1}{2}$ fermion or antifermion contributes $N = 2$; a physical photon contributes $N = 2$ (its two transverse polarizations).

The master formula of the chapter is now the statement that the unpolarized cross section is obtained from Eq. (18.10) by the single replacement $|\mathcal{M}|^2 \to \overline{|\mathcal{M}|^2}$.

Proposition 18.2 (Unpolarized master formula)**.** *The unpolarized differential cross section for a $2 \to 2$ QED process in the CM frame is*

$$\left.\frac{\mathrm{d}\sigma}{\mathrm{d}\Omega}\right|_{\text{CM}} = \frac{1}{64\pi^2 s} \frac{|\mathbf{p}_f|}{|\mathbf{p}_i|} \overline{|\mathcal{M}|^2}, \qquad \frac{\mathrm{d}\sigma}{\mathrm{d}t} = \frac{\overline{|\mathcal{M}|^2}}{16\pi\, \lambda(s, m_1^2, m_2^2)}, \tag{18.13}$$

with $\overline{|\mathcal{M}|^2}$ the averaged squared amplitude of Theorem 18.1. For a final state of indistinguishable particles a symmetry factor $\frac{1}{2}$ multiplies the total *cross section (one per pair of identical final particles), per Theorem 16.18.*

Proof. Fix, for the moment, definite spin/polarization labels on all four external legs, collected as α (initial) and β (final). For this definite choice the amplitude is $\mathcal{M}_{\beta\alpha}$, and Theorem 16.23 applies as written: the differential cross section to produce the specific final configuration β from the specific initial configuration α is

$$\left.\frac{\mathrm{d}\sigma_{\beta\alpha}}{\mathrm{d}\Omega}\right|_{\text{CM}} = \frac{1}{64\pi^2 s} \frac{|\mathbf{p}_f|}{|\mathbf{p}_i|} |\mathcal{M}_{\beta\alpha}|^2 . \tag{18.14}$$

The kinematic prefactor $\frac{1}{64\pi^2 s} |\mathbf{p}_f| / |\mathbf{p}_i|$ depends only on the momenta, not on the spins, because the flux factor and the two-body phase space of Chapter 16 are built from on-shell kinematics alone (the separation of dynamics from kinematics noted at Section 16.4.5); it therefore factors out of every spin operation below.

A detector blind to final spins counts every distinct final configuration β, and these are orthogonal asymptotic states, so the rates add:

$$\left.\frac{\mathrm{d}\sigma_{\alpha}}{\mathrm{d}\Omega}\right|_{\text{CM}} = \sum_{\beta} \left.\frac{\mathrm{d}\sigma_{\beta\alpha}}{\mathrm{d}\Omega}\right|_{\text{CM}} = \frac{1}{64\pi^2 s} \frac{|\mathbf{p}_f|}{|\mathbf{p}_i|} \sum_{\beta} |\mathcal{M}_{\beta\alpha}|^2 . \tag{18.15}$$

The incoming beams are unpolarized: each initial configuration $\alpha = (s_1, s_2)$ occurs with equal probability $1/(N_1 N_2)$, and the measured cross section is the statistical average of Eq. (18.15) over α,

$$\left.\frac{\mathrm{d}\sigma}{\mathrm{d}\Omega}\right|_{\text{CM}} = \frac{1}{N_1 N_2} \sum_{\alpha} \left.\frac{\mathrm{d}\sigma_{\alpha}}{\mathrm{d}\Omega}\right|_{\text{CM}} = \frac{1}{64\pi^2 s} \frac{|\mathbf{p}_f|}{|\mathbf{p}_i|} \frac{1}{N_1 N_2} \sum_{\alpha,\beta} |\mathcal{M}_{\beta\alpha}|^2 . \tag{18.16}$$

The double sum over α and β is exactly the sum over the spin/polarization labels of all external particles, and the prefactor $1/(N_1 N_2)$ is exactly the initial-state average; comparison with Eq. (18.12) identifies the right-hand factor as $\overline{|\mathcal{M}|^2}$, giving the first equality in Eq. (18.13). The invariant form follows identically from Theorem 16.24, whose prefactor is again spin-independent. The final-state symmetry factor is inherited unchanged from Theorem 16.18: it corrects the phase-space integration for the overcounting of indistinguishable final configurations and is a property of the kinematics, independent of the spin averaging carried out here. □

For every process in this chapter $N_1 = N_2 = 2$, so the averaging prefactor is uniformly $\frac{1}{4}$. It is worth noting *why* the four cases nonetheless differ: in Møller and Bhabha the factor $\frac{1}{4}$ averages over the four spin states of two incoming fermions, while in Compton it averages over the two electron spins *and* the two photon polarizations, and in annihilation over the two spins of the e^+e^- pair. The photon's appearance in the count for Compton and annihilation is the place where Theorem 18.1 meets the polarization-sum problem of Section 18.1.2: the sum over a photon's two physical polarizations is not, on its face, a covariant object, and reducing it to one is the business of the next section.

18.1.6 From spin sums to Dirac traces

The averaged squared amplitude Eq. (18.12) still contains an explicit sum over the spins of every external fermion, with the spinors u, v appearing bilinearly. The technology that evaluates such sums — the engine behind Section 17.3 and behind every fermion computation to come — is the pair of completeness relations of Theorem 11.12,

$$\sum_{s=1,2} u^s(p)\,\bar{u}^s(p) = \not{p} + m, \qquad \sum_{s=1,2} v^s(p)\,\bar{v}^s(p) = \not{p} - m, \tag{18.17}$$

the spin sums Eq. (11.73). Their effect is structural: a spin sum that an experiment forces on us, Eq. (18.17) converts into a *matrix* — the on-shell projector onto positive-energy electron (or positron) states — which then sits inside a product of gamma matrices. A product of such matrices, traced, is a number computable from the Mandelstam invariants by the identities of Chapter C. The entire spin sum thereby collapses into Dirac traces. We make the collapse precise once, in full generality, in the following worked example; the rest of the chapter applies it.

Worked Example 18.3 (The fundamental trace identity for a fermion line)**.** Every QED amplitude is, schematically, a product of *fermion lines*: each open fermion line contributes a bilinear $\bar{u}(p')\,\Gamma\,u(p)$, where Γ is a string of gamma matrices (and propagator numerators) assembled along the line, and p, p' are

the spinor momenta at its ends. We show that summing $|\bar{u}(p')\Gamma u(p)|^2$ over both spins turns it into a single Dirac trace.

Step 1: the conjugate bilinear. A bilinear $\bar{u}(p')\Gamma u(p)$ is a 1×1 matrix, i.e. an ordinary complex number, so its complex conjugate equals its Hermitian conjugate:

$$\big[\bar{u}(p')\,\Gamma\,u(p)\big]^{*} = \big[\bar{u}(p')\,\Gamma\,u(p)\big]^{\dagger} = u^{\dagger}(p)\,\Gamma^{\dagger}\,\bar{u}^{\,\dagger}(p'). \tag{18.18}$$

Now $\bar{u}^{\,\dagger}(p') = (u^{\dagger}(p')\gamma^0)^{\dagger} = \gamma^{0\dagger}u(p') = \gamma^0 u(p')$, using $\gamma^{0\dagger}=\gamma^0$. Insert $\mathbf{1}=\gamma^0\gamma^0$ before $\Gamma^{\dagger}$:

$$\big[\bar{u}(p')\,\Gamma\,u(p)\big]^{*} = u^{\dagger}(p)\,\gamma^0\,(\gamma^0\Gamma^{\dagger}\gamma^0)\,u(p') = \bar{u}(p)\,\bar{\Gamma}\,u(p'), \qquad \bar{\Gamma}\equiv\gamma^0\Gamma^{\dagger}\gamma^0, \tag{18.19}$$

where $\bar{u}(p)=u^{\dagger}(p)\gamma^0$ in the last step. The barred matrix $\bar{\Gamma}$ is the conjugate string; the conjugation simply runs the line backwards.

Step 2: barring an explicit string. For a single gamma matrix the conjugation property $\gamma^0\gamma^{\mu\dagger}\gamma^0=\gamma^{\mu}$ of Section C.4 gives $\bar{\gamma^{\mu}}=\gamma^{\mu}$. For a product, $\bar{\Gamma}=\gamma^0\Gamma^{\dagger}\gamma^0$ distributes by inserting $\gamma^0\gamma^0$ between each pair of factors, so the order reverses:

$$\overline{\gamma^{\mu_1}\gamma^{\mu_2}\cdots\gamma^{\mu_n}} = \gamma^{\mu_n}\cdots\gamma^{\mu_2}\gamma^{\mu_1}. \tag{18.20}$$

A photon propagator numerator $\eta_{\mu\nu}$ or an external ε^{μ} is a c-number and passes through the conjugation untouched (with $\varepsilon^{\mu}\to\varepsilon^{*\mu}$). Thus $\bar{\Gamma}$ is obtained from Γ by writing the gamma string in reverse order and complex-conjugating any polarization vectors — nothing more.

Step 3: sum over spins. Combining Eq. (18.19) with the original bilinear and summing over the spins s of p and s' of p',

$$\begin{aligned}\sum_{s,s'}\big|\bar{u}^{s'}(p')\,\Gamma\,u^{s}(p)\big|^2 &= \sum_{s,s'}\big[\bar{u}^{s'}(p')\,\Gamma\,u^{s}(p)\big]\big[\bar{u}^{s}(p)\,\bar{\Gamma}\,u^{s'}(p')\big]\\ &= \sum_{s,s'}\bar{u}^{s'}_{a}(p')\,\Gamma_{ab}\,u^{s}_{b}(p)\,\bar{u}^{s}_{c}(p)\,\bar{\Gamma}_{cd}\,u^{s'}_{d}(p'),\end{aligned} \tag{18.21}$$

where a,b,c,d are Dirac indices and repeated indices are summed. The two spin sums act on adjacent spinor pairs. Using Eq. (18.17) for the p sum, $\sum_s u^s_b(p)\bar{u}^s_c(p)=(\not{p}+m)_{bc}$, and for the p' sum, $\sum_{s'}u^{s'}_d(p')\bar{u}^{s'}_a(p')=(\not{p}'+m')_{da}$, equation Eq. (18.21) becomes

$$\sum_{s,s'}\big|\bar{u}^{s'}(p')\,\Gamma\,u^{s}(p)\big|^2 = (\not{p}'+m')_{da}\,\Gamma_{ab}\,(\not{p}+m)_{bc}\,\bar{\Gamma}_{cd} = \mathrm{tr}\big[(\not{p}'+m')\,\Gamma\,(\not{p}+m)\,\bar{\Gamma}\big], \tag{18.22}$$

the chain of index contractions $d\to a\to b\to c\to d$ closing into a trace. This is the fundamental identity: *a spin-summed fermion-line bilinear, squared, is the Dirac trace of its two on-shell projectors with the line's matrix string and its barred conjugate inserted between them.* For an antiparticle line one uses $\sum v\bar{v}=\not{p}-m$ in place of $\not{p}+m$ at the corresponding end, the only change being the sign of the mass term in that projector.

Table 18.2: The structural anatomy of the chapter's four tree processes. "Diagrams" counts the leading-order topologies; "ext. γ" the number of external photons (hence whether the polarization-sum problem and the tree Ward identity are needed); "rel. sign" the relative sign between the two diagrams set by statistics; "crossing" the partner process each is the analytic continuation of.

Process	Reaction	Diagrams	ext. γ	rel. sign	Crossing partner
Compton	$e^-\gamma \to e^-\gamma$	2 (s,u)	2	+ (Bose)	— (the parent)
Pair annihilation	$e^+e^- \to \gamma\gamma$	2 (t,u)	2	+ (Bose)	Compton
Møller	$e^-e^- \to e^-e^-$	2 (t,u)	0	− (Fermi)	— (the parent)
Bhabha	$e^+e^- \to e^+e^-$	2 (s,t)	0	− (Fermi)	Møller

The lemma Eq. (18.22) is the organizing computation of the chapter. It explains, in retrospect, the structure of Section 17.3: that process has *two* disjoint fermion lines — the electron line $\bar{v}(p_2)\gamma^\mu u(p_1)$ and the muon line $\bar{u}(p_3)\gamma^\nu v(p_4)$, joined only by the photon propagator's $\eta_{\mu\nu}$ — so its averaged squared amplitude factorizes into a *product of two independent traces*, one per line, contracted through the propagator indices. That factorization is exactly why the warm-up was tractable. The processes ahead complicate this template in the three ways catalogued in Section 18.1.2: Compton has a single fermion line but with a photon-propagator numerator $\not{k}$ inserted in the middle of Γ (so the trace is of a longer string); annihilation likewise; and Møller and Bhabha have two interfering diagrams, so $|\mathcal{M}|^2 = |\mathcal{M}_1 \pm \mathcal{M}_2|^2$ produces, besides two "direct" traces of the form Eq. (18.22), an *interference* trace in which the matrices of one diagram and the barred matrices of the other are threaded onto the *same* fermion lines, yielding a single long trace rather than a product. The trace identities of Section C.6 — the vanishing of odd traces (Theorem C.53), $\mathrm{tr}(\gamma^\mu\gamma^\nu) = 4\eta^{\mu\nu}$ (Eq. (C.152)), the four-gamma trace (Eq. (C.157)), and the recursion (Theorem C.54) — reduce every such trace to a polynomial in the Mandelstam invariants, and that polynomial, divided by the averaging factor and fed into Theorem 18.2, is the cross section.

18.1.7 Roadmap: which process exercises which feature

Table 18.2 records how the canonical quartet distributes the three novelties and the two principles across the chapter, so that each computation can be read as the addition of one new ingredient to the previous one. Compton is treated first because it isolates the external-photon problem with a single fermion line and the minimal pair of diagrams; pair annihilation then follows almost for free by crossing. Møller introduces the identical-fermion sign with no external photons; Bhabha follows from Møller by crossing, additionally exhibiting the interference between an annihilation channel and a scattering channel.

With the rules recalled (Section 18.1.1), the novelties named (Section 18.1.2),

the principles previewed (Section 18.1.3), the kinematic wrapper in place (Section 18.1.4), the master formula Theorem 18.2 established, and the trace engine Theorem 18.3 loaded, the shared toolkit is complete. One ingredient remains unjustified: the covariant photon polarization sum Eq. (18.7), which Theorem 18.1 demands the moment a real photon sits on an external leg. The sum runs over only the two physical, transverse polarizations of Section 13.3.3, and that restricted set is not manifestly Lorentz covariant; replacing it by $-\eta^{\mu\nu}$ silently reinstates the longitudinal and timelike states, which is legitimate only if the amplitude is blind to them — that is, only if $k_\mu \mathcal{M}^\mu = 0$. Proving that tree-level Ward identity, and with it converting the polarization-sum problem into the simple covariant rule Eq. (18.7), is the first organizing task of the chapter and the subject of the next section.

18.2 The tree-level Ward identity and photon polarization sums

The previous section assembled the toolkit and then handed us an unfinished obligation. The master formula for a spin- and polarization-averaged squared amplitude (Eq. (18.13)) instructed us, for every external photon, to sum the squared amplitude over the two physical polarization states; and we anticipated that this sum could be carried out covariantly, by the replacement $\sum_\lambda \epsilon_\lambda^\mu \epsilon_\lambda^{*\nu} \to -\eta^{\mu\nu}$, which trades an awkward, frame-dependent, two-term sum over transverse vectors for a single Lorentz tensor. We did not yet have the right to make that replacement. The replacement is licensed precisely when the amplitude, stripped of the photon's polarization vector and written as $\mathcal{M} = \epsilon_\mu(k)\mathcal{M}^\mu$, obeys the transversality condition $k_\mu \mathcal{M}^\mu = 0$. This condition is the *tree-level Ward identity*, and supplying its proof is the business of this section. It is the chapter's first organizing principle: once established, it is the single fact that makes every external-photon computation in this chapter — Compton scattering and pair annihilation above all — tractable, and it is the tree-level shadow of the all-orders Ward–Takahashi identity that Chapter 19 will erect on the full quantum theory.

The statement is not merely a computational convenience; it is the on-shell trace of gauge invariance. Recall from Section 8.1 that the photon enters QED only through the covariant derivative, and that the freedom $A_\mu \to A_\mu + \frac{1}{e}\partial_\mu \alpha$ is a redundancy of description carrying no physical content. In momentum space a gauge transformation shifts a photon's wavefunction by a multiple of its own momentum, $\epsilon_\mu(k) \to \epsilon_\mu(k) + c\, k_\mu$. An amplitude that depends on the physics and not on the bookkeeping must be blind to such a shift: $\mathcal{M} = \epsilon_\mu \mathcal{M}^\mu$ must not change when $\epsilon_\mu \to \epsilon_\mu + c\, k_\mu$, which is exactly $k_\mu \mathcal{M}^\mu = 0$. The Ward identity is therefore the demand that gauge redundancy not leak into observables, enforced amplitude by amplitude. We will prove it directly from the Feynman rules and the Dirac equation, then use it to make the polarization-sum replacement exact

at tree level.

Throughout, we use the QED vertex $-ie\gamma^\mu$ and the fermion propagator $i(\not{q}+m)/(q^2-m^2+i\varepsilon)$ established in Chapter 17, with the electron carrying charge $-e$, $e>0$, in the conventions fixed at the head of this chapter. Photons couple at tree level only to the fermion line — there is no elementary photon self-coupling in an abelian theory — so every external photon in a tree diagram attaches, at some vertex, to a continuous fermion line. That single structural fact is what the proof exploits.

18.2.1 The stripped amplitude and the statement of the identity

We first make precise the object whose transversality we will prove.

Definition 18.4 (Stripped photon amplitude)**.** Let $\mathcal{M}$ be a tree amplitude containing at least one external photon of on-shell momentum k ($k^2=0$) and polarization vector $\epsilon_\mu(k)$. Writing the dependence on that polarization explicitly,

$$\mathcal{M} = \epsilon_\mu(k)\,\mathcal{M}^\mu(k), \tag{18.23}$$

the Lorentz vector $\mathcal{M}^\mu(k)$ — the amplitude with the photon's polarization vector removed but its momentum and all other external data retained — is the *stripped amplitude* for that photon. For an outgoing photon one strips $\epsilon^*_\mu(k)$ instead; the construction and every statement below are identical, since ϵ^* is just another constant vector contracted with the same $\mathcal{M}^\mu$.

Theorem 18.5 (Tree-level Ward identity)**.** *Let $\mathcal{M}^\mu(k)$ be the stripped amplitude of Theorem 18.4 for an external photon of momentum k, formed from the* complete *set of tree diagrams of a QED process in which all other external particles are on their mass shells. Then*

$$\boxed{k_\mu\,\mathcal{M}^\mu(k)=0} \tag{18.24}$$

identically in the momenta and polarizations of all the other external particles. In particular, if the process contains several external photons with momenta $k_1,k_2,\dots$ and the amplitude is stripped of all their polarizations, $\mathcal{M}=\epsilon^{(1)}_{\mu_1}\epsilon^{(2)}_{\mu_2}\cdots\mathcal{M}^{\mu_1\mu_2\cdots}$, then contracting any one photon momentum into its own index annihilates the tensor,

$$k_{1\,\mu_1}\,\mathcal{M}^{\mu_1\mu_2\cdots}=0, \tag{18.25}$$

without *requiring the remaining polarization vectors to be transverse.*

The two emphasized words carry the whole content. "Complete": the identity holds for the sum of all diagrams, never for one diagram in isolation; the cancellation is between diagrams, and a calculation that drops even one of them will find a spurious nonzero $k_\mu\mathcal{M}^\mu$. "Without requiring … transverse":

Eq. (18.25) is an identity on the full Lorentz tensor $\mathcal{M}^{\mu_1\mu_2\cdots}$, valid even when the slots $\mu_2, \ldots$ are contracted with unphysical (longitudinal or scalar) directions. This stronger, tensorial statement is exactly what will be needed to perform the covariant polarization-sum replacement *simultaneously* on several photons, and we will see in Section 18.2.5 that the proof below delivers it for free.

18.2.2 Proof of the tree-level Ward identity

The proof rests on one algebraic identity at a single vertex, applied repeatedly. Contracting the photon momentum into the vertex turns the vertex Dirac matrix γ^μ into $\not{k}$, and the key observation is that $\not{k}$ can be split into a difference of inverse fermion propagators that cancel the two propagators adjacent to the vertex.

Lemma 18.6 (Vertex insertion identity)**.** *Consider a fermion line carrying momentum q into a vertex at which an external photon of momentum k is absorbed, so that the line carries $q+k$ out of the vertex. With the photon momentum contracted into the vertex, the propagator–vertex–propagator string evaluates to a difference of single propagators:*

$$\frac{i(\not{q}+\not{k}+m)}{(q+k)^2-m^2}\,(-ie\,\not{k})\,\frac{i(\not{q}+m)}{q^2-m^2} = e\left[\frac{i(\not{q}+\not{k}+m)}{(q+k)^2-m^2} - \frac{i(\not{q}+m)}{q^2-m^2}\right]. \tag{18.26}$$

Proof. Write $S(q) \equiv i(\not{q}+m)/(q^2-m^2)$ for the propagator. The entire content is the decomposition of the contracted vertex as a difference of inverse propagators,

$$\not{k} = (\not{q}+\not{k}-m) - (\not{q}-m), \tag{18.27}$$

which is an identity (the $\not{q}$ and m terms cancel). Each summand annihilates one adjacent propagator. On the right,

$$(\not{q}-m)\,S(q) = (\not{q}-m)\,\frac{i(\not{q}+m)}{q^2-m^2} = i\,\frac{\not{q}^2-m^2}{q^2-m^2} = i\,\frac{q^2-m^2}{q^2-m^2} = i\,\mathbf{1}, \tag{18.28}$$

where $\not{q}^2 = q_\mu q_\nu \gamma^\mu\gamma^\nu = q_\mu q_\nu\,\frac{1}{2}\{\gamma^\mu,\gamma^\nu\} = q^2\,\mathbf{1}$ by the Clifford algebra (Chapter 11). On the left, identically,

$$S(q+k)\,(\not{q}+\not{k}-m) = \frac{i(\not{q}+\not{k}+m)}{(q+k)^2-m^2}\,(\not{q}+\not{k}-m) = i\,\frac{(q+k)^2-m^2}{(q+k)^2-m^2} = i\,\mathbf{1}. \tag{18.29}$$

Therefore

$$\begin{aligned} S(q+k)\,(-ie\,\not{k})\,S(q) &= (-ie)\,S(q+k)\big[(\not{q}+\not{k}-m)-(\not{q}-m)\big]S(q) \\ &= (-ie)\big[\,i\,S(q) \;-\; i\,S(q+k)\,\big] = e\big[S(q+k)-S(q)\big], \end{aligned} \tag{18.30}$$

which is Eq. (18.26). The first term in the bracket used Eq. (18.29) to remove the *left* propagator (leaving $S(q)$), the second used Eq. (18.28) to remove the *right* propagator (leaving $S(q+k)$). □

The lemma says that contracting the longitudinal photon $\not{k}$ at an interior vertex is the same as not putting the photon there at all, but instead either (i) shifting all the momenta to the left of the vertex by $+k$ and deleting the right-hand propagator, or (ii) leaving the momenta alone and deleting the left-hand propagator, with a relative minus sign between the two. This is the engine of a telescoping cancellation once we sum over where the photon attaches.

Proof of Theorem 18.5. The telescoping sum. Fix a process and a single external photon of momentum k. The complete set of tree diagrams is generated by attaching this photon, in turn, to every possible point of the diagram; since the photon couples only to fermions, this means attaching it to each vertex slot along the fermion lines. Consider one continuous fermion line, running from an incoming external spinor $u(p)$ to an outgoing $\bar{u}(p')$, and carrying n *other* photon attachments (external or internal; at tree level their momenta are fixed c-numbers). Label the gaps between consecutive structures along the line by $a = 0, 1, \ldots, n$: gap 0 sits between $u(p)$ and the first existing vertex, gap n between the last vertex and $\bar{u}(p')$. Inserting the external photon into gap a produces one diagram; the sum of these $n+1$ diagrams, stripped of ϵ_μ and contracted with k_μ, is the line's contribution to $k_\mu \mathcal{M}^\mu$.

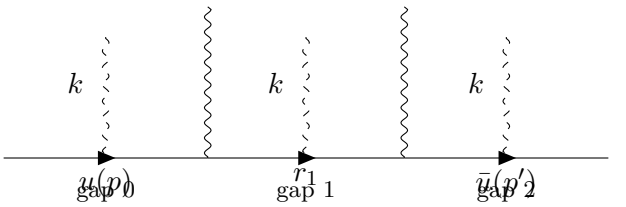

Figure 18.2: The telescoping sum behind the tree Ward identity, drawn for a fermion line with $n = 2$ pre-existing photon attachments (solid). The external photon of momentum k (dashed) is inserted, in turn, into each of the $n+1 = 3$ gaps along the line. By the insertion identity Eq. (18.26), the contraction $k_\mu \mathcal{M}^\mu$ of the gap-a diagram equals a difference of two amputated lines; the right piece of gap a cancels the left piece of gap $a+1$, and the whole sum collapses to the two endpoint terms, which vanish by the Dirac equation on $u(p)$ and $\bar{u}(p')$.

Apply Theorem 18.6 at each gap. For an *interior* gap a (with a propagator on both sides), the contracted diagram is, by Eq. (18.26), a difference $e[\, L_a^+ - L_a^- \,]$, where L_a^+ is the original line with the photon's momentum k added to every segment to the left of gap a and the propagator just left of the gap retained, while L_a^- is the original line with k added to the left segments but with the

propagator just left of the gap deleted — equivalently, L_a^+ is the line "with k flowing out through gap a and above" and L_a^- is the same with k flowing out through gap $a-1$ and above. The bookkeeping that matters is only this: the negative piece generated at gap a is *identical* to the positive piece generated at gap $a-1$, because both describe the line with k routed out above gap $a-1$ and the corresponding internal propagator restored. Hence in the sum

$$k_\mu \mathcal{M}^\mu\big|_{\text{line}} = e\sum_{a=0}^{n}\big[\,L_a^+ - L_a^-\,\big] = e\big[\,L_n^+ - L_0^-\,\big], \tag{18.31}$$

every interior term cancels against its neighbour and only the two endpoint terms survive. This is the telescope: a sum of differences collapses to the difference of the extremes.

The two surviving terms are precisely where the photon sits against an external spinor rather than against a propagator, and there the insertion identity is replaced by its boundary form. At gap 0 the object to the right of the contracted vertex is the external $u(p)$, not a propagator, so $\not{k}$ acts directly: using Eq. (18.27) with $q=p$ and the momentum-space Dirac equation $(\not{p}-m)u(p)=0$ of Eq. (11.50),

$$(-ie\,\not{k})\,u(p) = (-ie)\big[(\not{p}+\not{k}-m)-(\not{p}-m)\big]u(p) = (-ie)(\not{p}+\not{k}-m)\,u(p), \tag{18.32}$$

and the leftover piece $-(\not{p}-m)u(p)$ — which is the residual $-L_0^-$ of Eq. (18.31) — vanishes outright. Symmetrically, at gap n the object to the left is $\bar{u}(p')$, and the adjoint Dirac equation $\bar{u}(p')(\not{p}'-m)=0$ (obtained by conjugating Eq. (11.50), as in Chapter 11) kills the residual top piece $+L_n^+$:

$$\bar{u}(p')\,(-ie\,\not{k}) = (-ie)\,\bar{u}(p')\big[(\not{p}'-m)-(\not{p}'-\not{k}-m)\big] = -(-ie)\,\bar{u}(p')(\not{p}'-\not{k}-m). \tag{18.33}$$

The careful statement is that the two extreme terms in Eq. (18.31) are exactly the two pieces proportional to $(\not{p}-m)u(p)$ and $\bar{u}(p')(\not{p}'-m)$, each of which is zero on the mass shell. Thus the contribution of any single fermion line to $k_\mu\mathcal{M}^\mu$ vanishes.

Assembling the full amplitude. A general tree diagram may contain several distinct fermion lines (for example the two electron lines of a process built by photon exchange). The external photon attaches to exactly one line in any given diagram, and the complete amplitude is the sum, over all fermion lines, of the sum over all attachment points on that line. We have just shown each inner sum — the full set of diagrams in which the photon sits on one chosen line — telescopes to endpoint terms that vanish by the Dirac equation for that line's external spinors. Summing the (vanishing) contributions of the separate lines gives

$$k_\mu\mathcal{M}^\mu = \sum_{\text{fermion lines}} \big(k_\mu\mathcal{M}^\mu\big|_{\text{line}}\big) = 0, \tag{18.34}$$

which is Eq. (18.24). The argument used nothing about the other external particles except that the fermions are on shell (so their spinors obey the Dirac equation) and that the photon momentum is the one contracted; in particular the polarization vectors of any *other* external photons were carried inertly through the manipulation and never assumed transverse. Hence the contraction $k_{1\mu_1}\mathcal{M}^{\mu_1\mu_2\cdots} = 0$ holds as the tensorial identity Eq. (18.25), with the slots $\mu_2, \ldots$ free. This completes the proof of Theorem 18.5. □

Caution

The Ward identity is a statement about the *gauge-invariant sum of all diagrams at a given order*. Each individual diagram has nonzero $k_\mu \mathcal{M}^\mu_{\text{diagram}}$ — indeed the telescope works precisely by cancelling those nonzero pieces against each other. A computation that, say, retains the s-channel Compton diagram but forgets the u-channel one will not satisfy the Ward identity, will find unphysical polarizations contributing to the cross section, and will give a gauge-dependent, wrong answer. Checking $k_\mu \mathcal{M}^\mu = 0$ on the full amplitude is therefore one of the sharpest available tests that a tree-level QED calculation is complete and correctly assembled; we will use it as exactly such a check in every external-photon process of this chapter.

18.2.3 The canonical illustration: the Compton amplitude

The general telescope is most transparent in its smallest nontrivial case, $n = 1$, where there are two diagrams and the cancellation is the bare difference of two boundary terms. This is the Compton process $e^-(p)\,\gamma(k) \to e^-(p')\,\gamma(k')$, the flagship external-photon amplitude that the next section computes in full. We isolate here only its gauge structure, and verify Eq. (18.24) explicitly.

Worked Example 18.7 (Tree Ward identity for Compton scattering)**.** The two tree diagrams for $e^-(p)\gamma(k) \to e^-(p')\gamma(k')$ differ in the order in which the incoming photon k (polarization ϵ) and the outgoing photon k' (polarization ϵ'^*) attach to the single electron line. Momentum conservation reads $p + k = p' + k'$, and all external particles are on shell: $p^2 = p'^2 = m^2$, $k^2 = k'^2 = 0$. Writing the amplitude as $i\mathcal{M} = i\,\epsilon_\nu(k)\,\mathcal{M}^\nu$ and stripping the incoming photon's polarization, the two diagrams give

$$\mathcal{M}^\nu_s = -ie^2\,\bar{u}(p')\,\not{\epsilon}'^*\,\frac{\not{p} + \not{k} + m}{(p+k)^2 - m^2}\,\gamma^\nu\,u(p), \tag{18.35}$$

$$\mathcal{M}^\nu_u = -ie^2\,\bar{u}(p')\,\gamma^\nu\,\frac{\not{p} - \not{k}' + m}{(p-k')^2 - m^2}\,\not{\epsilon}'^*\,u(p), \tag{18.36}$$

where the two factors of the vertex $-ie\gamma$ and the propagator numerator $i(\not{q}+m)$ have combined to the prefactor $-ie^2$. In the s-channel diagram Eq. (18.35) the incoming photon attaches at the right vertex (against $u(p)$); in the u-channel diagram Eq. (18.36) it attaches at the left vertex (against $\bar{u}(p')$). The denominators simplify on shell to

$$(p+k)^2 - m^2 = 2p\cdot k, \qquad (p-k')^2 - m^2 = -2p\cdot k'. \tag{18.37}$$

Contracting the s-channel with k_ν. Set $\gamma^\nu \to \not{k}$ in Eq. (18.35) and split $\not{k} = (\not{p}+\not{k}-m) - (\not{p}-m)$. The second piece kills $u(p)$ by the Dirac equation, leaving

$$k_\nu \mathcal{M}_s^\nu = -ie^2\, \bar{u}(p')\, \not{\epsilon}'^{*}\, \frac{(\not{p}+\not{k}+m)(\not{p}+\not{k}-m)}{2p\cdot k}\, u(p). \tag{18.38}$$

The numerator is $(\not{p}+\not{k}+m)(\not{p}+\not{k}-m) = (p+k)^2 - m^2 = 2p\cdot k$, which cancels the denominator exactly, so

$$k_\nu \mathcal{M}_s^\nu = -ie^2\, \bar{u}(p')\, \not{\epsilon}'^{*}\, u(p). \tag{18.39}$$

Contracting the u-channel with k_ν. Set $\gamma^\nu \to \not{k}$ in Eq. (18.36). Here $\not{k}$ stands to the immediate right of $\bar{u}(p')$, so we use momentum conservation to route it onto the propagator and the outgoing spinor. With $\ell \equiv p - k'$ the propagator momentum, conservation $k = p' + k' - p$ gives $\not{k} = \not{p}' - \not{\ell}$ (since $\not{p} = \not{\ell} + \not{k}'$), hence $\not{k} = (\not{p}' - m) - (\not{\ell} - m)$. The first piece kills $\bar{u}(p')$ by the adjoint Dirac equation, leaving

$$k_\nu \mathcal{M}_u^\nu = -ie^2\, \bar{u}(p')\, [-(\not{\ell} - m)]\, \frac{\not{\ell} + m}{-2p\cdot k'}\, \not{\epsilon}'^{*}\, u(p). \tag{18.40}$$

Now $(\not{\ell}-m)(\not{\ell}+m) = \ell^2 - m^2 = (p-k')^2 - m^2 = -2p\cdot k'$ cancels the denominator, and the overall sign from the bracket gives

$$k_\nu \mathcal{M}_u^\nu = -ie^2\, \bar{u}(p')\, \frac{-(-2p\cdot k')}{-2p\cdot k'}\, \not{\epsilon}'^{*}\, u(p) = +ie^2\, \bar{u}(p')\, \not{\epsilon}'^{*}\, u(p). \tag{18.41}$$

The sum. Adding Eq. (18.39) and Eq. (18.41),

$$k_\nu \mathcal{M}^\nu = k_\nu \mathcal{M}_s^\nu + k_\nu \mathcal{M}_u^\nu = -ie^2\, \bar{u}(p')\, \not{\epsilon}'^{*}\, u(p) + ie^2\, \bar{u}(p')\, \not{\epsilon}'^{*}\, u(p) = 0, \tag{18.42}$$

exactly as Eq. (18.24) demands. The cancellation is the $n = 1$ telescope: the surviving s-channel boundary term (the photon pushed onto the incoming end, with the Dirac equation removing the would-be extra piece) is equal and opposite to the surviving u-channel boundary term (the photon pushed onto the outgoing end). Neither diagram alone is transverse; their sum is. Note that $\not{\epsilon}'^{*}$ rode through every step untouched: Eq. (18.42) holds for an *arbitrary* ϵ', so we have in fact established the tensor identity $k_\nu \mathcal{M}^{\mu\nu} = 0$ for the Compton amplitude, where μ is the outgoing photon's index. By the identical computation with the roles of the two photons exchanged, $k'_\mu \mathcal{M}^{\mu\nu} = 0$ as well. Both photons of Compton scattering thus satisfy the Ward identity as a tensor statement — the fact Section 18.2.5 needs to sum over both polarizations covariantly at once.

18.2.4 Physical polarizations and the covariant completeness identity

We now turn the Ward identity into the polarization-sum rule the master formula requires. The starting point is a concrete, covariant description of the two physical polarization states of an on-shell photon and the resolution of the identity they generate.

A real photon of momentum k ($k^2 = 0$, $k^0 = |\mathbf{k}| > 0$) has exactly two physical polarization states, the transverse ones; this is the two-degrees-of-freedom count established for the quantized photon in Chapter 13. To exhibit them covariantly, work in a frame in which the momentum points along the z-axis,

$$k^\mu = \omega\,(1, 0, 0, 1), \tag{18.43}$$

and introduce an auxiliary null *reference vector* pointing the other way along the light cone,

$$\bar{k}^\mu = \omega\,(1, 0, 0, -1), \qquad \bar{k}^2 = 0, \qquad k \cdot \bar{k} = 2\omega^2 \neq 0. \tag{18.44}$$

The two transverse polarizations are the purely spatial unit vectors orthogonal to $\mathbf{k}$,

$$\epsilon_1^\mu = (0, 1, 0, 0), \qquad \epsilon_2^\mu = (0, 0, 1, 0), \tag{18.45}$$

which obey, in the mostly-minus metric,

$$\epsilon_\lambda \cdot \epsilon_{\lambda'}^* = -\delta_{\lambda\lambda'}, \qquad \epsilon_\lambda \cdot k = 0, \qquad \epsilon_\lambda \cdot \bar{k} = 0, \qquad (\lambda, \lambda' = 1, 2). \tag{18.46}$$

These are the same transverse states defined in Theorem 13.9; the circular (helicity) combinations $\epsilon_\pm = \mp\frac{1}{\sqrt{2}}(\epsilon_1 \pm i\epsilon_2)$ of Eq. (13.70) are a unitary change of basis on the polarization label and satisfy the same relations Eq. (18.46) (now with $\epsilon_\pm^* = \epsilon_\mp \cdot (\mp)$ as recorded there). Everything below is basis-independent on the two-dimensional physical space, so we keep the index λ generic.

The four vectors $\{\epsilon_1, \epsilon_2, k, \bar{k}\}$ are linearly independent and hence a basis of Minkowski space. The resolution of the identity in this basis is the completeness relation we need.

Proposition 18.8 (Covariant polarization completeness)**.** *With the conventions Eq. (18.43)–Eq. (18.46), the sum over the two physical polarizations of an on-shell photon of momentum k is*

$$\boxed{\sum_{\lambda=1,2} \epsilon_\lambda^\mu\, \epsilon_\lambda^{*\nu} = -\eta^{\mu\nu} + \frac{k^\mu \bar{k}^\nu + \bar{k}^\mu k^\nu}{k \cdot \bar{k}}} \tag{18.47}$$

where $\bar{k}$ is the reference null vector Eq. (18.44).

Proof. For any basis $\{e_a\}$ of a vector space carrying a nondegenerate inner product, with Gram matrix $g_{ab} = e_a \cdot e_b$ and inverse $(g^{-1})^{ab}$, the metric is reconstructed as $\eta^{\mu\nu} = \sum_{a,b}(g^{-1})^{ab}\, e_a^\mu e_b^\nu$. We apply this to $e_1 = \epsilon_1$, $e_2 = \epsilon_2$, $e_3 = k$, $e_4 = \bar{k}$. The relations Eq. (18.46) and Eq. (18.44) make the Gram matrix block-diagonal: the transverse block is $\epsilon_\lambda \cdot \epsilon_{\lambda'} = -\delta_{\lambda\lambda'}$, with inverse $-\delta_{\lambda\lambda'}$; the $(k, \bar{k})$ block is

$$\begin{pmatrix} k\cdot k & k\cdot\bar{k} \\ \bar{k}\cdot k & \bar{k}\cdot\bar{k} \end{pmatrix} = \begin{pmatrix} 0 & N \\ N & 0 \end{pmatrix}, \qquad N \equiv k\cdot\bar{k}, \tag{18.48}$$

with inverse $\frac{1}{N}\left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right)$. Assembling the reconstruction,

$$\eta^{\mu\nu} = \sum_{\lambda,\lambda'}(-\delta_{\lambda\lambda'})\,\epsilon_\lambda^\mu\epsilon_{\lambda'}^\nu + \frac{1}{N}\left(k^\mu\bar{k}^\nu + \bar{k}^\mu k^\nu\right) = -\sum_\lambda \epsilon_\lambda^\mu\epsilon_\lambda^\nu + \frac{k^\mu\bar{k}^\nu + \bar{k}^\mu k^\nu}{k\cdot\bar{k}}. \tag{18.49}$$

For the real transverse vectors Eq. (18.45) we have $\epsilon_\lambda^* = \epsilon_\lambda$; for the circular basis the same identity holds because the change of basis is unitary, so $\sum_\lambda \epsilon_\lambda^\mu\epsilon_\lambda^{*\nu} = \sum_\lambda \epsilon_\lambda^\mu\epsilon_\lambda^\nu$ either way. Solving Eq. (18.49) for the polarization sum gives Eq. (18.47). □

The structure of Eq. (18.47) is exactly what one should expect physically. The full metric $-\eta^{\mu\nu}$ resolves the identity over *all four* components of a four-vector; the two unphysical directions — the longitudinal polarization $\propto k$ and the scalar/timelike polarization, mixed into the combination $k^\mu\bar{k}^\nu + \bar{k}^\mu k^\nu$ — are subtracted off, leaving only the two transverse states. The reference vector $\bar{k}$ is pure gauge: it specifies *which* mixture of timelike and longitudinal directions we call "the unphysical part," a choice with no physical content. A correct physical answer must therefore be independent of $\bar{k}$, and the role of the Ward identity is to guarantee exactly that.

18.2.5 The polarization-sum replacement

We can now state and prove the replacement rule, discharging the obligation left open in the previous section and at the same time supplying the hypothesis that Theorem 13.30 assumed when this rule was previewed in Chapter 13.

Theorem 18.9 (Covariant polarization-sum replacement at tree level)**.** *Let $\mathcal{M} = \epsilon_\mu(k)\mathcal{M}^\mu$ be a complete tree amplitude with an external photon of momentum k, so that the tree Ward identity $k_\mu\mathcal{M}^\mu = 0$ of Theorem 18.5 holds. Then the sum over the two physical polarizations of the squared amplitude may be computed by the covariant replacement $\sum_\lambda \epsilon_\lambda^\mu\epsilon_\lambda^{*\nu} \to -\eta^{\mu\nu}$:*

$$\sum_{\lambda=1,2}\left|\epsilon_\lambda^*(k)\cdot\mathcal{M}\right|^2 = \sum_\lambda \epsilon_\lambda^\mu\epsilon_\lambda^{*\nu}\,\mathcal{M}_\mu\mathcal{M}_\nu^* = -\eta^{\mu\nu}\,\mathcal{M}_\mu\mathcal{M}_\nu^* = -\mathcal{M}_\mu\mathcal{M}^{*\mu}. \tag{18.50}$$

If the amplitude contains several external photons, the replacement may be applied to each of them independently and simultaneously, $\prod_i \sum_{\lambda_i} \epsilon_{\lambda_i}^{\mu_i}\epsilon_{\lambda_i}^{*\nu_i} \to \prod_i(-\eta^{\mu_i\nu_i})$.

Proof. Insert the completeness identity Eq. (18.47) into the polarization sum:

$$\sum_\lambda \epsilon_\lambda^\mu \epsilon_\lambda^{*\nu}\, \mathcal{M}_\mu \mathcal{M}_\nu^* = -\eta^{\mu\nu}\mathcal{M}_\mu \mathcal{M}_\nu^* + \frac{(k^\mu \mathcal{M}_\mu)(\bar{k}^\nu \mathcal{M}_\nu^*) + (\bar{k}^\mu \mathcal{M}_\mu)(k^\nu \mathcal{M}_\nu^*)}{k\cdot\bar{k}}. \quad (18.51)$$

Each term in the numerator of the second piece contains a factor $k^\mu \mathcal{M}_\mu = k_\mu \mathcal{M}^\mu$ or its complex conjugate $k^\nu \mathcal{M}_\nu^* = (k_\mu \mathcal{M}^\mu)^*$. By the Ward identity Eq. (18.24) both vanish, so the entire $\bar{k}$-dependent piece drops, leaving $-\eta^{\mu\nu}\mathcal{M}_\mu \mathcal{M}_\nu^* = -\mathcal{M}_\mu \mathcal{M}^{*\mu}$, which is Eq. (18.50). That the reference vector $\bar{k}$ has disappeared is the consistency check promised after Theorem 18.8: the physical, polarization-summed rate cannot depend on the arbitrary choice of $\bar{k}$, and indeed it does not — precisely because of the Ward identity.

For several external photons the argument iterates. Replace the polarization sum on photon 1 first: Eq. (18.51) for that photon produces $-\eta^{\mu_1\nu_1}$ plus terms carrying $k_1^{\mu_1}$ or $\bar{k}_1^{\mu_1}$ contracted into the index μ_1 of $\mathcal{M}^{\mu_1\mu_2\cdots}$. The $\bar{k}_1$ terms come multiplied by $k_{1\mu_1}\mathcal{M}^{\mu_1\mu_2\cdots}$, which vanishes by the *tensor* Ward identity Eq. (18.25) — and this is the crucial point: Eq. (18.25) holds with the remaining indices $\mu_2, \ldots$ free, i.e. even though the polarization sums on the other photons have *not* yet been done and those indices are not contracted with transverse vectors. Hence the $\bar{k}_1$ terms drop and photon 1 is reduced to $-\eta^{\mu_1\nu_1}$, leaving $-\eta^{\mu_1\nu_1}\mathcal{M}_{\mu_1\cdots}\mathcal{M}^*_{\nu_1\cdots}$, an object that still obeys the tensor Ward identity in each remaining photon index. Repeating for photons $2, 3, \ldots$ gives the simultaneous replacement $\prod_i(-\eta^{\mu_i\nu_i})$. □

This is the rule the previous section anticipated and the rest of the chapter will use without further comment. It was previewed in Chapter 13 as Theorem 13.30, where it was proved *conditional* on the Ward identity; Theorem 18.5 has now supplied that condition at tree level, so the rule is established outright for every external-photon amplitude in this chapter. The all-orders upgrade — showing that loop corrections preserve $k_\mu \mathcal{M}^\mu = 0$, and hence that Eq. (18.50) survives radiative corrections — is the content of the Ward–Takahashi identity, deferred to Chapter 19.

Physical Insight

Why does replacing the sum over two physical polarizations by the full Minkowski metric — which manifestly includes two unphysical directions — give the right physical answer? Because the unphysical directions never reach the cross section. The longitudinal and scalar polarizations enter Eq. (18.51) only through the combination k^μ (and the gauge artefact $\bar{k}^\mu$), and an amplitude that respects gauge invariance is, by the Ward identity, exactly blind to k^μ. The covariant rule works *because* the theory is gauge invariant; it is gauge invariance, cashed out as current conservation on the external photon, masquerading as a bookkeeping convenience. The same

mechanism is what allowed the gauge-parameter (ξ) dependence of the internal photon propagator to cancel in Chapter 13: in both cases a k^μ runs into a conserved current and dies. The cost of this convenience in a non-abelian theory — where the analogous naive replacement fails because longitudinal gluons do *not* decouple by themselves — is the Faddeev–Popov ghost, which Chapter 26 introduces precisely to absorb the leftover unphysical polarizations. That QED needs no such ghost in external-state sums is the abelian gift we are cashing here.

With the Ward identity proved and the polarization-sum replacement licensed, the chapter's first organizing principle is in hand. We may now compute any external-photon process covariantly: strip the photon polarizations, square, and replace each $\sum_\lambda \epsilon^\mu_\lambda \epsilon^{*\nu}_\lambda$ by $-\eta^{\mu\nu}$, confident that the unphysical contributions cancel exactly and that the answer is gauge invariant. The next section puts this to work on the flagship case, Compton scattering $e^-\gamma \to e^-\gamma$, whose two-diagram amplitude we have already shown is transverse: there the rule Eq. (18.50), together with the gamma-matrix trace technology of Chapter 11 and Appendix C, will deliver the spin- and polarization-averaged $\overline{|\mathcal{M}|^2}$ and, from it, the Klein–Nishina cross section.

18.3 Compton scattering and the Klein–Nishina formula

The previous section earned us a licence. It proved that any tree amplitude carrying an external photon, written $\mathcal{M} = \epsilon_\mu(k)\mathcal{M}^\mu$, obeys the tree-level Ward identity $k_\mu \mathcal{M}^\mu = 0$ (Theorem 18.5), and it used that gauge-invariance statement to justify the covariant replacement

$$\sum_\lambda \epsilon^\mu_\lambda(k)\, \epsilon^{*\nu}_\lambda(k) \;\longrightarrow\; -\eta^{\mu\nu} \tag{18.52}$$

inside a squared, polarization-summed amplitude (Eq. (18.50)). With those two tools in hand we can finally attack a process with photons on external legs — the first time in QED that the gauge field appears as a physical particle entering and leaving the diagram rather than as an internal propagator. The flagship example is *Compton scattering*, $e^-\gamma \to e^-\gamma$: an electron absorbs a photon and re-emits one. It is the simplest QED amplitude built from *two* interfering diagrams, the cleanest place to watch the Ward identity do real work (each diagram alone is not gauge invariant; only their sum is), and it culminates in the Klein–Nishina formula, whose low-energy limit reproduces the classical Thomson cross section and so anchors the whole quantum computation to a number any nineteenth-century physicist could have measured. This section carries the calculation out

in full: amplitude, the explicit $k_\mu \mathcal{M}^\mu = 0$ check, the spin/polarization-averaged $\overline{|\mathcal{M}|^2}$ (including the trace of eight gamma matrices in the interference term), the Compton kinematic shift, the lab-frame phase space, and the cross section with its Thomson limit and total integral.

Throughout we use the standing conventions of this chapter: the electron has charge $-e$ with $e > 0$, the QED vertex is $-ie\gamma^\mu$ (Chapter 17), the metric is mostly-minus, $\alpha = e^2/4\pi$, and we work in Feynman gauge. The electron carries momentum p (mass m) and the photon momentum k in the initial state; primes denote the final state, p' and k'. All four external particles are on shell: $p^2 = p'^2 = m^2$, $k^2 = k'^2 = 0$.

18.3.1 The two diagrams and the amplitude

At order e^2 the process $e^-\gamma \to e^-\gamma$ receives contributions from exactly two connected tree diagrams, drawn in Fig. 18.3. They differ in the *time order* in which the two photons attach to the single electron line. In the first (the s-channel diagram, so named because the internal electron carries the total momentum $p + k$ whose square is the Mandelstam invariant s), the incoming photon k is absorbed first; the electron propagates with momentum $p + k$; then the outgoing photon k' is emitted. In the second (the u-channel diagram), the outgoing photon k' is emitted first; the electron propagates with momentum $p - k'$; then the incoming photon k is absorbed. There is no third diagram: with one electron line and two photons there are only two orderings, and there is no diagram with the photons attached to a closed loop at tree level.

(a) s-channel: absorb k, then emit k'.

(b) u-channel: emit k', then absorb k.

Figure 18.3: The two tree diagrams for Compton scattering $e^-\gamma \to e^-\gamma$. They are distinguished by the order in which the photons attach to the electron line; the internal electron carries $p+k$ (left) or $p-k'$ (right). Both enter the amplitude with a relative *plus* sign: the two photons are bosons attached to the same fermion line, so Fermi statistics imposes no relative minus here (contrast Section 18.5 for exchanged identical fermions).

We read each diagram with the QED Feynman rules of Chapter 17. An incoming electron contributes a spinor $u^s(p)$, an outgoing electron $\bar{u}^{s'}(p')$; an incoming photon contributes a polarization vector $\epsilon_\nu(k)$, an outgoing photon

$\epsilon^*_\mu(k')$; each vertex is $-ie\gamma^\mu$; the internal electron of momentum ℓ carries the propagator $i(\not\ell + m)/(\ell^2 - m^2 + i\epsilon)$. Reading the s-channel diagram *against* the fermion arrow, from $\bar u(p')$ on the left to $u(p)$ on the right, the outgoing-photon vertex sits next to $\bar u(p')$ and the incoming-photon vertex next to $u(p)$:

$$i\mathcal{M}_s = \bar u(p')\,(-ie\not\epsilon\,'^*)\,\frac{i(\not p + \not k + m)}{(p+k)^2 - m^2}\,(-ie\not\epsilon)\,u(p), \tag{18.53}$$

where $\not\epsilon \equiv \epsilon_\nu(k)\gamma^\nu$ and $\not\epsilon\,'^* \equiv \epsilon^*_\mu(k')\gamma^\mu$. The internal denominator is on the photon mass shell pure kinematics:

$$(p+k)^2 - m^2 = p^2 + 2p\cdot k + k^2 - m^2 = 2\,p\cdot k, \tag{18.54}$$

using $p^2 = m^2$, $k^2 = 0$. The factor $(-ie)^2 \cdot i = -ie^2$, so stripping the overall i,

$$\mathcal{M}_s = -\,e^2\,\frac{\bar u(p')\,\not\epsilon\,'^*\,(\not p + \not k + m)\,\not\epsilon\,u(p)}{2\,p\cdot k}. \tag{18.55}$$

The u-channel diagram is identical except that the two photon vertices are swapped — k' is emitted first, so $\not\epsilon\,'^*$ sits next to $u(p)$ and $\not\epsilon$ next to $\bar u(p')$ — and the internal momentum is $p - k'$, with

$$(p-k')^2 - m^2 = p^2 - 2p\cdot k' + k'^2 - m^2 = -\,2\,p\cdot k'. \tag{18.56}$$

Carrying the sign of Eq. (18.56) through,

$$\mathcal{M}_u = -\,e^2\,\frac{\bar u(p')\,\not\epsilon\,(\not p - \not k' + m)\,\not\epsilon\,'^*\,u(p)}{-\,2\,p\cdot k'} = +\,e^2\,\frac{\bar u(p')\,\not\epsilon\,(\not p - \not k' + m)\,\not\epsilon\,'^*\,u(p)}{2\,p\cdot k'}. \tag{18.57}$$

The full amplitude is the coherent sum:

$$\mathcal{M} = \mathcal{M}_s + \mathcal{M}_u = -\,e^2\,\bar u(p')\left[\frac{\not\epsilon\,'^*(\not p + \not k + m)\not\epsilon}{2\,p\cdot k} - \frac{\not\epsilon\,(\not p - \not k' + m)\not\epsilon\,'^*}{2\,p\cdot k'}\right]u(p). \tag{18.58}$$

The relative minus sign between the two bracketed terms is *not* a statistics sign — the two photons attach to the same fermion line and Bose symmetry gives them a relative plus — it descends purely from the opposite signs of the propagator denominators Eq. (18.54), Eq. (18.56). This is worth flagging because the genuinely statistical relative minus, between diagrams related by exchange of identical *external fermions*, is the central new feature of the Møller and Bhabha amplitudes treated in Section 18.5; Compton has no such exchange.

18.3.2 The explicit Ward-identity check

Before squaring, we verify that this concrete amplitude satisfies the tree-level Ward identity of Theorem 18.5. Write the dependence on the incoming-photon

polarization explicitly, $\mathcal{M} = \epsilon_\nu(k)\,\mathcal{M}^\nu$, and test gauge invariance by the replacement $\epsilon_\nu(k) \to k_\nu$, i.e. $\not\epsilon \to \not k$ in Eq. (18.58). The claim is $k_\nu \mathcal{M}^\nu = 0$. The check is instructive because it shows the two diagrams trading their gauge variations against one another.

Take the s-channel term first. With $\not\epsilon \to \not k$ it carries $(\not p + \not k + m)\not k\, u(p)$ acting to the right on $u(p)$. Using the Dirac equation $(\not p - m)u(p) = 0$, write $\not k\, u(p) = (\not p + \not k - m)u(p)$, so that

$$(\not p+\not k+m)\not k\, u(p) = (\not p+\not k+m)(\not p+\not k-m)u(p) = \big[(p+k)^2-m^2\big]u(p) = (2\,p\cdot k)\,u(p), \tag{18.59}$$

where the middle step used $(\not q + m)(\not q - m) = \not q\not q - m^2 = q^2 - m^2$ with $q = p + k$. The denominator $2\,p \cdot k$ cancels exactly, leaving the s-channel contribution to $k_\nu \mathcal{M}^\nu$ equal to $-e^2\,\bar u(p')\,\not\epsilon\,'^{*}\,u(p)$.

For the u-channel term the photon k attaches at the vertex adjacent to $\bar u(p')$, so we must move $\not k$ leftward through $\bar u(p')$. Momentum conservation $p+k = p'+k'$ gives $\not k = \not p' + \not k' - \not p$, and the outgoing Dirac equation $\bar u(p')(\not p' - m) = 0$ gives $\bar u(p')\not p' = m\,\bar u(p')$, hence

$$\bar u(p')\not k = \bar u(p')(\,-\not p + \not k' + m). \tag{18.60}$$

Then, with $B \equiv \not p - \not k'$,

$$\bar u(p')\,\not k\,(\not p - \not k' + m) = \bar u(p')\,(-B+m)(B+m) = \bar u(p')\,(m^2 - B^2) = \bar u(p')\,(2\,p\cdot k'), \tag{18.61}$$

since $B^2 = (p - k')^2 = m^2 - 2\,p\cdot k'$ so that $m^2 - B^2 = 2\,p\cdot k'$, matching the u-channel denominator. The u-channel contribution to $k_\nu\mathcal{M}^\nu$ is therefore $+e^2\,\bar u(p')\,\not\epsilon\,'^{*}\,u(p)$ — with the overall minus in front of the u-channel term in Eq. (18.58), it is $-(+e^2\bar u \not\epsilon\,'^{*} u)$. Adding the two:

$$k_\nu\mathcal{M}^\nu = -e^2\,\bar u(p')\,\not\epsilon\,'^{*}\,u(p) + e^2\,\bar u(p')\,\not\epsilon\,'^{*}\,u(p) = 0. \tag{18.62}$$

The cancellation is exact and total, and it manifestly needed both diagrams: the s-channel alone would have left a nonzero $-e^2\bar u \not\epsilon\,'^{*} u$, gauge-variant, and only the u-channel's equal and opposite remnant kills it. The same computation with $\epsilon^*_\mu(k') \to k'_\mu$ on the outgoing photon vanishes identically by the mirror argument. This is the concrete realization, on a real amplitude, of the abstract statement proved in Section 18.2.2, and it is precisely the gauge invariance that licenses us to use the polarization sum Eq. (18.52) in the next step.

Caution

A frequent error is to compute only the s-channel "seagull-free" diagram, or to drop the u-channel as a small correction. The Ward check shows why that is fatal: neither diagram is separately gauge invariant, so a single-

diagram "amplitude" would give different answers in different gauges and would not even be a well-defined cross section. Gauge invariance of an external-photon amplitude is a property of the *sum* of all diagrams at a given order.

18.3.3 Squaring: spin sums, polarization sums, and the traces

We want the unpolarized cross section, so we average over the initial electron spin and photon polarization (a factor $\tfrac{1}{2}$ each) and sum over the final spin and polarization:

$$\overline{|\mathcal{M}|^2} = \frac{1}{4}\sum_{s,s'}\sum_{\lambda,\lambda'} |\mathcal{M}_s + \mathcal{M}_u|^2. \tag{18.63}$$

Write $\mathcal{M} = \epsilon^*_\mu(k')\,\epsilon_\nu(k)\,\mathcal{M}^{\mu\nu}$, reading μ for the outgoing photon and ν for the incoming one. From Eq. (18.58),

$$\mathcal{M}_s^{\mu\nu} = -\frac{e^2}{2\,p\cdot k}\,\bar u(p')\,\gamma^\mu(\not p + \not k + m)\gamma^\nu\,u(p), \tag{18.64}$$

$$\mathcal{M}_u^{\mu\nu} = +\frac{e^2}{2\,p\cdot k'}\,\bar u(p')\,\gamma^\nu(\not p - \not k' + m)\gamma^\mu\,u(p). \tag{18.65}$$

The polarization sums act on the products $\epsilon^*_\mu\epsilon_\sigma \to -\eta_{\mu\sigma}$ and $\epsilon_\nu\epsilon^*_\rho \to -\eta_{\nu\rho}$ by Eq. (18.52), so the two minus signs combine to a plus and simply contract the loose photon indices of $\mathcal{M}^{\mu\nu}$ with those of its conjugate:

$$\sum_{\lambda,\lambda'} |\mathcal{M}|^2 = \mathcal{M}^{\mu\nu}\,(\mathcal{M}^{\sigma\rho})^*\,\eta_{\mu\sigma}\,\eta_{\nu\rho} = \mathcal{M}^{\mu\nu}\,\mathcal{M}^*{}_{\mu\nu}. \tag{18.66}$$

The remaining spin sums are handled by the completeness relations $\sum_s u(p)\bar u(p) = \not p + m$ and $\sum_{s'} u(p')\bar u(p') = \not p' + m$ of Eq. (11.73), together with the conjugation rule $\big[\bar u(p')\,\Gamma\,u(p)\big]^* = \bar u(p)\,\bar\Gamma\,u(p')$ with $\bar\Gamma = \gamma^0\Gamma^\dagger\gamma^0$; for a string of gammas this reverses their order, so $\overline{\gamma^\mu(\not q + m)\gamma^\nu} = \gamma^\nu(\not q + m)\gamma^\mu$. Each squared or interference term then collapses to a single Dirac trace. We treat the three pieces in turn, abbreviating

$$a \equiv p\cdot k, \qquad b \equiv p\cdot k'. \tag{18.67}$$

The s-channel square. Summing $|\mathcal{M}_s|^2$ over spins with Eq. (18.66),

$$\sum_{\text{spins}} |\mathcal{M}_s|^2 = \frac{e^4}{(2a)^2}\,T_s, \qquad T_s = \mathrm{Tr}\big[(\not p' + m)\gamma^\mu(\not q + m)\gamma^\nu(\not p + m)\gamma_\nu(\not q + m)\gamma_\mu\big], \tag{18.68}$$

with $q \equiv p + k$. The inner contraction is done first with the $d = 4$ identity $\gamma^\nu(\not p + m)\gamma_\nu = -2\not p + 4m$, which follows from $\gamma^\nu \not p \gamma_\nu = -2\not p$ and $\gamma^\nu\gamma_\nu = 4$

(Theorem C.58). Sandwiching the result and using the contraction identities $\gamma^\mu\gamma_\mu = 4$, $\gamma^\mu \not{a}\gamma_\mu = -2\not{a}$, $\gamma^\mu \not{a}\not{b}\gamma_\mu = 4\,a\cdot b$, and $\gamma^\mu \not{a}\not{b}\not{c}\gamma_\mu = -2\not{c}\not{b}\not{a}$ (Eqs. (C.168) to (C.171)) on the outer $\gamma^\mu \cdots \gamma_\mu$, the trace reduces (with $\mathrm{Tr}\,\mathbf{1} = 4$ and the four-gamma trace Eq. (C.178)) to

$$T_s = 32(m^4 + m^2\,a + a\,b), \tag{18.69}$$

where we used the on-shell kinematics $p\cdot q = m^2+a$, $p'\cdot q = m^2+a$, $q^2 = m^2+2a$, and $p\cdot p' = m^2 + a - b$ (derived in Section 18.3.4 below). Hence

$$\sum_{\text{spins}} |\mathcal{M}_s|^2 = \frac{8e^4}{a^2}(m^4 + m^2 a + ab) = 8e^4\left(\frac{m^4}{a^2} + \frac{m^2}{a} + \frac{b}{a}\right). \tag{18.70}$$

The u-channel square. The u-channel amplitude is obtained from the s-channel by the substitution $k \to -k'$, $k' \to -k$ (the two photons swap roles, incoming↔outgoing with a sign), which in our abbreviations sends $a \to -b$ and $b \to -a$. Applying this to Eq. (18.69) gives $T_u = 32(m^4 - m^2 b + ab)$, and since $|\mathcal{M}_u|^2$ carries the same overall e^4 with denominator $(2b)^2$,

$$\sum_{\text{spins}} |\mathcal{M}_u|^2 = \frac{8e^4}{b^2}(m^4 - m^2 b + ab) = 8e^4\left(\frac{m^4}{b^2} - \frac{m^2}{b} + \frac{a}{b}\right). \tag{18.71}$$

The interference term and the trace of eight gammas. The cross term is the genuinely new computation. Its spin sum is

$$\sum_{\text{spins}} 2\,\mathrm{Re}\,(\mathcal{M}_s\mathcal{M}_u^*) = -\frac{e^4}{2ab}\,T_x, \qquad T_x = \mathrm{Tr}\big[(\not{p}'+m)\gamma^\mu(\not{q}+m)\gamma^\nu(\not{p}+m)\gamma_\mu(\not{r}+m)\gamma_\nu\big], \tag{18.72}$$

with $q = p+k$, $r = p-k'$; the prefactor $-e^4/2ab$ collects the signs of Eqs. (18.64) and (18.65) and the two denominators $(2a)(2b)$, and the factor of two from $\mathcal{M}_s\mathcal{M}_u^* + \mathcal{M}_u\mathcal{M}_s^* = 2\,\mathrm{Re}(\mathcal{M}_s\mathcal{M}_u^*)$ together with the trace-reversal symmetry $T_x^* = T_x$. This is a trace of eight gamma matrices (four bare, plus up to four from the slashes), and brute force would generate $4!/(2!2!) \times \cdots$ terms; instead we again peel off the $\gamma^\mu \cdots \gamma_\mu$ contraction. Using the three-gamma identity $\gamma^\mu\gamma^\alpha\gamma^\nu\gamma^\beta\gamma_\mu = -2\gamma^\beta\gamma^\nu\gamma^\alpha$ and the two-gamma identity $\gamma^\mu\gamma^\alpha\gamma^\nu\gamma_\mu = 4\eta^{\alpha\nu}$ (both from Theorem C.58), the central block expands as

$$\gamma^\mu(\not{q}+m)\gamma^\nu(\not{p}+m)\gamma_\mu = -2\not{p}\,\gamma^\nu\not{q} + 4m\,(q+p)^\nu\mathbf{1} - 2m^2\gamma^\nu. \tag{18.73}$$

Insert Eq. (18.73) into Eq. (18.72), multiply by $(\not{r}+m)\gamma_\nu$, and trace against $(\not{p}'+m)$. Only terms with an even number of gamma matrices survive; the surviving traces are evaluated with $\gamma^\nu\not{a}\not{b}\gamma_\nu = 4\,a\cdot b$, $\gamma^\nu\not{a}\gamma_\nu = -2\not{a}$, $\gamma^\nu\gamma_\nu = 4$, the

two-gamma trace $\mathrm{Tr}(\not{a}\not{b}) = 4\,a\cdot b$ (Eq. (C.177)), and $\mathrm{Tr}\,\mathbf{1} = 4$. Term by term,

$$T_x = \underbrace{-32\,(q\cdot r)(p'\cdot p)}_{\text{4-slash}} + \underbrace{16m^2\big[(p\cdot q)+(q{+}p)\cdot p'+(q{+}p)\cdot r+(p'\cdot r)\big]}_{\text{2-slash}} \underbrace{-\,32m^4}_{\text{0-slash}}. \tag{18.74}$$

Now substitute the on-shell scalar products. With $q = p + k$ and $r = p - k'$ one finds, using $p^2 = m^2$, $k^2 = k'^2 = 0$, momentum conservation, and the relations $p'\cdot k = p\cdot k' = b$, $p'\cdot k' = p\cdot k = a$, $k\cdot k' = a - b$, $p\cdot p' = m^2 + a - b$ collected in Section 18.3.4:

$$q\cdot r = m^2, \quad p\cdot q = m^2{+}a, \quad (q{+}p)\cdot p' = 2m^2{+}2a{-}b, \quad (q{+}p)\cdot r = 2m^2{-}b, \quad p'\cdot r = m^2{-}b. \tag{18.75}$$

Plugging Eq. (18.75) into Eq. (18.74), the m^4 terms sum to $32m^4$, the $m^2 a$ terms to $16m^2 a$, and the $m^2 b$ terms to $-16m^2 b$, so the eight-gamma trace collapses to the compact

$$T_x = 16\,m^2\big(2m^2 + a - b\big). \tag{18.76}$$

Therefore

$$\sum_{\text{spins}} 2\,\mathrm{Re}(\mathcal{M}_s\mathcal{M}_u^*) = -\frac{e^4}{2ab}\,16m^2(2m^2+a-b) = -8e^4\left(\frac{2m^4}{ab} + \frac{m^2}{b} - \frac{m^2}{a}\right). \tag{18.77}$$

Assembling $\overline{|\mathcal{M}|^2}$. Adding Eqs. (18.70), (18.71) and (18.77) and dividing by the spin/polarization-averaging factor of 4 from Eq. (18.63),

$$\begin{aligned}\overline{|\mathcal{M}|^2} &= \frac{1}{4}\,8e^4\left[\frac{m^4}{a^2} + \frac{m^2}{a} + \frac{b}{a} + \frac{m^4}{b^2} - \frac{m^2}{b} + \frac{a}{b} - \frac{2m^4}{ab} - \frac{m^2}{b} + \frac{m^2}{a}\right] \\ &= 2e^4\left[\frac{b}{a} + \frac{a}{b} + 2m^2\left(\frac{1}{a} - \frac{1}{b}\right) + m^4\left(\frac{1}{a} - \frac{1}{b}\right)^2\right],\end{aligned} \tag{18.78}$$

where the four m^2-pieces combined as $2m^2(1/a - 1/b)$ and the three m^4-pieces formed the perfect square $m^4(1/a - 1/b)^2$. Restoring $a = p\cdot k$, $b = p\cdot k'$:

$$\boxed{\overline{|\mathcal{M}|^2} = 2e^4\left[\frac{p\cdot k'}{p\cdot k} + \frac{p\cdot k}{p\cdot k'} + 2m^2\left(\frac{1}{p\cdot k} - \frac{1}{p\cdot k'}\right) + m^4\left(\frac{1}{p\cdot k} - \frac{1}{p\cdot k'}\right)^2\right].} \tag{18.79}$$

This is the central dynamical result of the section. It is manifestly gauge invariant (it was built with the $-\eta^{\mu\nu}$ rule, whose use we earned in Eq. (18.62)), positive, and symmetric under $k \leftrightarrow -k'$ only up to the sign-changing m^2 term, a structure that crossing symmetry will make sense of in Section 18.4.

18.3.4 Mandelstam form and Compton kinematics

To hand the result to the crossing section we re-express Eq. (18.79) in Mandelstam invariants, and to compare with experiment we specialize to the laboratory frame. Both require the kinematic dictionary, which we now record. Label the legs $p_1 = p$, $p_2 = k$, $p_3 = p'$, $p_4 = k'$ in the conventions of Eqs. (16.118) and (16.120), so

$$s = (p+k)^2 = m^2 + 2\,p\cdot k, \qquad u = (p-k')^2 = m^2 - 2\,p\cdot k', \qquad t = (k-k')^2 = -2\,k\cdot k'. \tag{18.80}$$

Hence $a = p\cdot k = (s-m^2)/2$ and $b = p\cdot k' = (m^2-u)/2$. Momentum conservation $p + k = p' + k'$ together with the on-shell conditions yields the scalar products used above: squaring $p + k = p' + k'$ gives $p \cdot k = p' \cdot k'$, i.e. $p' \cdot k' = a$; squaring $p - k' = p' - k$ gives $p\cdot k' = p'\cdot k$, i.e. $p'\cdot k = b$; from $p\cdot p' = p\cdot(p+k-k') = m^2 + a - b$ and $k \cdot k' = p \cdot k - p \cdot k' = a - b$ the remaining entries follow. Substituting $a = (s - m^2)/2$, $b = (m^2 - u)/2$ into Eq. (18.79) gives the crossing-ready form

$$\overline{|\mathcal{M}|^2} = 2e^4 \left[\frac{m^2 - u}{s - m^2} + \frac{s - m^2}{m^2 - u} + 4m^2 \left(\frac{1}{s - m^2} - \frac{1}{m^2 - u} \right) + 4m^4 \left(\frac{1}{s - m^2} - \frac{1}{m^2 - u} \right)^2 \right]. \tag{18.81}$$

This is the analytic object the next section continues to the annihilation channel.

The lab frame and the Compton shift. Now sit in the rest frame of the incoming electron, $p = (m, \mathbf{0})$, with the incoming photon $k = (\omega, \omega\hat{\mathbf{z}})$ and the outgoing photon $k' = (\omega', \omega'\hat{\mathbf{n}})$ making an angle θ with $\hat{\mathbf{z}}$. Then

$$p \cdot k = m\omega, \qquad p \cdot k' = m\omega', \qquad k \cdot k' = \omega\omega'(1 - \cos\theta). \tag{18.82}$$

The identity $p \cdot k - p \cdot k' = k \cdot k'$ established above becomes $m\omega - m\omega' = \omega\omega'(1 - \cos\theta)$; dividing by $m\omega\omega'$ yields the celebrated Compton shift,

$$\boxed{\frac{1}{\omega'} - \frac{1}{\omega} = \frac{1 - \cos\theta}{m}.} \tag{18.83}$$

The outgoing photon is always softer than the incoming one ($\omega' < \omega$ for $\theta > 0$), by an amount set by the electron Compton wavelength $1/m$ — the kinematic fingerprint that told Compton in 1923 that radiation scatters off electrons as particles, not as a classical wave. Solving Eq. (18.83) for the frequency ratio,

$$\frac{\omega'}{\omega} = \frac{1}{1 + \dfrac{\omega}{m}(1 - \cos\theta)}. \tag{18.84}$$

Inserting Eq. (18.82) into Eq. (18.79), the m^2 and m^4 terms simplify beautifully. From Eq. (18.83), $1/(p\cdot k) - 1/(p\cdot k') = (1/m)(1/\omega - 1/\omega') = -(1-\cos\theta)/m^2$,

so $2m^2(\cdots) = -2(1-\cos\theta)$ and $m^4(\cdots)^2 = (1-\cos\theta)^2$. The kinematic terms give $p\cdot k'/p\cdot k = \omega'/\omega$ and $p\cdot k/p\cdot k' = \omega/\omega'$. Combining,

$$\overline{|\mathcal{M}|^2} = 2e^4\Big[\frac{\omega'}{\omega}+\frac{\omega}{\omega'}-2(1-\cos\theta)+(1-\cos\theta)^2\Big] = 2e^4\Big[\frac{\omega'}{\omega}+\frac{\omega}{\omega'}-\sin^2\theta\Big], \tag{18.85}$$

where the last step used $-2(1-\cos\theta)+(1-\cos\theta)^2 = -(1-\cos\theta)(1+\cos\theta) = -\sin^2\theta$. The lab-frame squared amplitude is thus a strikingly compact function of the frequency ratio and scattering angle.

18.3.5 The lab-frame phase space and the Klein–Nishina formula

The master cross-section formula $\mathrm{d}\sigma = F^{-1}\,\overline{|\mathcal{M}|^2}\,\mathrm{d}\Pi_2$ of Eq. (16.112) now needs the lab flux and the lab two-body phase space. Because the photon is massless, the invariant Møller flux of Theorem 16.16 reduces to

$$F = 4\sqrt{(p\cdot k)^2 - m^2\cdot 0} = 4\,p\cdot k = 4m\omega. \tag{18.86}$$

The two-body measure, before integration, is

$$\mathrm{d}\Pi_2 = \frac{\mathrm{d}^3p'}{(2\pi)^3\,2E'}\,\frac{\mathrm{d}^3k'}{(2\pi)^3\,2\omega'}\,(2\pi)^4\,\delta^{(4)}(p+k-p'-k'). \tag{18.87}$$

We integrate over $\mathbf{p}'$ against the three-momentum delta, fixing $\mathbf{p}' = \mathbf{k}-\mathbf{k}'$ (recall $\mathbf{p}=\mathbf{0}$) so that $E' = \sqrt{m^2+|\mathbf{k}-\mathbf{k}'|^2}$, and write $\mathrm{d}^3k' = \omega'^2\,\mathrm{d}\omega'\,\mathrm{d}\Omega$:

$$\mathrm{d}\Pi_2 = \frac{\omega'\,\mathrm{d}\omega'\,\mathrm{d}\Omega}{(2\pi)^2\,4E'}\,\delta(m+\omega-E'-\omega'). \tag{18.88}$$

The remaining ω' integral is done against the energy delta. Differentiating $E'^2 = m^2+\omega^2+\omega'^2-2\omega\omega'\cos\theta$ gives $E'\,\mathrm{d}E'/\mathrm{d}\omega' = \omega'-\omega\cos\theta$, so

$$\frac{\mathrm{d}}{\mathrm{d}\omega'}(E'+\omega') = \frac{\omega'-\omega\cos\theta}{E'}+1 = \frac{\omega'-\omega\cos\theta+E'}{E'}. \tag{18.89}$$

On the energy shell $E' = m+\omega-\omega'$, so the numerator is $m+\omega-\omega\cos\theta = m+\omega(1-\cos\theta) = m\omega/\omega'$ by Eq. (18.84). The delta function therefore contributes a Jacobian $|\mathrm{d}(E'+\omega')/\mathrm{d}\omega'|^{-1} = E'\omega'/(m\omega)$, and

$$\mathrm{d}\Pi_2 = \frac{\omega'}{(2\pi)^2\,4E'}\cdot\frac{E'\omega'}{m\omega}\,\mathrm{d}\Omega = \frac{1}{16\pi^2}\,\frac{\omega'^2}{m\omega}\,\mathrm{d}\Omega. \tag{18.90}$$

The electron energy E' has cancelled cleanly. Assembling with Eq. (18.86),

$$\frac{\mathrm{d}\sigma}{\mathrm{d}\Omega} = \frac{1}{F}\,\overline{|\mathcal{M}|^2}\,\frac{\mathrm{d}\Pi_2}{\mathrm{d}\Omega} = \frac{1}{4m\omega}\,\overline{|\mathcal{M}|^2}\,\frac{\omega'^2}{16\pi^2 m\omega} = \frac{\omega'^2}{64\pi^2m^2\omega^2}\,\overline{|\mathcal{M}|^2}. \tag{18.91}$$

Inserting the lab squared amplitude Eq. (18.85) and writing $e^4 = (4\pi\alpha)^2 = 16\pi^2\alpha^2$,

$$\boxed{\frac{\mathrm{d}\sigma}{\mathrm{d}\Omega} = \frac{\alpha^2}{2m^2}\left(\frac{\omega'}{\omega}\right)^2\left[\frac{\omega'}{\omega} + \frac{\omega}{\omega'} - \sin^2\theta\right],} \tag{18.92}$$

the Klein–Nishina formula (Klein and Nishina, 1929), with ω'/ω given by Eq. (18.84). It is one of the early triumphs of relativistic quantum theory: the full angular and energy dependence of photon–electron scattering, valid at any photon energy, from a single tree-level QED computation.

Physical Insight

The factor $(\omega'/\omega)^2$ in Eq. (18.92) is the phase-space penalty for the recoiling electron carrying away energy: at high ω the outgoing photon is strongly degraded (Eq. (18.84)) and back-scattering is suppressed, so Klein–Nishina scattering is forward-peaked — the physical basis for why high-energy photons in matter, and cosmic-ray photons traversing the microwave background, lose energy preferentially in the forward direction. As $\omega \to 0$ the recoil shuts off, $\omega' \to \omega$, and the distribution becomes the symmetric classical pattern of Eq. (18.93).

Worked Example 18.10 (From the trace to the Thomson cross section: the classical-physics check)**.** We complete the computation by taking the low-energy limit of Eq. (18.92) and integrating, recovering the classical Thomson result — the anchor that ties the entire quantum calculation to a measurable number.

Step 1: the Thomson differential cross section. In the limit $\omega \ll m$ the Compton shift Eq. (18.83) is negligible, so $\omega'/\omega \to 1$ at every angle. The Klein–Nishina formula Eq. (18.92) then becomes

$$\frac{\mathrm{d}\sigma}{\mathrm{d}\Omega} \xrightarrow{\omega \ll m} \frac{\alpha^2}{2m^2}(1 + 1 - \sin^2\theta) = \frac{\alpha^2}{2m^2}(1 + \cos^2\theta). \tag{18.93}$$

This is exactly the Thomson cross section of classical electromagnetism: an electromagnetic wave shakes the electron, which re-radiates as an oscillating dipole with the $(1 + \cos^2\theta)$ pattern. The amplitude scale is set by the classical electron radius $r_e = e^2/4\pi m = \alpha/m$, since $\alpha^2/2m^2 = \tfrac{1}{2}r_e^2$, so Eq. (18.93) reads $\mathrm{d}\sigma/\mathrm{d}\Omega = \tfrac{1}{2}r_e^2(1 + \cos^2\theta)$.

Step 2: the total Thomson cross section. Integrate Eq. (18.93) over the full solid angle. With $\mathrm{d}\Omega = 2\pi\,\mathrm{d}\cos\theta$ and $x = \cos\theta$,

$$\sigma_T = \frac{\alpha^2}{2m^2}\,2\pi\int_{-1}^{1}(1 + x^2)\,\mathrm{d}x = \frac{\pi\alpha^2}{m^2}\left(2 + \frac{2}{3}\right) = \frac{8\pi\alpha^2}{3m^2} = \frac{8\pi}{3}r_e^2. \tag{18.94}$$

This is the classical Thomson cross section, reproduced with no adjustable parameter from the QED amplitude. That a tree-level Feynman calculation,

built from gamma-matrix traces and the polarization sum, lands precisely on a result derivable from Maxwell's equations and Newton's second law is the cleanest possible sanity check on the entire apparatus of this part of the book.

Step 3: the full Klein–Nishina total cross section. Away from the Thomson limit the frequency ratio depends on the angle, so the integral is genuinely energy dependent. Write $x \equiv \omega/m$ (not to be confused with the integration variable above; we now use $u = \cos\theta$) and $R \equiv \omega'/\omega = [1 + x(1-u)]^{-1}$. From Eq. (18.92) with $\sin^2\theta = 1 - u^2$,

$$\sigma = \frac{\alpha^2}{2m^2}\, 2\pi \int_{-1}^{1} R^2 \Big[R + \frac{1}{R} - (1 - u^2) \Big] \mathrm{d}u = \frac{\pi\alpha^2}{m^2} \int_{-1}^{1} \left[R^3 + R - R^2(1-u^2) \right] \mathrm{d}u. \tag{18.95}$$

Substitute $w = 1 + x(1-u)$, so $u = (1 + x - w)/x$, $\mathrm{d}u = -\mathrm{d}w/x$, and w runs from $1 + 2x$ (at $u = -1$) to 1 (at $u = +1$). Then $\int_{-1}^{1} R^n \,\mathrm{d}u = \frac{1}{x}\int_{1}^{1+2x} w^{-n}\,\mathrm{d}w$, giving

$$\int_{-1}^{1} R\,\mathrm{d}u = \frac{L}{x}, \quad \int_{-1}^{1} R^2\,\mathrm{d}u = \frac{2}{1+2x}, \quad \int_{-1}^{1} R^3\,\mathrm{d}u = \frac{2(1+x)}{(1+2x)^2}, \qquad L \equiv \ln(1{+}2x), \tag{18.96}$$

while $1 - u^2 = (w-1)(1+2x-w)/x^2$ turns the last integral into

$$\int_{-1}^{1} R^2(1-u^2)\,\mathrm{d}u = \frac{1}{x^3}\big[(2+2x)L - 4x\big]. \tag{18.97}$$

Collecting the three pieces in Eq. (18.95),

$$\boxed{\sigma_{\mathrm{KN}} = \frac{\pi\alpha^2}{m^2}\left[\frac{2(1+x)}{(1+2x)^2} + \frac{L}{x} + \frac{4}{x^2} - \frac{2(1+x)L}{x^3} \right], \qquad L = \ln(1+2x), \quad x = \frac{\omega}{m}.} \tag{18.98}$$

This is the total Klein–Nishina cross section; it is equivalent to the standard textbook form $\sigma_{\mathrm{KN}} = 2\pi r_e^2\{\frac{1+x}{x^2}[\frac{2(1+x)}{1+2x} - \frac{L}{x}] + \frac{L}{2x} - \frac{1+3x}{(1+2x)^2}\}$ after using $r_e^2 = \alpha^2/m^2$.

Step 4: the low-energy limit, again. Expanding Eq. (18.98) for $x \ll 1$ with $L = 2x - 2x^2 + \frac{8}{3}x^3 - \cdots$, the $4/x^2$ in the third term is cancelled by the $-2(1+x)L/x^3$ in the fourth, and the surviving constant collects to $8/3$:

$$\sigma_{\mathrm{KN}} = \frac{8\pi\alpha^2}{3m^2}\Big(1 - 2x + \tfrac{26}{5}x^2 - \cdots\Big) = \sigma_T\Big(1 - \frac{2\omega}{m} + \cdots\Big). \tag{18.99}$$

The leading term is precisely σ_T of Eq. (18.94), confirming Eq. (18.98) against the classical limit, and the first correction $-2\omega/m$ is the familiar reduction of the cross section as the photon energy begins to probe the electron's recoil. The high-energy behaviour follows from the logarithm: for $x \gg 1$, $\sigma_{\mathrm{KN}} \simeq (\pi\alpha^2/m^2)(\ln 2x + \frac{1}{2})/x$, falling like $(\ln\omega)/\omega$ — matter becomes increasingly transparent to very energetic photons.

We have carried Compton scattering from its two diagrams to a fully closed-form cross section, checked gauge invariance on the concrete amplitude, and recovered classical physics in the soft limit. The decisive result for what follows is the analytic squared amplitude in Mandelstam form, Eq. (18.81): a single function of s and u, manifestly meromorphic in those invariants. The next section treats that function as the boundary value of one analytic object and continues it — by the crossing substitution $s \leftrightarrow$ the annihilation channel's energy invariant — directly into the amplitude for $e^+e^- \to \gamma\gamma$, obtaining a second physical process with no new trace algebra at all.

18.4 Crossing symmetry and pair annihilation

The previous section ended with a single rational function: the spin- and polarization-averaged squared amplitude $\overline{|\mathcal{M}|^2}_{\mathrm{C}}(s,u)$ for Compton scattering $e^-\gamma \to e^-\gamma$, assembled from the two diagrams of Section 18.3.1, squared with the polarization-sum rule and the gamma-matrix traces, and reduced (Eq. (18.81)) to the Klein–Nishina form. That function was computed to describe one experiment: a photon scattering off an electron. We now extract a *second* experiment from it without squaring a single new diagram. The observation is the one that already organized Chapter 17: the Mandelstam invariants s, t, u are not bound to any particular partition of the legs into "incoming" and "outgoing," and the amplitude is the boundary value of a single analytic function of them; moving a leg from one side of the reaction to the other—turning an incoming particle into an outgoing antiparticle—merely samples that same function in a different kinematic window. Applied to Compton scattering this maneuver lands on electron–positron pair annihilation, $e^+e^- \to \gamma\gamma$. The dynamics are already in hand; what remains is to make the continuation precise and to track the bookkeeping it changes.

Crossing was introduced and proved at tree level in Section 17.4, where we carried the continuation through the Dirac traces of $e^+e^- \to \mu^+\mu^-$ to obtain $e^-\mu^- \to e^-\mu^-$. That treatment crossed two fermion legs and no bosons, and it is the backbone we build on here rather than reprove. The present process is genuinely new in two respects that Chapter 17 did not exercise, and these are exactly what this section derives in full. First, one of the crossed legs is a *photon*: we must extend the crossing dictionary to an external gauge boson, including what happens to its polarization vector and to the polarization sum. Second, Compton and annihilation are related by crossing an *odd* number of fermion lines—precisely one—so the fermion crossing sign, which cancelled in the even case of Chapter 17, now survives as a physically decisive overall -1. We treat both, lay out the Mandelstam-plane geometry the continuation traverses, and then harvest $\overline{|\mathcal{M}|^2}$ and the cross section for $e^+e^- \to \gamma\gamma$, including the identical-photon phase-space factor.

18.4.1 The crossing dictionary, completed for external photons

We first recall the principle in the form fixed in Chapter 17, then add the entry for a photon leg. The origin of crossing is the analytic structure exposed by the LSZ reduction formula (Theorem 14.31): an S-matrix element is the multiple on-shell residue of a time-ordered correlator, and that correlator, as a function of the external four-momenta, is the boundary value of a function holomorphic in the complexified invariants away from the cuts and poles that unitarity demands at physical thresholds (Section 5.1, Section 5.4.1). At tree level there are no cuts at all—the amplitude is rational, with only the poles of the internal propagators—so continuation between physical regions is unambiguous and we may execute it by direct substitution. The general rule is Theorem 17.13: an incoming particle of species X and momentum p is exchanged for an outgoing antiparticle $\bar{X}$ of momentum p' by

$$p \;\longrightarrow\; -p', \qquad X \;\longleftrightarrow\; \bar{X}, \tag{18.100}$$

continued from the physical region of the original process to that of the crossed one, and conversely for an outgoing particle crossed to an incoming antiparticle. The momentum reversal is forced by the conservation delta function: a leg moved across the reaction enters the all-incoming momentum balance with the opposite sign.

For a *fermion* the continuation acts on the external wavefunctions through $u(p) \leftrightarrow v(-p')$ and $\bar{u}(p) \leftrightarrow \bar{v}(-p')$, as established in Theorem 17.13 from the Dirac equations: replacing $p \to -p$ in the antiparticle equation $(\not{p} + m)v(p) = 0$ gives $(\not{p} - m)v(-p) = 0$, the very equation obeyed by $u(p)$, so the two solution spaces are identified under momentum reversal. Working with the spin-summed completeness relations (Eq. (11.73))

$$\sum_s u^s(p)\,\bar{u}^s(p) = \not{p} + m, \qquad \sum_s v^s(p)\,\bar{v}^s(p) = \not{p} - m, \tag{18.101}$$

the crossing of a fermion leg is felt entirely through the relative sign of the mass term: continuing the particle projector $\not{p} + m$ to $p \to -p'$ produces $-\not{p}' + m = -(\not{p}' - m)$, i.e. (-1) times the antiparticle projector $\sum_s v^s(p')\bar{v}^s(p')$. This single sign, recorded per crossed fermion leg, is the source of the fermion crossing sign analyzed in Section 18.4.2.

The entry we must add is for a crossed *photon*. The photon is its own antiparticle, so the species swap $X \leftrightarrow \bar{X}$ is trivial; what we need is the rule for its polarization data. The relevant field-theory fact is again LSZ: the operator that annihilates an incoming photon of momentum k and helicity λ is the same free field A_μ whose positive-frequency part creates an outgoing photon, and the external-leg factor LSZ attaches is the polarization vector—$\epsilon^\mu(k,\lambda)$ for an incoming photon, $\epsilon^{*\mu}(k,\lambda)$ for an outgoing one (Section 17.1.4). Crossing the incoming photon to an outgoing one therefore replaces

$$k \;\longrightarrow\; -k', \qquad \epsilon^\mu(k,\lambda) \;\longrightarrow\; \epsilon^{*\mu}(k',\lambda), \tag{18.102}$$

the momentum reversal exactly as in Eq. (18.100) and the wavefunction passing from ϵ to its conjugate ϵ^*. The complex conjugation is the bosonic analogue of $u \leftrightarrow v$: it is the substitution that turns the annihilation wavefunction of an incoming quantum into the creation wavefunction of an outgoing one.

What matters for an unpolarized squared amplitude is not the individual polarization vectors but the polarization *sum*, and here the photon crossing is especially clean. For a gauge-invariant amplitude the physical-polarization sum may be performed with the covariant replacement (Theorem 17.10)

$$\sum_{\lambda=1,2} \epsilon_\mu(k,\lambda)\,\epsilon_\nu^*(k,\lambda) \;\longrightarrow\; -\eta_{\mu\nu}, \tag{18.103}$$

licensed by the tree-level Ward identity $k_\mu \mathcal{M}^\mu = 0$ established for these processes in Section 18.2.3. The right-hand side $-\eta_{\mu\nu}$ is a constant tensor: it carries no dependence on the photon momentum and no factor of i, and it is identical whether the photon is incoming or outgoing. Consequently the polarization sum of a crossed photon leg continues to itself with *no sign and no momentum substitution*—the entire content of crossing a photon, at the level of $\sum_{\text{pol}} |\mathcal{M}|^2$, is the momentum reversal $k \to -k'$ inside the kinematic factors. A boson leg contributes no crossing sign, in sharp contrast to the (-1) a fermion leg carries.

Caution

The replacement Eq. (18.103) is legitimate only because the amplitude obeys the Ward identity; the longitudinal and timelike pieces of the full $\sum_\lambda \epsilon\epsilon^*$ are discarded against $k_\mu \mathcal{M}^\mu = 0$. Crossing does not endanger this: gauge invariance is a property of the analytic amplitude, so if $k_\mu \mathcal{M}^\mu = 0$ holds in the Compton region it holds throughout, and the crossed annihilation amplitude is automatically transverse in both photon momenta. We will not re-establish the Ward identity here; it was proved for the external-photon amplitudes of this chapter in Section 18.2.3 and is promoted to the all-orders Ward–Takahashi identity in Chapter 19.

Collecting the entries, the complete crossing dictionary for QED tree amplitudes reads: an incoming particle becomes an outgoing antiparticle (and conversely) by $p \to -p'$; a crossed fermion leg replaces $u \leftrightarrow v$, equivalently flips the mass-term sign of its spin projector and contributes one factor (-1) to $\sum_{\text{spins}} |\mathcal{M}|^2$; a crossed photon leg replaces $\epsilon \leftrightarrow \epsilon^*$ and contributes no sign; and the spin-averaging prefactor $1/N_{\text{in}}$ is detached before continuing and recomputed from the initial state of the crossed process (Section 17.4.3).

18.4.2 The fermion crossing sign for an odd number of crossed lines

In Chapter 17 the relevant lesson was distilled as: *the squared amplitude carries a factor* (-1) *per crossed fermion line.* There two fermion lines were crossed, so the net sign was $(-1)^2 = +1$ and the continuation of $\sum_{\text{spins}} |\mathcal{M}|^2$ proceeded with no overall sign. Compton-to-annihilation is the complementary case. We will see in Section 18.4.3 that turning $e^-\gamma \to e^-\gamma$ into $e^+e^- \to \gamma\gamma$ crosses exactly one fermion leg (the outgoing electron, into an incoming positron) together with one photon leg (the incoming photon, into an outgoing photon). An odd number of fermion legs is crossed, and the net sign is $(-1)^1 = -1$, which now does not cancel. This sign is not a cosmetic bookkeeping artifact: it is exactly what renders the continued expression a positive squared amplitude, and getting it wrong produces a manifestly negative "cross section."

The derivation is the projector sign of Section 18.4.1, applied inside the trace. The Compton squared amplitude, before any averaging, has the schematic single-fermion-line structure

$$\sum_{\text{spins,pol}} |\mathcal{M}_{\mathrm{C}}|^2 \;=\; \mathrm{tr}\big[(\not{p}_1 + m)\,\Gamma\,(\not{p}_2 + m)\,\overline{\Gamma}\big], \tag{18.104}$$

where p_1 is the incoming electron, p_2 the outgoing electron (both particle projectors $\not{p} + m$ by Eq. (18.17)), and Γ is the string of vertices, internal electron propagators and photon polarization sums—a function of the photon momenta and of m, carrying the two $-\eta_{\mu\nu}$ factors of Eq. (18.103). The annihilation squared amplitude has the same fermion line read the other way: it runs from the incoming electron p_1 to the incoming positron p_2, so its trace is

$$\sum_{\text{spins,pol}} |\mathcal{M}_{\mathrm{A}}|^2 \;=\; \mathrm{tr}\big[(\not{p}_1 + m)\,\Gamma'\,(\not{p}_2 - m)\,\overline{\Gamma'}\big], \tag{18.105}$$

the positron leg now carrying the *antiparticle* projector $\not{p}_2 - m$ from Eq. (18.17), and Γ' being Γ with the crossed photon momentum reversed (the polarization sums are untouched, by Section 18.4.1). Now continue Eq. (18.104) by the dictionary: the incoming-electron leg p_1 is uncrossed and unchanged; the crossed photon sends $\Gamma \to \Gamma'$ with no sign; and the crossed outgoing-electron leg sends $p_2 \to -p_2$, so its projector becomes

$$\not{p}_2 + m \;\xrightarrow{\;p_2 \to -p_2\;}\; -\not{p}_2 + m \;=\; -(\not{p}_2 - m). \tag{18.106}$$

Pulling the single overall -1 out of the trace,

$$\Big[\sum_{\text{spins,pol}} |\mathcal{M}_{\mathrm{C}}|^2\Big]_{\text{continued}} = \mathrm{tr}\big[(\not{p}_1{+}m)\,\Gamma'\,(-(\not{p}_2{-}m))\,\overline{\Gamma'}\big] = -\,\mathrm{tr}\big[(\not{p}_1{+}m)\,\Gamma'\,(\not{p}_2{-}m)\,\overline{\Gamma'}\big] = -\,\mathrm{s}$$

(18.107)

The continued Compton trace equals (-1) times the genuine annihilation trace. Equivalently, the analytic continuation of the Compton spin-summed square gives the annihilation spin-summed square only after we restore the factor $(-1)^{n_f}$, with $n_f = 1$ the number of crossed fermion legs:

$$\boxed{\sum_{\text{spins,pol}} |\mathcal{M}_{\mathrm{A}}|^2 \;=\; (-1)^{n_f} \Big[\sum_{\text{spins,pol}} |\mathcal{M}_{\mathrm{C}}|^2 \Big]_{\text{continued}}, \qquad n_f = 1.} \tag{18.108}$$

This is the fermion crossing sign *derived*, not asserted: it is the product of the single projector flip Eq. (18.106) forced by $p \to -p'$ on a crossed fermion leg, with the photon leg contributing nothing. The same counting reproduces Chapter 17: there two fermion legs were crossed, $n_f = 2$, and $(-1)^2 = +1$. The rule $(-1)^{n_f}$ is the general statement; the cancellation seen earlier and the survival seen here are its even and odd instances.

Physical Insight

The crossing sign is harmless for a single squared diagram—it multiplies a positive quantity by ± 1 and is fixed by demanding the result be positive—but it becomes a measurable relative phase the moment two crossed diagrams interfere. Møller and Bhabha scattering in Section 18.5 are exactly that situation: the relative minus sign between their two diagrams is the same fermionic sign, now visible in an interference term rather than hidden inside an overall factor. The Compton-to-annihilation continuation is where we isolate the sign in its simplest guise, so that when it returns in the interference of the next section its origin is already settled.

18.4.3 Compton and annihilation on the Mandelstam plane

We now fix the momenta and read off how crossing acts on the invariants. Label Compton scattering as

$$\text{(C)} \qquad e^-(p_1)\,\gamma(k_1) \;\longrightarrow\; e^-(p_2)\,\gamma(k_2), \tag{18.109}$$

with the Mandelstam invariants of Theorem 16.20

$$s_{\mathrm{C}} = (p_1 + k_1)^2, \qquad t_{\mathrm{C}} = (p_1 - p_2)^2, \qquad u_{\mathrm{C}} = (p_1 - k_2)^2, \tag{18.110}$$

and label pair annihilation as

$$\text{(A)} \qquad e^-(p_1)\,e^+(p_2) \;\longrightarrow\; \gamma(k_1)\,\gamma(k_2), \tag{18.111}$$

with

$$s_{\mathrm{A}} = (p_1 + p_2)^2, \qquad t_{\mathrm{A}} = (p_1 - k_1)^2, \qquad u_{\mathrm{A}} = (p_1 - k_2)^2. \tag{18.112}$$

Both processes have external masses $(m, 0, m, 0)$, so both obey the same constraint (Eq. (16.121))

$$s + t + u = 2m^2. \tag{18.113}$$

To pass from (C) to (A) we cross two legs: the incoming photon $\gamma(k_1)$ of (C) becomes the outgoing photon $\gamma(k_1)$ of (A), and the outgoing electron $e^-(p_2)$ of (C) becomes the incoming positron $e^+(p_2)$ of (A); the incoming electron and the remaining photon are renamed directly. By Eq. (18.100) and Eq. (18.102) this is the momentum dictionary (all symbols on the right now denoting the annihilation momenta of Eq. (18.111))

$$p_1^{\mathrm{C}} = p_1, \qquad k_1^{\mathrm{C}} = -k_1, \qquad p_2^{\mathrm{C}} = -p_2, \qquad k_2^{\mathrm{C}} = k_2. \tag{18.114}$$

Exactly one fermion leg (p_2) and one boson leg (k_1) carry the minus sign, confirming $n_f = 1$ in Eq. (18.108). Substituting Eq. (18.114) into the Compton invariants Eq. (18.110) and reading them as annihilation invariants Eq. (18.112),

$$s_{\mathrm{C}} = (p_1^{\mathrm{C}} + k_1^{\mathrm{C}})^2 = (p_1 - k_1)^2 = t_{\mathrm{A}}, \tag{18.115}$$

$$u_{\mathrm{C}} = (p_1^{\mathrm{C}} - k_2^{\mathrm{C}})^2 = (p_1 - k_2)^2 = u_{\mathrm{A}}, \tag{18.116}$$

$$t_{\mathrm{C}} = (p_1^{\mathrm{C}} - p_2^{\mathrm{C}})^2 = (p_1 + p_2)^2 = s_{\mathrm{A}}. \tag{18.117}$$

The crossing therefore acts on the invariants as the swap

$$s_{\mathrm{C}} \longrightarrow t_{\mathrm{A}}, \qquad t_{\mathrm{C}} \longrightarrow s_{\mathrm{A}}, \qquad u_{\mathrm{C}} \longrightarrow u_{\mathrm{A}}, \tag{18.118}$$

that is, $s \leftrightarrow t$ with u inert. This is the precise content of the slogan "annihilation is Compton continued by $s \leftrightarrow t$." The photon that carried the Compton center-of-mass energy s_{C} becomes the photon exchanged in the annihilation t-channel, and the electron-exchange channel of Compton (the variable t_{C}, or rather the propagators living in s_{C} and u_{C}) reorganizes: the two Compton diagrams, with their internal electron propagators in the s- and u-channels, become the two annihilation diagrams with internal electron propagators in the t- and u-channels.

The shared analytic plane. Because (C) and (A) obey the same constraint Eq. (18.113), they live on the *same* Mandelstam plane—the two-dimensional surface $s + t + u = 2m^2$ introduced in Section 16.5.5 and drawn there for the equal-mass case (Fig. 16.5). Here the masses are unequal, $(m, 0, m, 0)$, so the physical wedges are not symmetric, but the principle is identical: a single analytic function $\mathcal{M}(s, t, u)$ is defined on the whole plane, and Compton and annihilation occupy disjoint physical regions of it. The boundaries are fixed by requiring the scattering angle to be real. For Compton, with center-of-mass energy $s_{\mathrm{C}} \geq m^2$, one finds (the two-body endpoints of Section 16.5.3 specialized to masses $(m, 0, m, 0)$) the physical region

$$\text{Compton:} \qquad t \leq 0 \quad \text{and} \quad su \leq m^4, \tag{18.119}$$

which comprises both the s-channel wedge ($s \geq m^2$) and the u-channel wedge ($u \geq m^2$)—these are the same physical reaction, since interchanging the two photons is the symmetry $s \leftrightarrow u$. For annihilation the center-of-mass energy is $s_{\mathrm{A}} = t_{\mathrm{C}}$, physical above the pair threshold $s_{\mathrm{A}} \geq 4m^2$, and the same angle-reality condition gives

$$\text{annihilation:} \qquad t \geq 4m^2 \quad \text{and} \quad su \geq m^4. \tag{18.120}$$

The hyperbola $su = m^4$ and the lines $t = 0$, $t = 4m^2$ are the boundaries; the two physical regions are the disjoint wedges of Fig. 18.4. No real point belongs to both, and the bridge between them is the analytic continuation Eq. (18.118), legitimate at tree level along any path avoiding the propagator poles.

Averaging factors. The averaging prefactor must be recomputed for (A), per the rule of Section 17.4.3: the analytic object that continues is the fully spin- and polarization-summed $\sum |\mathcal{M}|^2$, and the factor $1/N_{\text{in}}$ is reattached from the crossed initial state. Compton has an incoming electron (two spin states) and an incoming photon (two polarizations), so $N_{\text{in}}^{\mathrm{C}} = 2 \times 2 = 4$ and $\overline{|\mathcal{M}|^2}_{\mathrm{C}} = \frac{1}{4} \sum |\mathcal{M}_{\mathrm{C}}|^2$. Annihilation has an incoming electron and an incoming positron, two spin states each, so $N_{\text{in}}^{\mathrm{A}} = 2 \times 2 = 4$ and $\overline{|\mathcal{M}|^2}_{\mathrm{A}} = \frac{1}{4} \sum |\mathcal{M}_{\mathrm{A}}|^2$. The two averaging factors coincide—but, as in Chapter 17, for a reason, not by accident: both initial states carry four configurations. (Had we crossed instead to a state with a different initial multiplicity, the factor would change.) Combining the equal averaging factors with Eq. (18.108) for $n_f = 1$,

$$\overline{|\mathcal{M}|^2}_{\mathrm{A}}(t_{\mathrm{A}}, u_{\mathrm{A}}) \;=\; -\,\overline{|\mathcal{M}|^2}_{\mathrm{C}}(s_{\mathrm{C}} \to t_{\mathrm{A}},\, u_{\mathrm{C}} \to u_{\mathrm{A}}). \tag{18.121}$$

The overall minus is the fermion crossing sign Eq. (18.108); the averaging factors have cancelled. We now evaluate the right-hand side.

18.4.4 $e^+e^- \to \gamma\gamma$ from Klein–Nishina

Worked Example 18.11 (The annihilation squared amplitude by continuation of Klein–Nishina)**.** We carry Eq. (18.121) through to a closed expression. The starting point is the spin- and polarization-averaged Compton result of Section 18.3, which in terms of the invariant electron–photon products $p_1 \cdot k_1$ and $p_1 \cdot k_2$ reads (Eq. (18.79))

$$\overline{|\mathcal{M}|^2}_{\mathrm{C}} = 2e^4 \left[\frac{p_1 \cdot k_2}{p_1 \cdot k_1} + \frac{p_1 \cdot k_1}{p_1 \cdot k_2} + 2m^2 \left(\frac{1}{p_1 \cdot k_1} - \frac{1}{p_1 \cdot k_2} \right) + m^4 \left(\frac{1}{p_1 \cdot k_1} - \frac{1}{p_1 \cdot k_2} \right)^2 \right], \tag{18.122}$$

where here p_1 is the incoming electron, k_1 the incoming photon, k_2 the outgoing photon of Eq. (18.109). In Compton kinematics $s_{\mathrm{C}} - m^2 = 2\, p_1 \cdot k_1$ and $m^2 - u_{\mathrm{C}} =$

$2\,p_1\!\cdot\!k_2$, so

$$\overline{|\mathcal{M}|^2}_{\mathrm{C}} = 2e^4\left[\frac{m^2-u_{\mathrm{C}}}{s_{\mathrm{C}}-m^2}+\frac{s_{\mathrm{C}}-m^2}{m^2-u_{\mathrm{C}}}+4m^2\left(\frac{1}{s_{\mathrm{C}}-m^2}-\frac{1}{m^2-u_{\mathrm{C}}}\right)+4m^4\left(\frac{1}{s_{\mathrm{C}}-m^2}-\frac{1}{m^2-\right.\right. \tag{18.123}$$

Step 1: substitute the invariants. Apply $s_{\mathrm{C}}\to t_{\mathrm{A}}$, $u_{\mathrm{C}}\to u_{\mathrm{A}}$ from Eq. (18.118), and write the annihilation photon products from Eq. (18.112): $t_{\mathrm{A}}=(p_1-k_1)^2=m^2-2\,p_1\!\cdot\!k_1$ and $u_{\mathrm{A}}=(p_1-k_2)^2=m^2-2\,p_1\!\cdot\!k_2$, so now

$$t_{\mathrm{A}}-m^2=-2\,p_1\!\cdot\!k_1,\qquad m^2-u_{\mathrm{A}}=2\,p_1\!\cdot\!k_2. \tag{18.124}$$

The four terms of Eq. (18.123) become, with these signs,

$$\frac{m^2-u_{\mathrm{A}}}{t_{\mathrm{A}}-m^2}=\frac{2\,p_1\!\cdot\!k_2}{-2\,p_1\!\cdot\!k_1}=-\frac{p_1\!\cdot\!k_2}{p_1\!\cdot\!k_1},\qquad \frac{t_{\mathrm{A}}-m^2}{m^2-u_{\mathrm{A}}}=-\frac{p_1\!\cdot\!k_1}{p_1\!\cdot\!k_2}, \tag{18.125}$$

$$4m^2\left(\frac{1}{t_{\mathrm{A}}-m^2}-\frac{1}{m^2-u_{\mathrm{A}}}\right)=4m^2\left(\frac{1}{-2\,p_1\!\cdot\!k_1}-\frac{1}{2\,p_1\!\cdot\!k_2}\right)=-2m^2\left(\frac{1}{p_1\!\cdot\!k_1}+\frac{1}{p_1\!\cdot\!k_2}\right), \tag{18.126}$$

$$4m^4\left(\frac{1}{t_{\mathrm{A}}-m^2}-\frac{1}{m^2-u_{\mathrm{A}}}\right)^2=4m^4\cdot\frac{1}{4}\left(\frac{1}{p_1\!\cdot\!k_1}+\frac{1}{p_1\!\cdot\!k_2}\right)^2=m^4\left(\frac{1}{p_1\!\cdot\!k_1}+\frac{1}{p_1\!\cdot\!k_2}\right)^2. \tag{18.127}$$

Notice that the first two terms have flipped sign and the difference $1/(p\cdot k_1)-1/(p\cdot k_2)$ of Compton has become the *sum* $1/(p\cdot k_1)+1/(p\cdot k_2)$—the kinematic signature that the two photons are now both in the final state and symmetric under exchange.

Step 2: apply the crossing sign. By Eq. (18.121) the annihilation amplitude is (-1) times the continued Compton expression. Multiplying the bracket built from Eq. (18.125)–Eq. (18.127) by -1 flips every sign back, yielding a manifestly positive result:

$$\boxed{\overline{|\mathcal{M}|^2}_{e^+e^-\to\gamma\gamma}=2e^4\left[\frac{p_1\!\cdot\!k_2}{p_1\!\cdot\!k_1}+\frac{p_1\!\cdot\!k_1}{p_1\!\cdot\!k_2}+2m^2\left(\frac{1}{p_1\!\cdot\!k_1}+\frac{1}{p_1\!\cdot\!k_2}\right)-m^4\left(\frac{1}{p_1\!\cdot\!k_1}+\frac{1}{p_1\!\cdot\!k_2}\right)^2\right].} \tag{18.128}$$

Had we omitted the fermion crossing sign, the leading two terms would have entered with an overall minus and the expression would be negative at high energy, where they dominate—an immediate flag that the $(-1)^{n_f}$ of Eq. (18.108) is mandatory, not optional. The result Eq. (18.128) is symmetric under $k_1\leftrightarrow k_2$, as it must be for two identical final-state photons.

Step 3: Mandelstam form. Using $p_1\!\cdot\!k_1=(m^2-t_{\mathrm{A}})/2$ and $p_1\!\cdot\!k_2=(m^2-u_{\mathrm{A}})/2$ from Eq. (18.124) (now read forward), and dropping the subscript A,

$$\overline{|\mathcal{M}|^2}_{e^+e^-\to\gamma\gamma}=2e^4\left[\frac{m^2-u}{m^2-t}+\frac{m^2-t}{m^2-u}+4m^2\left(\frac{1}{m^2-t}+\frac{1}{m^2-u}\right)-4m^4\left(\frac{1}{m^2-t}+\frac{1}{m^2-\right.\right. \tag{18.129}$$

manifestly symmetric under $t \leftrightarrow u$ (the photon interchange) and finite throughout the physical region Eq. (18.120), where $m^2 - t < 0$ and $m^2 - u < 0$. This is the central dynamical result for pair annihilation, obtained from the Klein–Nishina amplitude by a substitution and a sign rather than by squaring the two annihilation diagrams afresh.

It is worth recording the compact algebraic form that the cross-section integral will use. Introduce

$$a \equiv m^2 - t = 2\,p_1\!\cdot\!k_1, \qquad b \equiv m^2 - u = 2\,p_1\!\cdot\!k_2, \tag{18.130}$$

both positive in the physical region. The constraint Eq. (18.113) gives $a + b = 2m^2 - t - u = 2m^2 - (2m^2 - s) = s$, the clean identity

$$a + b = s. \tag{18.131}$$

Then $\frac{b}{a} + \frac{a}{b} = \frac{a^2+b^2}{ab} = \frac{s^2-2ab}{ab}$, $\frac{1}{a} + \frac{1}{b} = \frac{s}{ab}$, and $(\frac{1}{a} + \frac{1}{b})^2 = \frac{s^2}{a^2b^2}$, so Eq. (18.129) collapses to

$$\overline{|\mathcal{M}|^2}_{e^+e^-\to\gamma\gamma} = 2e^4 \left[\frac{s^2 - 2ab + 4m^2 s}{ab} - \frac{4m^4 s^2}{a^2 b^2} \right]. \tag{18.132}$$

Worked Example 18.12 (Two checks on the annihilation amplitude)**.** Before assembling the cross section we confirm Eq. (18.129) against two independent expectations.

The massless limit and the photon-exchange poles. Setting $m \to 0$ (energies far above the electron mass), Eq. (18.129) reduces to

$$\overline{|\mathcal{M}|^2}_{e^+e^-\to\gamma\gamma} \xrightarrow{m\to 0} 2e^4 \left(\frac{u}{t} + \frac{t}{u} \right) = 2e^4\, \frac{t^2 + u^2}{tu}. \tag{18.133}$$

The denominators t and u are the squared momenta of the exchanged electron in the two annihilation diagrams (the propagator $1/(\not{p}_1 - \not{k}_1 - m)$ has denominator $t - m^2 \to t$, and likewise u for the crossed diagram), so the amplitude diverges as $t \to 0$ or $u \to 0$. These are the forward and backward directions, in which a photon is emitted collinear with the incoming electron or positron and the exchanged electron goes nearly on shell. The $1/t$ and $1/u$ singularities are the annihilation counterparts of the Coulomb forward pole met in Section 17.4.5; they are regulated by the electron mass, $m^2 - t \geq m^2$, which is why the collinear region is logarithmically, not power, sensitive to m—a fact that controls the total cross section below.

Reduction to nonrelativistic positronium-like kinematics. At threshold $s \to 4m^2$ the electron and positron are nearly at rest; with $a = b \to s/2 = 2m^2$ the bracket Eq. (18.132) becomes $\frac{s^2 - 2(s/2)^2 + 4m^2 s}{(s/2)^2} - \frac{4m^4 s^2}{(s/2)^4} = \frac{s^2/2 + 4m^2 s}{s^2/4} - \frac{4m^4 s^2}{s^4/16} = 2 + \frac{16m^2}{s} - \frac{64m^4}{s^2}$. At $s = 4m^2$ this is $2 + 4 - 4 = 2$, so $\overline{|\mathcal{M}|^2} \to 4e^4$, a finite nonzero constant. Annihilation at rest proceeds through an S-wave with a nonvanishing amplitude; the $1/\beta$ enhancement of the cross section near threshold, derived next, comes entirely from the flux and phase-space factors, not from the dynamics.

18.4.5 The cross section and the identical-photon factor

Worked Example 18.13 (Differential and total cross section for $e^+e^- \to \gamma\gamma$)**.** We fold Eq. (18.129) into the two-body kinematics of Chapter 16, taking care of the one feature absent from every process so far in this chapter: the two final-state particles are identical.

Kinematics. In the center-of-mass frame the incoming electron and positron have energy $\sqrt{s}/2$ and momentum

$$|\mathbf{p}_i| = \tfrac{1}{2}\sqrt{s - 4m^2} = \tfrac{\sqrt{s}}{2}\,\beta, \qquad \beta \equiv \sqrt{1 - \tfrac{4m^2}{s}}, \tag{18.134}$$

with β the electron velocity. The outgoing photons are massless, each with energy $\sqrt{s}/2$, so $|\mathbf{p}_f| = \sqrt{s}/2$ and the phase-space ratio of Theorem 16.23 is

$$\frac{|\mathbf{p}_f|}{|\mathbf{p}_i|} = \frac{\sqrt{s}/2}{\frac{\sqrt{s}}{2}\beta} = \frac{1}{\beta}. \tag{18.135}$$

The photon momentum transfer, with $E_1 = E_\gamma = \sqrt{s}/2$, is $t = (p_1 - k_1)^2 = m^2 - 2E_1E_\gamma + 2\,|\mathbf{p}_i|\,|\mathbf{p}_f|\cos\theta = m^2 - \frac{s}{2} + \frac{s}{2}\beta\cos\theta$, so in terms of $a = m^2 - t$ and $b = m^2 - u$ of Eq. (18.130),

$$a = \frac{s}{2}(1 - \beta\cos\theta), \qquad b = \frac{s}{2}(1 + \beta\cos\theta), \qquad ab = \frac{s^2}{4}(1 - \beta^2\cos^2\theta). \tag{18.136}$$

The identical-particle factor. For distinct final particles the CM differential cross section is Eq. (16.145). With two *identical* photons, a configuration with photon momenta $(\mathbf{k}, -\mathbf{k})$ is the same final state as $(-\mathbf{k}, \mathbf{k})$: integrating $d\sigma/d\Omega$ over the full solid angle counts every distinct two-photon state twice. The total cross section is therefore

$$\sigma = \frac{1}{2}\int_{4\pi} \frac{d\sigma}{d\Omega}\, d\Omega, \tag{18.137}$$

the factor $\frac{1}{2}$ being a phase-space symmetry factor, entirely distinct from the spin average. (Equivalently one integrates over a hemisphere, $\theta \in [0, \pi/2]$, without the $\frac{1}{2}$; the two prescriptions agree because Eq. (18.129) is symmetric under $\theta \to \pi - \theta$, i.e. $t \leftrightarrow u$.) The differential cross section itself, before the $\frac{1}{2}$, is

$$\frac{d\sigma}{d\Omega} = \frac{1}{64\pi^2 s}\,\frac{|\mathbf{p}_f|}{|\mathbf{p}_i|}\,\overline{|\mathcal{M}|^2} = \frac{1}{64\pi^2 s\,\beta}\,\overline{|\mathcal{M}|^2}_{e^+e^-\to\gamma\gamma}. \tag{18.138}$$

High-energy differential cross section. At $s \gg m^2$ ($\beta \to 1$), Eq. (18.133) with $t = -\frac{s}{2}(1-\cos\theta)$, $u = -\frac{s}{2}(1+\cos\theta)$ gives $\frac{t}{u} + \frac{u}{t} = \frac{(1-\cos\theta)^2 + (1+\cos\theta)^2}{(1-\cos\theta)(1+\cos\theta)} = \frac{2(1+\cos^2\theta)}{1-\cos^2\theta}$, so $\overline{|\mathcal{M}|^2} \to 4e^4\,\frac{1+\cos^2\theta}{\sin^2\theta}$ and

$$\frac{d\sigma}{d\Omega} \xrightarrow{s \gg m^2} \frac{4e^4}{64\pi^2 s}\,\frac{1+\cos^2\theta}{\sin^2\theta} = \frac{\alpha^2}{2s}\,\frac{1+\cos^2\theta}{\sin^2\theta}, \tag{18.139}$$

using $e^4 = (4\pi\alpha)^2 = 16\pi^2\alpha^2$. The angular distribution peaks sharply in the forward and backward directions, the $1/\sin^2\theta$ rise being the collinear singularity of Theorem 18.12 regulated, in the full massive amplitude, at $\sin^2\theta \sim 4m^2/s$.

Total cross section. We integrate the exact massive amplitude. Insert Eq. (18.132) with ab from Eq. (18.136) into Eq. (18.138), write $x = \cos\theta$, and use $4m^2 = s(1-\beta^2)$ to express the mass terms through β. The bracket of Eq. (18.132) becomes a function of x alone:

$$\frac{s^2 - 2ab + 4m^2 s}{ab} = \frac{s^2 + s^2(1-\beta^2) - \frac{s^2}{2}(1-\beta^2 x^2)}{\frac{s^2}{4}(1-\beta^2 x^2)} = \frac{6 - 4\beta^2 + 2\beta^2 x^2}{1-\beta^2 x^2}, \tag{18.140}$$

$$\frac{4m^4 s^2}{a^2 b^2} = \frac{\frac{s^4}{4}(1-\beta^2)^2}{\frac{s^4}{16}(1-\beta^2 x^2)^2} = \frac{4(1-\beta^2)^2}{(1-\beta^2 x^2)^2}, \tag{18.141}$$

so that

$$\overline{|\mathcal{M}|^2} = 2e^4\left[\frac{6 - 4\beta^2 + 2\beta^2 x^2}{1-\beta^2 x^2} - \frac{4(1-\beta^2)^2}{(1-\beta^2 x^2)^2}\right]. \tag{18.142}$$

The total cross section, with the identical-particle $\frac{1}{2}$ and $\int d\Omega = 2\pi\int_{-1}^{1} dx$, is

$$\sigma = \frac{1}{2}\cdot\frac{2\pi}{64\pi^2 s\,\beta}\int_{-1}^{1}\overline{|\mathcal{M}|^2}\,dx = \frac{1}{64\pi s\,\beta}\int_{-1}^{1}\overline{|\mathcal{M}|^2}\,dx. \tag{18.143}$$

The two elementary integrals needed are, with $L \equiv \ln\frac{1+\beta}{1-\beta}$,

$$\int_{-1}^{1}\frac{dx}{1-\beta^2x^2} = \frac{L}{\beta}, \qquad \int_{-1}^{1}\frac{x^2\,dx}{1-\beta^2x^2} = -\frac{2}{\beta^2} + \frac{L}{\beta^3}, \qquad \int_{-1}^{1}\frac{dx}{(1-\beta^2x^2)^2} = \frac{1}{1-\beta^2} + \frac{L}{2\beta}, \tag{18.144}$$

the first from $\int\frac{dx}{1-\beta^2x^2} = \frac{1}{2\beta}\ln\frac{1+\beta x}{1-\beta x}$, the second by writing $\frac{x^2}{1-\beta^2x^2} = -\frac{1}{\beta^2} + \frac{1}{\beta^2(1-\beta^2x^2)}$, and the third from the reduction $\int\frac{dx}{(1-\beta^2x^2)^2} = \frac{x}{2(1-\beta^2x^2)} + \frac{1}{4\beta}\ln\frac{1+\beta x}{1-\beta x}$ (verified by differentiation). Assembling Eq. (18.142),

$$\int_{-1}^{1}\frac{6 - 4\beta^2 + 2\beta^2x^2}{1-\beta^2x^2}\,dx = (6-4\beta^2)\frac{L}{\beta} + 2\beta^2\left(-\frac{2}{\beta^2} + \frac{L}{\beta^3}\right) = \frac{4L}{\beta}(2-\beta^2) - 4, \tag{18.145}$$

$$4(1-\beta^2)^2\int_{-1}^{1}\frac{dx}{(1-\beta^2x^2)^2} = 4(1-\beta^2)^2\left(\frac{1}{1-\beta^2} + \frac{L}{2\beta}\right) = 4(1-\beta^2) + \frac{2(1-\beta^2)^2 L}{\beta}. \tag{18.146}$$

Subtracting Eq. (18.146) from Eq. (18.145) and collecting the coefficient of L/β,

$$\frac{1}{2e^4}\int_{-1}^{1}\overline{|\mathcal{M}|^2}\,dx = \frac{L}{\beta}\left[4(2-\beta^2) - 2(1-\beta^2)^2\right] - 4 - 4(1-\beta^2) + 0 = \frac{2L}{\beta}(3-\beta^4) - 4(2-\beta^2), \tag{18.147}$$

where $4(2-\beta^2)-2(1-\beta^2)^2 = 8-4\beta^2-2(1-2\beta^2+\beta^4) = 6-2\beta^4$. Thus $\int_{-1}^{1}\overline{|\mathcal{M}|^2}\,dx = 4e^4\big[\frac{(3-\beta^4)}{\beta}L - 2(2-\beta^2)\big]$, and Eq. (18.143) gives, with $e^4 = 16\pi^2\alpha^2$ so that $e^4/(16\pi s\beta) = \pi\alpha^2/(s\beta)$,

$$\boxed{\sigma(e^+e^-\to\gamma\gamma) = \frac{2\pi\alpha^2}{s\,\beta}\left[\frac{3-\beta^4}{2\beta}\,\ln\frac{1+\beta}{1-\beta} - (2-\beta^2)\right], \qquad \beta = \sqrt{1-\frac{4m^2}{s}}.} \tag{18.148}$$

High-energy limit. As $s\to\infty$, $\beta\to 1$ and $1-\beta \simeq 2m^2/s$, so $\frac{1+\beta}{1-\beta} \simeq \frac{2}{2m^2/s} = \frac{s}{m^2}$ and the bracket tends to $\frac{3-1}{2}\ln\frac{s}{m^2} - (2-1) = \ln\frac{s}{m^2} - 1$:

$$\sigma(e^+e^-\to\gamma\gamma) \xrightarrow{s\gg m^2} \frac{2\pi\alpha^2}{s}\left[\ln\frac{s}{m^2} - 1\right]. \tag{18.149}$$

The logarithm is the integrated collinear enhancement of Eq. (18.139): the forward/backward $1/\sin^2\theta$ peaks, cut off by the electron mass, produce $\ln(s/m^2)$ upon angular integration. The cross section falls as $\ln s/s$, the characteristic $1/s$ scaling of a pointlike $2\to 2$ QED cross section, modulated by the collinear log.

Threshold limit. As $\beta\to 0$, $L = \ln\frac{1+\beta}{1-\beta} \simeq 2\beta + \frac{2}{3}\beta^3$, so $\frac{3-\beta^4}{2\beta}L \to 3+\beta^2$ and the bracket tends to $(3+\beta^2)-(2-\beta^2) = 1+2\beta^2 \to 1$. Hence

$$\sigma(e^+e^-\to\gamma\gamma) \xrightarrow{\beta\to 0} \frac{2\pi\alpha^2}{s\,\beta} \to \frac{\pi\alpha^2}{2m^2\,\beta}, \tag{18.150}$$

the $1/\beta$ growth being the threshold flux enhancement anticipated in Theorem 18.12: the dynamical amplitude is finite at rest ($\overline{|\mathcal{M}|^2}\to 4e^4$), and the rising cross section reflects the diverging time the slow pair spends within interaction range. This is the S-wave $1/v$ law that underlies the lifetime of para-positronium, whose dominant decay is precisely this two-photon annihilation.

18.4.6 The crossing web of Chapter 18

We have now produced two complete observables from a single Klein–Nishina computation, and it is worth seeing where this places the chapter's processes in one analytic family. Crossing organizes the QED tree amplitudes of this chapter into a small "web," each link being an analytic continuation we have made explicit. Compton scattering $e^-\gamma\to e^-\gamma$ and pair annihilation $e^+e^-\to\gamma\gamma$ are the link built in this section, related by the $s\leftrightarrow t$ swap Eq. (18.118) and the single fermion sign Eq. (18.108); the reverse continuation gives pair production $\gamma\gamma\to e^+e^-$, occupying the same orange wedge of Fig. 18.4. In Chapter 17 the fermion-only link tied $e^+e^-\to\mu^+\mu^-$ to $e^-\mu^-\to e^-\mu^-$ by a $t\leftrightarrow s$ continuation crossing two fermion lines (Theorem 17.14). The remaining link is the one with identical fermions, where crossing relates Møller scattering $e^-e^-\to e^-e^-$

to Bhabha scattering $e^+e^- \to e^+e^-$—and there, because the two contributing diagrams are themselves a crossed pair, the fermion sign $(-1)^{n_f}$ we isolated here reappears not as a harmless overall factor but as the relative minus sign between interfering amplitudes demanded by Fermi statistics.

That last link is the subject of the next section. With the crossing machinery now complete—momentum and spinor replacements, the photon polarization-sum rule, the $(-1)^{n_f}$ fermion sign, and the averaging-factor adjustment all derived—we turn to the two-fermion-line processes, where these tools combine with identical-particle antisymmetrization to produce the Møller and Bhabha cross sections, the latter obtained from the former by exactly the kind of continuation worked out above.

18.5 Møller and Bhabha scattering

The crossing machinery assembled in Section 18.4 did its work on processes with a single fermion line of charge flowing through the diagram: Compton scattering and its crossed relative, pair annihilation into two photons. We now turn to the two processes in which *two* charged fermion lines run side by side and the photon is the exchanged, internal quantum—electron–electron scattering, $e^-e^- \to e^-e^-$ (Møller), and electron–positron scattering, $e^+e^- \to e^+e^-$ (Bhabha). These are the processes in which the structural features that make QED amplitudes more than a single Feynman graph come fully into view. Each receives contributions from two distinct diagrams that must be added *coherently*, before squaring; the two diagrams interfere, and the interference term is as physical as the direct terms. In Møller scattering the two diagrams are related by the exchange of the two identical final electrons, and Fermi statistics demands that they enter the amplitude with a *relative minus sign*—a sign with no analogue in the scalar theory of Part IV, and the first place in the book where the antisymmetry of the electron field leaves a directly measurable fingerprint. In Bhabha scattering the two diagrams are of genuinely different character—one is the t-channel exchange that Møller also has, the other is the s-channel annihilation $e^+e^- \to \gamma^* \to e^+e^-$ already met in $e^+e^- \to \mu^+\mu^-$—yet, as crossing will show, the two processes are boundary values of one analytic function: Bhabha is Møller continued in the Mandelstam variables. We compute both unpolarized cross sections from the traces in full, verify the crossing relation between them as an independent check, and close by recovering the non-relativistic Coulomb (Rutherford–Mott) limit as the physical sanity test that every charged-particle scattering calculation must pass.

Throughout we use the QED Feynman rules of Chapter 17: the vertex $-ie\gamma^\mu$ (Eq. (17.10)), with electron charge $-e$ and $e > 0$; the photon propagator $-i\eta_{\mu\nu}/(q^2 + i\varepsilon)$ in Feynman gauge $\xi = 1$ (Eq. (17.18)); and the external-spinor wavefunctions of Chapter 11. Spin sums use the completeness relations

$\sum_s u^s(p)\bar{u}^s(p) = \not{p} + m$ and $\sum_s v^s(p)\bar{v}^s(p) = \not{p} - m$ (Theorem C.68), and the Dirac traces and γ-contraction identities are taken from Section C.6. We keep the electron mass m general in the Møller direct and interference traces—the Coulomb limit needs it—and pass to the high-energy massless forms only after the invariant answer is in hand.

18.5.1 The Møller amplitude and the Fermi sign

Label the process $e^-(p_1)\,e^-(p_2) \to e^-(p_3)\,e^-(p_4)$, all four particles electrons of mass m, with spins suppressed until the spin sum. The Mandelstam invariants are

$$s = (p_1 + p_2)^2, \qquad t = (p_1 - p_3)^2, \qquad u = (p_1 - p_4)^2, \qquad s + t + u = 4m^2, \tag{18.151}$$

the last identity following from $\sum_i p_i^2 = 4m^2$ and overall momentum conservation. At order e^2 the connected amplitude is built from two tree diagrams, drawn in Fig. 18.5. In the first, the incoming electron p_1 emits a virtual photon and emerges as p_3, while p_2 absorbs it and emerges as p_4; the exchanged photon carries momentum $p_1 - p_3$, so this is the t-channel diagram. In the second, the roles of the two outgoing electrons are interchanged: $p_1 \to p_4$ and $p_2 \to p_3$, the photon carrying $p_1 - p_4$, the u-channel. Because the two final electrons are identical particles, both wirings contribute to the same physical final state and both must be included.

The t-channel graph is assembled from two vertices, one photon propagator, and the four external spinors. The incoming p_1/outgoing p_3 vertex contributes the current $\bar{u}_3(-ie\gamma^\mu)u_1$; the incoming p_2/outgoing p_4 vertex contributes $\bar{u}_4(-ie\gamma^\nu)u_2$; the photon line between them contributes $-i\eta_{\mu\nu}/t$. Multiplying,

$$i\mathcal{M}_t = \left[\bar{u}_3(-ie\gamma^\mu)u_1\right]\frac{-i\eta_{\mu\nu}}{t}\left[\bar{u}_4(-ie\gamma^\nu)u_2\right] = \frac{ie^2}{t}\left[\bar{u}_3\gamma^\mu u_1\right]\left[\bar{u}_4\gamma_\mu u_2\right], \tag{18.152}$$

where the numerical coefficient is $(-ie)^2(-i) = ie^2$ and we abbreviate $u_i \equiv u^{s_i}(p_i)$. The u-channel graph is obtained by the replacement $p_3 \leftrightarrow p_4$ (equivalently $3 \leftrightarrow 4$ on the outgoing spinors), with the photon momentum now $p_1 - p_4$ so that the denominator is u:

$$i\mathcal{M}_u = \frac{ie^2}{u}\left[\bar{u}_4\gamma^\mu u_1\right]\left[\bar{u}_3\gamma_\mu u_2\right]. \tag{18.153}$$

The relative sign from Wick's theorem. The two diagrams cannot simply be added; antisymmetry of the fermionic fields fixes their relative sign, and getting it right is the whole point of the calculation. The cleanest derivation runs through Wick's theorem (Theorem 15.3). At second order in the interaction the relevant contribution to the S-matrix element is

$$\left\langle e^-(p_3)e^-(p_4)\middle|\mathcal{T}\left[\tfrac{(ie)^2}{2!}\int d^4x\,d^4y\,(\bar{\psi}\not{A}\psi)_x(\bar{\psi}\not{A}\psi)_y\right]\middle|e^-(p_1)e^-(p_2)\right\rangle, \tag{18.154}$$

in which two of the four fermion fields are contracted with the external electrons and the two photon fields are contracted with each other to make the internal line. The external incoming electrons are annihilated by the ψ fields and the outgoing ones created by the $\bar{\psi}$ fields. There are exactly two inequivalent ways to assign the two $\bar{\psi}$'s to the two outgoing momenta: $\bar{\psi}(x)\to p_3$, $\bar{\psi}(y)\to p_4$, which (after also assigning the ψ's and the photon contraction) reproduces Eq. (18.152); and $\bar{\psi}(x)\to p_4$, $\bar{\psi}(y)\to p_3$, which reproduces Eq. (18.153). These two assignments differ by the interchange of two anticommuting field operators in the contraction string: passing from one to the other transposes a single pair of fermionic creation operators, and each such transposition carries a factor (-1) from the canonical anticommutation relations of Chapter 11. The second contraction therefore enters with the opposite sign to the first. (The overall $1/2!$ of the Dyson expansion and the choice of which vertex, x or y, supplies p_3 are absorbed in the standard way: the two terms of the $1/2!$ sum are equal and cancel the factor, leaving one copy of each topology, exactly as in the scalar case of Section 15.4.) The result is that the two diagrams add with a relative minus,

$$i\mathcal{M} = i\mathcal{M}_t - i\mathcal{M}_u = ie^2\left\{\frac{[\bar{u}_3\gamma^\mu u_1][\bar{u}_4\gamma_\mu u_2]}{t} - \frac{[\bar{u}_4\gamma^\mu u_1][\bar{u}_3\gamma_\mu u_2]}{u}\right\}. \tag{18.155}$$

Physical Insight

The relative minus sign in Eq. (18.155) is the amplitude-level statement of the Pauli principle. Under interchange of the two identical outgoing electrons, $p_3 \leftrightarrow p_4$ (with their spins), the labels $t \leftrightarrow u$ swap and the two terms of Eq. (18.155) trade places; the relative minus makes the *total* amplitude antisymmetric, $\mathcal{M}(p_3,p_4) = -\mathcal{M}(p_4,p_3)$, exactly the antisymmetry the final two-electron state must have. It is not a convention one is free to choose: a relative plus would predict constructive interference where experiment, and the spin-statistics theorem (the subject of Chapter 15 and its statement of Wick's theorem), demand destructive. The sign survives into the cross section as the $+2s^2/tu$ interference term computed below, whose destructive (Pauli) character is directly visible in the angular distribution—showing as a genuinely negative contribution in the non-relativistic Mott limit, while at high energy the term itself is positive (Eq. (18.173)).

18.5.2 The unpolarized Møller cross section

For unpolarized beams and unobserved final spins we average over the four initial spin states and sum over the four final ones, the standard $\frac{1}{4}\sum_{\text{spins}}$ of Section 17.3. Writing $\mathcal{M} = \mathcal{M}_t - \mathcal{M}_u$ (with $\mathcal{M}_{t,u}$ the prefactors of i in Eq. (18.152)–Eq. (18.153)), the squared amplitude splits into two direct terms

and an interference term,

$$\overline{|\mathcal{M}|^2} = \tfrac{1}{4}\sum_{\text{spins}} \Big(|\mathcal{M}_t|^2 + |\mathcal{M}_u|^2 - 2\,\text{Re}\;\mathcal{M}_t\mathcal{M}_u^* \Big). \tag{18.156}$$

We compute the three pieces in turn.

The direct terms. The t-channel direct term is

$$\tfrac{1}{4}\sum_{\text{spins}} |\mathcal{M}_t|^2 = \frac{e^4}{4t^2}\;\text{tr}\big[(\not p_3 + m)\gamma^\mu(\not p_1 + m)\gamma^\nu\big]\;\text{tr}\big[(\not p_4 + m)\gamma_\mu(\not p_2 + m)\gamma_\nu\big], \tag{18.157}$$

where the spin sums $\sum u_1\bar u_1 = \not p_1 + m$, etc. (Theorem C.68) have turned each squared current into a Dirac trace. Each trace is evaluated with the four-γ identity $\text{tr}[(\not a + m)\gamma^\mu(\not b + m)\gamma^\nu] = 4[a^\mu b^\nu + a^\nu b^\mu - \eta^{\mu\nu}(a\cdot b - m^2)]$ of Section C.6 (the odd-γ traces vanish). Contracting the two resulting tensors is the same algebra met in $e^+e^- \to \mu^+\mu^-$; carrying the mass terms,

$$\text{tr}[(\not a+m)\gamma^\mu(\not b+m)\gamma^\nu]\;\text{tr}[(\not c+m)\gamma_\mu(\not d+m)\gamma_\nu] = 32\big[(a\cdot c)(b\cdot d)+(a\cdot d)(b\cdot c)-m^2(a\cdot b)-m^2(c\cdot d)+2 \tag{18.158}$$

With $a = p_3$, $b = p_1$, $c = p_4$, $d = p_2$ and the dot products read off from Eq. (18.151)—namely $p_1\cdot p_2 = p_3\cdot p_4 = \tfrac{1}{2}(s-2m^2)$, $p_1\cdot p_3 = p_2\cdot p_4 = \tfrac{1}{2}(2m^2-t)$, and $p_1\cdot p_4 = p_2\cdot p_3 = \tfrac{1}{2}(2m^2-u)$—the bracket of Eq. (18.158) becomes

$$\tfrac{1}{4}(s-2m^2)^2 + \tfrac{1}{4}(u-2m^2)^2 + m^2 t, \tag{18.159}$$

after using $s+t+u = 4m^2$ to eliminate $s+u = 4m^2 - t$. Hence

$$\tfrac{1}{4}\sum_{\text{spins}} |\mathcal{M}_t|^2 = \frac{2e^4}{t^2}\Big[(s-2m^2)^2 + (u-2m^2)^2 + 4m^2 t\Big]. \tag{18.160}$$

The u-channel direct term is obtained from Eq. (18.160) by the exchange $p_3 \leftrightarrow p_4$, i.e. $t \leftrightarrow u$:

$$\tfrac{1}{4}\sum_{\text{spins}} |\mathcal{M}_u|^2 = \frac{2e^4}{u^2}\Big[(s-2m^2)^2 + (t-2m^2)^2 + 4m^2 u\Big]. \tag{18.161}$$

In the high-energy limit $m \to 0$ these reduce to $2e^4(s^2+u^2)/t^2$ and $2e^4(s^2+t^2)/u^2$, the same t- and u-channel structures one expects from photon exchange.

The interference term. The cross term is where the two diagrams genuinely talk to each other, and it is the term the Fermi sign acts on. Spin-summing the product $\mathcal{M}_t\mathcal{M}_u^*$ ties the four currents into a *single* closed Dirac trace, because the spinor indices chain around: the conjugate currents $[\bar u_4\gamma^\nu u_1]^* = [\bar u_1\gamma^\nu u_4]$

and $[\bar{u}_3\gamma_\nu u_2]^* = [\bar{u}_2\gamma_\nu u_3]$ link u_1 to u_4 and u_2 to u_3, closing the loop $u_3 \to u_1 \to u_4 \to u_2 \to u_3$. With the relative minus from Eq. (18.156),

$$-\tfrac{1}{4}\sum_{\text{spins}} 2\,\mathrm{Re}\;\mathcal{M}_t\mathcal{M}_u^* = -\frac{e^4}{2tu}\,T, \qquad T \equiv \mathrm{tr}\big[(\not p_3+m)\gamma^\mu(\not p_1+m)\gamma^\nu(\not p_4+m)\gamma_\mu(\not p_2+m)\gamma_\nu\big]. \tag{18.162}$$

This eight-γ trace is evaluated in Theorem 18.14 using the contraction identities of Section C.6; the result is the remarkably compact

$$T = -8\,(s-2m^2)(s-6m^2), \tag{18.163}$$

so that the interference contribution to $\overline{|\mathcal{M}|^2}$ is

$$-\frac{e^4}{2tu}\,T = \frac{4e^4}{tu}\,(s-2m^2)(s-6m^2). \tag{18.164}$$

Worked Example 18.14 (The Møller interference trace)**.** We evaluate T of Eq. (18.162) by collapsing the two contracted index pairs from the inside out, using the four-dimensional contraction identities (Section C.6)

$$\gamma^\mu\gamma_\mu = 4, \quad \gamma^\mu \not a \gamma_\mu = -2\not a, \quad \gamma^\mu \not a \not b \gamma_\mu = 4\,a\cdot b, \quad \gamma^\mu \not a \not b \not c \gamma_\mu = -2\not c \not b \not a. \tag{18.165}$$

Expand $(\not p_1 + m)\gamma^\nu(\not p_4 + m)$ and contract the μ pair, treating γ^ν as a vector e^ν:

$$\begin{aligned}\gamma^\mu(\not p_1 + m)\gamma^\nu(\not p_4 + m)\gamma_\mu &= \gamma^\mu\big[\not p_1\gamma^\nu\not p_4 + m\,\not p_1\gamma^\nu + m\,\gamma^\nu\not p_4 + m^2\gamma^\nu\big]\gamma_\mu \\ &= -2\not p_4\gamma^\nu\not p_1 + 4m\,(p_1^\nu + p_4^\nu) - 2m^2\gamma^\nu,\end{aligned} \tag{18.166}$$

where the first term used the three-vector identity, the two single-mass terms used $\gamma^\mu \not a \gamma^\nu \gamma_\mu = 4a^\nu$ (the two-vector identity with one slot the free index ν), and the last used $\gamma^\mu\gamma^\nu\gamma_\mu = -2\gamma^\nu$. Insert this between $(\not p_3 + m)$ and $(\not p_2 + m)\gamma_\nu$ and take the trace term by term.

Term 1 $(-2\not p_4\gamma^\nu\not p_1)$: contracting the remaining ν pair through $\not p_1(\not p_2 + m)$ gives $\gamma^\nu\not p_1(\not p_2 + m)\gamma_\nu = 4(p_1\cdot p_2) - 2m\not p_1$, after which only even-$\gamma$ traces survive:

$$T_1 = -2\;\mathrm{tr}\big[(\not p_3 + m)\not p_4(4(p_1\cdot p_2) - 2m\not p_1)\big] = -32(p_1\cdot p_2)(p_3\cdot p_4) + 16m^2(p_1\cdot p_4). \tag{18.167}$$

Term 2 $(+4m(p_1^\nu + p_4^\nu))$: here $\gamma_\nu(p_1^\nu + p_4^\nu) = \not p_1 + \not p_4$, and

$$T_2 = 4m\;\mathrm{tr}\big[(\not p_3 + m)(\not p_2 + m)(\not p_1 + \not p_4)\big] = 16m^2\,(p_1 + p_4)\cdot(p_2 + p_3), \tag{18.168}$$

the only surviving traces being the two with a single mass insertion. *Term 3* $(-2m^2\gamma^\nu)$: using $\gamma^\nu(\not p_2 + m)\gamma_\nu = -2\not p_2 + 4m$,

$$T_3 = -2m^2\;\mathrm{tr}\big[(\not p_3 + m)(-2\not p_2 + 4m)\big] = 16m^2(p_2\cdot p_3) - 32m^4. \tag{18.169}$$

Adding $T_1 + T_2 + T_3$, the mass-squared terms assemble into the symmetric sum over all six dot products,

$$T = -32(p_1\cdot p_2)(p_3\cdot p_4) + 16m^2\sum_{i<j}(p_i\cdot p_j) - 32m^4. \tag{18.170}$$

With $(p_1\cdot p_2)(p_3\cdot p_4) = \frac{1}{4}(s-2m^2)^2$ and $\sum_{i<j} p_i\cdot p_j = 2(s-m^2)$ (from the dot-product values below Eq. (18.158) and $s+t+u=4m^2$),

$$T = -8(s-2m^2)^2+32m^2(s-m^2)-32m^4 = -8(s^2-8m^2s+12m^4) = -8(s-2m^2)(s-6m^2), \tag{18.171}$$

which is Eq. (18.163). As a check, $m\to 0$ gives $T=-8s^2$, and the interference contribution Eq. (18.164) reduces to $+4e^4s^2/tu$.

Assembly. Collecting Eq. (18.160), Eq. (18.161) and Eq. (18.164), the unpolarized Møller squared amplitude is

$$\boxed{\overline{|\mathcal{M}|^2}_{\text{Møl}} = \frac{2e^4}{t^2}\left[(s-2m^2)^2+(u-2m^2)^2+4m^2t\right] + \frac{2e^4}{u^2}\left[(s-2m^2)^2+(t-2m^2)^2+4m^2u\right]} \tag{18.172}$$

In the high-energy limit $m\to 0$ this collapses to the much-quoted form

$$\overline{|\mathcal{M}|^2}_{\text{Møl}} \xrightarrow{m\to 0} 2e^4\left[\frac{s^2+u^2}{t^2} + \frac{s^2+t^2}{u^2} + \frac{2s^2}{tu}\right]. \tag{18.173}$$

The three terms are manifest: t-channel exchange peaked at small momentum transfer, u-channel exchange peaked at backward angles, and the interference $2s^2/tu$ which, with $t<0$ and $u<0$ giving $tu>0$, is *positive* in the high-energy physical region. The destructive interference demanded by the Pauli antisymmetry is therefore not a blanket negative sign in $\overline{|\mathcal{M}|^2}$: the massive interference Eq. (18.164) carries the factor $(s-2m^2)(s-6m^2)$, positive at high energy but negative in the non-relativistic regime, where it produces the negative interference term of the Mott formula Eq. (18.191). The expression is manifestly symmetric under $t\leftrightarrow u$, as it must be: exchanging the two identical final electrons cannot change a physical probability.

18.5.3 Bhabha scattering: annihilation plus scattering

Now turn one of the electrons into a positron: $e^-(p_1)\,e^+(p_2)\to e^-(p_3)\,e^+(p_4)$. The Mandelstam variables keep the assignments

$$s=(p_1+p_2)^2, \qquad t=(p_1-p_3)^2, \qquad u=(p_1-p_4)^2, \qquad s+t+u=4m^2, \tag{18.174}$$

so that s is the squared total energy of the colliding pair, t the momentum transfer between the incoming and outgoing electron, and u that between the

electron and the outgoing positron. Two tree diagrams again contribute, but now of distinct physical character (Fig. 18.6). In the t-channel *scattering* diagram the electron and positron exchange a photon and recoil, the photon carrying $p_1 - p_3$; this is the direct analogue of the Møller t-channel. In the s-channel *annihilation* diagram the e^+e^- pair annihilates into a single virtual photon of momentum $p_1 + p_2$, which then materializes the outgoing pair—precisely the mechanism of $e^+e^- \to \mu^+\mu^-$ from Section 17.3, now with electrons in the final state.

Reading off the diagrams with the antifermion rules of Chapter 11—an incoming positron of momentum p_2 carries $\bar{v}_2$, an outgoing positron p_4 carries v_4—the two amplitudes are

$$i\mathcal{M}_t = [\bar{u}_3(-ie\gamma^\mu)u_1]\frac{-i\eta_{\mu\nu}}{t}[\bar{v}_2(-ie\gamma^\nu)v_4] = \frac{ie^2}{t}[\bar{u}_3\gamma^\mu u_1][\bar{v}_2\gamma_\mu v_4], \quad (18.175)$$

$$i\mathcal{M}_s = [\bar{v}_2(-ie\gamma^\mu)u_1]\frac{-i\eta_{\mu\nu}}{s}[\bar{u}_3(-ie\gamma^\nu)v_4] = \frac{ie^2}{s}[\bar{v}_2\gamma^\mu u_1][\bar{u}_3\gamma_\mu v_4]. \quad (18.176)$$

The relative sign is again fixed by Fermi statistics: the s- and t-channel contractions differ by the transposition of two anticommuting fields (here the ψ-field annihilating the incoming electron is paired, in one case, with the $\bar{\psi}$ creating the outgoing electron and, in the other, with the field annihilating the incoming positron), so the two diagrams enter with opposite sign. Choosing the conventional assignment,

$$i\mathcal{M} = i\mathcal{M}_t - i\mathcal{M}_s = ie^2\left\{\frac{[\bar{u}_3\gamma^\mu u_1][\bar{v}_2\gamma_\mu v_4]}{t} - \frac{[\bar{v}_2\gamma^\mu u_1][\bar{u}_3\gamma_\mu v_4]}{s}\right\}. \quad (18.177)$$

The squared amplitude, direct terms. The two direct terms reuse computations already done. The s-channel term is structurally identical to $e^+e^- \to \mu^+\mu^-$ of Section 17.3—two currents, each a vector bilinear, contracted across a photon of invariant mass $\sqrt{s}$—and the trace algebra is the same, giving in the massless limit

$$\tfrac{1}{4}\sum_{\text{spins}}|\mathcal{M}_s|^2 \xrightarrow{m\to 0} \frac{2e^4}{s^2}(t^2+u^2). \quad (18.178)$$

The t-channel term has exactly the form of the Møller t-channel Eq. (18.160) with the photon now spacelike; in the massless limit

$$\tfrac{1}{4}\sum_{\text{spins}}|\mathcal{M}_t|^2 \xrightarrow{m\to 0} \frac{2e^4}{t^2}(s^2+u^2). \quad (18.179)$$

The interference term. The new computation is the s–t interference. As in Møller, the conjugate currents chain the four bilinears into one closed trace; with

the relative minus of Eq. (18.177),

$$-\tfrac{1}{4}\sum_{\text{spins}} 2\ \mathrm{Re}\ \mathcal{M}_t\mathcal{M}_s^* = -\frac{e^4}{2st}\,T', \qquad T' \equiv \mathrm{tr}[\not p_3\gamma^\mu \not p_1\gamma^\nu \not p_2\gamma_\mu \not p_4\gamma_\nu] \quad (m\to 0), \tag{18.180}$$

where the massless spin sums $\sum u\bar u = \not p$, $\sum v\bar v = \not p$ have been used. Collapsing the μ pair through $\not p_1\gamma^\nu\not p_2$ with the three-vector identity of Eq. (18.165) gives $\gamma^\mu\not p_1\gamma^\nu\not p_2\gamma_\mu = -2\not p_2\gamma^\nu\not p_1$, and then the ν pair through $\not p_1\not p_4$ gives $\gamma^\nu\not p_1\not p_4\gamma_\nu = 4(p_1\cdot p_4)$:

$$T' = -2\ \mathrm{tr}[\not p_3\not p_2\gamma^\nu\not p_1\not p_4\gamma_\nu] = -8(p_1\cdot p_4)\ \mathrm{tr}[\not p_3\not p_2] = -32(p_1\cdot p_4)(p_2\cdot p_3) = -8u^2, \tag{18.181}$$

the last step using the massless values $p_1\cdot p_4 = p_2\cdot p_3 = -u/2$. Therefore the interference contribution is

$$-\frac{e^4}{2st}\,T' = \frac{4e^4u^2}{st}. \tag{18.182}$$

Collecting Eq. (18.178), Eq. (18.179) and Eq. (18.182),

$$\boxed{\overline{|\mathcal{M}|^2}_{\text{Bha}} \xrightarrow{m\to 0} 2e^4\left[\frac{s^2+u^2}{t^2} + \frac{t^2+u^2}{s^2} + \frac{2u^2}{st}\right].} \tag{18.183}$$

Three terms once more, but with the roles permuted relative to Møller: the divergent forward peak now sits in the t-channel (Coulomb scattering) alone, the s-channel annihilation is regular, and the cross term $2u^2/st$ is genuinely negative in the physical region (where $s>0$ and $t<0$, so $st<0$): annihilation and scattering interfere *destructively*, a hallmark of the Bhabha line shape.

18.5.4 Bhabha as a crossing of Møller

The two computations were carried out independently, but crossing symmetry (Section 18.4) predicts that they are not independent: Bhabha is Møller continued in the Mandelstam plane. Concretely, Møller $e^-(p_1)e^-(p_2)\to e^-(p_3)e^-(p_4)$ becomes Bhabha $e^-(p_1)e^+(p_2)\to e^-(p_3)e^+(p_4)$ when the incoming electron p_2 is crossed into an outgoing positron and the outgoing electron p_4 into an incoming positron. Under this exchange of the second and fourth legs the invariants transform as $s\leftrightarrow u$, while t is fixed—one checks directly from the definitions that interchanging p_2 and $-p_4$ sends $(p_1+p_2)^2\to(p_1-p_4)^2$ and $(p_1-p_4)^2\to(p_1+p_2)^2$, i.e. $s\leftrightarrow u$, leaving $t=(p_1-p_3)^2$ invariant. The crossing rules of Eq. (18.108) furthermore guarantee that the *spin-summed* squared amplitude continues without extra sign factors (the fermion-crossing sign squares to unity, and the spin-averaging factor $\tfrac14$ is the same for the two-fermion

initial state in both processes). Applying $s \leftrightarrow u$ to the massless Møller result Eq. (18.173) term by term,

$$\underbrace{\frac{s^2+u^2}{t^2}}_{\text{unchanged}} + \underbrace{\frac{s^2+t^2}{u^2}}_{\to \frac{u^2+t^2}{s^2}} + \underbrace{\frac{2s^2}{tu}}_{\to \frac{2u^2}{ts}} = \frac{s^2+u^2}{t^2} + \frac{t^2+u^2}{s^2} + \frac{2u^2}{st}, \tag{18.184}$$

which is exactly the Bhabha result Eq. (18.183). The two derivations agree: the direct trace computation and the analytic continuation give the same function, the strongest internal check available at tree level. The continuation also predicts the *massive* Bhabha amplitude with no further work—applying $s \leftrightarrow u$ to Eq. (18.172) (the equal masses are untouched by particle↔antiparticle crossing) gives

$$\overline{|\mathcal{M}|^2}_{\text{Bha}} = \frac{2e^4}{t^2}\left[(s-2m^2)^2+(u-2m^2)^2+4m^2t\right]+\frac{2e^4}{s^2}\left[(u-2m^2)^2+(t-2m^2)^2+4m^2s\right]+\frac{4e^4}{st}(u-2m^2 \tag{18.185}$$

whose $m \to 0$ limit reproduces Eq. (18.183).

Physical Insight

That the same analytic function describes electron–electron scattering and electron–positron scattering is not a coincidence of QED but a consequence of locality and unitarity, made precise by crossing in Section 18.4. The two processes probe different regions of the (s,t,u) plane—Møller lives where $s > 4m^2$ and $t,u < 0$, Bhabha where the roles of s and u are swapped—but the amplitude is one object analytically continued between them. Crossing thus turns every computation into two: having worked out Møller honestly, we obtained Bhabha for the price of a substitution, and the agreement of that substitution with the independent direct calculation is a nontrivial confirmation that both were done correctly.

18.5.5 Differential cross sections and the Coulomb limit

We now turn the squared amplitudes into cross sections and extract the physical limits that every charged-particle calculation must reproduce. Both processes are elastic with equal masses, so in the centre-of-mass frame the outgoing and incoming momenta have equal magnitude, $|\mathbf{p}_f| = |\mathbf{p}_i| \equiv p$, and the angular cross section of Theorem 16.23 simplifies to

$$\frac{d\sigma}{d\Omega} = \frac{\overline{|\mathcal{M}|^2}}{64\pi^2 s}, \tag{18.186}$$

the elastic specialization of Eq. (16.145). The CM kinematics fix the invariants in terms of the scattering angle θ as $t = -2p^2(1-\cos\theta) = -4p^2\sin^2(\theta/2)$ and $u = -2p^2(1+\cos\theta) = -4p^2\cos^2(\theta/2)$, with $s = 4(p^2+m^2)$. In the high-energy limit $p \to \sqrt{s}/2$, so $t = -\frac{s}{2}(1-\cos\theta) = -s\sin^2(\theta/2)$ and $u = -s\cos^2(\theta/2)$.

Møller. Substituting Eq. (18.173) into Eq. (18.186) with $e^4 = 16\pi^2\alpha^2$ and converting to half-angles,

$$\left.\frac{d\sigma}{d\Omega}\right|_{\text{Møl}} = \frac{\alpha^2}{2s}\left[\frac{1+\cos^4(\theta/2)}{\sin^4(\theta/2)} + \frac{1+\sin^4(\theta/2)}{\cos^4(\theta/2)} + \frac{2}{\sin^2(\theta/2)\cos^2(\theta/2)}\right]. \quad (18.187)$$

The first term is the t-channel forward peak, the second the u-channel backward peak—present because the two final electrons are identical and the detector cannot tell which one it caught—and the third is the interference. As $\theta \to 0$ the cross section diverges as $2/\sin^4(\theta/2)$, the Rutherford $1/\sin^4$ singularity of one-photon (Coulomb) exchange; the u-channel produces an identical divergence at $\theta \to \pi$, the symmetry of Eq. (18.187) under $\theta \to \pi - \theta$ being the angular face of the $t \leftrightarrow u$ symmetry of identical particles.

Bhabha. Substituting Eq. (18.183) into Eq. (18.186),

$$\left.\frac{d\sigma}{d\Omega}\right|_{\text{Bha}} = \frac{\alpha^2}{2s}\left[\frac{1+\cos^4(\theta/2)}{\sin^4(\theta/2)} + \frac{1+\cos^2\theta}{2} - \frac{2\cos^4(\theta/2)}{\sin^2(\theta/2)}\right], \quad (18.188)$$

where the middle term used $\frac{t^2+u^2}{s^2} = \frac{1}{2}(1+\cos^2\theta)$. Here only the t-channel diverges in the forward direction, again as $2/\sin^4(\theta/2)$; there is no backward divergence, because the final electron and positron are distinct and the u-channel is absent. The s-channel annihilation contributes the smooth $\frac{1}{2}(1+\cos^2\theta)$ piece—the very same angular distribution as $e^+e^- \to \mu^+\mu^-$ (Section 17.3), as it must be, since at high energy the annihilation diagram does not know whether the produced pair is muons or electrons. The forward Coulomb peak is the experimental signature exploited at every e^+e^- collider: Bhabha scattering at small angles is the standard luminosity monitor precisely because its rate is dominated by the calculable, large, t-channel QED cross section.

The identical-particle phase space for Møller. One subtlety distinguishes the two total cross sections. In Bhabha scattering the final e^- and e^+ are distinct, and the total cross section integrates Eq. (18.188) over the full solid angle. In Møller scattering the two final electrons are identical: the configurations with one electron at (θ, φ) and the other at $(\pi - \theta, \varphi + \pi)$ are the *same* physical final state, counted twice if one integrates Eq. (18.187) over all 4π. The correct total cross section therefore carries the identical-particle symmetry factor $\frac{1}{2}$ of Section 15.4 and Eq. (16.83),

$$\sigma_{\text{Møl}} = \frac{1}{2}\int d\Omega \left.\frac{d\sigma}{d\Omega}\right|_{\text{Møl}} \quad \Longleftrightarrow \quad \int_{\text{half space}} d\Omega \left.\frac{d\sigma}{d\Omega}\right|_{\text{Møl}}, \quad (18.189)$$

the two prescriptions being equivalent because the integrand is symmetric under $\theta \to \pi - \theta$. This is the same factor that appears in the final-state phase space of

any process with identical outgoing particles, here demanded already at the level of counting distinct events.

Worked Example 18.15 (The non-relativistic Coulomb limit of Møller scattering)**.** We recover the Rutherford–Mott cross section from Eq. (18.172) in the non-relativistic limit $p \ll m$, where the electrons move slowly and the photon exchange reduces to the static Coulomb interaction. In this limit $s = 4(p^2 + m^2) \to 4m^2$, so $s - 2m^2 \to 2m^2$ and $s - 6m^2 \to -2m^2$, while $t = -4p^2 \sin^2(\theta/2)$ and $u = -4p^2 \cos^2(\theta/2)$ remain $O(p^2)$. Evaluate the three pieces of Eq. (18.172) to leading order. The t-channel bracket becomes $(s-2m^2)^2 + (u-2m^2)^2 + 4m^2 t \to (2m^2)^2 + (2m^2)^2 + O(m^2 p^2) = 8m^4$, giving

$$\tfrac{1}{4}\sum |\mathcal{M}_t|^2 \to \frac{2e^4}{t^2}\, 8m^4 = \frac{16 e^4 m^4}{16 p^4 \sin^4(\theta/2)} = \frac{e^4 m^4}{p^4 \sin^4(\theta/2)}; \tag{18.190}$$

the u-channel gives the same with $\sin \to \cos$; and the interference $\frac{4e^4}{tu}(s-2m^2)(s-6m^2) \to \frac{4e^4}{tu}(2m^2)(-2m^2) = -16 e^4 m^4/(tu)$, with $tu = 16 p^4 \sin^2(\theta/2)\cos^2(\theta/2)$, giving $-e^4 m^4/[p^4 \sin^2(\theta/2)\cos^2(\theta/2)]$. Dividing by $64\pi^2 s \to 256\pi^2 m^2$ as in Eq. (18.186), writing $e^4 = 16\pi^2\alpha^2$ and $p = mv$ (so $p^4 = m^4 v^4$),

$$\left.\frac{d\sigma}{d\Omega}\right|_{\text{Møl}}^{\text{NR}} = \frac{\alpha^2}{16\, m^2 v^4}\left[\frac{1}{\sin^4(\theta/2)} + \frac{1}{\cos^4(\theta/2)} - \frac{1}{\sin^2(\theta/2)\cos^2(\theta/2)}\right]. \tag{18.191}$$

This is the *Mott cross section* for identical spin-$\frac{1}{2}$ particles. The first term, taken alone, is the Rutherford formula $d\sigma/d\Omega = \alpha^2/(16 E_{\text{kin}}^2 \sin^4(\theta/2))$ with $E_{\text{kin}} = mv^2$ the relative kinetic energy, exactly the non-relativistic Coulomb scattering of two unit charges. The second term is its mirror image, the identical-particle exchange contribution, and the third is the quantum interference between direct and exchange amplitudes—negative for unpolarized spin-$\frac{1}{2}$ fermions, the unmistakable signature of Fermi statistics surviving all the way down to the non-relativistic regime. The relative minus sign of Eq. (18.155), derived from Wick's theorem, is what produces the destructive interference here; a Bose statistics calculation would give $+1$ in its place. The recovery of Rutherford scattering with the correct coefficient is the physical check that the entire relativistic computation, traces and all, was assembled correctly.

The same non-relativistic reduction applied to Bhabha scattering keeps only the t-channel term of Eq. (18.188), since the annihilation diagram is suppressed by p^2/m^2 at low energy (the produced pair must carry the full rest energy $2m$, which the slow incoming pair barely has): one recovers the ordinary Rutherford scattering of opposite charges, $d\sigma/d\Omega \to \alpha^2/(16 E_{\text{kin}}^2 \sin^4(\theta/2))$, with no exchange term because electron and positron are distinguishable. Coulomb scattering thus emerges as the universal soft limit of both processes, the annihilation channel and the identical-particle exchange being the relativistic and quantum-statistical corrections that QED layers on top of it.

With the unpolarized Møller and Bhabha cross sections in hand, the canonical quartet of tree-level QED processes—Compton, pair annihilation, Møller, and Bhabha—is complete at the level of spin-summed observables. Each of the results Eq. (18.172) and Eq. (18.185) is, however, an incoherent sum over final spins and an average over initial ones, and it conceals a far richer structure: the individual helicity amplitudes, most of which vanish in the massless limit by a selection rule we have not yet stated. The next section opens that structure, introducing the spin-projection and helicity technology, proving the high-energy helicity-conservation rule, and showing that the incoherent sum of the helicity amplitudes reassembles precisely the unpolarized results computed here—the bridge to the spinor-helicity reframing of Part XVI.

18.6 Polarized amplitudes, helicity, and the high-energy limit

Every cross section computed so far in this chapter has been an average. We summed the squared amplitude over the spins of the final particles, averaged it over the spins of the initial ones, and let the spin-sum identities $\sum_s u_s \bar{u}_s = \not{p} + m$ and $\sum_s v_s \bar{v}_s = \not{p} - m$ collapse the four-spinor bilinears into traces over Dirac matrices. This is exactly the right thing to do when the apparatus neither prepares nor measures spin, and it produced the compact angular laws of the quartet: Compton, annihilation, Møller, and Bhabha. But the trace has thrown away information that is physically real and, as it turns out, computationally precious. The unpolarized $1 + \cos^2\theta$ of $e^+e^- \to \mu^+\mu^-$ is not a single mechanism; it is the incoherent sum of a small number of *helicity amplitudes*, each with its own, much simpler, angular shape. The task of this section is to undo the averaging — to resolve the spin-summed quartet into its polarized components — and to discover, in the process, that at high energy the resolution is not a complication but a radical simplification. We will build the projector that isolates a single spin state, prove that in the massless limit helicity coincides with chirality, derive the selection rule that kills all but a handful of helicity configurations, compute those that survive in full, and check that their incoherent sum rebuilds the unpolarized result we already trust. The payoff is conceptual: helicity, not the Lorentz index, is the natural label for a relativistic amplitude — the observation that the modern on-shell program of Chapter 58 will turn into a calculus.

18.6.1 The spin projection operator

To compute with a single spin state we need the analogue of the spin sum that retains, rather than discards, the polarization. Fix an on-shell momentum p ($p^2 = m^2$, $m > 0$ for now) and a direction of spin. Relativistically the spin

direction is encoded in a *spin four-vector* s^μ satisfying

$$s \cdot p = 0, \qquad s^2 = -1. \tag{18.192}$$

The first condition makes s purely spatial in the particle's rest frame; the second normalizes it. In the rest frame $p = (m, \mathbf{0})$ these force $s = (0, \hat{\mathbf{n}})$ with $\hat{\mathbf{n}}$ a unit spatial vector, the axis along which the spin is measured. The boost of this rest-frame $\hat{\mathbf{n}}$ to the frame where the momentum is $\mathbf{p}$ is what Eq. (18.192) encodes covariantly.

Definition 18.16 (Spin projector)**.** For an on-shell momentum p and a spin four-vector s obeying Eq. (18.192), the *spin projector* is

$$\Sigma(s) \equiv \frac{1 + \gamma^5 \not{s}}{2}. \tag{18.193}$$

The name is justified by the following two facts, which together make $\Sigma(s)$ the exact spin-resolved refinement of the energy projectors of Eq. (C.249).

Proposition 18.17 (Properties and outer-product form of $\Sigma(s)$)**.** *$\Sigma(s)$ is an idempotent, $\Sigma(s)^2 = \Sigma(s)$, with $\Sigma(s) + \Sigma(-s) = \mathbf{1}$; it commutes with $\not{p} \pm m$; and the rank-one outer products of the physical spinors are*

$$u(p,s)\,\bar{u}(p,s) = (\not{p} + m)\,\Sigma(s) = (\not{p} + m)\,\frac{1 + \gamma^5 \not{s}}{2}, \tag{18.194}$$

$$v(p,s)\,\bar{v}(p,s) = (\not{p} - m)\,\Sigma(s) = (\not{p} - m)\,\frac{1 + \gamma^5 \not{s}}{2}, \tag{18.195}$$

where $u(p,s)$ is the positive-frequency spinor whose rest-frame spin points along the $\hat{\mathbf{n}}$ of s, and $v(p,s)$ the corresponding antiparticle spinor.

Proof. Idempotency and completeness. Using $\not{s}\not{s} = s^2 = -1$ and the anticommutation $\gamma^5 \not{s} = -\not{s}\gamma^5$,

$$(\gamma^5 \not{s})^2 = \gamma^5 \not{s} \gamma^5 \not{s} = -\gamma^5 \gamma^5 \not{s}\not{s} = -(\gamma^5)^2 s^2 = -(1)(-1) = +1, \tag{18.196}$$

so $\gamma^5 \not{s}$ squares to the identity and $\Sigma(s) = \frac{1}{2}(1 + \gamma^5 \not{s})$ is therefore idempotent: $\Sigma(s)^2 = \frac{1}{4}(1 + 2\gamma^5 \not{s} + 1) = \frac{1}{2}(1 + \gamma^5 \not{s}) = \Sigma(s)$. Flipping $s \to -s$ flips the sign of the second term, so $\Sigma(s) + \Sigma(-s) = \mathbf{1}$: the two spin states exhaust the relevant subspace.

Commutation with $\not{p} \pm m$. It suffices to show $\gamma^5 \not{s}$ commutes with $\not{p}$. Anticommuting γ^5 through $\not{p}$ once and using $\not{s}\not{p} = 2(s \cdot p) - \not{p}\not{s} = -\not{p}\not{s}$ from Eq. (18.192),

$$\gamma^5 \not{s}\,\not{p} = -\gamma^5 \not{p}\,\not{s} = \not{p}\,\gamma^5 \not{s}, \tag{18.197}$$

where the last step used $\gamma^5 \not{p} = -\not{p}\gamma^5$. Hence $[\gamma^5 \not{s}, \not{p}] = 0$, and trivially $[\gamma^5 \not{s}, m] = 0$, so $\Sigma(s)$ commutes with $\not{p} \pm m$.

The outer products. We prove Eq. (18.194) in the rest frame and propagate it covariantly, exactly as the spin sums were established in Theorem C.68. In the rest frame $p = (m, \mathbf{0})$ the positive-frequency spinors satisfy $\gamma^0 u = u$ (they are the $+1$ eigenstates of γ^0, Section 11.2.5), and $s = (0, \hat{\mathbf{n}})$ gives $\not{s} = -\boldsymbol{\gamma} \cdot \hat{\mathbf{n}}$. We first show that $\gamma^5 \not{s}$ acts on the rest-frame u as the rest-frame spin operator along $\hat{\mathbf{n}}$. From the explicit chiral-basis forms one has the identity $\gamma^5 \gamma^i = -\gamma^0 \Sigma^i$, where $\Sigma^i = \mathrm{diag}(\sigma^i, \sigma^i)$ is the four-dimensional spin matrix of Section 11.2.5; indeed $\gamma^5 \gamma^3 = i\gamma^0\gamma^1\gamma^2\gamma^3\gamma^3 = -i\gamma^0\gamma^1\gamma^2$ while $\gamma^0 \Sigma^3 = \gamma^0\, i\gamma^1\gamma^2$, so the two differ by a sign, and rotational covariance extends the relation to every i. Therefore

$$\gamma^5 \not{s} = -\gamma^5\, \boldsymbol{\gamma} \cdot \hat{\mathbf{n}} = \gamma^0\, \boldsymbol{\Sigma} \cdot \hat{\mathbf{n}}, \tag{18.198}$$

and acting on a rest-frame u, where $\gamma^0 u = u$ and $\boldsymbol{\Sigma}$ commutes with γ^0 (both are block-diagonal),

$$\gamma^5 \not{s}\, u = \gamma^0 (\boldsymbol{\Sigma} \cdot \hat{\mathbf{n}})\, u = (\boldsymbol{\Sigma} \cdot \hat{\mathbf{n}})\, \gamma^0 u = (\boldsymbol{\Sigma} \cdot \hat{\mathbf{n}})\, u. \tag{18.199}$$

Thus on the rest-frame particle subspace $\Sigma(s) = \frac{1}{2}(1 + \boldsymbol{\Sigma} \cdot \hat{\mathbf{n}})$, the ordinary nonrelativistic projector onto spin-up along $\hat{\mathbf{n}}$; it keeps precisely the one spinor $u(p, s)$ and annihilates the opposite-spin $u(p, -s)$. Combining this with the rest-frame spin sum $\sum_{s'} u(p, s')\bar{u}(p, s') = \not{p} + m$ (Eq. (C.247)) and the fact that $\Sigma(s)$ selects one term,

$$u(p, s)\bar{u}(p, s) = \Big(\sum_{s'} u(p, s')\bar{u}(p, s') \Big) \Sigma(s) = (\not{p} + m)\, \Sigma(s), \tag{18.200}$$

where we used that $\Sigma(s)$ acts as the identity on $u(p, s)$ and as zero on $u(p, -s)$, so the only surviving term in the sum is the one we want, written through $\bar{u}(p, s)\Sigma(s) = \bar{u}(p, s)$. Both sides of Eq. (18.200) are now Lorentz-covariant matrices — the left transforms as $S\,(\cdot)\,S^{-1}$ under a boost S, and so does the right because $S(\not{p} + m)S^{-1}$ boosts p and $S\,\gamma^5 \not{s}\, S^{-1} = \gamma^5\, \gamma_\mu (\Lambda s)^\mu$ boosts s (using $S^{-1}\gamma^5 S = \gamma^5$ for proper transformations, Eq. (C.138)). Holding in one frame and transforming covariantly, the identity holds in all frames, which is Eq. (18.194). The antiparticle version Eq. (18.195) follows identically from $\sum_{s'} v\bar{v} = \not{p} - m$, with the sign of $\not{s}$ tracking the convention that the v-spinor's rest-frame spin is labelled by $\hat{\mathbf{n}}$. □

Theorem 18.17 is the entire technology of polarized amplitudes. Wherever an unpolarized computation inserts a spin sum and takes a trace, the polarized computation inserts the rank-one projector Eq. (18.194) instead, and the trace machinery of Section C.6 runs unchanged — now over a string that contains the extra factor $\gamma^5 \not{s}$. Concretely, for any process whose amplitude has the structure $\mathcal{M} = \bar{u}(p_f, s_f)\, \Gamma\, u(p_i, s_i)$ for some Dirac operator Γ built from the Feynman rules, the squared amplitude for fixed external spins is

$$|\mathcal{M}|^2 = \bar{u}(p_f, s_f)\Gamma u(p_i, s_i)\, \bar{u}(p_i, s_i)\bar{\Gamma} u(p_f, s_f) = \mathrm{tr}\Big[(\not{p}_f + m_f)\Sigma(s_f)\, \Gamma\, (\not{p}_i + m_i)\Sigma(s_i)\, \bar{\Gamma} \Big], \tag{18.201}$$

with $\bar{\Gamma} \equiv \gamma^0 \Gamma^\dagger \gamma^0$. Setting $s_i, s_f \to 0$ in Eq. (18.201), i.e. replacing each Σ by $\frac{1}{2}$ and summing the two spin projectors back up, recovers the unpolarized trace; the projector merely refines it. Every parity-odd correlation a polarized experiment can measure — a spin asymmetry, a longitudinal polarization — lives in the $\gamma^5 \not{s}$ pieces that the spin sum had been averaging to zero.

18.6.2 Helicity, chirality, and the massless limit

The spin axis $\hat{\mathbf{n}}$ in Eq. (18.192) is so far arbitrary. The physically natural choice for a moving particle is helicity: spin measured along the direction of motion, $\hat{\mathbf{n}} = \hat{\mathbf{p}}$. Its spin four-vector is obtained by boosting $(0, \hat{\mathbf{p}})$ to the frame of momentum $\mathbf{p}$,

$$s_h^\mu = \Big(\frac{|\mathbf{p}|}{m},\ \frac{E}{m}\,\hat{\mathbf{p}} \Big), \qquad s_h \cdot p = \frac{|\mathbf{p}| E}{m} - \frac{E}{m}\,\hat{\mathbf{p}} \cdot \mathbf{p} = 0, \qquad s_h^2 = \frac{|\mathbf{p}|^2 - E^2}{m^2} = -1, \tag{18.202}$$

where on-shell $E^2 - |\mathbf{p}|^2 = m^2$ gives the normalization. The two helicity states are $\Sigma(\pm s_h)$, and the projector Eq. (18.194) with $s = +s_h$ produces the positive-helicity spinor.

The structure of Eq. (18.202) already signals what happens at high energy: as $m \to 0$ at fixed energy, $|\mathbf{p}| \to E$ and the spin vector becomes

$$s_h^\mu \xrightarrow{m \to 0} \frac{p^\mu}{m}, \tag{18.203}$$

which diverges, but always paired with the m that the spinors carry, so that the combination is finite. Substituting $s_h = p/m$ into Eq. (18.194) and keeping every term as $m \to 0$,

$$u_h \bar{u}_h = (\not{p} + m) \frac{1}{2} \Big(1 + h\,\gamma^5\,\frac{\not{p}}{m} \Big) = \frac{1}{2}\not{p} + \frac{h}{2m} \not{p} \gamma^5 \not{p} + \frac{m}{2} + \frac{h}{2} \gamma^5 \not{p}, \tag{18.204}$$

where $h = \pm 1$ labels the helicity. The middle term contains $\not{p}\gamma^5\not{p} = -\gamma^5 \not{p}\not{p} = -\gamma^5 p^2$, and $p^2 = m^2 \to 0$ for a massless particle, so this term vanishes; the $m/2$ term vanishes directly; and using $\gamma^5 \not{p} = -\not{p}\gamma^5$ in the last term,

$$u_h \bar{u}_h \xrightarrow{m \to 0} \frac{1}{2}\not{p} + \frac{h}{2}\gamma^5 \not{p} = \frac{1 + h\gamma^5}{2}\,\not{p} = \begin{cases} P_R\,\not{p}, & h = +1, \\ P_L\,\not{p}, & h = -1, \end{cases} \tag{18.205}$$

with $P_{R,L} = \frac{1}{2}(1 \pm \gamma^5)$ the chiral projectors of Eq. (11.82) and Section C.3.5. The same computation on the antiparticle outer product Eq. (18.195), where the leading factor is $\not{p} - m$, gives

$$v_h \bar{v}_h \xrightarrow{m \to 0} \frac{1 - h\gamma^5}{2}\,\not{p} = \begin{cases} P_L\,\not{p}, & h = +1, \\ P_R\,\not{p}, & h = -1, \end{cases} \tag{18.206}$$

the opposite chirality assignment being the familiar feature that an antiparticle's helicity is labelled oppositely to its spinor chirality.

Equations (18.205) and (18.206) are the precise statement of a fact glimpsed already in Section 11.2.5 and rooted in the two-component Weyl structure of Section 3.4.3: *for a massless fermion, helicity equals chirality.* A positive-helicity massless particle is purely right-chiral; a negative-helicity one is purely left-chiral. The two notions, distinct and independently defined for $m > 0$ — chirality the Lorentz-invariant but non-conserved eigenvalue of γ^5, helicity the conserved but frame-dependent projection of spin on momentum — fuse into one in the massless limit, because the mass term that mixed the two chiralities in the Dirac equation has switched off. This single fusion is what makes the high-energy limit of QED so much simpler than the general case, and it is the reason the entire spinor-helicity formalism of Chapter 58 is built on chirality eigenstates.

Physical Insight

For $m > 0$ the spin projector Eq. (18.193) and the chiral projectors $P_{L,R}$ are genuinely different operators: $\Sigma(s)$ depends on the chosen axis s, while $P_{L,R}$ are fixed. The massless limit Eq. (18.205) is the statement that, once the axis is taken to be the direction of motion, the spin projector slides onto a chiral projector. Physically, a massless particle moves at the speed of light, so no observer can overtake it to reverse its momentum: helicity becomes Lorentz-invariant, just as chirality always was, and the two labels can no longer be told apart.

18.6.3 The helicity-conservation selection rule

The reason helicity organizes high-energy QED so powerfully is a selection rule that follows from a single algebraic fact about the QED vertex. The vertex is $-ie\gamma^\mu$; every fermion line is a string of gamma matrices, and the question is how chirality flows along it. The answer is governed by the intertwining relation between the chiral projectors and a single gamma matrix,

$$\gamma^\mu P_L = P_R\,\gamma^\mu, \qquad \gamma^\mu P_R = P_L\,\gamma^\mu, \tag{18.207}$$

which is immediate from $\{\gamma^5, \gamma^\mu\} = 0$ (Eq. (11.4)): moving γ^5 past one gamma matrix flips its sign, hence converts $P_L \leftrightarrow P_R$. Consider now the building block of every QED amplitude, the current along a fermion line carrying any odd number of vertices,

$$J^{\mu_1\cdots\mu_{2n+1}} = \bar{u}_2\,\gamma^{\mu_1}\not{q}_1\gamma^{\mu_2}\cdots\gamma^{\mu_{2n+1}}u_1, \tag{18.208}$$

the gammas coming from vertices and the $\not{q}_i$ from internal propagator numerators. (Internal propagators contribute $\not{q}_i + m$, but in the massless limit only the $\not{q}_i$

survives.) Decompose the incoming spinor into chiralities, $u_1 = P_L u_1 + P_R u_1$, and push, say, the P_L piece leftward through the string. Each gamma matrix it passes flips $P_L \leftrightarrow P_R$ by Eq. (18.207); passing through an *odd* total number of gamma matrices — $2n+1$ vertices plus $2n$ internal slashes is an odd count of gammas only when... let us count precisely.

Proposition 18.18 (Chirality is conserved along a fermion line)**.** *In the massless limit, a fermion line connecting an incoming spinor u_1 to an outgoing $\bar{u}_2$ through any number of QED vertices and propagators is nonzero only when u_1 and u_2 have the* same *chirality. Equivalently, the matrix element $\bar{u}_2 \,\Gamma\, u_1$ with Γ a product of an odd number of gamma matrices satisfies*

$$\bar{u}_2 \,\Gamma\, u_1 = \bar{u}_2 \, P_L \,\Gamma\, P_R \, u_1 + \bar{u}_2 \, P_R \,\Gamma\, P_L \, u_1, \tag{18.209}$$

so left-chiral and right-chiral incoming states map only to left- and right-chiral outgoing states respectively.

Proof. Each vertex and each (massless) propagator numerator contributes exactly one gamma matrix to the string Γ; a connected line therefore carries an odd number of gamma matrices, one per vertex plus one per internal segment, and for a line with V vertices and $V-1$ internal segments the total is $2V-1$, odd. Take Γ a product of an odd number of gammas and insert $\mathbf{1} = P_L + P_R$ on each side:

$$\bar{u}_2 \Gamma u_1 = \bar{u}_2 (P_L + P_R) \Gamma (P_L + P_R) u_1. \tag{18.210}$$

By Eq. (18.207), moving a projector through an odd number of gammas converts it to the opposite handedness: $P_R \Gamma = \Gamma P_L$ and $P_L \Gamma = \Gamma P_R$. Hence the same-handed terms vanish, $P_R \Gamma P_R = \Gamma P_L P_R = 0$ and $P_L \Gamma P_L = \Gamma P_R P_L = 0$, while the opposite-handed terms $P_L \Gamma P_R = \Gamma P_R$ and $P_R \Gamma P_L = \Gamma P_L$ survive, leaving Eq. (18.209). Note $\bar{u}_2 P_L = \overline{P_R u_2}$, so the surviving terms pair a right-chiral incoming u_1 with a right-chiral outgoing u_2 and likewise for left. Since for massless fermions chirality equals helicity by Eq. (18.205), the incoming and outgoing helicities along the line must agree. □

This is the helicity-conservation selection rule, and it has a sharp consequence for any amplitude with external photons or for an annihilation current. For a fermion that is scattered — the same particle in and out, as on the electron line of Compton or Møller — the rule says its helicity is preserved by every QED interaction in the massless limit: chirality flows through the vertex untouched. For a fermion and antifermion that *annihilate* into (or are created from) a photon, the rule is read on the single current $\bar{v}(p')\gamma^\mu u(p)$: inserting projectors and using Eq. (18.207),

$$\bar{v}(p')\gamma^\mu u(p) = \bar{v}(p') \, P_L \gamma^\mu P_R \, u(p) + \bar{v}(p') \, P_R \gamma^\mu P_L \, u(p), \tag{18.211}$$

where $\bar{v}\,P_L = \overline{P_R v}$ and the structure forces the electron and positron to carry *opposite* helicities (a right-chiral u pairs with a right-chiral v, which is a *negative*-helicity positron by Eq. (18.206)). Physically this is angular momentum conservation: the intermediate photon has spin 1, so the e^+e^- pair, collinear along the beam, must carry one unit of angular momentum along that axis — their spins must be parallel, hence their helicities, defined relative to opposite momenta, must be opposite. Of the four possible initial helicity combinations, only the two with opposite electron and positron helicity survive; the other two vanish identically in the massless limit.

18.6.4 The helicity amplitudes of $e^+e^- \to \mu^+\mu^-$

We now resolve the chapter's reference process into its helicity components and verify that they rebuild the unpolarized cross section established in Section 17.3. We continue QED with the exact model and conventions fixed there: incoming $e^-(p)\,e^+(p')$ annihilate through a single s-channel photon into $\mu^-(k)\,\mu^+(k')$, and we work in the high-energy limit $s \gg m_e^2, m_\mu^2$ where all masses are neglected.

Worked Example 18.19 (Polarized $e^+e^- \to \mu^+\mu^-$ and its incoherent sum)**.** The amplitude is the one diagram of Section 17.3,

$$\mathcal{M} = \frac{e^2}{s}\,[\bar{v}(p')\gamma^\mu u(p)]\,[\bar{u}(k)\gamma_\mu v(k')], \qquad s = (p+p')^2, \tag{18.212}$$

with the electron charge $-e$ ($e>0$) and Feynman gauge for the photon propagator. We place the collision in the centre-of-mass frame with the electron along $+z$ and the outgoing muon at polar angle θ,

$$p = \tfrac{\sqrt{s}}{2}(1,0,0,1), \quad p' = \tfrac{\sqrt{s}}{2}(1,0,0,-1), \quad k = \tfrac{\sqrt{s}}{2}(1,\sin\theta,0,\cos\theta), \quad k' = \tfrac{\sqrt{s}}{2}(1,-\sin\theta,0,- \tag{18.213}$$

all massless. The invariants are

$$s = 2p{\cdot}p' = 2k{\cdot}k', \qquad t = (p-k)^2 = -2p{\cdot}k = -\tfrac{s}{2}(1-\cos\theta), \qquad u = (p-k')^2 = -2p{\cdot}k' = -\tfrac{s}{2} \tag{18.214}$$

so that $s+t+u=0$ and $p\cdot k' = p'\cdot k = -u/2$, $p\cdot k = p'\cdot k' = -t/2$.

Selection rule. By Theorem 18.18 applied to the annihilation current Eq. (18.211), the electron and positron must have opposite helicities, and the same holds for the muon pair on the other current. The surviving configurations are the four

$$(e^-_R e^+_L),(e^-_L e^+_R) \;\otimes\; (\mu^-_R\mu^+_L),(\mu^-_L\mu^+_R), \tag{18.215}$$

where the subscript on a positron/antimuon L denotes its physical (negative) helicity; the remaining twelve of the sixteen helicity combinations vanish.

One amplitude in full. Take $e^-_R e^+_L \to \mu^-_R\mu^+_L$. With helicities fixed, no spin sum is needed: the outer products are the massless projector forms Eqs. (18.205)

and (18.206). For the right-handed electron, $u(p)\bar{u}(p) = P_R \not{p}$; for its negative-helicity positron partner, the selection rule requires $v(p')\bar{v}(p') = P_R \not{p}'$. The electron tensor is

$$L^{\mu\nu} = \big[\bar{v}(p')\gamma^\mu u(p)\big]\big[\bar{v}(p')\gamma^\nu u(p)\big]^* = \mathrm{tr}\big[\gamma^\mu\, u(p)\bar{u}(p)\,\gamma^\nu\, v(p')\bar{v}(p')\big] = \mathrm{tr}\big[\gamma^\mu P_R \not{p}\,\gamma^\nu P_R \not{p}'\big]. \tag{18.216}$$

Slide the projectors together with Eq. (18.207): $P_R \not{p} = \not{p} P_L$, then $P_L \gamma^\nu = \gamma^\nu P_R$ and $P_R P_R = P_R$, so the two projectors collapse to one, $L^{\mu\nu} = \mathrm{tr}[\gamma^\mu \not{p}\,\gamma^\nu \not{p}' P_L]$ with $P_L = \frac{1}{2}(1-\gamma^5)$. Using the four-gamma trace Eq. (C.178) and the γ^5 four-trace Eq. (C.179) (with $\epsilon^{0123} = +1$),

$$\begin{aligned} L^{\mu\nu} &= \tfrac{1}{2}\,\mathrm{tr}\,[\gamma^\mu \not{p}\,\gamma^\nu \not{p}'] - \tfrac{1}{2}\,\mathrm{tr}\,[\gamma^\mu \not{p}\,\gamma^\nu \not{p}'\gamma^5] \\ &= 2(p^\mu p'^\nu + p^\nu p'^\mu - \eta^{\mu\nu}\, p\cdot p') + 2i\,\epsilon^{\mu\alpha\nu\beta} p_\alpha p'_\beta, \end{aligned} \tag{18.217}$$

the antisymmetric ϵ-term being the signature of the definite chirality. The muon current is the mirror computation with $u(k)\bar{u}(k) = P_R \not{k}$ and $v(k')\bar{v}(k') = P_R \not{k}'$,

$$M_{\mu\nu} = \mathrm{tr}\big[\gamma_\mu P_R \not{k}'\,\gamma_\nu P_R \not{k}\big] = 2(k'_\mu k_\nu + k'_\nu k_\mu - \eta_{\mu\nu}\, k\cdot k') + 2i\,\epsilon_{\mu\rho\nu\sigma} k'^\rho k^\sigma. \tag{18.218}$$

The squared amplitude is $|\mathcal{M}|^2 = (e^4/s^2)\, L^{\mu\nu} M_{\mu\nu}$. The contraction splits into symmetric×symmetric and antisymmetric×antisymmetric pieces (the cross terms vanish, symmetric against antisymmetric in the index pair). The symmetric part is

$$L^{\mu\nu}_{\mathrm{sym}} M^{\mathrm{sym}}_{\mu\nu} = 8\big[(p\cdot k)(p'\cdot k') + (p\cdot k')(p'\cdot k)\big], \tag{18.219}$$

obtained by expanding the nine products and using $\eta^{\mu\nu}\eta_{\mu\nu} = 4$, which cancels the $(p\cdot p')(k\cdot k')$ terms. The antisymmetric part uses the Levi-Civita contraction Eq. (C.167), $\epsilon^{\mu\alpha\nu\beta}\epsilon_{\mu\rho\nu\sigma} = -2(\delta^\alpha_\rho\delta^\beta_\sigma - \delta^\alpha_\sigma\delta^\beta_\rho)$,

$$\begin{aligned} L^{\mu\nu}_{\mathrm{asym}} M^{\mathrm{asym}}_{\mu\nu} &= (2i)(2i)\,\epsilon^{\mu\alpha\nu\beta} p_\alpha p'_\beta\, \epsilon_{\mu\rho\nu\sigma} k'^\rho k^\sigma \\ &= -4\cdot(-2)(\delta^\alpha_\rho\delta^\beta_\sigma - \delta^\alpha_\sigma\delta^\beta_\rho) p_\alpha p'_\beta k'^\rho k^\sigma = 8\big[(p\cdot k')(p'\cdot k) - (p\cdot k)(p'\cdot k')\big]. \end{aligned} \tag{18.220}$$

Adding Eqs. (18.219) and (18.220), the $(p\cdot k)(p'\cdot k')$ terms cancel and the $(p\cdot k')(p'\cdot k)$ terms add:

$$L^{\mu\nu} M_{\mu\nu} = 16\,(p\cdot k')(p'\cdot k) = 16\cdot\frac{(-u)}{2}\cdot\frac{(-u)}{2} = 4u^2, \tag{18.221}$$

so that, using $-u = \frac{s}{2}(1+\cos\theta)$,

$$\big|\mathcal{M}(e^-_R e^+_L \to \mu^-_R \mu^+_L)\big|^2 = \frac{e^4}{s^2}\cdot 4u^2 = \frac{4e^4u^2}{s^2} = e^4(1+\cos\theta)^2. \tag{18.222}$$

The amplitude is forward-peaked: it is maximal at $\theta = 0$, where the outgoing μ^-_R continues in the direction of the incoming e^-_R with matched helicity, and it vanishes at $\theta = \pi$.

The other three by the same machinery. Flipping the muon-pair helicity to $\mu_L^- \mu_R^+$ replaces $u(k)\bar{u}(k) = P_L \not{k}$, which flips the sign of the muon tensor's ϵ-term; the antisymmetric contraction Eq. (18.220) then reverses sign, the surviving combination becomes $16(p \cdot k)(p' \cdot k) = 4t^2$, and

$$|\mathcal{M}(e_R^- e_L^+ \to \mu_L^- \mu_R^+)|^2 = \frac{4e^4 t^2}{s^2} = e^4(1 - \cos\theta)^2, \tag{18.223}$$

backward-peaked. Flipping instead the initial pair to $e_L^- e_R^+$ flips the electron tensor's ϵ-term; parity invariance of QED (the Lagrangian is parity-even) guarantees that flipping all four helicities at once returns the original result, so the four amplitudes pair up:

$$|\mathcal{M}_{LR\to LR}|^2 = |\mathcal{M}_{RL\to RL}|^2 = \frac{4e^4 u^2}{s^2}, \qquad |\mathcal{M}_{LR\to RL}|^2 = |\mathcal{M}_{RL\to LR}|^2 = \frac{4e^4 t^2}{s^2}, \tag{18.224}$$

where the compact subscript $RL \to RL$ means $e_R^- e_L^+ \to \mu_R^- \mu_L^+$ and so on.

Incoherent sum. The four helicity configurations are physically distinct final and initial states; they do not interfere, and the unpolarized squared amplitude is their average over the four initial spin states (factor $\frac{1}{4}$) and sum over final spins:

$$\overline{|\mathcal{M}|^2} = \frac{1}{4}\Big[\,2 \cdot \frac{4e^4 u^2}{s^2} + 2 \cdot \frac{4e^4 t^2}{s^2}\Big] = \frac{2e^4\,(t^2 + u^2)}{s^2}. \tag{18.225}$$

With $t^2 + u^2 = \frac{s^2}{4}[(1 - \cos\theta)^2 + (1 + \cos\theta)^2] = \frac{s^2}{2}(1 + \cos^2\theta)$ this is

$$\overline{|\mathcal{M}|^2} = e^4\,(1 + \cos^2\theta), \tag{18.226}$$

exactly the spin-averaged result of Section 17.3. The averaging that earlier appeared as a single opaque trace is now resolved: the smooth $1 + \cos^2\theta$ is the incoherent superposition of two forward-peaked $(1 + \cos\theta)^2$ amplitudes and two backward-peaked $(1 - \cos\theta)^2$ amplitudes, whose sum is forward–backward symmetric only because QED treats the two beam helicities even-handedly.

The internal consistency check is complete, but the deeper lesson is in the intermediate results Eqs. (18.222) and (18.223). Each helicity amplitude is a single monomial in the Mandelstam invariants — $|\mathcal{M}|^2 \propto u^2$ or $\propto t^2$ — vastly simpler than the unpolarized $t^2 + u^2$, and simpler still at the level of the amplitude itself, which is just $\mathcal{M} \propto u$ or $\mathcal{M} \propto t$ up to a phase. The trace machinery, with its symmetric and antisymmetric tensor pieces and its ϵ-contraction, was a heavy route to a light answer. That the polarized amplitudes are so simple is the first indication that the spinor and the Lorentz vector are the wrong variables, and that a formalism built directly on helicity — the spinor-helicity calculus of Chapter 58 — will write these amplitudes in a single line.

18.6.5 Angular distributions and forward–backward structure

The two angular shapes $(1 \pm \cos\theta)^2$ are not coincidences of QED; they are dictated by angular momentum. The s-channel photon carries total angular momentum $J = 1$ along no fixed axis, but the collinear initial state has a definite $J_z = \lambda_{e^-} - \lambda_{e^+} = \pm 1$ along the beam, and the collinear final state a definite $J_{z'} = \lambda_{\mu^-} - \lambda_{\mu^+} = \pm 1$ along the outgoing muon direction. The amplitude is therefore proportional to a single Wigner rotation matrix element connecting these,

$$\mathcal{M} \;\propto\; d^1_{\lambda\lambda'}(\theta), \qquad d^1_{1,1}(\theta) = d^1_{-1,-1}(\theta) = \frac{1+\cos\theta}{2}, \qquad d^1_{1,-1}(\theta) = d^1_{-1,1}(\theta) = \frac{1-\cos\theta}{2}, \tag{18.227}$$

the $J = 1$ rotation functions familiar from the addition of angular momentum. Squaring reproduces $(1 \pm \cos\theta)^2$ exactly: the helicity amplitudes *are* the rotation matrix elements of the intermediate spin-1 state, and QED supplies only the overall strength e^2 and the propagator $1/s$. This is why the same $(1 \pm \cos\theta)^2$ shapes appear in every spin-1-mediated annihilation; the dynamics sets the normalization, the kinematics of angular momentum sets the shape.

A single helicity configuration is strongly forward–backward asymmetric. Defining, for fixed initial helicities, the forward–backward asymmetry

$$A_{\mathrm{FB}} = \frac{\sigma(\cos\theta > 0) - \sigma(\cos\theta < 0)}{\sigma(\cos\theta > 0) + \sigma(\cos\theta < 0)}, \tag{18.228}$$

the $e^-_R e^+_L$ initial state, weighted by $\int_0^1 (1+\cos\theta)^2\, d\cos\theta$ forward against $\int_{-1}^0$ backward (the muon helicities summed), gives

$$A_{\mathrm{FB}}(e^-_R e^+_L) = \frac{\int_0^1 [(1+c)^2 + (1-c)^2]\, dc - \int_{-1}^0 [(1+c)^2 + (1-c)^2]\, dc}{\int_{-1}^1 [(1+c)^2 + (1-c)^2]\, dc} = 0, \tag{18.229}$$

because summing the two muon helicities already restores the symmetry. The asymmetry is exposed only by measuring the final helicity as well: for the pure transition $e^-_R e^+_L \to \mu^-_R \mu^+_L$,

$$A_{\mathrm{FB}} = \frac{\int_0^1 (1+c)^2 dc - \int_{-1}^0 (1+c)^2 dc}{\int_{-1}^1 (1+c)^2 dc} = \frac{\frac{7}{3} - \frac{1}{3}}{\frac{8}{3}} = \frac{3}{4}, \tag{18.230}$$

a large asymmetry that the unpolarized average Eq. (18.226), with its vanishing $\cos\theta$-odd part, completely hides. In pure QED, parity invariance guarantees that the fully unpolarized A_{FB} vanishes; a nonzero unpolarized forward–backward asymmetry is the hallmark of parity violation, and its measurement in $e^+e^- \to \mu^+\mu^-$ at higher energies is one of the cleanest signatures of the weak neutral current interfering with the photon — a story that belongs to the electroweak chapters but whose kinematic skeleton is precisely the helicity analysis done here. Figure 18.7 displays the decomposition.

Physical Insight

The spin-averaged $1 + \cos^2\theta$ looks like a smooth, structureless law; the helicity decomposition reveals it as the sum of two sharply directed processes. This is the recurring moral of polarized amplitudes: averaging is lossy, and what it loses — the correlation between an incoming spin and an outgoing direction — is often the most incisive observable. The same logic, applied to processes with external photons such as Compton scattering, shows that the photon's two physical polarizations are just its two helicities, and that the gauge redundancy of the polarization vector is invisible to a helicity amplitude. Helicity is the label in which gauge-invariant content is manifest.

We have now seen helicity do three things: refine the spin sum into a projector (Theorem 18.17), fuse with chirality at high energy (Eq. (18.205)), and select and simplify the surviving amplitudes (Theorem 18.18, Theorem 18.19). Each polarized amplitude turned out to be a single monomial, far simpler than the spin-summed total, and tied directly to the rotation functions of the intermediate spin. This is the empirical case that helicity, not the Lorentz index, is the amplitude's natural variable. The synthesis that closes this chapter will gather this observation together with Ward invariance and crossing into one picture of the tree-level QED amplitude, and will make explicit the forward pointer that the present section has earned: the spinor-helicity reframing of Chapter 58, where each of the four lines computed here collapses to a ratio of angle and square brackets and the trace technology disappears entirely.

18.7 Synthesis: the QED tree amplitude as one analytic object

We have now computed, with full traces and spin sums, the four processes that this chapter set out to confront: Compton scattering, pair annihilation, Møller scattering, and Bhabha scattering, together carrying the running thread forward from the single-diagram $e^+e^- \to \mu^+\mu^-$ amplitude of Section 17.3. Along the way we proved the tree-level Ward identity (Section 18.2), used it to justify the covariant photon polarization sum, established the crossing rules (Section 18.4) that continue one process into another, and finally resolved the amplitudes by helicity (Section 18.6), watching the spin-resolved pieces add up to the unpolarized squares. Each computation was presented as a self-contained event. The purpose of this closing section is to step back and see that they are not separate events at all: the entire tree-level QED amplitude family is a small number of analytic functions of the Mandelstam invariants, whose various boundary values are the physical processes, whose pole and gauge structure is fixed by the Ward identity,

and whose internal organization is helicity. Assembling this single picture is what makes the chapter cohere, and it is the picture that the loop chapter, the precision chapter, and ultimately the modern-amplitudes program will deform, refine, and exploit.

18.7.1 Tree amplitudes as boundary values of analytic functions

The first thing to make precise is the sense in which distinct physical processes are "the same amplitude." A tree-level Feynman diagram is a product of vertices $(-ie\gamma^\mu)$, internal propagators, and external wavefunctions, contracted into Lorentz invariants. For a $2 \to 2$ process the only invariants available are the Mandelstam variables

$$s = (p_1 + p_2)^2, \qquad t = (p_1 - p_3)^2, \qquad u = (p_1 - p_4)^2, \qquad s + t + u = \sum_i m_i^2, \tag{18.231}$$

with p_1, p_2 incoming and p_3, p_4 outgoing (recall Section 16.5). A tree diagram has a single internal line; its propagator denominator is one of $s - m^2$, $t - m^2$, or $u - m^2$. Therefore the spin-summed squared amplitude of any tree-level $2 \to 2$ QED process is a *rational function of s, t, u whose only singularities are simple poles at the physical thresholds of the exchanged particle*, with numerators that are polynomials of bounded degree fixed by the spins of the external legs. This is the structural fact behind crossing, and it deserves a precise statement.

Proposition 18.20 (Tree QED amplitudes are boundary values of a few rational functions)**.** *Fix the external particle content of a tree-level QED $2 \to 2$ process up to which legs are incoming and which are outgoing. The spin-summed quantity $\sum_{\text{spins}} |\mathcal{M}|^2$ is the restriction, to the physical region of that channel assignment, of a single rational function $R(s, t, u)$ on the surface (18.231). Two processes built from the same set of fields, differing only by the in/out assignment of the external legs, are restrictions of the* same *R to different physical regions; they are related by permuting s, t, u (and flipping the overall sign once per crossed fermion pair, from the spinor completeness relations $\sum u\bar{u} = \not{p} + m$ versus $\sum v\bar{v} = \not{p} - m$). The poles of R sit only at $c = m^2$ for the channel invariant c carried by an exchangeable particle of mass m.*

Proof. The amplitude $\mathcal{M}$ for a given diagram is a finite sum of terms, each a product of: external Dirac spinors and polarization vectors; vertex factors $-ie\gamma^\mu$; and propagator numerators ($\not{q} + m$ for a fermion of momentum q, $-\eta_{\mu\nu}$ for a Feynman-gauge photon) divided by denominators $q^2 - m^2 + i\varepsilon$. Each internal momentum q is a fixed integer combination of the external momenta, so q^2 equals one of s, t, u up to a shift by masses; the denominators are therefore among $\{s - m^2, t - m^2, u - m^2\}$. Squaring and summing over spins replaces external $u\bar{u}$ and $v\bar{v}$ by $\not{p} \pm m$ and collapses every polarization sum to $-\eta_{\mu\nu}$

(the Ward identity, Theorem 18.5, guarantees the gauge-dependent remainder of the photon sum drops out). The result is a trace of gamma matrices times rational denominators, i.e. a polynomial in scalar products $p_i \cdot p_j$ over the product of the denominators. Every $p_i \cdot p_j$ is a linear combination of s, t, u and masses by (18.231), so $\sum_{\text{spins}} |\mathcal{M}|^2 = R(s,t,u)$ is rational with poles only where a denominator vanishes, i.e. at $c = m^2$. Relabelling which external momenta are incoming is, at the level of these formulas, exactly a permutation of which linear combination is called s, t, or u, together with $p_i \to -p_i$ on the crossed legs; the latter sends $\not{p} + m \to -(\not{p} - m)$, i.e. it exchanges the u- and v-type completeness relations and contributes a sign (-1) for each crossed fermion line. Hence the two processes are restrictions of one R up to that sign. □

Theorem 18.20 is the analyticity half of the picture; the Ward identity is the gauge half; helicity is the organizing half. The remainder of this section makes each concrete by assembling the chapter's explicit results into one summary.

18.7.2 The crossing web

It is convenient to work in the massless (high-energy) limit, $m \to 0$, where $s + t + u = 0$ and the rational functions R take their simplest, most transparent form; the massive expressions computed earlier in the chapter reduce to these and were each checked to do so. Collecting the spin-averaged results — averaged over initial spins/polarizations, summed over final — we have the following six entries, the four new processes of this chapter together with the two from Chapter 17 that seed them.

The single-photon four-fermion family. For processes with two distinct charged-fermion lines exchanging one photon,

$$e^+e^- \to \mu^+\mu^- : \qquad \overline{|\mathcal{M}|^2} = 2e^4\,\frac{t^2+u^2}{s^2}, \tag{18.232}$$

$$e^-\mu^- \to e^-\mu^- : \qquad \overline{|\mathcal{M}|^2} = 2e^4\,\frac{s^2+u^2}{t^2}. \tag{18.233}$$

The first is the s-channel annihilation diagram of Section 17.3; the second is the t-channel scattering diagram, and the two are manifestly one function continued by $s \leftrightarrow t$. When the two fermion lines are made identical (electrons), Fermi statistics forces a second diagram and a relative minus sign between the two, producing Møller and Bhabha:

$$e^-e^- \to e^-e^- \text{ (Møller)} : \quad \overline{|\mathcal{M}|^2} = 2e^4\left[\frac{s^2+u^2}{t^2} + \frac{s^2+t^2}{u^2} + \frac{2s^2}{tu}\right], \tag{18.234}$$

$$e^+e^- \to e^+e^- \text{ (Bhabha)} : \quad \overline{|\mathcal{M}|^2} = 2e^4\left[\frac{t^2+u^2}{s^2} + \frac{s^2+u^2}{t^2} + \frac{2u^2}{st}\right]. \tag{18.235}$$

Process	Channels	Crossing	$\overline{\lvert\mathcal{M}\rvert^2}/2e^4$ (massless)
$e^+e^- \to \mu^+\mu^-$	s	seed (Section 17.3)	$\dfrac{t^2+u^2}{s^2}$
$e^-\mu^- \to e^-\mu^-$	t	$s \leftrightarrow t$ of above	$\dfrac{s^2+u^2}{t^2}$
Møller $e^-e^- \to e^-e^-$	t, u	identical-leg of $e^-\mu^-$	$\dfrac{s^2+u^2}{t^2} + \dfrac{s^2+t^2}{u^2} + \dfrac{2s^2}{tu}$
Bhabha $e^+e^- \to e^+e^-$	s, t	$s \leftrightarrow u$ of Møller	$\dfrac{t^2+u^2}{s^2} + \dfrac{s^2+u^2}{t^2} + \dfrac{2u^2}{st}$
Compton $e^-\gamma \to e^-\gamma$	s, u	seed (Compton master)	$-\left(\dfrac{s}{u} + \dfrac{u}{s}\right)$
pair annih. $e^+e^- \to \gamma\gamma$	t, u	$s \leftrightarrow t$ of Compton	$+\left(\dfrac{t}{u} + \dfrac{u}{t}\right)$

Table 18.3: The crossing web of the chapter's tree-level processes. "Channels" lists the Mandelstam invariants in which an internal line goes on shell. Every entry is a boundary value of one of two master functions. The Compton-family sign flip between rows five and six is the single-fermion-crossing sign of Theorem 18.20.

The Compton family. For processes with one charged-fermion line and two external photons, exchanging a virtual electron,

$$e^-\gamma \to e^-\gamma \text{ (Compton)}: \qquad \overline{|\mathcal{M}|^2} = -2e^4\left(\frac{s}{u} + \frac{u}{s}\right), \tag{18.236}$$

$$e^+e^- \to \gamma\gamma \text{ (pair annihilation)}: \qquad \overline{|\mathcal{M}|^2} = 2e^4\left(\frac{t}{u} + \frac{u}{t}\right). \tag{18.237}$$

Here $e^2 = 4\pi\alpha$, so $e^4 = 16\pi^2\alpha^2$. Each of these six expressions was derived in its own section; collected together they reveal the web shown in Fig. 18.8 and tabulated in Table 18.3. The web has exactly two connected components, one per master function, and within each component the entries are related by simple permutations of (s, t, u).

The four-fermion entries (18.232)–(18.235) are not merely *related*; they are assembled from one universal building block according to a rule that the explicit traces make obvious in hindsight.

Proposition 18.21 (Universal channel rule for single-photon four-fermion amplitudes)**.** *Let a tree QED process scatter two charged-fermion lines through single-photon exchange, and let $\mathcal{C} \subseteq \{s, t, u\}$ be the set of Mandelstam channels in which a photon can be exchanged for the given in/out assignment. In the massless limit,*

$$\overline{|\mathcal{M}|^2} = 2e^4\left[\sum_{c\in\mathcal{C}} \frac{\sigma_2(c)}{c^2} \;+\; [\,|\mathcal{C}| = 2\,]\,\frac{2\,w^2}{c_1\,c_2}\right], \tag{18.238}$$

where $\sigma_2(c)$ denotes the sum of the squares of the two invariants other than c, the bracket $[\,\cdot\,]$ is 1 when its condition holds and 0 otherwise, and for a two-channel process $\mathcal{C} = \{c_1, c_2\}$ the interference weight w is the single invariant absent from $\mathcal{C}$. The sign of the interference term is fixed by Fermi statistics and is positive in this invariant form.

Proof. A single c-channel photon-exchange diagram contributes $\mathcal{M}_c = (-ie)^2\,[\bar{u}\gamma^\mu u][\bar{u}\gamma_\mu u]/c$, the two currents being the two fermion lines and c the squared momentum on the photon. Squaring and summing over spins produces e^4/c^2 times a product of two traces, $\mathrm{tr}(\not{p}_a\gamma^\mu\not{p}_b\gamma^\nu)\ \mathrm{tr}(\not{p}_{a'}\gamma_\mu\not{p}_{b'}\gamma_\nu)$, each trace giving $4(p_a^\mu p_b^\nu + p_a^\nu p_b^\mu - \eta^{\mu\nu}p_a\cdot p_b)$. Contracting the two and using $2p_i\cdot p_j \in \{\pm s, \pm t, \pm u\}$ (massless) collapses, after averaging over the four initial spin states, to $2e^4\,\sigma_2(c)/c^2$: this is exactly the computation behind (18.232) for $c = s$ and (18.233) for $c = t$, where $\sigma_2(s) = t^2 + u^2$ and $\sigma_2(t) = s^2 + u^2$. When two channels are present the amplitude is $\mathcal{M}_{c_1} \pm \mathcal{M}_{c_2}$ (the sign $-$ when the two diagrams differ by the exchange of identical external fermions), so $\overline{|\mathcal{M}|^2}$ acquires, besides the two diagonal pieces, the cross term $\pm 2e^4\,\overline{\mathrm{Re}(\mathcal{M}_{c_1}\mathcal{M}_{c_2}^*)}$. Evaluating the single combined trace — now one closed fermion loop running through both photon vertices — gives $4e^4\,w^2/(c_1c_2)$ with w the absent invariant, and the statistics sign combines with the sign of that trace to make the contribution $+2e^4\cdot 2w^2/(c_1c_2)$. For Møller, $\mathcal{C} = \{t, u\}$ and $w = s$, reproducing (18.234); for Bhabha, $\mathcal{C} = \{s, t\}$ and $w = u$, reproducing (18.235). □

Theorem 18.21 compresses four separate trace computations into a single counting statement: tell me which channels carry a photon, and the spin-averaged rate is determined. It also exposes the physics of each interference. In Møller the absent invariant is s, so the interference $\propto s^2/tu$ is large precisely at fixed angle and high energy, where s dominates; in Bhabha the absent invariant is u, and the interference $\propto u^2/st$ carries the destructive cross-talk between annihilation and scattering that flips sign across the physical region because $st < 0$ there. These are not coincidences to be memorized but consequences of which diagrams Fermi statistics permits.

Worked Example 18.22 (Verifying the crossing web by substitution)**.** We check that the six entries (18.232)–(18.237) are mutually consistent under crossing, exactly as Theorem 18.20 requires. No new trace is computed; this is a consistency audit of results already in hand.

(i) $e^+e^- \to \mu^+\mu^-$ to $e^-\mu^- \to e^-\mu^-$. Crossing the incoming μ^+ to an outgoing μ^- (and the outgoing μ^- to an incoming μ^-) turns the s-channel annihilation into t-channel scattering, which at the level of invariants is $s \leftrightarrow t$. Applying $s \leftrightarrow t$ to (18.232),

$$2e^4\,\frac{t^2+u^2}{s^2} \quad \xrightarrow{s\leftrightarrow t} \quad 2e^4\,\frac{s^2+u^2}{t^2}, \tag{18.239}$$

which is (18.233). Two fermion lines are crossed (an even number), so there is no overall sign; both sides are positive, as required for a squared amplitude.

(ii) Møller to Bhabha. Bhabha is obtained from Møller by turning one incoming electron into an outgoing positron and one outgoing electron into an incoming positron. The Møller channels are $\{t, u\}$ with absent invariant s; the Bhabha channels are $\{s, t\}$ with absent invariant u, so the no-pole channel moves $s \to u$, i.e. the crossing is $s \leftrightarrow u$. Applying it to (18.234),

$$2e^4\left[\frac{s^2+u^2}{t^2}+\frac{s^2+t^2}{u^2}+\frac{2s^2}{tu}\right] \xrightarrow{s\leftrightarrow u} 2e^4\left[\frac{u^2+s^2}{t^2}+\frac{u^2+t^2}{s^2}+\frac{2u^2}{ts}\right], \tag{18.240}$$

where the first numerator is unchanged (it is symmetric in s, u), the second term's denominator becomes s^2, and the interference denominator $tu \to ts = st$. Reordering,

$$2e^4\left[\frac{t^2+u^2}{s^2}+\frac{s^2+u^2}{t^2}+\frac{2u^2}{st}\right], \tag{18.241}$$

which is precisely Bhabha, (18.235). Again an even number of fermion crossings, hence no sign, and both results are positive.

(iii) Compton to pair annihilation. Crossing the incoming Compton photon to an outgoing photon and the outgoing Compton electron to an incoming positron converts $e^-\gamma \to e^-\gamma$ into $e^+e^- \to \gamma\gamma$. The Compton s-channel electron pole, $s = (p_e + k)^2$, becomes the annihilation t-channel electron pole, $t = (p_e - k')^2$, while the Compton u-channel pole is carried to the annihilation u-channel pole; thus the crossing is $s \leftrightarrow t$. Applying it to (18.236),

$$-2e^4\left(\frac{s}{u}+\frac{u}{s}\right) \xrightarrow{s\leftrightarrow t} -2e^4\left(\frac{t}{u}+\frac{u}{t}\right). \tag{18.242}$$

Exactly *one* fermion line is crossed here (the electron → positron; the photon is a boson and contributes no sign), so by Theorem 18.20 the result picks up one factor (-1):

$$(-1)\times\left[-2e^4\left(\frac{t}{u}+\frac{u}{t}\right)\right] = +2e^4\left(\frac{t}{u}+\frac{u}{t}\right), \tag{18.243}$$

which is the pair-annihilation result (18.237). The lone fermion-crossing sign is the origin of the relative minus between the prefactors of (18.236) and (18.237), and the fact that it lands the annihilation rate at a manifestly positive value (recall $t, u < 0$ in the physical $e^+e^- \to \gamma\gamma$ region, so $t/u > 0$) is a nontrivial check on the whole sign bookkeeping.

Every arrow of Fig. 18.8 is thereby verified: the six physical squared amplitudes are boundary values of two analytic functions, in complete agreement with Theorem 18.20.

18.7.3 The Ward identity as the constraint that holds it together

Crossing is the analyticity face of the synthesis; the Ward identity is the gauge face, and the two are not independent. Recall the tree-level statement proved earlier (Theorem 18.5): if $\mathcal{M} = \epsilon_\mu(k)\,\mathcal{M}^\mu(k)$ is any QED amplitude with an on-shell external photon of momentum k, then replacing the polarization by the momentum annihilates it,

$$k_\mu\,\mathcal{M}^\mu(k) = 0. \tag{18.244}$$

This single identity does three jobs simultaneously, and seeing them as one is the point of the synthesis.

First, it *licenses the covariant polarization sum.* In summing $|\mathcal{M}|^2$ over physical photon polarizations one would like to use $\sum_\lambda \epsilon_\mu^{(\lambda)*}\epsilon_\nu^{(\lambda)} \to -\eta_{\mu\nu}$ rather than the cumbersome physical-state projector. The difference between the two is a sum of terms each proportional to k_μ or k_ν, which by (18.244) contract to zero against $\mathcal{M}^\mu$. Without (18.244) the Compton and pair-annihilation squares (18.236)–(18.237) would carry gauge-dependent garbage; with it, the simple covariant results stand. This is why the Compton family could be computed in Feynman gauge with no apology.

Second, it *guarantees gauge independence of the physical rate.* The amplitude depends on the photon propagator's gauge parameter ξ only through internal photon lines, and the ξ-dependent part of the propagator, $\propto (1-\xi)\,q_\mu q_\nu/q^2$, attaches its q_μ to a conserved current — the same Ward structure (18.244) applied to an off-shell leg — and vanishes. Every cross section in Table 18.3 is therefore ξ-independent, as the explicit Feynman-gauge computations and their crossings consistently returned.

Third, and most structurally, (18.244) *constrains the numerators* of the master functions in Theorem 18.20. Transversality is a polynomial identity among the gauge-index pieces of $\mathcal{M}^\mu$; it forces the individual diagrams (each non-transverse on its own) to combine into a transverse whole, which is exactly why a single Compton diagram is gauge-variant but their sum is not. The pole structure dictated by analyticity and the transversality dictated by gauge invariance together leave only the finite-dimensional space of numerators that the helicity decomposition (Section 18.6) then diagonalizes. Analyticity says *where* the function can be singular; the Ward identity says *how* the residues and the polynomial numerator must be arranged; helicity says *which* independent components there are. The tree QED amplitude is the unique object meeting all three demands.

Physical Insight

The three organizing principles of this chapter are three views of one object. Analyticity (crossing) is the statement that the amplitude is a function on

the (s,t,u) surface with controlled singularities; gauge invariance (Ward) is the statement that this function is transverse and ξ-independent; helicity is the statement that it block-diagonalizes under the little group of each external leg. A first course meets them as three separate tricks for getting answers faster. They are better understood as the defining properties of a single analytic amplitude, and the modern on-shell program (Part XVI) takes precisely this inversion — *define* amplitudes by their analyticity, little-group, and factorization properties, and reconstruct the Feynman expansion as a derived consequence rather than a starting point.

18.7.4 Forward map: loops, infrared structure, precision, and the on-shell viewpoint

The tree-level synthesis is the platform for everything that follows in QED, and it is worth naming exactly what is handed forward.

To the loop chapter (Chapter 19). The tree Ward identity (18.244) is promoted there to the all-orders Ward–Takahashi identity (Theorem 19.13), the exact statement $q_\mu \Gamma^\mu(p',p) = S^{-1}(p') - S^{-1}(p)$ relating the renormalized vertex to the electron self-energy, of which (18.244) is the on-shell tree shadow. The same explicit tree amplitudes assembled here are the leading terms whose radiative corrections Chapter 19 computes: the one-loop vacuum polarization dresses the photon line of (18.232) and (18.235), the self-energy dresses the electron lines of the Compton family, and the vertex correction dresses every $-ie\gamma^\mu$. Crucially, the tree amplitudes also fix the *infrared* structure. In the soft limit, where an external photon's energy $\omega \to 0$, the Compton and bremsstrahlung amplitudes factorize as $\mathcal{M} \to (\text{eikonal factor}) \times \mathcal{M}_{\text{hard}}$, the eikonal factor being a sum of $\epsilon\cdot p_i/(k\cdot p_i)$ over external charges — a structure already visible in the s,u poles of (18.236). In the collinear limit, where two massless legs become parallel, the same poles signal the mass singularities that dimensional regularization will tame. The cancellation of these infrared divergences between virtual and real emission (Bloch–Nordsieck, and more generally KLN), stated and organized in Chapter 19, takes the tree squares of this chapter as its real-emission input.

To the precision chapter (Chapter 20). The vertex correction whose tree seed is the bare $-ie\gamma^\mu$ produces, at one loop, the anomalous magnetic moment $a_e = \alpha/2\pi$ — Schwinger's number (Theorem 20.5) — and the running of the fine-structure constant $\alpha(q^2)$ from the vacuum polarization that dresses the s-channel photon of (18.232). The unpolarized $e^+e^- \to \mu^+\mu^-$ rate computed at tree level is, with that running coupling inserted, the leading term of a genuinely measured precision observable.

To the modern-amplitudes program (Part XVI, Chapter 58). The helicity reorganization begun in Section 18.6 — the observation that in the massless limit

the rational squares (18.232)–(18.237) are incoherent sums of a few simple helicity amplitudes — is the seed of the spinor-helicity formalism. There the master functions of Theorem 18.20 are written directly in angle and square brackets $\langle i\,j\rangle, [i\,j]$, the Ward identity is automatic (little-group covariance replaces it), and crossing becomes analytic continuation of the same bracket expression. The crossing web of Fig. 18.8 is, from that vantage, the shadow cast by a handful of holomorphic amplitudes onto the real Mandelstam regions. This chapter is where QED first stops being "formalism that yields one number" and becomes a structured family of amplitudes governed by symmetry and analyticity; Chapter 58 is where that structure is made the primary object.

With the tree-level Ward identity, the explicit master amplitudes, and the crossing web in hand, QED is poised for its first loops: Chapter 19 inherits (18.244) to promote into the Ward–Takahashi identity and the explicit tree squares to serve as the real-emission and Born-level inputs of its radiative corrections, and Chapter 20 inherits the dressed vertex and photon propagator that turn these amplitudes into $g-2$ and the running coupling.

Further reading

The four processes worked here are treated, with complementary conventions, in Peskin and Schroeder [396] (Compton scattering and pair annihilation in their Chapter 5, where crossing is also developed) and in Schwartz [432] (Møller and Bhabha scattering and the systematic use of Mandelstam variables and the Ward identity). The crossing-symmetry viewpoint and the analytic structure of tree amplitudes are presented at greater depth in Srednicki [454]. Weinberg [500] gives the field-theoretic origin of the Ward identity that Chapter 19 elevates to the Ward–Takahashi identity. For the helicity organization and its promotion to the spinor-helicity formalism developed in Chapter 58, Elvang and Huang [176] is the modern reference.

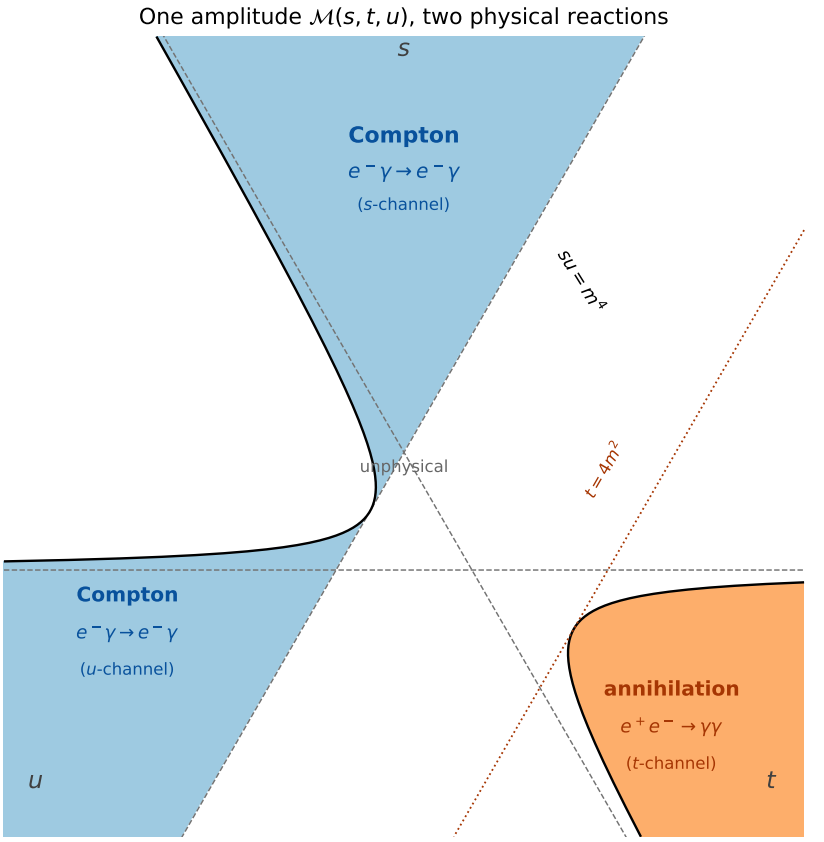

Figure 18.4: The Mandelstam plane $s+t+u = 2m^2$ shared by Compton scattering and pair annihilation, in the symmetric coordinates of Fig. 16.5 (with s increasing upward, t toward the lower right, u toward the lower left; units $m = 1$). One analytic amplitude $\mathcal{M}(s,t,u)$ lives on the whole plane. The blue wedges are the physical region of Compton scattering $e^-\gamma \to e^-\gamma$, Eq. (18.119), split into the s- and u-channel sub-wedges that describe the same reaction with the two photons interchanged. The orange wedge is the physical region of annihilation $e^+e^- \to \gamma\gamma$, Eq. (18.120); because $s_A = t_C$ it is the t-channel wedge, separated from the Compton region by the higher pair threshold $t = 4m^2$ and the boundary hyperbola $su = m^4$. The crossing $s \leftrightarrow t$ of Eq. (18.118) carries the amplitude from the blue s-wedge to the orange t-wedge.

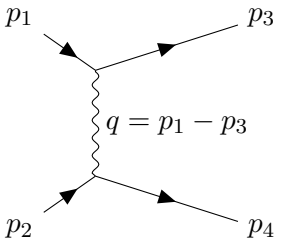
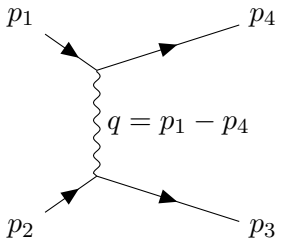
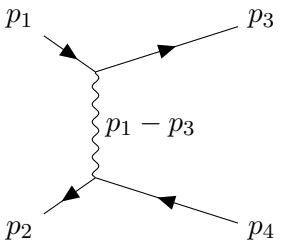


(a) t-channel

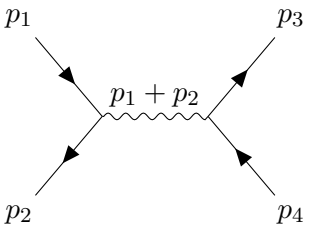


(b) u-channel

Figure 18.5: The two tree diagrams for Møller scattering $e^-e^- \to e^-e^-$. They are related by the exchange of the two identical outgoing electrons, $p_3 \leftrightarrow p_4$, which sends $t \leftrightarrow u$. Fermi statistics requires that they enter the amplitude with a relative minus sign, Eq. (18.155).



(a) t-channel (scattering)



(b) s-channel (annihilation)

Figure 18.6: The two tree diagrams for Bhabha scattering $e^+e^- \to e^+e^-$: t-channel photon exchange (scattering) and s-channel annihilation through a virtual photon. They enter with a relative minus sign, Eq. (18.177), and interfere in Eq. (18.182).

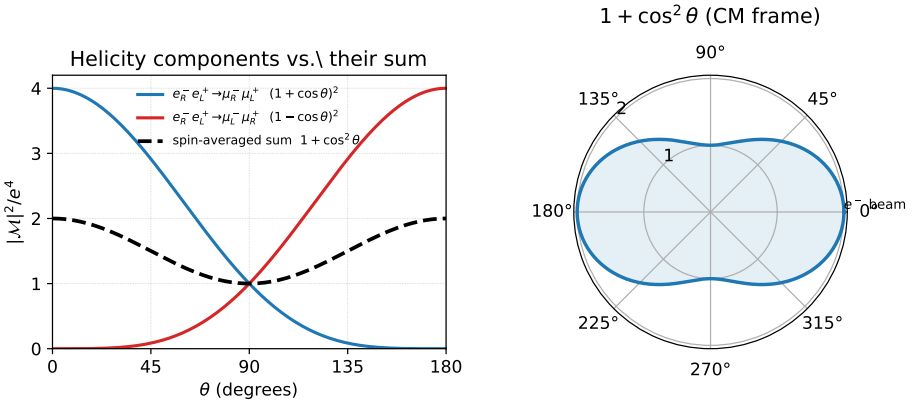


Figure 18.7: Helicity decomposition of $e^+e^- \to \mu^+\mu^-$ in the high-energy limit. *Left:* the two surviving angular shapes, the forward-peaked $(1+\cos\theta)^2$ (helicity-aligned, $\propto u^2$) and the backward-peaked $(1-\cos\theta)^2$ (anti-aligned, $\propto t^2$), each strongly forward–backward asymmetric, together with their spin-averaged sum $1+\cos^2\theta$. *Right:* the unpolarized $1+\cos^2\theta$ law as a centre-of-mass polar diagram; its forward–backward symmetry is the parity-even average of the asymmetric helicity components.

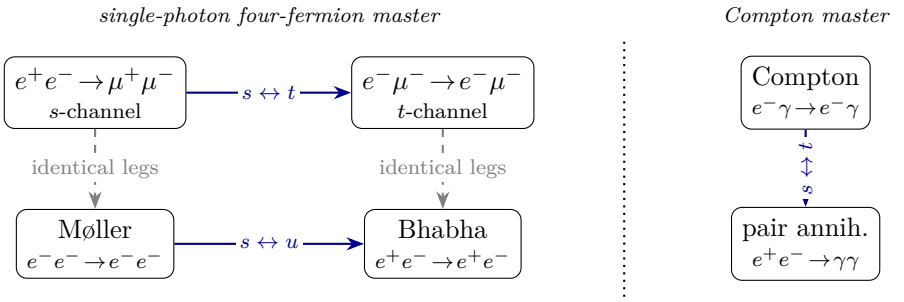

Figure 18.8: The tree-level QED crossing web. Solid arrows are crossing continuations (a permutation of the Mandelstam invariants, with the fermion-crossing sign); dashed arrows indicate that the identical-fermion processes are obtained by identifying two external lines and adding the Fermi-antisymmetrized exchange diagram. The two components correspond to the two master rational functions of Theorem 18.20.

Chapter 19

Radiative Corrections

With the tree-level QED amplitudes of Chapters 17 and 18 in hand — $e^+e^- \to \mu^+\mu^-$, Compton, Bhabha, and the tree Ward identity — we have computed every process the Feynman rules permit at leading order in e. This chapter takes the inevitable next step: the loop. At order e^2 beyond tree the theory confronts, for the first time, the ultraviolet infinities that nearly killed it in the 1930s, and the resolution of those infinities — renormalization — is the conceptual centre of the chapter. We work entirely at one loop and entirely with the carried QED thread, so that the famous numbers of Chapter 20 (the anomalous magnetic moment, the Lamb shift, the running coupling) emerge as bookkeeping on the finite remnants of computations done here.

There are exactly three one-particle-irreducible building blocks at one loop: the photon self-energy (vacuum polarization) $\Pi^{\mu\nu}(q)$, the electron self-energy $\Sigma(p)$, and the electron–photon vertex $\Gamma^{\mu}(p', p)$. The chapter computes all three from scratch, and the bulk of the labour is the loop-integral technology that makes them finite and meaningful. That technology — dimensional regularization in $d = 4-2\varepsilon$, Feynman parametrization, the Wick rotation, and the scalar master integrals — is built in the opening section and drawn in detail from Chapter D; the gamma-matrix trace identities the Dirac numerators require are those of Chapter C, and the mostly-minus metric, the covariant derivative $D_\mu = \partial_\mu - iqA_\mu$ with $q = -e$, and the propagator and vertex Feynman rules are the conventions fixed in Chapter A and Chapter 17. The branch-cut and dispersion structure we read off the vacuum polarization rests on the complex-analysis and Kramers–Kronig machinery reviewed in Section 5.5.5.

The arc is cumulative. Section 19.1 constructs the regulator and the renormalized-perturbation-theory framework, splitting the bare Lagrangian into a renormalized piece plus counterterms $\delta_1, \delta_2, \delta_3, \delta_m$ and fixing them by on-shell conditions. Section 19.2 computes $\Pi^{\mu\nu}$, finds it transverse exactly as gauge invariance demands, extracts Z_3 and the screening logarithm, and cross-checks its imaginary part against the optical theorem. Section 19.3 and Section 19.4 treat the electron

self-energy and the vertex, delivering δm, Z_2, Z_1, the Dirac form factor F_1, and — as the bridge to the next chapter — the Pauli form factor F_2. The empirical equality $Z_1 = Z_2$ that surfaces in the vertex computation is then elevated to a law in Section 19.5: the Ward–Takahashi identity, proved both from the generating functional and diagrammatically, which forces Π transverse, locks Σ to Γ^μ, and deposits the entire charge renormalization in the photon. The tree-level Ward identity and the covariant polarization sum it generalizes are imported from Chapter 18.

A single obstacle then remains between these renormalized loops and a physical number: the infrared divergence that survives in Z_2 and F_1. Section 19.6 confronts it, showing that the virtual divergence cancels against real soft-photon emission so that any sufficiently inclusive cross section is finite, and states the all-orders Bloch–Nordsieck, Kinoshita–Lee–Nauenberg, and Yennie–Frautschi–Suura results that organize this cancellation to every order. What this chapter does *not* do — the all-orders proof that the four counterterms suffice (renormalizability), the power counting that classifies divergences, and the renormalization-group flow that promotes the one-loop logarithm to a running coupling — is the subject of Chapters 21, 22 and 24; here those results are the organizing premise, and the one-loop input they will build on is exactly what we now compute.

19.1 Regularization and the One-Loop Program

At tree level the carried QED amplitudes of Chapters 17 and 18 were finite and algebraic: every diagram was a rational function of external momenta, gauge invariance was visible as the tree-level Ward identity $k_\mu \mathcal{M}^\mu = 0$ (Theorem 18.5), and the physical normalization of charge and mass was read straight off the Lagrangian. One loop changes the character of the problem. The moment a diagram contains a closed loop, the conservation of momentum at the vertices no longer fixes every internal line; one combination of internal momenta is unconstrained and must be integrated over all of momentum space. Those integrals generically diverge in the ultraviolet, and the divergence is not a calculational nuisance to be hidden but a structural feature that, handled correctly, turns QED from a tree-level caricature into a quantitative theory accurate to parts per billion. Handled incorrectly, it destroys the very gauge invariance that made the tree theory consistent.

This section builds the toolbox. It does three things, in order. First it names the three primitive one-particle-irreducible (1PI) objects out of which all of one-loop QED is assembled, and the diagrams that produce them. Then it confronts the divergences head-on and argues that the regulator must be chosen to respect gauge invariance — a hard momentum cutoff does not, dimensional regularization does — and constructs dimensional regularization in full: the loop measure in $d = 4 - 2\varepsilon$, the engineering dimension of the coupling and the renormalization

scale μ it forces upon us, the Feynman-parameter combination of denominators, the Wick rotation to Euclidean signature, and the scalar master integral to which every one-loop computation reduces. Finally it sets up renormalized perturbation theory: the split of the bare Lagrangian into a renormalized piece plus counterterms Z_1, Z_2, Z_3, δ_m, the counterterm Feynman rules, and the on-shell renormalization conditions that the next four sections will impose. The systematic all-orders justification of this machinery — power counting, the classification of divergences, the forest formula, the proof of renormalizability — is the business of Chapters 21 and 22; here we use those results only at the level of statements and concentrate on the explicit one-loop apparatus.

19.1.1 The three one-particle-irreducible building blocks

Recall from Chapter 15 the hierarchy connected $\to$ amputated $\to$ one-particle-irreducible: a 1PI diagram is one that cannot be severed into two by cutting a single internal line, and the full set of correlation functions is built by sewing 1PI blocks together with full propagators. At one loop in QED there are exactly three primitive 1PI amplitudes with ultraviolet divergences, one for each way of dressing the three ingredients of the theory — the photon, the electron, and their interaction. They are the objects the rest of the chapter computes.

The first is the *photon self-energy* or *vacuum polarization* $\Pi^{\mu\nu}(q)$, the 1PI two-point function of the photon. At one loop it is the single diagram in which a virtual electron–positron pair is created and annihilated, Fig. 19.1(a). With the QED vertex $-ie\gamma^\mu$ of Theorem 17.1 and the fermion propagator Eq. (17.15), the Feynman rules of Section 17.1 assign to it

$$i\Pi^{\mu\nu}(q) = -(-ie)^2 \int \frac{\mathrm{d}^d \ell}{(2\pi)^d}\, \mathrm{tr}\left[\gamma^\mu \, \frac{i(\not{\ell} + m)}{\ell^2 - m^2 + i\epsilon}\, \gamma^\nu \, \frac{i(\not{\ell} + \not{q} + m)}{(\ell+q)^2 - m^2 + i\epsilon}\right], \tag{19.1}$$

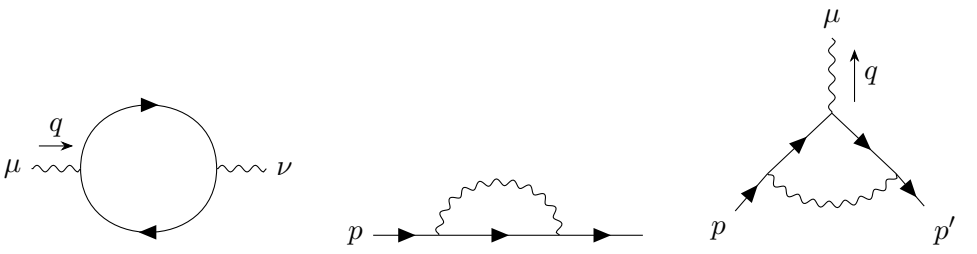
the overall minus sign being the closed-fermion-loop sign of Chapter 15 and the trace running over the Dirac indices that close around the loop. The second is the *electron self-energy* $\Sigma(p)$, the 1PI two-point function of the electron, Fig. 19.1(b): the electron emits and reabsorbs a virtual photon. With the photon propagator Eq. (17.18) in Feynman gauge,

$$-i\Sigma(p) = (-ie)^2 \int \frac{\mathrm{d}^d \ell}{(2\pi)^d}\, \gamma^\mu \, \frac{i(\not{p} - \not{\ell} + m)}{(p-\ell)^2 - m^2 + i\epsilon}\, \gamma^\nu \, \frac{-i\eta_{\mu\nu}}{\ell^2 + i\epsilon}. \tag{19.2}$$

The third is the *vertex correction* $\Gamma^\mu(p', p)$, the 1PI three-point function with one photon and two electron legs, Fig. 19.1(c). Writing the full amputated vertex as $-ie\,\Gamma^\mu(p',p)$ with $\Gamma^\mu = \gamma^\mu + \delta\Gamma^\mu$, the one-loop correction is

$$-ie\,\delta\Gamma^\mu(p',p) = (-ie)^3 \int \frac{\mathrm{d}^d \ell}{(2\pi)^d}\, \gamma^\alpha \, \frac{i(\not{p}' - \not{\ell} + m)}{(p'-\ell)^2 - m^2 + i\epsilon}\, \gamma^\mu \, \frac{i(\not{p} - \not{\ell} + m)}{(p-\ell)^2 - m^2 + i\epsilon}\, \gamma^\beta \, \frac{-i\eta_{\alpha\beta}}{\ell^2 + i\epsilon}. \tag{19.3}$$

Each of Eqs. (19.1) to (19.3) contains exactly one unconstrained loop momentum ℓ. Power-counting the integrands shows that $\Pi^{\mu\nu}$ is superficially quadratically divergent, Σ linearly divergent, and $\delta\Gamma^{\mu}$ logarithmically divergent — the systematic statement of which is the superficial degree of divergence developed in Chapter 21. Our immediate task is to give these integrals a precise, gauge-respecting meaning.



(a) $i\Pi^{\mu\nu}(q)$ (b) $-i\Sigma(p)$ (c) $-ie\,\delta\Gamma^{\mu}(p',p)$

Figure 19.1: The three primitive one-loop 1PI amplitudes of QED. (a) the photon self-energy / vacuum polarization Eq. (19.1), a fermion loop with two external photons; (b) the electron self-energy Eq. (19.2), an electron line emitting and reabsorbing a photon; (c) the vertex correction Eq. (19.3), the photon exchanged across the interaction vertex. All three carry a single unconstrained loop momentum and diverge in the ultraviolet; the Ward–Takahashi identity proved later in this chapter ties their divergences together.

19.1.2 Why a momentum cutoff fails and the regulator must be chosen

The most naive way to make sense of a divergent loop integral is to cut it off: integrate only over Euclidean loop momenta $|\ell_E| < \Lambda$ and study the dependence on Λ. For a scalar theory this is harmless. For a gauge theory it is a disaster, and the reason exposes exactly the property a good regulator must have.

Gauge invariance, through current conservation, constrains the photon self-energy to be *transverse*: the exact $\Pi^{\mu\nu}$ must take the form

$$\Pi^{\mu\nu}(q) = \left(q^2\eta^{\mu\nu} - q^{\mu}q^{\nu}\right)\Pi(q^2), \qquad q_{\mu}\Pi^{\mu\nu}(q) = 0. \tag{19.4}$$

This is the loop-level descendant of the tree Ward identity of Theorem 18.5; we prove it as part of the Ward–Takahashi identity later in the chapter, and it is verified by explicit computation in the next section. Its physical content is decisive: the only Lorentz-covariant rank-two tensor that *cannot* be written in the transverse form Eq. (19.4) is the one proportional to $\eta^{\mu\nu}$ with no factors of q, and that is precisely a photon mass term. Transversality is the statement that radiative corrections do not generate a photon mass; the photon stays massless to all orders. The superficial quadratic divergence of Eq. (19.1) is therefore not

allowed to survive as a $\Lambda^2\eta^{\mu\nu}$ contribution: gauge invariance forces the quadratic divergence to cancel, leaving only the logarithmic divergence carried by the transverse coefficient $\Pi(q^2)$.

The mechanism that enforces Eq. (19.4) in any honest manipulation of the loop integral is the freedom to shift the loop momentum, $\ell \to \ell + a$. Contracting q_μ into the integrand of Eq. (19.1) and using the Dirac algebra, one writes the result as a difference of two integrals related by exactly such a shift; if the shift is legal the difference vanishes and transversality follows. A hard cutoff breaks this: the region $|\ell_E| < \Lambda$ is not invariant under $\ell \to \ell + a$, so shifting the integration variable moves the boundary and leaves a surface term. That surface term is the spurious, non-transverse $\propto \Lambda^2\eta^{\mu\nu}$ photon mass. One would then be forced to add a non-gauge-invariant photon-mass counterterm, fine-tuned order by order to cancel it — abandoning the gauge symmetry that organizes the whole theory. The same disease afflicts a Pauli–Villars regulator for the gluon loops of Chapter 27 and, more subtly, any regulator that fails to preserve the symmetry whose Ward identity one needs.

Dimensional regularization, introduced by 't Hooft and Veltman [469] (and independently by Bollini and Giambiagi [84]), is built precisely to keep the shift legal. Because it introduces no dimensionful cutoff and no preferred frame, the analytically continued loop integral is exactly translation invariant, even when divergent. We isolate this as the property on which gauge invariance hinges.

Proposition 19.1 (Shift invariance of the dimensionally regularized measure)**.** *For any momentum a^μ and any integrand $f(\ell)$ to which the prescriptions below assign a finite value at generic non-integer d,*

$$\int \frac{\mathrm{d}^d\ell}{(2\pi)^d}\, f(\ell + a) = \int \frac{\mathrm{d}^d\ell}{(2\pi)^d}\, f(\ell). \tag{19.5}$$

Proof. For an integrand falling fast enough that the integral converges absolutely at the working d, Eq. (19.5) is the ordinary change of variables $\ell \to \ell - a$, with no boundary because there is no boundary. The content of the proposition is that it persists for the divergent integrands of QED once they are defined by analytic continuation in d. Expand $f(\ell + a) - f(\ell) = a^\mu\partial_\mu f(\ell) + \frac{1}{2}a^\mu a^\nu\partial_\mu\partial_\nu f(\ell) + \cdots$, a sum of total derivatives. Each term is the integral of a total derivative $\partial_\mu g(\ell)$. In dimensional regularization the integral of a total derivative vanishes: by Lorentz invariance $\int \mathrm{d}^d\ell\, \partial_\mu g$ is a vector built from no external momentum and so must be zero, and more concretely the radial part reduces to $\int_0^\infty \mathrm{d}\ell_E \frac{\mathrm{d}}{\mathrm{d}\ell_E}(\ell_E^{d-1}\tilde{g}(\ell_E))$, a boundary term $\ell_E^{d-1}\tilde{g}|_0^\infty$ that one continues from the strip of d in which it vanishes at both ends and which is therefore zero throughout by analytic continuation. (Equivalently, the difference of the two sides of Eq. (19.5) is a scaleless integral, and scaleless integrals vanish identically in dimensional regularization because their would-be ultraviolet and infrared poles cancel, as shown in Section D.7.2.)

Hence every term in the Taylor expansion integrates to zero and Eq. (19.5) holds. □

Theorem 19.1 is the conceptual payoff that justifies the regulator choice: with the shift legal, the Ward identity manipulations go through and $\Pi^{\mu\nu}$ comes out transverse automatically, with no fine-tuned photon-mass counterterm. We now construct the measure that makes Eq. (19.5) precise.

19.1.3 The loop measure in $d = 4 - 2\varepsilon$ dimensions

Dimensional regularization replaces the four-dimensional loop integral by its continuation to $d = 4 - 2\varepsilon$ complex dimensions. Concretely, one keeps the loop integrand — a rational function of Lorentz invariants $\ell^2, \ell \cdot q, \ldots$ built from the QED Feynman rules — and reinterprets the measure $\int \mathrm{d}^d\ell/(2\pi)^d$ for non-integer d. The only feature of the measure a one-loop integrand sees, after the angular integration, is the surface area of the unit sphere in d Euclidean dimensions,

$$\Omega_d = \frac{2\pi^{d/2}}{\Gamma(d/2)}, \tag{19.6}$$

which is manifestly an analytic function of d through the gamma function. A scalar integrand $f(\ell_E^2)$ then yields, after Wick rotation, $\Omega_d \int_0^\infty \mathrm{d}\ell_E\, \ell_E^{d-1} f(\ell_E^2)/(2\pi)^d$, and the radial integral converges in an open strip of d whenever f falls off at large ℓ_E and is integrable at the origin. Inside that strip the integral is a genuine, finite, analytic function of d; outside it the function is *defined* by analytic continuation. The ultraviolet and infrared divergences that plagued $d = 4$ do not disappear — they reappear as isolated *poles* of this analytic function. With the parametrization $d = 4 - 2\varepsilon$, a logarithmically ultraviolet-divergent integral develops a simple pole at $\varepsilon = 0$, and the residue is the coefficient of the would-be $\ln \Lambda$. The construction of Ω_d and the radial reduction are carried out in full in Section D.3; here we take them as established and exploit them.

Caution

Dimensional regularization regulates the ultraviolet and the infrared with the *same* parameter ε, but the two kinds of pole prefer opposite signs of ε: an ultraviolet pole is reached from $d < 4$ ($\varepsilon > 0$), an infrared pole from $d > 4$ ($\varepsilon < 0$). When both are present in one integral the bookkeeping must keep them distinct, since only the ultraviolet poles are removed by renormalization while the infrared ones are physical and cancel against real emission. The sign discipline and the proof that a scaleless integral vanishes through an exact cancellation of the two are given in Sections D.7.1 and D.7.2; we invoke that machinery when we reach the infrared section of this chapter.

Moving off $d = 4$ has an immediate consequence that we cannot avoid and that seeds the entire renormalization-group story of Chapter 24: the coupling is no longer dimensionless. In natural units the action is dimensionless, so the Lagrangian density has mass dimension d (because $\int \mathrm{d}^d x$ has dimension $-d$). Reading off the dimensions of the free kinetic terms $\bar{\psi}\, i\partial\!\!\!/\, \psi$ and $-\frac{1}{4} F_{\mu\nu}F^{\mu\nu}$ fixes

$$[\psi] = \frac{d-1}{2}, \qquad [A^\mu] = \frac{d-2}{2}, \qquad [\partial_\mu] = 1. \tag{19.7}$$

The interaction term $e\,\bar{\psi} A\!\!\!/\, \psi$ must also have dimension d, so

$$[e] = d - 2[\psi] - [A] = d - (d-1) - \frac{d-2}{2} = \frac{4-d}{2} = \varepsilon. \tag{19.8}$$

In exactly four dimensions $[e] = 0$ and the coupling is dimensionless, as it must be for a renormalizable theory. Away from four dimensions e carries mass dimension ε. To keep the coupling that appears in expansions dimensionless — so that $\alpha = e^2/4\pi$ remains a pure number and the perturbation series is an expansion in a number — we factor out the dimension with an arbitrary mass scale μ, the *renormalization scale*:

$$e_{(\dim\, \varepsilon)} \longrightarrow e\,\mu^{\varepsilon}, \qquad e \text{ dimensionless}, \qquad \alpha = \frac{e^2}{4\pi}. \tag{19.9}$$

Every QED vertex thus carries an explicit μ^{ε}, and an L-loop diagram carries $\mu^{2L\varepsilon}$ from its $2L$ powers of e^2 relative to tree level; equivalently each loop integral is accompanied by one factor $\mu^{2\varepsilon}$, the bookkeeping factor that appears throughout Chapter D. The scale μ is pure artifact at this stage — nothing physical can depend on it — but the requirement that physics be μ-independent is exactly the Callan–Symanzik equation, and the running of α it generates is the subject of Chapters 20 and 24. Its first appearance is here.

19.1.4 Combining denominators: the Feynman parametrization

Each loop integral Eqs. (19.1) to (19.3) is a ratio of polynomials in ℓ over a product of two or three quadratic denominators with different momentum offsets. The integral over a single quadratic denominator is doable; over a product it is not, because there is no single variable in which to complete the square. The Feynman parametrization rewrites the product as a single denominator at the cost of an integral over auxiliary parameters, after which one shift completes the square. We derive the two cases QED needs — two and three denominators — carrying the algebra; the general N-denominator statement and the Schwinger-representation route to it are in Theorem D.11.

Proposition 19.2 (Two- and three-denominator parametrizations)**.** *For nonzero A, B, C (with the Feynman $i\epsilon$ keeping the combined denominator off the real*

axis),

$$\frac{1}{AB} = \int_0^1 \mathrm{d}x \, \frac{1}{\big[xA + (1-x)B\big]^2}, \tag{19.10}$$

$$\frac{1}{ABC} = 2\int_0^1 \mathrm{d}x\,\mathrm{d}y\,\mathrm{d}z\;\delta(x+y+z-1)\,\frac{1}{\big[xA+yB+zC\big]^3}. \tag{19.11}$$

Proof. For Eq. (19.10), write the bracket as $B + x(A-B)$ and integrate directly in x, treating $A \neq B$:

$$\int_0^1 \mathrm{d}x \, \frac{1}{[B+x(A-B)]^2} = \left[\frac{-1}{(A-B)}\,\frac{1}{B+x(A-B)}\right]_0^1 = \frac{-1}{A-B}\left(\frac{1}{A}-\frac{1}{B}\right) = \frac{-1}{A-B}\cdot\frac{B-A}{AB} = \frac{1}{AB}$$

and the case $A = B$ follows by continuity. To reach Eq. (19.11) we first need the parametrization with a squared denominator, which we obtain by differentiating Eq. (19.10). Hold C fixed in $1/(FC) = \int_0^1 \mathrm{d}y\,[\,yF + (1-y)C\,]^{-2}$ and differentiate with respect to F:

$$\frac{\partial}{\partial F}\frac{1}{FC} = -\frac{1}{F^2 C}, \qquad \frac{\partial}{\partial F}\int_0^1 \mathrm{d}y\,\frac{1}{[yF+(1-y)C]^2} = -2\int_0^1 \mathrm{d}y\,\frac{y}{[yF+(1-y)C]^3},$$

where $\partial(yF + (1-y)C)/\partial F = y$. Equating gives

$$\frac{1}{F^2 C} = 2\int_0^1 \mathrm{d}y\,\frac{y}{[yF+(1-y)C]^3}. \tag{19.12}$$

Now set $F = xA + (1-x)B$, so that by Eq. (19.10) $1/(ABC) = \int_0^1 \mathrm{d}x\,(F^2 C)^{-1}$, and substitute Eq. (19.12):

$$\frac{1}{ABC} = 2\int_0^1 \mathrm{d}x \int_0^1 \mathrm{d}y\,\frac{y}{\big[\,y(xA+(1-x)B)+(1-y)C\,\big]^3} = 2\int_0^1 \mathrm{d}x \int_0^1 \mathrm{d}y\,\frac{y}{\big[\,yx\,A + y(1-x)B + (1-y)C\,\big]^3}.$$

Change variables to $u = yx$, $v = y(1-x)$, with $w \equiv 1-u-v = 1-y$. The Jacobian is

$$\frac{\partial(u,v)}{\partial(x,y)} = \det\begin{pmatrix} y & x \\ -y & 1-x \end{pmatrix} = y(1-x) + xy = y,$$

so $\mathrm{d}u\,\mathrm{d}v = y\,\mathrm{d}x\,\mathrm{d}y$ and the explicit weight y in the numerator is absorbed exactly. As (x,y) range over the unit square, (u,v) range over the triangle $u, v \geq 0$, $u+v \leq 1$. Reinstating the third parameter through $\int \mathrm{d}w\,\delta(u+v+w-1)$ symmetrizes the result:

$$\frac{1}{ABC} = 2\int \mathrm{d}u\,\mathrm{d}v\,\mathrm{d}w\;\delta(u+v+w-1)\,\frac{1}{[uA+vB+wC]^3},$$

which is Eq. (19.11) after renaming $(u,v,w) \to (x,y,z)$. The prefactor $2 = 2! = \Gamma(3)$ is the $N = 3$ case of the general $\Gamma(N)$ of Theorem D.11. □

The point of the parametrization is what it does to the loop integral. After it, the denominator is a single quadratic in ℓ raised to an integer power. Completing the square — shifting ℓ by a parameter-dependent combination of external momenta, which is legal by Theorem 19.1 — removes the linear term and turns every denominator into $(\ell^2 - \Delta + i\epsilon)^n$, where Δ is a function of the Feynman parameters and the external invariants, independent of ℓ. For two propagators with offsets 0 and q and masses m_1, m_2, for instance,

$$x(\ell^2-m_1^2)+(1-x)((\ell+q)^2-m_2^2) = (\ell+(1-x)q)^2-\Delta, \qquad \Delta = -x(1-x)q^2+xm_1^2+(1-x)m_2^2, \tag{19.13}$$

as one checks by expanding both sides and cancelling the linear-in-ℓ term $2(1-x)\,\ell\cdot q$ against the shift. The numerator algebra — the gamma-matrix traces, evaluated with the d-dimensional Clifford and trace identities of Sections C.6 and C.7 — is carried out after the shift, expressed in the shifted variable, and reduced by the symmetric-integration rule of the next subsection. Everything then rests on a single scalar integral.

19.1.5 Wick rotation and the scalar master integral

After parametrization and the shift, every one-loop QED integral is a linear combination of integrals of the form

$$I_n(\Delta) = \int \frac{\mathrm{d}^d\ell}{(2\pi)^d}\,\frac{1}{(\ell^2 - \Delta + i\epsilon)^n}, \tag{19.14}$$

possibly with extra factors of ℓ^μ in the numerator (handled below). The Minkowski integral Eq. (19.14) is evaluated by rotating the ℓ^0 contour onto the imaginary axis. The legality of this rotation is exactly the contour-deformation argument of Sections 5.3 and 5.4: the Feynman $i\epsilon$ places the poles of the integrand in ℓ^0, at $\ell^0 = \pm(\sqrt{\boldsymbol{\ell}^2 + \Delta} - i\epsilon)$, in the second and fourth quadrants of the complex ℓ^0-plane, leaving the first and third quadrants free, so the contour may be swung counterclockwise from the real axis to the imaginary axis without crossing a singularity and with vanishing arcs at infinity. Writing $\ell^0 = i\ell_E^0$ with ℓ_E^0 real, the rotation gives $\ell^2 = (\ell^0)^2 - \boldsymbol{\ell}^2 = -(\ell_E^0)^2 - \boldsymbol{\ell}^2 \equiv -\ell_E^2$ (a Euclidean square) and $\mathrm{d}^d\ell = i\,\mathrm{d}^d\ell_E$, so

$$I_n(\Delta) = i\,(-1)^n \int \frac{\mathrm{d}^d\ell_E}{(2\pi)^d}\,\frac{1}{(\ell_E^2 + \Delta)^n}. \tag{19.15}$$

The Euclidean integral is rotationally invariant, so the angular integral gives Ω_d of Eq. (19.6) and only the radial integral remains:

$$\int \frac{\mathrm{d}^d\ell_E}{(2\pi)^d}\,\frac{1}{(\ell_E^2 + \Delta)^n} = \frac{\Omega_d}{(2\pi)^d}\int_0^\infty \mathrm{d}\ell_E\,\frac{\ell_E^{d-1}}{(\ell_E^2 + \Delta)^n}.$$

Substitute $t = \ell_E^2/\Delta$, so $\ell_E = (\Delta t)^{1/2}$ and $\mathrm{d}\ell_E = \tfrac{1}{2}\Delta^{1/2} t^{-1/2}\mathrm{d}t$, turning the radial integral into an Euler Beta function:

$$\int_0^\infty \mathrm{d}\ell_E \, \frac{\ell_E^{d-1}}{(\ell_E^2+\Delta)^n} = \frac{1}{2}\,\Delta^{\frac{d}{2}-n}\int_0^\infty \mathrm{d}t\,\frac{t^{\frac{d}{2}-1}}{(1+t)^n} = \frac{1}{2}\,\Delta^{\frac{d}{2}-n}\,\frac{\Gamma\!\left(\frac{d}{2}\right)\Gamma\!\left(n-\frac{d}{2}\right)}{\Gamma(n)}, \tag{19.16}$$

where we used the standard Beta-integral $\int_0^\infty t^{a-1}(1+t)^{-(a+b)}\,\mathrm{d}t = \Gamma(a)\Gamma(b)/\Gamma(a+b)$ with $a = d/2$, $b = n - d/2$ (derived as part of the gamma-function technology of Section D.5). Collecting Eqs. (19.6), (19.15) and (19.16) and cancelling the $\Gamma(d/2)$ between Ω_d and the Beta function gives the scalar master integral:

$$\boxed{\int \frac{\mathrm{d}^d\ell}{(2\pi)^d}\,\frac{1}{(\ell^2-\Delta+i\epsilon)^n} = \frac{(-1)^n\, i}{(4\pi)^{d/2}}\,\frac{\Gamma\!\left(n-\frac{d}{2}\right)}{\Gamma(n)}\,\left(\frac{1}{\Delta}\right)^{n-\frac{d}{2}}.} \tag{19.17}$$

All of the ultraviolet behaviour now lives in the single gamma function $\Gamma(n-d/2)$: with $d = 4-2\varepsilon$, the argument is $n-2+\varepsilon$, and Γ has simple poles at non-positive integers, so $\Gamma(n-d/2)$ is singular as $\varepsilon \to 0$ precisely when $n \le 2$ — exactly the logarithmically-or-worse divergent cases. The case the QED self-energies and vertex reduce to after their tensor structure is stripped is $n = 2$, where $\Gamma(2-d/2) = \Gamma(\varepsilon) = 1/\varepsilon - \gamma_{\mathrm{E}} + O(\varepsilon)$. Restoring the $\mu^{2\varepsilon}$ of Eq. (19.9) and expanding (the gamma-function expansions being tabulated in Section D.5), this is exactly the renormalization-scale-dressed master of Eq. (D.136),

$$\mu^{2\varepsilon}\int \frac{\mathrm{d}^d\ell}{(2\pi)^d}\,\frac{1}{(\ell^2-\Delta+i\epsilon)^2} = \frac{i}{(4\pi)^2}\left[\frac{1}{\bar{\varepsilon}} + \ln\frac{\mu^2}{\Delta}\right] + O(\varepsilon), \qquad \frac{1}{\bar{\varepsilon}} \equiv \frac{1}{\varepsilon} - \gamma_{\mathrm{E}} + \ln 4\pi, \tag{19.18}$$

in which the divergence is an isolated, kinematics-independent $1/\bar{\varepsilon}$ pole and the entire finite, Δ-dependent content is the logarithm $\ln(\mu^2/\Delta)$. That clean separation — a universal pole that a local counterterm can absorb, plus a finite log that carries all the physics — is the structural fact Theorem D.31 attributes to locality, and it is what makes renormalization possible. We import Eq. (19.18) as the workhorse for the explicit computations to come, having derived the reduction to gamma functions Eq. (19.17) in full and quoted only the ε-expansion of $\Gamma(\varepsilon)$ from the appendix.

Numerators carrying loop momenta are handled by the same machinery once one notices that the shifted integrand is even in ℓ up to terms that integrate to zero. The next worked example establishes the rule and exhibits it on the tensor integral that appears in every one-loop QED computation.

Worked Example 19.3 (Symmetric integration and a representative tensor integral)**.** After completing the square, numerators contain factors of the shifted loop momentum such as $\ell^\mu \ell^\nu$. By Lorentz invariance, an integral that depends on ℓ only through ℓ^2 in its denominator can return only tensors built from the invariant tensor $\eta^{\mu\nu}$ (there is no external vector left after the shift), so an odd

number of ℓ's integrates to zero and an even number must be proportional to the symmetric tensor:

$$\int \frac{\mathrm{d}^d\ell}{(2\pi)^d}\,\frac{\ell^\mu}{(\ell^2-\Delta)^n}=0, \qquad \int \frac{\mathrm{d}^d\ell}{(2\pi)^d}\,\frac{\ell^\mu\ell^\nu}{(\ell^2-\Delta)^n}=\frac{\eta^{\mu\nu}}{d}\int \frac{\mathrm{d}^d\ell}{(2\pi)^d}\,\frac{\ell^2}{(\ell^2-\Delta)^n}. \tag{19.19}$$

The first identity holds because the integrand is odd under $\ell\to-\ell$, a symmetry of the (shift-invariant, Theorem 19.1) measure. The coefficient of $\eta^{\mu\nu}$ in the second is fixed by contracting both sides with $\eta_{\mu\nu}$: the left side becomes $\int \ell^2/(\ell^2-\Delta)^n$, the right side becomes $(\eta^\mu{}_\mu/d)\int \ell^2/(\ell^2-\Delta)^n = (d/d)\int \ell^2/(\ell^2-\Delta)^n$, using $\eta^\mu{}_\mu = d$ (Eq. (C.185)), so the two agree and the coefficient is $1/d$. The factor $1/d$, not $1/4$, is essential: multiplied against a $1/\varepsilon$ pole it shifts finite parts, exactly as the d-dependent gamma contractions of Section C.7 do.

To evaluate the right-hand side, write $\ell^2=(\ell^2-\Delta)+\Delta$ in the numerator, splitting it into two masters of the form Eq. (19.17):

$$\int \frac{\mathrm{d}^d\ell}{(2\pi)^d}\,\frac{\ell^2}{(\ell^2-\Delta)^n}=\int \frac{\mathrm{d}^d\ell}{(2\pi)^d}\,\frac{1}{(\ell^2-\Delta)^{n-1}}+\Delta\int \frac{\mathrm{d}^d\ell}{(2\pi)^d}\,\frac{1}{(\ell^2-\Delta)^n}.$$

Inserting Eq. (19.17) for each piece and using $\Gamma(z+1)=z\,\Gamma(z)$ to combine them,

$$\begin{aligned}\int \frac{\mathrm{d}^d\ell}{(2\pi)^d}\,\frac{\ell^2}{(\ell^2-\Delta)^n} &= \frac{(-1)^{n-1}i}{(4\pi)^{d/2}}\,\frac{\Gamma(n-1-\frac{d}{2})}{\Gamma(n-1)}\,\Delta^{\frac{d}{2}-n+1}+\Delta\,\frac{(-1)^n i}{(4\pi)^{d/2}}\,\frac{\Gamma(n-\frac{d}{2})}{\Gamma(n)}\,\Delta^{\frac{d}{2}-n}\\ &= \frac{(-1)^{n-1}i}{(4\pi)^{d/2}}\,\Delta^{\frac{d}{2}-n+1}\,\frac{1}{\Gamma(n)}\Big[(n-1)\,\Gamma(n-1-\tfrac{d}{2})-\Gamma(n-\tfrac{d}{2})\Big]\\ &= \frac{(-1)^{n-1}i}{(4\pi)^{d/2}}\,\frac{d}{2}\,\frac{\Gamma(n-1-\frac{d}{2})}{\Gamma(n)}\,\Delta^{\frac{d}{2}-n+1},\end{aligned} \tag{19.20}$$

where in the last step we used $\Gamma(n-\frac{d}{2})=(n-1-\frac{d}{2})\Gamma(n-1-\frac{d}{2})$ so that the bracket collapses to $[(n-1)-(n-1-\frac{d}{2})]\,\Gamma(n-1-\frac{d}{2})=\frac{d}{2}\,\Gamma(n-1-\frac{d}{2})$. Combining Eq. (19.20) with Eq. (19.19) gives the tensor master

$$\int \frac{\mathrm{d}^d\ell}{(2\pi)^d}\,\frac{\ell^\mu\ell^\nu}{(\ell^2-\Delta)^n}=\frac{(-1)^{n-1}i}{(4\pi)^{d/2}}\,\frac{\eta^{\mu\nu}}{2}\,\frac{\Gamma(n-1-\frac{d}{2})}{\Gamma(n)}\,\Delta^{\frac{d}{2}-n+1}, \tag{19.21}$$

the factor $d/2$ from Eq. (19.20) having cancelled the $1/d$ from Eq. (19.19). With Eqs. (19.17) and (19.21) every scalar and rank-two tensor one-loop integral of QED is reduced to gamma functions; higher-rank numerators reduce the same way, and the systematic algorithm for arbitrary tensor integrals is the Passarino–Veltman reduction of Section D.6.

19.1.6 Renormalized perturbation theory and the counterterms

We can now regulate any one-loop QED amplitude and extract its $1/\varepsilon$ pole and finite part. What remains is the framework that converts those poles into finite

predictions: renormalized perturbation theory. The idea is to recognize that the parameters in the Lagrangian written down at tree level are not the physically measured charge and mass. We rename them *bare* parameters and fields, and re-express the Lagrangian in terms of *renormalized* quantities — the ones tied to measurements — plus correction terms, the *counterterms*, whose job is to cancel the loop divergences order by order.

Begin from the bare QED Lagrangian, the carried QED model of Section 17.1 with every quantity given a subscript 0:

$$\mathcal{L} = \bar{\psi}_0(i\not{\partial} - m_0)\psi_0 - e_0\,\bar{\psi}_0 \not{A}_0\,\psi_0 - \tfrac{1}{4}F_{0\,\mu\nu}F_0^{\mu\nu} - \frac{1}{2\xi_0}(\partial_\mu A_0^\mu)^2, \tag{19.22}$$

with covariant derivative $D_\mu = \partial_\mu + ie_0 A_{0\mu}$ acting on the electron of charge $-e$ (the standing sign convention). The bare fields and parameters are related to renormalized ones by multiplicative renormalization constants,

$$\psi_0 = Z_2^{1/2}\,\psi, \qquad A_0^\mu = Z_3^{1/2}\,A^\mu, \qquad Z_2\,m_0 = m + \delta_m, \qquad e_0\,Z_2\,Z_3^{1/2} = Z_1\,e\,\mu^\varepsilon, \tag{19.23}$$

which define the electron field-strength renormalization Z_2, the photon field-strength renormalization Z_3, the mass shift δ_m, and the vertex renormalization Z_1. Solving the last relation for the bare coupling exhibits how the measured charge is dressed,

$$e_0 = Z_1\,Z_2^{-1}\,Z_3^{-1/2}\,\mu^\varepsilon\,e, \tag{19.24}$$

and previews the one relation that makes QED so economical: the Ward–Takahashi identity proved later in this chapter forces $Z_1 = Z_2$, so the field and vertex renormalizations cancel and $e_0 = Z_3^{-1/2}\mu^\varepsilon e$ depends only on the photon. This is why charge renormalization in QED is governed entirely by vacuum polarization and why the running of α is universal — a fact Chapters 20 and 24 exploit. Substituting Eq. (19.23) into Eq. (19.22) and writing $Z_i = 1 + \delta_i$ splits the Lagrangian cleanly into a renormalized piece of the same form as the tree Lagrangian, now in renormalized fields and parameters, plus counterterms:

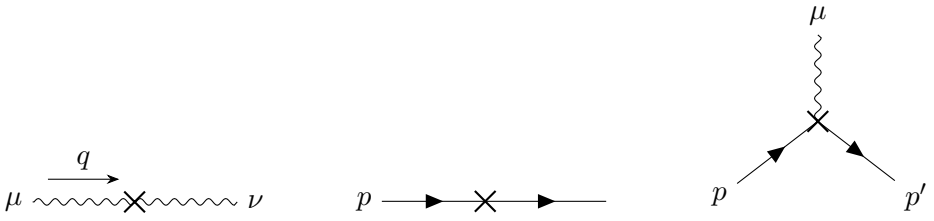
$$\begin{aligned}\mathcal{L} = &\underbrace{\bar{\psi}(i\not{\partial} - m)\psi - \tfrac{1}{4}F_{\mu\nu}F^{\mu\nu} - \frac{1}{2\xi}(\partial_\mu A^\mu)^2 - e\mu^\varepsilon\,\bar{\psi}\not{A}\,\psi}_{\text{renormalized}} \\ &+ \underbrace{\bar{\psi}(i\,\delta_2\not{\partial} - \delta_m)\psi - \tfrac{1}{4}\,\delta_3\,F_{\mu\nu}F^{\mu\nu} - e\mu^\varepsilon\,\delta_1\,\bar{\psi}\not{A}\,\psi}_{\text{counterterms}},\end{aligned} \tag{19.25}$$

where $\delta_2 = Z_2 - 1$, $\delta_3 = Z_3 - 1$, $\delta_1 = Z_1 - 1$, and $\delta_m = Z_2 m_0 - m$. The gauge-fixing term is not renormalized at one loop in this scheme (the longitudinal photon does not interact), so ξ carries no counterterm here. The renormalized piece generates exactly the QED Feynman rules of Chapter 17 with $e \to e\mu^\varepsilon$, and the counterterm piece generates three new vertices, read off as the momentum-space versions of the quadratic and cubic operators in the second line, shown in

Fig. 19.2:

photon 2-point: $i(\delta_3(q^2\eta^{\mu\nu}-q^\mu q^\nu))$; electron 2-point: $i(\delta_2 \not{p}-\delta_m)$; vertex: $-ie\mu^\varepsilon\,\delta_1\,\gamma^\mu$. (19.26)

The photon counterterm comes out transverse, $\propto (q^2\eta^{\mu\nu} - q^\mu q^\nu)$, because it descends from the gauge-invariant operator $F_{\mu\nu}F^{\mu\nu}$; it is structurally incapable of supplying a photon mass, which is the Lagrangian-level reason the cutoff's spurious $\Lambda^2\eta^{\mu\nu}$ of Section 19.1.2 could never be a legitimate counterterm. The counterterms enter at the same order in e as the one-loop diagrams (each $\delta_i = O(\alpha)$), so that at $O(\alpha)$ the renormalized 1PI functions are the sum of the loop of Fig. 19.1 and the counterterm of Fig. 19.2.



(a) $i\delta_3(q^2\eta^{\mu\nu} - q^\mu q^\nu)$ (b) $i(\delta_2\not{p} - \delta_m)$ (c) $-ie\mu^\varepsilon\delta_1\gamma^\mu$

Figure 19.2: The counterterm Feynman rules Eq. (19.26) from the second line of Eq. (19.25), drawn with a crossed vertex. Each enters at $O(\alpha)$ and cancels the divergence of the corresponding one-loop 1PI diagram of Fig. 19.1; the photon counterterm (a) is transverse by construction and so cannot generate a photon mass.

The four constants $\delta_1, \delta_2, \delta_3, \delta_m$ are fixed by four *renormalization conditions* — definitions that tie the renormalized parameters to physical quantities. This chapter adopts the *on-shell scheme*, in which the conditions are imposed at the physical pole of each propagator, so that m is the physical electron mass, e the charge measured at large distance (Thomson limit), and the fields normalized to unit residue at their poles. The conditions, to be imposed when the explicit computations are in hand, are:

Definition 19.4 (On-shell renormalization conditions)**.** Let $\Pi(q^2)$ be the scalar in the transverse decomposition Eq. (19.4) of the renormalized photon self-energy, $\Sigma(p)$ the renormalized electron self-energy, and $\Gamma^\mu(p', p)$ the renormalized amputated vertex. The on-shell scheme demands

$$\Pi(q^2 = 0) = 0 \qquad \text{(photon pole at } q^2 = 0\text{, unit} \tag{19.27}$$

$$\Sigma(\not{p})\big|_{\not{p}=m} = 0, \qquad \frac{\mathrm{d}\Sigma}{\mathrm{d}\not{p}}\bigg|_{\not{p}=m} = 0 \qquad \text{(electron pole at } \not{p} = m\text{, un} \tag{19.28}$$

$$\bar{u}(p)\,\Gamma^{\mu}(p,p)\,u(p) = \bar{u}(p)\,\gamma^{\mu}\,u(p) \quad \text{at } q = p' - p = 0 \quad \text{(vertex normalized to } -ie\gamma^{\mu}\text{)}. \tag{19.29}$$

The first condition fixes δ_3: it states that the full photon propagator still has its pole at $q^2 = 0$ (the photon stays massless) with residue one, so the photon field is canonically normalized. The two electron conditions fix δ_m and δ_2: the first places the pole of the full electron propagator at the physical mass m, the second normalizes its residue to one. The vertex condition fixes δ_1: at zero momentum transfer, between on-shell spinors, the full vertex must reduce to the tree value $-ie\gamma^{\mu}$, which is the statement that e is the physically measured charge. These four conditions are not independent of gauge invariance: the equality $Z_1 = Z_2$ forced by the Ward–Takahashi identity makes the vertex condition Eq. (19.29) a consequence of the electron-field condition Eq. (19.28), so the residue of the electron propagator and the normalization of the charge are locked together — the deep reason the on-shell charge is universal and not contaminated by the electron's self-interaction. We will see this happen explicitly. The all-orders statement that this finite set of counterterms suffices to render *every* amplitude finite — that QED is renormalizable — together with the power counting that identifies the divergent amplitudes in the first place, is established in Chapters 21 and 22; here it is the organizing premise.

With the regulator constructed — the d-dimensional measure Eq. (19.6), the shift invariance Theorem 19.1 that protects gauge invariance, the coupling's scale μ of Eq. (19.9), the Feynman parametrization Theorem 19.2, and the scalar and tensor master integrals Eqs. (19.17) and (19.21) feeding the $\overline{\text{MS}}$ master Eq. (19.18) — and with the counterterm framework Eq. (19.25) and on-shell conditions Theorem 19.4 in place, every one-loop QED computation is now a finite, well-posed problem. The next section applies the entire apparatus to the first and most instructive of the three building blocks, the photon self-energy $\Pi^{\mu\nu}(q)$ of Eq. (19.1): we compute it in dimensional regularization, verify that it comes out transverse exactly as Theorem 19.1 promised, renormalize it on shell to fix Z_3, and read off the analytic structure that drives charge screening and the running coupling.

19.2 Vacuum Polarization

The previous section built the only regulator that respects the gauge symmetry of QED — dimensional continuation to $d = 4 - 2\varepsilon$, with $\overline{\text{MS}}$ scale μ and the renormalized-perturbation-theory bookkeeping of counterterms and on-shell conditions (Section 19.1). It also recorded an expectation we now have to make good on. At tree level the Ward identity $k_\mu \mathcal{M}^{\mu} = 0$ (Theorem 18.5) said that the photon couples only to a conserved current, and that statement forced the longitudinal part of every photon line to decouple from physics. The first quantum correction to the photon's own propagation must inherit this

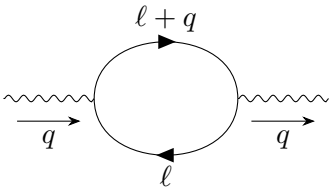


Figure 19.3: The one-loop photon self-energy (vacuum polarization). A photon of momentum q fluctuates into a virtual electron–positron pair, the two fermion propagators carrying loop momenta ℓ and $\ell + q$, before the pair annihilates back into a photon. The closed fermion loop supplies an overall minus sign and a Dirac trace. This is the only 1PI correction to the photon propagator at $O(e^2)$.

discipline: whatever the loop produces, it cannot generate a piece that an external photon's longitudinal polarization could detect, on pain of contradicting current conservation. Translated into the language of the photon two-point function, the requirement is *transversality* — the corrected inverse propagator must vanish when contracted with q^μ. We will compute the one-loop correction in full, watch transversality emerge from the algebra (not be imposed by hand), see exactly how it disposes of a divergence that naïvely looks quadratic, and read off from the finite remainder the first piece of running physics in the book: the dependence of the effective electric charge on the momentum at which it is probed.

The object of study is the photon self-energy, the sum of all one-particle-irreducible (1PI, Theorem 15.30) insertions on a photon line with the two external propagators amputated. We write it $i\Pi^{\mu\nu}(q)$, with q the photon momentum flowing through. At one loop in QED there is exactly one diagram: the photon converts to a virtual electron–positron pair which annihilates back to a photon, the fermion loop of Fig. 19.3. It is the first genuinely interacting two-point function of QED, and the whole of Chapter 20 — the running of α, the Uehling part of the Lamb shift, the hadronic blob in $g-2$ — is a reading of the function we are about to compute.

19.2.1 The amplitude and the fermion-loop sign

Reading the diagram with the QED Feynman rules established for QED — the vertex $-ie\gamma^\mu$ of Theorem 17.1 (recall the covariant derivative $D_\mu = \partial_\mu + ieA_\mu$ acts on the electron of charge $-e$, $e > 0$) and the fermion propagator $i(\not{\ell} + m)/(\ell^2 - m^2 + i\epsilon)$ of Eq. (17.15) — the loop assembles into

$$i\Pi^{\mu\nu}(q) = -(-ie)^2 \int \frac{\mathrm{d}^d \ell}{(2\pi)^d}\, \mathrm{tr}\left[\gamma^\mu \frac{i(\not{\ell} + m)}{\ell^2 - m^2 + i\epsilon}\, \gamma^\nu \frac{i(\not{\ell} + \not{q} + m)}{(\ell+q)^2 - m^2 + i\epsilon}\right]. \quad (19.30)$$

Three features deserve naming. The trace is over the Dirac indices: the two propagator numerators and the two vertices form a closed matrix chain along the fermion line, and a closed line is traced. The integral is over the single unconstrained loop momentum ℓ, the hallmark of a loop — momentum conservation at the two vertices fixes the difference of the two fermion momenta to be q but leaves ℓ free, and it is precisely this unrestricted integration that can diverge. And the overall sign is the celebrated minus sign of a closed fermion loop: it descends from the anticommuting nature of the fermion fields, where reordering the Grassmann operators to form the trace produces a single transposition relative to the bosonic case. We carry it explicitly as the prefactor $-(-ie)^2 = -(-e^2) = +e^2$; combined with the two factors of i from the propagators, $i^2 = -1$, the kinematic prefactor of the integral is $-e^2$.

Pulling the constants out and combining the two propagator denominators into the single product $\mathcal{D} \equiv (\ell^2 - m^2 + i\epsilon)\,[(\ell+q)^2 - m^2 + i\epsilon]$,

$$i\Pi^{\mu\nu}(q) = -e^2 \int \frac{\mathrm{d}^d \ell}{(2\pi)^d} \frac{N^{\mu\nu}(\ell, q)}{\mathcal{D}}, \qquad N^{\mu\nu}(\ell, q) \equiv \mathrm{tr}\big[\gamma^\mu (\not{\ell} + m)\gamma^\nu (\not{\ell} + \not{q} + m)\big]. \tag{19.31}$$

We compute the numerator trace first, then dispose of the loop integral.

19.2.2 The Dirac trace

Expanding the product inside $N^{\mu\nu}$ generates four terms; the two with an odd number of gamma matrices vanish by Eq. (C.197), leaving the $\not{\ell}\,(\not{\ell} + \not{q})$ term and the m^2 term. Using the four-gamma trace Eq. (C.199) for the first and the two-gamma trace Eq. (C.198) for the second, both unchanged in form in d dimensions because their derivation never used the integer value of $\eta^\mu{}_\mu$ inside the trace (Section C.7.3),

$$\begin{aligned} \mathrm{tr}\big[\gamma^\mu \not{\ell}\, \gamma^\nu (\not{\ell} + \not{q})\big] &= \ell_\alpha (\ell+q)_\beta \,\mathrm{tr}\big[\gamma^\mu \gamma^\alpha \gamma^\nu \gamma^\beta\big] = 4\,\ell_\alpha (\ell+q)_\beta \big(\eta^{\mu\alpha}\eta^{\nu\beta} - \eta^{\mu\nu}\eta^{\alpha\beta} + \eta^{\mu\beta}\eta^{\nu\alpha}\big) \\ &= 4\big[\ell^\mu (\ell+q)^\nu + \ell^\nu (\ell+q)^\mu - \eta^{\mu\nu}\, \ell\cdot(\ell+q)\big], \qquad (19.32) \\ m^2\,\mathrm{tr}\big[\gamma^\mu \gamma^\nu\big] &= 4\, m^2\, \eta^{\mu\nu}. \qquad (19.33) \end{aligned}$$

Adding the two,

$$N^{\mu\nu}(\ell, q) = 4\Big[\ell^\mu (\ell+q)^\nu + \ell^\nu (\ell+q)^\mu - \eta^{\mu\nu}\big(\ell\cdot(\ell+q) - m^2\big)\Big]. \tag{19.34}$$

This numerator is a polynomial of degree two in the loop momentum; against the two-power denominator the integral is, by naive power counting in four dimensions, quadratically divergent. We will find that gauge invariance reduces the genuine divergence to a single logarithm, and that the would-be quadratic piece cancels identically.

19.2.3 Feynman parametrization and the loop shift

To make the loop integration tractable the two denominators must be fused into one. The Feynman identity (built in the regularization toolkit, Eq. (19.10), and proved in general in Theorem D.11),

$$\frac{1}{AB} = \int_0^1 \mathrm{d}x \, \frac{1}{\big[xA + (1-x)B\big]^2}, \tag{19.35}$$

applied with $A = (\ell+q)^2 - m^2 + i\epsilon$ and $B = \ell^2 - m^2 + i\epsilon$, combines the denominators into

$$xA+(1-x)B = \ell^2+2x\,\ell\cdot q+x\,q^2-m^2+i\epsilon = (\ell+xq)^2-\Delta+i\epsilon, \qquad \Delta \equiv m^2-x(1-x)q^2, \tag{19.36}$$

where the second equality completes the square. The shift $\ell \to \ell - xq$ is a legitimate translation of the integration variable under the analytic continuation that defines the dimensionally regularized integral (the shift invariance Theorem 19.1); it removes the term linear in ℓ and leaves all external dependence sequestered in the single scalar Δ. Performing the same shift in the numerator and writing $\ell^\mu \to \ell^\mu - xq^\mu$, $(\ell+q)^\nu \to \ell^\nu + (1-x)q^\nu$,

$$N^{\mu\nu} = 4\Big[(\ell^\mu - xq^\mu)(\ell^\nu + (1-x)q^\nu) + (\mu \leftrightarrow \nu) - \eta^{\mu\nu}\big((\ell - xq)\cdot(\ell + (1-x)q) - m^2\big)\Big]. \tag{19.37}$$

The denominator $[(\ell^2-\Delta)]^2$ is now even in ℓ, so any term in the numerator with an odd number of factors of ℓ integrates to zero and may be dropped. Among the even terms, the rank-two piece $\ell^\mu\ell^\nu$ may be replaced under the symmetric integral by its Lorentz-covariant average: the integral $\int \mathrm{d}^d\ell\, \ell^\mu\ell^\nu f(\ell^2)$ is a symmetric Lorentz tensor built only from $\eta^{\mu\nu}$, and contracting both sides with $\eta_{\mu\nu}$ fixes the coefficient, so

$$\ell^\mu\ell^\nu \;\longrightarrow\; \frac{\ell^2}{d}\,\eta^{\mu\nu} \qquad (\text{under } \int \mathrm{d}^d\ell\,(\cdots)/(\ell^2-\Delta)^2). \tag{19.38}$$

Keeping only the surviving even terms, the cross product $\ell^\mu\ell^\nu$ appears twice (once from each ordering) and contributes $2(\ell^2/d)\eta^{\mu\nu}$; the products $-xq^\mu\cdot(1-x)q^\nu$ appear twice and contribute $-2x(1-x)q^\mu q^\nu$; and in the contraction $(\ell - xq)\cdot(\ell+(1-x)q) = \ell^2 - x(1-x)q^2 + (\text{odd})$ only the even part is kept. Assembling,

$$N^{\mu\nu} \;\longrightarrow\; 4\Big[\tfrac{2}{d}\,\ell^2\,\eta^{\mu\nu} - 2x(1-x)q^\mu q^\nu - \eta^{\mu\nu}\big(\ell^2 - x(1-x)q^2 - m^2\big)\Big]. \tag{19.39}$$

Group the ℓ^2 terms, whose coefficient is $4\eta^{\mu\nu}\,\ell^2\,(\frac{2}{d}-1) = 4\eta^{\mu\nu}\,\ell^2\,\frac{2-d}{d}$, the $q^\mu q^\nu$ term, and the constant $\eta^{\mu\nu}$ term proportional to $x(1-x)q^2 + m^2$. The decisive feature is the factor $\frac{2-d}{d}$ multiplying ℓ^2: it is exactly 1 less than what the naive four-dimensional manipulation would give, and that deficit is the dimensional-regularization fingerprint that will cancel the quadratic divergence. We turn to the integrals.

19.2.4 The loop integrals and the quadratic-divergence cancellation

Two scalar integrals occur, both special cases of the master scalar one-loop integral Eq. (19.17) established in the previous section,

$$\int \frac{\mathrm{d}^d\ell}{(2\pi)^d}\,\frac{1}{(\ell^2-\Delta+i\epsilon)^n} = \frac{(-1)^n\,i}{(4\pi)^{d/2}}\,\frac{\Gamma(n-\frac{d}{2})}{\Gamma(n)}\,\frac{1}{\Delta^{\,n-d/2}}, \tag{19.40}$$

established in the previous section (Eq. (19.17)) by Wick rotation and the radial integration. Write

$$I_2 \equiv \int \frac{\mathrm{d}^d\ell}{(2\pi)^d}\,\frac{1}{(\ell^2-\Delta)^2} = \frac{i}{(4\pi)^{d/2}}\,\Gamma(2-\tfrac{d}{2})\,\Delta^{d/2-2}, \tag{19.41}$$

$$I_1 \equiv \int \frac{\mathrm{d}^d\ell}{(2\pi)^d}\,\frac{1}{\ell^2-\Delta} = \frac{-i}{(4\pi)^{d/2}}\,\Gamma(1-\tfrac{d}{2})\,\Delta^{d/2-1}. \tag{19.42}$$

The integral of ℓ^2 against the squared denominator is reduced to these by the algebraic identity $\ell^2 = (\ell^2-\Delta)+\Delta$, which is the cleanest way to see the cancellation without ever writing down a spurious power divergence:

$$\int \frac{\mathrm{d}^d\ell}{(2\pi)^d}\,\frac{\ell^2}{(\ell^2-\Delta)^2} = I_1 + \Delta\, I_2. \tag{19.43}$$

Using $\Gamma(1-\frac{d}{2}) = \Gamma(2-\frac{d}{2})/(1-\frac{d}{2})$ we have $I_1 = \dfrac{-\Delta}{1-d/2}\,I_2 = \dfrac{2\Delta}{d-2}\,I_2$, whence

$$\int \frac{\mathrm{d}^d\ell}{(2\pi)^d}\,\frac{\ell^2}{(\ell^2-\Delta)^2} = \Big(\frac{2}{d-2}+1\Big)\Delta\, I_2 = \frac{d}{d-2}\,\Delta\, I_2. \tag{19.44}$$

Now combine the three numerator pieces of Eq. (19.39), each multiplied by the appropriate integral. The ℓ^2 piece carries the trace factor $4\,\frac{2-d}{d}\,\eta^{\mu\nu}$ and the integral Eq. (19.44):

$$4\,\frac{2-d}{d}\,\eta^{\mu\nu}\cdot\frac{d}{d-2}\,\Delta\, I_2 = 4\,\eta^{\mu\nu}\,\Delta\, I_2\cdot\frac{2-d}{d-2} = -4\,\eta^{\mu\nu}\,\Delta\, I_2. \tag{19.45}$$

The would-be most-divergent term has produced something finite-looking, proportional to $\Delta\, I_2$: the factor $d/(d-2)$ from the integral and the factor $(2-d)/d$ from the d-dimensional trace conspire to leave -1, the explicit manifestation in dimensional regularization that the apparent quadratic divergence is not there. Adding the constant $\eta^{\mu\nu}$ piece $4\eta^{\mu\nu}(x(1-x)q^2+m^2)\,I_2$ and recalling $\Delta = m^2 - x(1-x)q^2$,

$$\begin{aligned} -4\,\eta^{\mu\nu}\,\Delta\, I_2 + 4\,\eta^{\mu\nu}(x(1-x)q^2+m^2)I_2 &= 4\,\eta^{\mu\nu}\,I_2\big[-(m^2-x(1-x)q^2)+x(1-x)q^2+m^2\big] \\ &= 8\,x(1-x)\,q^2\,\eta^{\mu\nu}\,I_2. \end{aligned} \tag{19.46}$$

Together with the $q^\mu q^\nu$ piece $-8x(1-x)q^\mu q^\nu I_2$, the full integrated numerator is

$$\int \frac{\mathrm{d}^d\ell}{(2\pi)^d}\,\frac{N^{\mu\nu}}{(\ell^2-\Delta)^2} = 8\,x(1-x)\,(q^2\eta^{\mu\nu}-q^\mu q^\nu)\,I_2. \tag{19.47}$$

Two things have happened at once, and both are consequences of gauge invariance made arithmetic. The m^2 in the constant term, which by itself would have produced a q-independent $\propto \eta^{\mu\nu}$ contribution — a photon *mass* — has cancelled exactly against the m^2 inside Δ carried in from the ℓ^2 integral. And the surviving structure is precisely the transverse combination $q^2\eta^{\mu\nu}-q^\mu q^\nu$. There was no room for any other outcome: the calculation was forced to be transverse, and we never imposed it.

19.2.5 Transversality and the result for the scalar form factor

Restoring the prefactor $-e^2$ of Eq. (19.31) and the Feynman-parameter integral, and inserting the explicit I_2,

$$i\Pi^{\mu\nu}(q) = -e^2\int_0^1 \mathrm{d}x\; 8\,x(1-x)(q^2\eta^{\mu\nu}-q^\mu q^\nu)\,\frac{i}{(4\pi)^{d/2}}\,\Gamma(2-\tfrac{d}{2})\,\Delta^{d/2-2}\,\mu^{2\varepsilon}, \tag{19.48}$$

where the factor $\mu^{2\varepsilon}$ restores the engineering dimension of the coupling in $d=4-2\varepsilon$, as fixed by the regularization scheme of Section 19.1. This is manifestly of the transverse form, and we record it as the structural result of the section.

Proposition 19.5 (Transversality of the vacuum polarization)**.** *The one-loop photon self-energy is purely transverse,*

$$i\Pi^{\mu\nu}(q) = i(q^2\eta^{\mu\nu}-q^\mu q^\nu)\,\Pi(q^2), \qquad q_\mu\Pi^{\mu\nu}(q)=0, \tag{19.49}$$

with a single scalar form factor $\Pi(q^2)$. No term proportional to $\eta^{\mu\nu}$ alone (a photon-mass term) is generated. The all-orders statement, with transversality enforced diagram by diagram by the Ward–Takahashi identity, is proved in Theorem 19.13; here it has been verified by direct computation at one loop.

Proof. Equation Eq. (19.47) exhibits the integrated loop as a Feynman-parameter integral of $(q^2\eta^{\mu\nu}-q^\mu q^\nu)$ times a scalar, so $i\Pi^{\mu\nu}=i(q^2\eta^{\mu\nu}-q^\mu q^\nu)\Pi(q^2)$ with the scalar identified below. Contracting with q_μ gives $q_\mu(q^2\eta^{\mu\nu}-q^\mu q^\nu)=q^2q^\nu-q^2q^\nu=0$, which is transversality. □

Reading off the scalar form factor and simplifying the prefactor with $8/(4\pi)^2=1/(2\pi^2)$ and $e^2/(2\pi^2)=2\alpha/\pi$ (where $\alpha=e^2/4\pi$), the dimensional expansion of

$\Gamma(2-\frac{d}{2})\Delta^{d/2-2}\mu^{2\varepsilon}$ is exactly the logarithmic master integral Eq. (19.18) of the previous section (equivalently Eq. (D.136)),

$$\mu^{2\varepsilon}\int\frac{\mathrm{d}^d\ell}{(2\pi)^d}\,\frac{1}{(\ell^2-\Delta)^2}=\frac{i}{(4\pi)^2}\Big[\frac{1}{\bar\varepsilon}+\ln\frac{\mu^2}{\Delta}\Big]+O(\varepsilon),\qquad \frac{1}{\bar\varepsilon}\equiv\frac{1}{\varepsilon}-\gamma_{\mathrm{E}}+\ln 4\pi, \tag{19.50}$$

the modified-minimal-subtraction pole and finite part recalled from Appendix D. Hence the bare one-loop scalar form factor is

$$\Pi(q^2)=-\frac{2\alpha}{\pi}\int_0^1\mathrm{d}x\;x(1-x)\left[\frac{1}{\bar\varepsilon}+\ln\frac{\mu^2}{\Delta}\right],\qquad \Delta=m^2-x(1-x)q^2. \tag{19.51}$$

The ultraviolet divergence is the single $1/\bar\varepsilon$ pole; the dependence on the external momentum and the mass lives entirely in the finite logarithm. The Feynman-parameter integral $\int_0^1\mathrm{d}x\,x(1-x)=\frac{1}{6}$ makes the pole explicit,

$$\Pi(q^2)=-\frac{\alpha}{3\pi}\,\frac{1}{\bar\varepsilon}-\frac{2\alpha}{\pi}\int_0^1\mathrm{d}x\;x(1-x)\,\ln\frac{\mu^2}{\Delta}+O(\varepsilon), \tag{19.52}$$

and its value at zero momentum, where $\Delta\to m^2$, is the pure constant

$$\Pi(0)=-\frac{\alpha}{3\pi}\left[\frac{1}{\bar\varepsilon}+\ln\frac{\mu^2}{m^2}\right]. \tag{19.53}$$

A momentum cutoff would manufacture a photon mass

The cancellation of the $\eta^{\mu\nu}$-only term in Eq. (19.47) is delicate, and it is delicate *because* it is the place where the regulator either respects gauge invariance or betrays it. A naïve Euclidean cutoff $|\ell_E|<\Lambda$ on the integral Eq. (19.31) does not give the transverse answer. The quadratically divergent part of $\int\mathrm{d}^4\ell\,\ell^2/(\ell^2-\Delta)^2$ then evaluates to a term $\propto\Lambda^2\eta^{\mu\nu}$ with *no* accompanying $q^\mu q^\nu$, because a hard cutoff is not Lorentz invariant in the way dimensional continuation is and does not supply the compensating d-dependent trace factor of Eq. (19.45). The upshot would be a self-energy of the form $\Pi^{\mu\nu}\supset c\,\Lambda^2\,\eta^{\mu\nu}$, i.e. a photon-mass term $\frac{1}{2}c\Lambda^2A_\mu A^\mu$ generated radiatively — a gross violation of the Ward identity and of the masslessness of the photon, and an artifact of the regulator rather than physics. Dimensional regularization sets scaleless power divergences to zero and keeps the trace algebra d-dependent, so the spurious mass never appears: $\Pi^{\mu\nu}$ is transverse identically in ε. This is the concrete sense, promised in the chapter introduction, in which dim reg "preserves gauge invariance" while a cutoff corrupts it.

19.2.6 On-shell renormalization and Z_3

The divergence in Eq. (19.51) is removed by the photon field-strength counterterm of renormalized perturbation theory. Writing the bare photon kinetic term as $-\frac{1}{4}Z_3\,F_{\mu\nu}F^{\mu\nu}$ with $Z_3 = 1+\delta_3$ (Section 19.1), the counterterm contributes a two-point vertex $-i\,\delta_3\,(q^2\eta^{\mu\nu} - q^\mu q^\nu)$ — itself transverse, as it must be since it comes from a gauge-invariant operator. The renormalized self-energy is the sum,

$$i\Pi^{\mu\nu}_{\text{ren}}(q) = i\big(q^2\eta^{\mu\nu} - q^\mu q^\nu\big)\big[\Pi(q^2) - \delta_3\big]. \tag{19.54}$$

The on-shell renormalization condition fixes δ_3 by demanding that the full photon propagator have a pole at $q^2 = 0$ (the photon stays massless) with residue exactly 1 (unit normalization of the photon field at the pole). Both requirements are met by requiring the renormalized form factor to vanish at zero momentum,

$$\Pi_{\text{ren}}(0) = 0 \quad\Longrightarrow\quad \delta_3 = \Pi(0) = -\frac{\alpha}{3\pi}\left[\frac{1}{\bar\varepsilon} + \ln\frac{\mu^2}{m^2}\right]. \tag{19.55}$$

The field-strength renormalization constant is therefore

$$Z_3 = 1+\delta_3 = 1 - \frac{\alpha}{3\pi}\,\frac{1}{\bar\varepsilon} + (\text{finite}) = 1 - \frac{e^2}{12\pi^2}\,\frac{1}{\varepsilon} + \cdots, \tag{19.56}$$

the divergent part written in both the α and the e^2 normalizations. The minus sign — $Z_3 < 1$ — is the seed of charge screening, to which we return below; it is also, through the relation $e^2 = Z_3\,e_0^2$ that Chapter 20 uses to define the physical charge, the origin of the positive QED beta function $\beta_e = e^3/12\pi^2$ derived systematically in Chapter 24.

Dimensional convention and the pole of Z_3

We use the book's standing convention $d = 4-2\varepsilon$ (Section 19.1), in which the ultraviolet pole of a one-loop logarithm is $1/\varepsilon$. With this convention $Z_3 = 1 - \dfrac{e^2}{12\pi^2\varepsilon} + \cdots$ as in Eq. (19.56). Texts that set $d = 4-\varepsilon$ (a single ε, e.g. Peskin–Schroeder) have a logarithmic pole $2/\varepsilon$ and accordingly quote $Z_3 = 1 - \dfrac{e^2}{6\pi^2\varepsilon} + \cdots$. The two statements are identical physics written in two conventions for ε; the physical, convention-free content is the residue $-\alpha/3\pi$ of the pole in the $\overline{\text{MS}}$ variable $1/\bar\varepsilon$, which controls the running and is the same in both.

Subtracting Eq. (19.53) from Eq. (19.51) cancels the pole and the $\ln\mu^2$ together — the on-shell scheme trades the renormalization scale for the physical mass m — and leaves the finite, scale-independent, on-shell-subtracted form

factor,

$$\boxed{\widehat{\Pi}(q^2) \equiv \Pi(q^2) - \Pi(0) = -\frac{2\alpha}{\pi}\int_0^1 \mathrm{d}x\; x(1-x)\,\ln\frac{m^2}{m^2 - x(1-x)q^2}\,, \qquad \widehat{\Pi}(0) = 0.} \tag{19.57}$$

This is the central output of the section, the function Chapter 20 imports to build the running coupling and the Uehling potential. The logarithm is real for spacelike $q^2 < 0$ (where the argument exceeds 1, so $\widehat{\Pi} > 0$) and for timelike q^2 below the pair threshold $q^2 < 4m^2$; above threshold it develops an imaginary part, the subject of Section 19.2.8.

19.2.7 The two ends of the form factor

Two regimes carry most of the physics, and both follow from Eq. (19.57) by elementary integration.

Small momentum, $|q^2| \ll m^2$. Expand the logarithm: $\ln\frac{m^2}{m^2 - x(1-x)q^2} = -\ln\!\big(1 - x(1-x)q^2/m^2\big) = x(1-x)\frac{q^2}{m^2} + O(q^4)$. The leading term integrates against the weight using $\int_0^1 \mathrm{d}x\,[x(1-x)]^2 = \frac{1}{30}$,

$$\widehat{\Pi}(q^2) = -\frac{2\alpha}{\pi}\cdot\frac{q^2}{m^2}\int_0^1 \mathrm{d}x\,[x(1-x)]^2 + O(q^4) = -\frac{2\alpha}{\pi}\cdot\frac{1}{30}\cdot\frac{q^2}{m^2} + \cdots = -\frac{\alpha}{15\pi}\frac{q^2}{m^2} + \cdots . \tag{19.58}$$

The linear-in-q^2 coefficient $-\alpha/15\pi m^2$ is exactly the constant that, Fourier transformed, becomes the short-range Uehling correction to the Coulomb potential responsible for the vacuum-polarization part of the Lamb shift (Chapter 20).

Large spacelike momentum, $-q^2 \equiv Q^2 \gg m^2$. Now $m^2 - x(1-x)q^2 = m^2 + x(1-x)Q^2 \simeq x(1-x)Q^2$ away from the endpoints, so $\ln\frac{m^2}{m^2 - x(1-x)q^2} \to -\ln\frac{Q^2}{m^2} - \ln[x(1-x)]$. Using the two moments $\int_0^1 \mathrm{d}x\,x(1-x) = \frac{1}{6}$ and $\int_0^1 \mathrm{d}x\,x(1-x)\ln[x(1-x)] = -\frac{5}{18}$,

$$\widehat{\Pi}(q^2) = \frac{2\alpha}{\pi}\left[\frac{1}{6}\ln\frac{Q^2}{m^2} - \frac{5}{18}\right] + O\!\left(\frac{m^2}{Q^2}\right) = \frac{\alpha}{3\pi}\left[\ln\frac{-q^2}{m^2} - \frac{5}{3}\right] + O\!\left(\frac{m^2}{q^2}\right). \tag{19.59}$$

The leading behavior is the famous logarithm with coefficient $\alpha/3\pi = e^2/12\pi^2$ — the same number that sits in Z_3 and in β_e, as it must, since all three measure the strength of the single $1/\bar{\varepsilon}$ pole. The constant $-5/3$ is the finite remainder of the on-shell scheme and fixes the scale at which the running is referenced. We will see in Chapter 20 that resumming the geometric chain of these insertions turns Eq. (19.59) into the running fine-structure constant $\alpha(q^2) = \alpha/[1 - (\alpha/3\pi)\ln(-q^2/m^2)]$.

19.2.8 Analytic structure: the cut at $q^2 = 4m^2$ and the imaginary part

The renormalized form factor Eq. (19.57) is an analytic function of q^2 in the complex plane, but not an entire one. Its only singularity is a branch cut, and the location and content of that cut are physics. The argument of the logarithm, $\Delta/m^2 = 1 - x(1-x)q^2/m^2$, becomes negative when $x(1-x)q^2 > m^2$. As x ranges over $(0,1)$ the product $x(1-x)$ attains its maximum $\frac{1}{4}$ at $x = \frac{1}{2}$, so the first value of q^2 for which any x makes Δ negative is

$$q^2 = \frac{m^2}{\max_x x(1-x)} = \frac{m^2}{1/4} = 4m^2. \tag{19.60}$$

This is the branch point: $\widehat{\Pi}(q^2)$ is analytic for $q^2 < 4m^2$ (the whole spacelike axis and the sub-threshold timelike segment) and acquires a cut along $q^2 \geq 4m^2$. The threshold $q^2 = 4m^2$ is exactly the invariant mass-squared at which a timelike photon can create a real on-shell electron–positron pair, $2m$ being the minimum energy for that. The Feynman $i\epsilon$, carried since Eq. (19.30), fixes which boundary value of the cut is physical: $q^2 \to q^2 + i\epsilon$, i.e. $\Delta \to \Delta - i\epsilon$, so for $\Delta < 0$ the logarithm acquires a definite imaginary part,

$$\ln \frac{m^2}{\Delta - i\epsilon} = \ln \frac{m^2}{|\Delta|} + i\pi \qquad (\Delta < 0). \tag{19.61}$$

This is the Sokhotski–Plemelj boundary value of Section 5.1.5, and the appearance of a branch cut tied to a physical threshold is the general phenomenon of Section 5.5. The imaginary part of $\widehat{\Pi}$ is then the integral of $-\frac{2\alpha}{\pi} \cdot \pi\, x(1-x)$ over the sub-interval of x for which $\Delta < 0$.

Worked Example 19.6 (The imaginary part above threshold)**.** We evaluate $\operatorname{Im}\widehat{\Pi}(q^2)$ for $q^2 > 4m^2$ from Eq. (19.57). The condition $\Delta = m^2 - x(1-x)q^2 < 0$ is $x(1-x) > m^2/q^2$. The roots of $x(1-x) = m^2/q^2$ are

$$x_\pm = \tfrac{1}{2}(1 \pm \beta), \qquad \beta \equiv \sqrt{1 - \frac{4m^2}{q^2}}, \tag{19.62}$$

so $\Delta < 0$ precisely for $x \in (x_-, x_+)$, and there the logarithm contributes $+i\pi$. Hence

$$\operatorname{Im}\widehat{\Pi}(q^2) = -\frac{2\alpha}{\pi} \cdot \pi \int_{x_-}^{x_+} \mathrm{d}x\; x(1-x) = -2\alpha \int_{x_-}^{x_+} \mathrm{d}x\; x(1-x). \tag{19.63}$$

The remaining integral is elementary in the symmetric variable $u = x - \frac{1}{2} \in (-\frac{\beta}{2}, \frac{\beta}{2})$, where $x(1-x) = \frac{1}{4} - u^2$:

$$\int_{x_-}^{x_+} \mathrm{d}x\; x(1-x) = \int_{-\beta/2}^{\beta/2} \mathrm{d}u \left(\tfrac{1}{4} - u^2\right) = \frac{\beta}{4} - \frac{\beta^3}{12} = \frac{\beta}{12}(3 - \beta^2) = \frac{\beta}{6}\Big(1 + \frac{2m^2}{q^2}\Big), \tag{19.64}$$

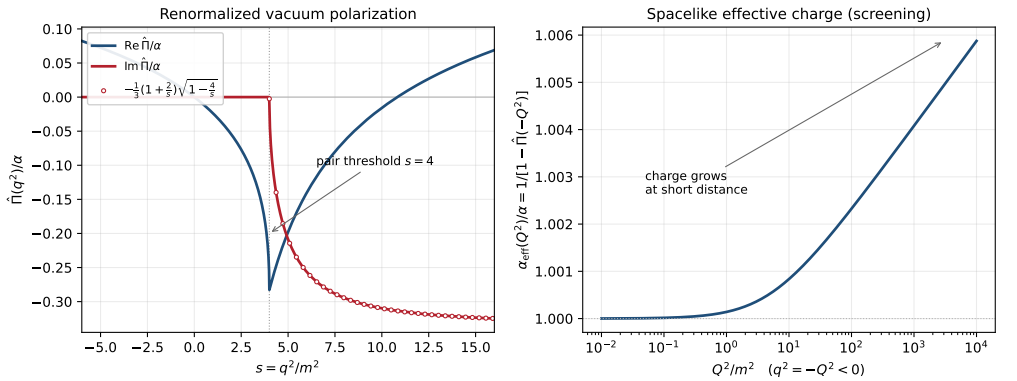

Figure 19.4: Left: the renormalized one-loop vacuum polarization $\widehat{\Pi}(q^2)/\alpha$ from Eq. (19.57), as a function of $s = q^2/m^2$. The real part (blue) is smooth through $s = 0$ where $\widehat{\Pi}(0) = 0$, grows logarithmically at large spacelike $|s|$ per Eq. (19.59), and has a cusp at the pair threshold $s = 4$. The imaginary part (red) is zero below threshold and, above it, follows the closed form $-\frac{1}{3}(1+2/s)\sqrt{1-4/s}$ of Eq. (19.65) (open circles), with the characteristic square-root onset and the plateau at $-\alpha/3$. Right: the spacelike effective charge $\alpha_{\text{eff}}(Q^2)/\alpha = 1/[1 - \widehat{\Pi}(-Q^2)]$, growing toward the ultraviolet: charge screening in momentum space, the seed of the running coupling developed in Chapter 20.

using $3 - \beta^2 = 2 + 4m^2/q^2$. Therefore

$$\operatorname{Im}\widehat{\Pi}(q^2) = -\frac{\alpha}{3}\Big(1 + \frac{2m^2}{q^2}\Big)\sqrt{1 - \frac{4m^2}{q^2}} \qquad (q^2 > 4m^2), \tag{19.65}$$

and $\operatorname{Im}\widehat{\Pi} = 0$ below threshold. The imaginary part switches on at $q^2 = 4m^2$ with the velocity factor $\beta = \sqrt{1 - 4m^2/q^2}$ — the speed of the produced pair — vanishing at threshold and rising to the plateau $\operatorname{Im}\widehat{\Pi} \to -\alpha/3$ as $q^2 \to \infty$, where the electron mass becomes negligible. Figure 19.4 plots $\operatorname{Re}\widehat{\Pi}$ and $\operatorname{Im}\widehat{\Pi}$ together and shows the square-root onset at the threshold.

The imaginary part is not optional bookkeeping: it is demanded by unitarity. Above threshold the virtual photon *can* decay into a real pair, and the optical theorem ties the discontinuity of the two-point function across its cut to the production rate of those physical states. We verify the match.

Worked Example 19.7 ($\operatorname{Im}\widehat{\Pi}$ from the optical theorem)**.** The generalized optical theorem (Theorem 14.37) is the statement, derived from $\mathbf{S}^\dagger\mathbf{S} = \mathbf{1}$, that the discontinuity of an amplitude across a physical cut equals a sum over on-shell intermediate states of the product of production and decay sub-amplitudes. Applied to the amputated photon two-point function, with the only state available at $O(e^2)$ being a single electron–positron pair, it reads (the Cutkosky construction

of the cut puts the two fermion lines on shell; Chapter 60 systematizes it)

$$2\,\mathrm{Im}\,\Pi^{\mu\nu}(q) = \int \mathrm{d}\Pi_2 \sum_{\text{spins}} \left[\bar{u}(p_1)(-ie\gamma^\mu)v(p_2)\right]\left[\bar{u}(p_1)(-ie\gamma^\nu)v(p_2)\right]^*, \quad (19.66)$$

where p_1, p_2 are the pair momenta ($p_1+p_2=q$, each on shell, $p_i^2=m^2$) and $\mathrm{d}\Pi_2$ is the Lorentz-invariant two-body phase space of Eq. (16.55). The spin sum is the same trace already met in e^+e^- annihilation (Chapter 17):

$$\sum_{\text{spins}} \left[\bar{u}_1\gamma^\mu v_2\right]\left[\bar{u}_1\gamma^\nu v_2\right]^* = \mathrm{tr}\left[(\not{p}_1+m)\gamma^\mu(\not{p}_2-m)\gamma^\nu\right] = 4\left[p_1^\mu p_2^\nu + p_1^\nu p_2^\mu - \eta^{\mu\nu}(p_1\cdot p_2+m^2)\right]. \quad (19.67)$$

Rather than carry the tensor structure we project onto the scalar form factor. Contract Eq. (19.66) with $\eta_{\mu\nu}$; the left side gives $2\,\mathrm{Im}[\eta_{\mu\nu}\Pi^{\mu\nu}] = 2\,\mathrm{Im}[(q^2 d - q^2)\Pi] \to 6q^2\,\mathrm{Im}\,\Pi$ at $d=4$ by Eq. (19.49). On the right, $\eta_{\mu\nu}$ times the spin trace is

$$4e^2\left[2\,p_1\cdot p_2 - 4(p_1\cdot p_2+m^2)\right] = -8e^2(p_1\cdot p_2+2m^2) = -4e^2\,q^2\Big(1+\frac{2m^2}{q^2}\Big), \quad (19.68)$$

where $p_1\cdot p_2 = \tfrac{1}{2}(q^2-2m^2)$ from $q^2=(p_1+p_2)^2$, so $p_1\cdot p_2+2m^2 = \tfrac{1}{2}q^2(1+2m^2/q^2)$. The integrand is independent of the emission angle, so the phase-space integral simply multiplies it by the total two-body phase-space volume $\int \mathrm{d}\Pi_2 = \beta/8\pi$ (Eq. (16.55)). Assembling,

$$6q^2\,\mathrm{Im}\,\Pi = \frac{\beta}{8\pi}\cdot\Big[-4e^2q^2\Big(1+\frac{2m^2}{q^2}\Big)\Big] \;\Longrightarrow\; \mathrm{Im}\,\Pi = -\frac{e^2}{12\pi}\,\beta\Big(1+\frac{2m^2}{q^2}\Big) = -\frac{\alpha}{3}\Big(1+\frac{2m^2}{q^2}\Big)\sqrt{1-\frac{4}{} \quad (19.69)$$

using $e^2=4\pi\alpha$. Since Π and $\widehat{\Pi}$ differ only by the real constant $\Pi(0)$, $\mathrm{Im}\,\Pi = \mathrm{Im}\,\widehat{\Pi}$, and the result is identical to Eq. (19.65). The loop computation and the unitarity cut agree exactly: the imaginary part of the photon self-energy *is* the rate at which a virtual photon makes real pairs, weighted by phase space. This is the cross-check promised in the section goal, and it is the physical content from which Chapter 20 reconstructs the whole of $\widehat{\Pi}$ by a dispersion relation, using the analyticity and Kramers–Kronig machinery of Section 5.5.5.

The vacuum as a polarizable medium

The function $\widehat{\Pi}(q^2)$ has a single, vivid physical reading. The QED vacuum is not empty: it teems with virtual electron–positron pairs, fluctuations permitted for a time $\sim 1/2m$ by the uncertainty principle. A bare charge placed in this medium polarizes those pairs — virtual positrons drawn inward, virtual electrons pushed outward — so the charge is partially screened by a co-moving cloud of opposite charge, exactly as a test charge in a dielectric is shielded by induced polarization. A probe at large

distance, i.e. small spacelike $-q^2$, sees the fully screened charge and measures the textbook $\alpha \approx 1/137$; a probe that penetrates the cloud, large $-q^2$, sees more of the bare charge and so a *larger* effective coupling. This is the content of Eq. (19.59): $\widehat{\Pi}$ grows like $+\frac{\alpha}{3\pi}\ln(-q^2/m^2)$, and through the resummation of Chapter 20 the effective charge grows with it. The sign $Z_3 < 1$ in Eq. (19.56) is the screening made quantitative. That fermion loops screen — driving α *up* in the ultraviolet — is the abelian face of the single most consequential sign in particle physics; its non-abelian counterpart, where gauge-boson self-interactions antiscreen and the coupling falls in the ultraviolet (asymptotic freedom, Chapter 27), is what makes QCD a sensible short-distance theory. The systematic statement of all this — promoting the one-loop logarithm to an all-orders renormalization-group flow — is the business of Chapter 24; the present section has supplied the one-loop input on which that flow is built.

We have delivered the first of the three one-loop building blocks of QED: a renormalized, manifestly transverse photon two-point function $\widehat{\Pi}(q^2)$ with $\widehat{\Pi}(0) = 0$, the field-strength renormalization Z_3 of Eq. (19.56), and the full analytic structure — branch cut at the pair threshold, imaginary part cross-checked against the optical theorem — that seeds charge screening and the running coupling. The loop-integral machinery assembled here (Feynman parametrization, the loop shift, the master integral, and the d-dimensional numerator algebra that enforces gauge invariance) is the template the next two sections reuse. We turn next to the electron self-energy $\Sigma(p)$, where the same toolkit confronts a new feature absent here — an infrared divergence — alongside the mass and field-strength renormalizations δm and Z_2 (Section 19.3).

19.3 The Electron Self-Energy
