exactly the chiral-symmetry-breaking pattern of ordinary QCD. The Goldstone bosons of this breaking are described by Section 29.3, now appearing inside an exactly solvable theory. At the *baryonic* point $M = 0$, $B = -\widetilde{B} = \Lambda^{N_c}$, the baryon vev breaks $\mathrm{U}(1)_B$ while preserving the full nonabelian flavor symmetry. In between, a continuous family of vacua interpolates. In all cases the low-energy spectrum consists of the gauge-singlet composites $M, B, \widetilde{B}$ subject to (46.94) and their superpartners: there are no massless gluons, the theory *confines*, and it does so with chiral symmetry breaking. That the massless fermionic composites correctly reproduce all the global 't Hooft anomalies of the microscopic quarks at each of these vacua — the consistency demanded by Theorem 37.26 — is the check that originally established this picture; we carry out the analogous computation in detail for the duality below.

Physical Insight

This is the book's confinement criterion made calculable. In Chapter 27 an area law for the Wilson loop, Theorem 27.20, was the operational definition of confinement, established at strong coupling on the lattice but inaccessible to weak-coupling methods. Here supersymmetry lets us follow a gauge theory all the way to its infrared and *prove* that color is confined — the spectrum is gauge-singlet mesons and baryons, full stop — and that chiral symmetry breaks, all without summing a single diagram. The price is that this particular theory has massless moduli rather than a mass gap; the pure super-Yang–Mills case $N_f = 0$, by contrast, has gaugino

condensation and a genuine gap, the closest supersymmetric cousin of real QCD confinement.

46.4.4 $N_f = N_c + 1$: s-confinement

Add one more flavor. Now the constraint is not deformed; instead the classical moduli space survives intact — the origin included — and the infrared is described by a *smooth* effective superpotential of the confined composites, with no constraint imposed by hand. This is the phenomenon Seiberg named *s-confinement*: confinement with a smooth description and an unbroken chiral symmetry at the origin.

The composites are the meson $M^i{}_{\tilde{j}}$ and the now-flavored baryons B^i, $\widetilde{B}_{\tilde{j}}$ ($i, \tilde{j} = 1, \ldots, N_f = N_c + 1$), each an (anti)fundamental of a flavor group. Holomorphy and symmetry fix their dynamics. With $b_0 = 3N_c - N_f = 2N_c - 1$ the scale is Λ^{2N_c-1}, and the unique superpotential built from $M, B, \widetilde{B}$ that is a flavor singlet, has baryon number zero, carries R-charge 2 (required of any superpotential, since $\mathrm{d}^2\theta$ carries $R = -2$), and reduces correctly in all limits is

$$\boxed{W \;=\; \frac{1}{\Lambda^{2N_c-1}}\Big(B^i\, M_i{}^{\tilde{j}}\, \widetilde{B}_{\tilde{j}} \;-\; \det M\Big)} \tag{46.99}$$

We verify the charge bookkeeping, since it is the entire content of the claim. At $N_f = N_c + 1$, Table 46.2 gives $R(M) = 2(N_f - N_c)/N_f = 2/(N_c + 1)$ and $R(B) = R(\widetilde{B}) = N_c(N_f - N_c)/N_f = N_c/(N_c + 1)$. Hence

$$R(\det M) = N_f\, R(M) = (N_c{+}1)\cdot\frac{2}{N_c+1} = 2, \quad R(BM\widetilde{B}) = \frac{N_c}{N_c+1}+\frac{2}{N_c+1}+\frac{N_c}{N_c+1} = \frac{2}{N} \tag{46.100}$$

so both terms carry $R = 2$, as a superpotential must. Both are $\mathrm{SU}(N_f)_L \times \mathrm{SU}(N_f)_R$ singlets ($BM\widetilde{B}$ contracts all flavor indices, $\det M$ is the invariant determinant) and have B-number $N_c - N_c = 0$ for the first term and 0 for $\det M$. The axial spurion charges match too: $A(\det M) = 2N_f$, while $A(BM\widetilde{B}) = N_c + 2 + N_c = 2N_c + 2 = 2N_f$, and $A(\Lambda^{2N_c-1}) = 2N_f$ from the one-instanton zero-mode count, so the prefactor $\Lambda^{-(2N_c-1)}$ exactly cancels the matter axial charge and leaves W with $A = 0$ as required. Holomorphy plus these selection rules leave (46.99) as the only possibility up to the overall normalization, which the deformation to $N_f = N_c$ fixes.

The superpotential (46.99) is not a constraint — it is a genuine interaction of the light composites — and its equations of motion reproduce the classical geometry as the supersymmetric vacuum condition. Varying with respect to M,

B, and $\widetilde{B}$,

$$\frac{\partial W}{\partial M_i{}^{\tilde{\jmath}}} = 0: \;\; B^i \widetilde{B}_{\tilde{\jmath}} = (\mathrm{cof}\, M)^i{}_{\tilde{\jmath}}, \qquad \frac{\partial W}{\partial B^i} = 0: \;\; M_i{}^{\tilde{\jmath}} \widetilde{B}_{\tilde{\jmath}} = 0, \qquad \frac{\partial W}{\partial \widetilde{B}_{\tilde{\jmath}}} = 0: \;\; B^i M_i{}^{\tilde{\jmath}} = 0, \tag{46.101}$$

where $(\mathrm{cof}\, M)^i{}_{\tilde{\jmath}}$ is the matrix of cofactors, $M\,(\mathrm{cof}\, M)^{\mathsf{T}} = (\det M)\,\mathbf{1}$. These are precisely the classical relations among mesons and baryons at $N_f = N_c + 1$ (a rank-N_c meson whose cofactor equals $B\widetilde{B}$, with baryons in the kernel of M). The moduli space is the classical one, the origin lies on it, and there the entire global symmetry G_{cl} is unbroken. The theory confines *without* breaking chiral symmetry, and the massless composites $M, B, \widetilde{B}$ at the origin must — and do — match every 't Hooft anomaly of the underlying quarks and gluons (Theorem 37.26). This anomaly match at the origin, with elementary quarks on one side and confined mesons and baryons on the other, is one of the cleanest confirmations of confinement in any four-dimensional theory.

46.4.5 Seiberg duality: the precise statement

Increase N_f further and a new organizing principle takes over. For $N_f > N_c + 1$ the composite description proliferates — more and more baryonic invariants, no smooth superpotential — and the right infrared variables are not the mesons and baryons of the electric theory at all. They are the fields of a *different* gauge theory.

Theorem 46.15 (Seiberg's electric–magnetic duality)**.** *For $N_f > N_c + 1$, the* $\mathrm{SU}(N_c)$ *gauge theory with N_f flavors $Q, \widetilde{Q}$ and no superpotential (the* electric *theory) flows in the infrared to the same fixed point as the following* magnetic *theory: an* $\mathrm{SU}(\widetilde{N}_c)$ *gauge theory with*

$$\widetilde{N}_c \;=\; N_f - N_c \tag{46.102}$$

colors, N_f magnetic quarks $q, \widetilde{q}$ in its (anti)fundamental, together with a gauge-singlet meson superfield $M^i{}_{\tilde{\jmath}}$ that is an $N_f \times N_f$ matrix, coupled through the cubic superpotential

$$\boxed{W_{\mathrm{mag}} \;=\; \frac{1}{\mu}\, M^i{}_{\tilde{\jmath}}\, \widetilde{q}_i\, q^{\tilde{\jmath}}} \tag{46.103}$$

with μ a scale relating the dimension-one singlet M to the dimension-two electric meson $\widetilde{Q}Q$ via the operator map $\widetilde{Q}Q = \mu M$. The two theories share the same global symmetry G_{cl} and the same chiral ring in the infrared.

Three features deserve emphasis at once. First, the duality is an *infrared* equivalence: the two theories are different in the ultraviolet (different gauge groups, different field content) and become indistinguishable only at long distances, where they describe the same physics. Second, the magnetic gauge group

	$\mathrm{SU}(\widetilde{N}_c)$	$\mathrm{SU}(N_f)_L$	$\mathrm{SU}(N_f)_R$	$\mathrm{U}(1)_B$	$\mathrm{U}(1)_R$
q	$\mathbf{\widetilde{N}_c}$	$\overline{\mathbf{N_f}}$	$\mathbf{1}$	$+\frac{N_c}{\widetilde{N}_c}$	$\frac{N_c}{N_f}$
$\widetilde{q}$	$\overline{\mathbf{\widetilde{N}_c}}$	$\mathbf{1}$	$\mathbf{N_f}$	$-\frac{N_c}{\widetilde{N}_c}$	$\frac{N_c}{N_f}$
M	$\mathbf{1}$	$\mathbf{N_f}$	$\overline{\mathbf{N_f}}$	0	$\frac{2(N_f-N_c)}{N_f}$

Table 46.3: Global charges of the magnetic theory of Theorem 46.15. The dual quark R-charge follows directly from the requirement $R(W_{\mathrm{mag}}) = R(M) + R(q) + R(\widetilde{q}) = 2$ with $R(M) = 2(N_f - N_c)/N_f$, giving $R(q) = R(\widetilde{q}) = N_c/N_f$. The dual quark sits in the conjugate flavor representation to the electric quark, so that the meson M and the composite $\widetilde{q}q$ carry identical flavor quantum numbers.

$\mathrm{SU}(N_f - N_c)$ shrinks as N_c grows toward N_f: when $N_f = N_c + 1$ it is $\mathrm{SU}(1)$, i.e. trivial, and the magnetic "theory" is just the meson and baryons with a superpotential — precisely the s-confining description (46.99), with the magnetic quarks identified as the baryons. The duality thus contains the s-confinement result as its boundary case. Third, the singlet M is indispensable: without it the cubic superpotential (46.103) could not be written, and, as we now show, the global anomalies would not match.

Caution

Seiberg duality is, as of the mid-2020s, a conjecture — an extraordinarily well-tested one, but not a theorem. There is no derivation of it from first principles in four dimensions; what we marshal below is *evidence*, in the strict sense of necessary consistency conditions that the conjecture passes non-trivially and that would each have killed it had any failed. The strongest evidence is exact (anomaly matching, deformation consistency); some is structural (embedding in string constructions, large-N_c checks); some is numerical (lattice studies of the conformal window). We are careful to label which is which.

The magnetic charges are fixed by the requirements that the global symmetries agree and that (46.103) be invariant. We record them in Table 46.3; the reader can verify each entry from the constraints $\widetilde{Q}Q = \mu M$ (so $R(M)$ is the electric meson R-charge, $B(M) = 0$), $R(W_{\mathrm{mag}}) = 2$, and the matching of baryon number between electric and magnetic baryons (electric $B \sim Q^{N_c}$ versus magnetic $b \sim q^{\widetilde{N}_c}$ must carry the same $\mathrm{U}(1)_B$ charge, forcing $B(q) = N_c/\widetilde{N}_c$).

46.4.6 Evidence I: 't Hooft anomaly matching

The first and sharpest test is exact. The global symmetry $G_{\rm cl}$ is the same in both descriptions, it is unbroken at the origin of moduli space (the common infrared fixed point), and its 't Hooft anomalies are renormalization -group invariant (Theorem 37.26): the triangle anomaly of any three global currents, computed on the ultraviolet fermions, must equal the same triangle computed on whatever massless fermions survive in the infrared. If the electric and magnetic theories flow to the same fixed point, they must reproduce the *same* set of global anomalies. There are several independent anomaly coefficients — $\mathrm{SU}(N_f)^3$, $\mathrm{SU}(N_f)^2\,\mathrm{U}(1)_B$, $\mathrm{SU}(N_f)^2\,\mathrm{U}(1)_R$, $\mathrm{U}(1)_B^2\,\mathrm{U}(1)_R$, $\mathrm{U}(1)_R$, $\mathrm{U}(1)_R^3$ — and all of them match. We compute one in complete detail, the mixed $\mathrm{SU}(N_f)_L^2\,\mathrm{U}(1)_R$ anomaly, because it is the one in which the singlet meson plays the decisive role; we then do a second, the pure $\mathrm{U}(1)_R$–gravitational anomaly, as a worked example, and quote the rest.

The $\mathrm{SU}(N_f)_L^2\,\mathrm{U}(1)_R$ anomaly. This coefficient is the sum, over all left-handed (Weyl) fermions charged under $\mathrm{SU}(N_f)_L$, of

$$\mathcal{A}\big[\mathrm{SU}(N_f)_L^2\,\mathrm{U}(1)_R\big] \;=\; \sum_{\text{fermions}} R_\psi\, T(r_\psi)\, d_\psi, \tag{46.104}$$

where R_ψ is the R-charge of the fermion (one less than that of its superfield), $T(r_\psi)$ the $\mathrm{SU}(N_f)_L$ Dynkin index of its flavor representation, and d_ψ the multiplicity from all *other* (color, flavor) labels it carries.

Electric side. The only fields charged under $\mathrm{SU}(N_f)_L$ are the quarks Q (the antiquarks $\widetilde{Q}$ are $\mathrm{SU}(N_f)_L$ singlets, and the gauginos are flavor singlets). The fermion in Q has R-charge $R_Q - 1 = (N_f - N_c)/N_f - 1 = -N_c/N_f$, sits in the fundamental of $\mathrm{SU}(N_f)_L$ with $T(\mathbf{N_f}) = \frac{1}{2}$, and comes in N_c colors. Hence

$$\mathcal{A}_{\rm el} \;=\; \underbrace{\Big(-\frac{N_c}{N_f}\Big)}_{R_\psi}\cdot\underbrace{\frac{1}{2}}_{T}\cdot\underbrace{N_c}_{d_\psi} \;=\; -\frac{N_c^2}{2N_f}. \tag{46.105}$$

Magnetic side. Two kinds of fermion are charged under $\mathrm{SU}(N_f)_L$: the dual quark q and the meson fermion ψ_M. The dual quark q has R-charge $R_q - 1 = N_c/N_f - 1 = -\widetilde{N}_c/N_f$, sits in the antifundamental of $\mathrm{SU}(N_f)_L$ with the same index $T(\overline{\mathbf{N_f}}) = \frac{1}{2}$, and comes in $\widetilde{N}_c$ magnetic colors. The meson M is an $\mathrm{SU}(N_f)_L$ fundamental (index i) with R-charge $R_M - 1 = 2(N_f - N_c)/N_f - 1 = (N_f - 2N_c)/N_f$, and its multiplicity from the second flavor index $\tilde{\jmath}$ is N_f. Therefore

$$\mathcal{A}_{\rm mag} = \underbrace{\Big(-\frac{\widetilde{N}_c}{N_f}\Big)\cdot\frac{1}{2}\cdot\widetilde{N}_c}_{\text{dual quark } q} + \underbrace{\Big(\frac{N_f - 2N_c}{N_f}\Big)\cdot\frac{1}{2}\cdot N_f}_{\text{meson } \psi_M}$$

$$= -\frac{\widetilde{N}_c^{\,2}}{2N_f} + \frac{N_f - 2N_c}{2} \;=\; \frac{-(N_f - N_c)^2 + N_f(N_f - 2N_c)}{2N_f}, \tag{46.106}$$

where in the last step we used $\widetilde{N}_c = N_f - N_c$ and put everything over $2N_f$. Expanding the numerator,

$$-(N_f - N_c)^2 + N_f(N_f - 2N_c) = -N_f^2 + 2N_fN_c - N_c^2 + N_f^2 - 2N_fN_c = -N_c^2, \tag{46.107}$$

so that

$$\mathcal{A}_{\text{mag}} \;=\; -\frac{N_c^2}{2N_f} \;=\; \mathcal{A}_{\text{el}}. \tag{46.108}$$

The two descriptions agree. The match is not trivial term by term: on the electric side the entire coefficient comes from N_c quarks, while on the magnetic side it is a difference between $\widetilde{N}_c$ dual quarks and the N_f^2-component meson, and the cancellation that leaves exactly $-N_c^2$ requires the meson's R-charge to be precisely $R_M - 1 = (N_f - 2N_c)/N_f$. Drop the singlet M from the magnetic theory and the anomaly fails by the meson term — which is the algebraic reason Theorem 46.15 cannot do without it.

Worked Example 46.16 (The $\mathrm{U}(1)_R$–gravitational anomaly matches)**.** The mixed R–gravitational anomaly is the simplest global anomaly to state: it is the sum of the R-charges of *all* massless Weyl fermions, weighted only by their multiplicities (gravity couples universally, so there is no group-theory index),

$$\mathcal{A}[\mathrm{U}(1)_R] \;=\; \sum_{\text{fermions}} R_\psi \,\dim(r_\psi). \tag{46.109}$$

Electric side. Three contributions: the gauginos, the quark fermions, and the antiquark fermions.

- Gauginos λ: $R = +1$, multiplicity $\dim(\text{adj}) = N_c^2 - 1$.
- Quark fermions ψ_Q: $R = R_Q - 1 = -N_c/N_f$, multiplicity N_cN_f (colors $\times$ flavors).
- Antiquark fermions $\psi_{\widetilde{Q}}$: same $R = -N_c/N_f$, multiplicity N_cN_f.

Summing,

$$\mathcal{A}_{\text{el}}[\mathrm{U}(1)_R] = (N_c^2 - 1)(+1) + 2\,N_cN_f\Big(-\frac{N_c}{N_f}\Big) = N_c^2 - 1 - 2N_c^2 = -N_c^2 - 1. \tag{46.110}$$

Magnetic side. Four contributions: the magnetic gauginos, the dual quark and antiquark fermions, and the meson fermions.

- Magnetic gauginos: $R = +1$, multiplicity $\widetilde{N}_c^{\,2} - 1$.

- Dual quark/antiquark fermions: $R = R_q - 1 = -\widetilde{N}_c/N_f$, multiplicity $\widetilde{N}_c N_f$ each, so two copies.
- Meson fermions ψ_M: $R = R_M - 1 = (N_f - 2N_c)/N_f$, multiplicity N_f^2.

Summing,

$$\begin{aligned}\mathcal{A}_{\text{mag}}[\mathrm{U}(1)_R] &= (\widetilde{N}_c^{\,2} - 1) + 2\,\widetilde{N}_c N_f\Big(-\frac{\widetilde{N}_c}{N_f}\Big) + N_f^2 \cdot \frac{N_f - 2N_c}{N_f} \\ &= \widetilde{N}_c^{\,2} - 1 - 2\widetilde{N}_c^{\,2} + N_f(N_f - 2N_c) \;=\; -\widetilde{N}_c^{\,2} - 1 + N_f(N_f - 2N_c).\end{aligned} \tag{46.111}$$

With $\widetilde{N}_c = N_f - N_c$,

$$-\widetilde{N}_c^{\,2} + N_f(N_f - 2N_c) = -(N_f - N_c)^2 + N_f^2 - 2N_f N_c = -N_c^2, \tag{46.112}$$

exactly as in (46.107), so $\mathcal{A}_{\text{mag}}[\mathrm{U}(1)_R] = -N_c^2 - 1 = \mathcal{A}_{\text{el}}[\mathrm{U}(1)_R]$. Again the balance is delicate: the magnetic gaugino contributes the analogue of the electric gauge contribution but with the *wrong* rank $\widetilde{N}_c^{\,2}$, and it is the meson's N_f^2-fold multiplicity, weighted by its specific R-charge, that repairs the difference to leave precisely $-N_c^2 - 1$. The universal "-1" — the lone gaugino over and above the matter — survives because $\dim(\text{adj}) = N_{\text{color}}^2 - 1$ on both sides and the color-squared pieces are exactly what the meson cancels.

The remaining coefficients are matched by the same bookkeeping. The $\mathrm{SU}(N_f)_L^2\,\mathrm{U}(1)_B$ anomaly receives $N_c \cdot \frac{1}{2} \cdot (+1) = N_c/2$ from the electric quarks; on the magnetic side the dual quark gives $\widetilde{N}_c \cdot \frac{1}{2} \cdot (N_c/\widetilde{N}_c) = N_c/2$ and the meson (with $B = 0$) does not contribute, so it matches. The pure $\mathrm{SU}(N_f)_L^3$ anomaly measures the net number of fundamentals minus antifundamentals charged under $\mathrm{SU}(N_f)_L$: electrically N_c fundamentals (the quark colors); magnetically N_c from the meson fundamental minus $\widetilde{N}_c$ antifundamentals from the dual quark, i.e. $N_c - \widetilde{N}_c + \ldots$, which again reduces to the electric value once the meson is included. Every coefficient matches, and only with the singlet meson present. This is the principal exact evidence for Theorem 46.15.

46.4.7 The conformal window and the unitarity bound

We can now read the phase diagram, Fig. 46.5, by asking, for each N_f, which of the two dual descriptions is weakly coupled in the infrared. The question is settled by the one-loop coefficient $b_0 = 3N_c - N_f$ in the electric theory and its magnetic counterpart $\widetilde{b}_0 = 3\widetilde{N}_c - N_f = 3(N_f - N_c) - N_f = 2N_f - 3N_c$. Asymptotic freedom requires a positive coefficient; a non-positive one means the gauge coupling is irrelevant and the theory is infrared-free.

The fixed point and the exact R-charge. For supersymmetric gauge theory the exact (NSVZ) β-function for the holomorphic coupling can be written

$$\beta(g) = -\frac{g^3}{16\pi^2}\,\frac{3N_c - N_f(1-\gamma(g))}{1 - N_c g^2/8\pi^2}, \tag{46.113}$$

where $\gamma(g)$ is the anomalous dimension of the quark superfield, common to Q and $\widetilde{Q}$ by the flavor symmetry; this is the exact statement of the nonrenormalization structure argued in Chapter 45. A nontrivial infrared fixed point $g_* \neq 0$ exists when the numerator vanishes,

$$3N_c - N_f(1-\gamma_*) = 0 \quad\Longrightarrow\quad \gamma_* = 1 - \frac{3N_c}{N_f}. \tag{46.114}$$

At such a fixed point the theory is a (super)conformal field theory, and the superconformal algebra ties the exact scaling dimension of a chiral primary operator $\mathcal{O}$ to its R-charge,

$$\Delta(\mathcal{O}) = \tfrac{3}{2}\,R(\mathcal{O}) \qquad \text{(chiral primary)}. \tag{46.115}$$

The relation (46.115) is forced by positivity. In the $\mathcal{N}=1$ superconformal algebra the dilatation D and R-charge sit in the anticommutator of a supercharge with its conformal partner, schematically $\{\bar{S}, \bar{Q}\} \sim D - \frac{3}{2}R$ acting on a primary; a chiral operator is annihilated by $\bar{Q}$ and a superconformal primary is annihilated by $\bar{S}$, so sandwiching the anticommutator in the state $\mathcal{O}|0\rangle$ and using $\|\bar{S}\,\mathcal{O}|0\rangle\|^2 \geq 0$, $\|\bar{Q}\,\mathcal{O}|0\rangle\|^2 \geq 0$ gives the bound $\Delta \geq \frac{3}{2}R$, saturated precisely for a chiral primary. (We take the superconformal representation theory from Chapter 47; the upshot, that a chiral primary has $\Delta = \frac{3}{2}R$ exactly, is all we use.) Applied to the meson $M = \widetilde{Q}Q$, whose R-charge is $R_M = 2(N_f - N_c)/N_f$,

$$\Delta(M) = \frac{3}{2}\cdot\frac{2(N_f - N_c)}{N_f} = \frac{3(N_f - N_c)}{N_f} = 3\Big(1 - \frac{N_c}{N_f}\Big). \tag{46.116}$$

The upper edge $N_f = 3N_c$. When $N_f \geq 3N_c$, $b_0 \leq 0$: the electric coupling is irrelevant, the theory is infrared-free, and the quarks and gluons of the electric description are themselves the correct, free, long -distance degrees of freedom. This is the *free electric phase*, the supersymmetric analogue of infrared-free QED. Just below $3N_c$, the fixed-point coupling g_* is parametrically small (a Banks–Zaks fixed point, controlled by the two-loop term), $\gamma_* = 1 - 3N_c/N_f$ is small and negative, and the interacting superconformal fixed point is under perturbative control. As N_f decreases, g_* grows and the fixed point becomes strongly coupled.

The lower edge $N_f = \frac{3}{2}N_c$ from unitarity. The interacting fixed point cannot persist to arbitrarily small N_f. Its undoing is a *unitarity bound*. In

any unitary conformal field theory in four dimensions, a gauge-invariant scalar primary operator has dimension at least that of a free field,

$$\Delta \geq 1, \tag{46.117}$$

with equality only for a free (decoupled) field obeying $\Box \mathcal{O} = 0$. This is the scalar case of the general unitarity bound proved from reflection positivity in Chapter 47; physically it states that a genuinely interacting scalar cannot have dimension below the free value without producing a negative-norm descendant. Apply it to the meson, using (46.116):

$$\Delta(M) = 3\Big(1 - \frac{N_c}{N_f}\Big) \geq 1 \quad \Longleftrightarrow \quad 3N_f - 3N_c \geq N_f \quad \Longleftrightarrow \quad N_f \geq \frac{3N_c}{2}. \tag{46.118}$$

So the interacting superconformal fixed point with the meson as an interacting operator can exist only for $N_f \geq \frac{3}{2}N_c$. The boundary $N_f = \frac{3}{2}N_c$ is where $\Delta(M) = 1$ exactly: the meson hits the unitarity bound and becomes a free field. This is not an artifact — it is the signal that for $N_f < \frac{3}{2}N_c$ the operator M has decoupled as a free field and the interacting description has reorganized itself. The reorganization is exactly Seiberg duality: below $\frac{3}{2}N_c$ the *magnetic* coefficient $\widetilde{b}_0 = 2N_f - 3N_c$ has gone negative, the magnetic gauge theory is infrared-free, and the correct long-distance physics is the free magnetic theory of Theorem 46.15 — $\mathrm{SU}(N_f - N_c)$ gauge fields, dual quarks, and the now-free meson, all weakly coupled. This is the *free magnetic phase*, $N_c + 1 < N_f \leq \frac{3}{2}N_c$.

Physical Insight

The two edges of the conformal window are the same statement seen from the two sides of the duality. The window is

$$\frac{3}{2}N_c < N_f < 3N_c, \tag{46.119}$$

and its upper edge $N_f = 3N_c$ is where the *electric* coupling stops being asymptotically free ($b_0 = 0$), while its lower edge $N_f = \frac{3}{2}N_c$ is where the *magnetic* coupling stops being asymptotically free ($\widetilde{b}_0 = 3\widetilde{N}_c - N_f = 2N_f - 3N_c = 0$). Inside the window both descriptions are asymptotically free in the ultraviolet and both flow to the same interacting superconformal fixed point in the infrared; one is the dual of the other. Outside, on each side, exactly one description goes free and takes over. That the unitarity bound on the electric meson (46.118) reproduces the loss of magnetic asymptotic freedom to the digit is a stringent, independent check of Theorem 46.15.

46.4.8 Evidence II: chiral ring, deformations, and the a-theorem

Anomaly matching tests the theory at one point, the origin. The second body of evidence tests its deformations — the statement that as we perturb the electric theory and the magnetic theory by corresponding operators, they continue to agree.

The chiral ring matches. The gauge-invariant chiral operators of the electric theory are the mesons and baryons of Section 46.4.2. In the magnetic theory the singlet M is the meson directly, $\widetilde{Q}Q = \mu M$, while the electric baryon $B \sim Q^{N_c}$ maps to the magnetic baryon built from $\widetilde{N}_c = N_f - N_c$ dual quarks, $b \sim q^{\widetilde{N}_c}$; the ϵ-tensor of $\mathrm{SU}(\widetilde{N}_c)$ has exactly $\widetilde{N}_c$ indices, so $q^{\widetilde{N}_c}$ is the unique baryonic invariant, and it carries the same flavor representation $\Lambda^{N_c}\mathbf{N_f} \cong \Lambda^{\widetilde{N}_c}\overline{\mathbf{N_f}}$ and the same baryon number N_c as the electric baryon. The chiral rings are isomorphic.

Mass deformations map consistently. The decisive structural test is that adding a mass for one electric flavor maps to a controlled symmetry breaking in the magnetic theory, and that the duality of the daughter theories is again Seiberg's. Give the N_f-th electric flavor a mass,

$$\delta W_{\mathrm{el}} = m\, M^{N_f}{}_{N_f} = m\, \widetilde{Q}_{N_f} Q^{N_f}. \tag{46.120}$$

Integrating out the massive flavor leaves the electric $\mathrm{SU}(N_c)$ theory with $N_f - 1$ flavors. On the magnetic side the same operator is, by $\widetilde{Q}Q = \mu M$, a linear term $m\mu\, M^{N_f}{}_{N_f}$ added to (46.103):

$$W_{\mathrm{mag}} + \delta W = \frac{1}{\mu} M^{i}{}_{\tilde{\jmath}} \widetilde{q}_i q^{\tilde{\jmath}} + m\mu\, M^{N_f}{}_{N_f}. \tag{46.121}$$

The equation of motion for the singlet $M^{N_f}{}_{N_f}$ now reads $\frac{1}{\mu}\widetilde{q}_{N_f} q^{N_f} + m\mu = 0$, i.e.

$$\widetilde{q}_{N_f} q^{N_f} = -m\mu^2 \neq 0, \tag{46.122}$$

forcing a vacuum expectation value for the N_f-th magnetic quark. A dual-quark vev Higgses the magnetic gauge group by one rank, $\mathrm{SU}(\widetilde{N}_c) \to \mathrm{SU}(\widetilde{N}_c - 1)$, and removes one flavor. The daughter magnetic theory is therefore $\mathrm{SU}(\widetilde{N}_c - 1)$ with $N_f - 1$ flavors. For this to be the Seiberg dual of the daughter electric theory $\mathrm{SU}(N_c)$ with $N_f - 1$ flavors, we need the magnetic rank to be $(N_f - 1) - N_c$. Indeed

$$\widetilde{N}_c - 1 = (N_f - N_c) - 1 = (N_f - 1) - N_c, \tag{46.123}$$

exactly as required. A mass on the electric side maps to a Higgsing on the magnetic side, and the dualities of the deformed theories close consistently. This is a non-trivial, infinitely-iterable check: starting anywhere in the window and

adding masses one at a time walks both descriptions down through the phases — conformal window, free magnetic, s-confinement, quantum-modified constraint, ADS runaway — with the two sides agreeing at every step. By the same token, a vacuum expectation value (Higgsing) on the electric side maps to a mass on the magnetic side, the mirror operation; and dualizing the magnetic theory a second time, $\mathrm{SU}(\widetilde{N}_c) \to \mathrm{SU}(N_f - \widetilde{N}_c) = \mathrm{SU}(N_c)$, returns the electric theory, the "meson of the meson" becoming the original quark bilinear through the cubic superpotentials. Seiberg duality is an involution.

Consistency with the a-theorem. A final, more recent check uses the four-dimensional a-anomaly — the coefficient of the Euler density in the trace anomaly on a curved background. The a-theorem (Komargodski–Schwimmer, 2011) states that $a_{\mathrm{UV}} > a_{\mathrm{IR}}$ along any renormalization -group flow, generalizing to four dimensions the two-dimensional c-theorem. For a superconformal fixed point, a is computed exactly from the 't Hooft anomalies of the superconformal R-symmetry,

$$a = \frac{3}{32}(3\ \mathrm{Tr}\, R^3 - \mathrm{Tr}\, R), \tag{46.124}$$

with the correct R-symmetry inside the conformal window selected by a-maximization (Intriligator–Wecht, 2003). Because the electric and magnetic theories flow to the *same* fixed point, they must yield the same a; (46.124) evaluated on the two sets of anomaly coefficients we computed above does indeed agree, by the same identities (46.107) that made the triangle anomalies match. And along the flow from the asymptotically free ultraviolet into the window, a decreases monotonically, consistent with the a-theorem. We state these as consistency checks at the level of results — the full machinery of the a-anomaly and a-maximization belongs to the conformal-field-theory part of the book (Chapter 47 and Part XIV) — but the message is that every independent handle we have on the infrared, exact anomalies, operator dimensions, and the monotone a, points the same way.

This completes the map. Reading Fig. 46.5 from left to right: $N_f < N_c$ has no vacuum (ADS runaway); $N_f = N_c$ confines on a quantum-modified moduli space with chiral symmetry breaking; $N_f = N_c + 1$ s-confines with a smooth superpotential and unbroken chiral symmetry; $N_c + 1 < N_f \le \frac{3}{2}N_c$ is the free magnetic phase; $\frac{3}{2}N_c < N_f < 3N_c$ is the conformal window with an interacting superconformal fixed point described equally well by the electric or the magnetic theory; and $N_f \ge 3N_c$ is the free electric phase. The whole of it is organized by holomorphy and by the electric–magnetic duality of Theorem 46.15.

We have arrived at the conceptual payoff that drives the rest of the chapter: a strongly coupled gauge theory can be *exactly equivalent* to a weakly coupled one built on a different gauge group, with the heavy composites of one appearing as the elementary quanta of the other. In SQCD this electric–magnetic exchange is a statement about an entire infrared fixed point. The next section takes the

same idea down to the level of individual states. Extending the algebra to $\mathcal{N} = 2$ supersymmetry, we will find short multiplets whose masses are fixed exactly by a central charge, $M = |Z|$, and we will see that the central charge counts electric and magnetic charges on an equal footing. That is the algebraic seed of the Seiberg–Witten solution, in which a magnetically charged object — a monopole — becomes light and condenses, turning the abstract electric–magnetic duality of this section into the concrete mechanism of confinement.

46.5 BPS States and Central Charges

The duality of the previous section is a statement about descriptions: the same physics admits an electric presentation, in which the elementary quanta are weakly coupled, and a magnetic one, in which the solitons are. For such a statement to have content we need quantities that can be computed in one description and trusted in the other — quantities that do not drift as the coupling is dialled from weak to strong. Generic masses are useless here: they receive corrections at every order and beyond. What we want is a class of states whose masses are fixed by the symmetry algebra itself, not by the dynamics, and are therefore the same number whether evaluated in the electric or the magnetic frame. Supersymmetry supplies exactly such a class. The mechanism is the *central charge*: a relaxation of the supersymmetry algebra, licensed by Haag–Łopuszański–Sohnius for extended supersymmetry, that ties the mass of certain states to a charge by an exact inequality, saturated on a distinguished short multiplet. This section builds that structure from the algebra, proves the resulting Bogomol'nyi–Prasad–Sommerfield bound by the same sum-of-squares positivity that gave $H \geq 0$ in Section 44.3.1, and identifies the central charge with the electric and magnetic charges of Section 41.6.4 — turning the classical Bogomol'nyi bound of Chapter 41 into an exact quantum mass formula. That formula is the spectral data the Seiberg–Witten solution will compute.

46.5.1 The centrally extended algebra

The $\mathcal{N} = 1$ algebra of Eqs. (44.61) and (44.62) has $\{Q_\alpha, Q_\beta\} = 0$: the like-chirality anticommutator vanishes. We saw in Section 44.4.4 that this vanishing is not a theorem of supersymmetry but an accident of having only one supercharge. The graded-Lie-algebra closure of Theorem 44.5 requires only that $\{Q_\alpha, Q_\beta\}$ be a *bosonic* operator that commutes with the momenta and transforms in the symmetric part of $(\tfrac{1}{2}, 0) \otimes (\tfrac{1}{2}, 0)$. The symmetric product decomposes as $(\tfrac{1}{2}, 0) \otimes (\tfrac{1}{2}, 0) = (1, 0) \oplus (0, 0)$, whose symmetric piece is the Lorentz scalar $(0, 0)$, carried by the antisymmetric tensor $\epsilon_{\alpha\beta}$. A scalar that commutes with all of Poincaré and with the internal symmetry is, by definition, a *central* element. The Haag–Łopuszański–Sohnius theorem (Theorem 44.6) states that this is the

most general allowed extension: the right-hand side of the like-chirality bracket may be a central charge,

$$\left\{Q^I_\alpha, Q^J_\beta\right\} \;=\; 2\,\epsilon_{\alpha\beta}\,Z^{IJ}, \qquad Z^{IJ} = -Z^{JI}, \tag{46.125}$$

exactly the relation Eq. (44.114) flagged there. The matrix Z^{IJ} is antisymmetric in the internal indices $I, J = 1, \ldots, \mathcal{N}$, which is why it has no components for $\mathcal{N} = 1$ (a single antisymmetric 1×1 matrix is zero) and first appears for $\mathcal{N} \geq 2$. It commutes with every generator of the superalgebra — with P_μ and $M_{\mu\nu}$ because it is a Poincaré scalar, and with the supercharges because, being central, it sits in the centre by construction; on any irreducible representation Schur's lemma (Theorem 2.23) then forces it to a c-number.

For the remainder of this section we work with $\mathcal{N} = 2$, the case relevant to the Seiberg–Witten solution. There are two supercharges Q^I_α $(I = 1, 2)$ and their conjugates $\bar{Q}_{I\,\dot\alpha} \equiv (Q^I_\alpha)^\dagger$. The antisymmetric 2×2 matrix Z^{IJ} has a single independent component, $Z^{IJ} = \epsilon^{IJ} Z$ with Z a single complex number ($\epsilon^{12} = -\epsilon^{21} = 1$). The complete $\mathcal{N} = 2$ super-Poincaré algebra is then

$$\left\{Q^I_\alpha, \bar{Q}_{J\,\dot\beta}\right\} = 2\,\sigma^\mu_{\alpha\dot\beta}\,P_\mu\,\delta^I_J, \tag{46.126}$$

$$\left\{Q^I_\alpha, Q^J_\beta\right\} = 2\,\epsilon_{\alpha\beta}\,\epsilon^{IJ}\,Z, \tag{46.127}$$

$$\left\{\bar{Q}_{I\,\dot\alpha}, \bar{Q}_{J\,\dot\beta}\right\} = 2\,\epsilon_{\dot\alpha\dot\beta}\,\epsilon_{IJ}\,\bar{Z}, \tag{46.128}$$

the last line being the Hermitian conjugate of the second. The first line is just Eq. (44.61) tensored with the internal identity δ^I_J: each supercharge still squares to the momentum. The novelty is entirely in Eq. (46.127): two supercharges of opposite internal index now anticommute not to zero but to the central charge Z.

Notation Watch

The same symbol Z denoted the complex combination $v(q + ig)$ of electric and magnetic charges in the classical analysis of Eq. (41.189). This is deliberate, not a clash: the central charge of Eq. (46.127) *is* that classical object promoted to an operator, as Section 46.5.4 establishes. Until that identification is made we treat Z as an abstract complex c-number sitting in the algebra.

A word on $\mathcal{N} = 1$. The point-particle algebra Eq. (44.62) has no room for a central charge, but the bracket Eq. (46.125) can be nonzero in $\mathcal{N} = 1$ when the charges Q_α are computed on field configurations with nontrivial behaviour at spatial infinity — domain walls and other extended objects. The surface term that obstructs the naive vanishing is precisely the topological charge ΔW that bounded the kink mass in Theorem 41.5, and the kink relation $M = |\Delta W|$ of

Theorem 41.6 is, read in this light, an $\mathcal{N}=1$ BPS bound. The mechanism below is identical; we phrase it for $\mathcal{N}=2$ because that is where it controls a four-dimensional particle spectrum.

46.5.2 The BPS bound from positivity

We now prove that the mass of any state is bounded below by the modulus of the central charge. The argument is the positivity argument of Section 44.3.1 run one level deeper: there we wrote H as a sum of squares of supercharges and concluded $H \geq 0$; here we form cleverer linear combinations of supercharges whose squared norms isolate the combination $M - |Z|$.

Work in the rest frame of a massive state, $P^\mu = (M,0,0,0)$ with $M>0$. As in Eq. (44.109) the right-hand side of Eq. (46.126) collapses, since $\sigma^\mu_{\alpha\dot\beta} P_\mu = M\,\sigma^0_{\alpha\dot\beta} = M\,\delta_{\alpha\dot\beta}$. Writing all brackets in terms of the four supercharges Q^I_α and their adjoints $(Q^I_\alpha)^\dagger$, and identifying the numerical values of dotted and undotted indices, the rest-frame algebra reads

$$\left\{Q^I_\alpha, (Q^J_\beta)^\dagger\right\} = 2M\,\delta_{\alpha\beta}\,\delta^{IJ}, \tag{46.129}$$

$$\left\{Q^I_\alpha, Q^J_\beta\right\} = 2\,\epsilon_{\alpha\beta}\,\epsilon^{IJ}\,Z. \tag{46.130}$$

The first relation says each supercharge has unit-normalised anticommutator with its own adjoint (the diagonal entries are $2M$) and anticommutes with the adjoint of any *different* supercharge. The second relation is nonzero only when both the spinor indices and the internal indices differ; with $\epsilon_{12}=\epsilon^{12}=1$ its only independent nonzero components are

$$\left\{Q^1_1, Q^2_2\right\} = 2Z, \qquad \left\{Q^1_2, Q^2_1\right\} = -2Z. \tag{46.131}$$

The supercharges thus split into two decoupled quartets, $\{Q^1_1, Q^2_2\}$ and $\{Q^1_2, Q^2_1\}$, each closing on M and on Z but not mixing with the other. Treat the first quartet. Write the central charge in polar form $Z = |Z|\,e^{i\delta}$ and define the two fermionic combinations

$$a \;=\; \tfrac{1}{\sqrt{2}}\Big(Q^1_1 + e^{i\delta}\,(Q^2_2)^\dagger\Big), \qquad b \;=\; \tfrac{1}{\sqrt{2}}\Big(Q^1_1 - e^{i\delta}\,(Q^2_2)^\dagger\Big), \tag{46.132}$$

the phase $e^{i\delta}$ chosen to align Z with the real axis in the computation that follows. These are genuine annihilation/creation-type operators because they are linear in the Q's; we compute their anticommutators with their adjoints. For a, using $a^\dagger = \frac{1}{\sqrt{2}}((Q^1_1)^\dagger + e^{-i\delta}Q^2_2)$ and the brackets Eqs. (46.129) and (46.131),

$$\left\{a, a^\dagger\right\} = \tfrac{1}{2}\Big(\left\{Q^1_1, (Q^1_1)^\dagger\right\} + e^{-i\delta}\left\{Q^1_1, Q^2_2\right\} + e^{i\delta}\left\{(Q^2_2)^\dagger, (Q^1_1)^\dagger\right\} + \left\{(Q^2_2)^\dagger, Q^2_2\right\}\Big)$$

$$= \tfrac{1}{2}\Big(2M + e^{-i\delta}\, 2Z + e^{i\delta}\, 2\bar{Z} + 2M\Big) = 2M + \big(e^{-i\delta} Z + e^{i\delta}\bar{Z}\big) = 2M + 2\,|Z|\,, \tag{46.133}$$

where in the last step $e^{-i\delta}Z = |Z|$ and its conjugate is again $|Z|$. The cross term $\Big\{(Q_2^2)^\dagger, (Q_1^1)^\dagger\Big\} = \big(\{Q_1^1, Q_2^2\}\big)^\dagger = 2\bar{Z}$ was used. An identical computation for b, which differs only in the sign of the off-diagonal piece, gives

$$\Big\{b, b^\dagger\Big\} = 2M - 2\,|Z|\,. \tag{46.134}$$

One checks directly from Eqs. (46.129) and (46.131) that $\Big\{a, b^\dagger\Big\} = \tfrac{1}{2}(2M - 2M) = 0$ and $\{a, b\} = \tfrac{1}{2}\big(\{Q_1^1, Q_1^1\} - e^{2i\delta}\Big\{(Q_2^2)^\dagger, (Q_2^2)^\dagger\Big\}\big) = 0$, so a and b are independent oscillators. The same construction applied to the second quartet $\{Q_2^1, Q_1^2\}$ — now with the opposite sign in Eq. (46.131), compensated by reversing the phase in the definitions — yields two more independent oscillators c, d with $\Big\{c, c^\dagger\Big\} = 2M + 2\,|Z|$ and $\Big\{d, d^\dagger\Big\} = 2M - 2\,|Z|$.

The bound is now immediate. The anticommutator $\Big\{b, b^\dagger\Big\} = bb^\dagger + b^\dagger b$ is, on any state $|\psi\rangle$, the sum of two squared norms:

$$\Big\langle \psi \Big| \Big\{b, b^\dagger\Big\} \Big| \psi \Big\rangle = \Big\| b^\dagger\,|\psi\rangle \Big\|^2 + \|b\,|\psi\rangle\|^2 \geq 0. \tag{46.135}$$

Combining with Eq. (46.134) and dividing by the positive norm $\langle\psi|\psi\rangle$,

$$2M - 2\,|Z| \geq 0 \qquad \Longrightarrow \qquad M \geq |Z|\,. \tag{46.136}$$

Theorem 46.17 (BPS bound)**.** *In any unitary representation of the $\mathcal{N} = 2$ super-Poincaré algebra Eqs. (46.126) to (46.128) on a Hilbert space with positive-definite inner product, every massive state satisfies*

$$M \;\geq\; |Z|\,, \tag{46.137}$$

with Z the central-charge eigenvalue on that state. For general $\mathcal{N}$ the same argument applied block by block to the skew eigenvalues Z_n of Z^{IJ} gives $M \geq \max_n |Z_n|$, the bound Eq. (44.115).

Proof. The displayed argument: Eq. (46.134) writes $2M - 2\,|Z|$ as the rest-frame expectation of $\Big\{b, b^\dagger\Big\}$, which Eq. (46.135) shows is a sum of squared norms and hence non-negative on every state, giving $M \geq |Z|$. The general-$\mathcal{N}$ statement follows by diagonalising the antisymmetric Z^{IJ} into 2×2 skew blocks with real skew eigenvalues $Z_n \geq 0$, after which each block reproduces the pair Eqs. (46.133) and (46.134) with $|Z| \to Z_n$; positivity of every b-type oscillator forces $M \geq Z_n$ for each n, hence $M \geq \max_n Z_n$. □

Two remarks fix the meaning. First, the bound is kinematic in precisely the sense the energy bound of Theorem 44.9 was: it follows from the algebra and Hilbert-space positivity alone, with no input from the Lagrangian or the coupling. Whatever the dynamics, no state can have $M < |Z|$. Second, the inequality is saturated, $M = |Z|$, exactly when the right-hand side of Eq. (46.134) vanishes, i.e. when the oscillators b and d have vanishing anticommutator with their adjoints. By Eq. (46.135) this happens if and only if $b\,|\psi\rangle = b^\dagger\,|\psi\rangle = 0$ (and likewise for d): the half of the supercharges packaged into b, d *annihilate* the state. Saturating the bound is the same as preserving half the supersymmetry.

46.5.3 Short multiplets and the protection of the mass

The representation-theoretic consequence of saturation is a collapse in the size of the multiplet, and it is this collapse that makes the BPS mass an exact, calculable quantity. We count states in the two cases.

Away from the bound, $M > |Z|$, all four oscillators a, b, c, d have nonvanishing $\left\{\cdot, \cdot^\dagger\right\}$; rescaled to unit anticommutators they generate a Clifford algebra of four fermionic modes. Its unique irreducible module is built by acting with the four creation operators on a Clifford vacuum $|\Omega\rangle$ annihilated by all four annihilators; since each creation operator squares to zero, the module is spanned by the $2^4 = 16$ products of distinct creation operators. If the vacuum carries little-group spin j, the full multiplet has $16(2j+1)$ states. This is the *long* (generic massive) $\mathcal{N} = 2$ multiplet — the $\mathcal{N} = 2$ analogue of the $4(2j+1)$ count for $\mathcal{N} = 1$ in Theorem 44.21, with four oscillators instead of two.

At the bound, $M = |Z|$, the two oscillators b, d annihilate every physical state and so act as zero: they cannot be used to build new states, because $b^\dagger\,|\psi\rangle$ has zero norm and is therefore the zero vector in a positive-definite Hilbert space. Only a and c remain as genuine creation operators. The module is now built on *two* oscillators, spanned by $2^2 = 4$ products, giving $4(2j+1)$ states. This is the *short* or *BPS* multiplet.

Theorem 46.18 (BPS shortening)**.** *A massive $\mathcal{N} = 2$ multiplet built on a Clifford vacuum of little-group spin j contains $16(2j+1)$ states when $M > |Z|$ and $4(2j+1)$ states when $M = |Z|$. The short multiplet is annihilated by half the supercharges — the combinations b, d of Eq. (46.132) and its partner — and is built from a Clifford algebra of half as many oscillators.*

Proof. The state counts are the dimensions of the irreducible Clifford modules on four and two fermionic oscillators, $2^4(2j+1)$ and $2^2(2j+1)$, established by the spanning argument above (each creation operator nilpotent, so the module is the exterior algebra on the creators tensored with the spin-j vacuum). That b, d annihilate every state in the short module is the content of Eq. (46.135) at saturation: $\left\|b^\dagger\,|\psi\rangle\right\|^2 + \|b\,|\psi\rangle\|^2 = 0$ in a positive-definite space forces $b\,|\psi\rangle =$

$b^\dagger|\psi\rangle = 0$, and the same for d; these four supercharge components — half of the eight real components of Q^I_α — thus act trivially throughout the multiplet. □

Physical Insight

The geometry of the collapse is the same one that organised Section 44.4.4: an oscillator pair survives or decouples according to whether the relevant diagonal entry of the anticommutator, here $2(M \pm |Z|)$, is nonzero or zero. The massless multiplet is the extreme degeneration $P^2 = 0$ in which the survival fraction is largest; the long massive multiplet is the opposite extreme; the BPS multiplet is the intermediate case in which exactly the $(M - |Z|)$-oscillators degenerate. A short multiplet is, in a literal sense, the "square root" of a long one — $\sqrt{16} = 4$ — because half the Clifford generators have been switched off.

The dimension count is the entire reason BPS masses are protected. The number of states in a multiplet is a non-negative integer, and supersymmetry acts on it by operators that vary continuously as we change the parameters of the theory — couplings, masses, and the moduli labelling the vacuum. A continuous deformation cannot change an integer; in particular it cannot turn a $4(2j+1)$-state short multiplet into a $16(2j+1)$-state long one, because the intermediate values are not attainable. The only way a short multiplet can leave the BPS bound is to combine with other short multiplets whose states add up to a complete long multiplet, and then move off as that long multiplet. Such *recombination* requires several short multiplets to collide at the same point of parameter space — a non-generic event. Generically, then, a state that is BPS at weak coupling stays BPS, and its mass remains locked to $|Z|$ as the coupling is varied all the way to strong coupling.

Worked Example 46.19 (The state count and the half-hypermultiplet)**.** We verify the smallest BPS multiplet and read off its field content. Take the Clifford vacuum to be a spin singlet, $j = 0$. By Theorem 46.18 the short multiplet has $4(2\cdot 0+1) = 4$ states, built on the two surviving oscillators a, c. The two creation operators each carry one undotted spinor index (they are linear in the Q^I_α), so under the rest-frame little group SU(2) they form a spin-$\frac{1}{2}$ doublet. The four states organise as

$$\underbrace{|\Omega\rangle}_{\text{spin } 0} \;\oplus\; \underbrace{a^\dagger|\Omega\rangle\,,\; c^\dagger|\Omega\rangle}_{\text{spin } \frac{1}{2}} \;\oplus\; \underbrace{a^\dagger c^\dagger|\Omega\rangle}_{\text{spin } 0}, \tag{46.138}$$

i.e. two spin-0 states and one spin-$\frac{1}{2}$ doublet: $n_B = 2$ bosonic and $n_F = 2$ fermionic states, as the equality $n_B = n_F$ of Theorem 44.15 demands. Completing to a CPT-invariant set doubles the scalars to a complex pair, giving one complex scalar and one Dirac fermion — the $\mathcal{N} = 2$ *hypermultiplet* of Section 44.4.4, now seen to be a *short* multiplet whenever it is massive. The W boson and

the monopole of the next worked example sit in such multiplets (with a spin-$\frac{1}{2}$ vacuum, giving the massive $\mathcal{N}=2$ vector multiplet), and the shortening is exactly why their masses are the protected quantities the duality demands. Had the same fields formed a long multiplet they would carry 16 states and their mass would be an unprotected dynamical number; the count $4 \neq 16$ is the difference between a calculable spectrum and an incalculable one.

46.5.4 The central charge as electric and magnetic charge

It remains to evaluate Z. Being central, Z commutes with all of Poincaré and with supersymmetry, so it must be a Lorentz-scalar conserved charge of the theory. In an $\mathcal{N}=2$ gauge theory broken to its abelian Coulomb phase — the setting of Chapter 41 and of the Seiberg–Witten solution — the available Lorentz-scalar conserved charges are exactly two: the unbroken-U(1) electric charge $q = \oint E_i \, \mathrm{d}S_i$ and the magnetic charge $g = \oint B_i \, \mathrm{d}S_i$. The central charge can therefore be at most a linear combination of these,

$$Z \;=\; v\,(q + i\,g), \tag{46.139}$$

and the coefficients are fixed by matching the algebraic bound to the classical one. This is not a guess: the central charge of a supersymmetric soliton is computed by evaluating the anticommutator Eq. (46.127) on the soliton background, where the supercharges are spatial integrals of the supercurrent and their anticommutator reduces, after integration by parts, to a *surface term* at spatial infinity. That surface term is built from the same gauge-invariant combination of the Higgs field ϕ and the field strength that appeared in the Bogomol'nyi completion of Eq. (41.173) and Eq. (41.187); it evaluates to precisely $v(q+ig)$, the complex central charge already identified classically in Eq. (41.189). The algebraic and the classical Z are the same object.

With Eq. (46.139) the BPS bound Eq. (46.137) becomes

$$M \;\geq\; |Z| \;=\; v\,\sqrt{q^2 + g^2}, \tag{46.140}$$

which is exactly the classical dyon bound Eq. (41.188). The quantum statement and the classical statement coincide — but their status is utterly different. Classically, Eq. (41.188) was a property of static solutions of one particular Lagrangian, saturated only in the Prasad–Sommerfield limit. Here it is a theorem about the Hilbert space of the full quantum theory, and the shortening of Theorem 46.18 guarantees that saturating states keep $M = |Z|$ as an exact equality, immune to quantum corrections. The classical Bogomol'nyi bound has been promoted to an exact quantum mass formula.

The charges that enter are quantised. As in Section 41.6.4, the magnetic charge is fixed by topology, $g = 4\pi n_m / e$ with $n_m \in \mathbb{Z}$, and the electric charge in integer units of the gauge coupling, $q = e\,n_e$ with $n_e \in \mathbb{Z}$ (shifted by the Witten

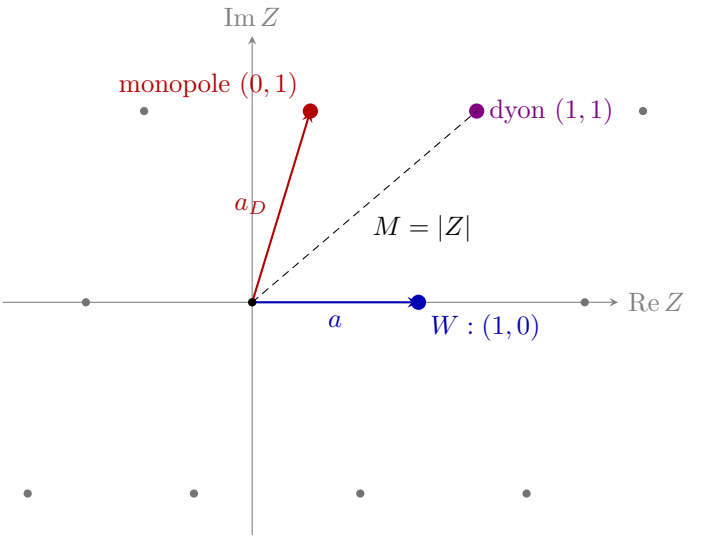

Figure 46.6: The BPS spectrum in the complex central-charge plane. Each charge state (n_e, n_m) maps to the lattice point $Z = a\,n_e + a_D\,n_m$ generated by the two complex periods a (electric) and a_D (magnetic) of Eq. (46.142); its BPS mass is the distance from the origin, $M = |Z|$ (dashed line, shown for the $(1,1)$ dyon). The elementary W boson sits at $(1,0)$ with $M = |a|$, the 't Hooft–Polyakov monopole at $(0,1)$ with $M = |a_D|$. As the modulus is varied the periods $a(u), a_D(u)$ move and the lattice deforms, but each point stays at $M = |Z|$ exactly: the protected data the Seiberg–Witten solution computes.

effect to $q = e(n_e + \frac{\theta}{2\pi} n_m)$ once a θ-angle is switched on). It is convenient to package the coupling and the angle into the single complex parameter

$$\tau \;=\; \frac{\theta}{2\pi} + \frac{4\pi i}{e^2}, \tag{46.141}$$

and to rescale the scalar vacuum value into the complex modulus $a \equiv e\,v$, which is the natural coordinate on the Coulomb branch. Substituting $q = e n_e$, $g = (4\pi/e) n_m$ (at $\theta = 0$) into Eq. (46.139) and collecting,

$$Z \;=\; v(e\,n_e + i\,\tfrac{4\pi}{e}\,n_m) \;=\; (ev)\,n_e + (ev)\,\tfrac{4\pi i}{e^2}\,n_m \;=\; a\,n_e + a_D\,n_m, \tag{46.142}$$

where the *dual period* is, at this classical/weak-coupling level, $a_D = \tau a$ (with the θ-term restoring the real part of τ). The central charge is thus a *linear function of the charge quantum numbers* (n_e, n_m) *with complex coefficients* (a, a_D): the BPS spectrum lives on the lattice $\{a\,n_e + a_D\,n_m\}$ in the complex Z-plane, and the BPS mass of a state is the distance of its lattice point from the origin, $M = |a\,n_e + a_D\,n_m|$ (Fig. 46.6).

Worked Example 46.20 (The W boson and the monopole as BPS states)**.** We check that the two cornerstones of the spectrum — the elementary charged

gauge boson and the soliton monopole — both saturate Eq. (46.137), and that the saturated masses reproduce the independently known classical values of Chapter 41.

The W boson: $(n_e, n_m) = (1, 0)$. A purely electric BPS state has $Z = a\, n_e = a$, so by Eq. (46.140),

$$M_W = |Z| = |a| = e\, v. \tag{46.143}$$

This is the mass an elementary gauge boson acquires when the adjoint scalar develops the vacuum value v and breaks the gauge group — the supersymmetric Higgs mechanism — and it is exactly the W-boson mass $m_W = ev$ recorded in Eq. (41.175). The elementary charged quanta of the theory are themselves BPS: they sit in short multiplets, and Eq. (46.143) is exact.

The monopole: $(n_e, n_m) = (1, 0)$ *in the dual frame, i.e.* $(n_e, n_m) = (0, 1)$. A purely magnetic BPS state has $Z = a_D\, n_m = a_D$, so

$$M_{\text{mon}} = |a_D| = \left|\tfrac{4\pi i}{e}\, v\right| = \frac{4\pi}{e}\, v = v\, |g|\,, \tag{46.144}$$

using $g = 4\pi/e$ for the unit monopole. This is precisely the saturated Bogomol'nyi bound $M = v\,|g|$ of Eq. (41.175), the mass of the Prasad–Sommerfield monopole computed in closed form in Theorem 41.32 as the $n_m = 1$ BPS soliton of the 't Hooft–Polyakov construction (Section 41.5). What was there an exact statement only in the classical $\lambda \to 0$ limit is here an exact statement about the quantum Hilbert space: the monopole is a short multiplet, and $M_{\text{mon}} = |a_D|$ holds to all orders.

The two masses stand in the ratio

$$\frac{M_{\text{mon}}}{M_W} = \frac{|a_D|}{|a|} = \frac{4\pi}{e^2} = \operatorname{Im}\tau, \tag{46.145}$$

inversely proportional to the coupling e^2: at weak coupling the monopole is heavy, as a soliton should be, while the W is light. This is the quantitative face of the strong–weak duality of the previous section — exchanging $a \leftrightarrow a_D$ (equivalently $\tau \to -1/\tau$) swaps the heavy and light sectors — and the mass formula Eq. (46.142) is the one quantity that survives the exchange intact.

Caution

The classical relation $a_D = \tau a$ holds only at weak coupling. Quantum mechanically a and a_D are independent functions of the Coulomb-branch modulus u, related by the holomorphy of the low-energy effective action rather than by a fixed proportionality. The lattice of Fig. 46.6 therefore deforms as u varies, and the periods can undergo monodromy around singular points of moduli space. Pinning down $a(u)$ and $a_D(u)$ as exact

functions — and reading off where BPS states become massless — is exactly the problem the next section solves. The structural fact established here, that $Z = a\,n_e + a_D\,n_m$ with $M = |Z|$ on BPS states, is the input to that solution, not its output.

We have what the duality demanded: a class of states whose masses are fixed by the algebra, computed identically in any frame, and protected against the flow to strong coupling. The central charge $Z = a\,n_e + a_D\,n_m$ packages the entire BPS spectrum into two holomorphic functions $a(u)$ and $a_D(u)$ on the Coulomb branch, and the BPS mass formula $M = |Z|$ turns knowledge of those two functions into the exact mass of every monopole, dyon, and gauge boson. Determining $a(u)$ and $a_D(u)$ — from holomorphy, the prepotential, and a single auxiliary curve whose periods they are — is the content of the Seiberg–Witten solution, to which we now turn.

46.6 The Seiberg–Witten Solution

The previous section handed us two instruments and the discipline to use them. The first is the BPS mass formula $M = |Z|$ of Eq. (46.142), which ties the mass of every short multiplet to a single complex number Z built from the conserved electric and magnetic charges; the second is the holomorphic-coupling technology of Section 46.2, which says that the low-energy gauge coupling is the second derivative of a single holomorphic function and runs, to all orders in perturbation theory, with the one-loop coefficient of Theorem 46.9. Each instrument alone is a strong constraint. Assembled, with one further physical input — that the low-energy effective theory must have a positive metric on its space of vacua — they over-determine the dynamics of a four-dimensional gauge theory so tightly that the answer is forced. The theory is $\mathcal{N} = 2$ SU(2) super-Yang–Mills, and the answer, due to Seiberg and Witten, is the first and still the cleanest example of a strongly coupled gauge theory solved exactly: its massless spectrum, its effective coupling at every energy, its complete set of stable BPS states, and — when the supersymmetry is softly broken — the mechanism of confinement, all written in closed form. This section carries that solution out. We will see the abstract demand "the effective coupling is holomorphic and its imaginary part is positive" collide with "the coupling runs," and watch the collision resolve itself by producing singularities in the moduli space; we will identify the physics at those singularities as massless monopoles and dyons; we will package the whole monodromy structure as the periods of a family of elliptic curves; and we will perturb the theory to make the monopole condense, realizing analytically the dual-superconductor picture of confinement that Theorem 27.20 could only state as a criterion.

46.6.1 The Coulomb branch and its low-energy effective theory

The microscopic theory is pure $\mathcal{N}=2$ super-Yang–Mills with gauge group SU(2). In the $\mathcal{N}=1$ language of Chapter 45 its field content is a vector multiplet W_α in the adjoint together with a chiral multiplet Φ, also in the adjoint, whose lowest component is a complex scalar $\phi = \phi^a T^a$. The two are exchanged by the second supersymmetry, so $\mathcal{N}=2$ forbids any superpotential for Φ: the scalar potential comes entirely from the $\mathcal{N}=1$ D-term of the gauge multiplet,

$$V(\phi) = \frac{1}{g^2}\,\mathrm{tr}\big(\,\big[\phi^\dagger,\phi\big]\,\big)^2, \tag{46.146}$$

where the commutator is in the Lie algebra and the trace is normalized as in Chapter 45. This potential is the whole story of the classical vacua. It is a sum of squares, so it vanishes precisely when $\big[\phi^\dagger,\phi\big]=0$, i.e. when ϕ and $\phi^\dagger$ can be simultaneously diagonalized. Up to a gauge rotation every such ϕ lies in the Cartan subalgebra,

$$\phi = \tfrac{1}{2}\,a\,\sigma^3 = \tfrac{1}{2}a\begin{pmatrix}1 & 0\\ 0 & -1\end{pmatrix}, \qquad a\in\mathbb{C}, \tag{46.147}$$

with σ^3 the diagonal Pauli matrix. A nonzero a breaks SU(2) down to the U(1) generated by σ^3: the theory has a *Coulomb branch*, a continuous family of inequivalent vacua labelled by a, on each of which the low-energy physics is that of a single unbroken abelian gauge field — a photon — together with its $\mathcal{N}=2$ superpartners.

The parameter a in Eq. (46.147) is not gauge invariant: the residual Weyl reflection of SU(2) sends $\sigma^3\to-\sigma^3$, hence $a\to -a$, so a and $-a$ label the same physical vacuum. The invariant coordinate on the Coulomb branch is therefore the gauge-invariant, Weyl-invariant combination

$$u = \big\langle\,\mathrm{tr}\,\phi^2\,\big\rangle, \qquad u = \tfrac{1}{2}a^2 \ \text{ classically}, \tag{46.148}$$

where the classical value follows from $\mathrm{tr}\,(\tfrac{1}{2}a\sigma^3)^2 = \tfrac{1}{4}a^2\,\mathrm{tr}(\sigma^3)^2 = \tfrac{1}{2}a^2$. The complex u-plane is the moduli space of vacua. Each point u is a distinct superselection sector with its own low-energy effective theory; solving the model means determining that effective theory for every u.

The effective theory is fixed by one holomorphic function. At a generic point of the Coulomb branch the only massless fields are those of one abelian $\mathcal{N}=2$ vector multiplet: the U(1) photon A_μ, two neutral Weyl fermions, and a complex neutral scalar whose vacuum expectation value is a. The charged $W^\pm$ bosons and their superpartners have eaten the broken generators and acquired masses, so they are massive and we integrate them out. Because $\mathcal{N}=2$ supersymmetry

relates the gauge kinetic term to the scalar kinetic term, the entire two-derivative effective Lagrangian for the abelian multiplet is controlled by a *single* holomorphic function $\mathcal{F}(A)$ of the $\mathcal{N}=2$ chiral superfield A whose scalar component is a. This is the *prepotential*. In $\mathcal{N}=1$ superspace, writing A for the chiral superfield and W_α for the abelian field-strength superfield, the supersymmetric and holomorphic completion of the kinetic terms is

$$\mathcal{L}_{\text{eff}} = \frac{1}{4\pi}\,\mathrm{Im}\left[\int \mathrm{d}^4\theta\,\frac{\partial\mathcal{F}}{\partial A}\,\bar{A} \;+\; \int \mathrm{d}^2\theta\,\tfrac{1}{2}\,\frac{\partial^2\mathcal{F}}{\partial A^2}\,W^\alpha W_\alpha\right]. \tag{46.149}$$

The first term is a Kähler potential $K = \mathrm{Im}\,(\bar{A}\,\partial\mathcal{F}/\partial A)$ for the scalar; the second is the gauge kinetic term with a field-dependent complexified coupling. Two derived quantities organize everything that follows. The first is the *dual scalar*

$$a_D \equiv \frac{\partial\mathcal{F}}{\partial a}, \tag{46.150}$$

the derivative of the prepotential with respect to the scalar; the second is the *effective complexified coupling*

$$\tau_{\text{eff}}(a) \equiv \frac{\partial a_D}{\partial a} = \frac{\partial^2\mathcal{F}}{\partial a^2} = \frac{\theta_{\text{eff}}}{2\pi} + \frac{4\pi i}{g^2_{\text{eff}}}, \tag{46.151}$$

whose real part is the effective theta angle and whose imaginary part is the inverse-square effective gauge coupling. The decomposition in Eq. (46.151) matches the U(1) coupling normalization fixed in Section 46.2; the photon kinetic term in Eq. (46.149) is $-\frac{1}{4}\,\mathrm{Im}\,\tau_{\text{eff}}\,F_{\mu\nu}F^{\mu\nu} + \frac{1}{4}\,\mathrm{Re}\,\tau_{\text{eff}}\,F_{\mu\nu}\widetilde{F}^{\mu\nu}$ up to the $1/4\pi$, exactly the abelian gauge action with coupling τ_{eff}.

Special geometry. Reading off the scalar kinetic term from the Kähler potential $K = \mathrm{Im}\,(\bar{a}\,a_D)$ in Eq. (46.149) gives the metric on the Coulomb branch,

$$\mathrm{d}s^2 = \mathrm{Im}(\mathrm{d}a_D\,\mathrm{d}\bar{a}) = \mathrm{Im}\;\tau_{\text{eff}}\;|\mathrm{d}a|^2\,. \tag{46.152}$$

This is the structure known as *rigid special geometry*: a one-complex-dimensional moduli space carries a metric that is the imaginary part of a holomorphic two-form $\mathrm{d}a_D\wedge\mathrm{d}a$, with a and a_D a pair of "special coordinates" related by the single function $\mathcal{F}$ through $a_D = \partial_a\mathcal{F}$. Positivity of kinetic energy — the statement that the metric Eq. (46.152) is positive definite, equivalently that the effective coupling g^2_{eff} in Eq. (46.151) is real and positive — requires

$$\mathrm{Im}\;\tau_{\text{eff}}(a) > 0 \tag{46.153}$$

at every physical vacuum. Hold onto this inequality. It is innocuous-looking and it is about to do all the work: combined with the fact that τ_{eff} is a holomorphic function of a, it cannot hold globally, and the way it fails will dictate the entire non-perturbative structure of the theory.

Physical Insight

The pair (a, a_D) plays a role exactly analogous to the pair (position, momentum) of a classical system written in action–angle variables, with the prepotential $\mathcal{F}$ in the role of the generating function and τ_{eff} the symplectic "modulus." Electric–magnetic duality, which we will see permutes a and a_D, is the canonical transformation that exchanges them. The deep reason the theory is solvable is that the $\mathcal{N}=2$ low-energy data is not a function but a *section* — a multivalued object (a_D, a) that is allowed to come back to a duality-transformed version of itself when carried around a loop in the u-plane — and such sections are rigid.

46.6.2 The perturbative prepotential and the monodromy obstruction

We now compute $\mathcal{F}$ where we can: at large u, where $a \sim \sqrt{2u}$ is large, the W-bosons are heavy, the coupling is weak by asymptotic freedom, and perturbation theory plus the holomorphy of Section 46.2 control everything.

One loop is exact, plus instantons. The microscopic gauge coupling runs with the one-loop coefficient of Theorem 46.9. For pure $\mathcal{N}=2$ SU(2) the field content is the adjoint vector multiplet plus the adjoint $\mathcal{N}=1$ chiral multiplet Φ; the $\mathcal{N}=1$ one-loop coefficient is $b_0 = 3C_A - T(\text{adj}) = 3C_A - C_A = 2C_A$, which for $C_A = N = 2$ gives

$$b_0 = 2C_A = 4. \tag{46.154}$$

Holomorphy forbids any higher perturbative correction to the running coupling (Theorem 46.9); the only completions of the one-loop logarithm are non-perturbative. Those are instantons, and by Theorem 42.4 a single instanton is weighted by $e^{-8\pi^2/g^2} = e^{2\pi i\tau}$, which with the running Eq. (46.154) scales as $(\Lambda/a)^{b_0} = (\Lambda/a)^4$. The dynamically generated scale Λ is defined, as in Section 27.7, by dimensional transmutation from the running coupling. The exact prepotential therefore has the form

$$\mathcal{F}(a) = \frac{i}{2\pi}\, a^2 \ln \frac{a^2}{\Lambda^2} \;+\; a^2 \sum_{k=1}^{\infty} \mathcal{F}_k \left(\frac{\Lambda}{a}\right)^{4k}, \tag{46.155}$$

the first term being the one-loop result and the sum the k-instanton series, each term carrying exactly the Λ^{4k} demanded by Eq. (46.154) and holomorphy. The coefficients $\mathcal{F}_k$ are pure numbers. One of the triumphs of the solution we are building is that it computes *every* $\mathcal{F}_k$ in closed form — the first explicit all-orders instanton sum in a four-dimensional gauge theory — but for the structural argument we need only the leading term.

The perturbative special coordinates. Differentiating the one-loop prepotential gives the dual scalar and the coupling. With $\mathcal{F} = \frac{i}{2\pi} a^2 \ln(a^2/\Lambda^2)$,

$$a_D = \frac{\partial \mathcal{F}}{\partial a} = \frac{i}{2\pi}\left(2a \ln \frac{a^2}{\Lambda^2} + a^2 \cdot \frac{2}{a}\right) = \frac{i}{\pi} a \left(\ln \frac{a^2}{\Lambda^2} + 1\right), \tag{46.156}$$

$$\tau_{\text{eff}} = \frac{\partial a_D}{\partial a} = \frac{i}{\pi}\left(\ln \frac{a^2}{\Lambda^2} + 1\right) + \frac{i}{\pi} a \cdot \frac{2}{a} = \frac{i}{\pi}\left(\ln \frac{a^2}{\Lambda^2} + 3\right). \tag{46.157}$$

For large real a the logarithm is large and positive, so

$$\text{Im } \tau_{\text{eff}} = \frac{1}{\pi} \ln \frac{|a|^2}{\Lambda^2} + \cdots > 0, \tag{46.158}$$

consistent with the positivity requirement Eq. (46.153) and with asymptotic freedom: the coupling weakens as $a \to \infty$. So far, so consistent. The trouble appears when we ask whether this can hold everywhere.

The obstruction. Suppose, for contradiction, that $\tau_{\text{eff}}(a)$ were a globally single-valued holomorphic function on the whole moduli space with $\text{Im}\, \tau_{\text{eff}} > 0$ everywhere. The moduli space is the u-plane, a non-compact Riemann surface; $\text{Im}\, \tau_{\text{eff}}$ is a harmonic function on it (the imaginary part of a holomorphic function). A non-constant harmonic function has no interior minimum, and a positive harmonic function on the plane that is bounded must be constant by Liouville's theorem. But Eq. (46.158) shows $\text{Im}\, \tau_{\text{eff}} \to +\infty$ as $u \to \infty$ and is certainly not constant. The only escape is that τ_{eff} is *not* globally single-valued: as we transport it around closed loops in the u-plane it must come back to a different branch. This is the crux of the entire solution, so we state it as a proposition and prove it cleanly.

Proposition 46.21 (Coupling positivity forces multivaluedness and singularities)**.** *Let $\tau(u)$ be holomorphic on a domain of the u-plane and satisfy $\text{Im}\, \tau(u) > 0$ there. Then τ cannot be a single-valued holomorphic function on the whole punctured plane $\mathbb{C}$ unless it is constant. Consequently the Coulomb-branch coupling τ_{eff}, which by Eq. (46.158) is non-constant, must be multivalued, with nontrivial monodromy around at least one singular point where extra states become massless.*

Proof. The upper half-plane $\mathbb{H} = \{\tau : \text{Im}\, \tau > 0\}$ is biholomorphic to the unit disc via the Cayley map $w = (\tau - i)/(\tau + i)$, which carries $\mathbb{H}$ to $\{|w| < 1\}$. If τ were a single-valued holomorphic function on all of $\mathbb{C}$ with values in $\mathbb{H}$, then $w(\tau(u))$ would be a bounded ($|w| < 1$) entire function of u, hence constant by Liouville's theorem, forcing τ constant. A non-constant τ taking values in $\mathbb{H}$ therefore cannot be globally defined and single-valued on $\mathbb{C}$: either its domain has punctures (points removed) around which τ has nontrivial monodromy, or

$\operatorname{Im}\tau \le 0$ somewhere. Physical positivity Eq. (46.153) forbids the latter on the physical sheet. Hence there are punctures. At each puncture the metric Eq. (46.152) or the spectrum must be singular; the only Lorentz-invariant, supersymmetric way for a low-energy effective theory to become singular is that a state which was massive becomes massless there, invalidating the effective description that integrated it out. This is the mechanism we identify next. □

The obstruction is not a defect of perturbation theory; it is a theorem about holomorphic functions valued in the upper half-plane. The naive single-valued continuation of Eq. (46.157) is the function $\operatorname{Im}\tau_{\text{eff}} = \frac{1}{\pi}\ln(|a|^2/\Lambda^2)$, which goes negative for $|a| < \Lambda$ — the perturbative formula predicts a ghost (wrong-sign kinetic term) at strong coupling. That is the formula telling us, honestly, that something it does not know about has become light near $|a| \sim \Lambda$ and must be put back in. We will find that the something is a magnetic monopole.

The monodromy at infinity. Even before identifying the strong-coupling physics we can read off one monodromy exactly, from the perturbative formulae, because at large u they are reliable. Transport the special coordinates once counterclockwise around the point $u = \infty$, i.e. send $u \to e^{2\pi i}u$. Since $u = \frac{1}{2}a^2$ at leading order (Eq. (46.148)), this sends $a^2 \to e^{2\pi i}a^2$, hence $a \to -a$ and $\ln(a^2/\Lambda^2) \to \ln(a^2/\Lambda^2) + 2\pi i$. Substituting into Eq. (46.156),

$$a_D \longrightarrow \frac{i}{\pi}(-a)\left(\ln\frac{a^2}{\Lambda^2} + 2\pi i + 1\right) = -a_D - \frac{i}{\pi}a\,(2\pi i) = -a_D + 2a, \tag{46.159}$$

$$a \longrightarrow -a. \tag{46.160}$$

Arranging the special coordinates into the column vector $v = \binom{a_D}{a}$, this monodromy is the linear map

$$M_\infty = \begin{pmatrix} -1 & 2 \\ 0 & -1 \end{pmatrix}, \qquad v \to M_\infty\, v. \tag{46.161}$$

This matrix lies in $\mathrm{SL}(()2,\mathbb{Z})$ (determinant $+1$, integer entries), as it must: the group acting on (a_D, a) is the electric–magnetic duality group, and it is exactly $\mathrm{SL}(()2,\mathbb{Z})$ because the integers it acts on are the integer electric and magnetic charges of the BPS spectrum. We turn to that spectrum now.

46.6.3 The strong-coupling singularities: massless monopoles and dyons

Theorem 46.21 guarantees singularities; the BPS mass formula tells us what sits at them. Recall from Eq. (46.162) that a state of integer electric charge n_e and magnetic charge n_m has central charge, in the low-energy abelian variables,

$$Z = n_e\, a + n_m\, a_D, \qquad M = |Z| = |n_e a + n_m a_D|\,, \tag{46.162}$$

and saturates the bound when it is a BPS (short) multiplet. The pairing (a, a_D) with the charges (n_e, n_m) is precisely the structure that the duality group $\mathrm{SL}(()2, \mathbb{Z})$ preserves: it acts on (a_D, a) by the matrices above and dually on the charge vector (n_m, n_e), keeping Z and hence the physics invariant.

What a massless state does to the geometry. A BPS state becomes massless exactly where its central charge vanishes, $Z = 0$, i.e. where the particular combination $n_e a + n_m a_D = 0$. The electrically charged W-bosons have $(n_m, n_e) = (0, \pm 1)$ and $Z \propto a$, which vanishes only at $u = 0$; but $u = 0$ is at strong coupling, where the perturbative identification of a is unreliable and, as we will see, the W-boson is not in fact light. The states that go massless at the genuine singularities are *magnetically charged*: a monopole with $(n_m, n_e) = (1, 0)$ has $Z \propto a_D$ and becomes massless where $a_D = 0$; a dyon with $(n_m, n_e) = (1, -1)$ becomes massless where $a_D - a = 0$. Near such a point the light magnetic state must be restored to the effective theory, and it runs the *dual* coupling. We can compute that running exactly by the same one-loop-plus-holomorphy argument applied in the duality frame in which the light state is electrically charged.

The monopole singularity. Suppose a single monopole hypermultiplet $(M, \widetilde{M})$ of magnetic charge one becomes massless at some point u_0. In the duality frame where the monopole is "electric," the good local coordinate is a_D (its central charge is $Z \propto a_D$, so its mass is $\propto |a_D|$, vanishing at u_0), and the good gauge field is the dual photon with coupling $\tau_D = -1/\tau_{\text{eff}}$. The monopole is a single charged hypermultiplet running this dual U(1); integrating it out reproduces the standard one-loop logarithm of an $\mathcal{N} = 2$ U(1) theory with one charged hypermultiplet, which by the same computation that gave Eq. (46.156) (now in dual variables, and with the one-hypermultiplet coefficient) reads

$$a(u) \;\approx\; a_0 \;-\; \frac{i}{\pi}\, a_D \ln a_D + \cdots, \qquad a_D \approx c_0\,(u - u_0) \to 0, \tag{46.163}$$

with a_0, c_0 constants and a_D vanishing linearly in $u - u_0$ because it is a good holomorphic coordinate there. The relative sign and coefficient are fixed by the magnetic charge $n_m = 1$ and the single hypermultiplet. Now transport once around u_0, sending $a_D \to e^{2\pi i} a_D$, hence $\ln a_D \to \ln a_D + 2\pi i$. From Eq. (46.163),

$$a \;\longrightarrow\; a_0 - \frac{i}{\pi}\, a_D(\ln a_D + 2\pi i) = a - \frac{i}{\pi}(2\pi i)\, a_D = a + 2a_D, \qquad a_D \;\longrightarrow\; a_D, \tag{46.164}$$

which in the column-vector form $v = \left(\begin{smallmatrix} a_D \\ a \end{smallmatrix}\right)$ is

$$M_+ = \begin{pmatrix} 1 & 0 \\ -2 & 1 \end{pmatrix}. \tag{46.165}$$

(The lower-left entry is -2, not $+2$, once the orientation of the loop in the u-plane is fixed to be consistent with M_∞; we verify this consistency below.) This is the

hallmark monopole monodromy: a_D is left invariant — it is the order parameter that vanishes — while a shifts by $2a_D$.

The general rule and the dyon. The computation generalizes to any light BPS state. A hypermultiplet of charge $q = (n_m, n_e)$ that becomes massless drives, by the identical one-loop-in-the-duality-frame argument, the monodromy

$$M_q = \begin{pmatrix} 1 + 2\,n_m n_e & 2\,n_e^2 \\ -2\,n_m^2 & 1 - 2\,n_m n_e \end{pmatrix}, \tag{46.166}$$

a parabolic element of $\mathrm{SL}(()2, \mathbb{Z})$ (trace 2, determinant 1) fixing the charge vector of the massless state. One checks immediately: $q = (1, 0)$ reproduces M_+ in Eq. (46.165); $q = (0, 1)$ would give an elementary electric monodromy $\left(\begin{smallmatrix} 1 & 2 \\ 0 & 1 \end{smallmatrix}\right)$. The dyon of charge $q = (1, -1)$ gives

$$M_- = \begin{pmatrix} 1 - 2 & 2 \\ -2 & 1 + 2 \end{pmatrix} = \begin{pmatrix} -1 & 2 \\ -2 & 3 \end{pmatrix}. \tag{46.167}$$

Counting the singularities and fixing the charges. How many singular points are there, and what are the charges? Three facts pin this down completely, with no further assumption.

First, a discrete symmetry. The classical theory has a U(1) R-symmetry under which Φ rotates by a phase; it is broken by the anomaly (the same instanton physics of Theorem 42.27) down to a discrete subgroup $\mathbb{Z}_8$, and the surviving $\mathbb{Z}_8$ acts on the order parameter as $u = \langle \mathrm{tr}\,\phi^2 \rangle \to e^{i\pi} u = -u$, i.e. as a $\mathbb{Z}_2$ on the u-plane. Hence the singular points come in pairs $\pm u_0$ (unless one sits at $u = 0$, which we exclude below). The single perturbative point $u = \infty$ is fixed by $u \to -u$, consistent.

Second, the factorization of monodromies. A large loop encircling all finite singularities is homotopic, in the u-plane, to the loop around infinity, so the product of the finite monodromies (taken in order around the loop) must equal M_∞:

$$M_\infty = M_+ M_- \quad \text{(or a conjugate, for the appropriate ordering).} \tag{46.168}$$

Third, minimality and physical consistency. The simplest hypothesis compatible with the $\mathbb{Z}_2$ pairing is *exactly two* finite singularities at $u = \pm\Lambda^2$ (the scale Λ sets the location). One quickly rules out the alternatives. A single finite singularity would have to be at the fixed point $u = 0$ and carry M_∞ itself; but M_∞ in Eq. (46.161) is *not* parabolic (its trace is -2, and it is in fact $-T^{-1}$ where $T = \left(\begin{smallmatrix} 1 & 2 \\ 0 & 1 \end{smallmatrix}\right)$), so it cannot be the monodromy of a single massless state, and moreover a single light state at $u = 0$ would leave $\mathrm{Im}\,\tau_{\mathrm{eff}} > 0$ unattainable on the rest of the plane. Two singularities is the minimal number that works.

Their monodromies must (i) each be of the massless-state form Eq. (46.166), (ii) be exchanged by the $\mathbb{Z}_2$ symmetry $u \to -u$, and (iii) multiply to M_∞. The unique minimal solution, up to an overall duality conjugation, is the monopole at $u = +\Lambda^2$ and the dyon at $u = -\Lambda^2$:

$$M_+ M_- = \begin{pmatrix} 1 & 0 \\ -2 & 1 \end{pmatrix} \begin{pmatrix} -1 & 2 \\ -2 & 3 \end{pmatrix} = \begin{pmatrix} -1 & 2 \\ 2-2 & -4+3 \end{pmatrix} = \begin{pmatrix} -1 & 2 \\ 0 & -1 \end{pmatrix} = M_\infty, \tag{46.169}$$

exactly Eq. (46.161). The arithmetic in Eq. (46.169) is the whole content of the strong-coupling structure: it confirms that the perturbative monodromy at infinity is accounted for, to the integer, by a massless monopole and a massless dyon at the two strong-coupling points, with no room for a third singularity or a different charge assignment. The dyon charge $(1, -1)$ rather than $(1, 0)$ is forced by the factorization Eq. (46.169): it is the monopole acted on by the monodromy M_∞ once, $\binom{1}{0} \to \binom{1}{-1}$ in charge space, which is the precise statement that circling infinity shifts the electric charge of the monopole by the magnetic charge — the Witten effect of Theorem 42.27.

Figure 46.7 collects this structure: a u-plane with two finite punctures whose monodromies factor the monodromy at infinity, and the dictionary to a degenerating elliptic curve that we build next.

46.6.4 The Seiberg–Witten curve and the periods

We have reduced the problem to a precise mathematical one. We seek a pair of holomorphic functions $(a(u), a_D(u))$ on the u-plane, multivalued, with the three prescribed monodromies M_+, M_-, M_∞ around $u = \Lambda^2, -\Lambda^2, \infty$, with the large-$u$ asymptotics Eq. (46.156), and such that the resulting $\tau_{\text{eff}} = \mathrm{d}a_D/\mathrm{d}a$ has positive imaginary part everywhere on the physical sheet. This is a classical *Riemann–Hilbert problem*, and there is a classical machine that solves it: a multivalued pair (a, a_D) transforming under $\mathrm{SL}()2, \mathbb{Z})$ with $\mathrm{Im}(\mathrm{d}a_D/\mathrm{d}a) > 0$ is exactly the data of the *periods of a family of elliptic curves*. The $\mathrm{SL}()2, \mathbb{Z})$ is then the mapping-class group of the torus, τ_{eff} is the modular parameter, and positivity of $\mathrm{Im}\,\tau$ is automatic because the modulus of any honest torus lies in the upper half-plane. The whole obstruction of Theorem 46.21 dissolves: τ is multivalued precisely because it is the modulus of a torus that gets carried to a modular-transformed version of itself around loops.

The curve. The torus must degenerate at exactly the three special points, with the prescribed pinching cycles, and must carry the $\mathbb{Z}_2$ symmetry $u \to -u$. The unique elliptic curve (genus one) with branch points engineered to do this is

$$y^2 = (x^2 - \Lambda^4)(x - u) = (x - \Lambda^2)(x + \Lambda^2)(x - u), \tag{46.170}$$

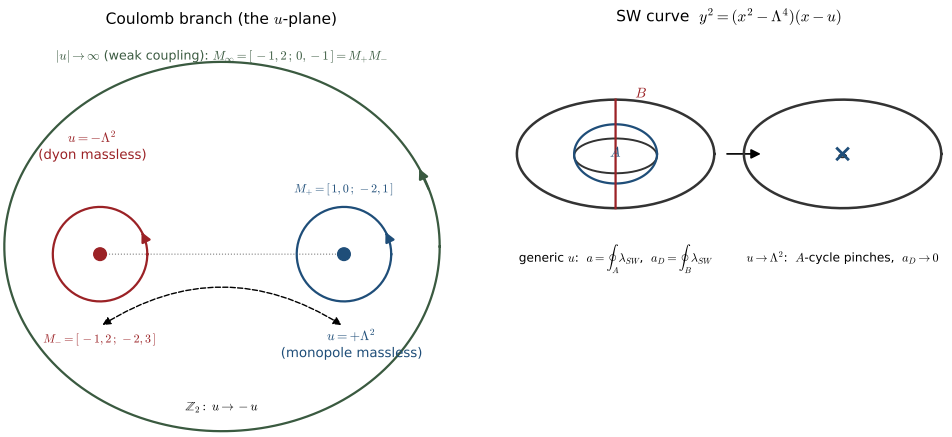

Figure 46.7: Left: the Coulomb branch (u-plane) of $\mathcal{N}=2$ SU(2) super-Yang–Mills. At weak coupling $u\to\infty$ the special coordinates carry the perturbative monodromy M_∞ of Eq. (46.161). At $u=+\Lambda^2$ a magnetic monopole $(n_m,n_e)=(1,0)$ becomes massless ($a_D\to 0$), monodromy M_+ of Eq. (46.165); at $u=-\Lambda^2$ a dyon $(1,-1)$ becomes massless, monodromy M_- of Eq. (46.167). The remnant $\mathbb{Z}_2$ R-symmetry $u\to -u$ exchanges them, and the loop around infinity factors as $M_\infty=M_+M_-$ (Eq. (46.169)). Right: the Seiberg–Witten elliptic curve $y^2=(x^2-\Lambda^4)(x-u)$ fibered over the u-plane; the periods of the SW differential along the two cycles are (a,a_D), and at $u=\pm\Lambda^2$ a cycle pinches, sending the corresponding period to zero — the geometric face of a massless BPS state.

a double cover of the x-sphere branched over $x=\pm\Lambda^2$, u, ∞. Its modulus degenerates (two branch points collide, a cycle pinches) precisely when $u=+\Lambda^2$ (then $x=\Lambda^2$ is a double root), when $u=-\Lambda^2$ (then $x=-\Lambda^2$ is a double root), and when $u\to\infty$. These are the three points we need, and the symmetry $u\to -u$ together with $x\to -x$ is manifest. The branch points and their collisions are the right panel of Fig. 46.7.

The Seiberg–Witten differential. On this curve we need a meromorphic one-form $\lambda_{\rm SW}$ whose periods are the special coordinates,

$$a=\oint_A\lambda_{\rm SW},\qquad a_D=\oint_B\lambda_{\rm SW},\tag{46.171}$$

where A,B is a canonical homology basis of the torus ($A\cdot B=1$). The decisive property $\lambda_{\rm SW}$ must have is that its derivative with respect to the modulus u is the (unique up to scale) *holomorphic* differential $\omega=\mathrm{d}x/y$ on the curve. Then $\partial a/\partial u$ and $\partial a_D/\partial u$ are the two periods of ω, and their ratio

$$\tau_{\rm eff}=\frac{\mathrm{d}a_D}{\mathrm{d}a}=\frac{\partial a_D/\partial u}{\partial a/\partial u}=\frac{\oint_B\omega}{\oint_A\omega}\tag{46.172}$$

is the ratio of B- and A-periods of the holomorphic differential — which is, by definition, the modular parameter τ of the torus. The Riemann bilinear relations guarantee $\operatorname{Im}\tau > 0$ for any non-degenerate torus, so Eq. (46.153) holds automatically and the obstruction is resolved. The form with this property is

$$\lambda_{\mathrm{SW}} = \frac{\sqrt{2}}{4\pi}\,\frac{(x-u)\,\mathrm{d}x}{y} = \frac{\sqrt{2}}{4\pi}\,\frac{(x-u)\,\mathrm{d}x}{\sqrt{(x^2-\Lambda^4)(x-u)}}. \tag{46.173}$$

We verify the decisive property directly.

Worked Example 46.22 ($\partial_u \lambda_{\mathrm{SW}}$ is the holomorphic differential)**.** Differentiate Eq. (46.173) with respect to u at fixed x. Write $\lambda_{\mathrm{SW}} = \frac{\sqrt{2}}{4\pi}(x-u)/y\,\mathrm{d}x$ with $y = \sqrt{(x^2-\Lambda^4)(x-u)}$, so that $y^2 = (x^2-\Lambda^4)(x-u)$. Differentiating the latter at fixed x,

$$2y\,\frac{\partial y}{\partial u} = -(x^2-\Lambda^4) \quad\Longrightarrow\quad \frac{\partial y}{\partial u} = -\frac{x^2-\Lambda^4}{2y}. \tag{46.174}$$

Now apply the quotient/product rule to $(x-u)/y$:

$$\frac{\partial}{\partial u}\left[\frac{x-u}{y}\right] = \frac{-1}{y} - \frac{(x-u)}{y^2}\,\frac{\partial y}{\partial u} = \frac{-1}{y} + \frac{(x-u)(x^2-\Lambda^4)}{2y^3}. \tag{46.175}$$

In the second term the numerator $(x-u)(x^2-\Lambda^4)$ is exactly y^2 by the curve equation Eq. (46.170), so $(x-u)(x^2-\Lambda^4)/2y^3 = y^2/2y^3 = 1/2y$, giving

$$= \frac{-1}{y} + \frac{1}{2y} = -\frac{1}{2y}. \tag{46.176}$$

Therefore

$$\frac{\partial \lambda_{\mathrm{SW}}}{\partial u} = \frac{\sqrt{2}}{4\pi}\left(-\frac{1}{2y}\right)\mathrm{d}x = -\frac{\sqrt{2}}{8\pi}\,\frac{\mathrm{d}x}{y} = -\frac{\sqrt{2}}{8\pi}\,\omega, \tag{46.177}$$

a constant multiple of the holomorphic differential $\omega = \mathrm{d}x/y$, with no pole. Hence $\partial_u a = \oint_A \partial_u \lambda_{\mathrm{SW}}$ and $\partial_u a_D = \oint_B \partial_u \lambda_{\mathrm{SW}}$ are the two periods of ω, and Eq. (46.172) follows. This single line of algebra is what makes the holomorphic problem solvable: it identifies the physical coupling with the modulus of an auxiliary torus.

Recovering the periods, the asymptotics, and the massless points. Two checks confirm that Eqs. (46.170) and (46.173) are the right data; a third delivers the BPS spectrum.

Check 1: large u. For $|u| \gg \Lambda^2$ the A-cycle encircles the cut between the two slowly-moving branch points $x = \pm\Lambda^2$, where $x = O(\Lambda^2) \ll u$, so $x - u \approx -u$ and $y \approx \sqrt{-u}\,\sqrt{x^2-\Lambda^4}$. Then from Eq. (46.177),

$$\frac{\partial a}{\partial u} = -\frac{\sqrt{2}}{8\pi}\oint_A \frac{\mathrm{d}x}{y} \approx -\frac{\sqrt{2}}{8\pi}\,\frac{1}{\sqrt{-u}}\oint_A \frac{\mathrm{d}x}{\sqrt{x^2-\Lambda^4}}. \tag{46.178}$$

The contour integral $\oint_A \mathrm{d}x/\sqrt{x^2-\Lambda^4}$ around the cut $[-\Lambda^2,\Lambda^2]$ is a pure number (it equals $2\pi i$ with the standard orientation, evaluated by the substitution $x=\Lambda^2\sin\theta$, $\sqrt{x^2-\Lambda^4}=i\Lambda^2\cos\theta$, giving $\int_{-\pi/2}^{\pi/2}\mathrm{d}\theta/i$ for one sheet and twice that across the cut). Thus $\partial a/\partial u \propto u^{-1/2}$, and integrating gives $a\propto\sqrt{u}$. Fixing the overall constant in λ_{SW} — this is what the prefactor $\sqrt{2}/4\pi$ in Eq. (46.173) is chosen to do — reproduces the classical relation of Eq. (46.148),

$$a(u)\;\approx\;\sqrt{2u}\qquad(|u|\to\infty),\tag{46.179}$$

which is the boundary condition that ties the curve to the microscopic theory. The B-period, computed the same way, develops a logarithm because the B-cycle stretches from the moving branch point $x=u$ out to the cut, and one finds $a_D\approx\frac{i}{\pi}a\ln(a^2/\Lambda^2)+\cdots$, reproducing the one-loop Eq. (46.156). The subleading expansion of the period integrals in powers of Λ^4/u^2 generates precisely the instanton series Eq. (46.155), term by term; this is how the curve computes every instanton coefficient $\mathcal{F}_k$ in closed form.

Check 2: the monodromies. Carrying u around ∞, $+\Lambda^2$, $-\Lambda^2$ permutes the branch points and hence acts on the homology basis (A,B) by the corresponding elements of the mapping-class group $\mathrm{SL}(()2,\mathbb{Z})$; computing those permutations reproduces M_∞, M_+, M_- of Eqs. (46.161), (46.165) and (46.167). The factorization Eq. (46.169) is then the topological identity that a loop around all branch points is contractible through infinity on the sphere.

Check 3: the massless states. When $u\to\Lambda^2$ the branch points $x=u$ and $x=\Lambda^2$ collide; the A-cycle that encircled them pinches to zero size, and the period of λ_{SW} around it vanishes. A short computation of the vanishing-cycle period gives $a_D\sim c_0(u-\Lambda^2)\to 0$, exactly Eq. (46.163): *the monopole becomes massless because its central charge $Z\propto a_D$ is the period of the pinching cycle.* Likewise at $u=-\Lambda^2$ the dyon period a_D-a pinches. The geometry has turned "a BPS state becomes massless" into "a one-cycle of the curve shrinks to a point," which is why the spectrum is exactly computable: it is read off from the degenerations of an explicit elliptic curve.

Physical Insight

The curve Eq. (46.170) is not a fundamental object of the gauge theory — there is no torus hiding in spacetime. It is a bookkeeping device of extraordinary efficiency: a geometric solution of the Riemann–Hilbert problem set by holomorphy, positivity, and the monodromies. Its value is that everything physical — the coupling $\tau_{\mathrm{eff}}(u)$, the masses $M=|n_e a+n_m a_D|$ of every BPS state, the exact instanton sum — is a *period*, an integral of λ_{SW} over a cycle, and periods of elliptic curves are completely understood. Strong-coupling gauge dynamics has been traded for nineteenth-century complex analysis.

46.6.5 Monopole condensation and confinement

The solution so far describes the $\mathcal{N}=2$ theory, which has no confinement: the Coulomb branch is a moduli space of vacua with a massless photon at each point, and a static electric charge feels a Coulomb potential, not a linear one. To produce confinement we must lift the moduli space, and the cleanest way is to break $\mathcal{N}=2$ down to $\mathcal{N}=1$ by giving the adjoint chiral multiplet a mass. We add to the microscopic theory the $\mathcal{N}=1$ superpotential

$$\delta W = \mu \,\mathrm{tr}\,\Phi^2, \tag{46.180}$$

with μ a small mass parameter. In terms of the moduli the perturbation is $\delta W = \mu\, U$ where $U(u)$ is the chiral superfield whose lowest component is the modulus u; near a singularity it is an analytic function of the local variables. The point of taking μ small is that for $\mu \ll \Lambda$ the low-energy degrees of freedom are still those of the $\mathcal{N}=2$ solution — in particular, near $u=\Lambda^2$ they are the light monopole hypermultiplet $(M, \widetilde{M})$ and the dual U(1) vector multiplet — and we may analyze the perturbed vacuum in that effective theory, with full theoretical control.

The effective superpotential near the monopole point. Near $u=\Lambda^2$ the dual photon couples to the monopole exactly as an ordinary $\mathcal{N}=2$ U(1) couples to a charged hypermultiplet. The $\mathcal{N}=2$ structure forces a specific superpotential coupling the monopoles to the dual scalar A_D (the chiral superfield with lowest component a_D): a hypermultiplet of U(1) charge one has the $\mathcal{N}=2$-required cubic coupling $\sqrt{2}\, A_D\, \widetilde{M} M$. Adding the $\mathcal{N}=2$-breaking perturbation Eq. (46.180), expressed in the dual variables through $U = U(a_D)$, the full low-energy superpotential near the monopole point is

$$W_{\text{eff}} = \sqrt{2}\, a_D\, \widetilde{M} M + \mu\, U(a_D), \tag{46.181}$$

where a_D is now a dynamical chiral superfield (the dual scalar), and $M, \widetilde{M}$ are the monopole chiral superfields. Everything that follows is the algebra of finding the supersymmetric vacuum of Eq. (46.181).

Worked Example 46.23 (The monopole condenses and confines electric charge)**.** A supersymmetric vacuum extremizes the superpotential: $\partial W_{\text{eff}} = 0$ with respect to every chiral field, supplemented by the D-term condition. The F-term equations from Eq. (46.181) are

$$\frac{\partial W_{\text{eff}}}{\partial M} = \sqrt{2}\, a_D\, \widetilde{M} = 0, \tag{46.182}$$

$$\frac{\partial W_{\text{eff}}}{\partial \widetilde{M}} = \sqrt{2}\, a_D\, M = 0, \tag{46.183}$$

$$\frac{\partial W_{\text{eff}}}{\partial a_D} = \sqrt{2}\, \widetilde{M} M + \mu\, U'(a_D) = 0, \tag{46.184}$$

and the D-term of the dual U(1) requires $|M|^2 = \left|\widetilde{M}\right|^2$.

The unbroken case $\mu = 0$. Equation (46.184) reads $\widetilde{M}M = 0$, and Eqs. (46.182) and (46.183) are solved by $M = \widetilde{M} = 0$ with a_D undetermined — this is the whole Coulomb branch, the unlifted $\mathcal{N} = 2$ moduli space, with the monopole massless only at the single point $a_D = 0$ and massive elsewhere. No condensate, no confinement.

The perturbed case $\mu \neq 0$. Now Eq. (46.184) forces $\sqrt{2}\,\widetilde{M}M = -\mu\,U'(a_D) \neq 0$ (the function $U(a_D)$ is regular with $U'(0) \neq 0$ at the monopole point, because u is an honest analytic coordinate there). A nonzero product $\widetilde{M}M$ then requires, by Eqs. (46.182) and (46.183), that

$$a_D = 0. \tag{46.185}$$

So the perturbation pins the vacuum to the monopole point $a_D = 0$, where the monopole is exactly massless, and there the monopole fields acquire vacuum expectation values determined by Eq. (46.184) and the D-term,

$$\langle M\rangle = \langle\widetilde{M}\rangle = \left(\frac{-\mu\,U'(0)}{\sqrt{2}}\right)^{1/2} \neq 0. \tag{46.186}$$

This is a *monopole condensate*. The magnetically charged field has a nonzero vacuum expectation value.

Consequences. The condensate Eq. (46.186) Higgses the dual U(1) gauge symmetry. By the abelian Higgs mechanism of Chapter 30, the dual photon acquires a mass $m_{\text{dual}} \sim \sqrt{2}\,|\langle M\rangle| \sim (\mu\Lambda)^{1/2}$, so the theory develops a *mass gap*: there is no massless photon, dual or ordinary. Crucially, it is the *dual* U(1) that is Higgsed — the gauge symmetry under which the monopole is electrically charged — so the condensate carries magnetic charge with respect to the *original* electric U(1). A medium in which magnetic charge condenses is a dual superconductor: it expels the original electric field by a dual Meissner effect, squeezing the electric flux between an external quark and antiquark into a thin Abrikosov–Nielsen–Olesen flux tube of fixed tension $\sigma \sim m_{\text{dual}}^2 \sim \mu\Lambda$. The energy of a static quark–antiquark pair separated by distance R is then the tube energy $V(R) = \sigma R$ — a linearly rising potential. Electric charge is confined.

Theorem 46.23 is the payoff of the chapter. The linear potential $V(R) = \sigma R$ it produces is exactly the area-law behavior that Theorem 27.20 identified as the criterion for confinement: the Wilson loop of the original electric U(1) obeys $\langle W\rangle \sim e^{-\sigma\,\text{Area}}$, and the static potential rises linearly with tension $\sigma \sim \mu\Lambda$. There the area law was a *criterion* — a diagnostic that one hoped lattice simulations or strong-coupling expansions would confirm. Here it is a *theorem*: starting from a Lagrangian, using only holomorphy, the BPS mass formula, and the explicit Seiberg–Witten curve, we have computed the confining string tension in closed

form and exhibited the order parameter (the monopole condensate) that drives it. The dual-superconductor picture of confinement, conjectured by 't Hooft and Mandelstam and built on the monopoles of Section 41.5, is here not a picture but an analytic fact about a controlled four-dimensional gauge theory.

Physical Insight

The logic is worth stating in one breath because it is the template for the entire subject. Electric confinement is hard because it is a statement about the strongly coupled electric U(1). But near $u = \Lambda^2$ the theory is *weakly coupled in the magnetic frame*: the light degrees of freedom are the monopole and the dual photon, and they interact weakly. In that frame confinement is just the Higgs mechanism — the most elementary strong-coupling-free phenomenon there is. Electric–magnetic duality has converted an intractable strong-coupling problem into a textbook weak-coupling one. That conversion, made exact by holomorphy and $\mathcal{N} = 2$ supersymmetry, is the single idea behind every exact result in this chapter.

Caution

The two singular points are physically distinct vacua of the $\mathcal{N} = 1$ theory. At $u = +\Lambda^2$ the monopole $(1, 0)$ condenses and confines electric charge in the ordinary way; at $u = -\Lambda^2$ it is the dyon $(1, -1)$ that condenses, and the resulting flux tube confines a dyonic combination — this is 't Hooft's *oblique confinement*. Both are genuine, gapped, confining vacua; the $\mathbb{Z}_2$ R-symmetry $u \to -u$ relates them. The perturbation Eq. (46.180) thus produces exactly two vacua, in agreement with the Witten index $\mathrm{Tr}(-1)^F = 2$ computed independently for $\mathcal{N} = 1$ SU(2) super-Yang–Mills.

This completes the exact solution: from a microscopic Lagrangian we have determined the effective coupling at every scale, the complete BPS spectrum, and the confinement mechanism, all in closed form and all forced by holomorphy together with one positivity requirement. The synthesis section that follows steps back from the machinery to extract the methodological lesson — that holomorphy, symmetry, and BPS protection together convert non-perturbative questions into solvable ones — and to assess honestly which of these results are theorems and which remain extraordinarily well-tested conjectures as of the mid-2020s, before pointing forward to the frontier parts that inherit this technology.

46.7 Supersymmetry as a Controlled Laboratory

The Seiberg–Witten solution of Section 46.6 is the high-water mark of this chapter, and it is worth pausing to register exactly what was accomplished there.

We took $\mathcal{N} = 2$ super-Yang–Mills with gauge group SU(2) — an asymptotically free, strongly coupled theory with no small parameter at low energies — and we wrote down, in closed form, its exact low-energy effective coupling as a function on the Coulomb branch, the exact spectrum of stable BPS states, the location of the points where extra states become massless, and the mechanism (monopole condensation) by which a small $\mathcal{N} = 1$-preserving perturbation drives the theory into a confining phase. Not one Feynman diagram was summed. The dynamics that lattice gauge theory (Chapter 43) can only approach numerically, and that the Wilson-loop criterion of Theorem 27.20 can only diagnose phenomenologically, here fell out of complex analysis: the prepotential is a holomorphic function, the effective coupling is its second derivative, and the monodromies of that function around the singular points of a one-complex-dimensional moduli space fix everything.

This is the moment to step back from the three escalating demonstrations of the chapter — the dynamically generated superpotential of Section 46.1, Seiberg's electric–magnetic duality of Section 46.4, and the Seiberg–Witten solution just recalled — and ask what they have in common. They are not three tricks. They are three deployments of one engine. The purpose of this closing section is to name that engine precisely, to catalogue the distinct tools it comprises and state what each one buys; to be scrupulously honest about which of the results we have reached are *theorems* and which are *conjectures* however overwhelmingly supported, dating that status to the mid-2020s; and to draw the forward map showing that the frontier of the subject — holography, the conformal bootstrap, the modern amplitudes program — does not sit beside supersymmetry as an unrelated development but grows directly out of the exact-results technology assembled here. No new load-bearing result is proved below; every claim points back to where in this book it was established.

46.7.1 The exact-results toolkit

Every exact statement in supersymmetric quantum field theory is assembled from a small kit of mutually reinforcing tools. Stated in isolation each is a modest observation; the power comes from using them together, where the output of one becomes the hypothesis of the next. We list them in the order they typically enter a calculation, with a back-reference to the proof and a one-line statement of what the tool delivers.

Tool 1 — Holomorphy of the superpotential. The superpotential W is a holomorphic function of the chiral superfields, with no dependence on their conjugates (Theorem 44.40); the boson–fermion grammar of superspace forces every term of the effective action that can be written as a chiral (F-term) integral $\int \mathrm{d}^2\theta\, W$ to inherit that holomorphy (Theorem 44.41 and Section 44.7.8). The decisive amplification, carried out in Section 46.1, is the *spurion* promotion: the

coupling constants of W — a mass m, a cubic coupling g, the dynamical scale Λ — are treated as the lowest components of background chiral superfields, so the *full* quantum-corrected effective superpotential W_{eff} must be a single holomorphic function of the dynamical fields *and* these spurion couplings. What it buys: holomorphy collapses the space of allowed quantum corrections from a function of two real variables (a coupling and its conjugate) to a function of one complex variable, and a holomorphic function is rigid — pinned down by its singularities and its asymptotic behaviour. This is the formal reason a strong-coupling answer can be computed from weak-coupling data.

Tool 2 — Symmetry and spurion selection rules. The global symmetries of a supersymmetric theory — ordinary flavour and baryon $U(1)$'s, and crucially the R-symmetry, which acts on the Grassmann coordinate θ and therefore assigns a definite charge to the measure $\mathrm{d}^2\theta$ and hence to W itself — act on the spurion couplings as well as the fields. An effective superpotential must be invariant under every non-anomalous symmetry and must carry R-charge 2 (the charge of $\int \mathrm{d}^2\theta$). Anomalous symmetries are not lost: they remain exact symmetries once the dynamical scale Λ is assigned the spurious charge that compensates the anomaly, because Λ^{b_0} is the gauge-invariant one-instanton amplitude and the instanton soaks up exactly the fermion zero modes that the anomaly counts (Theorem 42.3, Chapter 36). What it buys: combined with Tool 1, the selection rules typically fix W_{eff} up to a single overall numerical constant — the entire functional form is determined by charge bookkeeping, as we demonstrate explicitly in Theorem 46.24.

Tool 3 — One-loop and NSVZ exactness of the gauge coupling. The holomorphic gauge coupling

$$\tau \;=\; \frac{\theta}{2\pi} \;+\; \frac{4\pi i}{g^2} \tag{46.187}$$

is the lowest component of a chiral spurion multiplying the gauge kinetic F-term $\int \mathrm{d}^2\theta\, W^\alpha W_\alpha$ (Chapter 45). Holomorphy in τ, together with the shift symmetry $\theta \to \theta + 2\pi$ that quantizes instanton number, forbids the *holomorphic* coupling from running beyond one loop: its β-function is exhausted at one loop, all higher orders being non-holomorphic artefacts of the field rescaling that converts the holomorphic coupling to the physical (canonical) one. Tracking that rescaling through the anomalous Jacobian of the path-integral measure (Chapter 36) produces the exact Novikov–Shifman–Vainshtein–Zakharov (NSVZ) β-function recalled in Section 46.1,

$$\beta(g) \;=\; -\,\frac{g^3}{16\pi^2}\,\frac{3\,C_A - \sum_r T(r)\,(1-\gamma_r)}{1 - C_A\,g^2/8\pi^2}, \tag{46.188}$$

where C_A is the adjoint Casimir, $T(r)$ the Dynkin index of matter representation r, and γ_r its anomalous dimension (Casimir/index data in Appendix B). What it buys: an all-orders statement about the running coupling — and hence the location of conformal windows and the onset of strong coupling — from a one-loop computation plus knowledge of the anomalous dimensions.

Tool 4 — BPS protection. The supersymmetry algebra admits central charges Z in its anticommutator $\{Q, Q\} \sim Z$ (Eq. (44.114)), and positivity of the Hamiltonian (Theorem 44.9) then forces the Bogomolny–Prasad–Sommerfield bound $M \geq |Z|$ (Eq. (44.115)). States saturating it sit in *short* multiplets, annihilated by half the supercharges. A short multiplet cannot smoothly become long — the dimensions of the two representations differ — so the relation $M = |Z|$ is stable against continuous deformations of the couplings: the BPS mass is a protected quantity, computable at weak coupling and valid at strong coupling. The same algebraic shortening protects the Witten index $\mathrm{Tr}(-1)^F$ (Chapter 44), an integer invariant under continuous deformation that obstructs supersymmetry breaking. What it buys: exact masses of solitonic states — the monopoles and dyons of Theorem 41.23 reappearing as the BPS states of the Seiberg–Witten spectrum (Section 46.6) — and an exact criterion for whether supersymmetry is dynamically broken.

Tool 5 — Duality. When two different microscopic Lagrangians flow to the same infrared physics, each is a legitimate description and one is weakly coupled precisely where the other is strong. The chapter met two faces of this. Seiberg's electric–magnetic duality (Section 46.4) relates $\mathcal{N} = 1$ SQCD with gauge group $\mathrm{SU}(N_c)$ and N_f flavours to a "magnetic" $\mathrm{SU}(N_f - N_c)$ theory with the same global symmetries and the same chiral ring; Montonen–Olive/Seiberg–Witten duality (Section 46.6, building on [350]) exchanges electric charges with the monopoles of Eq. (41.176) and acts on τ by the modular group. What it buys: access to strong coupling through a weakly coupled dual, the analytic underpinning of the confinement mechanism (the magnetic variables are weakly coupled near the monopole point, so their condensation is a controlled Higgs effect), and — in the $\mathcal{N} = 4$ case below — an exact statement about the theory's behaviour under $g \to 1/g$.

These five tools are not independent axioms; they interlock. Figure 46.8 records the dependency: holomorphy (Tool 1) is the master constraint, symmetry (Tool 2) supplies the boundary conditions that make a holomorphic function unique, the NSVZ result (Tool 3) is holomorphy applied to the gauge coupling, BPS protection (Tool 4) is holomorphy and positivity applied to the spectrum, and duality (Tool 5) is the statement that the holomorphic data of two theories coincide. The single sentence that organizes the whole chapter is therefore: *holomorphy, sharpened by symmetry and protected by the BPS/index structure,*

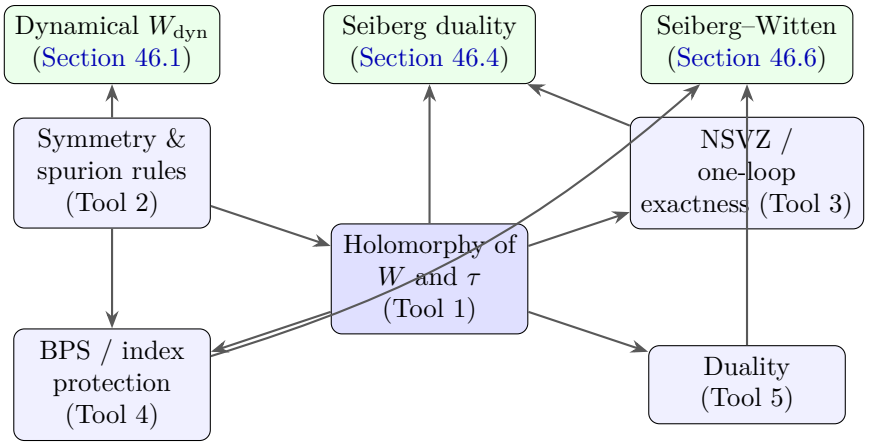

Figure 46.8: The exact-results toolkit. Holomorphy is the master constraint; symmetry supplies the boundary data that makes a holomorphic function unique; NSVZ exactness, BPS protection, and duality are holomorphy applied respectively to the coupling, the spectrum, and the comparison of two theories. The three escalating demonstrations of the chapter (top row) each combine a specific subset of the tools.

makes a class of physical quantities into rigid analytic functions, which duality lets us read off at whichever end of the coupling is weak.

Worked Example 46.24 (Selection rules reconstruct the Affleck–Dine–Seiberg superpotential)**.** The cleanest demonstration that "holomorphy + symmetry = exact answer up to a constant" is the reconstruction of the dynamically generated superpotential of $\mathcal{N}=1$ SQCD with gauge group $\mathrm{SU}(N_c)$ and $N_f < N_c$ flavours, whose existence and coefficient are established dynamically in Section 46.1 (see also [7]). Here we recover its functional form using nothing but Tools 1 and 2 — the methodological lesson of the chapter in miniature.

Setup. The matter is N_f chiral superfields Q^i in the fundamental $\mathbf{N_c}$ and N_f superfields $\widetilde{Q}_{\tilde{\jmath}}$ in the antifundamental $\overline{\mathbf{N_c}}$, $i,\tilde{\jmath}=1,\dots,N_f$. The only gauge-invariant chiral composite available to build a superpotential from is the meson matrix $M^i{}_{\tilde{\jmath}} = \widetilde{Q}_{\tilde{\jmath}} Q^i$ (for $N_f < N_c$ there are no baryons). The effective superpotential, by holomorphy (Tool 1), must be a holomorphic function of M and of the holomorphic scale, which enters only through the one-instanton factor Λ^{b_0} with $b_0 = 3N_c - N_f$ the one-loop coefficient. By gauge and flavour invariance the only flavour-singlet built from M is $\det M$, so

$$W_{\rm dyn} \;=\; c\,(\Lambda^{b_0})^{a}\,(\det M)^{p}, \tag{46.189}$$

with constants a, p, c to be fixed and det the $N_f \times N_f$ determinant.

The two relevant $U(1)$ symmetries and their charges. Consider the anomalous axial $U(1)_A$ under which both Q and $\widetilde{Q}$ carry charge $+1$, and a non-anomalous

$U(1)_R$ under which the quarks carry charge $R(Q) = R(\widetilde{Q}) = r$ to be determined. Their action on the building blocks is bookkeeping:

- Under $U(1)_A$: $M = \widetilde{Q}Q$ has charge 2, so $\det M$ (a product of N_f entries up to permutations) has charge $2N_f$. The scale is not inert: the $U(1)_A$ rotation is anomalous, and a one-instanton background has $2N_f$ fermionic zero modes (one from each of the $2N_f$ quark Weyl fermions), so the gauge-invariant instanton amplitude Λ^{b_0} carries $U(1)_A$ charge $+2N_f$. This is Tool 2's spurion rule: the anomaly is restored as an exact symmetry by charging Λ.
- Under $U(1)_R$: the measure $\mathrm{d}^2\theta$ has R-charge -2, so W must have R-charge $+2$. The condition that $U(1)_R$ be non-anomalous fixes r: the mixed R–$\mathrm{SU}(N_c)^2$ anomaly cancels when

$$C_A \cdot (1) \;+\; 2N_f\, T_F\,(r-1) \;=\; 0, \qquad C_A = N_c,\;\; T_F = \tfrac{1}{2}, \tag{46.190}$$

the first term from the gaugino (R-charge 1) and the second from the $2N_f$ quark fermions (R-charge $r-1$), each in a representation of index $T_F = \frac{1}{2}$. Solving, $r = \dfrac{N_f - N_c}{N_f}$. Hence $\det M$ has R-charge $2N_f\, r = 2(N_f - N_c)$, while Λ^{b_0} is R-neutral (the R-symmetry being non-anomalous by construction).

Imposing invariance. The ansatz Eq. (46.189) must be $U(1)_A$ invariant and carry R-charge 2:

$$U(1)_A: \quad a\,(2N_f) + p\,(2N_f) = 0 \;\;\Longrightarrow\;\; a = -p, \tag{46.191}$$

$$U(1)_R: \quad a\,(0) + p\,\big[2(N_f - N_c)\big] = 2 \;\;\Longrightarrow\;\; p = \frac{1}{N_f - N_c} = -\frac{1}{N_c - N_f}. \tag{46.192}$$

Therefore $a = -p = \dfrac{1}{N_c - N_f}$, and the form is completely fixed:

$$\boxed{W_{\mathrm{dyn}} \;=\; c\left(\frac{\Lambda^{3N_c - N_f}}{\det M}\right)^{1/(N_c - N_f)}}. \tag{46.193}$$

Holomorphy and two charge equations have determined a non-perturbative superpotential up to the single dimensionless number c. That number is not accessible to symmetry — it requires the actual dynamics — and is fixed in Section 46.1 (via an explicit one-instanton computation for $N_f = N_c - 1$ and consistency under integrating out a flavour for general N_f) to be $c = N_c - N_f$. The lesson is exactly the chapter's thesis: the entire *functional dependence* of a strong-coupling effect — here a potential that lifts the classical moduli space and, for $N_f < N_c$, drives the would-be vacuum to infinity — is legislated by holomorphy and symmetry, leaving dynamics to supply only an overall constant.

46.7.2 Theorem versus conjecture: an honest scope

A textbook that has just exhibited closed-form strong-coupling physics owes the reader a precise accounting of epistemic status. The results of this chapter do not all stand on the same footing, and conflating a theorem with a superbly tested conjecture would be exactly the false closure the book forbids. The following inventory is dated to the mid-2020s.

Theorems (proved, in this book or by the standard of mathematical physics). The perturbative *nonrenormalization theorem* for the superpotential — that W receives no corrections at any finite order of perturbation theory — is a theorem; it follows from holomorphy and the spurion selection rules, and it was argued diagrammatically in Chapter 45 and from holomorphy in Sections 44.7.8 and 46.1. The *BPS bound* $M \geq |Z|$ is a theorem: it is an algebraic inequality forced by positivity of the Hamiltonian on the central-extended supersymmetry algebra (Theorem 44.9, Eq. (44.115)), with no dynamical assumption whatsoever. The integrality and deformation-invariance of the *Witten index* $\mathrm{Tr}(-1)^F$ is a theorem in the same sense [520]. The *NSVZ exactness* of the holomorphic gauge coupling Eq. (46.188) is a theorem at the level of rigour of the anomaly–Jacobian argument that produces it [370]; its only soft point is the scheme-dependence relating holomorphic and canonical couplings, which is itself controlled and explained, not assumed.

Conjectures with overwhelming evidence (no proof). *Seiberg's electric–magnetic duality* (Section 46.4, [435]) is a statement about the infrared equivalence of two *different* ultraviolet Lagrangians. There is no proof that the $\mathrm{SU}(N_c)$ and $\mathrm{SU}(N_f - N_c)$ theories flow to the same fixed point. What there is, is a stack of nontrivial consistency checks that would be miraculous coincidences were the duality false: 't Hooft anomaly matching of all global symmetries between electric and magnetic descriptions (Chapter 37); matching of the chiral rings and of the gauge-invariant operators; consistency under every relevant and mass deformation (adding a quark mass on one side must reproduce the flow on the other, and it does, recursively in N_f); the agreement of the superconformal index, a protected partition function computable independently on both sides; and, where it has been attempted, lattice and numerical evidence for the conformal-window boundaries the duality predicts. The accumulation is so strong that no working physicist doubts it — but it is evidence, not a derivation, and we say so.

The *Seiberg–Witten solution* (Section 46.6, [436]) was originally obtained by an inspired ansatz: assume the low-energy coupling $\tau(u)$ is a holomorphic, modular section with exactly the singularities physically demanded (one at weak coupling from asymptotic freedom, two at strong coupling where a monopole and a dyon become massless), and show that these data fix a unique elliptic curve and hence the prepotential. The internal consistency is total — the monodromies

close, the BPS spectrum is consistent, the weak-coupling expansion reproduces the known one-loop and instanton corrections term by term — but the original argument *assumed* the singularity structure rather than deriving it. The status improved markedly in the 2000s: Nekrasov's instanton-counting partition function [361] computes the prepotential's instanton expansion directly from the path integral and reproduces the Seiberg–Witten result order by order, and Pestun's exact localization of the theory on the four-sphere [399] provides a first-principles evaluation of the same data. As of the mid-2020s the prepotential's weak-coupling expansion is therefore on extremely firm ground; the global analytic continuation to strong coupling and the identification of the singular points still rest on physical input rather than a theorem. It is a near-certainty, not a proof.

Caution

"Conjecture" here does not mean "speculative." Seiberg duality and the Seiberg–Witten solution are among the best-tested statements in theoretical physics, verified through independent windows (anomalies, deformations, indices, localization, lattice) that have no business agreeing unless the statements are true. The honest word is nonetheless *conjecture*: there is no mathematical derivation of the infrared equivalence (Seiberg) or of the assumed singularity structure (Seiberg–Witten). Distinguishing this from the theorems above — nonrenormalization, the BPS bound, the Witten index, NSVZ — is a matter of intellectual hygiene, not of confidence in the physics.

46.7.3 The forward map: where this technology re-enters

The exact-results toolkit is not the terminus of the book; it is the seed of three of the four frontier parts. Each picks up the technology of this chapter at a specific point and carries it forward, and flagging those entry points is the chapter's final obligation.

$\mathcal{N} = 4$ super-Yang–Mills and the gateway to holography. The maximally supersymmetric theory, $\mathcal{N} = 4$ SYM, is the most special point in the landscape mapped above: its β-function vanishes *identically* (the numerator of Eq. (46.188) is zero for the $\mathcal{N} = 4$ matter content, so the theory is exactly conformal for all g), and it enjoys an exact Montonen–Olive/S-duality under which the complexified coupling τ of Eq. (46.187) transforms by the modular group $SL(2,\mathbb{Z})$, $\tau \to (a\tau + b)/(c\tau + d)$, exchanging the gauge group with its Langlands dual and electric quanta with the monopoles. This is Tool 5 in its sharpest form, and it is exactly the structure that, in the large-N limit, becomes the strongest piece of evidence for the AdS/CFT correspondence: a finite, exactly conformal, S-self-dual gauge theory is precisely the object that can be dual to a gravitational

theory on anti-de Sitter space. Chapter 53 takes $\mathcal{N} = 4$ SYM and its large-N limit (Section 53.1) as the entry point to holography; the finiteness and duality established by the methods of this chapter are what make that correspondence credible rather than fanciful. *This is where the SUSY exact-results thread re-enters the book as holography.*

The conformal window and the bootstrap. The NSVZ relation Eq. (46.188) predicts that SQCD with enough flavours ($\frac{3}{2}N_c < N_f < 3N_c$ for SU(N_c)) flows to an interacting infrared fixed point — a nontrivial conformal field theory, the "conformal window," whose existence and boundaries are inferred from holomorphy and Seiberg duality. These superconformal theories are concrete, strongly coupled CFTs with computable protected spectra, and they are exactly the kind of input the conformal bootstrap of Part XIV takes as target data: the dimensions and OPE coefficients fixed by superconformal symmetry provide both checks and seeds for the bootstrap equations (Chapter 49). The exact-results technology hands the bootstrap a supply of rigorously characterized fixed points to test its machinery against. *This is where the conformal-window output of this chapter re-enters as the bootstrap.*

Planar $\mathcal{N} = 4$ and the amplituhedron. In the planar (large-N, fixed g^2N) limit, $\mathcal{N} = 4$ SYM is the most symmetric interacting quantum field theory known, and its scattering amplitudes exhibit a hidden positive-geometric structure: the integrand of the planar amplitude is computed as the canonical form of a region called the amplituhedron (Chapter 62, Section 62.6, [32]), with locality and unitarity emerging from positivity rather than being imposed. That this arena exists at all is owed to the special status — conformal symmetry, dual conformal symmetry, integrability — that the exact-results technology of this chapter both relies on and explains. *This is where planar $\mathcal{N} = 4$ re-enters as the modern amplitudes frontier.*

Dynamical supersymmetry breaking and the landscape. Finally, the Witten index (Tool 4) and the dynamically generated superpotentials (Tool 1+2, Theorem 46.24) are the working tools of model building at the frontier: whether a given supersymmetric theory breaks supersymmetry dynamically is decided by the index and by the runaway or stabilization of the ADS-type potential Eq. (46.193) [7], and the proliferation of metastable supersymmetry-breaking vacua feeds the still-unsettled question of the string landscape. This remains live, model-dependent, and phenomenologically open as of the mid-2020s — the one direction in the forward map that is genuinely a research frontier rather than an established bridge.

We close Part XIII here. The single lesson the reader should carry forward is the one this section has tried to make unmistakable: in the supersymmetric

corner of quantum field theory, holomorphy — sharpened by symmetry, protected by the BPS and index structure, and exploited through duality — turns non-perturbative dynamics into rigid analytic data, and it is exactly this control that the frontier inherits. The chapters on holography, the bootstrap, and the amplituhedron that follow are not a change of subject; they are what happens when the exact-results laboratory is taken to its limits.

Further reading

The foundational papers of the exact-results program are Seiberg's analysis of the space of vacua and holomorphy [434], his electric–magnetic duality [435], and the Seiberg–Witten solution of $\mathcal{N} = 2$ super-Yang–Mills [436]; the dynamically generated superpotential and dynamical supersymmetry breaking originate with Affleck, Dine, and Seiberg [7], and the exact gauge β-function with Novikov, Shifman, Vainshtein, and Zakharov [370]. Witten's index argument for the obstruction to supersymmetry breaking is [520], and the electric–magnetic duality conjecture for $\mathcal{N} = 4$ traces to Montonen and Olive [350]. The pedagogical lectures of Intriligator and Seiberg [275] remain the standard entry point to holomorphy, duality, and the conformal window; Terning's monograph [472], the third volume of Weinberg [502], and the superspace reference of Wess and Bagger [505] give textbook treatments. For the modern, near-rigorous status of the $\mathcal{N} = 2$ prepotential see Nekrasov's instanton counting [361] and Pestun's localization [399]. The forward connections are developed in Chapter 53 (holography, the original correspondence being Maldacena's [331]), Chapter 49 (the bootstrap), and Chapter 62 (the amplituhedron of Arkani-Hamed and Trnka [32]).

Part XIV

Conformal Field Theory and the Bootstrap

Chapter 47

Conformal Symmetry

Part VI left us with a striking promise and an unpaid debt. The Wilsonian renormalization group of Chapter 23 taught us that the long-distance physics of a quantum field theory is governed by the fixed points of its flow, that a fixed point is by construction invariant under the rescaling of all lengths, and that the critical exponents of a phase transition are the scaling dimensions of operators at such a point. What it did not establish is that the symmetry at a fixed point is anything larger than that one-parameter dilatation. This chapter makes good on the promise: it shows that, under hypotheses that hold in every interacting fixed point of physical interest, scale invariance is automatically enhanced to the full conformal group, and it builds from that enhancement the entire apparatus—primaries, the state–operator correspondence, symmetry-fixed correlators, the operator product expansion—on which the rest of Part XIV stands.

The development is deliberately self-contained, but it leans on four earlier strands of the book. From Chapter 7 we take the symmetric, conserved stress tensor and the Noether machinery that turns a spacetime symmetry into a conserved current; the improvement that trades the canonical stress tensor for a traceless one is the technical heart of the scale-to-conformal upgrade. From Chapter 3 we borrow the Lorentz and Poincaré algebras and the rotation generators $M_{\mu\nu}$, which sit inside the conformal algebra as a subalgebra and whose representation theory labels operators by spin. From Chapter 5 we use the Euclidean continuation and the contour and distributional technology that make radial quantization and the convergence of the OPE precise statements rather than formal manipulations; the state–operator map itself is most transparent in the Euclidean path integral of Chapter 10. And from Chapter 23 we inherit the very notion of a scaling dimension: the abstract weight Δ of a conformal primary and the RG scaling dimension of Theorem 23.22 are, at a fixed point, one and the same number, so the anomalous dimension that measured the breaking of classical scale invariance reappears here as the conformal weight of a local operator.

The arc of the chapter is from kinematics to representation theory to dynamics. We begin in flat space, distinguishing scale from conformal invariance through the local certificate of a traceless stress tensor, solving the conformal Killing equation to enumerate the conformal transformations in $d \geq 3$, and settling honestly the question of when scale invariance forces the larger symmetry. Exponentiating these generators yields the conformal group and its algebra, which we identify with $\mathfrak{so}(d+1,1)$. With the algebra in hand we pass to representations: local operators organize into multiplets built on primaries—lowest-weight states annihilated by the special conformal generator—graded by the dilatation eigenvalue, and unitarity imposes sharp lower bounds on the allowed dimensions. Symmetry alone then fixes the two- and three-point functions of primaries completely, up to a single number per triple, and reduces the four-point function to a function of two cross-ratios.

To make the operator product expansion a convergent statement rather than an asymptotic one we develop radial quantization: the foliation of Euclidean space by spheres, the dilatation operator as the Hamiltonian generating radial time, and the reflection-positive inner product. This furnishes the rigorous setting for the state–operator isomorphism, proved here in full—every state of the radially quantized theory is created by a unique local operator, so the spectrum of the dilatation Hamiltonian *is* the spectrum of operator dimensions. The OPE then follows from completeness, its coefficients are the three-point data, and it converges inside a finite radius; decomposing the four-point function in two channels exhibits the conformal blocks as eigenfunctions of the quadratic Casimir and sets up the crossing equation that Chapter 49 will elevate into the bootstrap. We close by checking the whole construction against the two theories ϕ^4 theory has carried this far: the free massless scalar, which realizes the spectrum exactly at the unitarity bound with its equation of motion appearing as a null descendant, and the Wilson–Fisher fixed point, whose anomalous dimensions—computed as RG quantities in Part VI—are recast here as the conformal data that feeds the bootstrap, the $d = 2$ Virasoro analysis of Chapter 48, and the critical-phenomena synthesis of Chapter 52.

47.1 From Scale Invariance to Conformal Invariance

The renormalization group taught us to read a quantum field theory as a trajectory in the space of couplings, and it located the physics of long distances at the endpoints of that trajectory: the fixed points, where the flow stalls and the theory ceases to change as we coarse-grain (Section 23.5). A fixed point is, by construction, a theory that has forgotten every length scale. There is no correlation length to set a unit of distance, no mass gap, no preferred resolution; the dimensionless couplings sit at stationary values and the dimensionful ones have been tuned away. Universality (Theorem 23.26) made this forgetting

physically consequential: whole basins of microscopically distinct theories flow to the same fixed point and share its critical exponents, which is why a lattice of magnetic spins and a fluid near its critical point obey the same power laws. The phrase that summarizes the endpoint is *scale invariance*: the fixed-point theory looks identical at every magnification.

This chapter takes that physical statement and turns it into a rigid algebraic structure. The first step is to recognize that "scale invariance" is not the end of the symmetry story but the beginning of it. A theory invariant under the single one-parameter group of dilatations turns out, under hypotheses that are mild and that we will make precise, to be invariant under a much larger finite-dimensional group — the *conformal group* — obtained by adjoining to the Poincaré and dilatation transformations a further d *special conformal* transformations. The enlargement is not optional decoration: it is forced, in the cases that matter, by the same locality and unitarity that organize every field theory in this book, and it is the reason a critical point carries so much more structure than a bare scaling law. Our task in this opening section is threefold. We first identify the local certificate of scale invariance — a stress tensor whose trace can be improved to zero — recalling the classical analysis of Section 7.7 and recasting it as a statement about RG endpoints. We then define a conformal transformation intrinsically, as a coordinate change that rescales the metric and therefore preserves angles, and we solve the equation that selects such transformations in flat space of dimension $d \geq 3$, enumerating them completely. Finally we state, and scope honestly, the theorem that promotes scale invariance to conformal invariance — a theorem that is settled in $d = 2$ and (under standard assumptions) $d = 4$, and that remains open in general dimension as of the mid-2020s. Throughout, the two concrete theories driving the chapter are the ones ϕ^4 theory has carried to this point: the massless free scalar, and the interacting Wilson–Fisher fixed point reached by tuning $\lambda\phi^4$ in $d = 4 - \epsilon$ (Chapter 52). The free scalar's improvement to a traceless stress tensor, built in Theorem 7.45, is the worked illustration we carry here.

47.1.1 The local certificate of scale invariance

Scale invariance is a statement about a symmetry, and by Noether's first theorem (Theorem 7.10) a continuous symmetry is detected locally by a conserved current. For dilatations that current is the *dilatation current*, assembled in Section 7.7.2 from the symmetric, conserved stress tensor $\Theta^{\mu\nu}$ as

$$D^\mu = x_\nu \, \Theta^{\mu\nu} + V^\mu, \tag{47.1}$$

the sum of an orbital piece $x_\nu \Theta^{\mu\nu}$ and the field *virial* V^μ recording the intrinsic scaling weight of the fields. Its divergence collapses, by the kinematic identity Eq. (7.188), to

$$\partial_\mu D^\mu = \Theta^\mu{}_\mu + \partial_\mu V^\mu, \tag{47.2}$$

so that conservation of D^μ — scale invariance — is equivalent to the trace of the stress tensor being a total derivative on shell, $\Theta^\mu{}_\mu = -\partial_\mu V^\mu$. When the virial is itself the divergence of a local tensor, $V^\mu = \partial_\nu \sigma^{\nu\mu}$, the same superpotential technology that symmetrized the canonical tensor into the Belinfante tensor can be turned to a second purpose: it absorbs the virial into the stress tensor and produces an *improved* tensor $\Theta^{\mu\nu}_{\rm c}$ that is symmetric, conserved, and *traceless on shell*, $\Theta^\mu_{{\rm c}\,\mu} = 0$ (Theorem 7.45). At that point the dilatation current is simply $D^\mu = x_\nu \Theta^{\mu\nu}_{\rm c}$ with no separate virial, and its conservation is manifest:

$$\partial_\mu (x_\nu \Theta^{\mu\nu}_{\rm c}) = \Theta^\mu_{{\rm c}\,\mu} = 0. \tag{47.3}$$

This is the dictionary we carry into the quantum theory. A scale-invariant theory is one possessing an improved stress tensor with vanishing trace; the trace $\Theta^\mu_{{\rm c}\,\mu}$ is the single local operator whose vanishing certifies that no length scale survives. At an RG fixed point the statement is exact at the quantum level: the beta functions vanish, and the operator equation for the trace — which away from a fixed point reads $\Theta^\mu_{{\rm c}\,\mu} = \sum_i \beta_i \mathcal{O}_i$ in terms of the running couplings (the quantum descendant of the classical formula Eq. (7.204)) — reduces to $\Theta^\mu_{{\rm c}\,\mu} = 0$. The trace, classically the sum over dimensionful couplings weighted by their mass dimensions (Eq. (7.201)), becomes quantum-mechanically the sum over beta functions; a fixed point is precisely where that sum vanishes. The remainder of this section asks what symmetry a vanishing trace actually generates, and the answer is larger than dilatations alone.

47.1.2 Conformal transformations as angle-preserving maps

We have approached scale transformations through the field-theoretic back door, as the symmetry whose current is built from the trace. It pays to step back and ask what dilatations are *geometrically*, because the geometric question has a sharper and more general answer. A dilatation $x^\mu \to \lambda x^\mu$ multiplies the flat metric by a constant: under it the line element $ds^2 = \eta_{\mu\nu}\, dx^\mu dx^\nu$ becomes $\lambda^2\, ds^2$. It rescales all lengths by the same factor everywhere, and in doing so it leaves *angles* untouched, since an angle is a ratio of lengths in which a common rescaling cancels. The natural geometric generalization is to allow the rescaling factor to depend on position. This is the definition of a conformal transformation.

Definition 47.1 (Conformal transformation)**.** Let (M, g) be a (pseudo-)Riemannian manifold. A diffeomorphism $x \mapsto x'(x)$ is a *conformal transformation* if it rescales the metric by a positive, position-dependent factor:

$$g'_{\mu\nu}(x') = \Omega(x)^{-2}\, g_{\mu\nu}(x), \tag{47.4}$$

where $g'_{\mu\nu}(x') = \dfrac{\partial x^\rho}{\partial x'^\mu}\dfrac{\partial x^\sigma}{\partial x'^\nu}\, g_{\rho\sigma}(x)$ is the transformed metric and $\Omega(x) > 0$ is the (local) *conformal factor* or *Weyl factor*, defined as the local stretching of lengths

under the forward map: the Jacobian factorizes as $\partial x'^{\mu}/\partial x^{\nu} = \Omega(x)\, R^{\mu}{}_{\nu}(x)$ with R orthogonal, so that $\partial x^{\rho}/\partial x'^{\mu} = \Omega(x)^{-1}(R^{-1})^{\rho}{}_{\mu}$ and the pullback metric above carries the reciprocal weight Ω^{-2}. The transformation is a (rigid) isometry when $\Omega \equiv 1$, a dilatation when Ω is a nonzero constant, and a genuinely local conformal map when Ω varies with x. In flat space we take $g_{\mu\nu} = \eta_{\mu\nu}$ throughout.

The name is justified by the following elementary but defining property: Eq. (47.4) is exactly the condition that the map preserve angles.

Proposition 47.2 (Conformal maps preserve angles)**.** *A diffeomorphism satisfies Eq. (47.4) for some $\Omega(x) > 0$ if and only if, at every point and for every pair of tangent vectors u, v, the quantity*

$$\cos\angle(u,v) \;=\; \frac{g(u,v)}{\sqrt{g(u,u)}\,\sqrt{g(v,v)}} \tag{47.5}$$

is unchanged by the map (with the obvious caveat that in Lorentzian signature this is literally an angle only for vectors of like timelike or like spacelike character; in general the invariant statement is that the map preserves the causal structure, sending null vectors to null vectors).

Proof. Push forward u, v by the differential of the map; their inner products are then evaluated with the transformed metric g'. If Eq. (47.4) holds, every inner product picks up the same factor Ω^{-2}: $g'(u,v) = \Omega^{-2} g(u,v)$, $g'(u,u) = \Omega^{-2} g(u,u)$, $g'(v,v) = \Omega^{-2} g(v,v)$. The factor cancels between numerator and denominator of Eq. (47.5), leaving $\cos\angle$ unchanged; in particular a null vector $g(u,u) = 0$ maps to a null vector. Conversely, suppose the ratio Eq. (47.5) is preserved for all u, v at a point. Taking $u = v$ shows that $g'(u,u)/g(u,u)$ is independent of u (it is the squared length ratio, and preservation of all angles forces it to be a single positive scalar, which we write as Ω^{-2} at that point), and the polarization identity then extends $g' = \Omega^{-2} g$ to mixed inner products. Hence Eq. (47.4) holds. □

Theorem 47.2 is the geometric heart of the subject: conformal transformations are the angle-preserving (equivalently, light-cone-preserving) coordinate changes, and the conformal factor $\Omega(x)$ measures the purely local stretching they apply. Figure 47.1 illustrates the simplest nontrivial example, the inversion $x^{\mu} \to x^{\mu}/x^2$, which bends straight coordinate lines into circles yet preserves the right angle at every crossing.

47.1.3 The conformal Killing equation

To enumerate the conformal transformations of flat space we work infinitesimally, as one always does to expose the Lie-algebra structure; the exponentiation to

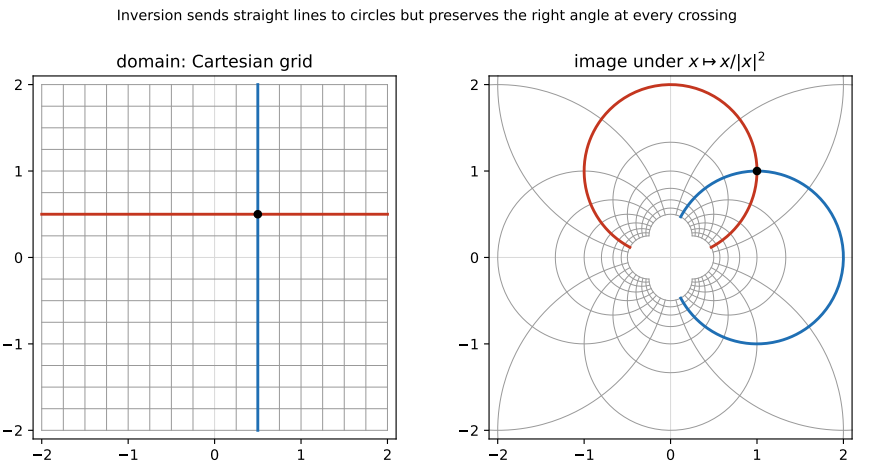

Figure 47.1: A conformal transformation that is neither a Poincaré transformation nor a dilatation: the inversion $x \mapsto x/|x|^2$ in the plane. The Cartesian grid (left) is mapped to a family of circles (right) — straightness and length are destroyed — yet the highlighted vertical and horizontal lines, orthogonal in the domain, map to circles that still meet orthogonally at the image of their crossing point. This is the content of Theorem 47.2: the conformal factor $\Omega(x) = 1/|x|^2$ rescales all lengths at a point by the same amount, so the angle between any two curves is preserved.

finite transformations is the business of the next section. Write the infinitesimal coordinate change as

$$x'^{\mu} = x^{\mu} + \xi^{\mu}(x) + \mathcal{O}(\xi^2), \tag{47.6}$$

with ξ^{μ} a vector field. (We denote the generating vector field ξ^{μ} throughout, matching the conformal Killing vector of Eq. (7.206); the symbol is interchangeable with the ε^{μ} of much of the CFT literature.) To first order $\partial x^{\rho}/\partial x'^{\mu} = \delta^{\rho}_{\mu} - \partial_{\mu}\xi^{\rho}$, so the transformed flat metric is

$$\eta'_{\mu\nu}(x') = (\delta^{\rho}_{\mu} - \partial_{\mu}\xi^{\rho})(\delta^{\sigma}_{\nu} - \partial_{\nu}\xi^{\sigma})\,\eta_{\rho\sigma} = \eta_{\mu\nu} - \partial_{\mu}\xi_{\nu} - \partial_{\nu}\xi_{\mu} + \mathcal{O}(\xi^2), \tag{47.7}$$

where indices on ξ are lowered with η. The defining condition Eq. (47.4), in the form $\eta'_{\mu\nu}(x') = \Omega(x)^{-2}\eta_{\mu\nu}$, requires this to be a local rescaling of $\eta_{\mu\nu}$; writing $\Omega(x)^{-2} = 1 - \omega(x)$ for some infinitesimal ω and matching at first order,

$$\partial_{\mu}\xi_{\nu} + \partial_{\nu}\xi_{\mu} = \omega(x)\,\eta_{\mu\nu}. \tag{47.8}$$

The scalar ω is fixed by tracing: contracting both sides with $\eta^{\mu\nu}$ gives $2\,\partial\cdot\xi = \omega\, d$, hence $\omega = \frac{2}{d}\,\partial\cdot\xi$. Substituting back, the vector fields generating conformal transformations are exactly those satisfying the *conformal Killing equation*

$$\boxed{\partial_{\mu}\xi_{\nu} + \partial_{\nu}\xi_{\mu} = \frac{2}{d}\,(\partial\cdot\xi)\,\eta_{\mu\nu}\ ,} \tag{47.9}$$

which is Eq. (7.206). Equivalently: a vector field is a conformal Killing vector when the symmetric part of its gradient is pure trace. The infinitesimal Weyl factor it generates is

$$\Omega(x) = 1 + \tfrac{1}{d}\,(\partial\cdot\xi) + \mathcal{O}(\xi^2). \tag{47.10}$$

Setting the right-hand side of Eq. (47.9) to zero recovers the ordinary Killing equation, whose solutions are the Poincaré generators (constant translations $\xi^\mu = a^\mu$ and antisymmetric Lorentz rotations $\xi^\mu = \omega^\mu{}_\nu x^\nu$, $\omega_{\mu\nu} = -\omega_{\nu\mu}$). The conformal Killing equation relaxes "isometry" to "isometry up to a local rescaling," and we now find that this relaxation admits exactly two new families of solutions in dimension three and above.

47.1.4 Complete solution in $d \geq 3$

Equation (7.207) exhibited four families of solutions of Eq. (47.9) and verified that each solves it. What was not shown there — and what is the central mathematical result of this section — is that these four families are the *complete* list when $d \geq 3$: there are no other conformal Killing vectors, and in particular the conformal group of flat space in $d \geq 3$ is finite-dimensional. We prove this now, by extracting from Eq. (47.9) a differential consequence so restrictive that it forces every conformal Killing vector to be at most quadratic in x.

Theorem 47.3 (Complete solution of the conformal Killing equation, $d \geq 3$)**.** *In flat space of dimension $d \geq 3$, every solution of the conformal Killing equation Eq. (47.9) is a polynomial in x of degree at most two, and has the form*

$$\xi^\mu(x) = \underbrace{a^\mu}_{\text{translation}} + \underbrace{\omega^\mu{}_\nu\, x^\nu}_{\text{Lorentz}} + \underbrace{\lambda\, x^\mu}_{\text{dilatation}} + \underbrace{2(b\cdot x)\, x^\mu - x^2\, b^\mu}_{\text{special conformal}}, \tag{47.11}$$

with a^μ, b^μ constant vectors, $\omega_{\mu\nu} = -\omega_{\nu\mu}$ a constant antisymmetric tensor, and λ a constant scalar. The space of solutions has dimension $\frac{1}{2}(d+1)(d+2)$.

Proof. Write $\sigma(x) \equiv \partial\cdot\xi$ for the divergence, so that the conformal Killing equation reads $\partial_\mu\xi_\nu + \partial_\nu\xi_\mu = \frac{2}{d}\,\sigma\,\eta_{\mu\nu}$. We extract constraints by differentiating and contracting.

Step 1: the divergence σ is at most linear. Apply ∂^μ to the conformal Killing equation. Using $\partial^\mu\partial_\mu = \Box$ and $\partial^\mu\xi_\mu = \sigma$,

$$\Box\xi_\nu + \partial_\nu\sigma = \frac{2}{d}\,\partial_\nu\sigma \quad\Longrightarrow\quad \Box\xi_\nu = \frac{2-d}{d}\,\partial_\nu\sigma. \tag{47.12}$$

Now apply $\Box$ to the conformal Killing equation and feed in Eq. (47.12). The left-hand side is $\Box(\partial_\mu\xi_\nu + \partial_\nu\xi_\mu) = \partial_\mu\Box\xi_\nu + \partial_\nu\Box\xi_\mu = \frac{2-d}{d}(\partial_\mu\partial_\nu + \partial_\nu\partial_\mu)\sigma = \frac{2(2-d)}{d}\,\partial_\mu\partial_\nu\sigma$, while the right-hand side is $\frac{2}{d}\,\eta_{\mu\nu}\Box\sigma$. Equating,

$$(2-d)\,\partial_\mu\partial_\nu\sigma = \eta_{\mu\nu}\,\Box\sigma. \tag{47.13}$$

Contracting Eq. (47.13) with $\eta^{\mu\nu}$ gives $(2-d)\Box\sigma = d\,\Box\sigma$, i.e. $2(1-d)\Box\sigma = 0$, so $\Box\sigma = 0$ for every $d \neq 1$. Feeding $\Box\sigma = 0$ back into Eq. (47.13) leaves $(2-d)\,\partial_\mu\partial_\nu\sigma = 0$, and *here is where* $d \geq 3$ *enters*: for $d \neq 2$ the prefactor is nonzero, so

$$\partial_\mu\partial_\nu\sigma = 0, \tag{47.14}$$

and σ is an affine function of x, $\sigma(x) = \sigma_0 + \sigma_\mu x^\mu$ with σ_0, σ_μ constant. (In $d = 2$ the prefactor $2-d$ vanishes and Eq. (47.13) imposes no constraint beyond $\Box\sigma = 0$; the divergence is then an arbitrary harmonic function and the solution space is infinite-dimensional. This is the algebraic root of the special status of two dimensions, taken up in Chapter 48.)

Step 2: ξ is at most quadratic. We obtain a closed expression for the second derivatives of ξ. Differentiate the conformal Killing equation and write the three index permutations

$$\partial_\rho\partial_\mu\xi_\nu + \partial_\rho\partial_\nu\xi_\mu = \tfrac{2}{d}\,\eta_{\mu\nu}\,\partial_\rho\sigma, \tag{47.15}$$
$$\partial_\mu\partial_\nu\xi_\rho + \partial_\mu\partial_\rho\xi_\nu = \tfrac{2}{d}\,\eta_{\nu\rho}\,\partial_\mu\sigma, \tag{47.16}$$
$$\partial_\nu\partial_\rho\xi_\mu + \partial_\nu\partial_\mu\xi_\rho = \tfrac{2}{d}\,\eta_{\rho\mu}\,\partial_\nu\sigma. \tag{47.17}$$

Form *Eq. (47.16) + Eq. (47.17) − Eq. (47.15)*. Since partial derivatives commute, the left-hand side collapses: the terms $\partial_\rho\partial_\mu\xi_\nu$ and $\partial_\rho\partial_\nu\xi_\mu$ from Eq. (47.15) cancel against the matching terms in Eq. (47.16) and Eq. (47.17), leaving $2\,\partial_\mu\partial_\nu\xi_\rho$. Hence

$$\partial_\mu\partial_\nu\xi_\rho = \frac{1}{d}\Big(\eta_{\nu\rho}\,\partial_\mu\sigma + \eta_{\rho\mu}\,\partial_\nu\sigma - \eta_{\mu\nu}\,\partial_\rho\sigma\Big). \tag{47.18}$$

By Eq. (47.14) the gradient $\partial_\mu\sigma = \sigma_\mu$ is constant, so the right-hand side of Eq. (47.18) is constant in x, and therefore $\partial_\lambda\partial_\mu\partial_\nu\xi_\rho = 0$: every third derivative of ξ vanishes. Consequently ξ^μ is a polynomial of degree at most two,

$$\xi_\mu(x) = a_\mu + b_{\mu\nu}\,x^\nu + c_{\mu\nu\rho}\,x^\nu x^\rho, \qquad c_{\mu\nu\rho} = c_{\mu\rho\nu}, \tag{47.19}$$

with $a_\mu, b_{\mu\nu}, c_{\mu\nu\rho}$ constant.

Step 3: identify the coefficients. We substitute Eq. (47.19) into the conformal Killing equation order by order in x.

Constant part. The constant a_μ enters ξ but not $\partial_\mu\xi_\nu$; it is unconstrained and supplies the d *translations* $\xi^\mu = a^\mu$.

Linear part. The linear term contributes $\partial_\alpha\xi_\beta\big|_{\text{lin}} = b_{\beta\alpha}$. The conformal Killing equation at zeroth order in x reads $b_{\nu\mu} + b_{\mu\nu} = \frac{2}{d}(\eta^{\alpha\beta}b_{\beta\alpha})\,\eta_{\mu\nu}$. Decompose $b_{\mu\nu}$ into its symmetric and antisymmetric parts, $b_{\mu\nu} = s_{\mu\nu} + \omega_{\mu\nu}$. The antisymmetric part drops out of the left-hand side, and matching forces $2s_{\mu\nu} = \frac{2}{d}(s^\alpha{}_\alpha)\eta_{\mu\nu}$, i.e. the symmetric part is pure trace, $s_{\mu\nu} = \lambda\,\eta_{\mu\nu}$ with $\lambda \equiv \frac{1}{d}\,s^\alpha{}_\alpha$. The antisymmetric $\omega_{\mu\nu}$ is unconstrained. Thus the linear term is

$$b_{\mu\nu}\,x^\nu = \omega_{\mu\nu}\,x^\nu + \lambda\,x_\mu, \tag{47.20}$$

supplying the $\frac{1}{2}d(d-1)$ *Lorentz rotations* (ω antisymmetric) and the single *dilatation* (λ).

Quadratic part. For the quadratic term, $\partial_\nu \xi_\mu\big|_{\text{quad}} = 2c_{\mu\nu\rho}x^\rho$ (using $c_{\mu\nu\rho} = c_{\mu\rho\nu}$), so its second derivative is $\partial_\mu\partial_\nu\xi_\rho = 2c_{\rho\mu\nu}$. Comparing with the master relation Eq. (47.18) and writing $\partial_\mu\sigma$ for the quadratic part as $\partial_\mu\sigma = 2c^\lambda{}_{\lambda\mu}$ (the divergence of the quadratic piece is $\sigma|_{\text{quad}} = 2c^\lambda{}_{\lambda\rho}x^\rho$), we get

$$2c_{\rho\mu\nu} = \frac{2}{d}\Big(\eta_{\nu\rho}\,c^\lambda{}_{\lambda\mu} + \eta_{\rho\mu}\,c^\lambda{}_{\lambda\nu} - \eta_{\mu\nu}\,c^\lambda{}_{\lambda\rho}\Big). \tag{47.21}$$

Defining the constant vector $b_\mu \equiv \frac{1}{d}\,c^\lambda{}_{\lambda\mu}$ this reads

$$c_{\rho\mu\nu} = \eta_{\nu\rho}\,b_\mu + \eta_{\rho\mu}\,b_\nu - \eta_{\mu\nu}\,b_\rho, \tag{47.22}$$

which is consistent: tracing Eq. (47.22) on $(\mu\nu)$ recovers $c^\lambda{}_{\lambda\rho} = \eta^{\mu\nu}c_{\rho\mu\nu} = b_\rho + d\,b_\rho - b_\rho = d\,b_\rho$, matching the definition of b_μ. Contracting Eq. (47.22) with $x^\mu x^\nu$,

$$\xi_\rho\big|_{\text{quad}} = c_{\rho\mu\nu}x^\mu x^\nu = 2(b{\cdot}x)\,x_\rho - x^2\,b_\rho, \tag{47.23}$$

the d *special conformal transformations* parametrized by b^μ.

Collecting the three parts gives Eq. (47.11). The parameter count is d (from a^μ) $+\,\frac{1}{2}d(d-1)$ (from ω) $+\,1$ (from λ) $+\,d$ (from b^μ), and

$$d + \tfrac{1}{2}d(d-1) + 1 + d = \tfrac{1}{2}d^2 + \tfrac{3}{2}d + 1 = \tfrac{1}{2}(d+1)(d+2), \tag{47.24}$$

as claimed. This is Eq. (7.208); in $d = 4$ it equals 15. □

The four families warrant a clean restatement, since the next section exponentiates them and assembles their commutators. Writing them as the action on coordinates:

$$\begin{aligned}
\text{translations } (d): &\quad \xi^\mu = a^\mu, && \partial{\cdot}\xi = 0,\\
\text{Lorentz } (\tfrac{1}{2}d(d-1)): &\quad \xi^\mu = \omega^\mu{}_\nu\,x^\nu, && \partial{\cdot}\xi = 0,\\
\text{dilatation } (1): &\quad \xi^\mu = \lambda\,x^\mu, && \partial{\cdot}\xi = \lambda\,d,\\
\text{special conformal } (d): &\quad \xi^\mu = 2(b{\cdot}x)\,x^\mu - x^2\,b^\mu, && \partial{\cdot}\xi = 2d\,(b{\cdot}x).
\end{aligned} \tag{47.25}$$

The first two families have vanishing divergence and are genuine isometries (Poincaré); the dilatation has constant divergence, generating a uniform rescaling; the special conformal transformation has divergence linear in x, generating a position-dependent rescaling. The Weyl factor $\Omega = 1 + \frac{1}{d}\partial{\cdot}\xi$ of Eq. (47.10) is, accordingly, 1 for Poincaré, $1+\lambda$ for the dilatation, and $1 + 2(b{\cdot}x)$ for the special conformal transformation.

Caution

Theorem 47.3 assumes $d \geq 3$ at the decisive step Eq. (47.13), where the factor $(2-d)$ is divided out. In $d = 2$ that factor vanishes and the argument breaks: the conformal Killing equation reduces to the Cauchy–Riemann equations, every holomorphic and antiholomorphic map is conformal, and the solution space is infinite-dimensional. The finite-dimensional conformal group enumerated here is therefore strictly a $d \geq 3$ phenomenon; the global part of the $d = 2$ group is the $\frac{1}{2}\cdot 3\cdot 4 = 6$-dimensional Möbius group $\mathfrak{so}(3,1)$ that survives as the subgroup of *globally* well-defined maps, but the local enhancement to the Virasoro algebra is the subject of Chapter 48. In $d = 1$ there is no metric structure to preserve and the notion degenerates.

47.1.5 One conserved current per conformal generator

The enumeration of Theorem 47.3 is a statement about flat-space geometry; its physical bite comes from pairing it with a traceless stress tensor. The mechanism, established in full in Theorem 7.48, is worth recalling in one line because it explains why a vanishing trace — the certificate of scale invariance — is automatically the certificate of the larger conformal symmetry. Given a symmetric, conserved stress tensor $\Theta^{\mu\nu}_{\mathrm{c}}$, contract it with any vector field ξ_ν to form

$$J^{\mu}_{(\xi)} = \Theta^{\mu\nu}_{\mathrm{c}}\,\xi_\nu, \qquad \partial_\mu J^{\mu}_{(\xi)} = \tfrac{1}{2}\,\Theta^{\mu\nu}_{\mathrm{c}}(\partial_\mu\xi_\nu + \partial_\nu\xi_\mu), \tag{47.26}$$

where conservation $\partial_\mu\Theta^{\mu\nu}_{\mathrm{c}} = 0$ killed the first term and symmetry replaced $\partial_\mu\xi_\nu$ by its symmetric part. For an isometry the symmetric derivative vanishes and $J^{\mu}_{(\xi)}$ is conserved — this is the standard packaging of the ten Poincaré currents into $\Theta^{\mu\nu}$. But when ξ is a conformal Killing vector, Eq. (47.9) makes the symmetric derivative pure trace, and Eq. (47.26) becomes

$$\partial_\mu J^{\mu}_{(\xi)} = \tfrac{1}{2}\,\Theta^{\mu\nu}_{\mathrm{c}}\cdot\tfrac{2}{d}(\partial\cdot\xi)\eta_{\mu\nu} = \tfrac{1}{d}\,(\partial\cdot\xi)\,\Theta^{\mu}_{\mathrm{c}\,\mu}. \tag{47.27}$$

The current is conserved *for every conformal Killing vector* precisely when the trace vanishes. This is the engine of the whole subject: tracelessness, contracted against the $\frac{1}{2}(d+1)(d+2)$ solutions of the conformal Killing equation, produces exactly that many conserved currents and hence that many conserved charges. The dilatation current Eq. (47.1) is the case $\xi^\mu = x^\mu$, for which $J^{\mu}_{(\xi)} = x_\nu\Theta^{\mu\nu}_{\mathrm{c}} = D^\mu$ and $\partial\cdot\xi = d$, so Eq. (47.27) reproduces $\partial_\mu D^\mu = \Theta^{\mu}_{\mathrm{c}\,\mu}$ — the identity Eq. (47.3) that we used to define scale invariance. The special conformal currents are the case $\xi^\mu = 2(b\cdot x)x^\mu - x^2 b^\mu$,

$$K^{\mu\rho} = 2\,x^\rho x_\nu\,\Theta^{\mu\nu}_{\mathrm{c}} - x^2\,\Theta^{\mu\rho}_{\mathrm{c}}, \qquad \partial_\mu K^{\mu\rho} = 2\,x^\rho\,\Theta^{\mu}_{\mathrm{c}\,\mu}, \tag{47.28}$$

which is Eq. (7.212): the same trace controls their conservation. The lesson is structural and worth stating once plainly: *the dilatation current and the special*

conformal currents are both built from the stress tensor with explicit factors of x, and both are conserved if and only if the trace $\Theta^{\mu}_{\mathrm{c}\,\mu}$ vanishes. Scale and conformal symmetry are not independent inputs at the level of currents — they are governed by the same single operator. What is *not* automatic is that a theory which is scale invariant (trace a total derivative) can always be improved so that the trace vanishes outright (conformal); that is the genuine content of the upgrade, and we turn to it last.

The concrete realization we carry is the massless free scalar. Its canonical stress tensor has trace $\frac{2-d}{2}(\partial\phi)^2 \neq 0$, but the improvement Eq. (7.194) with coefficient $\xi_d = \frac{d-2}{4(d-1)}$ produces the traceless tensor $\Theta^{\mu\nu}_{\mathrm{c}}$ of Theorem 7.45, whose trace vanishes identically on shell in every dimension (the worked computation Theorem 7.46 carries this with the full $\lambda\phi^4$ trace, which collapses to $\Theta^{\mu}_{\mathrm{c}\,\mu} = 0$ when $m = 0$ and $d = 4$). By Eq. (47.27) the free massless scalar therefore carries the complete set of $\frac{1}{2}(d+1)(d+2)$ conserved conformal currents: it is a conformal field theory, the simplest one, and the seed of ϕ^4 theory's quantum fixed-point description.

Worked Example 47.4 (Finite conformal factors of the four families)**.** The infinitesimal Weyl factor Eq. (47.10) is useful, but it pays to record the *finite* conformal factors of each family, both to confirm that the families integrate to genuine conformal maps and because the next section needs them to build the global group. We compute $\Omega(x)$ from Eq. (47.4) directly.

Translation $x'^{\mu} = x^{\mu} + a^{\mu}$ and Lorentz $x'^{\mu} = \Lambda^{\mu}{}_{\nu}x^{\nu}$. The Jacobians are δ^{μ}_{ν} and $\Lambda^{\mu}{}_{\nu}$ respectively; the latter satisfies $\Lambda^{\rho}{}_{\mu}\Lambda^{\sigma}{}_{\nu}\eta_{\rho\sigma} = \eta_{\mu\nu}$ by definition of the Lorentz group. In both cases $\eta'_{\mu\nu} = \eta_{\mu\nu}$, so $\Omega = 1$: these are isometries.

Dilatation $x'^{\mu} = \lambda\, x^{\mu}$. The Jacobian is $\partial x'^{\mu}/\partial x^{\nu} = \lambda\,\delta^{\mu}_{\nu}$, so $\partial x^{\rho}/\partial x'^{\mu} = \lambda^{-1}\delta^{\rho}_{\mu}$ and $\eta'_{\mu\nu} = \lambda^{-2}\eta_{\mu\nu}$. Reading off Eq. (47.4) in the form $\eta'_{\mu\nu} = \Omega^{-2}\eta_{\mu\nu}$, the conformal factor is the constant $\Omega = \lambda$ — the position-independent rescaling that defines a dilatation.

Inversion $x'^{\mu} = x^{\mu}/x^2$. This is the elementary discrete conformal map (Fig. 47.1); the finite special conformal transformations are built from it by conjugation with a translation in the next section, so its conformal factor is the key input. Differentiate:

$$\frac{\partial x'^{\mu}}{\partial x^{\nu}} = \frac{\delta^{\mu}_{\nu}}{x^2} - \frac{2x^{\mu}x_{\nu}}{(x^2)^2} = \frac{1}{x^2}\Big(\delta^{\mu}_{\nu} - \frac{2x^{\mu}x_{\nu}}{x^2}\Big). \tag{47.29}$$

The matrix $R^{\mu}{}_{\nu} \equiv \delta^{\mu}_{\nu} - 2x^{\mu}x_{\nu}/x^2$ is a reflection: it squares to the identity, $R^{\mu}{}_{\rho}R^{\rho}{}_{\nu} = \delta^{\mu}_{\nu}$, as one checks from $R^{\mu}{}_{\rho}R^{\rho}{}_{\nu} = \delta^{\mu}_{\nu} - 4x^{\mu}x_{\nu}/x^2 + 4x^{\mu}x_{\nu}(x\cdot x)/(x^2)^2 = \delta^{\mu}_{\nu}$, and it preserves η, $R^{\rho}{}_{\mu}R^{\sigma}{}_{\nu}\eta_{\rho\sigma} = \eta_{\mu\nu}$. Hence

$$\eta'_{\mu\nu} = \frac{\partial x^{\rho}}{\partial x'^{\mu}}\frac{\partial x^{\sigma}}{\partial x'^{\nu}}\eta_{\rho\sigma} = (x^2)^2\,(R^{-1})^{\rho}{}_{\mu}(R^{-1})^{\sigma}{}_{\nu}\,\frac{\eta_{\rho\sigma}}{(x^2)^2}\cdot\frac{1}{1} = (x^2)^2\,\eta_{\mu\nu}, \tag{47.30}$$

where we used that the inverse Jacobian is $x^2 R$ (since $R^2 = 1$) and that R preserves η. Reading this off through Eq. (47.4) in the form $\eta'_{\mu\nu} = \Omega^{-2}\eta_{\mu\nu}$, so that $\Omega^{-2} = (x^2)^2$, the inversion has the position-dependent conformal factor

$$\Omega(x) = \frac{1}{x^2}, \tag{47.31}$$

confirming Theorem 47.2: lengths are rescaled by the local factor $1/x^2$ (shrunk for $|x| > 1$, stretched for $|x| < 1$), which diverges at the origin and vanishes at infinity, but angles are untouched. That the inversion is conformal yet not connected to the identity (it has Jacobian determinant of fixed sign but maps the origin to infinity) is the first sign that the conformal group has nontrivial global structure — the theme of the next section.

47.1.6 Does scale invariance imply conformal invariance?

We have shown that a *traceless* stress tensor generates the full conformal group, and that scale invariance only guarantees the trace is a *total derivative*, $\Theta^\mu{}_\mu = \partial_\mu V^\mu$ with V^μ the virial current. The gap between these two statements is the precise content of the question in the heading. Improving the trace away requires that the virial itself be a total derivative, $V^\mu = \partial_\nu L^{\nu\mu}$ for some local tensor $L^{\nu\mu}$ (Eq. (7.190) is exactly this for the scalar, with $L^{\nu\mu} = \frac{\Delta}{2}\eta^{\nu\mu}\phi^2$); only then can a Belinfante-style improvement absorb it and leave a traceless tensor, as in Theorem 7.48. A scale-invariant theory whose virial current is *not* a total derivative — one carrying a genuine conserved virial charge — is scale but not conformally invariant. The logical possibility is real; the physical question is whether it is ever realized in a sensible (unitary, local) theory.

Theorem 47.5 (Scale invariance and the conformal upgrade, with scope)**.** *Let a theory be Poincaré invariant, scale invariant, and unitary, with a local stress tensor. Whether it is necessarily invariant under the full conformal group depends on the dimension:*

- $d = 2$ (settled). *Under the further standing assumptions of a discrete operator spectrum and a bounded-below energy, scale invariance implies conformal invariance. The virial can always be improved away.*
- $d = 4$ (settled under standard assumptions). *Scale invariance implies conformal invariance, established perturbatively to all orders and argued nonperturbatively under the assumptions standard for unitary local QFT (a sensible a-anomaly, no decoupled free sectors of the pathological kind).*
- general d (open, as of the mid-2020s). *No general theorem and no unitary counterexample is known. The known scale-invariant-but-not-conformal theories (free Maxwell theory in $d \neq 4$, theories of elasticity) are either non-unitary or fail the locality/discreteness hypotheses.*

The improving condition — virial current a total derivative — holds for every interacting fixed point relevant to this book, so for the theories we study (the free scalar and the Wilson–Fisher point of ϕ^4 theory) the upgrade is unconditional.

Discussion and proof sketch. The forward direction — conformal ⇒ scale — is trivial, since dilatations are a subgroup. The content is the converse, and the proof in each dimension proceeds by analyzing the virial current V^μ.

$d = 2$. The decisive tool is Zamolodchikov's c-theorem [531]: a monotone function $c(g)$ along RG flows, nonincreasing toward the infrared and stationary exactly at fixed points, built from two-point functions of the stress tensor. At a scale-invariant point the c-function is stationary, and Polchinski [404] showed that stationarity together with unitarity and a discrete spectrum forces the trace two-point function $\langle \Theta^\mu{}_\mu(x)\, \Theta^\nu{}_\nu(0)\rangle$ to vanish, hence (by reflection positivity, the Euclidean unitarity statement of Chapter 10) the operator $\Theta^\mu{}_\mu$ itself to be a total derivative that can be improved to zero. The virial charge is then trivial and conformal invariance follows. The full argument is the centerpiece of Polchinski's analysis; we will not reproduce its operator-algebra details here, but its logical skeleton — monotone c-function, stationary at the fixed point, forcing the trace to vanish — is exactly the $d = 2$ shadow of the $d = 4$ argument below, and the reader has all its ingredients (the stress-tensor two-point function and reflection positivity) from earlier chapters.

$d = 4$. The four-dimensional analogue of the c-function is the a-anomaly coefficient, and the statement that it decreases monotonically along unitary RG flows is the *a-theorem*, proven by Komargodski and Schwimmer [301] by studying the dilaton effective action that compactly encodes the response of the theory to a position-dependent scale transformation. Luty, Polchinski, and Rattazzi [329] and Dymarsky, Komargodski, Schwimmer, and Theisen [166] sharpened this into a proof that, in a unitary four-dimensional theory, a nonzero virial current obstructing the conformal upgrade would generate a unitarity-violating contribution to the dilaton amplitude; consistency forces the virial to be improvable away, so scale invariance implies conformal invariance. The argument is perturbatively airtight and, under the assumptions standard for a local unitary QFT, is regarded as settled nonperturbatively.

general d. For arbitrary dimension there is neither a proven monotone c/a-type function of the required strength nor a constructed unitary counterexample. The status is genuinely open: it is expected on physical grounds that unitary, local, scale-invariant theories are conformal in any dimension, but this remains a conjecture rather than a theorem. The standard reference surveying the evidence and the gaps is Nakayama's review [356]. □

Physical Insight

The distinction between scale and conformal invariance is subtle precisely because it almost never matters: in every interacting theory of physical interest the virial current is a total derivative and the upgrade is automatic. But the distinction is not empty. It marks the difference between a one-parameter rescaling symmetry and a $\frac{1}{2}(d+1)(d+2)$-parameter group, and the entire predictive machinery of conformal field theory — two- and three-point functions fixed by symmetry, the operator product expansion, the bootstrap — rests on the larger group. A merely scale-invariant theory would have far weaker constraints. That the endpoints of physical RG flows are conformal, and not just scale-invariant, is what makes the abstract phrase "critical phenomenon" carry the rigid algebraic skeleton this part of the book will exploit.

With the conformal transformations of flat space enumerated — the four families Eq. (47.25) packaged in the general conformal Killing vector Eq. (47.11) — and with the assurance that the scale-invariant theories of ϕ^4 theory are genuinely conformal, the next task is purely algebraic: to exponentiate these infinitesimal generators into finite transformations, read off their commutators, and recognize the resulting structure as the Lie algebra $\mathfrak{so}(d+1,1)$ in Euclidean signature (equivalently $\mathfrak{so}(d,2)$ in Lorentzian signature). That construction, together with the global structure exposed by the inversion of Theorem 47.4 and the conformal compactification it forces, is the subject of the section that follows.

47.2 The Conformal Group and Algebra

The previous section solved the conformal Killing equation and found, in every dimension $d > 2$, exactly four families of infinitesimal angle-preserving transformations: the d translations, the $\frac{1}{2}d(d-1)$ rotations (Lorentz transformations in Lorentzian signature), the single dilatation, and the d special conformal transformations (Section 47.1). Counting parameters gives $d + \frac{1}{2}d(d-1) + 1 + d = \frac{1}{2}(d+1)(d+2)$ independent generators — a *finite* number, in sharp contrast with the infinite-dimensional algebra that the same calculation produces in $d = 2$ and which Chapter 48 is devoted to. Our task now is to turn these infinitesimal motions into the finite transformations they integrate to, to read off the abstract Lie algebra they close into, and to recognize that algebra as nothing more exotic than the rotation algebra of a flat space with two extra dimensions. That last fact is the organizing principle of the entire subject: the awkward nonlinear action of special conformal transformations on $\mathbb{R}^d$ becomes an ordinary linear rotation once we lift to a $(d+2)$-dimensional embedding space, and the representation theory that the rest of this chapter builds is, at bottom, the representation theory of $\mathfrak{so}(d+1,1)$.

Throughout, $\eta_{\mu\nu}$ denotes the flat metric in whatever signature is in force: in Euclidean signature $\eta_{\mu\nu} = \delta_{\mu\nu}$, in Lorentzian signature $\eta_{\mu\nu} = \mathrm{diag}(+, -, \ldots, -)$ as fixed in Section 47.1. We write $x^2 \equiv \eta_{\mu\nu} x^\mu x^\nu$ and $b \cdot x \equiv \eta_{\mu\nu} b^\mu x^\nu$, with indices raised and lowered by η. The two signatures differ only at the very end, where they select between the real forms $\mathfrak{so}(d+1,1)$ and $\mathfrak{so}(d,2)$ of one complex algebra; until then every formula is signature-blind.

47.2.1 Finite transformations

Three of the four families exponentiate to transformations the reader already knows. A finite translation by a^μ is

$$x'^\mu = x^\mu + a^\mu, \tag{47.32}$$

the integral of the constant Killing vector $\delta x^\mu = a^\mu$. A finite rotation is

$$x'^\mu = \Lambda^\mu{}_\nu \, x^\nu, \qquad \Lambda^{\mathsf{T}} \eta \, \Lambda = \eta, \tag{47.33}$$

the exponential of an antisymmetric generator $\omega^\mu{}_\nu$, i.e. an element of $\mathrm{SO}(d)$ (Euclidean) or the Lorentz group $\mathrm{SO}^+(1, d-1)$ (Lorentzian), imported wholesale from Section 3.2. A finite dilatation is the uniform rescaling

$$x'^\mu = \lambda \, x^\mu, \qquad \lambda = e^\sigma > 0, \tag{47.34}$$

integrating $\delta x^\mu = \sigma \, x^\mu$. Each of Eqs. (47.32) to (47.34) rescales the metric by a constant or unit Weyl factor and so is manifestly angle-preserving.

The fourth family — special conformal transformations (SCTs) — is the one whose finite form is not obvious, and it is most cleanly obtained not by direct exponentiation but through a discrete transformation that is itself conformal: the *inversion*.

Definition 47.6 (Inversion)**.** The inversion I is the map

$$I: \quad x^\mu \longmapsto \frac{x^\mu}{x^2}, \tag{47.35}$$

defined on all x with $x^2 \neq 0$.

Inversion is an involution, $I \circ I = \mathrm{id}$, since $(x/x^2)^2 = x^2/(x^2)^2 = 1/x^2$ and so $I(x/x^2) = (x^\mu/x^2)/(1/x^2) = x^\mu$. It is not continuously connected to the identity — it cannot be reached by exponentiating any Killing vector — so it is a genuinely new, discrete element of the symmetry. That it is nonetheless conformal we verify in full in Section 47.2.5 below, where we compute its Weyl factor. Granting that for the moment, conjugating a translation by inversion produces a new continuous family of conformal maps, and this family is precisely the special conformal transformations.

Definition 47.7 (Special conformal transformation)**.** The special conformal transformation with parameter b^μ is the map $x \mapsto x'$ that becomes an ordinary translation by $-b^\mu$ after inversion,

$$\frac{x'^\mu}{x'^2} \;=\; \frac{x^\mu}{x^2} - b^\mu, \tag{47.36}$$

that is, $\mathrm{SCT}_b = I \circ T_b \circ I$ with T_b the translation $y \mapsto y - b$ acting on the inverted coordinate.

Proposition 47.8 (Finite special conformal transformation)**.** *The relation Eq. (47.36) solves to*

$$x'^\mu \;=\; \frac{x^\mu - b^\mu\, x^2}{1 - 2\, b\cdot x + b^2\, x^2}. \tag{47.37}$$

Proof. We compose the three maps in Theorem 47.7 explicitly. Start from x^μ and invert: $y^\mu = x^\mu/x^2$. Translate by $-b$: $y'^\mu = y^\mu - b^\mu = x^\mu/x^2 - b^\mu = (x^\mu - b^\mu x^2)/x^2$. Now compute the squared length of y',

$$\begin{aligned}(y')^2 &= \Big(\frac{x^\mu}{x^2} - b^\mu\Big)\Big(\frac{x_\mu}{x^2} - b_\mu\Big) = \frac{x^2}{(x^2)^2} - 2\,\frac{b\cdot x}{x^2} + b^2 \\ &= \frac{1 - 2\, b\cdot x + b^2 x^2}{x^2}.\end{aligned} \tag{47.38}$$

Inverting once more, $x'^\mu = y'^\mu/(y')^2$, and substituting both pieces,

$$x'^\mu = \frac{(x^\mu - b^\mu x^2)/x^2}{(1 - 2\, b\cdot x + b^2 x^2)/x^2} = \frac{x^\mu - b^\mu x^2}{1 - 2\, b\cdot x + b^2 x^2}, \tag{47.39}$$

the factors of x^2 cancelling, which is Eq. (47.37). □

Expanding Eq. (47.37) to first order in b confirms the identification with the SCT Killing vector found in the previous section: the numerator gives $x^\mu - b^\mu x^2$ and the denominator $(1 - 2b\cdot x)^{-1} \approx 1 + 2b\cdot x$, so

$$\delta x^\mu = x'^\mu - x^\mu = 2\,(b\cdot x)\, x^\mu - x^2\, b^\mu + O(b^2), \tag{47.40}$$

which is exactly the special conformal Killing vector. The sign of the parameter b^μ in Eq. (47.36) — the choice of translating by $-b$ rather than $+b$ on the inverted side — is a pure convention; it fixes the sign of the generator K_μ below, and we adopt the choice that makes Eq. (47.37) and Eq. (47.40) carry the standard minus signs.

Notation Watch

The denominator $1 - 2b \cdot x + b^2 x^2$ in Eq. (47.37) equals x'^2/x^2 up to the inversion bookkeeping; it vanishes on a $(d-1)$-dimensional locus, where the SCT pushes a finite point to infinity. This is not a pathology of the formula but a signal that the conformal group does not act on $\mathbb{R}^d$ as it stands — it acts on a compactification, the subject of Section 47.2.5. Until then, all finite SCT statements are understood to hold away from this locus.

47.2.2 The generators as differential operators

To extract the algebra we represent each family by the first-order differential operator that generates it on functions of x. For an infinitesimal motion $x \mapsto x + \delta x$ a scalar function transforms by $\delta f = -\delta x^\mu \, \partial_\mu f$; writing $\delta x^\mu = \xi_a^\mu \, \epsilon^a$ for the Killing vector of the a-th family with parameter ϵ^a, the Hermitian generator is $G_a = -i \, \xi_a^\mu \, \partial_\mu$, so that $\delta f = i \, \epsilon^a G_a f$. (The factor $-i$ makes G_a Hermitian and matches the translation convention $U(\mathbf{1}, a) = e^{ia \cdot P}$ of Eq. (3.136).) Reading the four Killing vectors — a^μ for translations, $\omega^\mu{}_\nu x^\nu$ for rotations, σx^μ for dilatations, and the SCT vector of Eq. (47.40) — this prescription gives

$$\boxed{\begin{aligned} P_\mu &= -i \, \partial_\mu, & M_{\mu\nu} &= i(x_\mu \partial_\nu - x_\nu \partial_\mu), \\ D &= -i \, x^\mu \partial_\mu, & K_\mu &= -i(2 \, x_\mu \, x^\nu \partial_\nu - x^2 \, \partial_\mu). \end{aligned}} \tag{47.41}$$

Here P_μ and $M_{\mu\nu}$ are exactly the momentum and Lorentz generators of Section 3.5, in their differential-operator realization on fields; one checks immediately, raising indices, that $M^{\mu\nu} = i(x^\mu \partial^\nu - x^\nu \partial^\mu)$ reproduces the Poincaré bracket $[M^{\mu\nu}, P^\rho] = i(\eta^{\nu\rho} P^\mu - \eta^{\mu\rho} P^\nu)$ of Eq. (3.148). The two new generators are the dilatation D, which simply counts the degree of homogeneity of a function in x, and the special conformal generator K_μ. These differential operators carry no information about the intrinsic spin or scaling weight of the field they act on; Section 47.3 reinstates those by adding the appropriate matrix and dimension terms. For deriving the algebra, the orbital pieces in Eq. (47.41) suffice, because the extra terms are x-independent constants that drop out of every commutator that determines a structure constant.

47.2.3 The conformal algebra

We now compute the brackets. The Poincaré sector $[P, P] = 0$, $[M, P]$, $[M, M]$ is imported unchanged from Eqs. (3.147) to (3.149); we derive the brackets involving D and K in full.

The dilatation grades momentum and special conformal generators. Using $[x^\nu\partial_\nu, \partial_\mu] = x^\nu\partial_\nu\partial_\mu - \partial_\mu(x^\nu\partial_\nu) = -\partial_\mu$ (the inhomogeneous term being $-\delta^\nu_\mu\partial_\nu$),

$$[D, P_\mu] = (-i)(-i)\,[x^\nu\partial_\nu, \partial_\mu] = -\,[x^\nu\partial_\nu, \partial_\mu] = \partial_\mu = i\,P_\mu. \tag{47.42}$$

The same calculation with K_μ in place of P_μ gives the opposite sign. Write $K_\mu = -i\,k_\mu$ with $k_\mu = 2x_\mu x^\nu\partial_\nu - x^2\partial_\mu$, a vector field homogeneous of degree $+1$ in x. Since $[x^\nu\partial_\nu, \cdot\,]$ measures degree, acting on a degree-$(+1)$ field it returns the field itself: $[x^\nu\partial_\nu, k_\mu] = +k_\mu$ (verified directly below). Hence

$$[D, K_\mu] = (-i)(-i)\,[x^\nu\partial_\nu, k_\mu] = -\,k_\mu = -\,i\,K_\mu. \tag{47.43}$$

To make the degree statement explicit, compute $[x^\nu\partial_\nu,\, x^2\partial_\mu]$ and $[x^\nu\partial_\nu,\, x_\mu x^\rho\partial_\rho]$ from the Leibniz rule; using $x^\nu\partial_\nu x^2 = 2x^2$ and $x^\nu\partial_\nu x_\mu = x_\mu$ one finds each equals the operator itself, so their combination k_μ has degree $+1$, confirming Eq. (47.43).

Equations Eqs. (47.42) and (47.43) are the heart of the whole subject: under the dilatation, P_μ *raises* a scaling eigenvalue by one unit and K_μ *lowers* it by one. This $\mathbb{Z}$-grading of the algebra by the eigenvalue of D is what the next section exploits to define primaries and descendants.

Special conformal and momentum generators. This is the one bracket whose structure is genuinely new, so we carry every step. With $P_\nu = -i\partial_\nu$ and $K_\mu = -i(2x_\mu x^\rho\partial_\rho - x^2\partial_\mu)$,

$$[K_\mu, P_\nu] = (-i)(-i)\,\Big[\,2x_\mu x^\rho\partial_\rho - x^2\partial_\mu\,,\,\partial_\nu\,\Big] = -\,\Big[\,2x_\mu x^\rho\partial_\rho - x^2\partial_\mu\,,\,\partial_\nu\,\Big]. \tag{47.44}$$

We need two elementary commutators. First, using $\partial_\nu x^2 = 2x_\nu$,

$$\Big[x^2\partial_\mu, \partial_\nu\Big] = x^2\partial_\mu\partial_\nu - \partial_\nu(x^2\partial_\mu) = -\,(\partial_\nu x^2)\,\partial_\mu = -\,2\,x_\nu\,\partial_\mu. \tag{47.45}$$

Second, with $\partial_\nu x_\mu = \eta_{\mu\nu}$ and $\partial_\nu x^\rho = \delta^\rho_\nu$,

$$\begin{aligned}[x_\mu x^\rho\partial_\rho, \partial_\nu] &= x_\mu x^\rho\partial_\rho\partial_\nu - \partial_\nu(x_\mu x^\rho\partial_\rho)\\ &= x_\mu x^\rho\partial_\rho\partial_\nu - \eta_{\mu\nu}x^\rho\partial_\rho - x_\mu\,\partial_\nu - x_\mu x^\rho\partial_\nu\partial_\rho\\ &= -\,\eta_{\mu\nu}\,x^\rho\partial_\rho - x_\mu\,\partial_\nu,\end{aligned} \tag{47.46}$$

the two second-derivative terms cancelling. Substituting Eqs. (47.45) and (47.46) into Eq. (47.44),

$$\begin{aligned}[K_\mu, P_\nu] &= -\Big[\,2(-\eta_{\mu\nu}x^\rho\partial_\rho - x_\mu\partial_\nu) - (-2x_\nu\partial_\mu)\Big]\\ &= 2\,\eta_{\mu\nu}\,x^\rho\partial_\rho + 2\,x_\mu\partial_\nu - 2\,x_\nu\partial_\mu.\end{aligned} \tag{47.47}$$

Finally re-express the right-hand side in generators. From Eq. (47.41), $x^\rho\partial_\rho = i\,D$ and $x_\mu\partial_\nu - x_\nu\partial_\mu = -i\,M_{\mu\nu}$, so

$$[K_\mu, P_\nu] = 2\,\eta_{\mu\nu}\,(iD) + 2\,(-i\,M_{\mu\nu}) = 2\,i\,(\eta_{\mu\nu}\,D - M_{\mu\nu}). \tag{47.48}$$

This is the defining nonlinear bracket of the conformal algebra: a momentum and a special conformal generator do not commute; their commutator closes onto the dilatation and the rotations, with the metric $\eta_{\mu\nu}$ tying the two together.

The remaining brackets. Three brackets remain, and each follows from a short argument rather than a long computation. That K_μ transforms as a vector under rotations,

$$[M_{\mu\nu}, K_\rho] = i(\eta_{\nu\rho}K_\mu - \eta_{\mu\rho}K_\nu), \tag{47.49}$$

holds because K_ρ carries a single lower vector index built covariantly from x and ∂; the bracket is fixed to have the same form as $[M_{\mu\nu}, P_\rho]$ of Eq. (3.148), and a one-line repetition of that computation with the operator k_ρ confirms the coefficient. The dilatation is a rotational scalar,

$$[M_{\mu\nu}, D] = 0, \tag{47.50}$$

since $D = -ix^\rho\partial_\rho$ is built from the rotation-invariant contraction $x^\rho\partial_\rho$. Finally the special conformal generators commute among themselves,

$$[K_\mu, K_\nu] = 0. \tag{47.51}$$

The cleanest proof of Eq. (47.51) is geometric and uses Theorem 47.7: a finite SCT is $I \circ T_b \circ I$, so the composition of two SCTs is

$$\mathrm{SCT}_{b_1} \circ \mathrm{SCT}_{b_2} = I T_{b_1} I\, I T_{b_2} I = I\,T_{b_1} T_{b_2}\,I = I\,T_{b_1+b_2}\,I = \mathrm{SCT}_{b_1+b_2}, \tag{47.52}$$

because the two inversions in the middle annihilate ($I^2 = \mathrm{id}$) and translations form an abelian group, $T_{b_1}T_{b_2} = T_{b_1+b_2} = T_{b_2}T_{b_1}$. The SCTs are therefore an abelian subgroup, isomorphic as a group to the translations conjugated by I, and their generators commute. We can now collect everything.

Theorem 47.9 (The conformal algebra in $d > 2$)**.** *The generators* $\{P_\mu, M_{\mu\nu}, D, K_\mu\}$ *of Eq. (47.41) close into the Lie algebra*

$$[M_{\mu\nu}, M_{\rho\sigma}] = i(\eta_{\nu\rho}M_{\mu\sigma} - \eta_{\mu\rho}M_{\nu\sigma} - \eta_{\nu\sigma}M_{\mu\rho} + \eta_{\mu\sigma}M_{\nu\rho}), \tag{47.53a}$$

$$[M_{\mu\nu}, P_\rho] = i(\eta_{\nu\rho}P_\mu - \eta_{\mu\rho}P_\nu), \qquad [M_{\mu\nu}, K_\rho] = i(\eta_{\nu\rho}K_\mu - \eta_{\mu\rho}K_\nu), \tag{47.53b}$$

$$[D, P_\mu] = i\,P_\mu, \qquad [D, K_\mu] = -\,i\,K_\mu, \tag{47.53c}$$

$$[K_\mu, P_\nu] = 2\,i\,(\eta_{\mu\nu}D - M_{\mu\nu}), \tag{47.53d}$$

with all other brackets — $[P_\mu, P_\nu]$, $[K_\mu, K_\nu]$, $[M_{\mu\nu}, D]$, $[D, M_{\mu\nu}]$ — vanishing. This algebra has dimension $\frac{1}{2}(d+1)(d+2)$.

Proof. The brackets are Eqs. (3.148), (3.149), (47.42), (47.43), (47.48) and (47.49) together with the vanishing brackets Eqs. (47.50) and (47.51) and $[P_\mu, P_\nu] = 0$ from Eq. (3.147). Closure is manifest: every right-hand side is a linear combination of the same generators. The dimension count adds the $\frac{1}{2}d(d-1)$ generators $M_{\mu\nu}$, the d generators P_μ, the d generators K_μ, and the single D:

$$\tfrac{1}{2}d(d-1)+d+d+1 = \tfrac{1}{2}(d^2-d+4d+2) = \tfrac{1}{2}(d^2+3d+2) = \tfrac{1}{2}(d+1)(d+2). \qquad \square$$

Physical Insight

The Poincaré algebra of Section 3.5 sits inside Eq. (47.53) as the subalgebra $\{P_\mu, M_{\mu\nu}\}$; adding the dilatation D gives the algebra of *scale-invariant* theories, with P graded but K still absent. The single bracket Eq. (47.53d) is what distinguishes a conformal theory from a merely scale-invariant one: it forces the special conformal generators into the algebra the moment one demands closure with both P and D present. This is the algebraic face of the statement, made physical in Section 47.1, that under mild hypotheses scale invariance is promoted to full conformal invariance — the extra symmetry is not optional once the bracket structure is taken seriously.

47.2.4 Isomorphism with $\mathfrak{so}(d+1,1)$

The dimension $\frac{1}{2}(d+1)(d+2)$ is exactly the dimension of the rotation algebra $\mathfrak{so}(p,q)$ on a $(d+2)$-dimensional space, $p+q=d+2$, whose generators $J_{AB} = -J_{BA}$ $(A,B = 0,1,\ldots,d+1)$ number $\frac{1}{2}(d+2)(d+1)$. This is not a numerical coincidence. We now construct an explicit isomorphism.

Introduce a $(d+2)$-dimensional space with coordinates X^A and flat metric

$$G_{AB} = \mathrm{diag}(\eta_{\mu\nu}, +1, -1), \qquad A,B \in \{0,\ldots,d-1,\, d,\, d+1\}, \tag{47.54}$$

so that the two new directions X^d and X^{d+1} are respectively spacelike and timelike with respect to G. The rotation generators of this space obey the $\mathfrak{so}(p,q)$ algebra, which is the $(d+2)$-dimensional version of the Lorentz bracket Eq. (3.135),

$$[J_{AB}, J_{CD}] = i(G_{AD}J_{BC} + G_{BC}J_{AD} - G_{AC}J_{BD} - G_{BD}J_{AC}). \tag{47.55}$$

Theorem 47.10 (Conformal algebra as $\mathfrak{so}(d+1,1)$)**.** *The assignment*

$$M_{\mu\nu} = J_{\mu\nu}, \qquad P_\mu = J_{\mu,d} + J_{\mu,d+1}, \qquad K_\mu = J_{\mu,d} - J_{\mu,d+1}, \qquad D = J_{d+1,d}, \tag{47.56}$$

equivalently $J_{\mu,d} = \frac{1}{2}(P_\mu + K_\mu)$ and $J_{\mu,d+1} = \frac{1}{2}(P_\mu - K_\mu)$, is a Lie-algebra isomorphism from Eq. (47.55) onto the conformal algebra Eq. (47.53). In Euclidean signature $\eta_{\mu\nu} = \delta_{\mu\nu}$ the metric Eq. (47.54) has signature $(d+1,1)$, so the conformal algebra is $\mathfrak{so}(d+1,1)$; in Lorentzian signature $\eta_{\mu\nu} = \mathrm{diag}(+,-,\ldots,-)$ it is $\mathfrak{so}(d,2) \cong \mathfrak{so}(2,d)$.

Proof. We verify that the brackets Eq. (47.55) reproduce Eq. (47.53) under the dictionary Eq. (47.56); since both algebras have the same dimension and the map is a linear bijection, this establishes the isomorphism. The purely $\mu\nu$ brackets are immediate: with A, B, C, D all in $\{0, \ldots, d-1\}$, Eq. (47.55) is verbatim the Lorentz bracket Eq. (47.53a), and $M_{\mu\nu} = J_{\mu\nu}$.

Dilatation grading. Take $D = J_{d+1,d}$ and compute its bracket with $J_{\mu,d}$, using Eq. (47.55) with $(A, B, C, D) = (d+1, d, \mu, d)$. The only nonzero metric contraction is $G_{d+1,d+1} = -1$ in the term $-G_{BD}J_{AC} = -G_{dd}J_{d+1,\mu}$; with $G_{dd} = +1$,

$$[J_{d+1,d}, J_{\mu,d}] = i(-G_{dd}J_{d+1,\mu}) = -\,i\,J_{d+1,\mu} = +\,i\,J_{\mu,d+1}. \tag{47.57}$$

The analogous computation with $(A, B, C, D) = (d+1, d, \mu, d+1)$ singles out $-G_{BD}J_{AC} = -G_{d,d+1}\ldots$, more carefully the surviving term is $G_{AD}J_{BC} = G_{d+1,d+1}J_{d,\mu} = -J_{d,\mu} = +J_{\mu,d}$, giving

$$[J_{d+1,d}, J_{\mu,d+1}] = +\,i\,J_{\mu,d}. \tag{47.58}$$

Adding and subtracting,

$$[D, P_\mu] = [J_{d+1,d}, J_{\mu,d} + J_{\mu,d+1}] = i(J_{\mu,d+1} + J_{\mu,d}) = i\,P_\mu, \tag{47.59}$$

$$[D, K_\mu] = [J_{d+1,d}, J_{\mu,d} - J_{\mu,d+1}] = i(J_{\mu,d+1} - J_{\mu,d}) = -\,i\,K_\mu, \tag{47.60}$$

reproducing Eq. (47.53c).

The $[K, P]$ bracket. Expand using bilinearity,

$$[K_\mu, P_\nu] = [J_{\mu,d} - J_{\mu,d+1},\ J_{\nu,d} + J_{\nu,d+1}] = [J_{\mu d}, J_{\nu d}] + [J_{\mu d}, J_{\nu,d+1}] - [J_{\mu,d+1}, J_{\nu d}] - [J_{\mu,d+1}, J_{\nu,d} \tag{47.61}$$

Each of the four is read off from Eq. (47.55), keeping only the nonzero metric components $G_{\mu\nu} = \eta_{\mu\nu}$, $G_{dd} = +1$, $G_{d+1,d+1} = -1$:

$$[J_{\mu d}, J_{\nu d}] = i(-G_{dd}J_{\mu\nu}) = -\,i\,M_{\mu\nu}, \tag{47.62}$$

$$[J_{\mu d}, J_{\nu,d+1}] = i(-G_{\mu\nu}J_{d,d+1}) = i\,\eta_{\mu\nu}\,J_{d+1,d} = i\,\eta_{\mu\nu}\,D, \tag{47.63}$$

$$[J_{\mu,d+1}, J_{\nu d}] = i(-G_{\mu\nu}J_{d+1,d}) = -\,i\,\eta_{\mu\nu}\,D, \tag{47.64}$$

$$[J_{\mu,d+1}, J_{\nu,d+1}] = i(-G_{d+1,d+1}J_{\mu\nu}) = +\,i\,M_{\mu\nu}. \tag{47.65}$$

(In the second and third lines we used $J_{d,d+1} = -J_{d+1,d} = -D$.) Assembling Eq. (47.61),

$$[K_\mu, P_\nu] = -iM_{\mu\nu} + i\eta_{\mu\nu}D - (-i\eta_{\mu\nu}D) - iM_{\mu\nu} = 2\,i\,(\eta_{\mu\nu}D - M_{\mu\nu}), \tag{47.66}$$

which is Eq. (47.53d). The vector brackets Eq. (47.53b) follow identically from the mixed $\mu\nu$–d and $\mu\nu$–$(d+1)$ components of Eq. (47.55), and $[P, P] = [K, K] = 0$ follow from $[J_{\mu d} + J_{\mu,d+1}, J_{\nu d} + J_{\nu,d+1}]$ collapsing once the $M_{\mu\nu}$ contributions cancel against each other (the $+iM$ from the $(d+1, d+1)$ term cancels the $-iM$ from the (d, d) term). All brackets of Eq. (47.53) are thus reproduced.

Signature. The metric Eq. (47.54) appends one $+$ and one $-$ to η. Euclidean $\eta = \delta$ has d plus signs, so G has $d+1$ plus and one minus: signature $(d+1,1)$, the algebra $\mathfrak{so}(d+1,1)$. Lorentzian $\eta = \mathrm{diag}(+,-,\dots,-)$ has one plus and $d-1$ minus, so G has two plus and d minus: signature $(2,d)$, the algebra $\mathfrak{so}(2,d) \cong \mathfrak{so}(d,2)$. □

Physical Insight

The same complex Lie algebra $\mathfrak{so}(d+2,\mathbb{C})$ underlies both signatures; the Wick rotation of Chapter 5 that turns a Lorentzian QFT into a Euclidean one is, on the conformal side, exactly the move between the real forms $\mathfrak{so}(d,2)$ and $\mathfrak{so}(d{+}1,1)$. This is why the Euclidean bootstrap of Chapters 49 and 50 and the Lorentzian, causal statements of Chapter 51 are two faces of one structure: they share an algebra and differ only in which generators are taken anti-Hermitian. The maximal compact subalgebra in the Euclidean case is $\mathfrak{so}(d) \oplus \mathfrak{so}(2)$ — spatial rotations together with the rotation in the (X^d, X^{d+1}) plane generated by D — and its two Casimir labels, spin and the eigenvalue of that $\mathfrak{so}(2)$, are the conformal analogue of the mass and spin that label Poincaré representations in Theorem 3.19.

47.2.5 Inversion preserves angles; the embedding null cone

Two debts remain: to prove that inversion is conformal (used freely in Section 47.2.1), and to give the linear realization of the conformal action promised in the introduction. Both are settled by the same embedding-space geometry.

Inversion is conformal. Under $x'^\mu = x^\mu/x^2$ the Jacobian is

$$\frac{\partial x'^\mu}{\partial x^\nu} = \frac{\delta^\mu_\nu}{x^2} - \frac{2\,x^\mu x_\nu}{(x^2)^2} = \frac{1}{x^2}\,R^\mu{}_\nu(x), \qquad R^\mu{}_\nu(x) \equiv \delta^\mu_\nu - \frac{2\,x^\mu x_\nu}{x^2}. \tag{47.67}$$

The matrix $R(x)$ is the reflection across the hyperplane orthogonal to x, and it is an orthogonal transformation for the metric η: contracting,

$$\begin{aligned} \eta_{\mu\nu}\,R^\mu{}_\rho\,R^\nu{}_\sigma &= \Big(\delta^\mu_\rho - \frac{2x^\mu x_\rho}{x^2}\Big)\Big(\eta_{\mu\sigma} - \frac{2x_\mu x_\sigma}{x^2}\Big) \\ &= \eta_{\rho\sigma} - \frac{2x_\rho x_\sigma}{x^2} - \frac{2x_\rho x_\sigma}{x^2} + \frac{4\,(x^\mu x_\mu)\,x_\rho x_\sigma}{(x^2)^2} \\ &= \eta_{\rho\sigma} - \frac{4x_\rho x_\sigma}{x^2} + \frac{4\,x_\rho x_\sigma}{x^2} = \eta_{\rho\sigma}, \end{aligned} \tag{47.68}$$

where the last cross term used $x^\mu x_\mu = x^2$. Therefore the metric pulled back by inversion is

$$\eta_{\mu\nu}\,\mathrm{d}x'^\mu\,\mathrm{d}x'^\nu = \frac{1}{(x^2)^2}\,\eta_{\rho\sigma}\,R^\mu{}_\rho R^\nu{}_\sigma\,\mathrm{d}x^\rho\,\mathrm{d}x^\sigma = \frac{1}{(x^2)^2}\,\eta_{\rho\sigma}\,\mathrm{d}x^\rho\,\mathrm{d}x^\sigma, \tag{47.69}$$

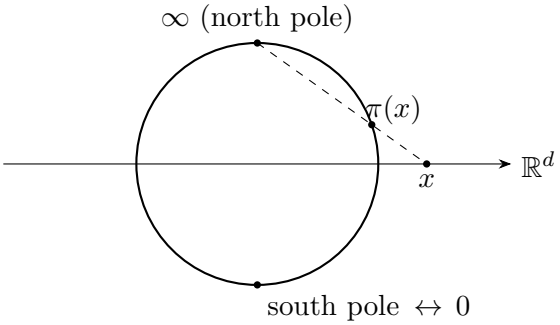

Figure 47.2: Stereographic projection identifies $\mathbb{R}^d \cup \{\infty\}$ with the sphere S^d (shown in cross-section). A point $x \in \mathbb{R}^d$ maps to the second intersection $\pi(x)$ of the line through the north pole and x with the sphere; the north pole itself is the adjoined point at infinity, and the origin maps to the south pole. On S^d the conformal group acts without singularity: inversion is the smooth rotation exchanging the two poles.

a pure Weyl rescaling by $\Omega(x)^2 = (x^2)^{-2}$, i.e. $\Omega(x) = 1/x^2$. Inversion multiplies all lengths at x by the same factor and so leaves all angles fixed: it is conformal, as claimed. Because every finite conformal transformation is a product of the elements in Section 47.2.1 and inversions, Eq. (47.69) completes the proof that the maps enumerated there are the full conformal group; Theorem 47.11 carries the Weyl factor for a general SCT.

Compactification. The inversion $x \mapsto x/x^2$ is singular at the origin, where $x^2 = 0$ and the image runs off to infinity; conversely it has no preimage of a finite point for the would-be image of the origin. Likewise the finite SCT Eq. (47.37) sends the locus $1 - 2b \cdot x + b^2 x^2 = 0$ to infinity. The conformal group thus fails to act on $\mathbb{R}^d$ as a set of bijections. The cure is to adjoin a single point at infinity. In Euclidean signature the resulting space $\mathbb{R}^d \cup \{\infty\}$ is the d-sphere S^d, via stereographic projection (Fig. 47.2); inversion becomes a smooth rotation of S^d exchanging the two poles, with no singularity anywhere. The conformal group acts on S^d as its group of (orientation-preserving, with inversion) conformal automorphisms. This is the precise sense in which the conformal group is $\mathrm{O}(d+1,1)$ acting on the compactified Euclidean space, the connected component giving the transformations reachable from the identity and the inversion living in a disconnected component.

The projective null cone. The cleanest carrier of the conformal action is the embedding space of Section 47.2.4 itself. Consider in $\mathbb{R}^{d+2}$ with metric G of Eq. (47.54) the null cone

$$X^2 \equiv G_{AB}\, X^A X^B = 0, \qquad X \neq 0, \tag{47.70}$$

and identify points along the same ray, $X^A \sim \lambda X^A$ for $\lambda > 0$ (this is the *projective* null cone). It is convenient to use light-cone combinations of the two extra coordinates, $X^{\pm} = X^d \pm X^{d+1}$, in which

$$X^2 = G_{\mu\nu}X^\mu X^\nu + (X^d)^2 - (X^{d+1})^2 = \eta_{\mu\nu}X^\mu X^\nu + X^+X^-. \tag{47.71}$$

On the cone we may use the projective rescaling to fix $X^+ = 1$; the null condition Eq. (47.71) then determines $X^- = -\eta_{\mu\nu}X^\mu X^\nu = -X^2_{\text{(d-dim)}}$. Writing the remaining d components as $X^\mu = x^\mu$, we obtain the *Poincaré section*

$$X^A(x) = (\,X^+,\, X^-,\, X^\mu\,) = (\,1,\, -x^2,\, x^\mu\,), \tag{47.72}$$

a one-to-one parametrization of the cone (modulo rays) by the points $x^\mu \in \mathbb{R}^d$, with $X^+ = 0$ furnishing exactly the adjoined point at infinity. A linear $\mathrm{O}(d+1,1)$ rotation $X \mapsto \Lambda X$ preserves Eq. (47.71), hence maps the cone to itself; it generally moves a representative off the section $X^+ = 1$, and the projective rescaling that returns it to the section is what makes the induced action on x^μ nonlinear. The *linear* $\mathfrak{so}(d+1,1)$ action on X *is* the conformal action on x.

To see inversion in these terms, note that I corresponds to the linear reflection $X^+ \leftrightarrow X^-$. On the section Eq. (47.72) this sends $(1, -x^2, x^\mu) \mapsto (-x^2, 1, x^\mu)$; rescaling by the positive factor $1/(-x^2)$ to restore $X^+ = 1$ gives $(1,\, -1/x^2,\, x^\mu/x^2)$... up to the overall sign of the timelike pair, which is the projective identification — and reading off the last d components recovers $x^\mu \mapsto x^\mu/x^2$, the inversion. This is the precise statement that inversion maps the null cone to itself and reduces, on the section, to Eq. (47.35). The embedding-space formalism, which the correlator computations of Section 47.4 and the conformal-block technology of Chapter 49 take as their starting point, is therefore the natural *linear* home of the nonlinearly-realized conformal symmetry: every tensorial conformal covariant on $\mathbb{R}^d$ lifts to an ordinary $\mathfrak{so}(d+1,1)$ tensor on the cone.

Caution

The two added directions are not interchangeable: X^d is spacelike and X^{d+1} timelike with respect to G, and the dilatation $D = J_{d+1,d}$ is a *boost* in that mixed plane, not a compact rotation. Its real eigenvalues are the scaling dimensions of operators; the compact rotation that pairs with it in the maximal compact subalgebra is the one used in *radial quantization* (Section 47.5), where D becomes the Hamiltonian generating dilatations about a chosen origin. Conflating the boost D with a compact rotation is the most common error in setting up the state–operator map.

Worked Example 47.11 (The Weyl factor of a special conformal transformation)**.** We confirm directly that the finite SCT Eq. (47.37) is conformal and extract its Weyl factor, both as a check on Theorem 47.7 and because the factor $\Omega(x)$ is the object every conformal correlator is built from. Write the denominator

as $\gamma(x) \equiv 1 - 2\,b\cdot x + b^2x^2$, so that $x'^\mu = \gamma^{-1}(x^\mu - b^\mu x^2)$. The fastest route uses Theorem 47.7: a finite SCT is $I \circ T_{-b} \circ I$, and the Weyl factor of a composition is the product of the factors. Inversion has factor $\Omega_I(x) = 1/x^2$ by Eq. (47.69); translation has factor 1; and the second inversion acts at the translated point $y' = x/x^2 - b$, contributing $\Omega_I(y') = 1/(y')^2$. By Eq. (47.38), $(y')^2 = \gamma(x)/x^2$. Multiplying the three factors and tracking that the metric is rescaled once by each inversion,

$$\Omega_{\mathrm{SCT}}(x) = \Omega_I(x)\cdot 1\cdot \frac{1}{\Omega_I(y')}\Big|_{\text{reassembled}} = \frac{1/x^2}{(y')^2} = \frac{1/x^2}{\gamma(x)/x^2} = \frac{1}{\gamma(x)} = \frac{1}{1 - 2\,b\cdot x + b^2x^2}. \tag{47.73}$$

As an independent check, expand the Jacobian $\partial x'^\mu/\partial x^\nu$ of Eq. (47.37) directly. Differentiating $x'^\mu = \gamma^{-1}(x^\mu - b^\mu x^2)$ and using $\partial_\nu\gamma = -2b_\nu + 2b^2x_\nu$ gives, after algebra that organizes itself into a reflection times a scalar exactly as in Eq. (47.67),

$$\frac{\partial x'^\mu}{\partial x^\nu} = \frac{1}{\gamma(x)}\,\widetilde{R}^\mu{}_\nu(x), \qquad \eta_{\mu\nu}\widetilde{R}^\mu{}_\rho\widetilde{R}^\nu{}_\sigma = \eta_{\rho\sigma}, \tag{47.74}$$

with $\widetilde{R}$ orthogonal, so $\eta_{\mu\nu}\mathrm{d}x'^\mu\mathrm{d}x'^\nu = \gamma^{-2}\,\eta_{\rho\sigma}\mathrm{d}x^\rho\mathrm{d}x^\sigma$ and the Weyl factor is again $\Omega_{\mathrm{SCT}} = 1/\gamma$, confirming Eq. (47.73). The two routes agree, and the SCT is conformal with the local rescaling $\Omega(x) = (1 - 2b\cdot x + b^2x^2)^{-1}$.

Worked Example 47.12 (The dilatation as a boost on the null cone)**.** The abstract identification $D = J_{d+1,d}$ becomes concrete and geometric on the Poincaré section. A finite dilatation is generated by the boost $e^{-i\sigma D}$ in the (X^d, X^{d+1}) plane; in the light-cone basis $X^\pm = X^d \pm X^{d+1}$ this boost acts as the scaling

$$X^+ \mapsto e^{\sigma}\,X^+, \qquad X^- \mapsto e^{-\sigma}\,X^-, \qquad X^\mu \mapsto X^\mu, \tag{47.75}$$

which manifestly preserves the null form $X^+X^- + \eta_{\mu\nu}X^\mu X^\nu$ of Eq. (47.71). Apply Eq. (47.75) to the section point $X(x) = (1, -x^2, x^\mu)$:

$$X \;\longmapsto\; \big(\,e^{\sigma},\, -e^{-\sigma}x^2,\, x^\mu\,\big). \tag{47.76}$$

This representative has $X^+ = e^\sigma \neq 1$, so it is off the section; rescale by the projective factor $e^{-\sigma}$ to return to $X^+ = 1$:

$$\big(\,e^{\sigma},\, -e^{-\sigma}x^2,\, x^\mu\,\big) \;\sim\; \big(\,1,\, -e^{-2\sigma}x^2,\, e^{-\sigma}x^\mu\,\big) = \big(\,1,\, -(x')^2,\, x'^\mu\,\big), \quad x'^\mu = e^{-\sigma}x^\mu. \tag{47.77}$$

The new section point has spatial part $x'^\mu = e^{-\sigma}x^\mu$ and middle component $-e^{-2\sigma}x^2 = -(x')^2$, consistent with the null condition. Thus the linear boost Eq. (47.75) induces precisely the dilatation $x^\mu \mapsto \lambda x^\mu$ with $\lambda = e^{-\sigma}$ of Eq. (47.34). The nonlinearity of conformal transformations on $\mathbb{R}^d$ — here even the simple rescaling — is entirely an artifact of projecting a linear motion of the cone back onto a fixed section. The same mechanism turns the linear $X^+ \leftrightarrow X^-$

reflection into the inversion and a linear translation in the X^μ–X^+ plane into a special conformal transformation; the conformal group is, with no remainder, the rotation group of the cone.

We have exponentiated the conformal Killing vectors into the finite group of Section 47.2.1, distilled them into the abstract algebra Eq. (47.53) of Theorem 47.9, identified that algebra with $\mathfrak{so}(d+1,1)$ (Euclidean) or $\mathfrak{so}(d,2)$ (Lorentzian) in Theorem 47.10, and exhibited its global, singularity-free action on the compactified space and on the projective null cone. The decisive structural fact for everything that follows is the dilatation grading Eq. (47.53c): D assigns each generator an eigenvalue, with P_μ raising it and K_μ lowering it. The next section turns this grading into representation theory, organizing local operators by their dilatation and rotation eigenvalues — scaling dimension and spin — and identifying the lowest-weight states annihilated by K_μ as the primary operators from which every conformal multiplet is built.

47.3 Primary Operators, Descendants, and Unitarity Bounds

The previous section closed with the conformal algebra of Theorem 47.9 and the single observation that, under the dilatation, the momentum generator P_μ raises the scaling eigenvalue by one unit while the special conformal generator K_μ lowers it (Eqs. (47.42) and (47.43)). That observation is the seed of the entire representation theory. A conformal field theory is not a Lagrangian and a set of Feynman rules; it is a list of local operators organized into representations of the conformal algebra, and the algebra is so rigid that the representations are labelled by just two pieces of data — a number and a spin — with everything else fixed. This section builds that classification. We attach to each local operator at a point its dilatation and rotation eigenvalues, we use the grading by P_μ and K_μ to split the operator content into *primaries* (lowest-weight vectors, annihilated by K_μ) and their towers of *descendants*, we exponentiate the infinitesimal action into the finite transformation law that a primary obeys under any conformal map, and finally we extract the sharp inequalities — the *unitarity bounds* — that the requirement of a positive-definite Hilbert space imposes on the allowed dimensions. The bounds are saturated exactly by the free field, the conserved current, and the stress tensor, three objects we have met repeatedly; here they reappear as the boundary of the allowed region in representation space.

The generators of Eq. (47.41) were written as pure orbital differential operators, carrying, as that section noted, "no information about the intrinsic spin or scaling weight of the field they act on." Reinstating that information is the first task. Throughout this section we work in Euclidean signature and use the conformal algebra in the *real form* natural to radial quantization, in which the

dilatation is a self-adjoint operator with real spectrum and the rotation generators are anti-self-adjoint; this is the form in which the representation theory and the positivity arguments are cleanest, and it is the form already used implicitly by the conformal Ward identities of Eq. (47.113) and by the Hilbert-space construction of Section 47.5.

Notation Watch

The abstract algebra of Eq. (47.53) was written with Hermitian generators (factors of i, Lorentzian metric $\eta_{\mu\nu}$), matching the Poincaré conventions of Chapter 3. For the representation theory we pass to the Euclidean real form: replace $\eta_{\mu\nu} \to \delta_{\mu\nu}$ and absorb the explicit i's so that

$$[D, P_\mu] = P_\mu, \quad [D, K_\mu] = -K_\mu, \quad [K_\mu, P_\nu] = 2(\delta_{\mu\nu} D - M_{\mu\nu}), \quad [M_{\mu\nu}, P_\rho] = \delta_{\nu\rho} P_\mu - \delta_{\mu\rho} P \tag{47.78}$$

with $[M_{\mu\nu}, K_\rho] = \delta_{\nu\rho} K_\mu - \delta_{\mu\rho} K_\nu$, $[D, M_{\mu\nu}] = 0$, $[P_\mu, P_\nu] = [K_\mu, K_\nu] = 0$, and the $\mathfrak{so}(d)$ bracket $[M_{\mu\nu}, M_{\rho\sigma}] = \delta_{\nu\rho} M_{\mu\sigma} - \delta_{\mu\rho} M_{\nu\sigma} - \delta_{\nu\sigma} M_{\mu\rho} + \delta_{\mu\sigma} M_{\nu\rho}$. This is the same Lie algebra $\mathfrak{so}(d+1,1)$ of Theorem 47.10; only the basis labels differ. In this form the radial-quantization adjoints (Theorem 47.35) are $D^\dagger = D$, $M_{\mu\nu}^\dagger = -M_{\mu\nu}$, $P_\mu^\dagger = K_\mu$.

47.3.1 Scaling dimension and spin from the Cartan generators

Inside the conformal algebra the dilatation D and the rotations $M_{\mu\nu}$ commute, Eq. (47.50); they form (together with a Cartan subalgebra of $\mathfrak{so}(d)$) a maximal set of mutually commuting generators, and we organize operators by their simultaneous eigenvalues, exactly as one organizes the states of a hydrogen atom by energy and angular momentum. The full action of the conformal generators on a local operator $\mathcal{O}_a(x)$, where a runs over the components of a finite-dimensional representation of the rotation group $\mathfrak{so}(d)$, is obtained by adjoining to the orbital operators of Eq. (47.41) a number Δ and a matrix $\Sigma_{\mu\nu}$ acting on the index a:

$$[P_\mu, \mathcal{O}_a(x)] = \partial_\mu \mathcal{O}_a(x), \tag{47.79a}$$

$$[D, \mathcal{O}_a(x)] = (x\cdot\partial + \Delta)\, \mathcal{O}_a(x), \tag{47.79b}$$

$$[M_{\mu\nu}, \mathcal{O}_a(x)] = (x_\mu \partial_\nu - x_\nu \partial_\mu)\, \mathcal{O}_a(x) + (\Sigma_{\mu\nu})_a{}^b\, \mathcal{O}_b(x), \tag{47.79c}$$

$$[K_\mu, \mathcal{O}_a(x)] = (2x_\mu\, x\cdot\partial - x^2\partial_\mu + 2\Delta\, x_\mu)\mathcal{O}_a(x) - 2x^\nu (\Sigma_{\mu\nu})_a{}^b\, \mathcal{O}_b(x). \tag{47.79d}$$

The matrices $\Sigma_{\mu\nu} = -\Sigma_{\nu\mu}$ are the generators of $\mathfrak{so}(d)$ in the representation carried by $\mathcal{O}$; one verifies that Eq. (47.79) closes into the real-form algebra Eq. (47.78) for any such Σ, the extra Δ- and Σ-terms being precisely what the orbital pieces alone could not supply. Everything we do follows from Eq. (47.79) and the algebra.

The two intrinsic labels are read off at the origin, where every term in Eq. (47.79) that carries an explicit factor of x drops out:

$$[D, \mathcal{O}_a(0)] = \Delta\, \mathcal{O}_a(0), \qquad [M_{\mu\nu}, \mathcal{O}_a(0)] = (\Sigma_{\mu\nu})_a{}^b\, \mathcal{O}_b(0). \tag{47.80}$$

Definition 47.13 (Scaling dimension and spin)**.** The *scaling dimension* Δ of a local operator $\mathcal{O}_a$ is its eigenvalue under ad_D at the origin, Eq. (47.80). The *spin* of $\mathcal{O}_a$ is the representation of the Euclidean rotation group $\mathfrak{so}(d)$ generated by the matrices $\Sigma_{\mu\nu}$; for a symmetric traceless tensor of rank ℓ we call ℓ the spin and write the operator as $\mathcal{O}_{\mu_1 \cdots \mu_\ell}$.

The label Δ is exactly the renormalization-group scaling dimension of Theorem 23.22: there it was defined as the exponent governing the rescaling step of the RG and, equivalently, the power in the fixed-point two-point function $\langle \mathcal{O}(x)\, \mathcal{O}(0) \rangle \propto |x|^{-2\Delta}$. We will see in Section 47.4 that conformal symmetry forces precisely this power law, so the two definitions coincide as they must: the operators of a CFT *are* the scaling operators at the RG fixed point, and their dimensions are RG data. In particular the relation

$$\Delta = \Delta_{\mathrm{cl}} + \gamma, \tag{47.81}$$

with Δ_{cl} the engineering dimension and γ the anomalous dimension of Theorems 23.12 and 24.2, is the statement that the conformal scaling dimension is the classical dimension corrected by loops — a point we return to at the close of the section and exploit in full for the Wilson–Fisher fixed point in Theorem 47.55.

The spin label is the conformal analog of the Poincaré classification of Theorem 3.44: there a massive one-particle state was labelled by its mass and by a representation of the little group $\mathrm{SO}(3)$; here, because a CFT has no scale and hence no mass, P^2 is no longer a Casimir (it does not commute with K_μ or D), and the role of "intrinsic angular momentum" is played instead by the representation of the rotation subgroup $\mathfrak{so}(d)$ that survives at a point. The first Casimir P^2 of the Poincaré algebra, Theorem 3.35, is replaced by the quadratic Casimir of the full conformal group, which we construct in Section 47.7.5; its eigenvalue is a function of (Δ, ℓ) alone.

47.3.2 Momentum raises, special conformal lowers

The grading of Eqs. (47.42) and (47.43) acquires its full force once we ask how it acts on operators of definite dimension. Differentiating an operator, or acting with K_μ, produces a new operator; the question is what dimension the new operator carries.

Theorem 47.14 (P_μ and K_μ shift the dimension)**.** *If $\mathcal{O}$ has scaling dimension Δ, then $\partial_\mu \mathcal{O} = [P_\mu, \mathcal{O}]$ has dimension $\Delta + 1$ and $[K_\mu, \mathcal{O}]$ has dimension $\Delta - 1$.*

Proof. The dimension of an operator $\mathcal{O}'$ is the coefficient in $[D, \mathcal{O}'(0)] = \Delta' \mathcal{O}'(0)$. Use the Jacobi identity in the form $[D, [P_\mu, \mathcal{O}]] = [[D, P_\mu], \mathcal{O}] + [P_\mu, [D, \mathcal{O}]]$. With $[D, P_\mu] = P_\mu$ from Eq. (47.78) and $[D, \mathcal{O}(0)] = \Delta\, \mathcal{O}(0)$,

$$[D, [P_\mu, \mathcal{O}(0)]] = [P_\mu, \mathcal{O}(0)] + [P_\mu, \Delta\, \mathcal{O}(0)] = (\Delta + 1)\, [P_\mu, \mathcal{O}(0)]\,. \tag{47.82}$$

Thus $\partial_\mu \mathcal{O}$ has dimension $\Delta + 1$. The identical computation with $[D, K_\mu] = -K_\mu$ gives

$$[D, [K_\mu, \mathcal{O}(0)]] = -\,[K_\mu, \mathcal{O}(0)] + (\Delta)\, [K_\mu, \mathcal{O}(0)] = (\Delta - 1)\, [K_\mu, \mathcal{O}(0)]\,, \tag{47.83}$$

so $[K_\mu, \mathcal{O}]$ has dimension $\Delta - 1$. □

In the language of radial quantization, where the dilatation is the Hamiltonian (Theorem 47.30) and a local operator at the origin creates a state $|\mathcal{O}\rangle \equiv \mathcal{O}(0)\,|0\rangle$ with $D\,|\mathcal{O}\rangle = \Delta\,|\mathcal{O}\rangle$ (Eq. (47.159)), Theorem 47.14 reads

$$D\,(P_\mu\,|\mathcal{O}\rangle) = (\Delta + 1)\, P_\mu\,|\mathcal{O}\rangle\,, \qquad D\,(K_\mu\,|\mathcal{O}\rangle) = (\Delta - 1)\, K_\mu\,|\mathcal{O}\rangle\,. \tag{47.84}$$

The P_μ are creation operators and the K_μ annihilation operators for the "radial energy" D. This is structurally the harmonic oscillator, with one crucial difference set by Theorem 3.22: the conformal group is non-compact, and as that theorem records, a non-compact group has no nontrivial finite-dimensional unitary representation. The unitary representations of interest here are therefore infinite-dimensional — a primary together with its endless tower of descendants — even though the operator that builds the tower sits at a single point.

47.3.3 Primaries, descendants, and the conformal multiplet

Since K_μ lowers the dimension and the spectrum of dimensions in a sensible theory cannot run off to $-\infty$ (we prove this below), the chain $\mathcal{O}$, $K\mathcal{O}$, $KK\mathcal{O}, \ldots$ must terminate. The bottom of the chain is the central object.

Definition 47.15 (Primary and descendant)**.** A local operator $\mathcal{O}_a$ is a *primary* if it is annihilated by all special conformal generators at the origin,

$$[K_\mu, \mathcal{O}_a(0)] = 0 \qquad \text{for all } \mu, \tag{47.85}$$

equivalently $K_\mu\,|\mathcal{O}_a\rangle = 0$. A *descendant* of a primary $\mathcal{O}$ is any operator obtained by acting on it with one or more momentum generators, i.e. a derivative $\partial_{\mu_1} \cdots \partial_{\mu_n} \mathcal{O}$ (with $n \geq 1$). The primary together with all its descendants is the *conformal multiplet* (or *conformal family*) of $\mathcal{O}$, denoted $[\mathcal{O}]$.

A primary is the lowest-dimension operator in its multiplet: K_μ would lower the dimension further, but it annihilates the primary, so there is nothing below. The descendants are organized by *level*: level n consists of the operators

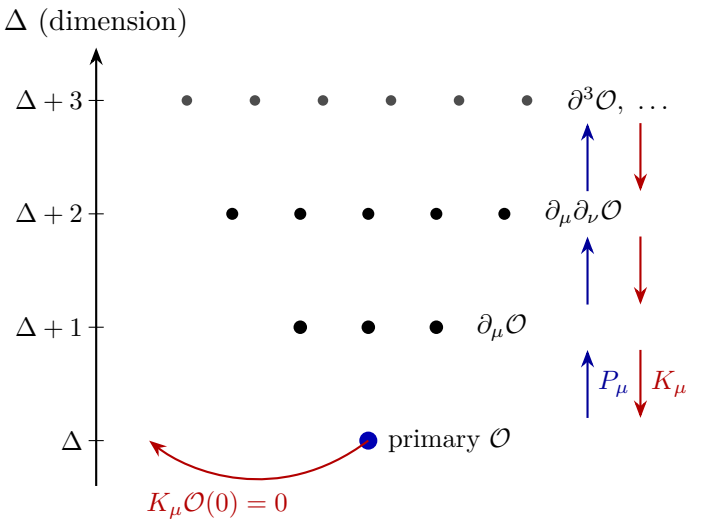

Figure 47.3: The conformal multiplet $[\mathcal{O}]$ as a lowest-weight module. The primary $\mathcal{O}$ (lowest dimension Δ, annihilated by every K_μ) sits at the bottom; the momentum generators P_μ raise the dimension by one unit at each level, generating the descendants $\partial^n\mathcal{O}$ of dimension $\Delta + n$. The special conformal generators K_μ lower the dimension and map each level to the one below, annihilating the primary. The number of independent operators at each level grows without bound: the module is infinite-dimensional, as Theorem 3.22 requires for a unitary representation of the non-compact conformal group.

$\partial_{\mu_1}\cdots\partial_{\mu_n}\mathcal{O}$, all of dimension $\Delta + n$, and they fill out representations of $\mathfrak{so}(d)$ obtained by tensoring the spin of $\mathcal{O}$ with the n symmetrized vector indices of the derivatives. The multiplet is the conformal counterpart of a highest-weight (here lowest-weight) module of a semisimple Lie algebra: the primary is the lowest-weight vector, P_μ are the raising operators that generate the module, and K_μ are the lowering operators that annihilate the lowest weight. Figure 47.3 displays the structure.

That a primary always exists in a physically admissible representation is not an assumption but a theorem, resting only on the dilatation spectrum being bounded below. In a unitary theory it is: the dilatation is the Hamiltonian conjugate to radial time and is bounded below by the vacuum energy (Theorem 47.30). We isolate the algebraic content.

Theorem 47.16 (Existence of a primary)**.** *Let V be a representation of the conformal algebra on which D is diagonalizable with a spectrum of dimensions bounded below. Then V contains a nonzero vector $|\mathcal{O}\rangle$ annihilated by every K_μ, i.e. a primary.*

Proof. Let Δ_0 be the infimum of the dimension spectrum and let $|\psi\rangle$ be an

eigenvector with $D|\psi\rangle = \Delta_0|\psi\rangle$. By Eq. (47.84), $K_\mu|\psi\rangle$ is either zero or an eigenvector of D with eigenvalue $\Delta_0 - 1 < \Delta_0$. The latter is impossible because Δ_0 is the smallest dimension present. Hence $K_\mu|\psi\rangle = 0$ for every μ, and $|\psi\rangle$ is the required primary. □

The argument also shows that every state in a lowest-bounded representation lies in some multiplet: starting from any state, repeated application of K_μ strictly decreases the dimension and so terminates after finitely many steps on a primary, and the original state is then a descendant of that primary. The classification of operators is thereby reduced to the classification of primaries, each labelled by (Δ, ℓ) together with its spin representation. This is the sense in which "the content of a CFT is a list of primaries."

47.3.4 The finite transformation law of a primary

The infinitesimal action Eq. (47.79) integrates to a clean statement of how a primary transforms under any finite conformal map, and that statement is what the next section feeds into the Ward identities. We first restate the infinitesimal law in a manifestly geometric form. For an infinitesimal conformal transformation $x^\mu \mapsto x^\mu + \varepsilon^\mu(x)$, the vector field ε^μ obeys the conformal Killing equation Eq. (47.9), $\partial_\mu\varepsilon_\nu + \partial_\nu\varepsilon_\mu = \frac{2}{d}(\partial\cdot\varepsilon)\,\delta_{\mu\nu}$. Collecting the four families in Eq. (47.79), the change of a primary $\mathcal{O}_a$ is

$$\delta\mathcal{O}_a(x) = -\Big[\varepsilon^\mu\partial_\mu + \tfrac{\Delta}{d}\,(\partial\cdot\varepsilon) + \tfrac{1}{2}(\partial_\mu\varepsilon_\nu)\,(\Sigma^{\mu\nu})_a{}^b\Big]\mathcal{O}_b(x), \tag{47.86}$$

where the symmetric part of $\partial_\mu\varepsilon_\nu$ is pure trace by the Killing equation and contributes only through $\partial\cdot\varepsilon$, while the antisymmetric part $\frac{1}{2}(\partial_\mu\varepsilon_\nu - \partial_\nu\varepsilon_\mu)$ is the infinitesimal local rotation that contracts with $\Sigma^{\mu\nu}$. The two scalars $\frac{1}{d}(\partial\cdot\varepsilon)$ and $\frac{1}{2}(\partial_\mu\varepsilon_\nu - \partial_\nu\varepsilon_\mu)$ are exactly the infinitesimal versions of a local scale factor and a local rotation. Exponentiating them gives the finite law.

Theorem 47.17 (Finite transformation of a primary)**.** *Under a finite conformal map $x \mapsto x'(x)$, whose Jacobian factorizes as*

$$\frac{\partial x'^\mu}{\partial x^\nu} = \Omega(x)\,R^\mu{}_\nu(x), \qquad R(x) \in \mathrm{SO}(d), \qquad \Omega(x) = \Big|\frac{\partial x'}{\partial x}\Big|^{1/d}, \tag{47.87}$$

a primary $\mathcal{O}_a$ of dimension Δ and spin representation $\mathcal{D}[\cdot]$ transforms as

$$\mathcal{O}'_a(x') = \Omega(x)^{-\Delta}\,\mathcal{D}\big[R(x)\big]_a{}^b\,\mathcal{O}_b(x) = \Big|\frac{\partial x'}{\partial x}\Big|^{-\Delta/d}\,\mathcal{D}\big[R(x)\big]_a{}^b\,\mathcal{O}_b(x). \tag{47.88}$$

Proof. That the Jacobian of a conformal map factorizes as in Eq. (47.87) is the definition of conformality (Theorem 47.1): the map rescales the metric by a positive function and so its derivative is a position-dependent scale Ω times

an orthogonal matrix R; taking determinants gives $|\partial x'/\partial x| = \Omega^d$, which is Eq. (47.87). It remains to show that the rule Eq. (47.88) reproduces Eq. (47.86) infinitesimally and composes correctly.

Infinitesimal check. Write $x'^\mu = x^\mu + \varepsilon^\mu$ to first order. Then $\partial x'^\mu/\partial x^\nu = \delta^\mu_\nu + \partial_\nu \varepsilon^\mu$, so comparing with Eq. (47.87),

$$\Omega = 1 + \tfrac{1}{d}\,\partial\cdot\varepsilon + O(\varepsilon^2), \qquad R^\mu{}_\nu = \delta^\mu_\nu + \tfrac{1}{2}(\partial^\mu\varepsilon_\nu - \partial_\nu\varepsilon^\mu) + O(\varepsilon^2), \tag{47.89}$$

the split being precisely into the trace (Ω) and antisymmetric (R) parts of $\partial_\nu\varepsilon^\mu$, with the symmetric traceless part absent by the Killing equation. Hence $\Omega^{-\Delta} = 1 - \frac{\Delta}{d}\partial\cdot\varepsilon$ and $\mathcal{D}[R] = \mathbf{1} + \frac{1}{2}(\partial_\mu\varepsilon_\nu)\Sigma^{\mu\nu}$ to first order (the symmetric part of $\partial_\mu\varepsilon_\nu$ contracts to zero against the antisymmetric $\Sigma^{\mu\nu}$). The transformed field at the *same* coordinate point is $\delta\mathcal{O}_a(x) = \mathcal{O}'_a(x) - \mathcal{O}_a(x)$; since Eq. (47.88) gives $\mathcal{O}'_a$ at x', we transport back by $\mathcal{O}'_a(x) = \mathcal{O}'_a(x'-\varepsilon) = \mathcal{O}'_a(x') - \varepsilon^\mu\partial_\mu\mathcal{O}_a + O(\varepsilon^2)$, yielding

$$\delta\mathcal{O}_a(x) = -\varepsilon^\mu\partial_\mu\mathcal{O}_a - \tfrac{\Delta}{d}(\partial\cdot\varepsilon)\,\mathcal{O}_a - \tfrac{1}{2}(\partial_\mu\varepsilon_\nu)(\Sigma^{\mu\nu})_a{}^b\mathcal{O}_b, \tag{47.90}$$

which is Eq. (47.86). The finite rule and the algebra therefore agree at first order.

Composition (cocycle) check. For two conformal maps g_1, g_2 with Jacobian factors (Ω_1, R_1) and (Ω_2, R_2), the chain rule gives for the composite $g_2\circ g_1$ the factor $\Omega_{21}(x) = \Omega_2(g_1x)\,\Omega_1(x)$ and $R_{21}(x) = R_2(g_1x)\,R_1(x)$. Applying Eq. (47.88) twice,

$$\mathcal{O}''(x'') = \Omega_2(x')^{-\Delta}\mathcal{D}[R_2(x')]\,\mathcal{O}'(x') = \Omega_2(x')^{-\Delta}\Omega_1(x)^{-\Delta}\,\mathcal{D}[R_2(x')]\mathcal{D}[R_1(x)]\,\mathcal{O}(x), \tag{47.91}$$

and using $\Omega_2(x') = \Omega_2(g_1x)$ and the homomorphism property $\mathcal{D}[R_2]\mathcal{D}[R_1] = \mathcal{D}[R_2R_1]$ this equals $\Omega_{21}(x)^{-\Delta}\mathcal{D}[R_{21}(x)]\mathcal{O}(x)$, the rule for the composite map. The transformation law is consistent with the group structure, so it is the exponentiation of Eq. (47.86). □

The two basic conformal maps illustrate the law. For a dilatation $x' = \lambda x$ the Jacobian is $\lambda\,\delta^\mu_\nu$, so $\Omega = \lambda$, $R = \mathbf{1}$, and Eq. (47.88) gives $\mathcal{O}'(x') = \lambda^{-\Delta}\mathcal{O}(x)$ — identical to the RG rescaling $\mathcal{O}(x) = b^{-\Delta}\mathcal{O}'(x/b)$ of Theorem 23.22, the cleanest confirmation that the conformal Δ *is* the RG scaling dimension. For the inversion $x'^\mu = x^\mu/x^2$ (Theorem 47.6) the Jacobian is $\partial x'^\mu/\partial x^\nu = x^{-2}(\delta^\mu_\nu - 2x^\mu x_\nu/x^2)$, the bracket being the orthogonal reflection $I^\mu{}_\nu(x)$; thus $\Omega = x^{-2}$, $R = I(x)$, and a scalar primary obeys $\mathcal{O}'(x') = (x^2)^{\Delta}\mathcal{O}(x)$. These are exactly the finite conformal factors worked out in Theorem 47.4, now promoted to act on operators carrying a dimension and a spin. The transformation law Eq. (47.88) is the workhorse of Section 47.4.

47.3.5 Unitarity bounds

We now turn to the central quantitative result: not every pair (Δ, ℓ) corresponds to an operator in a *unitary* CFT. Unitarity — the existence of a positive-definite

inner product on the Hilbert space, equivalently Osterwalder–Schrader reflection positivity of the Euclidean theory — means that every state has nonnegative norm. Applied to the descendant states $P_{\mu_1}\cdots P_{\mu_n}|\mathcal{O}\rangle$, this forces inequalities on Δ. The tool is the radial-quantization inner product of Theorem 47.34, under which (Theorem 47.35)

$$P_\mu^\dagger = K_\mu, \qquad D^\dagger = D, \qquad M_{\mu\nu}^\dagger = -M_{\mu\nu}. \tag{47.92}$$

We construct the Gram matrix of the level-one descendants and demand that it be positive semidefinite. The momentum index of the descendant tensors with the spin of the primary, and the bound comes from the channel that is closest to going null.

The scalar bound. For a scalar primary ($\ell = 0$, $\Sigma_{\mu\nu} = 0$) the level-one Gram matrix was computed in Theorem 47.36: using Eq. (47.92) and the algebra Eq. (47.78),

$$\mathcal{G}_{\mu\nu} = \langle\mathcal{O}|\, K_\mu P_\nu\,|\mathcal{O}\rangle = \langle\mathcal{O}|\,[K_\mu, P_\nu]\,|\mathcal{O}\rangle = \langle\mathcal{O}|\,2(\delta_{\mu\nu}D - M_{\mu\nu})\,|\mathcal{O}\rangle = 2\Delta\,\delta_{\mu\nu}, \tag{47.93}$$

since $K_\mu|\mathcal{O}\rangle = 0$, $D|\mathcal{O}\rangle = \Delta|\mathcal{O}\rangle$, and $M_{\mu\nu}|\mathcal{O}\rangle = 0$. Positivity of the diagonal gives $\Delta \geq 0$, with equality only for the identity operator (Eq. (47.173)). This level-one analysis is not yet sharp. The strongest scalar bound comes from level two: the unique scalar descendant $P^2|\mathcal{O}\rangle$ has norm

$$\big\|P^2|\mathcal{O}\rangle\big\|^2 = 8\,d\,\Delta\Big(\Delta - \tfrac{d-2}{2}\Big), \tag{47.94}$$

whose non-negativity yields the sharp scalar bound. We carry this level-two computation in full in Theorem 47.54, where it is tied directly to the equation of motion; the upshot is

$$\boxed{\Delta \;\geq\; \frac{d-2}{2} \qquad (\ell = 0),} \tag{47.95}$$

with equality exactly when $P^2|\mathcal{O}\rangle$ is null, i.e. when $\partial^2\mathcal{O} = 0$ as an operator equation. That is the free massless scalar's equation of motion: the free field saturates the scalar unitarity bound, $\Delta_\phi = (d-2)/2$ (Eq. (47.260)).

The spin-ℓ bound. For $\ell \geq 1$ the sharp constraint already appears at level one, because the spin index opens new channels. Let $\mathcal{O}_a$ be a primary in a spin-ℓ representation, $\Sigma_{\mu\nu}$ the corresponding $\mathfrak{so}(d)$ generators, normalized so that the quadratic Casimir is

$$C_2(\ell) \equiv -\tfrac{1}{2}\,\Sigma_{\mu\nu}\Sigma^{\mu\nu} = \ell(\ell + d - 2) \tag{47.96}$$

on the symmetric traceless rank-ℓ representation (and $C_2(V) = d-1$ on the vector V). The level-one Gram matrix carries both the momentum index (ν) and the spin index (b):

$$\mathcal{G}_{(\mu a)(\nu b)} = \langle \mathcal{O}_a | \, K_\mu P_\nu \, | \mathcal{O}_b \rangle = \langle \mathcal{O}_a | \, 2(\delta_{\mu\nu} D - M_{\mu\nu}) \, | \mathcal{O}_b \rangle = 2\Delta \, \delta_{\mu\nu}\delta_{ab} - 2(\Sigma_{\mu\nu})_{ab}, \tag{47.97}$$

where $(\Sigma_{\mu\nu})_{ab} = \langle \mathcal{O}_a | \, M_{\mu\nu} \, | \mathcal{O}_b \rangle$ is the spin matrix. This is a matrix on the tensor-product space $V \otimes R_\ell$ (vector index μ times spin index a); its eigenvalues are read off by decomposing $V \otimes R_\ell$ into irreducibles. The cross term is a spin–orbit coupling. Treating the row index μ as the vector index, define the vector-representation generators $(\Sigma^V_{\rho\sigma})^\mu{}_\nu = \delta^\mu_\rho \delta_{\sigma\nu} - \delta^\mu_\sigma \delta_{\rho\nu}$; then for any vector v^ν and spin state $|b\rangle$,

$$\Sigma^V_{\rho\sigma}\Sigma^{R,\rho\sigma} \, (v \otimes |b\rangle) = \sum_{\rho\sigma} (\Sigma^V_{\rho\sigma})^\mu{}_\nu (\Sigma^R_{\rho\sigma})_{ab} \, v^\nu \, |b\rangle \; e_\mu = 2 \, (\Sigma^R_{\mu\nu})_{ab} \, v^\nu \, |b\rangle \; e_\mu, \tag{47.98}$$

so the second term in Eq. (47.97) is precisely $-(\Sigma^V \cdot \Sigma^R)$. The $\mathfrak{so}(d)$ Casimir identity for the diagonal generators $J_{\mu\nu} = \Sigma^V_{\mu\nu} + \Sigma^R_{\mu\nu}$ on $V \otimes R_\ell$,

$$C_2(\text{total}) = C_2(V) + C_2(\ell) - \Sigma^V \cdot \Sigma^R \quad \Longrightarrow \quad \Sigma^V \cdot \Sigma^R = C_2(V) + C_2(\ell) - C_2(j), \tag{47.99}$$

(where j labels the irreducible component, $-\Sigma^V \cdot \Sigma^R = -\Sigma^V_{\mu\nu}\Sigma^{R\,\mu\nu}$ is twice the cross term in $-\frac{1}{2}JJ$) lets us diagonalize. On the component of spin j,

$$\mathcal{G}_j = 2\Delta + C_2(j) - C_2(V) - C_2(\ell). \tag{47.100}$$

The decomposition of a vector times a spin-ℓ symmetric traceless tensor is $V \otimes R_\ell = R_{\ell+1} \oplus R_\ell \oplus R_{\ell-1}$ (raising the rank, mixed symmetry, and the divergence). The smallest eigenvalue — the binding constraint — comes from the divergence channel $j = \ell - 1$, because C_2 is increasing in j. Using $C_2(\ell-1) - C_2(\ell) = -(2\ell + d - 3)$ and $C_2(V) = d-1$,

$$\mathcal{G}_{\ell-1} = 2\Delta - (2\ell + d - 3) - (d-1) = 2\big[\Delta - (\ell + d - 2)\big]. \tag{47.101}$$

Non-negativity of this eigenvalue is the spin-ℓ unitarity bound:

$$\boxed{\Delta \;\geq\; \ell + d - 2 \qquad (\ell \geq 1).} \tag{47.102}$$

The other two channels give weaker constraints: $\mathcal{G}_{\ell+1} = 2\Delta + 2\ell \geq 0$ (i.e. $\Delta \geq -\ell$, automatic) and $\mathcal{G}_\ell = 2\Delta - (d-1)$, both implied by Eq. (47.102). We collect the two bounds.

Theorem 47.18 (Unitarity bounds)**.** *In a unitary conformal field theory in $d \geq 3$ dimensions, the dimension of a primary of spin ℓ obeys*

$$\Delta \geq \frac{d-2}{2} \;\; (\ell = 0, \;\; \textit{or } \Delta = 0 \textit{ for the identity}), \qquad \Delta \geq \ell + d - 2 \;\; (\ell \geq 1). \tag{47.103}$$

Equality at $\ell = 0$ holds iff $\partial^2 \mathcal{O} = 0$ (the free scalar). Equality at $\ell \geq 1$ holds iff the divergence descendant $\partial^\mu \mathcal{O}_{\mu\mu_2\cdots\mu_\ell}$ is null, i.e. vanishes as an operator — the conservation law $\partial^\mu \mathcal{O}_{\mu\cdots} = 0$.

Proof. The two inequalities are Eqs. (47.95) and (47.102); their derivations above use only the positivity of the Gram matrices of descendant states, guaranteed by unitarity (Theorem 47.34). Saturation occurs exactly when the relevant descendant has zero norm. A zero-norm state in a unitary (hence positive-definite, after quotienting the null space) Hilbert space must itself vanish; that vanishing is the operator equation. For $\ell = 0$ the null state is $P^2 |\mathcal{O}\rangle$, whose vanishing is $\partial^2 \mathcal{O} = 0$. For $\ell \geq 1$ the null state is the $j = \ell - 1$ component of $P_\mu |\mathcal{O}_{\nu\cdots}\rangle$, namely $P^\mu |\mathcal{O}_{\mu\mu_2\cdots\mu_\ell}\rangle$, whose vanishing is $\partial^\mu \mathcal{O}_{\mu\mu_2\cdots\mu_\ell} = 0$. □

The saturating cases are old friends. We isolate the two most important.

Worked Example 47.19 (Conserved currents and the stress tensor saturate the bound)**.** Specialize Eqs. (47.101) and (47.102) to $\ell = 1$ and $\ell = 2$.

Spin one ($\ell = 1$). The divergence channel is the scalar $j = 0$, and Eq. (47.101) gives $\mathcal{G}_0 = 2[\Delta - (d-1)]$, so $\Delta \geq d - 1$. We can verify this directly without the Casimir machinery. For a vector primary $\mathcal{O}_\rho$ the spin matrices are those of the vector representation, $(\Sigma_{\mu\nu})_{\rho\sigma} = \delta_{\mu\rho}\delta_{\nu\sigma} - \delta_{\mu\sigma}\delta_{\nu\rho}$, and Eq. (47.97) reads $\mathcal{G}_{(\mu\alpha)(\nu\rho)} = 2\Delta\,\delta_{\mu\nu}\delta_{\alpha\rho} - 2(\delta_{\mu\alpha}\delta_{\nu\rho} - \delta_{\mu\rho}\delta_{\nu\alpha})$. The divergence state is $|\chi\rangle = P^\rho |\mathcal{O}_\rho\rangle$; its norm is obtained by contracting the bra index α with μ and the ket index ρ with ν:

$$\begin{aligned} \|\chi\|^2 &= \delta^{\mu\alpha}\delta^{\nu\rho}\,\mathcal{G}_{(\mu\alpha)(\nu\rho)} = 2\Delta\,d - 2\big(\delta^{\mu\alpha}\delta^{\nu\rho}\delta_{\mu\alpha}\delta_{\nu\rho} - \delta^{\mu\alpha}\delta^{\nu\rho}\delta_{\mu\rho}\delta_{\nu\alpha}\big) \\ &= 2\Delta\,d - 2\big(d^2 - d\big) = 2d\big[\Delta - (d-1)\big]. \end{aligned} \tag{47.104}$$

Non-negativity gives $\Delta \geq d-1$, saturated when $|\chi\rangle = P^\rho |\mathcal{O}_\rho\rangle = 0$, i.e. $\partial^\mu \mathcal{O}_\mu = 0$. A spin-one primary of dimension exactly $d-1$ is therefore a *conserved current*. This is the same dimension that conservation forces on a current's two-point function in Theorem 47.23, now derived from pure representation theory.

Spin two ($\ell = 2$). The divergence channel is $j = \ell - 1 = 1$, with $C_2(1) = d-1$ and $C_2(2) = 2d$, so Eq. (47.100) gives $\mathcal{G}_1 = 2\Delta + (d-1) - (d-1) - 2d = 2(\Delta - d)$, hence $\Delta \geq d$. A spin-two primary saturating the bound, $\Delta = d$, has a null divergence, $\partial^\mu \mathcal{O}_{\mu\nu} = 0$: it is a *conserved symmetric tensor of dimension d*, which is precisely the stress tensor (its dimension equals d because the integral $\int d^{d-1}x\, T^{0\nu}$ must be dimensionless, fixing $[T_{\mu\nu}] = d$). Thus $\Delta_T = d$ saturates the $\ell = 2$ unitarity bound, and the existence of a stress tensor in a local CFT means that the spin-two spectrum touches the unitarity boundary exactly at d.

The pattern is uniform: the unitarity bound is saturated precisely by operators obeying a conservation or wave equation, and the saturating operator's descendant module is *short* — the would-be descendants in the null channel are set to zero.

A free scalar ($\ell = 0$, $\Delta = (d-2)/2$), a conserved current ($\ell = 1$, $\Delta = d-1$), and the stress tensor ($\ell = 2$, $\Delta = d$) are the three canonical short multiplets. For higher spin the bound $\Delta = \ell + d - 2$ is saturated by conserved higher-spin currents; a theorem we will not need here states that interacting unitary CFTs in $d \geq 3$ cannot have such currents beyond $\ell = 2$, which is why generic CFT spectra have $\Delta > \ell + d - 2$ for $\ell \geq 3$.

47.3.6 The dimension as RG data: setting up the thread

The relation Eq. (47.81), $\Delta = \Delta_{\mathrm{cl}} + \gamma$, is the bridge back to Part VI. The engineering dimension of a canonically normalized scalar field in d dimensions is $\Delta_{\mathrm{cl}} = (d-2)/2$, read off from the kinetic term $\int d^d x\, (\partial\phi)^2$; the loop corrections shift it by the anomalous dimension γ_ϕ defined through the wavefunction renormalization in Theorems 23.12 and 24.2. At a free fixed point $\gamma_\phi = 0$ and $\Delta_\phi = (d-2)/2$ exactly — the massless scalar of ϕ^4 theory sits on the unitarity bound, as Theorem 47.18 demanded. At the interacting Wilson–Fisher fixed point in $d = 4 - \varepsilon$ the anomalous dimension is nonzero, $\gamma_\phi = O(\varepsilon^2)$, and the conformal scaling dimension of the field becomes

$$\Delta_\phi = \frac{d-2}{2} + \gamma_\phi = \frac{2-\varepsilon}{2} + \gamma_\phi, \tag{47.105}$$

strictly above the unitarity bound, as required for an interacting operator that is not free. The leading anomalous dimension and the dimension of the composite ϕ^2 are the conformal data of the Wilson–Fisher CFT; they are precisely the numbers Part VI computed as RG quantities, and we assemble them into CFT form in Theorem 47.55. The point to register now is conceptual: the abstract Δ of Theorem 47.13 and the RG scaling dimension of Theorem 23.22 are the same number, so the anomalous dimension that quantified the breaking of classical scale invariance under renormalization is, at the fixed point, nothing but the conformal weight of a primary operator.

With each primary now labelled by (Δ, ℓ), subject to the unitarity bounds of Theorem 47.18 and transforming by the finite law Eq. (47.88), the content of a CFT has been reduced to a discrete list. The next section shows that this list, together with one number per triple of primaries, fixes the low-point correlators completely: conformal symmetry determines the two-point function up to normalization and the three-point function up to a single coefficient, leaving only a function of cross-ratios undetermined at four points.

47.4 Correlators Fixed by Conformal Symmetry

The previous section gave each local operator a pair of labels — a scaling dimension Δ and a Lorentz (or, in Euclidean signature, rotation-group) representation

fixing its spin — and singled out the *primaries* as the operators annihilated by the special conformal generator K^μ at the origin, the lowest-weight vectors of the conformal modules (Section 47.3.3, Theorem 47.18). It also recorded how a primary transforms under a finite conformal map: not merely by being carried to its image point, but by picking up a local Jacobian weight set by its dimension and spin (Eq. (47.88)). That transformation law is a constraint, and the present section is the systematic exploitation of it. We will see that it is so strong that the position dependence of the lowest correlators is fixed entirely by symmetry: the two-point function down to a single number, the three-point function down to a single number per triple of operators, and the four-point function down to one *function* of two scalar invariants. The fourth statement is the doorway to the rest of Part XIV: that function, $g(u, v)$, is the object the operator product expansion will organise and the bootstrap will pin down by crossing.

Throughout we work in Euclidean signature, the natural home for the correlators of a conformal field theory and the setting in which the next section will build the radial-quantization Hilbert space. Points live in $\mathbb{R}^d$ with the positive-definite metric $\delta_{\mu\nu}$; we write $x \cdot y = \delta_{\mu\nu} x^\mu y^\nu$, $x^2 = x \cdot x \geq 0$, and $|x| = \sqrt{x^2}$. The Euclidean correlators are the Schwinger functions obtained by Wick rotation from the Lorentzian theory (Theorem 10.30); reflection positivity (Theorem 10.32) is what guarantees they descend from a unitary Lorentzian theory, and we will use it once, to fix the sign of the two-point normalization.

Notation Watch

Because every correlator in this section is Euclidean, indices are raised and lowered with $\delta_{\mu\nu}$ and there is no distinction between upper and lower placement; we keep indices upstairs for readability. This is a deliberate departure from the mostly-minus Lorentzian metric $\eta_{\mu\nu} = \mathrm{diag}(+, -, -, -)$ used elsewhere in the book. The continuation back to Lorentzian signature is the subject of Chapter 48 and of the analytic-continuation discussion in Chapter 51; here it never intrudes.

47.4.1 The covariance law for correlators

A conformal transformation is a smooth invertible map $x \mapsto \bar{x}(x)$ of (a patch of) $\mathbb{R}^d$ that rescales the metric by a positive local factor. Concretely, its Jacobian factorizes as

$$\frac{\partial \bar{x}^\mu}{\partial x^\nu} \;=\; \Omega(x)\, R^\mu{}_\nu(x), \qquad R^\mu{}_\rho R^\nu{}_\sigma\, \delta_{\mu\nu} = \delta_{\rho\sigma}, \tag{47.106}$$

where $\Omega(x) > 0$ is the *local scale factor* and $R(x) \in \mathrm{O}(d)$ is a local rotation. Equivalently $\partial_\mu \bar{x}^\rho\, \partial_\nu \bar{x}_\rho = \Omega(x)^2\, \delta_{\mu\nu}$: the map preserves angles and stretches lengths by Ω. The finite conformal group of $\mathbb{R}^d$ (more precisely of its conformal compactification, the sphere S^d) is generated by four kinds of maps, whose scale

factors and rotations we will need repeatedly:

$$\begin{aligned}
&\text{translation} && \bar{x} = x + a, && \Omega = 1, && R = \mathbf{1};\\
&\text{rotation} && \bar{x} = \Lambda x \ (\Lambda \in \mathrm{SO}(d)), && \Omega = 1, && R = \Lambda;\\
&\text{dilatation} && \bar{x} = \lambda x \ (\lambda > 0), && \Omega = \lambda, && R = \mathbf{1};\\
&\text{inversion} && \bar{x}^\mu = \frac{x^\mu}{x^2}, && \Omega(x) = \frac{1}{x^2}, && R^\mu{}_\nu = I^\mu{}_\nu(x).
\end{aligned} \tag{47.107}$$

Here we have met the object that will run through the entire section, the *inversion tensor*

$$I^\mu{}_\nu(x) \;\equiv\; \delta^\mu_\nu - 2\,\frac{x^\mu x_\nu}{x^2}, \tag{47.108}$$

which is the rotation $R(x)$ of an inversion: a short computation gives $\partial_\nu \bar{x}^\mu = \partial_\nu(x^\mu/x^2) = x^{-2}\delta^\mu_\nu - 2x^\mu x_\nu/x^4 = x^{-2}\, I^\mu{}_\nu(x)$, matching Eq. (47.106) with $\Omega = 1/x^2$. The tensor $I^\mu{}_\nu(x)$ is orthogonal, $I^\mu{}_\rho I^\nu{}_\sigma \delta_{\mu\nu} = \delta_{\rho\sigma}$ (check: $(\delta - 2\hat{x}\hat{x})^2 = \delta - 4\hat{x}\hat{x} + 4\hat{x}\hat{x} = \delta$ with $\hat{x} = x/|x|$), with determinant -1; it is the reflection through the hyperplane perpendicular to x. The special conformal transformation (SCT) is the conjugate of a translation by an inversion, $\bar{x} = \mathrm{inv} \circ \mathrm{transl}_b \circ \mathrm{inv}$, giving the finite form

$$\bar{x}^\mu = \frac{x^\mu - b^\mu x^2}{\gamma(x)}, \qquad \gamma(x) = 1 - 2\,b\cdot x + b^2 x^2, \qquad \Omega(x) = \frac{1}{\gamma(x)}. \tag{47.109}$$

That translations, rotations, dilatations and inversion generate the whole group is the finite-transformation counterpart of the algebra $\mathfrak{so}(d+1,1)$ assembled from the conserved charges in Theorem 7.48; in checking covariance it therefore suffices to impose invariance under these four, and SCT invariance can be obtained either from the finite inversion or from its infinitesimal generator. We will use whichever is more economical.

The bridge from the transformation law of operators to a statement about correlators is the invariance of the vacuum and of the (regularized, conformally invariant) path-integral measure: a symmetry maps the set of correlators to itself, so the correlator of the transformed operators equals the correlator of the originals,

$$\langle\, \mathcal{O}'_1(y_1)\cdots\mathcal{O}'_n(y_n)\,\rangle \;=\; \langle\, \mathcal{O}_1(y_1)\cdots\mathcal{O}_n(y_n)\,\rangle. \tag{47.110}$$

For a scalar primary the transformed operator is, by the law imported from Eq. (47.88),

$$\mathcal{O}'(\bar{x}) \;=\; \Omega(x)^{-\Delta}\,\mathcal{O}(x), \tag{47.111}$$

the dimension Δ appearing exactly as the power of the local rescaling, just as it does for the dilatation eigenvalue. Evaluating Eq. (47.110) at the image points $y_k = \bar{x}_k$ and substituting Eq. (47.111) for each factor, the left side becomes $\prod_k \Omega(x_k)^{-\Delta_k}\langle \mathcal{O}_1(x_1)\cdots\mathcal{O}_n(x_n)\rangle$, while the right side is $\langle \mathcal{O}_1(\bar{x}_1)\cdots\mathcal{O}_n(\bar{x}_n)\rangle$. Solving for the unprimed correlator gives the master identity that organizes everything below.

Proposition 47.20 (Conformal covariance of scalar correlators)**.** *Let $\mathcal{O}_1, \dots, \mathcal{O}_n$ be scalar primaries of dimensions $\Delta_1, \dots, \Delta_n$. Under any conformal map $x \mapsto \bar{x}(x)$ with scale factor $\Omega(x)$,*

$$\langle\, \mathcal{O}_1(x_1) \cdots \mathcal{O}_n(x_n) \,\rangle \;=\; \prod_{k=1}^{n} \Omega(x_k)^{\Delta_k}\, \langle\, \mathcal{O}_1(\bar{x}_1) \cdots \mathcal{O}_n(\bar{x}_n) \,\rangle. \tag{47.112}$$

It is worth seeing the infinitesimal face of Eq. (47.112), since one of our two derivations of the two-point function uses it. Write a small transformation as $\bar{x}^\mu = x^\mu + \delta x^\mu$ with scale factor $\Omega(x) = 1 + \sigma(x)$. Expanding Eq. (47.112) to first order, $0 = \sum_k \big[\delta x_k^\mu\, \partial_{k\mu} + \Delta_k\, \sigma(x_k)\big] G$, where G denotes the correlator. Reading δx and σ from Eq. (47.107) and the infinitesimal limit of Eq. (47.37) gives the four conformal Ward identities,

$$\text{translations:} \quad \sum_k \partial_k^\mu\, G = 0, \tag{47.113a}$$

$$\text{rotations:} \quad \sum_k \left(x_k^\mu \partial_k^\nu - x_k^\nu \partial_k^\mu\right) G = 0, \tag{47.113b}$$

$$\text{dilatations:} \quad \sum_k \left(x_k \cdot \partial_k + \Delta_k\right) G = 0, \tag{47.113c}$$

$$\text{SCT:} \quad \sum_k \left(2 x_k^\mu\, x_k \cdot \partial_k - x_k^2\, \partial_k^\mu + 2\Delta_k x_k^\mu\right) G = 0. \tag{47.113d}$$

The SCT identity Eq. (47.113d) uses $\delta x_k^\mu = 2(b\cdot x_k)x_k^\mu - b^\mu x_k^2$ and $\sigma(x_k) = +2\, b\cdot x_k$ (from $\Omega = 1/\gamma = 1 + 2b\cdot x + O(b^2)$), with the arbitrary parameter b^μ stripped off. These are the same charges whose algebra was assembled in Theorem 7.48, now acting differentially on a correlator of primaries; the extra $+2\Delta_k x_k^\mu$ term, absent from a naive coordinate transformation, is the imprint of the operators' scaling weight and is precisely what will force dimensions to match.

47.4.2 The two-point function

We determine $G_2(x_1, x_2) = \langle \mathcal{O}_1(x_1)\mathcal{O}_2(x_2)\rangle$ for two scalar primaries by feeding it the Ward identities Eq. (47.113) one at a time.

Translations and rotations. Identity Eq. (47.113a) says G_2 depends only on the difference $x_{12} \equiv x_1 - x_2$. Identity Eq. (47.113b) then says it depends on x_{12} only through the rotation invariant $x_{12}^2 = |x_1 - x_2|^2$. Hence $G_2 = f(x_{12}^2)$ for some function f of one variable.

Dilatations. With $G_2 = f(x_{12}^2)$, the Euler operator $\sum_k x_k \cdot \partial_k$ counts the degree of homogeneity in (x_1, x_2) jointly; since x_{12}^2 is homogeneous of degree 2, $\sum_k x_k \cdot \partial_k\, f(x_{12}^2) = 2\, x_{12}^2 f'(x_{12}^2)$. The dilatation Ward identity Eq. (47.113c) reads $2\, x_{12}^2 f' + (\Delta_1 + \Delta_2) f = 0$, a first-order equation whose solution is the power law

$$G_2(x_1, x_2) \;=\; \frac{C_{12}}{(x_{12}^2)^{(\Delta_1+\Delta_2)/2}} \;=\; \frac{C_{12}}{|x_1 - x_2|^{\Delta_1+\Delta_2}}, \tag{47.114}$$

with C_{12} a constant of integration. Poincaré symmetry and scale invariance alone, then, already reduce the two-point function to a single power and a single number. They do not yet say anything about the relation between Δ_1 and Δ_2; that information is carried only by the special conformal transformations.

Special conformal transformations. We impose Eq. (47.113d) on the form Eq. (47.114). Write $\Delta_+ = \Delta_1 + \Delta_2$, $A^\mu = x_{12}^\mu = (x_1 - x_2)^\mu$, $r^2 = x_{12}^2 = A^2$, and abbreviate $P = (r^2)^{-\Delta_+/2-1}$, so that $G_2 = C_{12}\, r^2 P$ and the derivatives are

$$\partial_1^\mu G_2 = -C_{12}\,\Delta_+\, A^\mu P, \qquad \partial_2^\mu G_2 = +C_{12}\,\Delta_+\, A^\mu P, \tag{47.115}$$

since $\partial_1^\mu (r^2)^{-\Delta_+/2} = -\frac{\Delta_+}{2}(r^2)^{-\Delta_+/2-1}\cdot 2A^\mu$ and ∂_2^μ flips the sign. The SCT operator $\mathcal{K}^\mu \equiv \sum_{k=1,2}(2x_k^\mu\, x_k{\cdot}\partial_k - x_k^2\partial_k^\mu + 2\Delta_k x_k^\mu)$ acting on G_2 has, after dividing by $C_{12}P$, two kinds of contributions. The derivative terms collect into

$$\begin{aligned} B^\mu &\equiv \frac{1}{C_{12}\Delta_+ P}\sum_k (2x_k^\mu\, x_k{\cdot}\partial_k - x_k^2\partial_k^\mu)G_2 \\ &= -2x_1^\mu(x_1{\cdot}A) + x_1^2 A^\mu + 2x_2^\mu(x_2{\cdot}A) - x_2^2 A^\mu. \end{aligned} \tag{47.116}$$

Using $x_1\cdot A = x_1^2 - x_1{\cdot}x_2$ and $x_2\cdot A = x_1{\cdot}x_2 - x_2^2$ and collecting the coefficients of x_1^μ and x_2^μ separately, both turn out to equal $-(x_1^2 - 2x_1{\cdot}x_2 + x_2^2) = -r^2$, so that

$$B^\mu = -r^2(x_1^\mu + x_2^\mu). \tag{47.117}$$

The weight terms give $\sum_k 2\Delta_k x_k^\mu G_2 = 2(r^2P)C_{12}(\Delta_1 x_1^\mu + \Delta_2 x_2^\mu)$. Assembling,

$$\mathcal{K}^\mu G_2 = C_{12}P\Big[\Delta_+ B^\mu + 2r^2(\Delta_1 x_1^\mu + \Delta_2 x_2^\mu)\Big] = C_{12}P\, r^2\,(\Delta_1 - \Delta_2)\,(x_1 - x_2)^\mu, \tag{47.118}$$

where in the last step the $-\Delta_+(x_1^\mu + x_2^\mu)$ from Eq. (47.117) combined with $2(\Delta_1 x_1^\mu + \Delta_2 x_2^\mu)$ to leave $(\Delta_1 - \Delta_2)(x_1^\mu - x_2^\mu)$. For the two-point function to be special-conformally invariant, Eq. (47.118) must vanish for all configurations; since the kinematic factor $C_{12}Pr^2(x_1 - x_2)^\mu$ is generically nonzero, this requires

$$C_{12}\,(\Delta_1 - \Delta_2) = 0. \tag{47.119}$$

Either the constant vanishes or the two dimensions coincide. We have proved the central rigidity of the two-point function.

Theorem 47.21 (Two-point function of scalar primaries)**.** *For scalar primaries $\mathcal{O}_1, \mathcal{O}_2$ of dimensions Δ_1, Δ_2, conformal invariance forces*

$$\langle\, \mathcal{O}_1(x_1)\, \mathcal{O}_2(x_2)\,\rangle \;=\; \delta_{\Delta_1\Delta_2}\,\frac{C_{12}}{|x_1 - x_2|^{2\Delta_1}}. \tag{47.120}$$

In particular, two scalar primaries of unequal dimension are orthogonal: their two-point function vanishes identically.

The same conclusion follows from finite inversion, which is instructive as an independent check and as a warm-up for the three-point function. Under inversion $\bar{x}_k = x_k/x_k^2$, Eq. (47.107) gives $\Omega(x_k) = 1/x_k^2$, and the elementary identity

$$\bar{x}_{12}^2 = \Big(\frac{x_1}{x_1^2} - \frac{x_2}{x_2^2}\Big)^2 = \frac{1}{x_1^2} - \frac{2x_1\cdot x_2}{x_1^2 x_2^2} + \frac{1}{x_2^2} = \frac{x_{12}^2}{x_1^2\, x_2^2} \tag{47.121}$$

shows how distances transform. (Identity Eq. (47.121) is nothing but the covariance $\bar{x}_{ij}^2 = \Omega(x_i)\Omega(x_j)x_{ij}^2$, which one checks holds for every generator in Eq. (47.107), and hence for the whole group.) Feeding Eq. (47.114) into Eq. (47.112),

$$\frac{C_{12}}{(x_{12}^2)^{\Delta_+/2}} = (x_1^2)^{-\Delta_1}(x_2^2)^{-\Delta_2}\,\frac{C_{12}}{(\bar{x}_{12}^2)^{\Delta_+/2}} = C_{12}\,(x_1^2)^{(\Delta_2-\Delta_1)/2}(x_2^2)^{(\Delta_1-\Delta_2)/2}\,\frac{1}{(x_{12}^2)^{\Delta_+/2}}, \tag{47.122}$$

using Eq. (47.121) for $\bar{x}_{12}^2$. The leftover factors of x_1^2 and x_2^2 cancel only if $\Delta_1 = \Delta_2$, reproducing Eq. (47.120).

Sign of the normalization, and canonical normalization. The constant C_{12} in the diagonal case $\Delta_1 = \Delta_2$ is not fixed by symmetry, but its sign is fixed by reflection positivity. Let Θ be the reflection $x = (\tau, \mathbf{x}) \mapsto \Theta x = (-\tau, \mathbf{x})$ in a chosen Euclidean time coordinate. Osterwalder–Schrader positivity (Theorem 10.32) states that for any real operator $\mathcal{O}$ supported at $\tau > 0$, $\langle (\Theta\mathcal{O})\,\mathcal{O}\rangle \geq 0$. Applied to a Hermitian scalar primary inserted at $x = (\tau, \mathbf{0})$ with $\tau > 0$, its reflection sits at $\Theta x = (-\tau, \mathbf{0})$, the separation is $|x - \Theta x| = 2\tau$, and Eq. (47.120) gives $\langle (\Theta\mathcal{O})(x)\,\mathcal{O}(x)\rangle = C/(2\tau)^{2\Delta} \geq 0$, hence $C \geq 0$; it is strictly positive unless $\mathcal{O}$ is a null operator (one whose every correlator vanishes), which we exclude. Because $C > 0$ we may rescale the operator,

$$\mathcal{O} \;\longrightarrow\; \mathcal{O}/\sqrt{C}, \tag{47.123}$$

a redefinition that changes nothing physical, to reach the *canonical normalization*

$$\boxed{\big\langle\, \mathcal{O}(x_1)\,\mathcal{O}(x_2)\,\big\rangle = \frac{1}{|x_1 - x_2|^{2\Delta}}} \tag{47.124}$$

for every primary. We adopt this convention henceforth; with it the three-point coefficient C_{123} introduced below acquires an unambiguous meaning, and the orthogonality of distinct primaries of equal dimension can be arranged by diagonalizing the (positive-definite, by reflection positivity) matrix of two-point coefficients C_{ij} on any degenerate subspace — a Gram–Schmidt step that is always available precisely because that matrix is positive. From here on "the primaries" means an orthonormal basis in this sense.

Physical Insight

The power law Eq. (47.124) is the statement that a CFT has no length scale to build a correlator out of: the only conformally meaningful function of two points is their distance, and the only scale-covariant function of one distance is a power, with exponent locked to the dimension. The contrast with a massive theory is sharp: there the Euclidean two-point function is the Yukawa form $\sim e^{-m|x|}/|x|^{d-2}$ (Theorem 10.30), which singles out the correlation length $1/m$. Sending $m \to 0$ at an RG fixed point erases that scale and leaves exactly the pure power demanded here.

Remark 47.22 (Momentum space). The Fourier transform of the canonical two-point function, computed with the tempered-distribution machinery of Section 5.2, is again a pure power,

$$\int d^d x \, \frac{e^{\,ip\cdot x}}{|x|^{2\Delta}} = \frac{\pi^{d/2}\, 2^{\,d-2\Delta}\, \Gamma\!\left(\frac{d}{2}-\Delta\right)}{\Gamma(\Delta)} \, \frac{1}{|p|^{\,d-2\Delta}}, \tag{47.125}$$

valid as an analytic continuation away from the poles at $\Delta = \frac{d}{2} + n$. The momentum-space exponent $d - 2\Delta$ is fixed by dimensional analysis alone (the transform carries dimension $+d$ from $d^d x$ and -2Δ from the integrand), which is why scale invariance suffices to know it; the Γ-function prefactor is the content of the actual integral. The poles in $\Gamma(\frac{d}{2} - \Delta)$ at $\Delta = \frac{d}{2}, \frac{d}{2}+1, \dots$ are the positions where the position-space power $|x|^{-2\Delta}$ becomes too singular to Fourier-transform without subtraction, and they will reappear in Chapter 48 and Chapter 53 as the dimensions at which contact terms and anomalies live.

47.4.3 Spinning two-point functions and conserved currents

Operators with spin carry rotation indices, and their correlators must transform under the local rotation $R(x)$ of Eq. (47.106) in addition to the scale weight. The inversion tensor Eq. (47.108) is exactly the covariant tensor that does this, because under inversion the relevant rotation *is* $I^{\mu}{}_{\nu}$. For a symmetric traceless primary $\mathcal{O}^{\mu_1\cdots\mu_\ell}$ of spin ℓ and dimension Δ, conformal covariance (the same master identity Eq. (47.112) dressed with rotation matrices on each index) fixes the two-point function to

$$\langle\, \mathcal{O}^{\mu_1\cdots\mu_\ell}(x)\, \mathcal{O}^{\nu_1\cdots\nu_\ell}(0)\,\rangle = \frac{C_{\mathcal{O}}}{|x|^{2\Delta}} \Big(I^{(\mu_1(\nu_1}(x)\cdots I^{\mu_\ell)\nu_\ell)}(x) - \text{traces} \Big), \tag{47.126}$$

where the parentheses denote symmetrization within each index group and "$-$traces" removes the $\delta^{\mu_i\mu_j}$ and $\delta^{\nu_i\nu_j}$ pieces so the structure lives in the symmetric-traceless representation. The scalar case $\ell = 0$ recovers Eq. (47.120); the rank-ℓ tensor is the unique conformally covariant structure because $I^{\mu}{}_{\nu}(x)$ is the only

available tensor built from a single separation x that transforms as a product of one rotation at each endpoint.

The most important spinning operator in any local CFT is a conserved current. We now verify the statement, anticipated in Theorem 7.48, that conservation forces a current's dimension to a specific value, and we do so by direct computation on Eq. (47.126) at $\ell = 1$.

Worked Example 47.23 (Conservation fixes the dimension of a current)**.** Take a vector primary J^μ of dimension Δ, with two-point function

$$\langle\, J^\mu(x)\, J^\nu(0)\,\rangle = \frac{C_J}{(x^2)^\Delta}\, I^{\mu\nu}(x), \qquad I^{\mu\nu}(x) = \delta^{\mu\nu} - 2\frac{x^\mu x^\nu}{x^2}. \tag{47.127}$$

We impose the conservation Ward identity $\partial_\mu \langle J^\mu(x) J^\nu(0)\rangle = 0$ for $x \neq 0$ and read off the allowed Δ. Write the correlator as $C_J\big[\delta^{\mu\nu}(x^2)^{-\Delta} - 2x^\mu x^\nu (x^2)^{-\Delta-1}\big]$ and differentiate. The first term gives

$$\partial_\mu\big[\delta^{\mu\nu}(x^2)^{-\Delta}\big] = \partial^\nu (x^2)^{-\Delta} = -2\Delta\, x^\nu (x^2)^{-\Delta-1}. \tag{47.128}$$

For the second term we use $\partial_\mu(x^\mu x^\nu) = d\, x^\nu + x^\nu = (d+1)x^\nu$ and $x^\mu x^\nu \partial_\mu (x^2)^{-\Delta-1} = -2(\Delta+1)x^2 x^\nu (x^2)^{-\Delta-2} = -2(\Delta+1)x^\nu (x^2)^{-\Delta-1}$, so

$$\partial_\mu\big[-2x^\mu x^\nu (x^2)^{-\Delta-1}\big] = -2\big[(d+1) - 2(\Delta+1)\big] x^\nu (x^2)^{-\Delta-1} = -2\,(d-1-2\Delta)\, x^\nu (x^2)^{-\Delta-1}. \tag{47.129}$$

Adding the two contributions,

$$\partial_\mu \langle J^\mu(x) J^\nu(0)\rangle = C_J\big[-2\Delta - 2(d-1-2\Delta)\big] x^\nu (x^2)^{-\Delta-1} = 2C_J\,(\Delta - (d-1))\, x^\nu (x^2)^{-\Delta-1}. \tag{47.130}$$

This vanishes for all $x \neq 0$ precisely when

$$\boxed{\Delta_J = d - 1} \tag{47.131}$$

Conservation thus saturates the spin-1 unitarity bound $\Delta \geq d-1$ derived in Theorem 47.18: a conserved current is exactly the operator that sits at the bottom edge of the allowed window, and the saturation is equivalent to the existence of a null descendant $\partial_\mu J^\mu$. The same computation with the stress tensor's spin-2 structure gives $\Delta_T = d$, the dimension demanded of $\Theta^{\mu\nu}$ by Theorem 7.48.

For three or more points the spinning structures proliferate, but always into a *finite* list. A correlator of operators with spins $\ell_1, \dots, \ell_n$ is fixed by conformal symmetry up to one constant per linearly independent tensor structure, each structure built from the covariant bilinears $I^{\mu\nu}(x_{ij})$ and the conformally covariant vectors $Z_i^\mu \propto x_{ij}^\mu / x_{ij}^2 - x_{ik}^\mu / x_{ik}^2$; conservation Ward identities like the one above

then impose linear relations among the constants, cutting the list down. For a scalar–scalar– spin-ℓ correlator there is a unique structure,

$$\langle\, \mathcal{O}_1(x_1)\, \mathcal{O}_2(x_2)\, \mathcal{O}^{\mu_1\cdots\mu_\ell}(x_3)\,\rangle = C_{12\mathcal{O}}\, \frac{Z^{\mu_1}\cdots Z^{\mu_\ell} - \text{traces}}{(x_{12}^2)^{\frac{\Delta_1+\Delta_2-\Delta+\ell}{2}} (x_{13}^2)^{\frac{\Delta_1+\Delta-\Delta_2-\ell}{2}} (x_{23}^2)^{\frac{\Delta_2+\Delta-\Delta_1-\ell}{2}}}, \qquad Z^\mu = \frac{x^\mu}{x^\mu}$$

(47.132)

and we will meet exactly this object again when the operator product expansion attaches a spinning exchanged operator to two scalars. The systematic index-free packaging of all such structures (the embedding-space and polarization-vector formalism) is developed in the references collected at the end of the chapter; we will need only the scalar correlators and the single structure Eq. (47.132) in what follows.

47.4.4 The three-point function

We now show that the three-point function of scalar primaries is fixed up to a single overall constant. The strategy is the same as for two points, but the conclusion is sharper because three points carry no conformal invariant at all.

Translations, rotations, dilatations. By Eqs. (47.113a) and (47.113b) the correlator $G_3 = \langle \mathcal{O}_1(x_1)\mathcal{O}_2(x_2)\mathcal{O}_3(x_3)\rangle$ depends on the three points only through the three pairwise distances $r_{ij} = |x_i - x_j|$, $1 \le i < j \le 3$. The dilatation identity Eq. (47.113c) then makes it homogeneous of degree $-(\Delta_1+\Delta_2+\Delta_3)$ in these distances jointly. So far G_3 could be any homogeneous function of r_{12}, r_{13}, r_{23} of that degree — equivalently, $r_{23}^{-(\Delta_1+\Delta_2+\Delta_3)}$ times an arbitrary function of the two ratios r_{12}/r_{23} and r_{13}/r_{23}. The remaining symmetry, inversion, removes this freedom entirely.

Inversion. Posit the monomial ansatz $G_3 = C_{123}\, r_{12}^{-\alpha_{12}} r_{13}^{-\alpha_{13}} r_{23}^{-\alpha_{23}}$ with exponents to be determined; we will see the ansatz is forced. Under inversion, Eq. (47.121) gives $r_{ij} \mapsto r_{ij}/(|x_i||x_j|)$, while Eq. (47.107) gives $\Omega(x_i) = 1/x_i^2$. The covariance law Eq. (47.112) requires

$$G_3(x_i) = \prod_{i=1}^{3} (x_i^2)^{-\Delta_i}\, G_3(\bar{x}_i) = \prod_{i=1}^{3} (x_i^2)^{-\Delta_i}\, C_{123} \prod_{i<j} \Big(\frac{r_{ij}}{|x_i||x_j|}\Big)^{-\alpha_{ij}}. \tag{47.133}$$

The distances reassemble into the original $\prod r_{ij}^{-\alpha_{ij}}$, and the spurious factors of $|x_i|$ collect, point by point, into

$$\prod_{i<j} \big(|x_i|\,|x_j|\big)^{\alpha_{ij}} = (x_1^2)^{(\alpha_{12}+\alpha_{13})/2}\, (x_2^2)^{(\alpha_{12}+\alpha_{23})/2}\, (x_3^2)^{(\alpha_{13}+\alpha_{23})/2}. \tag{47.134}$$

For these to cancel the $\prod (x_i^2)^{-\Delta_i}$ point by point, the exponents must satisfy the linear system

$$\alpha_{12}+\alpha_{13} = 2\Delta_1, \qquad \alpha_{12}+\alpha_{23} = 2\Delta_2, \qquad \alpha_{13}+\alpha_{23} = 2\Delta_3, \tag{47.135}$$

whose unique solution is

$$\alpha_{12} = \Delta_1 + \Delta_2 - \Delta_3, \quad \alpha_{13} = \Delta_1 + \Delta_3 - \Delta_2, \quad \alpha_{23} = \Delta_2 + \Delta_3 - \Delta_1. \tag{47.136}$$

(Summing the three equations recovers $\alpha_{12}+\alpha_{13}+\alpha_{23} = \Delta_1+\Delta_2+\Delta_3$, consistent with the dilatation degree, so the system is non-degenerate.) That the monomial ansatz is not merely consistent but forced follows from the count of invariants: three points have no conformal invariant. Indeed translations fix $x_3 \to 0$, an inversion then sends $x_2 \to \infty$, dilatations and rotations place x_1 on a fixed unit vector, and nothing is left free — the $\frac{1}{2}(d+1)(d+2)$-dimensional conformal group acts transitively on (generic) triples for $d \geq 2$. With no invariant to depend on, any putative extra factor multiplying the monomial would have to be a conformal scalar function of the three points, hence a constant; the constant is absorbed into C_{123}. We record the result.

Theorem 47.24 (Three-point function of scalar primaries)**.** *For scalar primaries of dimensions $\Delta_1, \Delta_2, \Delta_3$, conformal invariance fixes*

$$\boxed{\langle\, \mathcal{O}_1(x_1)\, \mathcal{O}_2(x_2)\, \mathcal{O}_3(x_3)\, \rangle = \frac{C_{123}}{|x_{12}|^{\Delta_1+\Delta_2-\Delta_3}\, |x_{13}|^{\Delta_1+\Delta_3-\Delta_2}\, |x_{23}|^{\Delta_2+\Delta_3-\Delta_1}}} \tag{47.137}$$

up to the single constant C_{123}. With the canonical two-point normalization Eq. (47.124), C_{123} is a scheme-independent physical datum of the theory.

Physical Insight

The numbers C_{123} are the *OPE coefficients* of the theory: the same constant that appears in front of $\mathcal{O}_3$ when the product $\mathcal{O}_1(x_1)\mathcal{O}_2(x_2)$ is expanded in local operators is the coefficient of the three-point function Eq. (47.137), as the operator product expansion in the next-but-one section will make precise. Together with the dimensions Δ_i and spins ℓ_i, the list $\{C_{ijk}\}$ constitutes the *CFT data*. Theorem 47.21 and Theorem 47.24 are the statement that two- and three-point functions store *no* information beyond this data: all of their position dependence is dictated by symmetry. Everything dynamical in a CFT therefore lives in the discrete CFT data and in how that data is constrained — which is the entire content of the bootstrap programme of Chapters 49 to 51.

47.4.5 Cross-ratios: the invariants of four points

The rigidity stops at three points. Four points do admit conformal invariants, and counting them is the key to the four-point function. The configuration of n points in $\mathbb{R}^d$ is nd real numbers; the conformal group has dimension $\frac{1}{2}(d+1)(d+2)$; the number of independent invariants is nd minus the dimension of a generic

orbit, i.e. minus $\frac{1}{2}(d+1)(d+2)$ plus the dimension of the stabilizer of a generic configuration. For $n=3$ this gave zero. For $n=4$ we count by explicitly using up the symmetry.

Proposition 47.25 (Two cross-ratios)**.** *For $d \geq 2$, a generic configuration of four points in $\mathbb{R}^d$ has exactly two independent conformal invariants.*

Proof. Use the conformal group to bring the four points to a standard frame. A translation places $x_1 = 0$; an inversion (followed, if needed, by a translation) sends $x_4 \to \infty$; a dilatation and the rotations then place x_3 at a fixed unit vector e. We have spent the translations (d parameters), the dilatation (1), the special conformal transformations (d, used to send x_4 to infinity and keep x_1 at the origin), and enough rotations to align x_3 with e: aligning a direction in $\mathbb{R}^d$ costs $d-1$ of the $\frac{1}{2}d(d-1)$ rotations, leaving the subgroup $\mathrm{SO}(d-1)$ of rotations about the e-axis as the residual symmetry. The last point x_2 ranges over $\mathbb{R}^d$ (d coordinates) modulo this residual $\mathrm{SO}(d-1)$. Decompose $x_2 = (x_2^{\parallel}, \mathbf{x}_2^{\perp})$ into its component along e and its $(d-1)$ perpendicular components; $\mathrm{SO}(d-1)$ acts only on $\mathbf{x}_2^{\perp}$, with generic orbit the sphere S^{d-2} of dimension $d-2$. The invariants are therefore $x_2^{\parallel}$ and $|\mathbf{x}_2^{\perp}|$: exactly two real numbers. The count $d-(d-2)=2$ is independent of d for $d \geq 2$. □

The two invariants are conventionally packaged into the dimensionless *cross-ratios*

$$u = \frac{x_{12}^2\, x_{34}^2}{x_{13}^2\, x_{24}^2}, \qquad v = \frac{x_{14}^2\, x_{23}^2}{x_{13}^2\, x_{24}^2}, \tag{47.138}$$

where $x_{ij}^2 = |x_i - x_j|^2$. Their conformal invariance is immediate from the covariance $x_{ij}^2 \mapsto \Omega(x_i)\Omega(x_j)\, x_{ij}^2$ established below Eq. (47.121): each cross-ratio is a ratio in which every point appears the same number of times in the numerator and the denominator, so all scale factors cancel,

$$u \mapsto \frac{\Omega_1\Omega_2 x_{12}^2\, \Omega_3\Omega_4 x_{34}^2}{\Omega_1\Omega_3 x_{13}^2\, \Omega_2\Omega_4 x_{24}^2} = u, \tag{47.139}$$

and likewise for v. Any conformal invariant of four points is a function of u and v, since by Theorem 47.25 there are only two of them.

It is often cleaner to trade (u, v) for a single complex coordinate. After the conformal frame of Theorem 47.25, the four points lie in a common 2-plane (the plane through the configuration); choosing complex coordinates on it and placing $x_1 \to 0$, $x_3 \to 1$, $x_4 \to \infty$, the remaining point becomes $x_2 \to z$, and Eq. (47.138) reduce to

$$u = z\,\bar{z}, \qquad v = (1-z)(1-\bar{z}), \tag{47.140}$$

with $\bar{z}$ the complex conjugate of z in Euclidean signature (in Lorentzian signature z and $\bar{z}$ become independent real variables, the source of the lightcone limits exploited in Chapter 51). Figure 47.4 shows the frame.

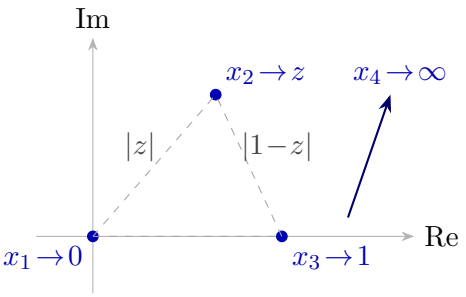

Figure 47.4: The conformal frame for four points. Three points are fixed to 0, 1, ∞ using the conformal group; the position of the fourth, z, is the single complex invariant, related to the cross-ratios by $u = z\bar{z} = |z|^2$ and $v = (1-z)(1-\bar{z}) = |1-z|^2$. The two independent real invariants of Theorem 47.25 are $\mathrm{Re}\, z$ and $\mathrm{Im}\, z$.

Remark 47.26 (Low-point and collinear subtleties). The clean answer "two" requires $d \geq 2$ and a generic configuration. In $d = 1$ the conformal group is only $\mathrm{SL}(2,\mathbb{R})$ (dimension 3) and four points on the line carry a *single* cross-ratio, $z = \bar{z}$ in Eq. (47.140). In any $d \geq 2$ a *collinear* configuration (all four points on one line, equivalently $\mathbf{x}_2^{\perp} = 0$ in the proof above) is non-generic: the residual $\mathrm{SO}(d-1)$ acts trivially on it, the orbit collapses, and only one invariant survives, again $z = \bar{z}$. Thus $z = \bar{z}$ (real) is the collinear/Lorentzian- lightcone locus and $z = \bar{z}^*$ (complex) the generic Euclidean situation — a distinction that matters when the four-point function is continued in Chapter 51. For five or more points new invariants beyond functions of pairwise cross-ratios appear once $n > d+2$, but that is past what we need.

47.4.6 The four-point function and the function $g(u,v)$

For four points the existence of invariants means symmetry can no longer fix the full functional form: it can fix a covariant *prefactor* carrying all the weight, leaving an arbitrary function of u and v. To build the prefactor we look for a quantity $K(x_1,\dots,x_4)$ that transforms exactly as the correlator does under Eq. (47.112), i.e. that has "conformal weight Δ_i" at each point x_i; then the ratio $\langle \mathcal{O}_1\mathcal{O}_2\mathcal{O}_3\mathcal{O}_4\rangle / K$ is invariant and hence a function of the cross-ratios only.

A product $K = \prod_{i<j}(x_{ij}^2)^{p_{ij}}$ has, under a conformal map, the transformation $K \mapsto K \prod_i \Omega(x_i)^{\sum_{j\neq i} p_{ij}}$, using $x_{ij}^2 \mapsto \Omega_i\Omega_j x_{ij}^2$. Comparing with Eq. (47.112), which demands the weight $-\Delta_i$ at each point when the prefactor is pulled to the image side, K matches the correlator iff

$$\sum_{j\neq i} p_{ij} = -\Delta_i \qquad (i = 1,\dots,4). \tag{47.141}$$

This is four equations for the six exponents p_{ij}; the two-parameter family of solutions is the freedom to multiply K by powers of the invariant cross-ratios, which is exactly the freedom we will dump into $g(u,v)$. A convenient choice — the one standard in the bootstrap literature — uses only the pairs $(12),(34),(13),(14),(24)$ and reads

$$K = \frac{1}{(x_{12}^2)^{\frac{\Delta_1+\Delta_2}{2}}\,(x_{34}^2)^{\frac{\Delta_3+\Delta_4}{2}}} \left(\frac{x_{24}^2}{x_{14}^2}\right)^{\frac{\Delta_1-\Delta_2}{2}} \left(\frac{x_{14}^2}{x_{13}^2}\right)^{\frac{\Delta_3-\Delta_4}{2}}. \tag{47.142}$$

One verifies Eq. (47.141) directly. Reading off the exponents, $p_{12} = -\frac{\Delta_1+\Delta_2}{2}$, $p_{34} = -\frac{\Delta_3+\Delta_4}{2}$, $p_{24} = \frac{\Delta_1-\Delta_2}{2}$, $p_{13} = -\frac{\Delta_3-\Delta_4}{2}$, $p_{14} = -\frac{\Delta_1-\Delta_2}{2} + \frac{\Delta_3-\Delta_4}{2}$, and $p_{23} = 0$, the sums are

$$\begin{aligned}
&\text{at } 1: p_{12}+p_{13}+p_{14} = -\tfrac{\Delta_1+\Delta_2}{2} - \tfrac{\Delta_1-\Delta_2}{2} = -\Delta_1,\\
&\text{at } 2: p_{12}+p_{23}+p_{24} = -\tfrac{\Delta_1+\Delta_2}{2} + \tfrac{\Delta_1-\Delta_2}{2} = -\Delta_2,\\
&\text{at } 3: p_{13}+p_{23}+p_{34} = -\tfrac{\Delta_3-\Delta_4}{2} - \tfrac{\Delta_3+\Delta_4}{2} = -\Delta_3,\\
&\text{at } 4: p_{14}+p_{24}+p_{34} = \tfrac{\Delta_3-\Delta_4}{2} - \tfrac{\Delta_3+\Delta_4}{2} = -\Delta_4,
\end{aligned} \tag{47.143}$$

where in the first and fourth lines the $\Delta_3-\Delta_4$ and $\Delta_1-\Delta_2$ contributions cancel, respectively. So K carries precisely the conformal weight of the four-point function, and the quotient is a conformal invariant.

Theorem 47.27 (Four-point function of scalar primaries)**.** *For scalar primaries $\mathcal{O}_1,\dots,\mathcal{O}_4$ of dimensions Δ_i, conformal invariance fixes*

$$\boxed{\langle\, \mathcal{O}_1(x_1)\mathcal{O}_2(x_2)\mathcal{O}_3(x_3)\mathcal{O}_4(x_4)\,\rangle = \left(\frac{x_{24}^2}{x_{14}^2}\right)^{\frac{\Delta_1-\Delta_2}{2}} \left(\frac{x_{14}^2}{x_{13}^2}\right)^{\frac{\Delta_3-\Delta_4}{2}} \frac{g(u,v)}{(x_{12}^2)^{\frac{\Delta_1+\Delta_2}{2}}(x_{34}^2)^{\frac{\Delta_3+\Delta_4}{2}}}} \tag{47.144}$$

where $g(u,v)$ is an arbitrary function of the cross-ratios Eq. (47.138), undetermined by symmetry. For four identical scalars of dimension Δ the prefactor collapses and

$$\langle\, \mathcal{O}(x_1)\mathcal{O}(x_2)\mathcal{O}(x_3)\mathcal{O}(x_4)\,\rangle = \frac{g(u,v)}{(x_{12}^2\,x_{34}^2)^{\Delta}}. \tag{47.145}$$

Proof. The ratio $g \equiv \langle\mathcal{O}_1\mathcal{O}_2\mathcal{O}_3\mathcal{O}_4\rangle / K$ is conformally invariant because numerator and denominator have identical weight by Eq. (47.141), verified above for the choice Eq. (47.142). By Theorem 47.25 a conformal invariant of four points is a function of u and v alone, so $g = g(u,v)$. Multiplying through by K gives Eq. (47.144); setting all $\Delta_i = \Delta$ kills the two ratio factors and uses $\frac{\Delta_1+\Delta_2}{2} = \frac{\Delta_3+\Delta_4}{2} = \Delta$ to give Eq. (47.145). □

Caution

The split of the four-point function into prefactor and $g(u, v)$ is a *choice*, not a physical boundary. A different admissible prefactor — any other solution of Eq. (47.141) — multiplies g by a fixed power of u and v, redefining the function without changing the correlator. When comparing formulas across the bootstrap literature one must therefore track which prefactor convention is in force; we fix Eq. (47.142) throughout Part XIV. What *is* convention-independent is the statement that, once a prefactor is chosen, conformal symmetry leaves exactly one free function of two variables.

Physical Insight

The descent through correlators is a descent in how much symmetry can do. Two points: symmetry fixes everything but a sign-definite constant, which normalization sets to 1. Three points: symmetry fixes everything but one number per operator triple, the OPE coefficient. Four points: symmetry fixes everything but one function of two variables. The reason the staircase has a step at four is purely kinematic — four points are the first that cannot all be moved to a standard position by the conformal group, so they retain the two cross-ratios u, v on which a genuine function can depend. That function $g(u, v)$ is where the dynamics of the theory hides, and the rest of Part XIV is the study of the constraints it must obey.

The function $g(u, v)$ is the object handed to the next stage of the development. The operator product expansion will expand it in a discrete sum of *conformal blocks*, one per primary exchanged between the pairs $(\mathcal{O}_1\mathcal{O}_2)$ and $(\mathcal{O}_3\mathcal{O}_4)$, with coefficients $C_{12k}C_{34k}$ built from the three-point data of Theorem 47.24; and the crossing equation — the statement that the same correlator is obtained by expanding in the pair $(\mathcal{O}_1\mathcal{O}_4)$ instead — will turn the freedom of $g(u, v)$ into the central constraint of the conformal bootstrap in Chapter 49. Before we can carry out that expansion we need the Hilbert-space picture that makes the OPE convergent: the foliation of Euclidean space by spheres, the dilatation operator as a Hamiltonian, and the state–operator correspondence. That radial-quantization framework is the subject of the next section.

47.5 Radial Quantization

Up to this point the conformal algebra of Section 47.2 and the operator data of Section 47.3 have acted *formally*: the generators P_μ, K_μ, D, $M_{\mu\nu}$ were realized as differential operators shuffling local fields around spacetime, and a primary

was a local operator with a prescribed transformation law. Nothing in that description was a Hilbert space. There were no states, no inner product, no notion of a norm, and therefore no place to even *state* the unitarity bounds that the structure of representations was begging us to impose. The dilatation D graded the operators by dimension, but a grading on a vector space of operators is not yet a spectrum of a self-adjoint Hamiltonian.

This section repairs that. We will build the genuine Hilbert space on which the conformal algebra acts as operators, and we will do it by exploiting the single feature that distinguishes a CFT from a generic quantum field theory: the absence of any scale, which makes the dilatation D a symmetry. The construction — *radial quantization* — foliates Euclidean space not by the flat time-slices of ordinary canonical quantization but by spheres centered at the origin, promotes D to the role of the Hamiltonian generating evolution between concentric spheres, and reads off the inner product from the reflection (Osterwalder–Schrader) positivity of the Euclidean path integral established in Section 10.6. The payoff is immediate: the energy of a state is its scaling dimension, the spectrum is bounded below precisely when the unitarity bounds hold, and the abstract Hermiticity relations $D^\dagger = D$, $P_\mu^\dagger = K_\mu$ turn the norm computations we have been postponing into honest statements about a positive-definite inner product. The next section will then promote this picture into the structural theorem of the subject — the one-to-one correspondence between local operators and states.

Throughout we work in Euclidean signature, reached from the Minkowski theory by the Wick rotation $x^0 \to -ix_E^d$ of Theorem 5.30 (Section 5.4); the Euclidean correlators are the moments of the path integral with weight e^{-S_E}, S_E the Euclidean action of Theorem 10.27. Radial quantization is intrinsically Euclidean: the foliating surfaces are spheres, and "time" is the logarithm of the radius, a real parameter only after the rotation. We denote Euclidean coordinates x^μ, $\mu = 1, \dots, d$, with flat metric $\delta_{\mu\nu}$, and write $x^2 \equiv \delta_{\mu\nu} x^\mu x^\nu = |x|^2$.

47.5.1 The radial foliation and the Weyl map to the cylinder

In ordinary canonical quantization one slices spacetime by surfaces of constant time $x^0 = \text{const}$, declares the fields on one slice to be the dynamical data, and uses the time-translation generator H to evolve from one slice to the next. The choice of slicing is a choice of which one-parameter subgroup of the spacetime symmetry one elects to call "time evolution." Poincaré invariance makes the constant-time slicing natural because $H = P^0$ is a symmetry generator with a spectrum bounded below. In a CFT there is a more natural and far more powerful choice. Because the theory is invariant under dilatations $x \mapsto \lambda x$, the family of *spheres centered at the origin*, $|x| = \text{const}$, is permuted among itself by a symmetry. We take these spheres as our equal-"time" slices.

Definition 47.28 (Radial foliation and radial time)**.** Foliate $\mathbb{R}^d \setminus \{0\}$ by the

spheres $S_r = \{x : |x| = r\}$ of radius $r > 0$. Introduce the *radial time*

$$\tau \equiv \log r = \log|x|, \qquad n^\mu \equiv \frac{x^\mu}{|x|} \in S^{d-1}, \tag{47.146}$$

so that (τ, n) are coordinates on the cylinder $\mathbb{R}\times S^{d-1}$, with $\tau \in \mathbb{R}$ the noncompact (time) direction and n a point on the unit sphere. The origin $x = 0$ is the infinite past $\tau \to -\infty$ and spatial infinity is the infinite future $\tau \to +\infty$.

The reason this slicing is not merely a reparametrization but a genuine change of physical picture is geometric: written in the coordinates (τ, n), the flat metric is a position-dependent rescaling of the *cylinder* metric, and a CFT is insensitive to exactly such rescalings.

Proposition 47.29 (Weyl map to the cylinder)**.** *The flat Euclidean metric on $\mathbb{R}^d \setminus \{0\}$ is Weyl-equivalent to the metric of the cylinder $\mathbb{R} \times S^{d-1}$:*

$$\mathrm{d}s^2_{\mathbb{R}^d} = \mathrm{d}r^2 + r^2\,\mathrm{d}\Omega^2_{d-1} = r^2(\mathrm{d}\tau^2 + \mathrm{d}\Omega^2_{d-1}) = e^{2\tau}\,\mathrm{d}s^2_{\mathrm{cyl}}, \qquad \mathrm{d}s^2_{\mathrm{cyl}} \equiv \mathrm{d}\tau^2 + \mathrm{d}\Omega^2_{d-1}, \tag{47.147}$$

where $\mathrm{d}\Omega^2_{d-1}$ is the round metric on the unit $(d-1)$-sphere and the Weyl factor is $\Omega(x)^2 = r^2 = e^{2\tau}$.

Proof. In spherical coordinates the flat metric is $\mathrm{d}s^2_{\mathbb{R}^d} = \mathrm{d}r^2 + r^2\,\mathrm{d}\Omega^2_{d-1}$; this is the statement that a small displacement decomposes into a radial part $\mathrm{d}r$ and an angular part of length $r\,|\mathrm{d}n|$. Substitute $r = e^\tau$, so $\mathrm{d}r = e^\tau\,\mathrm{d}\tau$ and $\mathrm{d}r^2 = e^{2\tau}\mathrm{d}\tau^2$, while $r^2 = e^{2\tau}$. Then

$$\mathrm{d}s^2_{\mathbb{R}^d} = e^{2\tau}\mathrm{d}\tau^2 + e^{2\tau}\,\mathrm{d}\Omega^2_{d-1} = e^{2\tau}(\mathrm{d}\tau^2 + \mathrm{d}\Omega^2_{d-1}), \tag{47.148}$$

which is Eq. (47.147). The overall factor $e^{2\tau} = r^2$ multiplies the entire cylinder metric and is therefore a Weyl rescaling, not a change of the conformal class. □

Fig. 47.5 shows the two pictures side by side. The content of Theorem 47.29 is that a conformal field theory does not distinguish $\mathrm{d}s^2_{\mathbb{R}^d}$ from $\mathrm{d}s^2_{\mathrm{cyl}}$ except through the response of its operators to the Weyl factor. A massless theory has no intrinsic length to compare r against, so the only imprint of the rescaling is the conformal weight carried by each operator. We make this precise. Recall (Theorem 47.15) that under a Weyl rescaling of the metric $g_{\mu\nu} \to \Omega(x)^2 g_{\mu\nu}$ a primary scalar $\mathcal{O}$ of dimension Δ transforms homogeneously,

$$\mathcal{O}(x) \longmapsto \Omega(x)^{-\Delta}\,\mathcal{O}(x). \tag{47.149}$$

To pass from the flat description to the cylinder we read Eq. (47.147) as $\mathrm{d}s^2_{\mathrm{cyl}} = \Omega^{-2}\,\mathrm{d}s^2_{\mathbb{R}^d}$ with $\Omega = r = e^\tau$, i.e. we rescale the flat metric *down* by Ω^{-2}. The

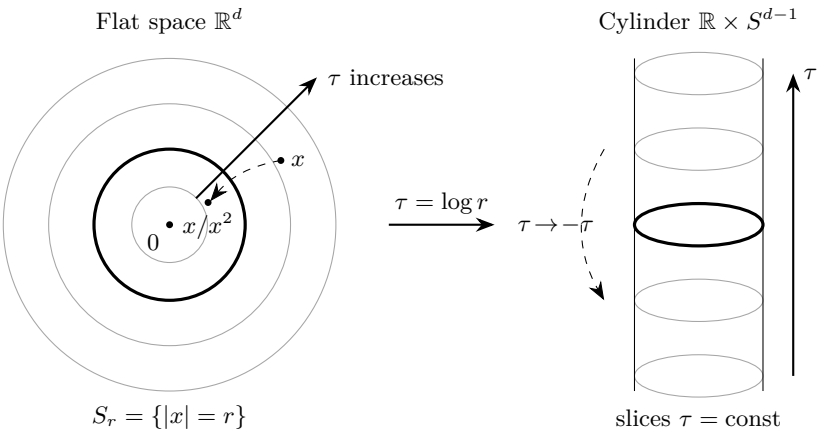

Figure 47.5: The Weyl map of Theorem 47.29. Left: Euclidean space foliated by spheres S_r; radial time is $\tau = \log r$, the origin is $\tau \to -\infty$. The inversion $x \mapsto x/x^2$ exchanges the interior and exterior of the unit sphere (thick) and is the geometric realization of Hermitian conjugation. Right: the same data on the cylinder, where the slices become the round spheres $\tau = \text{const}$ and the inversion becomes the time reflection $\tau \mapsto -\tau$ — precisely the Osterwalder–Schrader reflection.

operator on the cylinder is therefore obtained from the flat-space operator with the inverse weight,

$$\mathcal{O}_{\text{cyl}}(\tau, n) \;=\; \Omega^{+\Delta}\, \mathcal{O}_{\mathbb{R}^d}(x) \;=\; r^{\Delta}\, \mathcal{O}_{\mathbb{R}^d}(x) \;=\; e^{\Delta\tau}\, \mathcal{O}_{\mathbb{R}^d}(x), \qquad x = e^{\tau} n. \tag{47.150}$$

Equivalently the flat-space operator is the cylinder operator dressed with the $r^{-\Delta}$ *factor*,

$$\mathcal{O}_{\mathbb{R}^d}(x) \;=\; r^{-\Delta}\, \mathcal{O}_{\text{cyl}}(\tau, n), \tag{47.151}$$

the single most useful translation between the two pictures: a primary inserted at small r in flat space is, on the cylinder, an excitation in the far past whose flat-space amplitude is suppressed by r^{Δ}.

47.5.2 The dilatation as the radial Hamiltonian

A dilatation $x \mapsto \lambda x$ with $\lambda > 0$ acts on the radius by $r \mapsto \lambda r$ and on radial time by

$$\tau \;=\; \log r \;\longmapsto\; \log(\lambda r) \;=\; \tau + \log \lambda, \tag{47.152}$$

a rigid translation of τ that leaves the angular point $n = x/|x|$ untouched. On the cylinder, then, the dilatation is nothing but a translation in the time direction. The generator of τ-translations is by definition the Hamiltonian of the cylinder

theory, so we are forced to identify

$$H_{\text{cyl}} \;=\; D. \tag{47.153}$$

This identification is the heart of radial quantization. We now show it is consistent at the level of operators and extract the spectrum.

The dilatation generator acts on a local operator by the differential representation recalled in Eq. (47.53), which for a scalar primary reads $[D, \mathcal{O}(x)] = (\Delta + x^\mu \partial_\mu)\,\mathcal{O}(x)$. Exponentiating a finite dilatation by the parameter s, the unitary $U(s) = e^{sD}$ acts as

$$e^{sD}\,\mathcal{O}(x)\,e^{-sD} \;=\; e^{\,s(\Delta + x\cdot\partial)}\,\mathcal{O}(x) \;=\; e^{s\Delta}\,\mathcal{O}(e^s x), \tag{47.154}$$

where the second equality uses the elementary fact that $x\cdot\partial = x^\mu\partial_\mu$ generates rescalings, $e^{s\,x\cdot\partial} f(x) = f(e^s x)$, proved by checking that both sides solve $\partial_s F = (x\cdot\partial)F$ with $F|_{s=0} = f$. Setting $s = \tau$ and $x = n$ on the unit sphere, Eq. (47.154) evolves an operator from the slice $\tau = 0$ outward to radius e^τ:

$$\mathcal{O}(e^\tau n) \;=\; e^{\tau\Delta}\,e^{\tau D}\,\mathcal{O}(n)\,e^{-\tau D}. \tag{47.155}$$

Comparing with Eq. (47.150), the explicit $r^\Delta = e^{\tau\Delta}$ prefactor is exactly the Weyl weight, and the residual operator $e^{\tau D}\mathcal{O}(n)e^{-\tau D}$ is the Heisenberg-picture cylinder operator evolved by the Hamiltonian D. The Euclidean evolution operator that carries data from the slice at τ_1 to the slice at $\tau_2 > \tau_1$ is therefore

$$U(\tau_2, \tau_1) \;=\; e^{-(\tau_2 - \tau_1)D}, \tag{47.156}$$

the precise analog of the Euclidean time-evolution $e^{-(\tau_2-\tau_1)H}$ of an ordinary field theory after Wick rotation. Two remarks fix the picture.

First, Eq. (47.156) makes "energy on the cylinder = scaling dimension" a theorem, not a slogan. A state $|\psi\rangle$ that is a dilatation eigenstate, $D\,|\psi\rangle = E\,|\psi\rangle$, evolves as $U(\tau, 0)\,|\psi\rangle = e^{-E\tau}\,|\psi\rangle$; the decay rate in radial time is its eigenvalue E, which equals the scaling dimension of the operator that creates it. The spectrum of the cylinder Hamiltonian *is* the spectrum of dimensions $\{\Delta\}$ of the theory.

Proposition 47.30 (Dilatation as the radial Hamiltonian)**.** *In radial quantization the Euclidean evolution between concentric spheres is generated by the dilatation D, Eq. (47.156). Consequently the energy of any state on the sphere equals the dilatation eigenvalue, and (anticipating Theorem 47.34) the conformal spectrum is real and, in a unitary theory, bounded below.*

Second, the descendants are the higher-energy excitations built on a primary. From the algebra $[D, P_\mu] = P_\mu$ and $[D, K_\mu] = -K_\mu$ (recall Eq. (47.53)) one reads off

$$D\,(P_\mu\,|\psi\rangle\,) = (E+1)\,P_\mu\,|\psi\rangle\,, \qquad D\,(K_\mu\,|\psi\rangle\,) = (E-1)\,K_\mu\,|\psi\rangle\,, \tag{47.157}$$

so P_μ *raises* the energy by one unit and K_μ *lowers* it. In the radial-quantization Hilbert space the conformal algebra has acquired the ladder structure familiar from the harmonic oscillator, with D playing the role of the number operator graded by dimension. This is the structure the state–operator map of Section 47.6 will exploit.

47.5.3 States from operator insertions and radial ordering

We have a Hamiltonian and an evolution; we now need states. In an ordinary quantum field theory a state on a time slice is prepared by performing the path integral over all field configurations in the past of that slice, with sources or operator insertions specifying the preparation. The same prescription, transcribed to the radial foliation, says: a state on the sphere S_r is prepared by the path integral over the *ball* $B_r = \{|x| \le r\}$ interior to that sphere, with whatever local operators one wishes inserted inside the ball.

Definition 47.31 (State created by an insertion)**.** Let $\mathcal{O}$ be a local operator. The state it creates on a sphere enclosing the origin is

$$|\mathcal{O}\rangle \;\equiv\; \mathcal{O}(0)\,|0\rangle\,, \tag{47.158}$$

where $|0\rangle$ is the conformally invariant vacuum prepared by the path integral over an infinitesimal ball with no insertion. More generally, inserting operators $\mathcal{O}_1(x_1)\cdots\mathcal{O}_n(x_n)$ at points x_i with $|x_i| < r$ and integrating over the fields in B_r prepares a (generally non-primary) state on S_r.

That $\mathcal{O}(0)\,|0\rangle$ is well defined — i.e. that inserting an operator at the origin, the infinite past $\tau \to -\infty$, produces a normalizable state rather than a divergence — is exactly the statement that the dilatation spectrum is bounded below: evolving the insertion from $\tau = -\infty$ forward damps every component by $e^{-E\tau}$ with $E \ge 0$, and the lowest-dimension operator (the identity, $\Delta = 0$) produces the vacuum itself. For a primary, Eq. (47.158) gives a dilatation eigenstate, because

$$D\,|\mathcal{O}\rangle = D\,\mathcal{O}(0)\,|0\rangle = [D,\mathcal{O}(0)]\,|0\rangle + \mathcal{O}(0)\,D\,|0\rangle = \Delta\,\mathcal{O}(0)\,|0\rangle + 0 = \Delta\,|\mathcal{O}\rangle\,, \tag{47.159}$$

where we used $[D,\mathcal{O}(0)] = \Delta\,\mathcal{O}(0)$ (the $x\cdot\partial$ piece vanishes at the origin) and $D\,|0\rangle = 0$ (the vacuum is scale invariant). Likewise $K_\mu\,|\mathcal{O}\rangle = 0$, since $[K_\mu,\mathcal{O}(0)] = 0$ for a primary at the origin and $K_\mu\,|0\rangle = 0$: the primary state is the lowest rung of its ladder, annihilated by the lowering operators K_μ, and its descendants are obtained by acting with the raising operators P_μ.

Correlation functions in this picture are radially ordered, the analog of time ordering. A product of operators inside the path integral is unambiguous, but to interpret it as a matrix element of Hilbert-space operators — which must be applied in a definite order — we must order the insertions by their radius, outermost acting last.

Definition 47.32 (Radial ordering)**.** For local operators the radial-ordering symbol $\mathcal{R}$ arranges a product in order of decreasing radius from left to right,

$$\mathcal{R}\{\mathcal{O}_1(x_1)\,\mathcal{O}_2(x_2)\} \;=\; \begin{cases} \mathcal{O}_1(x_1)\,\mathcal{O}_2(x_2), & |x_1|>|x_2|, \\ \mathcal{O}_2(x_2)\,\mathcal{O}_1(x_1), & |x_2|>|x_1|, \end{cases} \tag{47.160}$$

with bosonic operators commuting and fermionic ones anticommuting under reordering. The Euclidean correlators of Theorem 10.27 equal the vacuum expectation values of the radially ordered products, $\langle \mathcal{O}_1(x_1)\cdots\mathcal{O}_n(x_n)\rangle = \langle 0|\,\mathcal{R}\{\mathcal{O}_1(x_1)\cdots\mathcal{O}_n(x_n)\}\,|0\rangle$.

Radial ordering is to the sphere foliation what time ordering is to the flat foliation: it is the prescription that makes a path-integral correlator equal to an operator matrix element, and it is what guarantees, for instance, that the operator product expansion converges inside the largest sphere that separates two insertions from the rest — a point developed in Section 47.7.3.

47.5.4 The inner product from reflection positivity

A Hilbert space needs an inner product. We have kets $|\mathcal{O}\rangle$; we need bras $\langle\mathcal{O}|$, and we need to know that $\langle\mathcal{O}|\mathcal{O}\rangle \geq 0$. Both come from a single geometric operation: the reflection that the cylinder picture makes obvious.

On the cylinder the natural reflection is $\tau \mapsto -\tau$, exchanging past and future across the slice $\tau = 0$ (the unit sphere). Under the map Eq. (47.146) this is $\log|x| \mapsto -\log|x|$ at fixed angle n, i.e. $|x| \mapsto 1/|x|$, which is the *inversion through the unit sphere*

$$\theta: \quad x^\mu \;\longmapsto\; \frac{x^\mu}{x^2}. \tag{47.161}$$

This θ is precisely the Osterwalder–Schrader reflection of Section 10.6, written in the radial slicing: it reflects the Euclidean "time" τ about the slice $\tau = 0$, exchanging the interior B_1 of the unit ball with its exterior. We use it to define Hermitian conjugation of operators and hence the bra states.

Definition 47.33 (Radial conjugate of an operator)**.** For a scalar primary $\mathcal{O}$ of dimension Δ, Hermitian conjugation in radial quantization acts geometrically by the inversion Eq. (47.35) together with the Weyl weight it carries,

$$\big[\mathcal{O}(x)\big]^\dagger \;=\; \frac{1}{(x^2)^\Delta}\,\mathcal{O}\Big(\frac{x}{x^2}\Big). \tag{47.162}$$

The factor $(x^2)^{-\Delta} = |x|^{-2\Delta}$ is the Jacobian weight Eq. (47.149) of the inversion (whose conformal factor is $\Omega(x) = 1/|x|^2$ acting on $\mathcal{O}$ of dimension Δ contributes the radial scaling that keeps the cylinder operator unit-normalized). The bra dual to $|\mathcal{O}\rangle = \mathcal{O}(0)\,|0\rangle$ is then

$$\langle\mathcal{O}| \;=\; \big(\mathcal{O}(0)\,|0\rangle\,\big)^\dagger \;=\; \lim_{x\to 0}\langle 0|\,\big[\mathcal{O}(x)\big]^\dagger \;=\; \lim_{y\to\infty}(y^2)^\Delta\,\langle 0|\,\mathcal{O}(y), \tag{47.163}$$

the operator sent off to spatial infinity $y = x/x^2 \to \infty$ with the compensating factor that keeps the limit finite.

Theorem 47.34 (The radial-quantization inner product is reflection positive)**.** *The pairing $\langle \mathcal{O}|\mathcal{O}'\rangle$ defined by Eq. (47.163) coincides with an Osterwalder–Schrader reflection inner product of the Euclidean theory. Consequently it is positive semidefinite,*

$$\langle \Psi|\Psi\rangle \;\geq\; 0 \qquad \textit{for every state } |\Psi\rangle \textit{ prepared inside the unit ball,} \tag{47.164}$$

and in a unitary (reflection-positive) CFT it is positive definite on the space of states.

Proof. Let $|\Psi\rangle$ be prepared by inserting operators $F = \mathcal{O}_1(x_1)\cdots\mathcal{O}_n(x_n)$ at points strictly inside the unit ball, $|x_i| < 1$, acting on the vacuum: $|\Psi\rangle = F\,|0\rangle$. By Eq. (47.162) the conjugate insertion is built from the reflected operators $\theta(F) = [\mathcal{O}_n(x_n)]^\dagger \cdots [\mathcal{O}_1(x_1)]^\dagger$, each supported at the inverted point x_i/x_i^2 with $|x_i/x_i^2| = 1/|x_i| > 1$: all the reflected insertions lie strictly *outside* the unit ball. The norm is the radially ordered Euclidean correlator

$$\langle \Psi|\Psi\rangle \;=\; \langle 0|\,\mathcal{R}\{\theta(F)\,F\}\,|0\rangle \;=\; \langle\, \theta(F)\,F\,\rangle, \tag{47.165}$$

in which every operator of F sits inside B_1 ($\tau < 0$) and every operator of $\theta(F)$ sits in the reflected region outside B_1 ($\tau > 0$); the radial ordering is automatic because the reflected points all have larger radius. Eq. (47.165) is exactly the bilinear form $\langle \theta(F)\,F\rangle$ to which Osterwalder–Schrader reflection positivity applies (Theorem 10.32): with θ the reflection about the slice $\tau = 0$ and F supported on one side of it, that theorem states $\langle \theta(F)\,F\rangle \geq 0$. Hence Eq. (47.164). Reflection positivity is the Euclidean avatar of unitarity established in Section 10.6; a CFT is called unitary precisely when this form has no null or negative-norm directions on the physical state space, i.e. when it is positive definite. (A nonzero state of zero norm would, by the Cauchy–Schwarz inequality applied to Eq. (47.165), decouple from all correlators and could be quotiented out; a state of negative norm violates unitarity and is excluded by hypothesis.) □

The single most important consequence is that the dimensions are real and the energies are bounded below: a self-adjoint operator D on a space with a positive-definite inner product has a real spectrum, and Eq. (47.164) applied to descendant states will in a moment force $\Delta \geq 0$ (and, with spin, the full unitarity bounds). The norm computations of Section 47.3.5 that we deferred are now well posed: they are statements about a genuine positive-definite Hilbert space.

47.5.5 Hermiticity of the generators: $P_\mu^\dagger = K_\mu$

The inner product of Theorem 47.34 determines the adjoints of the conformal generators. The geometric content is already visible in Fig. 47.5: conjugation

is the inversion θ, and inversion conjugates translations into special conformal transformations. We now prove the Hermiticity relations algebraically, using only the reality of the inner product, the identification Eq. (47.153) of D as a self-adjoint Hamiltonian, and the conformal algebra of Eq. (47.53).

Proposition 47.35 (Hermiticity in radial quantization)**.** *With respect to the radial-quantization inner product the conformal generators satisfy*

$$D^\dagger = D, \qquad M_{\mu\nu}^\dagger = -M_{\mu\nu}, \qquad P_\mu^\dagger = K_\mu, \qquad K_\mu^\dagger = P_\mu. \tag{47.166}$$

Proof. *D is self-adjoint.* By Theorem 47.30 the Euclidean evolution is $U(\tau) = e^{-\tau D}$, Eq. (47.156). Reflection positivity endows the state space with a positive-definite inner product in which the transfer operator relating a slice to its reflection is self-adjoint and positive; concretely, Eq. (47.165) pairs a state evolved forward by τ with its reflection evolved forward by τ, so the bilinear form is invariant under $U(\tau) \mapsto U(\tau)^\dagger = U(\tau)$. Hence $e^{-\tau D}$ is self-adjoint for all real τ, which gives $D^\dagger = D$ and a real dilatation spectrum.

$M_{\mu\nu}$ is anti-self-adjoint. The Euclidean rotations $SO(d)$ act geometrically on the sphere S^{d-1}, commute with D, and map the unit ball to itself; they are therefore realized by operators that preserve the inner product Eq. (47.165), i.e. unitarily, $e^{\theta M_{\mu\nu}}$ unitary for real θ. In our convention (the algebra Eq. (47.53) carries no factor of i in the rotation generators) a unitary one-parameter group $e^{\theta M_{\mu\nu}}$ has an anti-self-adjoint generator, $M_{\mu\nu}^\dagger = -M_{\mu\nu}$.

$P_\mu^\dagger$ has dilatation weight -1. Take the adjoint of $[D, P_\mu] = P_\mu$ (recall Eq. (47.53)). For any operators, $[A, B]^\dagger = [B^\dagger, A^\dagger]$, so using $D^\dagger = D$,

$$[D, P_\mu]^\dagger = [P_\mu^\dagger, D] = -[D, P_\mu^\dagger] = P_\mu^\dagger \quad \Longrightarrow \quad [D, P_\mu^\dagger] = -P_\mu^\dagger. \tag{47.167}$$

Thus $P_\mu^\dagger$ lowers the dilatation eigenvalue by one unit. Among the generators only K_μ has dilatation weight -1 (from $[D, K_\mu] = -K_\mu$), and like $P_\mu^\dagger$ it transforms as a vector under $M_{\mu\nu}$ (this follows from taking the adjoint of $[M_{\mu\nu}, P_\rho]$ and using $M^\dagger = -M$). Hence $P_\mu^\dagger = c\, K_\mu$ for a single constant c.

The constant is $c = 1$. Take the adjoint of the commutator $[K_\mu, P_\nu] = 2(\delta_{\mu\nu} D - M_{\mu\nu})$ (recall Eq. (47.53)). The left side gives, with $K_\mu^\dagger = \bar{c}\, P_\mu$ from $P_\mu^\dagger = cK_\mu$,

$$[K_\mu, P_\nu]^\dagger = [P_\nu^\dagger, K_\mu^\dagger] = [c\, K_\nu, \bar{c}\, P_\mu] = |c|^2\, [K_\nu, P_\mu] = |c|^2 \cdot 2(\delta_{\mu\nu} D - M_{\nu\mu}) = 2|c|^2(\delta_{\mu\nu} D + M_{\mu\nu}) \tag{47.168}$$

using $M_{\nu\mu} = -M_{\mu\nu}$. The right side gives, using $D^\dagger = D$ and $M_{\mu\nu}^\dagger = -M_{\mu\nu}$,

$$\Big(2(\delta_{\mu\nu} D - M_{\mu\nu})\Big)^\dagger = 2(\delta_{\mu\nu} D - M_{\mu\nu}^\dagger) = 2(\delta_{\mu\nu} D + M_{\mu\nu}). \tag{47.169}$$

Equating the two and matching the (linearly independent) D and $M_{\mu\nu}$ structures forces $|c|^2 = 1$. Because the inversion Eq. (47.35) is a real geometric operation

with no accompanying phase — the conjugation Eq. (47.162) carries the real weight $(x^2)^{-\Delta}$ and no i — the constant is real and positive, $c = 1$. Therefore $P_\mu^\dagger = K_\mu$, and conjugating, $K_\mu^\dagger = P_\mu$. □

The relation $P_\mu^\dagger = K_\mu$ is the radial-quantization counterpart of the familiar $a^\dagger/a$ pairing of the oscillator: the raising operators P_μ that generate descendants are the Hermitian conjugates of the lowering operators K_μ that annihilate primaries. This is exactly what is needed to turn a string of descendant states into a computable, manifestly real norm. We close with the computation that does so, and that supplies the Hilbert-space meaning of the scalar unitarity bound.

Worked Example 47.36 (The level-one descendant norm and the scalar unitarity bound)**.** Let $\mathcal{O}$ be a scalar primary of dimension Δ, normalized to $\langle\mathcal{O}|\mathcal{O}\rangle = 1$, and consider its first descendants $P_\nu|\mathcal{O}\rangle$. Their Gram matrix is the inner product of $P_\mu|\mathcal{O}\rangle$ with $P_\nu|\mathcal{O}\rangle$,

$$\mathcal{G}_{\mu\nu} \equiv (P_\mu|\mathcal{O}\rangle)^\dagger (P_\nu|\mathcal{O}\rangle) = \langle\mathcal{O}|P_\mu^\dagger P_\nu|\mathcal{O}\rangle = \langle\mathcal{O}|K_\mu P_\nu|\mathcal{O}\rangle, \tag{47.170}$$

where the last step used $P_\mu^\dagger = K_\mu$ from Theorem 47.35. Now move K_μ to the right past P_ν using $[K_\mu, P_\nu] = 2(\delta_{\mu\nu}D - M_{\mu\nu})$:

$$K_\mu P_\nu = [K_\mu, P_\nu] + P_\nu K_\mu = 2(\delta_{\mu\nu}D - M_{\mu\nu}) + P_\nu K_\mu. \tag{47.171}$$

Acting on the primary state, $K_\mu|\mathcal{O}\rangle = 0$ kills the second term, while $D|\mathcal{O}\rangle = \Delta|\mathcal{O}\rangle$ and $M_{\mu\nu}|\mathcal{O}\rangle = 0$ (the scalar carries no spin), so

$$\mathcal{G}_{\mu\nu} = \langle\mathcal{O}|\,2(\delta_{\mu\nu}D - M_{\mu\nu})\,|\mathcal{O}\rangle = 2\,\delta_{\mu\nu}\,\Delta\,\langle\mathcal{O}|\mathcal{O}\rangle = 2\,\Delta\,\delta_{\mu\nu}. \tag{47.172}$$

By Theorem 47.34 the Gram matrix of any set of states is positive semidefinite, so its diagonal entries are nonnegative: taking $\mu = \nu$ (no sum), $\mathcal{G}_{\mu\mu} = 2\Delta \geq 0$, hence

$$\boxed{\Delta \geq 0} \tag{47.173}$$

for every scalar primary. The bound is saturated, $\Delta = 0$, only when $\mathcal{G} = 0$, i.e. when $P_\mu|\mathcal{O}\rangle = 0$ for all μ: the state is annihilated by translations and is therefore the conformally invariant vacuum, created by the identity operator. Thus $\Delta = 0$ is reached by the identity alone, and every other scalar primary in a unitary CFT has $\Delta > 0$.

This is the simplest instance of the general unitarity bounds. Repeating the computation for a primary in a nontrivial $SO(d)$ representation keeps the spin terms $M_{\mu\nu}|\mathcal{O}\rangle \neq 0$ in Eq. (47.172); positivity of the resulting (now matrix-valued) Gram form yields the bound $\Delta \geq (d-2)/2$ for scalars excluding the identity and the stronger spin-ℓ bounds catalogued in Section 47.3.5. The point established here is structural: those bounds are not assumptions but consequences of Eq. (47.164), the reflection positivity of the Euclidean path integral.

We now have what the construction promised: a Hilbert space carrying a positive-definite inner product, with the dilatation D as a self-adjoint Hamiltonian whose spectrum is the set of scaling dimensions, the primaries sitting at the bottom of conformal ladders ($K_\mu |\mathcal{O}\rangle = 0$) and their descendants generated by the raising operators $P_\mu = K_\mu^\dagger$. The next section turns this dictionary into an exact theorem — the state–operator correspondence — showing that *every* state of this Hilbert space is $\mathcal{O}(0)|0\rangle$ for a unique local operator $\mathcal{O}$, so that the spectrum of D and the spectrum of local operators are one and the same.

47.6 The State-Operator Map

Radial quantization handed us a Hilbert space $\mathcal{H}_{S^{d-1}}$ of states on the sphere, a Hamiltonian — the dilatation generator D, generating evolution in the radial time $\tau = \ln r$ (Section 47.5) — and an inner product certified positive by Osterwalder–Schrader reflection positivity (Theorem 10.32). What we do not yet have is any reason to believe that this Hilbert space is small, computable, or related to the data we already control: the local operators of the theory, organized in Section 47.3 into primaries and their descendants. The central structural theorem of conformal field theory closes exactly this gap. It says that the two lists — "local operators" and "states on the sphere" — are not merely analogous but *identical*: there is a canonical, invertible, conformally covariant map between them. A local operator is a state; a state is a local operator; the spectrum of scaling dimensions and the spectrum of the radial Hamiltonian are one and the same list. This is the fact that makes a CFT a discretely indexed object — a list of dimensions and spins, not a continuum of fields — and it is the rigorous footing on which the convergence of the operator product expansion (Section 47.4, and the next section) will rest.

The map is forced on us by the geometry of radial quantization, and we build it in four movements. First we send an operator to a state by inserting it at the center of the ball and performing the path integral, and we show that the dilatation grading makes this insertion converge as the ball shrinks. Second we run the construction backwards, reproducing any state on the sphere by a (generally infinite) sum of operators inserted at the origin, and we prove the two directions are mutually inverse. Third we show the map intertwines the conformal action: acting with a generator on the state equals taking the state of the transformed operator, so that primaries — the operators annihilated by K_μ — correspond exactly to the lowest-weight states, and descendants $P_{\mu_1}\cdots P_{\mu_n}$ acting on a primary state correspond to the derivative operators $\partial_{\mu_1}\cdots\partial_{\mu_n}\mathcal{O}$. Finally we read off the consequence that organizes the rest of the part: the partition function on the cylinder is a sum over operator dimensions, and the lowest dimension above the identity is the radial-quantization gap.

Notation Watch

Throughout this section we use the *radial-quantization generators* of Section 47.5 rather than the differential operators of Eq. (47.41). In the Euclidean radial picture the dilatation D is a Hermitian operator with *real* spectrum — the radial Hamiltonian — so its eigenvalues are the scaling dimensions Δ directly, and the grading brackets Eq. (47.53c) are taken in the form

$$[D, P_\mu] = P_\mu, \qquad [D, K_\mu] = -K_\mu, \qquad [K_\mu, P_\nu] = 2(\delta_{\mu\nu} D - M_{\mu\nu}), \tag{47.174}$$

the factors of i in Eq. (47.53) having been absorbed into this Euclidean normalization (equivalently, the radial dilatation is $-i$ times the Lorentzian one, which turns its imaginary eigenvalue $i\Delta$ into the real dimension Δ). The Euclidean signature is reflected in the adjoint relation established with the inner product in Section 47.5,

$$D^\dagger = D, \qquad M_{\mu\nu}^\dagger = -M_{\mu\nu}, \qquad P_\mu^\dagger = K_\mu, \tag{47.175}$$

so that K_μ is the Hermitian conjugate of P_μ — the lowering operator conjugate to the raising operator. We write $|0\rangle$ for the conformally invariant vacuum.

47.6.1 From an operator to a state

The construction begins with the path-integral definition of a state in radial quantization (Section 47.5, built on Section 10.3). A state on the sphere S_r^{d-1} of radius r is a functional of the field values ϕ_b on that sphere, produced by integrating over all field configurations *inside* the ball B_r with those boundary values held fixed:

$$\Psi[\phi_b] = \int_{\phi|_{\partial B_r} = \phi_b} \mathcal{D}\phi \; e^{-S_E[\phi]}, \tag{47.176}$$

with S_E the Euclidean action and $\mathcal{D}\phi$ the measure of Theorem 10.16. With no insertion this prepares the vacuum $|0\rangle$. The state-operator map is what we obtain by inserting a local operator at the one point the ball distinguishes — its center, the origin, which is the fixed point of every dilatation and rotation.

Definition 47.37 (The map from operators to states)**.** For a local operator $\mathcal{O}$ of the theory, define the state

$$|\mathcal{O}\rangle \;\equiv\; \mathcal{O}(0)\,|0\rangle\,, \tag{47.177}$$

realized as the wavefunctional obtained from Eq. (47.176) with $\mathcal{O}$ inserted at the center of the ball:

$$\Psi_{\mathcal{O}}[\phi_b] = \int_{\phi|_{\partial B_r} = \phi_b} \mathcal{D}\phi \; e^{-S_E[\phi]}\, \mathcal{O}(0). \tag{47.178}$$

We call $|\mathcal{O}\rangle$ the state *created by* $\mathcal{O}$.

The first thing to verify is that this is a genuine, radius-independent element of $\mathcal{H}_{S^{d-1}}$, and that it is graded by the dilatation in the cleanest possible way: it is an eigenstate of the radial Hamiltonian with eigenvalue equal to the scaling dimension. This is what makes the dilatation grading the engine of the whole map.

Proposition 47.38 (Created states are dilatation eigenstates)**.** *Let $\mathcal{O}$ be a scaling operator of dimension Δ, so that $[D, \mathcal{O}(0)] = \Delta\, \mathcal{O}(0)$ in the conventions of Eq. (47.174). Then*

$$D\ |\mathcal{O}\rangle = \Delta\ |\mathcal{O}\rangle\,. \tag{47.179}$$

Proof. The vacuum is annihilated by D — it carries no scale, and we prove its full conformal invariance in Theorem 47.41 below — so $D\,|0\rangle = 0$. Then

$$D\ |\mathcal{O}\rangle = D\,\mathcal{O}(0)\,|0\rangle = [D, \mathcal{O}(0)]\,|0\rangle + \mathcal{O}(0)\,D\,|0\rangle = \Delta\,\mathcal{O}(0)\,|0\rangle = \Delta\ |\mathcal{O}\rangle\,, \tag{47.180}$$

using $[D, \mathcal{O}(0)] = \Delta\,\mathcal{O}(0)$, which is the statement (Section 47.3) that $\mathcal{O}$ has definite scaling dimension Δ. □

Equation (47.179) is the reason the construction is well posed. Because $|\mathcal{O}\rangle$ is an eigenstate of the radial Hamiltonian, the radial evolution $e^{-\tau D}$ from one sphere to another acts on it by a pure number $e^{-\tau\Delta}$: the state is the same abstract vector regardless of the radius $r = e^{\tau}$ at which we read it off, the radius only rescaling its normalization. An operator inserted anywhere *other* than the origin would not enjoy this; only the dilatation fixed point produces a clean eigenstate. Figure 47.6(a) shows the picture.

47.6.2 Shrinking the ball: convergence of the insertion

Inserting an operator at the exact center is a limit, and we owe a demonstration that the limit exists. The clean way to control it is to displace the insertion to a nearby point x inside the ball and expand. Because P_μ generates translations on operators, $[P_\mu, \mathcal{O}(y)] = \partial_\mu \mathcal{O}(y)$ (Section 47.3), the finite translation that carries the origin to x is implemented by $e^{x\cdot P}$, in the sense that $\mathcal{O}(x) = e^{x\cdot P}\,\mathcal{O}(0)\,e^{-x\cdot P}$. Acting on the vacuum and using translation invariance of the vacuum, $P_\mu\,|0\rangle = 0$ (Theorem 47.41), the right factor is trivial and we obtain the exact statement

$$\mathcal{O}(x)\ |0\rangle = e^{x\cdot P}\,\mathcal{O}(0)\ |0\rangle = \sum_{n=0}^{\infty} \frac{1}{n!}\,(x\cdot P)^n\ |\mathcal{O}\rangle\,. \tag{47.181}$$

This is the precise content of Fig. 47.6(b): the state created by an off-center insertion is a sum of the primary state $|\mathcal{O}\rangle$ and its *descendant* states $(x\cdot P)^n\,|\mathcal{O}\rangle$.

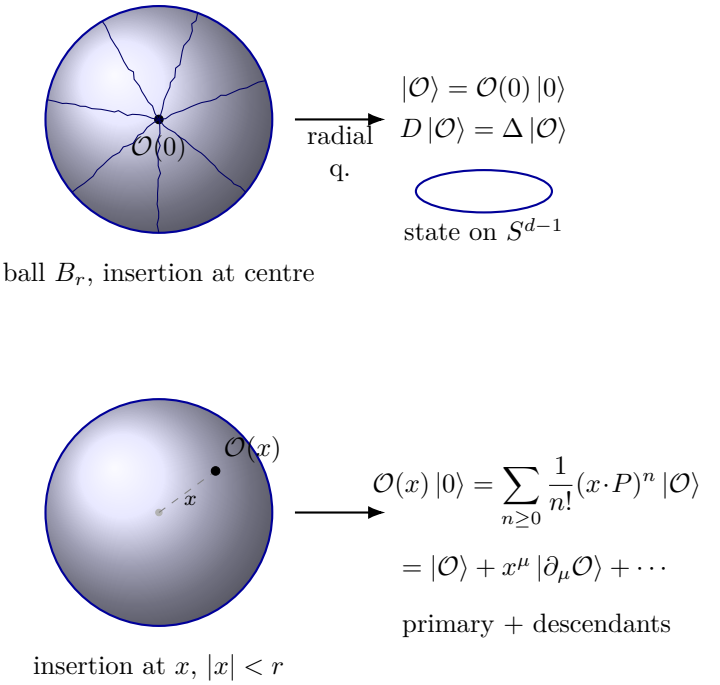

Figure 47.6: The state-operator map. (a) An operator inserted at the center of the ball — the fixed point of dilatations — prepares a state on the bounding sphere S^{d-1}; by Theorem 47.38 it is an eigenstate of the radial Hamiltonian D with eigenvalue equal to the scaling dimension Δ. (b) The same operator displaced to x prepares not an eigenstate but the convergent sum Eq. (47.181) of the primary state and its descendants; bringing $x \to 0$ (shrinking the ball around the insertion) projects onto the leading term $|\mathcal{O}\rangle$, the dilatation grading suppressing the n-th descendant by $|x|^n$.

Each term is itself a dilatation eigenstate, because P_μ raises the dimension by one unit: from $[D, P_\mu] = P_\mu$ in Eq. (47.174),

$$D\,(x\cdot P)^n\,|\mathcal{O}\rangle = (\Delta + n)\,(x\cdot P)^n\,|\mathcal{O}\rangle\,. \tag{47.182}$$

The grading Eq. (47.182) is exactly what makes the series Eq. (47.181) convergent and the $x \to 0$ limit controlled. Read the radial evolution as a damping: a state of dimension $\Delta + n$ scales as $r^{\Delta+n}$ as the bounding sphere shrinks ($r \to 0$), so relative to the leading term the n-th descendant contributes a factor $|x|^n$ (more precisely $(|x|/r)^n$ at fixed reference radius r). For an insertion isolated inside the ball — no other operator within distance R of the origin — the series converges for $|x| < R$, the radius of convergence being set by the nearest other singularity, exactly as for the operator product expansion of the next section; for a single insertion in otherwise empty space it converges for all finite x. The decisive point is that the spectrum of D is bounded below (the vacuum sits at $\Delta = 0$ and there

is a positive gap to the first nontrivial operator, established in Section 47.5 from reflection positivity), so the descendant tower marches upward in dimension and the high-n terms are uniformly suppressed.

Taking $x \to 0$ in Eq. (47.181), every term with $n \geq 1$ carries an explicit factor of x and vanishes, leaving the leading term alone:

$$\lim_{x\to 0} \mathcal{O}(x)\,|0\rangle = |\mathcal{O}\rangle\,. \tag{47.183}$$

Geometrically this is the statement that shrinking the ball down onto the insertion point projects the prepared state onto the primary state, the descendants being radial fluctuations that die away as the sphere closes in. Equation (47.183) is therefore not a definition imposed by hand but a convergent limit, justified by the dilatation grading. The created state $|\mathcal{O}\rangle$ is a well-defined, normalizable vector in $\mathcal{H}_{S^{d-1}}$, with norm fixed by the two-point function as we record next.

The conjugate state deserves a word, because it is what the inner product of Section 47.5 pairs $|\mathcal{O}\rangle$ against. Reflection positivity builds the bra from the operator inserted at the point conjugate to the origin under inversion — namely the point at infinity. Defining $\mathcal{O}(\infty) \equiv \lim_{x\to\infty} |x|^{2\Delta}\,\mathcal{O}(x)$, the conjugate state is $\langle\mathcal{O}| = \lim_{x\to\infty} |x|^{2\Delta}\,\langle 0|\,\mathcal{O}(x)$, and the inner product of two created states is precisely the coefficient of their two-point function (Eq. (47.120)):

$$\langle\mathcal{O}|\mathcal{O}'\rangle = \lim_{x\to\infty} |x|^{2\Delta}\,\langle 0|\,\mathcal{O}(x)\,\mathcal{O}'(0)\,|0\rangle = C_{\mathcal{O}}\,\delta_{\mathcal{O}\mathcal{O}'}, \tag{47.184}$$

nonzero only between operators of equal dimension (and spin), with $C_{\mathcal{O}}$ the two-point normalization. The state-operator map is thus not merely a bijection of vector spaces but an *isometry* once operators are normalized to unit two-point coefficient — the radial inner product on states equals the two-point pairing on operators.

47.6.3 From a state back to an operator

We now run the construction in reverse and prove it is invertible. The claim is that every state on the sphere is created by some local operator at the origin, and that distinct operators create distinct states.

Proposition 47.39 (Surjectivity: every state comes from an operator)**.** *The created states $\{|\mathcal{O}\rangle\}$, as $\mathcal{O}$ ranges over all local operators of the theory (primaries together with all their descendants), span $\mathcal{H}_{S^{d-1}}$.*

Proof. By the Osterwalder–Schrader reconstruction of the Hilbert space (Theorem 10.32), $\mathcal{H}_{S^{d-1}}$ is generated by acting on the vacuum with field operators inserted in the interior of the ball: states of the form $\mathcal{O}_1(x_1)\cdots\mathcal{O}_k(x_k)\,|0\rangle$ with all $|x_i| < r$ span a dense subspace, the field algebra acting on $|0\rangle$ being dense by the reconstruction theorem. It therefore suffices to show each such multi-insertion

state lies in the span of $\{|\mathcal{O}\rangle\}$. Take first a single insertion $\mathcal{O}(x)\,|0\rangle$ with $|x| < r$. By Eq. (47.181) it is the convergent series $\sum_n \frac{1}{n!}(x\cdot P)^n\,|\mathcal{O}\rangle$, every term of which is a created state (the descendant $(x\cdot P)^n\mathcal{O}$ is a local operator). Hence $\mathcal{O}(x)\,|0\rangle$ lies in the closed span of created states. For a product of insertions, the same expansion applies term by term: each operator can be Taylor-expanded about the origin into its conformal family, and the product of local operators near the origin is, by the operator product expansion (Section 47.4), itself a convergent sum of local operators at the origin — a statement whose rigorous footing is precisely the present map, and which the next section establishes as a consequence of completeness rather than assuming it. Thus the dense set of multi-insertion states lies in the closed span of $\{|\mathcal{O}\rangle\}$, and the span is all of $\mathcal{H}_{S^{d-1}}$. □

Proposition 47.40 (Injectivity: distinct operators give distinct states)**.** *If $|\mathcal{O}\rangle = |\mathcal{O}'\rangle$ as states in $\mathcal{H}_{S^{d-1}}$, then $\mathcal{O} = \mathcal{O}'$ as local operators.*

Proof. A local operator is determined by its correlation functions with all other operators (Theorem 10.16): two operators agreeing inside every correlator are the same operator. Suppose $|\mathcal{O}\rangle = |\mathcal{O}'\rangle$. For any state $\langle\Psi|$ in the dense spanning set of Theorem 47.39 — a product of insertions $\mathcal{O}_1(y_1)\cdots\mathcal{O}_k(y_k)$ at points outside the ball, $|y_i| > r$, acting on the vacuum from the left — the overlap with the created state is, by the path-integral construction Eq. (47.178) glued across the sphere, the correlation function

$$\langle\Psi|\mathcal{O}\rangle = \langle 0|\,\mathcal{O}_1(y_1)\cdots\mathcal{O}_k(y_k)\,\mathcal{O}(0)\,|0\rangle\,. \tag{47.185}$$

Equality of the states $|\mathcal{O}\rangle = |\mathcal{O}'\rangle$ forces these correlators to coincide for every choice of external insertions:

$$\langle 0|\,\mathcal{O}_1(y_1)\cdots\mathcal{O}_k(y_k)\,\mathcal{O}(0)\,|0\rangle = \langle 0|\,\mathcal{O}_1(y_1)\cdots\mathcal{O}_k(y_k)\,\mathcal{O}'(0)\,|0\rangle \tag{47.186}$$

for all k and all y_i. Since correlators determine the operator, $\mathcal{O}(0) = \mathcal{O}'(0)$, hence $\mathcal{O} = \mathcal{O}'$. □

Together Theorems 47.39 and 47.40 establish that Eq. (47.177) is a bijection between local operators and states. Combined with the conformal covariance of the next subsection, this is the state-operator *isomorphism*.

47.6.4 The map intertwines the conformal action

A bijection of sets becomes a theorem about representations once we check it commutes with the conformal generators. The key input is that the vacuum is conformally invariant, which we now prove, having used it twice above.

Proposition 47.41 (Conformal invariance of the vacuum)**.** *The radial-quantization vacuum is annihilated by every conformal generator:*

$$P_\mu\,|0\rangle = 0, \qquad M_{\mu\nu}\,|0\rangle = 0, \qquad D\,|0\rangle = 0, \qquad K_\mu\,|0\rangle = 0. \tag{47.187}$$

Proof. The vacuum is the state Eq. (47.176) prepared by the path integral over the ball with no insertion. The action S_E and the measure $\mathcal{D}\phi$ of a conformal field theory are invariant under the conformal group — this is the operator statement, established in Section 47.1, that the improved stress tensor is conserved and traceless, so that the conserved charges $\{P_\mu, M_{\mu\nu}, D, K_\mu\}$ generate symmetries of the functional integral. A symmetry transformation acts on the no-insertion functional by relabeling the integration variable, under which the integral is unchanged; with no operator inserted there is nothing to carry a position, a scale, or a direction that the transformation could move. Hence the vacuum functional is fixed by every finite conformal transformation $U_g\,|0\rangle = |0\rangle$, and differentiating at the identity gives $G\,|0\rangle = 0$ for each generator G. Equivalently and more physically: $D\,|0\rangle = 0$ says the vacuum has dimension zero (it is the state of the identity operator); $P_\mu\,|0\rangle = 0$ and $M_{\mu\nu}\,|0\rangle = 0$ are Poincaré invariance; and $K_\mu\,|0\rangle = 0$ is invariance under special conformal transformations, the new content of conformal symmetry. That a single state is annihilated by both the raising operators P_μ and the lowering operators K_μ is consistent precisely because it sits at the bottom *and* is unique: it is the conformally invariant vacuum. □

With the vacuum invariant, the action of any generator on a created state collapses onto a commutator, which is again a local operator at the origin — and therefore again a created state. This is the intertwining property.

Theorem 47.42 (The state-operator isomorphism)**.** *The map* $\mathcal{O} \mapsto |\mathcal{O}\rangle = \mathcal{O}(0)\,|0\rangle$ *is a bijection between the local operators of the CFT and the states of* $\mathcal{H}_{S^{d-1}}$*, and it intertwines the conformal action: for every generator* $G \in \{P_\mu, M_{\mu\nu}, D, K_\mu\}$*,*

$$G\;|\mathcal{O}\rangle = [G, \mathcal{O}(0)]\;|0\rangle = |\,G{\cdot}\mathcal{O}\,\rangle\,, \tag{47.188}$$

where $G{\cdot}\mathcal{O}$ *denotes the local operator* $[G, \mathcal{O}(0)]$ *reinstated at the origin. Consequently the conformal representation carried by the operators (Section 47.3) and the representation carried by the Hilbert space are isomorphic as representations of* $\mathfrak{so}(d+1,1)$*.*

Proof. Bijectivity is Theorems 47.39 and 47.40. For the intertwining, expand the generator through the operator using $G\,|0\rangle = 0$ from Theorem 47.41:

$$G\;|\mathcal{O}\rangle = G\,\mathcal{O}(0)\,|0\rangle = [G, \mathcal{O}(0)]\,|0\rangle + \mathcal{O}(0)\,G\,|0\rangle = [G, \mathcal{O}(0)]\,|0\rangle\,. \tag{47.189}$$

The commutator $[G, \mathcal{O}(0)]$ is, by the transformation law of operators under the conformal generators (Section 47.3), a local operator evaluated at the origin; calling it $G{\cdot}\mathcal{O}$, the last expression is $|G \cdot \mathcal{O}\rangle$ by Eq. (47.177). Since this holds for every generator and the map is a bijection, it is an isomorphism of $\mathfrak{so}(d+1,1)$ representations. □

Equation (47.188) is the whole theorem in one line, and reading it off generator by generator dictionary gives the correspondence between the two languages. The dilatation reproduces Theorem 47.38, $D\,|\mathcal{O}\rangle = \Delta\,|\mathcal{O}\rangle$. The momentum acts as the derivative,

$$P_\mu\,|\mathcal{O}\rangle = [P_\mu, \mathcal{O}(0)]\,|0\rangle = \partial_\mu \mathcal{O}(0)\,|0\rangle = |\partial_\mu \mathcal{O}\rangle\,, \tag{47.190}$$

so raising the state by P_μ corresponds to differentiating the operator, in accord with the dimension rising by one. The Lorentz generators rotate the spin indices, $M_{\mu\nu}\,|\mathcal{O}\rangle = |\,\mathcal{S}_{\mu\nu}\mathcal{O}\,\rangle$ with $\mathcal{S}_{\mu\nu}$ the spin matrix. The new and decisive entry is the special conformal generator. By the definition of a primary operator (Theorem 47.15), $[K_\mu, \mathcal{O}(0)] = 0$; therefore

$$K_\mu\,|\mathcal{O}\rangle = [K_\mu, \mathcal{O}(0)]\,|0\rangle = 0 \qquad \text{for } \mathcal{O} \text{ primary.} \tag{47.191}$$

This is the cornerstone of the map.

Corollary 47.43 (Primaries are lowest-weight states; descendants are their orbit)**.** *Under the state-operator map:*

1. *A* primary operator $\mathcal{O}$ *of dimension* Δ *and spin* ℓ *corresponds to a* lowest-weight *(conformal-primary) state* $|\mathcal{O}\rangle$*: a* D*-eigenstate of eigenvalue* Δ *in the spin-*ℓ *representation of the rotation group, annihilated by all the lowering operators,* $K_\mu\,|\mathcal{O}\rangle = 0$*.*

2. *The* descendants *of* $\mathcal{O}$ *— the operators* $\partial_{\mu_1}\cdots\partial_{\mu_n}\mathcal{O}$ *(Theorem 47.15) — correspond to the states obtained by acting with the raising operators on the primary state,*

$$|\partial_{\mu_1}\cdots\partial_{\mu_n}\mathcal{O}\rangle = P_{\mu_1}\cdots P_{\mu_n}\,|\mathcal{O}\rangle\,. \tag{47.192}$$

   The conformal multiplet generated by $\mathcal{O}$ *maps isomorphically onto the conformal module* $\{P_{\mu_1}\cdots P_{\mu_n}\,|\mathcal{O}\rangle\}$ *built on the lowest-weight state.*

Proof. Item (1) collects Theorem 47.38, the spin statement under $M_{\mu\nu}$, and Eq. (47.191). That K_μ is a lowering operator — $[D, K_\mu] = -K_\mu$ in Eq. (47.174) sends a state of dimension Δ to one of dimension $\Delta - 1$ — makes "annihilated by K_μ" synonymous with "lowest-weight": there is nothing below it in the module. Item (2) is Eq. (47.190) iterated: each application of P_μ both adds a derivative to the operator, by Eq. (47.188), and raises the dimension by one, by $[D, P_\mu] = P_\mu$. The map being a vector-space isomorphism (Theorem 47.42) and respecting the P-action, it carries the operator family bijectively onto the state module. □

The picture is now complete and rigid. Every state of $\mathcal{H}_{S^{d-1}}$ sits in a tower built on a lowest-weight state $|\mathcal{O}\rangle$ killed by K_μ; the towers are the conformal multiplets; the lowest-weight states are the primaries; the upper floors are reached

by the raising operators P_μ and are the descendants. Acting with K_μ moves *down* a tower until it hits the primary and annihilates. This is the abstract shadow of the OPE: a complete basis of states, sorted into multiplets, each labeled by a primary's dimension and spin.

Physical Insight

The state-operator map is special to conformal field theory; it has no analogue in a massive theory. In a massive QFT the states on a spatial slice are multiparticle configurations with continuous momenta and energies bounded below by particle masses, while the local operators form an entirely different bookkeeping; there is no natural isomorphism between them. What makes the CFT case work is the absence of any scale: radial slices are all equivalent up to a dilatation, the ball can be shrunk to a point, and "operator inserted at a point" becomes literally the same data as "state on the surrounding sphere." The dilatation generator playing the double role of *Hamiltonian* (in the radial picture) and *dimension counter* (on operators) is the hinge on which the whole equivalence turns.

47.6.5 One spectrum: the cylinder partition function and the gap

The isomorphism of Theorem 47.42 has an immediate and far-reaching consequence: the list of scaling dimensions of local operators and the list of energies of the radial Hamiltonian are the same list. We make this quantitative on the cylinder, where the radial Hamiltonian is literally an energy.

Radial quantization on $\mathbb{R}^d$ is, by the Weyl rescaling that strips the overall r^2 from the flat metric, a theory on the cylinder $\mathbb{R}\times S^{d-1}$ (Section 47.5): writing $x^\mu = r\,n^\mu$ with n a unit vector and $\tau = \ln r$,

$$\mathrm{d}s^2 = \mathrm{d}r^2 + r^2\,\mathrm{d}\Omega^2 = r^2\big(\mathrm{d}\tau^2 + \mathrm{d}\Omega^2\big), \tag{47.193}$$

which is the cylinder metric $\mathrm{d}\tau^2 + \mathrm{d}\Omega^2_{S^{d-1}}$ up to the Weyl factor r^2. Under this map the dilatation generator D becomes the generator of translations in cylinder time τ — the Hamiltonian H_{cyl} of the theory quantized on the spatial sphere S^{d-1} of unit radius. Up to a c-number Casimir energy E_0, induced by the Weyl anomaly of the rescaling Eq. (47.193) (a constant shift, computable from the central charge, that we do not need in detail here),

$$H_{\mathrm{cyl}} = D + E_0. \tag{47.194}$$

The energy of a state on the sphere therefore equals the scaling dimension of the corresponding operator, $E = \Delta + E_0$. The state-operator map turns this into the headline statement: *the energy spectrum of the CFT on S^{d-1} is the list of operator dimensions.*

Corollary 47.44 (Cylinder partition function as a sum over dimensions)**.** *The thermal partition function of the CFT on the spatial sphere S^{d-1}, at inverse temperature β (geometrically, the theory on $S^1_\beta \times S^{d-1}$), is a sum over all local operators of the theory:*

$$Z(\beta) = \mathrm{Tr}_{\mathcal{H}_{S^{d-1}}} e^{-\beta H_{\mathrm{cyl}}} = e^{-\beta E_0} \sum_{\text{all } \mathcal{O}} e^{-\beta \Delta_{\mathcal{O}}} = e^{-\beta E_0} \sum_{\text{primaries } p} \chi_{\Delta_p, \ell_p}(\beta), \tag{47.195}$$

where the trace runs over the complete basis of created states, the second sum runs over every primary and the descendants of its multiplet, and $\chi_{\Delta_p,\ell_p}(\beta) = \sum_{n\geq 0}(\text{level-}n\text{ degeneracy})\, e^{-\beta(\Delta_p+n)}$ is the conformal character collecting the primary p together with its descendant tower.

Proof. The trace over $\mathcal{H}_{S^{d-1}}$ is, by Theorem 47.42, a sum over the complete basis of created states $|\mathcal{O}\rangle$; each contributes $e^{-\beta H_{\mathrm{cyl}}} = e^{-\beta(\Delta_{\mathcal{O}}+E_0)}$ by Eq. (47.194) and Eq. (47.179). Pulling out $e^{-\beta E_0}$ gives the first equality. Grouping the operators by multiplet — each primary p of dimension Δ_p together with its descendants $\partial^n \mathcal{O}_p$ at dimension $\Delta_p + n$, per Theorem 47.43 — resums each tower into the character χ_{Δ_p,ℓ_p}, giving the second equality. □

The lowest dimension above the identity controls the small-β-independent structure of Eq. (47.195) and is the central spectral datum of radial quantization. The vacuum (the identity operator) sits at $\Delta = 0$ and supplies the leading $e^{-\beta E_0}$; the first nontrivial term comes from the operator of lowest dimension $\Delta_{\mathrm{gap}} > 0$ above it:

$$\Delta_{\mathrm{gap}} = \min\{\Delta_{\mathcal{O}} : \mathcal{O} \neq \mathbf{1}\} \tag{47.196}$$

is precisely the energy gap of the radial Hamiltonian above its ground state. A positive gap is the unitarity-plus-locality input from Section 47.5; the state-operator map identifies it with the lowest operator dimension, the most basic invariant of the CFT data. Everything the bootstrap will constrain — where the lowest operators sit, how their dimensions are bounded — is a statement about this spectrum, which is now, by the theorem of this section, simultaneously a statement about states on the sphere.

Worked Example 47.45 (The free scalar: its state, its tower, and the gap)**.** We make the entire construction explicit on the theory ϕ^4 theory has carried to this point: the massless free scalar ϕ in d dimensions, the simplest CFT, whose conformal status was established in Section 47.1.5. Its primary field ϕ has scaling dimension $\Delta_\phi = \frac{d-2}{2}$ (the engineering dimension of a canonically normalized scalar, which here is exact because the theory is free).

The state and its dimension. The map sends ϕ to the state $|\phi\rangle = \phi(0)\,|0\rangle$, a scalar (spin-0) eigenstate of the radial Hamiltonian of dimension $\Delta_\phi = \frac{d-2}{2}$ by Eq. (47.179). In $d = 4$ this is $\Delta_\phi = 1$.

ϕ is primary: $K_\mu |\phi\rangle = 0$. By Theorem 47.43 this is equivalent to $|\phi\rangle$ being lowest-weight. We can see it directly from the spectrum without invoking the differential realization. The state $K_\mu |\phi\rangle$, if nonzero, would have dimension $\Delta_\phi - 1 = \frac{d-4}{2}$ (since K_μ lowers the dimension by one, Eq. (47.174)) and would carry a single vector index, i.e. it would be a spin-1 state. But there is no operator of dimension $\frac{d-4}{2}$ in the free theory below ϕ except possibly the identity, at dimension 0; and the identity creates the spin-0 vacuum, which cannot equal a spin-1 state. By rotational covariance $K_\mu |\phi\rangle$ must therefore vanish: ϕ is a primary, and $|\phi\rangle$ is a lowest-weight state.

The descendant tower. The raising operators build the multiplet. The first descendant is

$$P_\mu |\phi\rangle = |\partial_\mu \phi\rangle \,, \tag{47.197}$$

a spin-1 state of dimension $\Delta_\phi + 1 = \frac{d}{2}$, corresponding to the operator $\partial_\mu \phi$. At the next level the symmetric traceless part $\partial_{(\mu}\partial_{\nu)}\phi$ is a spin-2 descendant, and so on. But the trace part is special, and exhibits the one subtlety of a free field.

The null descendant and the unitarity bound. Consider the scalar level-2 descendant $P^2 |\phi\rangle = P^\mu P_\mu |\phi\rangle$, corresponding to $\partial^2\phi = \Box\phi$. The free equation of motion is $\Box\phi = 0$, so this operator vanishes identically and the corresponding state must be *null* (zero norm). We verify this from the algebra alone, which simultaneously reproduces the scalar unitarity bound. For a scalar primary $\mathcal{O}$ of dimension Δ (so $M_{\mu\nu}|\mathcal{O}\rangle = 0$ and $K_\mu |\mathcal{O}\rangle = 0$), compute the norm of $P^2 |\mathcal{O}\rangle$ using $P_\mu^\dagger = K_\mu$ from Eq. (47.175):

$$\left\| P^2 |\mathcal{O}\rangle \right\|^2 = \langle \mathcal{O}| K^\sigma K_\sigma P^\mu P_\mu |\mathcal{O}\rangle \,. \tag{47.198}$$

We first move one K through P^2. Using $[K_\sigma, P_\nu] = 2(\delta_{\sigma\nu} D - M_{\sigma\nu})$ from Eq. (47.174) and the Leibniz rule,

$$\begin{aligned} [K_\sigma, P^\mu P_\mu] &= [K_\sigma, P^\mu]\, P_\mu + P^\mu\, [K_\sigma, P_\mu] \\ &= 2(D P_\sigma - M_\sigma{}^\mu P_\mu) + 2(P_\sigma D - P^\mu M_{\sigma\mu}). \end{aligned} \tag{47.199}$$

The rotation terms combine using $[M_{\sigma\mu}, P^\mu] = (d-1)P_\sigma$ (from $[M_{\mu\nu}, P_\rho] = \delta_{\nu\rho}P_\mu - \delta_{\mu\rho}P_\nu$, contracting): writing $M_\sigma{}^\mu P_\mu = P^\mu M_{\sigma\mu} + (d-1)P_\sigma$, the two rotation pieces add to $2P^\mu M_{\sigma\mu} + (d-1)P_\sigma$ with an overall minus. The dilatation terms give $DP_\sigma + P_\sigma D = 2P_\sigma D + P_\sigma$ via $[D, P_\sigma] = P_\sigma$. Collecting,

$$\left[K_\sigma, P^2\right] = 4P_\sigma D - 4P^\mu M_{\sigma\mu} + (4 - 2d)P_\sigma. \tag{47.200}$$

Acting on the scalar primary, $M_{\sigma\mu}|\mathcal{O}\rangle = 0$ and $D|\mathcal{O}\rangle = \Delta|\mathcal{O}\rangle$, and $K_\sigma|\mathcal{O}\rangle = 0$, so

$$K_\sigma P^2 |\mathcal{O}\rangle = \left[K_\sigma, P^2\right] |\mathcal{O}\rangle = (4\Delta + 4 - 2d) P_\sigma |\mathcal{O}\rangle = 2(2\Delta + 2 - d) P_\sigma |\mathcal{O}\rangle \,. \tag{47.201}$$

Contracting with the second K and using $K^\sigma P_\sigma |\mathcal{O}\rangle = [K^\sigma, P_\sigma]\,|\mathcal{O}\rangle = 2dD\,|\mathcal{O}\rangle = 2d\Delta\,|\mathcal{O}\rangle$ (here $[K^\sigma, P_\sigma] = 2(d\,D - M^\sigma{}_\sigma) = 2dD$ since $M^\sigma{}_\sigma = 0$),

$$\left\| P^2\,|\mathcal{O}\rangle \right\|^2 = 2(2\Delta + 2 - d)\cdot 2d\Delta\;\|\mathcal{O}\|^2 = 4d\,\Delta(2\Delta + 2 - d)\;\|\mathcal{O}\|^2\,. \quad (47.202)$$

Positivity of the norm in a unitary theory requires $2\Delta + 2 - d \geq 0$, i.e. the scalar *unitarity bound*

$$\Delta \geq \frac{d-2}{2}, \quad (47.203)$$

with equality exactly when $\left\| P^2\,|\mathcal{O}\rangle \right\|^2 = 0$, i.e. when the level-2 scalar descendant is null. The free scalar saturates the bound, $\Delta_\phi = \frac{d-2}{2}$, so $P^2\,|\phi\rangle$ is null — the algebraic statement of the equation of motion $\Box\phi = 0$. The free-field multiplet is therefore a *short* multiplet: the primary ϕ with all descendants $\partial_{\mu_1}\cdots\partial_{\mu_n}\phi$ except those proportional to $\Box\phi$, which are removed. This is the conformal-representation-theoretic content of "ϕ obeys a free equation of motion," read straight off the state-operator map.

The gap. In the free scalar the operators are the normal-ordered products of ϕ and its derivatives. Above the identity ($\Delta = 0$), the lowest-dimension operator is ϕ itself, at $\Delta_\phi = \frac{d-2}{2}$ (the next, the bilinear $:\!\phi^2\!:$, sits at $d-2$, and the stress tensor at d). Hence the radial-quantization gap Eq. (47.196) of the free scalar is

$$\Delta_{\text{gap}} = \frac{d-2}{2}, \quad (47.204)$$

which in $d = 4$ equals 1: the energy of the lightest state on S^3 above the vacuum, in units where the sphere has unit radius, is exactly the dimension of the free field. This is the concrete seed from which ϕ^4 theory's account of the Wilson–Fisher fixed point (Chapter 52) will grow: turning on the interaction in $d = 4 - \epsilon$ shifts Δ_ϕ to $\frac{d-2}{2} + \gamma_\phi$ with $\gamma_\phi = O(\epsilon^2)$, deforming this gap by the anomalous dimension while the entire state-operator architecture built here carries over unchanged.

We have proved the structural theorem on which the rest of the part stands: local operators and radial-quantization states are the same data, primaries are the lowest-weight states annihilated by K_μ, descendants are their P-orbit, and the spectrum of operator dimensions is the spectrum of the dilatation Hamiltonian. Because the states $\{|\mathcal{O}\rangle\}$ form a complete, conformally graded basis, any product of two operators inserted inside a sphere can be resolved against this basis — a finite-radius-of-convergence expansion in primaries and their descendants. That resolution is the conformal operator product expansion, and its convergence, which we have just supplied the rigorous footing for, is the subject of the next section.

47.7 The Operator Product Expansion and Its Convergence

The state–operator isomorphism of the previous section did more than match local operators to states of the radial-quantization Hilbert space; it gave us a *complete* basis. Every state on a sphere is a superposition of the lowest-weight states created by primaries and their conformal-algebra orbit of descendants (Theorem 47.42), and these multiplets together resolve the identity (Eq. (47.207)). We now cash in that completeness. The product of two local operators inserted at nearby points is, when acted on the vacuum, just a state on any sphere that encloses both insertions. Expanding that state in the complete basis turns the product of two operators at separate points into a single sum of local operators at one point — the *operator product expansion*. This is the structural fact that makes a conformal field theory finitely specified: once we know the spectrum of primaries and the constants that govern how two primaries fuse, every correlation function is determined. The whole of this section is the unpacking of that claim. We define the conformal OPE, show that its coefficients are exactly the three-point constants already computed in Section 47.4, argue — honestly, with the rigorous part separated from the physically expected part — that the expansion genuinely converges inside a finite radius, and finally use it twice over to reduce the four-point function to a sum of universal kinematic functions, the conformal blocks, whose defining differential equation we identify.

Throughout this section we work in Euclidean signature, as in the radial-quantization construction of Section 47.5: $\mathbb{R}^d$ with $x \cdot y = \delta_{\mu\nu} x^\mu y^\nu$ and $|x|^2 = x \cdot x \geq 0$, so that $|x_{ij}|$ with $x_{ij} \equiv x_i - x_j$ is an ordinary Euclidean distance and there are no light cones to navigate. Scaling dimensions Δ are the eigenvalues of the dilatation generator D in the sense fixed in Theorem 23.22 and realized on operators in Section 47.2.

47.7.1 The operator product expansion from completeness

Fix two scalar primaries $\mathcal{O}_1, \mathcal{O}_2$ of dimensions Δ_1, Δ_2. Place the second at the origin and the first at a point x with $|x|$ small, and act on the vacuum:

$$|\Psi(x)\rangle \;\equiv\; \mathcal{O}_1(x)\,\mathcal{O}_2(0)\,|0\rangle\,. \tag{47.205}$$

By construction this is a definite vector in the radial-quantization Hilbert space: it is the state read off on any sphere $|y| = \rho$ with $\rho > |x|$, since both insertions then lie strictly inside that sphere. The state–operator map (Theorem 47.42) furnishes a complete orthogonal basis of that Hilbert space, organized into conformal multiplets: one lowest-weight state $|\mathcal{O}\rangle$ for each primary $\mathcal{O}$, together with its descendants, the states

$$P_{\mu_1} \cdots P_{\mu_k}\,|\mathcal{O}\rangle\,, \qquad k = 0, 1, 2, \ldots, \tag{47.206}$$

of dimension $\Delta_{\mathcal{O}} + k$ obtained by acting with the raising operators P_μ (recall $[D, P_\mu] = P_\mu$, Eq. (47.53)). Because this basis is orthonormal and complete, it resolves the identity on the radial-quantization Hilbert space,

$$\mathbf{1} \;=\; \sum_{n} |n\rangle \langle n| \,, \tag{47.207}$$

the sum running over the orthonormal basis $\{|n\rangle\}$ formed by all primaries and their descendants. Inserting the resolution of the identity Eq. (47.207) into Eq. (47.205) writes $|\Psi(x)\rangle$ as a sum over all such basis states, each weighted by the overlap $\langle n|\, \mathcal{O}_1(x)\mathcal{O}_2(0)\, |0\rangle$.

Two features of those overlaps are decisive. First, the bra $\langle n|$ is, under the state–operator map, the conjugate of a descendant of some primary $\mathcal{O}$ placed at spatial infinity; the overlap $\langle n|\, \mathcal{O}_1(x)\mathcal{O}_2(0)\, |0\rangle$ is therefore a three-point function of $\mathcal{O}_1$, $\mathcal{O}_2$, and (a descendant of) $\mathcal{O}$. Conformal symmetry — as we are about to verify — fixes every such three-point function up to a *single* constant per primary $\mathcal{O}$. Second, the x-dependence of each overlap is fixed by dilatation covariance alone. The composite $\mathcal{O}_1(x)\mathcal{O}_2(0)$ carries total dimension $\Delta_1 + \Delta_2$ at separation $|x|$; a basis state of dimension Δ_n is reached only if the accompanying coefficient supplies the missing dimension, i.e. scales as $|x|^{\Delta_n - \Delta_1 - \Delta_2}$. Collecting the k-th descendant level of a primary $\mathcal{O}$, where $\Delta_n = \Delta_{\mathcal{O}} + k$, the coefficient scales as $|x|^{\Delta_{\mathcal{O}} - \Delta_1 - \Delta_2 + k}$: the leading power is set by the primary and each descendant level adds one integer power of $|x|$.

Reinterpreting each basis state $|n\rangle = \big(\text{descendant operator}\big)(0)\, |0\rangle$ back as a local operator at the origin, the expansion of the state Eq. (47.205) becomes an operator equation, valid inside any correlation function in which no other insertion intrudes between the two operators and the sphere:

$$\mathcal{O}_1(x)\, \mathcal{O}_2(0) \;=\; \sum_{\mathcal{O}} C_{12\mathcal{O}}\, |x|^{\Delta_{\mathcal{O}} - \Delta_1 - \Delta_2}\, \mathcal{C}_{\Delta_{\mathcal{O}}, \ell_{\mathcal{O}}}(x, \partial)\, \mathcal{O}(0), \tag{47.208}$$

where the sum runs over *primaries* $\mathcal{O}$ only, $C_{12\mathcal{O}}$ is a single number for each primary, and $\mathcal{C}_{\Delta_{\mathcal{O}}, \ell_{\mathcal{O}}}(x, \partial) = 1 + (\text{const})\, x^\mu \partial_\mu + \dots$ is a power series in x and ∂ that packages the descendant contributions. The differential operator $\mathcal{C}$ generates, term by term, the operators $\partial_{\mu_1} \cdots \partial_{\mu_k} \mathcal{O}(0)$ that are the operator-language images of the descendant states Eq. (47.206). The descendants do not bring new free constants: they are entirely fixed by conformal symmetry in terms of the single primary coefficient $C_{12\mathcal{O}}$, as the next subsection proves explicitly at first order and explains in general.

Definition 47.46 (Conformal operator product expansion)**.** Let $\mathcal{O}_1, \mathcal{O}_2$ be primaries of a conformal field theory. The *operator product expansion* is the convergent operator identity Eq. (47.208), the sum running over the primary operators $\mathcal{O}$ of the theory, in which:

- the leading power $|x|^{\Delta_{\mathcal{O}} - \Delta_1 - \Delta_2}$ is dictated by the dimensions and is the same in every correlator;

- the number $C_{12\mathcal{O}}$ is the *OPE coefficient* of the fusion $\mathcal{O}_1 \times \mathcal{O}_2 \to \mathcal{O}$, one constant per primary;
- the differential operator $\mathcal{C}_{\Delta_\mathcal{O},\ell_\mathcal{O}}(x,\partial)$, normalized to begin with the identity, is a power series in x fixed entirely by conformal symmetry (the dimension $\Delta_\mathcal{O}$ and spin $\ell_\mathcal{O}$ of $\mathcal{O}$), encoding the contributions of all descendants of $\mathcal{O}$.

The identity holds as an operator statement inside any correlation function, provided every other operator insertion lies farther from the origin than x does (the precise convergence statement is Theorem 47.48).

The identity operator $\mathbf{1}$ is always among the primaries on the right-hand side when $\mathcal{O}_2 = \mathcal{O}_1$ (or more generally when $\mathcal{O}_1, \mathcal{O}_2$ share a fusion channel into it): with $\Delta_\mathbf{1} = 0$ it contributes the leading singularity $C_{11\mathbf{1}}\,|x|^{-2\Delta_1}\,\mathbf{1}$. Unit-normalizing the two-point function $\langle \mathcal{O}_1(x)\mathcal{O}_1(0)\rangle = |x|^{-2\Delta_1}$ fixes $C_{11\mathbf{1}} = 1$, so the identity channel of the OPE simply reproduces the two-point function — a consistency check we will use repeatedly.

Physical Insight

The OPE replaces "two operators at two points" by "one tower of operators at one point." Physically it is the statement that, probed from far enough away, a pair of nearby excitations is indistinguishable from a single local disturbance — and conformal symmetry tells us *exactly* which local disturbances, with which relative strengths. The infinitely many descendants might look like infinitely much data, but they are not: each multiplet contributes precisely one new number, $C_{12\mathcal{O}}$. This is why the list of primary dimensions, spins, and OPE coefficients — the "CFT data" — is a *complete* specification of the theory. Everything else is symmetry.

47.7.2 The coefficients are the three-point data

The claim that $C_{12\mathcal{O}}$ is a single number per primary, equal to the three-point constant of Section 47.4, is proved by inserting the OPE into a three-point function and matching. Recall the form fixed there by conformal symmetry: for scalar primaries,

$$\langle \mathcal{O}_1(x_1)\,\mathcal{O}_2(x_2)\,\mathcal{O}_3(x_3)\rangle = \frac{C_{123}}{|x_{12}|^{\Delta_1+\Delta_2-\Delta_3}\,|x_{23}|^{\Delta_2+\Delta_3-\Delta_1}\,|x_{13}|^{\Delta_1+\Delta_3-\Delta_2}}, \tag{47.209}$$

with C_{123} a single theory-dependent constant (Eq. (47.137)), and the orthonormalized two-point function

$$\langle \mathcal{O}_i(x)\,\mathcal{O}_j(0)\rangle = \frac{\delta_{ij}}{|x|^{2\Delta_i}}, \tag{47.210}$$

which vanishes between primaries of different dimension (Eq. (47.120)).

Take the correlator $\langle \mathcal{O}_1(x)\mathcal{O}_2(0)\,\mathcal{O}_3(y)\rangle$ with $|x|$ small and $|y|$ large, and apply the OPE Eq. (47.208) to the pair $\mathcal{O}_1(x)\mathcal{O}_2(0)$:

$$\langle \mathcal{O}_1(x)\,\mathcal{O}_2(0)\,\mathcal{O}_3(y)\rangle = \sum_{\mathcal{O}} C_{12\mathcal{O}}\,|x|^{\Delta_{\mathcal{O}}-\Delta_1-\Delta_2}\,\langle \mathcal{C}_{\Delta_{\mathcal{O}},\ell_{\mathcal{O}}}(x,\partial)\,\mathcal{O}(0)\;\mathcal{O}_3(y)\rangle. \tag{47.211}$$

At leading order in $|x|$ the differential operator is the identity, and only the term $\mathcal{O}=\mathcal{O}_3$ survives the two-point orthogonality Eq. (47.210): $\langle \mathcal{O}(0)\mathcal{O}_3(y)\rangle = \delta_{\mathcal{O},\mathcal{O}_3}\,|y|^{-2\Delta_3}$. Hence the leading behavior is

$$\langle \mathcal{O}_1(x)\,\mathcal{O}_2(0)\,\mathcal{O}_3(y)\rangle \xrightarrow{|x|\to 0} C_{12\mathcal{O}_3}\,\frac{|x|^{\Delta_3-\Delta_1-\Delta_2}}{|y|^{2\Delta_3}}. \tag{47.212}$$

We compare this against the small-$|x|$ limit of the exact three-point function Eq. (47.209) with $x_1=x$, $x_2=0$, $x_3=y$. As $|x|\to 0$, $|x_{12}|=|x|$, $|x_{23}|=|y|$, and $|x_{13}|=|x-y|\to|y|$, so

$$\langle \mathcal{O}_1(x)\,\mathcal{O}_2(0)\,\mathcal{O}_3(y)\rangle \xrightarrow{|x|\to 0} \frac{C_{123}}{|x|^{\Delta_1+\Delta_2-\Delta_3}\,|y|^{(\Delta_2+\Delta_3-\Delta_1)+(\Delta_1+\Delta_3-\Delta_2)}} = C_{123}\,\frac{|x|^{\Delta_3-\Delta_1-\Delta_2}}{|y|^{2\Delta_3}}. \tag{47.213}$$

The two expressions are identical provided

$$\boxed{C_{12\mathcal{O}_3} = C_{123}\,.} \tag{47.214}$$

The OPE coefficient is the three-point constant. This is the central economy of the conformal program: the same finite list of numbers $\{C_{ijk}\}$ that parametrizes all three-point functions also governs how operators fuse, and therefore — through repeated use of the OPE — determines every higher correlator.

It remains to see that the descendant tail $\mathcal{C}_{\Delta_{\mathcal{O}},\ell_{\mathcal{O}}}$ carries no further freedom. The subleading terms in Eq. (47.211) must reproduce the subleading terms in the expansion of the exact Eq. (47.209) about $|x|=0$, and the only structure available on the exact side is the expansion of $|x-y|^{-(\Delta_1+\Delta_3-\Delta_2)}$ in powers of x. That expansion is completely determined by the dimensions; matching it order by order fixes every coefficient of $\mathcal{C}$ in terms of $C_{12\mathcal{O}}$ and the dimensions, with no new constants. We carry out the first order in the following worked example, both to exhibit the mechanism and to record the coefficient that the conformal-block literature uses constantly.

Worked Example 47.47 (The first descendant coefficient)**.** We determine the leading correction to the identity in $\mathcal{C}$ for a scalar primary $\mathcal{O}$ of dimension Δ exchanged between scalars $\mathcal{O}_1,\mathcal{O}_2$. Write the OPE through first order in x,

$$\mathcal{O}_1(x)\,\mathcal{O}_2(0) = C_{12\mathcal{O}}\,|x|^{\Delta-\Delta_1-\Delta_2}\Big[\,\mathcal{O}(0)+\beta\,x^{\mu}\partial_{\mu}\mathcal{O}(0)+O(x^2)\,\Big]+(\text{other primaries}), \tag{47.215}$$

with β the unknown to be fixed. We need the two-point functions of $\mathcal{O}$ with its own first descendant. From Eq. (47.210),

$$\langle \partial_\mu \mathcal{O}(z)\, \mathcal{O}(y)\rangle\Big|_{z=0} = \partial_{z^\mu} |z-y|^{-2\Delta}\Big|_{z=0} = -2\Delta\,(z-y)_\mu\, |z-y|^{-2\Delta-2}\Big|_{z=0} = 2\Delta\,\frac{y_\mu}{|y|^{2\Delta+2}}. \tag{47.216}$$

Insert Eq. (47.215) into $\langle \mathcal{O}_1(x)\mathcal{O}_2(0)\,\mathcal{O}(y)\rangle$ and use Eqs. (47.210) and (47.216):

$$\langle \mathcal{O}_1(x)\,\mathcal{O}_2(0)\,\mathcal{O}(y)\rangle = C_{12\mathcal{O}}\,|x|^{\Delta-\Delta_1-\Delta_2}\left[\frac{1}{|y|^{2\Delta}} + 2\Delta\,\beta\,\frac{x\cdot y}{|y|^{2\Delta+2}} + O(x^2)\right]. \tag{47.217}$$

On the exact side, factor the prefactor $|x|^{\Delta-\Delta_1-\Delta_2}$ out of Eq. (47.209) (using $-(\Delta_1+\Delta_2-\Delta) = \Delta-\Delta_1-\Delta_2$) and expand the remaining $|x-y|$ dependence. With $a \equiv \Delta_1+\Delta-\Delta_2$ and $|x-y|^2 = |y|^2 - 2\,x\cdot y + |x|^2$,

$$|x-y|^{-a} = |y|^{-a}\Big(1 - \tfrac{2\,x\cdot y}{|y|^2} + \tfrac{|x|^2}{|y|^2}\Big)^{-a/2} = |y|^{-a}\Big(1 + a\,\frac{x\cdot y}{|y|^2} + O(x^2)\Big). \tag{47.218}$$

The two powers of $|y|$ on the exact side combine as $|y|^{-(\Delta_2+\Delta-\Delta_1)}\,|y|^{-a} = |y|^{-2\Delta}$, so

$$\langle \mathcal{O}_1(x)\,\mathcal{O}_2(0)\,\mathcal{O}(y)\rangle = C_{123}\,|x|^{\Delta-\Delta_1-\Delta_2}\left[\frac{1}{|y|^{2\Delta}} + a\,\frac{x\cdot y}{|y|^{2\Delta+2}} + O(x^2)\right]. \tag{47.219}$$

The zeroth-order terms reconfirm $C_{12\mathcal{O}} = C_{123}$. Matching the first-order terms gives $2\Delta\,\beta = a = \Delta_1+\Delta-\Delta_2$, i.e.

$$\boxed{\beta = \frac{\Delta+\Delta_1-\Delta_2}{2\Delta}\,,} \tag{47.220}$$

which for equal external dimensions $\Delta_1 = \Delta_2$ collapses to the symmetric value $\beta = \frac{1}{2}$. The first descendant coefficient is fixed by the dimensions alone, exactly as claimed; no information beyond $C_{12\mathcal{O}}$ entered. The same matching at order x^2, x^3, … determines $\mathcal{C}$ to all orders, and the resummed series is precisely what the conformal block of the next subsections repackages.

47.7.3 Convergence of the operator product expansion

In ordinary perturbative quantum field theory the OPE is an *asymptotic* short-distance statement, valid term by term as $|x| \to 0$ with no claim of convergence at finite separation. In a conformal field theory the situation is far stronger, and the strength comes directly from radial quantization: the OPE is the expansion of an honest, normalizable state in a complete orthonormal basis, and such expansions converge.

Theorem 47.48 (Convergence of the conformal OPE)**.** *In a unitary conformal field theory with a discrete spectrum of primaries, the operator product expansion*

Eq. (47.208) of $\mathcal{O}_1(x_1)\mathcal{O}_2(x_2)$, inserted in a correlation function with any number of further operators $\mathcal{O}_3(x_3), \dots, \mathcal{O}_n(x_n)$, converges — in the sense of convergence of the resulting numerical series — whenever there exists a sphere centered on the pair $\{x_1, x_2\}$ that separates them from all the other insertions. Concretely, if the pair is enclosed in a ball of radius r_{12} and the nearest other operator sits at distance $r_{\text{near}} > r_{12}$ from the center, the expansion converges, and it converges exponentially fast in the ratio r_{12}/r_{near}. The radius of convergence is set by the distance to the nearest other insertion.

Argument. Center radial quantization on the midpoint (or any convenient point) of the pair $\{x_1, x_2\}$ and place all other operators at radii larger than r_{near}. The vector

$$|\Psi\rangle = \mathcal{O}_1(x_1)\,\mathcal{O}_2(x_2)\,|0\rangle \tag{47.221}$$

is the state read off on any sphere of radius ρ with $r_{12} < \rho < r_{\text{near}}$, since on such a sphere the two operators lie inside and none of the others has yet been crossed. Reflection positivity — the Euclidean form of unitarity established by the Osterwalder–Schrader reconstruction (Chapter 10) — guarantees that the Hilbert space has a positive-definite inner product and that $|\Psi\rangle$ has finite norm, because that norm is the convergent two-point-of-pairs correlator

$$\big\||\Psi\rangle\big\|^2 = \big\langle \mathcal{O}_2(x_2^\theta)\,\mathcal{O}_1(x_1^\theta)\;\mathcal{O}_1(x_1)\,\mathcal{O}_2(x_2)\big\rangle, \tag{47.222}$$

with x^θ the radial-reflection image of x, a four-point function evaluated at strictly separated points and therefore finite. Now expand $|\Psi\rangle$ in the complete orthonormal basis of Eq. (47.207), which is exactly the sum over primaries and descendants. Because the basis is complete and $|\Psi\rangle$ has finite norm, the partial sums converge to $|\Psi\rangle$ in the Hilbert-space norm; equivalently the squared coefficients sum to $\big\||\Psi\rangle\big\|^2 < \infty$. Pairing this convergent expansion of $|\Psi\rangle$ against the state produced by the remaining operators $\mathcal{O}_3(x_3)\cdots\mathcal{O}_n(x_n)\,|0\rangle$ on the same sphere yields the OPE expansion of the full correlator as a convergent numerical series. This is precisely the OPE Eq. (47.208) term by term, since each basis state is the image of a descendant operator.

The rate is controlled by the radial coordinate. A state of dimension Δ_n contributes to $|\Psi\rangle$ on the sphere of radius ρ a factor scaling as $(r_{12}/\rho)^{\Delta_n}$ relative to the leading term, by dilatation covariance (the same power counting that produced the $|x|^{\Delta_n-\Delta_1-\Delta_2}$ of the OPE). Summing over the spectrum and taking ρ up to its maximal value r_{near}, the high-dimension tail is suppressed by $(r_{12}/r_{\text{near}})^{\Delta_n}$; since unitarity bounds the density of states (the spectrum is discrete and grows in a controlled way), the series converges geometrically in r_{12}/r_{near}. The expansion fails to converge precisely when no separating sphere exists, i.e. when a third operator lies as close to the pair as the pair members are to each other — the radius of convergence is the distance to the nearest other insertion. □

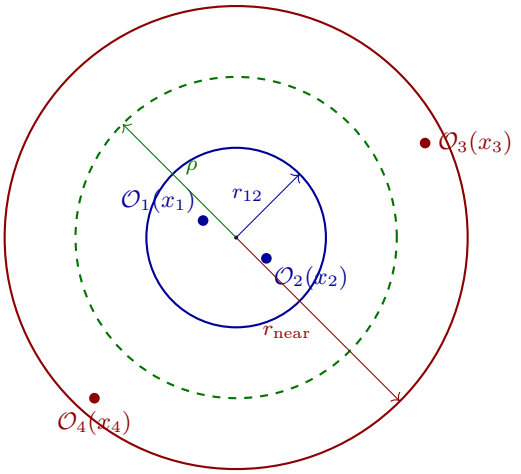

Figure 47.7: Radial quantization and the convergence of the OPE (Theorem 47.48). The pair $\mathcal{O}_1, \mathcal{O}_2$ to be fused sits inside the ball of radius r_{12} (blue); the nearest other insertion lies at radius r_{near} (red). On any quantization sphere of intermediate radius ρ (green dashed, $r_{12} < \rho < r_{\text{near}}$) the state $\mathcal{O}_1(x_1)\mathcal{O}_2(x_2)\,|0\rangle$ is a definite finite-norm vector, and its expansion in the complete basis of primaries and descendants is the OPE. The series converges geometrically in r_{12}/r_{near}; it breaks down only when a third operator approaches the pair and no separating sphere survives.

Caution

The honest scope of Theorem 47.48, dated to the present (mid-2020s). The convergence statement is a *theorem*, not merely a physical expectation, but it is a theorem *within* the standard axioms of a conformal field theory: a Hilbert space with a positive inner product (reflection positivity / unitarity), a discrete spectrum of operators bounded below in dimension, and the state–operator map of Theorem 47.42. Granting those axioms, the expansion converges with a finite radius and a quantitative (exponential) rate; the careful estimates were given by Pappadopulo, Rychkov, Espin, and Rattazzi [376], building on the older formal partial-wave analyses [190]. What is an *assumption* rather than a derived fact is that a given physical theory — say the lattice realization of a critical point — actually satisfies those axioms with a genuine state–operator isomorphism. For the theories of this book that is established or overwhelmingly evidenced: the free scalar exactly, the Wilson–Fisher fixed point order by order in ϵ, the 3D Ising CFT to extraordinary numerical precision. The convergence is therefore as rigorous as the axiomatic foundation it rests on, and that foundation is exactly the reflection positivity of Chapter 10 together with

the radial quantization of Section 47.5.

The contrast with the asymptotic Wilsonian OPE of the renormalization-group analysis is worth stating once plainly. There, the short-distance expansion was organized by the engineering dimensions of operators and truncated; here, the conformal OPE is a *convergent* expansion in a basis fixed by the exact scaling dimensions, valid out to a finite separation, not merely as $|x| \to 0$. This finite radius is what makes the OPE a computational tool rather than a formal device, and it is the property the bootstrap of Chapter 49 will exploit when it demands that two different OPE channels of the same four-point function agree.

47.7.4 The four-point function and conformal blocks

The first genuinely dynamical correlator — the one not fixed outright by symmetry — is the four-point function. Conformal symmetry fixes two- and three-point functions completely (Section 47.4); for four points the same kinematics leaves one undetermined function of the two conformally invariant cross-ratios. Recall (Eq. (47.138)) the cross-ratios built from four points,

$$u = \frac{x_{12}^2\, x_{34}^2}{x_{13}^2\, x_{24}^2}, \qquad v = \frac{x_{14}^2\, x_{23}^2}{x_{13}^2\, x_{24}^2}, \tag{47.223}$$

which are invariant under all conformal transformations (including the inversion of Theorem 47.4), and the standard stripping of the four-point function of four identical scalars $\mathcal{O}_1 = \cdots = \mathcal{O}_4 = \phi$ of dimension Δ_ϕ into a kinematic prefactor times a function of the cross-ratios (Eq. (47.145)),

$$\langle \phi(x_1)\, \phi(x_2)\, \phi(x_3)\, \phi(x_4) \rangle = \frac{g(u,v)}{x_{12}^{2\Delta_\phi}\, x_{34}^{2\Delta_\phi}}. \tag{47.224}$$

Symmetry has done all it can; the content of the theory is hidden in the single function $g(u,v)$. The OPE turns that function into a sum over the operator content.

Apply the OPE Eq. (47.208) to the pair (12) and, independently, to the pair (34):

$$\langle \phi(x_1)\phi(x_2)\, \phi(x_3)\phi(x_4) \rangle = \sum_{\mathcal{O},\mathcal{O}'} C_{\phi\phi\mathcal{O}}\, C_{\phi\phi\mathcal{O}'} \Big\langle [\mathcal{C}\,\mathcal{O}](x_2)\ [\mathcal{C}\,\mathcal{O}'](x_4) \Big\rangle. \tag{47.225}$$

The two-point function of a descendant of $\mathcal{O}$ with a descendant of $\mathcal{O}'$ vanishes unless $\mathcal{O}$ and $\mathcal{O}'$ are the same primary, by the orthogonality Eq. (47.210) extended to whole multiplets (descendants of distinct primaries are orthogonal). The double sum collapses to a single sum over exchanged primaries:

$$\langle \phi\phi\, \phi\phi \rangle = \sum_{\mathcal{O}} C_{\phi\phi\mathcal{O}}^2 \ (\text{contribution of the full multiplet of } \mathcal{O}). \tag{47.226}$$

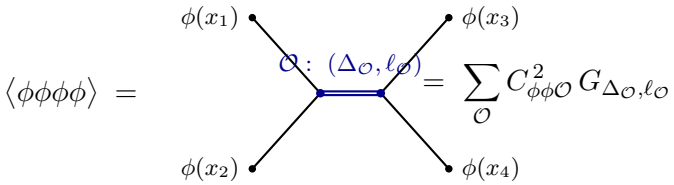

Figure 47.8: The conformal block decomposition Eq. (47.227). Fusing $\phi(x_1)\phi(x_2)$ and $\phi(x_3)\phi(x_4)$ by the OPE projects the four-point function onto exchanged primaries $\mathcal{O}$; each exchanged multiplet (double line, carrying dimension $\Delta_\mathcal{O}$ and spin $\ell_\mathcal{O}$) contributes a universal conformal block $G_{\Delta_\mathcal{O},\ell_\mathcal{O}}(u,v)$ weighted by the squared OPE coefficient $C^2_{\phi\phi\mathcal{O}}$. The block resums the primary and all of its descendants. The explicit closed forms of the blocks are computed in Chapter 49.

The multiplet contribution, once the kinematic prefactor of Eq. (47.224) is stripped off, depends only on the cross-ratios and on the quantum numbers $(\Delta_\mathcal{O}, \ell_\mathcal{O})$ of the exchanged primary — it is a purely kinematic, theory-independent function. This function is the conformal block.

Definition 47.49 (Conformal block)**.** The *conformal block* $G_{\Delta,\ell}(u,v)$ is the contribution to the stripped four-point function $g(u,v)$ of a single primary $\mathcal{O}$ of dimension Δ and spin ℓ together with *all* of its descendants, exchanged in the (12)(34) channel, normalized so that the OPE coefficients appear as in Eq. (47.227). It resums the entire descendant tail $\mathcal{C}_{\Delta,\ell}$ of Eq. (47.208) on both sides of Eq. (47.225), and is fixed entirely by conformal symmetry — independent of the particular theory.

With this definition the four-point function decomposes as

$$\boxed{g(u,v) = \sum_\mathcal{O} C^2_{\phi\phi\mathcal{O}}\; G_{\Delta_\mathcal{O},\ell_\mathcal{O}}(u,v)\;,} \tag{47.227}$$

and for non-identical externals the same construction gives $g(u,v) = \sum_\mathcal{O} C_{12\mathcal{O}}\, C_{34\mathcal{O}}\, G_{\Delta_\mathcal{O},\ell_\mathcal{O}}(u$ with the block additionally depending on the dimension differences Δ_{12}, Δ_{34} through its descendant structure. This is the *conformal block decomposition*. It is the cleanest statement of how the abstract CFT data — the dimensions and spins of primaries and the OPE coefficients — assemble into a measurable correlator: the squared OPE coefficients are the weights, and the blocks are universal kinematic functions common to all conformal field theories in d dimensions. Figure 47.8 renders the decomposition diagrammatically as a sum over exchanged primaries.

The explicit functional form of $G_{\Delta,\ell}(u,v)$ — in even dimensions a finite combination of hypergeometric functions, in general dimension a solution defined by a recursion or by the Casimir equation below — is a computation we defer

to Section 49.2, where it is needed for the bootstrap. What we owe here is the property that makes the block well defined and computable in the first place: it is the eigenfunction of a single differential operator, the conformal Casimir.

47.7.5 The conformal Casimir and the block equation

The conformal group $\mathfrak{so}(d+1,1)$ has, like any Lie group, a quadratic Casimir invariant: the unique (up to normalization) quadratic combination of generators that commutes with all of them. Built from the field-theory generators $D, P_\mu, K_\mu, M_{\mu\nu}$ of Eq. (47.53), it is

$$C_2 \;=\; D^2 \;-\; \tfrac{1}{2}\{P_\mu, K^\mu\} \;-\; \tfrac{1}{2}\, M_{\mu\nu}M^{\mu\nu}, \tag{47.228}$$

the image of $-\frac{1}{2}L_{AB}L^{AB}$ under the embedding of the conformal algebra into the rotations L_{AB} of $\mathfrak{so}(d+1,1)$, with the overall sign fixed so that the eigenvalue comes out as below. Because C_2 commutes with every generator, it is constant on each irreducible conformal multiplet; it therefore takes a single value on the entire orbit of a primary, and that value labels the multiplet.

Proposition 47.50 (Casimir eigenvalue on a primary)**.** *On a primary state $|\Delta,\ell\rangle$ of dimension Δ and spin ℓ (a symmetric traceless rank-ℓ representation of the rotation subgroup $\mathfrak{so}(d)$), the quadratic Casimir Eq. (47.228) acts as the scalar*

$$C_2\,|\Delta,\ell\rangle = c_{\Delta,\ell}\,|\Delta,\ell\rangle\,, \qquad c_{\Delta,\ell} = \Delta(\Delta-d)+\ell(\ell+d-2). \tag{47.229}$$

Proof. A primary state is annihilated by the lowering generators, $K_\mu\,|\Delta,\ell\rangle = 0$, is a dilatation eigenstate, $D\,|\Delta,\ell\rangle = \Delta\,|\Delta,\ell\rangle$, and carries the spin-$\ell$ representation of $\mathfrak{so}(d)$ (Theorem 47.15). Evaluate the three pieces of Eq. (47.228) in turn.

The first piece is immediate: $D^2\,|\Delta,\ell\rangle = \Delta^2\,|\Delta,\ell\rangle$.

For the second, write $\{P_\mu, K^\mu\} = P_\mu K^\mu + K^\mu P_\mu$ (the index μ summed with the Euclidean δ). Acting on the primary, the first term vanishes because K^μ does, $P_\mu K^\mu\,|\Delta,\ell\rangle = 0$. The second term we reduce with the algebra by commuting K to the right, where it annihilates the state:

$$K^\mu P_\mu\,|\Delta,\ell\rangle = \big[K^\mu, P_\mu\big]\,|\Delta,\ell\rangle + P_\mu K^\mu\,|\Delta,\ell\rangle = \big[K^\mu, P_\mu\big]\,|\Delta,\ell\rangle\,. \tag{47.230}$$

The commutator is the conformal-algebra relation $[K_\mu, P_\nu] = 2(\delta_{\mu\nu}D - M_{\mu\nu})$ of Eq. (47.53). Contracting $\mu=\nu$ and summing, $\delta_\mu{}^\mu = d$ and $M_\mu{}^\mu = 0$ by antisymmetry, so

$$\big[K^\mu, P_\mu\big] = 2\,(d\,D - M_\mu{}^\mu) = 2d\,D. \tag{47.231}$$

Therefore $K^\mu P_\mu\,|\Delta,\ell\rangle = 2d\,D\,|\Delta,\ell\rangle = 2d\,\Delta\,|\Delta,\ell\rangle$, and the second piece contributes $-\frac{1}{2}\{P_\mu,K^\mu\}\,|\Delta,\ell\rangle = -d\,\Delta\,|\Delta,\ell\rangle$.

For the third, the combination $-\frac{1}{2}M_{\mu\nu}M^{\mu\nu}$ appearing in Eq. (47.228) is the quadratic Casimir of the rotation subalgebra $\mathfrak{so}(d)$ in the no-i convention used here: since $M_{\mu\nu}$ acts on the primary as the spin matrix $\Sigma_{\mu\nu}$, it is exactly $C_2(\ell) = -\frac{1}{2}\Sigma_{\mu\nu}\Sigma^{\mu\nu}$ of Eq. (47.96), which on the symmetric traceless rank-ℓ representation takes the standard value $\ell(\ell+d-2)$ (the $\mathfrak{so}(d)$ Casimir, recorded in Chapter B), vanishing for a scalar, $\ell = 0$. Equivalently $\frac{1}{2}M_{\mu\nu}M^{\mu\nu} = -\ell(\ell+d-2)$ on the representation, the sign reflecting that the no-i rotation generators are anti-self-adjoint (Theorem 47.35).

Summing the three contributions,

$$C_2\,|\Delta,\ell\rangle = \left[\Delta^2 - d\,\Delta + \ell(\ell+d-2)\right]|\Delta,\ell\rangle = \left[\Delta(\Delta-d) + \ell(\ell+d-2)\right]|\Delta,\ell\rangle\,, \tag{47.232}$$

which is Eq. (47.229). The scalar case $\ell = 0$, in which only the D and $\{P, K\}$ terms contribute, gives $c_{\Delta,0} = \Delta(\Delta - d)$ and is the cleanest illustration of the mechanism: the entire eigenvalue is generated by commuting one lowering operator past one raising operator. □

The eigenvalue Eq. (47.229) is the bridge to the conformal block. Inside the four-point function, the Casimir built from the generators acting on the pair of points (x_1, x_2) — call it $\mathcal{D}_2$, the differential operator obtained by realizing $C_2^{(1)} + C_2^{(2)}$ on the coordinates through the conformal Ward identities — acts on the (12)(34) OPE channel. Because the OPE organizes the correlator into conformal multiplets and C_2 is diagonal on each multiplet with eigenvalue $c_{\Delta_\mathcal{O},\ell_\mathcal{O}}$, the contribution of the multiplet of $\mathcal{O}$ is an eigenfunction of $\mathcal{D}_2$ with that eigenvalue. Acting on the stripped function and using Eq. (47.227), every block must independently satisfy

$$\boxed{\mathcal{D}_2\,G_{\Delta,\ell}(u,v) = c_{\Delta,\ell}\,G_{\Delta,\ell}(u,v), \qquad c_{\Delta,\ell} = \Delta(\Delta-d) + \ell(\ell+d-2)\,.} \tag{47.233}$$

This second-order partial differential equation in the cross-ratios — the *conformal Casimir equation* of Dolan and Osborn [155, 156] — together with the boundary condition that $G_{\Delta,\ell}$ begin with the leading power $u^{(\Delta-\ell)/2}$ dictated by the OPE, defines the block uniquely. It is the differential equation we will integrate explicitly in Chapter 49; here we have established its existence, its eigenvalue, and the symmetry reason — the Casimir is constant on multiplets — that the blocks are its eigenfunctions. The explicit operator $\mathcal{D}_2$ and its closed-form solutions are deferred, but the structural claim is complete: *the conformal blocks are the eigenfunctions of the quadratic conformal Casimir, with eigenvalues fixed by the dimension and spin of the exchanged primary.*

We have, with this section, assembled the last piece of the CFT data and its kinematics: a convergent operator product expansion whose coefficients are the three-point constants, and a decomposition of the four-point function into OPE-coefficient-weighted conformal blocks obeying the Casimir equation. The

squared coefficients $C^2_{\phi\phi\mathcal{O}}$ and the spectrum $\{(\Delta_\mathcal{O}, \ell_\mathcal{O})\}$ are now exposed as the complete, finite input from which $g(u,v)$ is built — and the demand that the *same* four-point function be reproduced by fusing a different pair of operators is the crossing equation that Chapter 49 elevates into the conformal bootstrap. Before turning the machine on an unknown theory, however, we close the chapter by checking it against the two theories ϕ^4 theory has carried this far: the next section verifies that the free massless scalar realizes all of this structure explicitly — its $\phi \times \phi$ OPE producing the identity, the composite $:\!\phi^2\!:$, and the stress tensor — and identifies the Wilson–Fisher fixed point as the interacting conformal field theory whose anomalous dimensions feed the bootstrap.

47.8 The Free Scalar and the Wilson–Fisher Fixed Point as CFTs

The preceding sections built the conformal toolkit as an abstract structure: the Euclidean conformal algebra $\mathfrak{so}(d+1,1)$ and its unitary representations organized into primaries and descendants, the radial quantization that turns the dilatation into a Hamiltonian and supplies the state–operator map, the two- and three-point functions pinned by symmetry, and finally the operator product expansion with its convergent decomposition of the four-point function into conformal blocks. Every one of those constructions was stated for a generic conformal field theory, defined by a list of primary dimensions and spins together with their OPE coefficients. It is time to exhibit that list for the two theories ϕ^4 theory has carried through the book. We will verify that the massless free scalar realizes the toolkit exactly — its operator content is precisely the spectrum the general theory predicts at the unitarity bound — and then identify the Wilson–Fisher fixed point as a genuinely interacting CFT whose low-lying scaling dimensions are the engineering dimensions of the free theory *shifted by the anomalous dimensions computed in Part VI*. The endpoint is the handoff: a short list of conformal data, Δ_ϕ, Δ_{ϕ^2}, and a few OPE coefficients, that the numerical bootstrap of Chapter 50 will pin to extraordinary precision for the three-dimensional Ising universality class, and whose full development is the business of Chapter 52.

47.8.1 The free massless scalar is a conformal field theory

We begin with the logical certificate. The opening section of this chapter established that a theory with a symmetric, conserved, *traceless* stress tensor carries one conserved current for each of the $\frac{1}{2}(d+1)(d+2)$ conformal Killing vectors, by the contraction $J^\mu_{(\xi)} = \Theta^{\mu\nu}_{\rm c}\xi_\nu$ whose divergence is proportional to the trace (Eq. (47.27)). The massless free scalar supplies exactly such a tensor: its canonical stress tensor has the nonzero trace $\frac{2-d}{2}(\partial\phi)^2$ of Eq. (7.191), but because the field virial is a total derivative (Eq. (7.190)) the Belinfante-style

improvement of Theorem 7.45 absorbs it and produces a tensor $\Theta_{\mathrm{c}}^{\mu\nu}$ that is symmetric, conserved, and traceless on shell in every dimension. The free scalar therefore carries the full set of conformal charges; it is a conformal field theory, and the simplest one. What remains is not to re-prove this but to read off its conformal data and check it against the representation theory.

The two-point function and the dimension of ϕ. The single most important number is the scaling dimension of the elementary field, and it is fixed by its two-point function. We work in Euclidean signature throughout this section, as the conformal toolkit and the bootstrap demand; the Wick rotation is the one defined in Chapter 10, and reflection positivity (Chapter 10) is the Euclidean avatar of unitarity that makes the operator-state inner products below positive. The massless Euclidean propagator is the $m \to 0$ limit of the Schwinger function of Theorem 10.30. In four dimensions the worked computation of Theorem 10.31 already gave $G_E \to 1/(4\pi^2 r^2)$ as $m \to 0$; we now need its form in general d, since the entire interest of the fixed-point story lies in varying the dimension.

Worked Example 47.51 (The massless scalar two-point function in d dimensions)**.** We evaluate the massless propagator

$$\langle \phi(x)\phi(0)\rangle = \int \frac{d^d p}{(2\pi)^d}\,\frac{e^{\,ip\cdot x}}{p^2} \tag{47.234}$$

in closed form for general d, repeating the proper-time method of Theorem 10.31 with the dimension kept arbitrary. Write the denominator as a Schwinger integral, $1/p^2 = \int_0^\infty ds\, e^{-sp^2}$, legitimate because $p^2 \geq 0$ in Euclidean signature, and do the Gaussian momentum integral in d dimensions,

$$\int \frac{d^d p}{(2\pi)^d}\, e^{-sp^2 + ip\cdot x} = \frac{1}{(4\pi s)^{d/2}}\, e^{-x^2/4s}, \qquad x^2 \equiv |x|^2 = r^2, \tag{47.235}$$

which is the product of d identical one-dimensional Gaussians and is manifestly finite for every $s > 0$. Hence

$$\langle \phi(x)\phi(0)\rangle = \frac{1}{(4\pi)^{d/2}} \int_0^\infty ds\, s^{-d/2}\, e^{-r^2/4s}. \tag{47.236}$$

Substitute $s = r^2/(4w)$, so $ds = -\,(r^2/4w^2)\,dw$ and $s^{-d/2} = (4w/r^2)^{d/2}$; the limits flip and

$$\int_0^\infty ds\, s^{-d/2}\, e^{-r^2/4s} = \Big(\frac{r^2}{4}\Big)^{1-d/2} \int_0^\infty dw\, w^{d/2-2}\, e^{-w} = \Big(\frac{r^2}{4}\Big)^{1-d/2} \Gamma\Big(\tfrac{d}{2} - 1\Big), \tag{47.237}$$

the last step being the definition of the Gamma function, convergent for $d > 2$. Assembling the constants, $(4\pi)^{-d/2}(r^2/4)^{1-d/2} = (4\pi)^{-d/2} 4^{d/2-1} r^{2-d} =$

$\frac{1}{4}\pi^{-d/2}r^{2-d}$, so

$$\boxed{\langle\phi(x)\phi(0)\rangle = \frac{C_d}{|x|^{\,d-2}}\,, \qquad C_d = \frac{\Gamma(\frac{d}{2}-1)}{4\,\pi^{d/2}}\,.} \tag{47.238}$$

The four-dimensional case $C_4 = \Gamma(1)/(4\pi^2) = 1/(4\pi^2)$ recovers Theorem 10.31, and the power $1/|x|^{d-2}$ is the position-space form of the massless propagator $1/p^2$ in any dimension.

The conformal toolkit fixes the two-point function of any scalar primary of dimension Δ to be $\langle\mathcal{O}(x)\mathcal{O}(0)\rangle \propto |x|^{-2\Delta}$ (the symmetry-determined form derived earlier in this chapter, Eq. (47.120)). Comparing with Eq. (47.238), the exponents match if and only if

$$2\Delta_\phi = d-2, \qquad \text{i.e.} \qquad \boxed{\Delta_\phi = \frac{d-2}{2}\,.} \tag{47.239}$$

This is the engineering dimension of the scalar field, the value $[\phi] = (d-2)/2$ that dimensional analysis and the classical scale symmetry both demanded (Eq. (7.185)); the free quantum theory carries no anomalous correction to it, because there is no interaction to renormalize the field. Two structural facts follow immediately.

First, Δ_ϕ *saturates the scalar unitarity bound.* The representation theory established earlier (Theorem 47.18) that a unitary scalar primary in $d \geq 3$ obeys $\Delta \geq (d-2)/2$, with equality permitted only for a free field. The free scalar sits exactly at this floor. We will see in Section 47.8.3 that the saturation is not a coincidence but the operator-algebra shadow of the equation of motion $\Box\phi = 0$.

Second, ϕ *is a primary, not a descendant.* A descendant is a conformal-derivative $P_{\mu_1}\cdots P_{\mu_n}$ of some primary of strictly lower dimension. The only operator in the free theory of dimension below $\Delta_\phi = (d-2)/2$ is the identity $\mathbf{1}$ (dimension 0), whose every descendant $\partial_{\mu_1}\cdots\mathbf{1}$ vanishes identically. There is therefore nothing for ϕ to be a descendant *of*: it is the lowest-dimension nontrivial operator in the theory, and any such operator is automatically a conformal primary. We can also see this directly from the transformation law: the propagator Eq. (47.238) transforms covariantly under the inversion $x \mapsto x/x^2$ with the weight $\Delta_\phi = (d-2)/2$.

Worked Example 47.52 (Inversion covariance of the free propagator)**.** A scalar primary of dimension Δ transforms under a conformal map $x \mapsto x'$ as $\phi(x) = \left|\partial x'/\partial x\right|^{\Delta/d}\phi'(x')$ (the finite primary transformation law Eq. (47.88)). For the inversion $x'^\mu = x^\mu/x^2$ the Jacobian factor was computed in Theorem 47.4: the conformal factor is $\Omega(x) = x^2$, and the Jacobian determinant is $\left|\partial x'/\partial x\right| = \Omega(x)^{-d} = (x^2)^{-d}$, so $\left|\partial x'/\partial x\right|^{\Delta/d} = (x^2)^{-\Delta}$. A primary two-point function must then satisfy

$$\langle\phi(x)\phi(y)\rangle = (x^2)^{-\Delta}(y^2)^{-\Delta}\,\langle\phi(x')\phi(y')\rangle\,. \tag{47.240}$$

The key geometric identity is that the inversion contracts chordal distances multiplicatively,

$$|x'-y'|^2 = \Big|\frac{x}{x^2}-\frac{y}{y^2}\Big|^2 = \frac{x^2}{(x^2)^2} - \frac{2\,x\cdot y}{x^2 y^2} + \frac{y^2}{(y^2)^2} = \frac{|x-y|^2}{x^2\,y^2}, \tag{47.241}$$

where the middle step expands the square and the last collects over the common denominator x^2y^2. Insert the trial form $\langle\phi(x)\phi(y)\rangle = C/|x-y|^{2\Delta}$ into the right-hand side of Eq. (47.240):

$$(x^2)^{-\Delta}(y^2)^{-\Delta}\,\frac{C}{|x'-y'|^{2\Delta}} = (x^2)^{-\Delta}(y^2)^{-\Delta}\,C\,\Big(\frac{x^2y^2}{|x-y|^2}\Big)^{\Delta} = \frac{C}{|x-y|^{2\Delta}}, \tag{47.242}$$

which reproduces the left-hand side identically. The power law $|x-y|^{-2\Delta}$ is thus inversion-covariant for *any* Δ; what makes ϕ a primary of the specific dimension $(d-2)/2$ is that its propagator Eq. (47.238) has precisely this form with $2\Delta = d-2$. Translations, rotations, and dilatations are covariance checks that the power law passes trivially; the inversion is the one genuinely new generator of the conformal group, and passing it confirms ϕ transforms as a primary under the full $\mathfrak{so}(d+1,1)$, not merely under the Poincaré–dilatation subgroup.

47.8.2 The $\phi\times\phi$ OPE and the operator content of the free theory

With ϕ established as a primary of dimension $(d-2)/2$, the operator content of the free theory is laid bare by a single OPE: the product of two elementary fields. Because the theory is Gaussian, this OPE is computed not by the abstract block expansion but directly by Wick's theorem, and the result can then be matched term by term against the conformal decomposition of Eq. (47.208). Point-split the product and normal-order: the only Wick contraction of $\phi(x)$ with $\phi(0)$ is the propagator Eq. (47.238), so

$$\phi(x)\,\phi(0) = \frac{C_d}{|x|^{\,d-2}}\,\mathbf{1} + \;:\!\phi(x)\,\phi(0)\!:, \tag{47.243}$$

where $:\cdots:$ denotes normal ordering and the singular c-number is the contraction. Taylor-expanding the regular normal-ordered piece about the midpoint generates an infinite tower of local composite operators,

$$:\!\phi(x)\,\phi(0)\!: = \sum_{n=0}^{\infty}\frac{1}{n!}\,x^{\mu_1}\cdots x^{\mu_n}\;:\!\partial_{\mu_1}\cdots\partial_{\mu_n}\phi(0)\;\phi(0)\!:, \tag{47.244}$$

all of them *bilinear* in ϕ. The content of the conformal OPE is the statement that these bilinears organize into conformal families, each consisting of a primary and its descendants. We identify the primaries.

The identity. The leading singular term in Eq. (47.243) is the identity operator $\mathbf{1}$, of dimension 0 and spin 0, with OPE coefficient equal to the two-point normalization C_d. Its presence is equivalent to the statement $\langle\phi\phi\rangle \neq 0$ and is universal to any $\phi \times \phi$ OPE.

The scalar $:\phi^2:$. The $n = 0$ term of Eq. (47.244) is the composite scalar $:\phi^2:(0)$. It is a primary of dimension

$$\Delta_{\phi^2} = 2\Delta_\phi = d - 2 \qquad \text{(free theory)}, \tag{47.245}$$

twice the dimension of the constituent field, with spin 0. That it is primary follows because the special conformal generator acts as a derivation on composites and annihilates the elementary primary at the origin:

$$[K_\mu, :\phi^2:(0)] = 2\ :\phi(0)\,[K_\mu, \phi(0)]: = 0, \qquad \text{since } [K_\mu, \phi(0)] = 0. \tag{47.246}$$

Thus $:\phi^2:$ is a new scalar primary, not a descendant of ϕ (the descendants of ϕ are $\partial_{\mu_1}\cdots\partial_{\mu_n}\phi$, which are not bilinear), and it is the lightest operator in the theory beyond the identity and ϕ itself. In the language of statistical mechanics $:\phi^2:$ is the energy operator, the one that couples to a temperature deviation, and its dimension controls the relevant direction of the RG flow — a point we make quantitative for the interacting fixed point in Section 47.8.4.

The conserved currents and the stress tensor. The terms with $n \geq 1$ in Eq. (47.244) carry vector indices and decompose into symmetric traceless tensors of every even rank. To extract the primaries cleanly it is best to package a symmetric traceless spin-ℓ tensor $J^{(\ell)}_{\mu_1\cdots\mu_\ell}$ by contracting its indices with an auxiliary *null* polarization vector z^μ, $z^2 = 0$, forming the index-free polynomial $J^{(\ell)}(x, z) = J^{(\ell)}_{\mu_1\cdots\mu_\ell} z^{\mu_1}\cdots z^{\mu_\ell}$; nullity of z automatically discards the trace terms. The bilinear spin-ℓ operators of the free scalar are then

$$J^{(\ell)}(x, z) = \sum_{k=0}^{\ell} c_k^{(\ell)}\ (z\cdot\partial)^k\phi(x)\ (z\cdot\partial)^{\ell-k}\phi(x), \tag{47.247}$$

a sum over ways of distributing ℓ derivatives between the two fields. Each term has dimension $2\Delta_\phi + \ell = d - 2 + \ell$, so $J^{(\ell)}$ is a candidate spin-ℓ primary of dimension

$$\Delta_\ell = \ell + d - 2. \tag{47.248}$$

The coefficients $c_k^{(\ell)}$ are not free: they are fixed by demanding that $J^{(\ell)}$ be *conserved*, $\partial^{\mu_1} J^{(\ell)}_{\mu_1\cdots\mu_\ell} = 0$, which is the condition that the spin-ℓ operator saturate the unitarity bound and sit at the top of a short multiplet. We now determine them and prove conservation.

Theorem 47.53 (Free higher-spin currents and their conservation)**.** *For each even $\ell \geq 0$ the bilinear Eq. (47.247) with coefficients*

$$c_k^{(\ell)} = (-1)^k \binom{\ell}{k} \tag{47.249}$$

is a symmetric traceless conserved current of the free massless scalar: $\partial^{\mu_1} J^{(\ell)}_{\mu_1 \cdots \mu_\ell} = 0$ on shell. It is a conformal primary of spin ℓ and dimension $\Delta_\ell = \ell + d - 2$, saturating the spin-$\ell$ unitarity bound (Eq. (47.102)). For odd ℓ the bilinear vanishes as a primary. The case $\ell = 0$ is $:\phi^2:$; the case $\ell = 2$ is the stress tensor (up to an improvement term); the cases $\ell \geq 4$ are the higher-spin currents whose existence reflects the infinite-dimensional higher-spin symmetry of the free theory.

Proof. Conservation of a symmetric traceless current contracted into null polarizations is the statement that $(\partial_x \cdot \partial_z)\, J^{(\ell)}(x, z) = 0$, where $\partial_z^\mu \equiv \partial/\partial z_\mu$ strips one polarization and the x-derivative supplies the divergence; trace terms drop because they carry an explicit $\eta_{\mu_i \mu_j}$ that contracts to $z^2 = 0$. Apply ∂_z^μ to Eq. (47.247) using $\partial_z^\mu (z\cdot\partial)^k = k\,(z\cdot\partial)^{k-1}\partial^\mu$:

$$\partial_z^\mu J^{(\ell)} = \sum_k c_k^{(\ell)} \Big[k\,(z\partial)^{k-1} \partial^\mu\phi\,(z\partial)^{\ell-k}\phi + (z\partial)^k \phi\,(\ell-k)(z\partial)^{\ell-k-1}\partial^\mu\phi \Big]. \tag{47.250}$$

Now act with ∂_μ (the spacetime divergence), which hits each field by the Leibniz rule. Of the four resulting terms, the two in which ∂_μ lands on the same field already carrying ∂^μ produce a $\Box\phi$ and vanish on shell, $\Box\phi = 0$. The surviving cross terms, in which ∂_μ and ∂^μ act on different fields, are

$$(\partial_x\partial_z) J^{(\ell)} = \sum_k c_k^{(\ell)} \Big[k\,(z\partial)^{k-1} \partial_\mu\phi\,(z\partial)^{\ell-k}\partial^\mu\phi + (\ell-k)\,(z\partial)^k \partial^\mu\phi\,(z\partial)^{\ell-k-1}\partial_\mu\phi \Big]. \tag{47.251}$$

Every term is of the form $(z\cdot\partial)^a \partial_\mu\phi\,(z\cdot\partial)^b \partial^\mu\phi$ with $a + b = \ell - 1$. Reindexing the first sum by $a = k - 1$ (so $k = a + 1$, coefficient $c_{a+1}^{(\ell)}(a+1)$) and the second by $a = k$ (coefficient $c_a^{(\ell)}(\ell - a)$), the total coefficient of the structure labelled by a is

$$(a+1)\, c_{a+1}^{(\ell)} + (\ell - a)\, c_a^{(\ell)}, \qquad a = 0, \ldots, \ell - 1. \tag{47.252}$$

Demanding that each vanish gives the recursion $c_{a+1}^{(\ell)} = -\frac{\ell-a}{a+1}\, c_a^{(\ell)}$, whose solution normalized to $c_0^{(\ell)} = 1$ is $c_k^{(\ell)} = (-1)^k \binom{\ell}{k}$, which is Eq. (47.249). With these coefficients $(\partial_x \cdot \partial_z) J^{(\ell)} = 0$ on shell, establishing conservation.

That $J^{(\ell)}$ is a primary follows from conservation: a conserved symmetric traceless spin-ℓ current is annihilated by K_μ at the origin, and conversely the conservation condition is exactly the shortening condition $\Delta = \ell + d - 2$ for a spin-ℓ multiplet (Eq. (47.248)); thus $J^{(\ell)}$ is a primary at the bound. For odd ℓ, exchanging the two identical fields sends $k \to \ell - k$ and $c_k^{(\ell)} \to c_{\ell-k}^{(\ell)} =$

$(-1)^{\ell-k}\binom{\ell}{k} = (-1)^{\ell} c_k^{(\ell)}$, so for odd ℓ the symmetric bilinear is antisymmetric under the relabeling and vanishes as an operator; only even-spin currents survive, as expected for a single real scalar with no internal symmetry to carry a current.

Finally we read off the named cases. For $\ell = 0$, $c_0^{(0)} = 1$ and $J^{(0)} = \phi^2 =: \phi^2 :$ (up to the subtracted c-number), the scalar of dimension $d-2$. For $\ell = 2$, $(c_0, c_1, c_2) = (1, -2, 1)$ gives, stripping the polarizations,

$$J^{(2)}_{\mu\nu} \;\propto\; \phi\,\partial_\mu\partial_\nu\phi - \partial_\mu\phi\,\partial_\nu\phi \qquad \text{(traceless, null-projected)}, \tag{47.253}$$

which is conserved by the same on-shell computation, $\partial^\mu J^{(2)}_{\mu\nu} = \phi\,\partial_\nu\Box\phi - \Box\phi\,\partial_\nu\phi = 0$. This is the spin-2 conserved current of dimension $\Delta_2 = d$, which is the stress tensor: it differs from the improved tensor $\Theta^{\mu\nu}_{\rm c}$ of Theorem 7.45 only by an identically conserved improvement term, and as a conformal primary the two coincide. The dimension $\Delta_2 = d$ and spin 2 are exactly the universal quantum numbers of the stress tensor in any CFT, here realized concretely. □

The free $\phi \times \phi$ OPE is now completely characterized. Reassembling the families,

$$\phi(x)\,\phi(0) \;\sim\; \frac{C_d}{|x|^{\,d-2}}\,\mathbf{1} \;+\; \underbrace{:\!\phi^2\!:(0)}_{\Delta=d-2,\ \ell=0} \;+\; \underbrace{\sum_{\ell\geq 2,\ \text{even}} J^{(\ell)}(0)}_{\Delta_\ell=\ell+d-2} \;+\; (\text{descendants}), \tag{47.254}$$

the appearing primaries are exactly the identity, the single scalar bilinear $:\!\phi^2\!:$, and one conserved current $J^{(\ell)}$ of dimension $\ell + d - 2$ for each even spin $\ell \geq 2$ — the stress tensor at $\ell = 2$ and an infinite tower of higher-spin currents above it. There is no operator of twist (dimension minus spin) below $d-2$, the common twist of every bilinear; this is the hallmark of a free theory, and it is the structural fact the interacting fixed point will spoil. Every dimension in Eq. (47.254) saturates the relevant unitarity bound: $\Delta_\phi = (d-2)/2$ saturates the scalar bound, and $\Delta_\ell = \ell + d - 2$ saturates the spin-ℓ bound. A free CFT lives entirely on the floor of the unitarity allowed region.

Physical Insight

The infinite tower of conserved higher-spin currents is the diagnostic of a free theory. A theorem of conformal representation theory (the higher-spin no-go statement, established in the literature for $d \geq 3$) says that a unitary CFT with even one conserved current of spin $\ell > 2$ is necessarily free: such currents generate an infinite-dimensional symmetry algebra that, in $d \geq 3$, is so rigid it forces all correlators to be those of free fields. Conversely, the way an interacting CFT *must* differ from the free scalar is by lifting these currents off the unitarity bound — giving them anomalous dimensions

$\gamma_\ell > 0$ so that $\Delta_\ell > \ell + d - 2$ and they cease to be conserved. The single current that cannot be lifted is the spin-2 stress tensor at $\Delta = d$, protected by the exact conservation of energy and momentum (translation invariance is never anomalous), together with any spin-1 currents of exact internal symmetries. The Wilson–Fisher fixed point realizes exactly this scenario.

47.8.3 The equation of motion as a null descendant

We promised that the saturation $\Delta_\phi = (d-2)/2$ is the operator-algebra expression of the free equation of motion $\Box\phi = 0$. The mechanism is the appearance of a *null state* in the conformal multiplet of ϕ, and exhibiting it both explains the unitarity bound and sets up precisely what the interaction lifts.

Work in radial quantization, where the state-operator map (built earlier in this chapter) sends the primary ϕ to a state $|\mathcal{O}\rangle$ with $D\,|\mathcal{O}\rangle = \Delta_\phi\,|\mathcal{O}\rangle$ and $K_\mu\,|\mathcal{O}\rangle = 0$, and where the Hermiticity assignment $K_\mu = P_\mu^\dagger$ (the radial-quantization adjoint, Eq. (47.175)) makes the descendant inner products computable from the algebra. Descendants are built by acting with P_μ. The level-two descendant of interest is $P^2\,|\mathcal{O}\rangle = P_\mu P^\mu\,|\mathcal{O}\rangle$, the state created by $\Box\phi$. Its norm measures whether $\Box\phi$ is an independent operator or must vanish.

Proposition 47.54 (The level-two scalar norm and the unitarity bound)**.** *For a scalar primary $|\mathcal{O}\rangle$ of dimension Δ in d dimensions, in the radial-quantization conventions $[D, P_\mu] = P_\mu$, $[D, K_\mu] = -K_\mu$, $[K_\mu, P_\nu] = 2(\delta_{\mu\nu} D - M_{\mu\nu})$, $[M_{\mu\nu}, P_\rho] = \delta_{\nu\rho} P_\mu - \delta_{\mu\rho} P_\nu$, with $K_\mu = P_\mu^\dagger$ and $M_{\mu\nu}\,|\mathcal{O}\rangle = 0$,*

$$\left\| P^2\,|\mathcal{O}\rangle \right\|^2 = \Big\langle \mathcal{O}\Big| K^2 P^2 \Big|\mathcal{O}\Big\rangle = 4\,d\,\Delta\Big(\Delta - \tfrac{d-2}{2}\Big)\,\langle\mathcal{O}|\mathcal{O}\rangle\,. \tag{47.255}$$

The norm is nonnegative for all unitary scalars, which is the scalar unitarity bound $\Delta \geq (d-2)/2$; it vanishes precisely at the bound $\Delta = (d-2)/2$, where $P^2\,|\mathcal{O}\rangle$ is a null state.

Proof. We move $K^2 = K_\mu K^\mu$ through $P^2 = P_\nu P^\nu$ using the algebra, all the way to $K_\mu\,|\mathcal{O}\rangle = 0$. First compute $K_\mu P^2\,|\mathcal{O}\rangle$:

$$\begin{aligned} K_\mu P_\nu P^\nu\,|\mathcal{O}\rangle &= [K_\mu, P_\nu] P^\nu\,|\mathcal{O}\rangle + P_\nu K_\mu P^\nu\,|\mathcal{O}\rangle \\ &= 2(\delta_{\mu\nu} D - M_{\mu\nu}) P^\nu\,|\mathcal{O}\rangle + P_\nu [K_\mu, P^\nu]\,|\mathcal{O}\rangle\,, \end{aligned} \tag{47.256}$$

where in the second term $K_\mu\,|\mathcal{O}\rangle = 0$ was used. Evaluate the two pieces. In the first, $\delta_{\mu\nu} P^\nu = P_\mu$ and $D P_\mu\,|\mathcal{O}\rangle = (\Delta + 1) P_\mu\,|\mathcal{O}\rangle$ (since $[D, P_\mu] = P_\mu$), while $M_{\mu\nu} P^\nu\,|\mathcal{O}\rangle = [M_{\mu\nu}, P^\nu]\,|\mathcal{O}\rangle = (\delta^\nu_\nu P_\mu - P_\mu)\,|\mathcal{O}\rangle = (d-1) P_\mu\,|\mathcal{O}\rangle$, using $M_{\mu\nu}\,|\mathcal{O}\rangle = 0$ and the rotation commutator. Hence the first piece is $2(\Delta +$

$1)P_\mu|\mathcal{O}\rangle - 2(d-1)P_\mu|\mathcal{O}\rangle = 2(\Delta - d + 2)P_\mu|\mathcal{O}\rangle$. In the second term, $[K_\mu, P^\nu]|\mathcal{O}\rangle = 2(\delta_\mu{}^\nu D - M_\mu{}^\nu)|\mathcal{O}\rangle = 2\delta_\mu{}^\nu \Delta|\mathcal{O}\rangle$, so $P_\nu[K_\mu, P^\nu]|\mathcal{O}\rangle = 2\Delta P_\mu|\mathcal{O}\rangle$. Adding,

$$K_\mu P^2|\mathcal{O}\rangle = 2(2\Delta - d + 2)\, P_\mu|\mathcal{O}\rangle\,. \tag{47.257}$$

Now contract with K^μ from the left and take the inner product. Using Eq. (47.257),

$$\Big\langle \mathcal{O}\Big|K^2P^2\Big|\mathcal{O}\Big\rangle = 2(2\Delta - d + 2)\ \langle \mathcal{O}|K^\mu P_\mu|\mathcal{O}\rangle\,. \tag{47.258}$$

The remaining matrix element is the level-one norm: $\langle \mathcal{O}|K^\mu P_\mu|\mathcal{O}\rangle = \langle \mathcal{O}|[K^\mu, P_\mu]|\mathcal{O}\rangle = \Big\langle \mathcal{O}\Big|2(\delta^\mu_\mu D - M^\mu{}_\mu)\Big|\mathcal{O}\Big\rangle = 2d\Delta\,\langle \mathcal{O}|\mathcal{O}\rangle$, since $\delta^\mu_\mu = d$ and $M^\mu{}_\mu = 0$. Therefore

$$\Big\langle \mathcal{O}\Big|K^2P^2\Big|\mathcal{O}\Big\rangle = 2(2\Delta - d + 2)\cdot 2d\Delta\ \langle \mathcal{O}|\mathcal{O}\rangle = 4d\Delta(2\Delta - d + 2)\,\langle \mathcal{O}|\mathcal{O}\rangle\,, \tag{47.259}$$

and since $2\Delta - d + 2 = 2(\Delta - \frac{d-2}{2})$ this is Eq. (47.255). For $\Delta > 0$ the norm is nonnegative iff $\Delta \geq (d-2)/2$, with equality giving a vanishing (null) descendant. □

The interpretation is exactly the promised one. The free scalar sits at $\Delta_\phi = (d-2)/2$, where Eq. (47.255) vanishes: the descendant $P^2|\mathcal{O}\rangle$, the state created by $\Box\phi$, has zero norm. A zero-norm state in a unitary theory must be set to zero (it decouples from all correlators by Cauchy–Schwarz), and setting it to zero is exactly the free equation of motion as an operator statement:

$$\boxed{\Box\phi = 0 \quad\Longleftrightarrow\quad P^2|\mathcal{O}\rangle \text{ is null} \quad\Longleftrightarrow\quad \Delta_\phi = \tfrac{d-2}{2}.} \tag{47.260}$$

The free multiplet is therefore *short*: the conformal family of ϕ is the full Verma module with its level-two scalar descendant removed, and the removal is the equation of motion. This is the conformal-algebra origin of the statement, familiar since Chapter 9, that a free field has no independent operator $\Box\phi$.

Physical Insight

The shortening makes precise why the free scalar is so much more constrained than a generic CFT primary, and what an interaction must do. A generic ("long") scalar primary of dimension $\Delta > (d-2)/2$ has $\Box\phi$ as a genuine, independent operator of dimension $\Delta + 2$. The free scalar trades that operator for the constraint $\Box\phi = 0$. Turning on the $\lambda\phi^4$ interaction of ϕ^4 theory does not abolish the descendant; it *populates* it. The classical equation of motion $\Box\phi = -\frac{\lambda}{3!}\phi^3$ (the carried EOM of Section 7.7.5) says the level-two descendant of ϕ is no longer zero but proportional to the composite $:\phi^3:$. The multiplet lengthens, and consistency of the lengthened multiplet with unitarity forces Δ_ϕ to rise above the bound: $\Delta_\phi = (d-2)/2 + \gamma_\phi$ with $\gamma_\phi > 0$. The anomalous dimension is the amount

by which the interaction lifts ϕ off the unitarity floor, equivalently the amount by which $\Box\phi$ acquires a nonzero norm. This is the bridge between Part VI's diagrammatic γ_ϕ and the conformal data of the fixed point.

47.8.4 The Wilson–Fisher fixed point as an interacting CFT

We now assemble the conformal data of the interacting fixed point. The Wilsonian and Callan–Symanzik analyses of Part VI located, in $d = 4 - \varepsilon$ dimensions, a nontrivial zero of the beta function: the Wilson–Fisher fixed point at $\lambda_* = \frac{16\pi^2}{3}\varepsilon + O(\varepsilon^2)$ (Theorem 23.36, Eq. (23.195), Theorem 24.31). At that fixed point the dimensionless coupling has stopped running, the theory is scale invariant, and — the virial current being a total derivative exactly as for the free scalar, since the interaction $\lambda\phi^4$ adds only a potential term whose virial is again $\propto \partial^\mu(\phi^2)$ — the improvement of Theorem 7.45 again produces a traceless stress tensor. By the current construction of the chapter's opening section, *the Wilson–Fisher fixed point is a conformal field theory.* What distinguishes it from the free scalar is its spectrum of dimensions, which we now compute by importing the Part VI results and reading them as conformal scaling dimensions.

Worked Example 47.55 (Wilson–Fisher scaling dimensions from the Part VI data)**.** We assemble the two lightest scalar dimensions of the Wilson–Fisher CFT, Δ_ϕ and Δ_{ϕ^2}, from the anomalous dimension and the relevant RG eigenvalue computed in Part VI, and exhibit them as conformal data. We work in the dimension-deficit convention $\varepsilon = 4 - d$ of Theorem 24.31, with the one-component (Ising) universality class.

The dimension of ϕ. Theorem 24.30 established the general fixed-point statement that the scaling dimension of the field is its engineering dimension shifted by the field anomalous dimension evaluated at the fixed point,

$$\Delta_\phi = \frac{d-2}{2} + \gamma_*, \qquad \gamma_* \equiv \gamma_\phi(\lambda_*), \tag{47.261}$$

which is Eq. (24.246) and Eq. (24.203) read as a conformal dimension: the very γ_ϕ computed from wavefunction renormalization *is* the anomalous part of a primary's conformal dimension. At the Wilson–Fisher point the leading anomalous dimension is second order in ε (Eq. (24.256)),

$$\gamma_* = \frac{\eta}{2}, \qquad \eta = \frac{\varepsilon^2}{54} + O(\varepsilon^3) \quad \text{(one component)}, \tag{47.262}$$

so that the field anomalous dimension is $\gamma_* = \varepsilon^2/108 + O(\varepsilon^3)$ and

$$\boxed{\Delta_\phi = \frac{d-2}{2} + \frac{\varepsilon^2}{108} + O(\varepsilon^3) = 1 - \frac{\varepsilon}{2} + \frac{\varepsilon^2}{108} + O(\varepsilon^3).} \tag{47.263}$$

The smallness of the correction — it is $O(\varepsilon^2)$, not $O(\varepsilon)$ — is the conformal restatement of the Part VI fact that the field strength renormalization Z_ϕ of ϕ^4 first moves at two loops: ϕ stays close to the unitarity bound, lifted off it only at second order. By Eq. (47.260) this is precisely the statement that the interaction gives the descendant $\Box\phi \propto :\phi^3:$ a norm that is $O(\varepsilon^2)$ small.

The dimension of ϕ^2. The composite scalar $:\phi^2:$ is the relevant operator that drives the RG flow away from criticality — physically, the energy density that couples to the reduced temperature. Its dimension is fixed by the relevant eigenvalue of the linearized flow about the fixed point. The mass perturbation $\delta S = \int d^d x\, t\, :\phi^2:(x)$ is relevant with RG eigenvalue $y_t = d - \Delta_{\phi^2}$ (the coupling t has dimension $d - \Delta_{\phi^2}$, and an operator is relevant precisely when its dimension is below d). This eigenvalue is the inverse correlation-length exponent, $y_t = 1/\nu$, computed at the Wilson–Fisher point in Part VI to be $1/\nu = 2 - \varepsilon/3 + O(\varepsilon^2)$ (Theorem 23.36). Therefore

$$\Delta_{\phi^2} = d - \frac{1}{\nu} = (4-\varepsilon) - \Big(2 - \frac{\varepsilon}{3}\Big) = \boxed{2 - \frac{2\varepsilon}{3} + O(\varepsilon^2).} \tag{47.264}$$

Comparing with the free value $\Delta_{\phi^2}^{\text{free}} = d - 2 = 2 - \varepsilon$, the interaction shifts the dimension of $:\phi^2:$ upward by $\Delta_{\phi^2} - (d-2) = \varepsilon/3 + O(\varepsilon^2)$: a *first-order* anomalous dimension $\gamma_{\phi^2} = \varepsilon/3$, far larger than the $O(\varepsilon^2)$ shift of ϕ itself. This asymmetry — ϕ barely moving while ϕ^2 moves at leading order — is the quantitative signature of the interacting fixed point, and it is why the energy operator and the order parameter are cleanly distinguished in the critical theory.

The higher-spin currents. The free tower of conserved currents $J^{(\ell)}$ of Theorem 47.53 survives at $\ell = 2$ as the exactly conserved stress tensor of dimension $\Delta_2 = d$ (energy–momentum conservation is never anomalous). For $\ell \geq 4$ the interaction lifts each current off the unitarity bound, $\Delta_\ell = \ell + d - 2 + \gamma_\ell$ with $\gamma_\ell > 0$ of order ε^2; the currents are no longer conserved, and the higher-spin symmetry of the free theory is broken — exactly as the no-go statement of Section 47.8.2 requires of any interacting CFT. The fixed point thus has the minimal conserved-current content of a unitary local CFT: the stress tensor and nothing of higher spin.

Figure 47.9 displays the two leading dimensions as functions of ε, comparing the free engineering values, the leading ε-expansion of the Wilson–Fisher CFT, and the high-precision numerical-bootstrap values at $\varepsilon = 1$ (i.e. $d = 3$).

Caution

The numbers Eqs. (47.263) and (47.264) are the leading terms of the ε-expansion, an asymptotic (non-convergent) series in $\varepsilon = 4 - d$. The physically interesting case is $d = 3$, i.e. $\varepsilon = 1$, which is not small; truncating the series there gives only a rough estimate ($\Delta_\phi \approx 1 - \frac{1}{2} + \frac{1}{108} \approx 0.509$ against

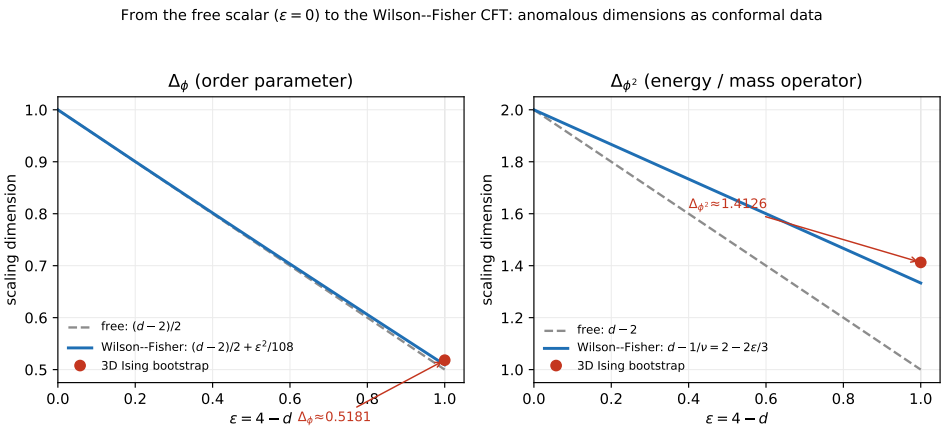

Figure 47.9: The two lightest scalar primary dimensions of ϕ^4 theory, from the free Gaussian theory ($\varepsilon = 0$) to the interacting Wilson–Fisher CFT, as functions of the dimension deficit $\varepsilon = 4 - d$. Dashed: the free (engineering) dimensions $\Delta_\phi = (d-2)/2$ and $\Delta_{\phi^2} = d - 2$, which saturate the unitarity bounds. Solid: the Wilson–Fisher dimensions to leading order in ε from Eqs. (47.263) and (47.264), carrying the anomalous pieces $\gamma_\phi = \varepsilon^2/108$ (a tiny lift of ϕ off the bound) and $\gamma_{\phi^2} = \varepsilon/3$ (a first-order shift of the energy operator). Markers at $\varepsilon = 1$: the three-dimensional Ising values $\Delta_\phi \approx 0.518$, $\Delta_{\phi^2} \approx 1.413$ obtained by the numerical conformal bootstrap, the target to which Chapter 50 pins this data far beyond the reach of the perturbative series. The ε-expansion is an asymptotic series evaluated at $\varepsilon = 1$, so the leading curves only point toward, rather than reach, the bootstrap numbers — which is precisely why the bootstrap is needed.

the true 0.5181…). The ε-expansion establishes the *existence and qualitative structure* of the interacting fixed point and its conformal data, but it does not, on its own, deliver precise three-dimensional dimensions. The precision comes from the bootstrap, which uses no perturbative expansion at all — only conformal symmetry, unitarity, and crossing — and for which these few low-lying dimensions are the data to be determined. This is the sense in which the ε-expansion and the bootstrap are complementary, dated to the current understanding of the mid-2020s.

47.8.5 Closing the loop: two genuine CFTs, and the handoff

The chapter opened with a question inherited from Part VI: the renormalization group identifies the long-distance physics of a theory with the fixed points of its flow, and a fixed point is scale invariant, but is it conformally invariant? We can now answer it concretely for the two theories ϕ^4 theory has carried. Both the free

massless scalar and the Wilson–Fisher fixed point possess a virial current that is a total derivative, so by the improvement construction of Section 47.1.1 both have a symmetric, conserved, traceless stress tensor; and by the current-counting argument Eq. (47.27) a traceless stress tensor generates the full conformal group. Both theories are therefore not merely scale invariant but genuine conformal field theories, with the elementary field realized as a primary of dimension Δ_ϕ. The abstract machinery of this chapter — primaries and descendants, unitarity bounds, radial quantization, symmetry-fixed correlators, the OPE — has been checked on each construction: the free scalar realizes the spectrum exactly at the unitarity bound, with its equation of motion appearing as a null descendant, and the Wilson–Fisher point lifts ϕ and ϕ^2 off the free values by the anomalous dimensions of Part VI, recast here as conformal data.

This completes ϕ^4 theory's transition from "RG fixed point" to "conformal field theory." The small list of numbers assembled in Theorem 47.55 — the dimensions Δ_ϕ and Δ_{ϕ^2}, the stress tensor at $\Delta = d$, and (implicitly) the OPE coefficients of the $\phi \times \phi$ expansion Eq. (47.254) — is exactly the conformal data the rest of this part will work with. Two destinations follow immediately. In $d = 2$ the free scalar is special: the conformal Killing equation degenerates and the finite-dimensional group enlarges to the infinite-dimensional Virasoro algebra, the subject of Chapter 48, where the free scalar and the Ising CFT are solved exactly. And in $d = 3$ the Wilson–Fisher data become the input to the conformal bootstrap: Chapter 49 sets up the crossing equation on these dimensions, Chapter 50 pins them numerically to the values shown in Fig. 47.9, and Chapter 52 closes the loop with Part VI by identifying the result as the three-dimensional Ising universality class. The conformal data computed here is the seed; the bootstrap is the cultivation.

Further reading

The modern, bootstrap-oriented development of conformal symmetry in $d \geq 3$ followed here is presented at greater length in Rychkov's EPFL lectures [421] and in Simmons-Duffin's TASI lectures [442]; the comprehensive review of Poland et al. [402] surveys the field through the numerical bootstrap and is the natural next step. The two-dimensional theory, the Virasoro algebra, and the minimal-model classification are treated definitively in the book of Di Francesco et al. [147]. The question of when scale invariance is enhanced to conformal invariance is the subject of Polchinski [404] in $d = 2$ and of Luty et al. [329] for the $d = 4$ unitary case via the a-theorem. The classic papers establishing the conformal algebra, the operator product expansion, and the covariance of correlators are Ferrara et al. [190]; the conformal blocks and the Casimir equation used to organize the four-point function are due to Dolan and Osborn [155, 156].

Chapter 48

CFT in Two Dimensions

The previous chapter built conformal symmetry in general dimension and found it powerful but finite: solving the conformal Killing equation in $d \geq 3$ returned the $\frac{1}{2}(d+1)(d+2)$ generators of $\mathrm{SO}(d+1,1)$ (Theorem 47.3), enough to fix two- and three-point functions up to constants but no more. This chapter is the story of what happens when that count becomes infinite. In two dimensions the conformal Killing equation degenerates exactly into the Cauchy–Riemann condition, every holomorphic map is a conformal transformation, and the symmetry algebra swells from a finite Lie algebra into two commuting infinite-dimensional copies of the Witt algebra. The consequence, developed over the seven sections that follow, is that an entire discrete family of theories becomes *exactly solvable* from symmetry alone — their operator content, their fusion rules, and every correlation function determined with no Lagrangian and no perturbation series. Two-dimensional conformal field theory is the one corner of interacting quantum field theory where the program of fixing everything by symmetry is carried to completion, and it is the proving ground for the bootstrap philosophy that the rest of Part XIV pursues in higher dimensions.

The chapter imports its kinematic backbone from Chapter 47 — the definition of primary and quasi-primary operators (Theorems 47.15 and 48.4), radial quantization and the state–operator map, the OPE, and the general-dimension forms of the two- and three-point functions against which every two-dimensional result is checked. It is computational in a complex-analytic register, so it leans throughout on the analysis toolbox of Chapter 5: the Wick rotation $t \to -i\tau$ (Section 5.4) that carries the mostly-minus Minkowski theory of Appendix A to the Euclidean plane, and Cauchy's theorem and the residue calculus (Theorem 5.23) that turn the action of the symmetry into contour integrals. The Lie-algebraic language of generators acting as vector fields is that of Chapter 2, and the unitarity arguments rest on the reflection positivity established in Chapter 10. Where the carried ϕ^4 thread reaches its Wilson–Fisher fixed point it hands off to conformal field theory; here that handoff is realized concretely, since the Ising

CFT worked in full below *is* the fixed point governing the critical scalar, and its critical exponents reproduce Onsager's.

The arc is cumulative. Section 48.1 specializes the conformal Killing equation to $d = 2$, derives the Witt algebra and its globally well-defined subalgebra $\mathfrak{sl}(2, \mathbb{C})$, fixes the complex-coordinate conventions and the conformal weights $(h, \bar{h})$, and confirms consistency by recovering the two- and three-point functions of Chapter 47 in factorized form. Section 48.2 makes the symmetry dynamical: tracelessness forces a holomorphic stress tensor $T(z)$, the conformal Ward identity expresses every variation as a contour integral of T, and the operator product $T(z)T(w)$ produces the one number the classical analysis could not see — the central charge c, with its finite-transformation avatar the Schwarzian. Section 48.3 quantizes radially, expands T in modes L_n, and turns the TT operator product into the Virasoro algebra, the central extension of Witt; L_0 becomes the Hamiltonian and primaries become highest-weight states. Section 48.4 studies the resulting Verma modules, computes the Gram matrix and states the Kac determinant, locates the null vectors that signal degenerate representations, and extracts the Friedan–Qiu–Shenker unitarity bound and its discrete series. Section 48.5 reaps the harvest: the minimal models, their finite Kac tables, the BPZ differential equations that null vectors impose on correlators, and the fusion rules that close the operator algebra. Section 48.6 works the simplest nontrivial example, the $c = \frac{1}{2}$ Ising CFT, end to end — three primaries, fusion algebra, the spin four-point function from the BPZ equation, the free-Majorana realization, and the dictionary to Onsager's exponents. Section 48.7 closes with the free-field realizations — the boson and its vertex operators, the compact boson and $R \to 1/R$ duality, the Majorana fermion, and the Coulomb-gas/Feigin–Fuks construction whose screening integrals reproduce the Ising four-point function a third independent way.

A brief word on scope and rigor. Essentially everything here is proved in full: the collapse of the Killing equation to Cauchy–Riemann, the Witt and Virasoro brackets computed mode by mode, the central charge extracted from explicit free-field correlators, the Kac determinant deployed (its general proof attributed but the low-level cases computed by hand), the BPZ equations derived from null vectors, and the Ising four-point function assembled to the last constant by three independent methods. The single number c threads the whole chapter, computed for the boson ($c = 1$), the Majorana fermion ($c = \frac{1}{2}$), and the minimal series, and it reappears downstream as the coefficient of the universal entanglement entropy $\frac{c}{3} \ln \ell$ in Chapter 55. The conformal blocks that the null-vector ODEs deliver here are the same objects that, recast as Casimir eigenfunctions, become the analytic backbone of crossing symmetry in Chapters 49 and 51.

48.1 Local Conformal Symmetry in Two Dimensions: the Witt Algebra

The previous chapter left us with a finite-dimensional symmetry. Solving the conformal Killing equation in flat space of dimension $d \geq 3$ (Theorem 47.3) returned exactly $\frac{1}{2}(d+1)(d+2)$ independent generators — translations, rotations, one dilatation, and d special conformal transformations — assembling into the algebra of $\mathrm{SO}(d+1,1)$ recorded in Eq. (47.53). The count is rigid because the equation is overdetermined: in $d \geq 3$ the third derivative of the conformal factor is forced to vanish, so every conformal generator is at most quadratic in the coordinates, and the list closes. The single place where that argument has no force is $d = 2$, where the overdetermination evaporates and the equation acquires infinitely many solutions. This section carries out the specialization to two dimensions in full, and the result reorganizes everything that follows: the local conformal transformations become the holomorphic maps of the complex plane, the symmetry algebra becomes two commuting copies of an infinite-dimensional Lie algebra — the *Witt algebra* — and the closed finite-dimensional group of Chapter 47 survives only as the small globally well-defined subalgebra $\mathfrak{sl}(2,\mathbb{C})$. We also fix here, once and for all, the complex-coordinate conventions used throughout the chapter, and we check the whole apparatus against the general-dimension correlators of Chapter 47.

48.1.1 Complex coordinates on the Euclidean plane

Conformal field theory is most transparent in Euclidean signature, and the computational engine of the subject is complex analysis, so the first move is to Wick-rotate and complexify. We follow the rotation $t \to -i\tau$ introduced in Section 5.4: the mostly-minus Minkowski conventions of the book (Chapter 47) enter only through this continuation, after which the two-dimensional theory lives on the Euclidean plane $\mathbb{R}^2$ with positive-definite line element

$$ds^2 = (dx^1)^2 + (dx^2)^2, \tag{48.1}$$

and all subsequent manipulations are complex-analytic. On this plane introduce the complex coordinate and its conjugate,

$$z = x^1 + i\,x^2, \qquad \bar{z} = x^1 - i\,x^2, \tag{48.2}$$

with the corresponding Wirtinger derivatives, obtained by inverting Eq. (48.2),

$$\partial_z \equiv \partial = \tfrac{1}{2}(\partial_1 - i\,\partial_2), \qquad \partial_{\bar{z}} \equiv \bar{\partial} = \tfrac{1}{2}(\partial_1 + i\,\partial_2), \tag{48.3}$$

which satisfy $\partial z = 1$, $\partial \bar{z} = 0$, $\bar{\partial} z = 0$, $\bar{\partial}\bar{z} = 1$. The line element Eq. (48.1) becomes $ds^2 = dz\,d\bar{z}$, so the metric components in the $(z,\bar{z})$ frame are

$$g_{zz} = g_{\bar{z}\bar{z}} = 0, \qquad g_{z\bar{z}} = g_{\bar{z}z} = \tfrac{1}{2}, \qquad g^{z\bar{z}} = g^{\bar{z}z} = 2, \tag{48.4}$$

and the Euclidean area element is $d^2x = dx^1\,dx^2 = \tfrac{1}{2}\,|dz \wedge d\bar{z}|$, i.e. $d^2x = \tfrac{1}{2}\,dz\,d\bar{z}$ as a measure once one fixes orientation. The Laplacian is $\partial_1^2 + \partial_2^2 = 4\,\partial\bar{\partial}$.

There is a conceptual subtlety that we adopt as a standing convention. On the physical Euclidean plane z and $\bar{z}$ are not independent: $\bar{z}$ is the complex conjugate of z, and x^1, x^2 are real. It is nonetheless enormously convenient — and, by the analytic-continuation theorems of Section 5.4, legitimate — to treat z and $\bar{z}$ as two *independent* complex variables, recovering the physical configuration at the end by imposing the reality slice $\bar{z} = z^*$. Concretely, $\mathbb{R}^2$ is complexified to $\mathbb{C}^2$ with coordinates $(z, \bar{z})$, holomorphic and antiholomorphic dependence are treated separately, and "$\bar{z}$" is then merely a label for the second variable rather than a function of the first. Every formula we write is to be read on this complexified space; physical correlators are its restriction to $\bar{z} = z^*$.

Definition 48.1 (Holomorphic factorization)**.** Working on the complexified plane with independent coordinates $(z, \bar{z})$, a quantity *factorizes holomorphically* when it is a sum of products of a function of z alone (the *holomorphic* or *chiral* part) and a function of $\bar{z}$ alone (the *antiholomorphic* or *antichiral* part). A function $f(z)$ with $\bar{\partial} f = 0$ is called *holomorphic* (chiral); a function $\bar{f}(\bar{z})$ with $\partial \bar{f} = 0$ is *antiholomorphic* (antichiral). The reality slice $\bar{z} = z^*$ recombines the two parts into a real-analytic function on $\mathbb{R}^2$.

The reason this notion will be so powerful is the theorem we are about to prove: in two dimensions a local conformal transformation *is* a holomorphic map, so the symmetry itself respects the holomorphic/antiholomorphic splitting. Holomorphic factorization is therefore not an accident of special correlators but a structural feature inherited from the symmetry algebra, and it is what allows the contour-integral and residue machinery of Chapter 47 — ultimately Cauchy's theorem, Theorem 5.23 — to do the heavy lifting for the rest of the chapter.

48.1.2 The conformal Killing equation collapses to Cauchy–Riemann

A conformal transformation is an infinitesimal coordinate change $x^\mu \to x^\mu + \xi^\mu(x)$ whose only effect on the metric is a local rescaling. In Chapter 47 this requirement was reduced to the conformal Killing equation Eq. (47.9),

$$\partial_\mu \xi_\nu + \partial_\nu \xi_\mu = \frac{2}{d}\,(\partial\cdot\xi)\,\delta_{\mu\nu}, \tag{48.5}$$

written here in Euclidean signature, where indices are raised and lowered with $\delta_{\mu\nu}$ so that $\xi_\mu = \xi^\mu$. We now set $d = 2$ and read off its content componentwise. The factor $2/d$ becomes unity. The equation has three independent components.

The two diagonal components, $\mu = \nu = 1$ and $\mu = \nu = 2$, both reduce to the same statement,

$$2\,\partial_1\xi_1 = \partial_1\xi_1 + \partial_2\xi_2 \quad\Longrightarrow\quad \partial_1\xi_1 = \partial_2\xi_2, \tag{48.6}$$

and the off-diagonal component $\mu = 1, \nu = 2$ gives

$$\partial_1 \xi_2 + \partial_2 \xi_1 = 0. \tag{48.7}$$

These two real equations are exactly the Cauchy–Riemann equations. To see it, assemble the components of ξ into a complex field,

$$\varepsilon(z, \bar{z}) \equiv \xi^1 + i\,\xi^2, \qquad \bar{\varepsilon}(z, \bar{z}) \equiv \xi^1 - i\,\xi^2, \tag{48.8}$$

and compute its antiholomorphic derivative using Eq. (48.3),

$$\bar{\partial}\,\varepsilon = \tfrac{1}{2}(\partial_1 + i\,\partial_2)(\xi^1 + i\,\xi^2) = \tfrac{1}{2}(\partial_1 \xi^1 - \partial_2 \xi^2) + \tfrac{i}{2}(\partial_1 \xi^2 + \partial_2 \xi^1). \tag{48.9}$$

The real part of the bracket vanishes by Eq. (48.6) and the imaginary part vanishes by Eq. (48.7). Hence

$$\boxed{\bar{\partial}\,\varepsilon = 0, \qquad \partial\,\bar{\varepsilon} = 0} \tag{48.10}$$

where the second equation follows identically by taking the complex conjugate of the first (equivalently, by repeating the computation with $\partial\bar{\varepsilon}$). The conclusion is the headline of the chapter: *in two dimensions an infinitesimal conformal transformation is generated by a holomorphic function $\varepsilon(z)$ together with an independent antiholomorphic function $\bar{\varepsilon}(\bar{z})$*. The local conformal map is $z \mapsto z + \varepsilon(z)$, $\bar{z} \mapsto \bar{z} + \bar{\varepsilon}(\bar{z})$, and finite conformal transformations are precisely the holomorphic maps $z \mapsto f(z)$ (with $f' \neq 0$), together with their antiholomorphic partners.

The contrast with $d \geq 3$ could not be sharper, and it is worth pausing on why the count exploded. In $d \geq 3$ the conformal Killing equation forces, via Eq. (47.13), the conformal factor to be at most linear in x, so ξ is at most quadratic and the solution space is finite. In $d = 2$ the obstruction disappears: the trace condition $\frac{2}{d}(\partial\cdot\xi)$ uses up the entire equation, leaving no further constraint on the second derivatives, and Eq. (48.10) is solved by *any* holomorphic $\varepsilon(z)$ whatsoever. The space of local solutions is infinite-dimensional. This is the precise sense in which "$d = 2$ is special": the conformal Killing equation degenerates exactly into the Cauchy–Riemann condition that defines complex differentiability.

Caution

"Holomorphic" here means complex-differentiable, i.e. $\bar{\partial}\varepsilon = 0$, and includes functions with poles and essential singularities — $\varepsilon(z)$ may be any element of a Laurent series. The *local* conformal transformations are these germs of holomorphic maps; whether a given $\varepsilon(z)$ extends to a globally well-defined transformation of the Riemann sphere is a separate question, answered in Section 48.1.4, and it is what distinguishes the infinite Witt algebra from its finite global subalgebra. A holomorphic map preserves angles (it is

conformal in the elementary complex-analysis sense) precisely where $f' \neq 0$; this is the two-dimensional avatar of the angle-preservation proposition Theorem 47.2.

48.1.3 The Witt algebra

A holomorphic function on a punctured neighbourhood of the origin has a Laurent expansion, and each Laurent monomial generates one independent infinitesimal conformal transformation. It is therefore natural to expand $\varepsilon(z)$ in integer powers of z and read off a basis of generators. Recall (Theorem 2.39) that the generators of a transformation acting on functions are the vector fields implementing the infinitesimal change of coordinates: under $z \mapsto z' = z+\varepsilon(z)$ a field ϕ transforms as $\delta\phi = -\varepsilon(z)\,\partial\phi - \bar{\varepsilon}(\bar{z})\,\bar{\partial}\phi$, so the holomorphic part is generated by the differential operator $-\varepsilon(z)\,\partial$. Expanding $\varepsilon(z) = -\sum_{n\in\mathbb{Z}} a_n\, z^{n+1}$ (the offset $n+1$ and the overall sign are chosen to make the algebra below take its standard form) identifies the basis of holomorphic generators

$$\ell_n = -\,z^{\,n+1}\,\partial_z, \qquad n \in \mathbb{Z}, \tag{48.11}$$

together with the independent antiholomorphic copy

$$\bar{\ell}_n = -\,\bar{z}^{\,n+1}\,\partial_{\bar{z}}, \qquad n \in \mathbb{Z}. \tag{48.12}$$

These are countably infinite families, in stark contrast to the finite list of Chapter 47. We now compute their Lie brackets directly.

Theorem 48.2 (The Witt algebra)**.** *The vector fields Eq. (48.11) satisfy the commutation relations*

$$[\ell_m, \ell_n] = (m-n)\,\ell_{m+n}, \qquad \big[\bar{\ell}_m, \bar{\ell}_n\big] = (m-n)\,\bar{\ell}_{m+n}, \qquad \big[\ell_m, \bar{\ell}_n\big] = 0, \tag{48.13}$$

for all $m, n \in \mathbb{Z}$. The algebra defined by the first bracket is the Witt algebra*; the full local conformal algebra in two dimensions is two commuting copies of it, $\mathfrak{Witt} \oplus \overline{\mathfrak{Witt}}$.*

Proof. We compute the holomorphic bracket on an arbitrary test function $f(z)$, keeping every step. Using Eq. (48.11),

$$[\ell_m, \ell_n]\, f = (z^{m+1}\partial)\big(z^{n+1}\partial f\big) - (z^{n+1}\partial)\big(z^{m+1}\partial f\big). \tag{48.14}$$

Expand the first term with the product rule,

$$z^{m+1}\partial\big(z^{n+1}\partial f\big) = z^{m+1}\Big[(n+1)\,z^{n}\,\partial f + z^{n+1}\,\partial^2 f\Big] = (n+1)\,z^{m+n+1}\,\partial f + z^{m+n+2}\,\partial^2 f, \tag{48.15}$$

and the second term identically with $m \leftrightarrow n$,

$$z^{n+1}\partial(z^{m+1}\partial f) = (m+1)\, z^{m+n+1}\,\partial f + z^{m+n+2}\,\partial^2 f. \tag{48.16}$$

The second-derivative pieces $z^{m+n+2}\partial^2 f$ are identical and cancel in the difference — this cancellation is the reason the bracket of two first-order operators is again first order. Subtracting Eq. (48.16) from Eq. (48.15),

$$[\ell_m, \ell_n]\, f = \big[(n+1) - (m+1)\big]\, z^{m+n+1}\,\partial f = (n-m)\, z^{m+n+1}\,\partial f. \tag{48.17}$$

Finally recognize $z^{m+n+1}\partial = -\ell_{m+n}$ from Eq. (48.11), so that $(n-m)\, z^{m+n+1}\partial = -(n-m)\,\ell_{m+n} = (m-n)\,\ell_{m+n}$, giving the first relation in Eq. (48.13). The antiholomorphic computation is identical with $z \to \bar z$, $\partial \to \bar\partial$. The cross bracket vanishes because ℓ_m contains only z and ∂_z while $\bar\ell_n$ contains only $\bar z$ and $\partial_{\bar z}$, and on the complexified plane these act on independent variables: $\partial_z \bar z = 0 = \partial_{\bar z} z$, so the two operators commute term by term. This proves Eq. (48.13). □

The structure constants $(m-n)$ are antisymmetric in m, n as a Lie bracket must be, and one checks the Jacobi identity directly: for any ℓ, m, n,

$$[\ell_\ell, [\ell_m, \ell_n]] + \text{cyclic} = (m-n)(\ell - m - n)\,\ell_{\ell+m+n} + \text{cyclic} = 0, \tag{48.18}$$

the three cyclic terms summing to zero by direct expansion. The Witt algebra is thus a bona fide infinite-dimensional Lie algebra, and the two commuting copies act on the holomorphic and antiholomorphic sectors entirely independently. This independence is the algebraic origin of holomorphic factorization (Theorem 48.1): because the symmetry splits, so do the objects it constrains.

Physical Insight

The single most consequential fact in two-dimensional conformal field theory is that this symmetry is *infinite*-dimensional. A finite-dimensional symmetry constrains correlators but cannot fix them; an infinite one can. The Witt algebra (after the central extension to the Virasoro algebra in the next section, which the quantum theory forces upon us) is rigid enough that, for an entire discrete family of theories, it determines the operator content, the operator product coefficients, and every correlation function with no Lagrangian and no perturbation series. The remainder of this part shows how. Everything begins with the elementary observation that in two dimensions "conformal" and "holomorphic" are the same word.

48.1.4 The global subalgebra: only $\mathfrak{sl}(2,\mathbb{C})$ survives on the sphere

The Witt generators Eq. (48.11) are local: they are defined as differential operators near a point. But a genuine symmetry of a field theory on a closed

surface must be implemented by a transformation that is well defined *everywhere*, with no singularity it cannot account for. The natural closed surface here is the Riemann sphere $\mathbb{C} \cup \{\infty\}$ — the conformal compactification of the Euclidean plane, just as in higher dimensions the conformal group acts on a compactified space — and the requirement of global regularity will cut the infinite family down to exactly three holomorphic generators. The argument is a clean exercise in changing charts.

The sphere needs two coordinate charts. Near the origin we use z; near the point at infinity we use

$$w = \frac{1}{z}, \tag{48.19}$$

so that $z = \infty$ is the regular point $w = 0$. A vector field that generates a globally defined transformation must be nonsingular in *both* charts. We examine each generator $\ell_n = -z^{n+1}\partial_z$ at the two poles.

Regularity at $z = 0$. The coefficient $-z^{n+1}$ is regular at the origin if and only if $n + 1 \geq 0$, that is

$$n \geq -1. \tag{48.20}$$

For $n \leq -2$ the field blows up at the south pole.

Regularity at $z = \infty$. We must rewrite ℓ_n in the w chart. From $w = 1/z$ we have $z = 1/w$ and, by the chain rule, $\partial_z = \dfrac{dw}{dz}\,\partial_w = -\dfrac{1}{z^2}\,\partial_w = -w^2\,\partial_w$. Also $z^{n+1} = w^{-(n+1)}$. Therefore

$$\ell_n = -\,z^{n+1}\,\partial_z = -\,w^{-(n+1)}\big(-\,w^2\,\partial_w\big) = w^{\,1-n}\,\partial_w. \tag{48.21}$$

This is regular at the north pole $w = 0$ if and only if $1 - n \geq 0$, that is

$$n \leq 1. \tag{48.22}$$

Imposing *both* Eq. (48.20) and Eq. (48.22) leaves exactly

$$n \in \{-1, 0, 1\}, \tag{48.23}$$

and likewise $\bar{n} \in \{-1, 0, 1\}$ for the antiholomorphic copy. The globally well-defined conformal transformations of the sphere are generated by six real vector fields: $\{\ell_{-1}, \ell_0, \ell_1\}$ and $\{\bar{\ell}_{-1}, \bar{\ell}_0, \bar{\ell}_1\}$.

Restricting Eq. (48.13) to $n \in \{-1, 0, 1\}$ gives a closed three-dimensional algebra,

$$[\ell_0, \ell_{-1}] = \ell_{-1}, \qquad [\ell_0, \ell_1] = -\ell_1, \qquad [\ell_{-1}, \ell_1] = -2\,\ell_0, \tag{48.24}$$

which is the Lie algebra $\mathfrak{sl}(2)$. Together with the antiholomorphic copy and the reality condition relating the two on the physical slice, the global algebra is the complexification $\mathfrak{sl}(2,\mathbb{C}) \cong \mathfrak{sl}(2) \oplus \overline{\mathfrak{sl}(2)}$, exponentiating to the group

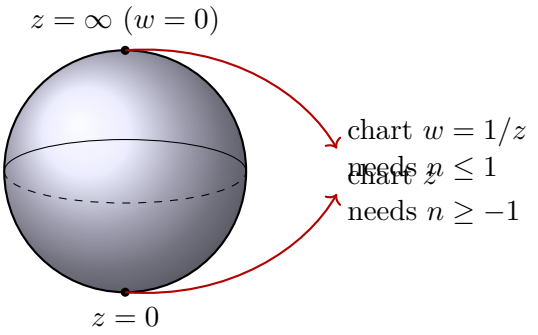

Figure 48.1: The Riemann sphere $\mathbb{C} \cup \{\infty\}$ with its two coordinate charts. A Witt generator $\ell_n = -z^{n+1}\partial_z$ must be nonsingular at the south pole $z = 0$ (forcing $n \ge -1$) and, after the transition to $w = 1/z$, at the north pole $w = 0$ (forcing $n \le 1$). Only $n \in \{-1, 0, 1\}$ pass both tests: these generate the global conformal group $\mathrm{SL}(2, \mathbb{C})/\mathbb{Z}_2$.

$\mathrm{SL}(2, \mathbb{C})$ (acting on the sphere as $\mathrm{SL}(2, \mathbb{C})/\mathbb{Z}_2 \cong \mathrm{PSL}(2, \mathbb{C})$). This is precisely the global conformal group of Chapter 47 specialized to $d = 2$: indeed $\mathrm{SO}(3, 1) \cong \mathrm{SL}(2, \mathbb{C})/\mathbb{Z}_2$, and the count $\frac{1}{2}(d + 1)(d + 2) = \frac{1}{2} \cdot 3 \cdot 4 = 6$ matches the six real generators we just found. The infinite Witt algebra is the genuinely new structure of two dimensions; the global $\mathrm{SL}(2, \mathbb{C})$ is the part that agrees with the higher-dimensional story.

The three holomorphic generators have transparent geometric meanings, fixing the dictionary we will use throughout:

- $\ell_{-1} = -\partial_z$ generates *translations* $z \mapsto z + a$.
- $\ell_0 = -z\,\partial_z$ generates complex *scalings* $z \mapsto \lambda z$. Its real part (combined with $\bar{\ell}_0$) is the dilatation; its imaginary part is the rotation. Explicitly, $\ell_0 + \bar{\ell}_0$ generates dilatations and $i(\ell_0 - \bar{\ell}_0)$ generates rotations.
- $\ell_1 = -z^2\,\partial_z$ generates *special conformal transformations* $z \mapsto z/(1 - bz)$.

We make the third statement precise, and exhibit the finite Möbius group it integrates to, in Theorem 48.6.

48.1.5 Conformal weights and primary fields

Having identified the symmetry, we now classify the local operators that carry its representations. In Chapter 47 a primary operator was defined by its behaviour under the global conformal group: it transforms with a definite scaling dimension and is annihilated by the special conformal generators at the origin (Theorem 47.15). In two dimensions the natural eigenvalues to track are those

of the two commuting generators ℓ_0 and $\bar{\ell}_0$, which measure holomorphic and antiholomorphic scaling separately.

Definition 48.3 (Conformal weights)**.** A local field $\mathcal{O}(z,\bar{z})$ in a two-dimensional CFT has *conformal weights* $(h,\bar{h})$ if under the holomorphic and antiholomorphic scalings generated by $\ell_0,\bar{\ell}_0$ it carries those eigenvalues; equivalently, under $z\mapsto\lambda z$, $\bar{z}\mapsto\bar{\lambda}\bar{z}$ it scales as $\mathcal{O}\mapsto\lambda^{-h}\bar{\lambda}^{-\bar{h}}\mathcal{O}$. The *scaling dimension* and *spin* are

$$\Delta = h+\bar{h}, \qquad s = h-\bar{h}, \tag{48.25}$$

so that Δ is the eigenvalue of the dilatation $\ell_0+\bar{\ell}_0$ and s is the eigenvalue of the rotation generator $i(\ell_0-\bar{\ell}_0)$. The weights $h,\bar{h}$ are independent real numbers; reality and unitarity (developed later) constrain them, but kinematically h and $\bar{h}$ are unrelated.

The relations Eq. (48.25) are the two-dimensional refinement of the higher-dimensional labels: a generic CFT operator is labelled by a dimension Δ and a Lorentz/rotation representation, and in $d=2$ the rotation group is the abelian $\mathrm{SO}(2)$, whose irreducible representations are one-dimensional and labelled by a single integer or half-integer spin s. Splitting (Δ,s) into $(h,\bar{h})$ via Eq. (48.25) is the operator-level shadow of holomorphic factorization: a field of definite weights behaves as a product of a weight-h holomorphic object and a weight-$\bar{h}$ antiholomorphic object.

The strongest fields are those that transform tensorially not just under the global group but under the full local conformal symmetry. We promote the primary definition of Theorem 47.15 to its two-dimensional, finite form.

Definition 48.4 (Primary field)**.** A field $\mathcal{O}(z,\bar{z})$ of weights $(h,\bar{h})$ is *primary* if under *every* local holomorphic change of coordinates $z\mapsto z'=f(z)$, $\bar{z}\mapsto\bar{z}'=\bar{f}(\bar{z})$ (with $f'\neq 0$) it transforms as a tensor of those weights,

$$\mathcal{O}'(z',\bar{z}') = \left(\frac{dz'}{dz}\right)^{-h}\left(\frac{d\bar{z}'}{d\bar{z}}\right)^{-\bar{h}}\mathcal{O}(z,\bar{z}). \tag{48.26}$$

A field obeying Eq. (48.26) only for the global subgroup $f\in\mathrm{SL}(2,\mathbb{C})$ — i.e. only for ℓ_{-1},ℓ_0,ℓ_1 — is called *quasi-primary* (the terminology of Theorem 47.15). Every primary is quasi-primary; the converse fails, and the failure is governed by the central extension of the next section.

The infinitesimal form of Eq. (48.26) is the statement we will use most. For $f(z)=z+\varepsilon(z)$ with $\bar{f}(\bar{z})=\bar{z}+\bar{\varepsilon}(\bar{z})$, expanding to first order with $dz'/dz = 1+\varepsilon'(z)$ gives $(dz'/dz)^{-h}=1-h\,\varepsilon'(z)+\cdots$, so

$$\delta_{\varepsilon,\bar{\varepsilon}}\mathcal{O} = -\Big(\varepsilon\,\partial + h\,\varepsilon'\Big)\mathcal{O} - \Big(\bar{\varepsilon}\,\bar{\partial} + \bar{h}\,\bar{\varepsilon}'\Big)\mathcal{O}. \tag{48.27}$$

The terms $h\,\varepsilon'$ and $\bar{h}\,\bar{\varepsilon}'$ beyond the naive transport $\varepsilon\,\partial\mathcal{O}$ encode the tensor weight; they are what distinguishes a primary of nonzero weight from a scalar function. We will recover this same variation in the next section from the operator product of the stress tensor with $\mathcal{O}$, which is the dynamical way the symmetry acts.

48.1.6 Consistency: recovering the two- and three-point functions

A non-negotiable check on the formalism is that the correlators it predicts agree with the general-dimension forms fixed in Chapter 47. There the two- and three-point functions of (quasi-)primaries were determined up to constants by conformal invariance alone. We re-derive them here from global $\mathrm{SL}(2,\mathbb{C})$ invariance in complex coordinates, both to confirm consistency and to display holomorphic factorization in action.

Worked Example 48.5 (The two-point function from global invariance)**.** Let $\mathcal{O}_1, \mathcal{O}_2$ be quasi-primaries of weights $(h_1, \bar{h}_1)$, $(h_2, \bar{h}_2)$. We determine $G(z_1, \bar{z}_1; z_2, \bar{z}_2) = \langle \mathcal{O}_1(z_1, \bar{z}_1)\, \mathcal{O}_2(z_2, \bar{z}_2)\rangle$ by imposing invariance under each of $\ell_{-1}, \ell_0, \ell_1$ (the antiholomorphic copy works identically and multiplies the holomorphic answer). A correlator of primaries is invariant when the sum of the variations Eq. (48.27) acting on each insertion vanishes; we use the global modes $\varepsilon(z) = -z^{n+1}$ for $n = -1, 0, 1$. Because the two sectors decouple, write $G = g(z_1, z_2)\,\bar{g}(\bar{z}_1, \bar{z}_2)$ and solve for the holomorphic factor g.

Translations (ℓ_{-1}, $\varepsilon = \text{const}$): the variation is $-(\partial_{z_1} + \partial_{z_2})g = 0$, so g depends only on the difference $z_{12} \equiv z_1 - z_2$.

Scaling (ℓ_0, $\varepsilon = -z$): each insertion contributes $z_i\partial_{z_i} + h_i$, so invariance reads $(z_1\partial_{z_1} + z_2\partial_{z_2} + h_1 + h_2)g = 0$. With $g = g(z_{12})$ this is the homogeneity condition $(z_{12}\,\partial_{z_{12}} + h_1 + h_2)g = 0$, solved by the power law

$$g(z_{12}) = \frac{C_{12}}{z_{12}^{\,h_1+h_2}}. \tag{48.28}$$

Special conformal (ℓ_1, $\varepsilon = -z^2$): each insertion contributes $z_i^2\partial_{z_i} + 2h_i z_i$. Acting on Eq. (48.28),

$$\begin{aligned}\Big(z_1^2\partial_{z_1} + z_2^2\partial_{z_2} + 2h_1 z_1 + 2h_2 z_2\Big)\frac{C_{12}}{z_{12}^{\,h_1+h_2}} &= C_{12}\Big[-(h_1+h_2)\frac{z_1^2 - z_2^2}{z_{12}^{\,h_1+h_2+1}} + \frac{2h_1 z_1 + 2h_2 z_2}{z_{12}^{\,h_1+h_2}}\Big] \\ &= \frac{C_{12}}{z_{12}^{\,h_1+h_2}}\Big[-(h_1+h_2)(z_1+z_2) + 2h_1 z_1 + 2h_2 z_2\Big] \\ &= \frac{C_{12}}{z_{12}^{\,h_1+h_2}}\,(h_1 - h_2)(z_1 - z_2), \end{aligned} \tag{48.29}$$

where the first line used $\partial_{z_1} z_{12}^{-p} = -p\, z_{12}^{-p-1}$ and $z_1^2 - z_2^2 = (z_1 + z_2)z_{12}$. This vanishes for all z_1, z_2 if and only if $h_1 = h_2$. Hence the holomorphic two-point

function is nonzero only when the weights match, and then

$$\langle \mathcal{O}_1 \mathcal{O}_2 \rangle = \frac{C_{12}\, \delta_{h_1 h_2}\, \delta_{\bar{h}_1 \bar{h}_2}}{z_{12}^{2h}\, \bar{z}_{12}^{2\bar{h}}}, \qquad h \equiv h_1 = h_2,\ \bar{h} \equiv \bar{h}_1 = \bar{h}_2. \tag{48.30}$$

On the physical slice $\bar{z}_{12} = z_{12}^*$, a spinless field ($\bar{h} = h$, $s = 0$) gives $\langle \mathcal{O}\mathcal{O} \rangle = C\,|z_{12}|^{-4h} = C\,|z_{12}|^{-2\Delta}$ with $\Delta = 2h$, reproducing exactly the $|x|^{-2\Delta}$ two-point form of Eq. (47.120). The complex formalism has merely refined that result, resolving it into a holomorphic and an antiholomorphic factor and exposing the spin through the unequal powers of z_{12} and $\bar{z}_{12}$.

Worked Example 48.6 (The three-point function and the global Möbius group)**.** The same three conditions fix the three-point function up to one constant. Translation invariance makes the holomorphic factor a function of the differences z_{12}, z_{13}, z_{23}; scaling invariance makes it homogeneous of total degree $-(h_1 + h_2 + h_3)$; and special conformal invariance, applied as in Eq. (48.29) but now with three insertions, fixes the individual powers. Carrying out the same algebra (the special-conformal condition becomes three linear equations for the three exponents, with the unique solution below) gives

$$\langle \mathcal{O}_1 \mathcal{O}_2 \mathcal{O}_3 \rangle = \frac{C_{123}}{z_{12}^{h_1+h_2-h_3}\, z_{23}^{h_2+h_3-h_1}\, z_{13}^{h_1+h_3-h_2}} \times (\text{antiholomorphic},\ h \to \bar{h}), \tag{48.31}$$

which is the holomorphically factorized version of the general-dimension three-point form Eq. (47.137): setting $\bar{h}_i = h_i$ and restricting to the slice converts each $z_{ij}^p \bar{z}_{ij}^p = |z_{ij}|^{2p}$ into the $|x_{ij}|$ powers of Chapter 47, with $\Delta_i = 2h_i$.

It is illuminating to verify the special-conformal piece of this rigidity by integrating the global generators to finite transformations. The flow generated by $\ell_1 = -z^2\partial_z$ solves $\dfrac{dz}{dt} = -(-z^2) = z^2$ — here the minus sign in ℓ_n and the sign in $\delta\phi = -\varepsilon\,\partial\phi$ combine so that the parameter b below is the physical special-conformal parameter — giving $-d(1/z)/dt = 1$, hence $1/z(t) = 1/z_0 - t$ and

$$z \;\longmapsto\; \frac{z}{1 - b\,z}, \qquad b = t. \tag{48.32}$$

Composing with the translation $z \mapsto z + a$ generated by ℓ_{-1} and the scaling $z \mapsto \lambda z$ generated by ℓ_0, the most general finite global transformation is the *Möbius transformation*

$$z \;\longmapsto\; \frac{az + b}{cz + d}, \qquad ad - bc = 1, \quad a, b, c, d \in \mathbb{C}, \tag{48.33}$$

the determinant condition $ad - bc = 1$ being exactly the statement that the matrix $\left(\begin{smallmatrix} a & b \\ c & d \end{smallmatrix}\right)$ lies in $\mathrm{SL}(2,\mathbb{C})$. The map Eq. (48.33) is the unique holomorphic bijection of the Riemann sphere; the overall sign of the matrix is unphysical (it acts trivially on z), which is why the group acting on the sphere is $\mathrm{SL}(2,\mathbb{C})/\mathbb{Z}_2$.

This is the global conformal group of Fig. 48.1, now exhibited concretely as fractional linear maps, and it is the largest group under which *all* correlators — not merely two- and three-point functions — are invariant.

The consistency is complete: the complex-coordinate machinery reproduces, and sharpens through factorization, every kinematic constraint of Chapter 47, while adding the infinite tower of *local* generators ℓ_n with $|n| \geq 2$ that has no higher-dimensional analogue. These local generators do not preserve correlators globally — they are singular somewhere on the sphere — but they nonetheless act on the local operator algebra, and it is their action that the next section turns into dynamics.

With the holomorphic vector fields $\ell_n = -z^{n+1}\partial_z$, the Witt brackets Eq. (48.13), the weight labels $(h, \bar{h})$ of Theorem 48.3, and the primary law Eq. (48.26) now in hand, we are ready to ask how this symmetry is realized on quantum operators. The generators will be produced by contour integrals of a single holomorphic field, the stress tensor $T(z)$, and the quantum theory will refuse to leave the Witt algebra untouched: it inserts a central term proportional to a number c. That central extension — the passage from Witt to Virasoro — is the subject of Section 48.2, where c enters as the anomaly in the $T(z)T(w)$ operator product and as the Schwarzian in the finite transformation of T.

48.2 The Stress Tensor, Conformal Ward Identities, and the Central Charge

The previous section was kinematics. We learned that in two dimensions the local conformal transformations are the holomorphic maps $z \mapsto f(z)$ and their antiholomorphic partners $\bar{z} \mapsto \bar{f}(\bar{z})$, that the symmetry algebra is the infinite-dimensional Witt algebra in two commuting copies (Eq. (48.13)), that correlators holomorphically factorize (Theorem 48.1), and that the building blocks are *primary fields* carrying a pair of conformal weights $(h, \bar{h})$ (Theorem 48.3). What we did *not* do is connect any of this to a dynamical object that the theory itself produces. Symmetry, so far, is a property we impose; it has not yet told us how the theory computes. The bridge from one to the other is the *stress tensor*. In every local field theory the stress tensor is the Noether current of spacetime symmetry; here we will see that in two dimensions its holomorphic component $T(z)$ is the generating object of the entire local conformal symmetry. Inserting $T(z)$ into a correlator and deforming the integration contour — the residue calculus of Theorem 5.23 becomes the computational engine of the chapter — turns the abstract Witt action into a concrete operational rule, the *conformal Ward identity*, that reads off the transformation of every field from the singularities of its operator product with T. Pushing this one step further, to the operator product of T with *itself*, exposes a number that no amount of kinematics

could have anticipated: the *central charge* c, the single anomaly coefficient that measures the failure of the stress tensor to be a primary field and that will, in the next section, centrally extend the Witt algebra to the Virasoro algebra.

48.2.1 Tracelessness and the holomorphic stress tensor

We begin with the object inherited from the foundations. A Poincaré-invariant local field theory possesses a symmetric, conserved stress tensor; the canonical tensor can always be improved to the symmetric, gauge-invariant Belinfante form $\Theta_{\mathrm{c}}^{\mu\nu}$ of Section 7.7.3, which satisfies

$$\Theta_{\mathrm{c}}^{\mu\nu} = \Theta_{\mathrm{c}}^{\nu\mu}, \qquad \partial_\mu \Theta_{\mathrm{c}}^{\mu\nu} = 0. \tag{48.34}$$

Throughout this chapter we write $T_{\mu\nu} \equiv \Theta^{\mathrm{c}}_{\mu\nu}$ for this symmetric, conserved tensor; no confusion with the time-ordering symbol will arise because in the Euclidean two-dimensional setting of Chapter 48 all correlators are radially ordered. The decisive extra input is the result of Theorem 7.43, sharpened in Eq. (47.3): a scale-invariant theory whose dilatation current is the virial-improved $D^\mu = x_\nu T^{\mu\nu}$ has a *traceless* stress tensor, and (in the flat-space, $d = 2$ setting where scale invariance is upgraded to full conformal invariance, Theorem 47.5) this tracelessness is the local certificate of the entire conformal symmetry:

$$T^{\mu}{}_{\mu} = 0. \tag{48.35}$$

Equations (48.34) and (48.35) are the only dynamical facts we need; everything below is their two-dimensional consequence.

We now pass to the complex coordinates fixed in the previous section. After the Euclidean continuation of Theorem 5.31 the two-dimensional plane carries coordinates x^1, x^2, and we set

$$z = x^1 + i x^2, \qquad \bar{z} = x^1 - i x^2, \qquad \partial \equiv \partial_z = \tfrac{1}{2}(\partial_1 - i\partial_2), \qquad \bar{\partial} \equiv \partial_{\bar{z}} = \tfrac{1}{2}(\partial_1 + i\partial_2). \tag{48.36}$$

The flat Euclidean line element $\mathrm{d}s^2 = (\mathrm{d}x^1)^2 + (\mathrm{d}x^2)^2 = \mathrm{d}z\,\mathrm{d}\bar{z}$ has metric components $g_{z\bar{z}} = g_{\bar{z}z} = \tfrac{1}{2}$, $g_{zz} = g_{\bar{z}\bar{z}} = 0$, with inverse $g^{z\bar{z}} = g^{\bar{z}z} = 2$, $g^{zz} = g^{\bar{z}\bar{z}} = 0$. A symmetric two-tensor has three independent components T_{zz}, $T_{\bar{z}\bar{z}}$, and $T_{z\bar{z}} = T_{\bar{z}z}$. The trace is

$$T^{\mu}{}_{\mu} = g^{\mu\nu} T_{\mu\nu} = g^{z\bar{z}} T_{z\bar{z}} + g^{\bar{z}z} T_{\bar{z}z} = 4\, T_{z\bar{z}}, \tag{48.37}$$

so the tracelessness condition (48.35) is simply

$$\boxed{T_{z\bar{z}} = T_{\bar{z}z} = 0} \tag{48.38}$$

The off-diagonal component of the stress tensor vanishes identically in a conformal theory. Only T_{zz} and $T_{\bar{z}\bar{z}}$ survive.

Now impose conservation (48.34). Raising the free index with the inverse metric, $\partial^\mu T_{\mu\nu} = g^{\mu\rho}\partial_\rho T_{\mu\nu} = 0$. The nonzero entries of $g^{\mu\rho}$ pair z with $\bar z$, so $\partial^z = g^{z\bar z}\partial_{\bar z} = 2\bar\partial$ and $\partial^{\bar z} = 2\partial$. Taking the free index $\nu = z$,

$$0 = \partial^\mu T_{\mu z} = \partial^z T_{zz} + \partial^{\bar z} T_{\bar z z} = 2\bar\partial\, T_{zz} + 2\partial\, T_{\bar z z} = 2\bar\partial\, T_{zz}, \tag{48.39}$$

where the second term dropped by (48.38). Likewise the choice $\nu = \bar z$ gives $\partial\, T_{\bar z\bar z} = 0$. We have proved that in any two-dimensional conformal theory

$$\bar\partial\, T_{zz} = 0, \qquad \partial\, T_{\bar z\bar z} = 0 \qquad \Longrightarrow \qquad T_{zz} = T_{zz}(z), \quad T_{\bar z\bar z} = T_{\bar z\bar z}(\bar z). \tag{48.40}$$

The surviving components are respectively a holomorphic and an antiholomorphic function (away from operator insertions, where the equations of motion fail and contact terms appear; we return to this below). This is the dynamical origin of holomorphic factorization: it is the stress tensor that splits the dynamics into a holomorphic sector and an independent antiholomorphic one. We give the holomorphic component its standard name and normalization,

$$T(z) \equiv -2\pi\, T_{zz}(z), \qquad \bar T(\bar z) \equiv -2\pi\, T_{\bar z\bar z}(\bar z), \tag{48.41}$$

the factor -2π being chosen, as we verify below, so that the conformal Ward identity and the operator products take their canonical residue form. We call $T(z)$ the *holomorphic* (or chiral) stress tensor and $\bar T(\bar z)$ the antiholomorphic one. From here the antiholomorphic sector is a verbatim copy under $z \leftrightarrow \bar z$, $T \leftrightarrow \bar T$, $h \leftrightarrow \bar h$; we develop the holomorphic side in full and state the antiholomorphic results.

Notation Watch

We use the real area measure $\mathrm{d}^2x = \mathrm{d}x^1\,\mathrm{d}x^2$ and the delta function normalized by $\int \mathrm{d}^2x\,\delta^{(2)}(x) = 1$. With these conventions the planar Green's function identity (derived in Eq. (48.46) below) reads $\bar\partial\,(z-w)^{-1} = \pi\,\delta^{(2)}(x-x_w)$. References that adopt the rescaled measure $\mathrm{d}^2z \equiv 2\,\mathrm{d}x^1\,\mathrm{d}x^2$ with $\int \mathrm{d}^2z\,\delta^{(2)}(z,\bar z) = 1$ instead write the familiar $\bar\partial\,(z-w)^{-1} = 2\pi\,\delta^{(2)}$; the factor of two is purely the measure convention and never enters a physical weight h or the central charge c, both of which we fix through the residue normalization of (48.41) and check independently against the free boson.

48.2.2 The conformal Ward identity

We can now make the symmetry operational. An infinitesimal conformal transformation is generated by a conformal Killing vector ξ^μ; in two dimensions (48.36) this is precisely a holomorphic vector field, $\xi^z = \epsilon(z)$ with $\bar\partial\epsilon = 0$, together with its antiholomorphic partner $\xi^{\bar z} = \bar\epsilon(\bar z)$. The associated Noether current is,

by Theorem 7.48 and Eq. (47.26), the contraction of the stress tensor with the Killing vector,

$$J^\mu = T^{\mu\nu}\xi_\nu, \qquad \partial_\mu J^\mu = \tfrac{1}{2}T^{\mu\nu}(\partial_\mu\xi_\nu + \partial_\nu\xi_\mu) = \tfrac{1}{d}\,T^\mu{}_\mu\,\partial\cdot\xi = 0, \tag{48.42}$$

the divergence vanishing by tracelessness (48.35). The content of this section is to translate the conservation law into the complex coordinates and to read off how the current acts on operators.

Lower the indices on the current. With $\xi^z = \epsilon$, $\xi^{\bar z} = \bar\epsilon$ and $\xi_z = g_{z\bar z}\xi^{\bar z} = \tfrac{1}{2}\bar\epsilon$, $\xi_{\bar z} = \tfrac{1}{2}\epsilon$, the holomorphic component of the current is

$$J_z = T_{z\nu}\xi^\nu = T_{zz}\xi^z + T_{z\bar z}\xi^{\bar z} = T_{zz}\,\epsilon(z) = -\frac{1}{2\pi}\,\epsilon(z)\,T(z), \tag{48.43}$$

where $T_{z\bar z} = 0$ was used and (48.41) substituted. Because $\epsilon(z)$ and $T(z)$ are both holomorphic, J_z is holomorphic, $\bar\partial J_z = 0$; symmetrically $J_{\bar z} = -\frac{1}{2\pi}\bar\epsilon(\bar z)\bar T(\bar z)$ is antiholomorphic. The conservation law $\partial_\mu J^\mu = 2(\partial J_{\bar z} + \bar\partial J_z) = 0$ is satisfied identically away from insertions, and is in this sense empty: holomorphy already encodes it. Its physical content lives entirely in the *contact terms* at operator insertions, which is exactly what the Ward identity extracts.

The Noether–Ward identity established in general in Theorem 7.10 states that the divergence of a symmetry current inside a correlator is a sum of delta functions, one per insertion, whose coefficients are the infinitesimal variations of the operators:

$$\partial_\mu\big\langle J^\mu(x)\,O_1(x_1)\cdots O_n(x_n)\big\rangle = -\sum_{i=1}^{n}\delta^{(2)}(x-x_i)\,\big\langle O_1\cdots\delta_\epsilon O_i\cdots O_n\big\rangle. \tag{48.44}$$

This is the precise statement that the conserved charge generates the transformation: integrating x over a small disk D_i that contains only the insertion at x_i and using the divergence theorem turns the left-hand side into a boundary flux and the right-hand side into the single variation $-\langle\cdots\delta_\epsilon O_i\cdots\rangle$. We carry out exactly this integration in complex coordinates.

We need the planar Stokes identity. For any smooth $h(z,\bar z)$ and a region D with boundary ∂D traversed counterclockwise,

$$\oint_{\partial D} h\,\mathrm{d}z = \int_D \mathrm{d}(h\,\mathrm{d}z) = \int_D \bar\partial h\;\mathrm{d}\bar z\wedge\mathrm{d}z = 2i\int_D \bar\partial h\;\mathrm{d}^2x \quad\Longrightarrow\quad \int_D \bar\partial h\;\mathrm{d}^2x = \frac{1}{2i}\oint_{\partial D} h\,\mathrm{d}z, \tag{48.45}$$

using $\mathrm{d}\bar z\wedge\mathrm{d}z = 2i\,\mathrm{d}x^1\wedge\mathrm{d}x^2$. The conjugate identity is $\int_D \partial g\,\mathrm{d}^2x = -\frac{1}{2i}\oint_{\partial D} g\,\mathrm{d}\bar z$. As an immediate corollary, applying (48.45) to $h = (z-w)^{-1}$ and using $\oint_{\partial D}(z-w)^{-1}\mathrm{d}z = 2\pi i$ from Theorem 5.23 for any disk enclosing w gives the Green's function identity

$$\bar\partial\,\frac{1}{z-w} = \pi\,\delta^{(2)}(x-x_w), \tag{48.46}$$

the precise statement that the holomorphic function $1/(z-w)$ fails to be holomorphic exactly at w, where its $\bar\partial$ is a contact term. This is the analytic fact underlying the entire residue machinery: a simple pole in an operator product is the holomorphic shadow of a delta-function contact term.

Now integrate the local identity (48.44) over a disk D containing all n insertions. The left-hand side, using $\partial_\mu J^\mu = 2(\partial J_{\bar z} + \bar\partial J_z)$ together with (48.45) and its conjugate, becomes a boundary contour integral,

$$\begin{aligned}\int_D \mathrm{d}^2x\, \partial_\mu \langle J^\mu X\rangle &= 2\int_D \mathrm{d}^2x\, \big(\bar\partial\langle J_z X\rangle + \partial\langle J_{\bar z} X\rangle\big)\\ &= 2\Big(\frac{1}{2i}\oint_{\partial D}\langle J_z X\rangle\,\mathrm{d}z - \frac{1}{2i}\oint_{\partial D}\langle J_{\bar z} X\rangle\,\mathrm{d}\bar z\Big)\\ &= -\frac{1}{2\pi i}\oint_{\partial D}\mathrm{d}z\,\epsilon(z)\langle T(z)X\rangle + \frac{1}{2\pi i}\oint_{\partial D}\mathrm{d}\bar z\,\bar\epsilon(\bar z)\langle \bar T(\bar z)X\rangle,\end{aligned} \tag{48.47}$$

where in the last line we inserted (48.43), writing $X = O_1\cdots O_n$. The right-hand side of (48.44) integrates to $-\sum_i\langle\cdots\delta_\epsilon O_i\cdots\rangle = -\delta_\epsilon\langle X\rangle$, the total variation. Equating the two and renaming the boundary $\partial D \to C$ (any contour enclosing all insertions) yields the *conformal Ward identity*:

$$\boxed{\delta_\epsilon\langle X\rangle = -\frac{1}{2\pi i}\oint_C \mathrm{d}z\,\epsilon(z)\,\langle T(z)\,X\rangle \;-\; \frac{1}{2\pi i}\oint_C \mathrm{d}\bar z\,\bar\epsilon(\bar z)\,\langle \bar T(\bar z)\,X\rangle} \tag{48.48}$$

where the antiholomorphic contour carries the orientation conjugate to the holomorphic one. This is the master formula of two-dimensional conformal field theory. It says: the response of *any* correlation function to *any* infinitesimal conformal transformation is computed by encircling the insertions with a contour and reading off the residues of the stress tensor's operator products. The infinite-dimensional symmetry, abstract in the Witt algebra, has become an explicit residue calculus. Notice that the choice -2π in (48.41) is exactly what produced the clean prefactor $-1/2\pi i$ here; this is the promised normalization check.

Physical Insight

The Ward identity is the precise sense in which $T(z)$ *is* the local conformal symmetry. A single insertion of $T(z)$, integrated against an arbitrary holomorphic parameter $\epsilon(z)$ on a contour, generates the most general infinitesimal holomorphic reparametrization. There is no separate "symmetry generator" to introduce: the stress tensor, the Noether current of translations, already contains the entire infinite tower because in two dimensions every conformal motion is built from T contracted with a holomorphic vector field. When we mode-expand $T(z)$ in the next section, these contours will become the Virasoro generators L_n.

48.2.3 Primary fields and the T–O operator product

The Ward identity is only useful once we know the singular operator product of $T(z)$ with the fields in the correlator. We now show that for a primary field this singular structure is completely fixed — it is forced to be a double pole plus a single pole, with coefficients dictated by the weight — and that this is the cleanest possible *definition* of a primary.

Recall from Theorem 48.3 the defining transformation law of a primary field of weights $(h,\bar h)$: under a holomorphic map $z\mapsto f(z)$, $\bar z\mapsto \bar f(\bar z)$,

$$O'(z',\bar z') = \Big(\frac{\mathrm{d}f}{\mathrm{d}z}\Big)^{-h}\Big(\frac{\mathrm{d}\bar f}{\mathrm{d}\bar z}\Big)^{-\bar h} O(z,\bar z), \tag{48.49}$$

so that $O(z,\bar z)\,(\mathrm{d}z)^h(\mathrm{d}\bar z)^{\bar h}$ is invariant. The infinitesimal version with $z'=z+\epsilon(z)$, $\bar z'=\bar z+\bar\epsilon(\bar z)$ is obtained by expanding $f'=1+\partial\epsilon$ and Taylor-expanding the argument; to first order,

$$\delta_\epsilon O(w,\bar w) = -\big(\,\epsilon(w)\,\partial + h\,\partial\epsilon(w)\,\big)O(w,\bar w) - \big(\,\bar\epsilon(\bar w)\,\bar\partial + \bar h\,\bar\partial\bar\epsilon(\bar w)\,\big)O(w,\bar w). \tag{48.50}$$

This is the transformation we must reproduce. Suppose the operator product of T with O has the Laurent form

$$T(z)\,O(w,\bar w) \sim \cdots + \frac{O^{(2)}(w,\bar w)}{(z-w)^2} + \frac{O^{(1)}(w,\bar w)}{z-w} + (\text{regular}), \tag{48.51}$$

with possibly higher-order poles indicated by the dots; here $\sim$ denotes equality up to terms regular as $z\to w$, in the sense of the operator product expansion of Theorem 47.46. Feed a single such operator into the Ward identity (48.48): the holomorphic variation of $O(w,\bar w)$ inside any correlator is the residue

$$\delta_\epsilon O(w,\bar w) = -\frac{1}{2\pi i}\oint_w \mathrm{d}z\,\epsilon(z)\,T(z)O(w,\bar w) = -\operatorname{Res}_{z\to w}\big[\epsilon(z)\,T(z)O(w,\bar w)\big], \tag{48.52}$$

the contour now shrunk to a small circle about w alone. Expanding $\epsilon(z)=\epsilon(w)+\partial\epsilon(w)\,(z-w)+\frac12\partial^2\epsilon(w)(z-w)^2+\cdots$ and extracting the coefficient of $(z-w)^{-1}$ in $\epsilon(z)\,T(z)O(w)$,

$$\delta_\epsilon O(w,\bar w) = -\Big[\,\epsilon(w)\,O^{(1)} + \partial\epsilon(w)\,O^{(2)} + \tfrac12\partial^2\epsilon(w)\,O^{(3)} + \cdots\Big], \tag{48.53}$$

where $O^{(3)}$ is the coefficient of the triple pole, and so on. Now compare term by term with the primary law (48.50). The coefficient of $\epsilon(w)$ forces $O^{(1)}=\partial O$; the coefficient of $\partial\epsilon(w)$ forces $O^{(2)}=h\,O$; and crucially the primary law (48.50) contains *no* $\partial^2\epsilon$, $\partial^3\epsilon,\dots$ terms, so all higher poles must vanish, $O^{(3)}=O^{(4)}=\cdots=0$. The operator product is therefore exactly a double pole plus a single pole:

$$\boxed{\,T(z)\,O(w,\bar w) \sim \frac{h\,O(w,\bar w)}{(z-w)^2} + \frac{\partial O(w,\bar w)}{z-w}\,} \tag{48.54}$$

with the antiholomorphic companion $\bar{T}(\bar{z})O(w,\bar{w}) \sim \bar{h}\,O/(\bar{z}-\bar{w})^2 + \bar{\partial}O/(\bar{z}-\bar{w})$. We take this as the working definition.

Definition 48.7 (Primary field via the stress tensor)**.** A local field $O(w,\bar{w})$ is *primary* of weights $(h,\bar{h})$ if its operator products with the holomorphic and antiholomorphic stress tensors terminate at the double pole, as in (48.54) and its conjugate, with no pole of order three or higher. Equivalently, by the computation above, O transforms covariantly under the full local conformal group according to (48.49). A field whose T–O product contains higher-order poles is called *non-primary*; the fields appearing in those higher poles are its *descendants* in the sense of Theorem 47.15, organized into the conformal family of O.

The two characterizations of a primary — the geometric transformation law (48.49) and the algebraic pole structure (48.54) — are now proved equivalent. The first is how a primary behaves; the second is how the theory detects it. The double pole measures the weight (the local scaling and rotation), the single pole is the translation ∂O, and the absence of higher poles is the precise statement that O is annihilated by the would-be raising part of the symmetry — a "highest-weight" condition that the next section will phrase as $L_n O = 0$ for $n > 0$.

48.2.4 The T–T operator product and the central charge

The natural next question is whether the stress tensor is itself a primary field. It is a holomorphic field of weight $(2,0)$: it carries two lower holomorphic indices, $T(z) \propto T_{zz}$, and the conformal factor $(\mathrm{d}z)^2$ shows it scales with $h=2$, $\bar{h}=0$. If T were primary, its self–operator product would, by (48.54) with $h=2$, be exactly

$$T(z)\,T(w) \overset{?}{\sim} \frac{2\,T(w)}{(z-w)^2} + \frac{\partial T(w)}{z-w}. \tag{48.55}$$

This cannot be the whole story. Dimensional analysis allows one further singular term. The product $T(z)T(w)$ has total holomorphic weight 4, so a term proportional to the identity operator dressed by $(z-w)^{-4}$ is permitted by scaling, with a c-number coefficient (the identity has weight zero, and $(z-w)^{-4}$ supplies the missing weight 4). No lower power of $(z-w)$ can multiply the identity: $(z-w)^{-3}$ times the identity has weight 3, odd under the exchange symmetry, and would require an operator of weight 1 which a unitary conformal theory built on the identity does not supply at this order; we confirm its absence by symmetry just below. The most general singular operator product consistent with holomorphy, weight $(2,0)$, and the presence of the identity in the spectrum is therefore

$$\boxed{T(z)\,T(w) \sim \frac{c/2}{(z-w)^4} + \frac{2\,T(w)}{(z-w)^2} + \frac{\partial T(w)}{z-w}} \tag{48.56}$$

The constant c is the *central charge*.

Definition 48.8 (Central charge)**.** The *central charge* c of a two-dimensional conformal field theory is the coefficient defined by the leading singularity of the holomorphic stress tensor's self–operator product, $T(z)T(w) \sim \frac{c/2}{(z-w)^4} + \cdots$, as in (48.56). The antiholomorphic sector carries an independent constant $\bar{c}$ defined identically from $\bar{T}(\bar{z})\bar{T}(\bar{w})$; for the theories of this chapter, built from local actions, $c = \bar{c}$. The number c is the unique central datum of the symmetry algebra: it is a property of the theory, not of any field, and it measures precisely the failure of T to be primary.

Three remarks fix the structure. First, the absence of the odd singularity. Bose symmetry of the stress tensor requires $T(z)T(w) = T(w)T(z)$ as an operator identity, hence the singular part must be symmetric under $z \leftrightarrow w$. Under this exchange $(z-w) \to -(z-w)$, so $(z-w)^{-4}$ is even (allowed for a constant coefficient), the pair $2T(w)/(z-w)^2 + \partial T(w)/(z-w)$ is symmetric once $T(w)$ is Taylor-expanded about z (we verify this directly in the worked example below), while an isolated $(z-w)^{-3}$ term would be odd and cannot be matched; it is therefore forbidden. Second, the two middle terms are non-negotiable: they are exactly (48.54) with $h = 2$, expressing that T *does* transform with weight 2 under translations and dilatations — the parts of the symmetry under which it is well-behaved. Third, the $c/2$ term is genuinely new information that no symmetry argument fixes; it is an anomaly, measured by the theory, and we now compute it for the canonical example.

Physical Insight

The central charge is the conformal field theory's irreducible quantum number. Heuristically it counts the "number of degrees of freedom": a free real boson contributes $c = 1$, a free Majorana fermion $c = \frac{1}{2}$, and in a precise sense (Zamolodchikov's c-theorem, the entanglement-entropy coefficient of Chapter 55, the Casimir energy on a cylinder) c controls the universal response of the theory to curvature and to finite size. It is the single number that distinguishes one conformal universality class from another at the level of the symmetry algebra, before any operator content is specified.

48.2.5 The finite transformation of T: the Schwarzian

Because T is not primary, it does not transform by the simple covariant law (48.49). We now compute its actual transformation, first infinitesimally from the T–T product, then integrate to the finite law. The result, the appearance of the Schwarzian derivative, is one of the most consequential formulas in the subject: it is what makes the central charge physically detectable, for example as the Casimir energy on a cylinder.

Apply the Ward identity (48.52) to $O = T$ using the full product (48.56). The infinitesimal variation is minus the residue of $\epsilon(z)T(z)T(w)$ at $z = w$. Expand $\epsilon(z) = \sum_{k\geq 0} \frac{1}{k!}\partial^k\epsilon(w)\,(z-w)^k$ and collect the coefficient of $(z-w)^{-1}$ from each term of (48.56):

$$\frac{c/2}{(z-w)^4}\,\epsilon(z): \qquad \frac{c}{2}\cdot\frac{1}{3!}\partial^3\epsilon(w) = \frac{c}{12}\,\partial^3\epsilon(w), \tag{48.57}$$

$$\frac{2T(w)}{(z-w)^2}\,\epsilon(z): \qquad 2T(w)\,\partial\epsilon(w), \tag{48.58}$$

$$\frac{\partial T(w)}{z-w}\,\epsilon(z): \qquad \epsilon(w)\,\partial T(w). \tag{48.59}$$

Summing and negating,

$$\delta_\epsilon T(w) = -\Big[\,\epsilon(w)\,\partial T(w) + 2\,\partial\epsilon(w)\,T(w) + \frac{c}{12}\,\partial^3\epsilon(w)\Big]. \tag{48.60}$$

The first two terms are exactly the weight-2 primary transformation (48.50) (with $h = 2$, $\bar h = 0$); the third, proportional to c and to the *third* derivative of the parameter, is the anomaly. It is inhomogeneous — a c-number shift, not a rescaling of T — which is why c is called a central extension: it commutes with everything.

We integrate (48.60) to a finite holomorphic map $z \mapsto w(z)$ (we relabel the target coordinate w for the moment). The natural ansatz is the covariant weight-2 law corrected by an additive anomalous piece $A(z)$ that must be built from the map and must vanish for the infinitesimal case to reproduce the $\partial^3\epsilon$ term:

$$T'(w) = \Big(\frac{\mathrm{d}w}{\mathrm{d}z}\Big)^{-2}\big[\,T(z) - \tfrac{c}{12}\,A(z)\,\big]. \tag{48.61}$$

We determine $A(z)$ by demanding two things: that it reduce to $\partial^3\epsilon$ infinitesimally, and that the composition of two transformations be consistent (the transformations form a group, so applying $z \to w$ then $w \to u$ must equal applying $z \to u$ directly). Both requirements are met by the *Schwarzian derivative*

$$\{w, z\} \equiv \frac{w'''}{w'} - \frac{3}{2}\Big(\frac{w''}{w'}\Big)^2, \qquad w' \equiv \frac{\mathrm{d}w}{\mathrm{d}z},\ \text{etc.}, \tag{48.62}$$

giving the finite transformation law of the stress tensor:

$$\boxed{\,T'(w) = \Big(\frac{\mathrm{d}w}{\mathrm{d}z}\Big)^{-2}\Big[\,T(z) - \frac{c}{12}\,\{w, z\}\,\Big]\,} \tag{48.63}$$

We verify both defining properties.

Infinitesimal check. Put $w = z+\epsilon(z)$, so $w' = 1+\partial\epsilon$, $w'' = \partial^2\epsilon$, $w''' = \partial^3\epsilon$. To first order in ϵ the squared term $(w''/w')^2 = (\partial^2\epsilon)^2(1+\cdots)$ is second order and

drops, while $w'''/w' = \partial^3\epsilon\,(1-\partial\epsilon+\cdots) = \partial^3\epsilon + O(\epsilon^2)$, so $\{w,z\} = \partial^3\epsilon(z) + O(\epsilon^2)$. The prefactor is $(1+\partial\epsilon)^{-2} = 1 - 2\partial\epsilon + O(\epsilon^2)$. Hence

$$T'(w) = (1-2\partial\epsilon)\,[T(z) - \tfrac{c}{12}\partial^3\epsilon] + O(\epsilon^2) = T(z) - 2\partial\epsilon\,T(z) - \tfrac{c}{12}\partial^3\epsilon + O(\epsilon^2). \tag{48.64}$$

The active variation at a fixed point is $\delta_\epsilon T(z) \equiv T'(z) - T(z)$. Since $T'(w) = T'(z+\epsilon) = T'(z) + \epsilon\,\partial T(z) + O(\epsilon^2)$, we move the shift to the left: $T'(z) = T'(w) - \epsilon\partial T(z) + O(\epsilon^2)$, and so

$$\delta_\epsilon T(z) = -\epsilon\,\partial T - 2\partial\epsilon\,T - \tfrac{c}{12}\partial^3\epsilon, \tag{48.65}$$

which is precisely (48.60). The Schwarzian is the correct integrated anomaly.

Composition (cocycle) check. For the finite law to be consistent under composition $z \xrightarrow{w} w \xrightarrow{u} u$, the Schwarzian must satisfy the chain rule

$$\{u,z\} = \Big(\frac{\mathrm{d}w}{\mathrm{d}z}\Big)^2\{u,w\} + \{w,z\}. \tag{48.66}$$

We verify this directly. Write $u'_z = u'_w\,w'_z$ (chain rule), and differentiate repeatedly. With shorthand $w' = w'_z$, $u'_w = \mathrm{d}u/\mathrm{d}w$,

$$\frac{\mathrm{d}u}{\mathrm{d}z} = u'_w\,w', \tag{48.67}$$

$$\frac{\mathrm{d}^2u}{\mathrm{d}z^2} = u''_w\,(w')^2 + u'_w\,w'', \tag{48.68}$$

$$\frac{\mathrm{d}^3u}{\mathrm{d}z^3} = u'''_w\,(w')^3 + 3u''_w\,w'\,w'' + u'_w\,w'''. \tag{48.69}$$

Form $\{u,z\} = \dfrac{\mathrm{d}^3u/\mathrm{d}z^3}{\mathrm{d}u/\mathrm{d}z} - \dfrac{3}{2}\Big(\dfrac{\mathrm{d}^2u/\mathrm{d}z^2}{\mathrm{d}u/\mathrm{d}z}\Big)^2$. The first ratio is

$$\frac{u'''_w(w')^3 + 3u''_w w' w'' + u'_w w'''}{u'_w w'} = (w')^2\frac{u'''_w}{u'_w} + 3\frac{u''_w}{u'_w}w'' + \frac{w'''}{w'}, \tag{48.70}$$

and the second, expanding the square,

$$\frac{3}{2}\Big(\frac{u''_w(w')^2 + u'_w w''}{u'_w w'}\Big)^2 = \frac{3}{2}\Big[(w')^2\Big(\frac{u''_w}{u'_w}\Big)^2 + 2\frac{u''_w}{u'_w}w'' + \Big(\frac{w''}{w'}\Big)^2\Big]. \tag{48.71}$$

Subtracting, the cross term $3(u''_w/u'_w)w''$ cancels against $\frac{3}{2}\cdot 2(u''_w/u'_w)w''$, and the survivors regroup as

$$\{u,z\} = (w')^2\Big[\frac{u'''_w}{u'_w} - \frac{3}{2}\Big(\frac{u''_w}{u'_w}\Big)^2\Big] + \Big[\frac{w'''}{w'} - \frac{3}{2}\Big(\frac{w''}{w'}\Big)^2\Big] = (w')^2\{u,w\} + \{w,z\}, \tag{48.72}$$

which is (48.66). This is exactly the inhomogeneous term required so that (48.63) composes correctly: the prefactors $(\mathrm{d}w/\mathrm{d}z)^{-2}$ multiply as a weight-2 tensor, and

the Schwarzian terms add up with precisely the cocycle weight that compensates. The anomaly is a one-cocycle on the group of holomorphic maps.

Möbius invariance. The Schwarzian vanishes on the global conformal group. For a Möbius map $w = (az + b)/(cz + d)$ with $ad - bc = 1$, one computes $\{w, z\} = 0$. The quickest route is the cocycle: every Möbius map is a composition of a translation $z \mapsto z + b$, a scaling $z \mapsto az$, and the inversion $z \mapsto 1/z$. The first two are affine, $w'' = 0$, so $\{w, z\} = 0$ trivially. For the inversion $w = 1/z$: $w' = -z^{-2}$, $w'' = 2z^{-3}$, $w''' = -6z^{-4}$, whence

$$\{1/z, z\} = \frac{-6z^{-4}}{-z^{-2}} - \frac{3}{2}\Big(\frac{2z^{-3}}{-z^{-2}}\Big)^2 = \frac{6}{z^2} - \frac{3}{2}\cdot\frac{4}{z^2} = 0. \tag{48.73}$$

By the cocycle (48.66), a composition of maps each with vanishing Schwarzian, multiplied by smooth nonzero prefactors, again has vanishing Schwarzian; hence $\{w, z\} = 0$ for every Möbius transformation. The physical consequence is decisive: under the *global* conformal group T transforms as an honest weight-2 primary, with no anomaly. The central charge is invisible to the finite-dimensional Möbius symmetry $\mathfrak{so}(3, 1)$ and surfaces only in the genuinely local, infinite-dimensional part of the symmetry — the part that distinguishes two dimensions from all higher dimensions. This is the same statement that the central extension of the Witt algebra to Virasoro affects only the modes L_n with $|n| \geq 2$, as we will see in Chapter 48.

Caution

The Schwarzian carries a definite weight: $\{w, z\}$ transforms with the factor $(\mathrm{d}w/\mathrm{d}z)^2$ in (48.66), not as a scalar. Consequently the shift $-\frac{c}{12}\{w, z\}$ in (48.63) is added to $T(z)$ *inside* the bracket, before the weight-2 prefactor acts. Reading the law with the Schwarzian outside the bracket, or as a scalar, is a common and physically wrong simplification — it would spoil the composition law just verified.

48.2.6 Worked example: the free boson has $c = 1$

We now compute the central charge of the simplest interacting-free conformal field theory, the massless free boson, directly from the definition (48.8), by Wick-contracting the T–T product. This is the foundational benchmark $c = 1$; every later construction (the Coulomb gas, the minimal models, the Ising fermion at $c = \frac{1}{2}$) is calibrated against it.

Worked Example 48.9 (Central charge of the free boson)**.** The massless free scalar in two Euclidean dimensions is governed, after the Wick rotation of Theorem 5.31, by the action

$$S = \frac{1}{8\pi}\int \mathrm{d}^2x\, \partial_\mu X\, \partial^\mu X = \frac{1}{2\pi}\int \mathrm{d}^2x\, \partial X\, \bar\partial X, \tag{48.74}$$

the second form using (48.36) and $\partial_\mu X \partial^\mu X = 4\,\partial X \bar\partial X$ in the complex frame; the normalization $1/8\pi$ is chosen so that the propagator has unit-normalized logarithm. The equation of motion is $\partial\bar\partial X = 0$, whose Green's function follows from (48.46): the two-point function (cf. Eq. (47.120) for the general primary form) is

$$\langle X(z,\bar z)\, X(w,\bar w)\rangle = -\ln|z-w|^2 = -\ln(z-w) - \ln(\bar z - \bar w). \tag{48.75}$$

The field X itself is not a good conformal primary (it appears only through its derivatives and exponentials), but its holomorphic derivative $\partial X(z)$ is. Differentiating (48.75) once in each argument gives the basic contraction we will use repeatedly,

$$\langle \partial X(z)\, \partial X(w)\rangle = \partial_z \partial_w\big[-\ln(z-w)\big] = \partial_z\Big[\frac{1}{z-w}\Big] = -\frac{1}{(z-w)^2}, \tag{48.76}$$

where $\partial_w[-\ln(z-w)] = 1/(z-w)$ was used. Write $a(z) \equiv \partial X(z)$ for brevity; (48.76) reads $\langle a(z)a(w)\rangle = -(z-w)^{-2}$.

The stress tensor. The classical stress tensor of (48.74) has holomorphic component $T_{zz} \propto (\partial X)^2$; in the normalization (48.41) the quantum stress tensor is the normal-ordered bilinear

$$T(z) = -\tfrac{1}{2}\,{:}\partial X(z)\,\partial X(z){:} = -\tfrac{1}{2}\,{:}a(z)a(z){:}, \tag{48.77}$$

the normal ordering $:\,:$ subtracting the (divergent) self-contraction so that $\langle T\rangle = 0$. We first confirm that ∂X is primary with $h = 1$, then compute c.

∂X is primary, $h = 1$. Compute $T(z)\,a(w)$ by Wick's theorem, contracting one $a(z)$ from T with the external $a(w)$ (there are two such contractions, one for each factor in $:a(z)a(z):$):

$$T(z)\,a(w) = -\tfrac{1}{2}\,{:}a(z)a(z){:}\,a(w) \sim -\tfrac{1}{2}\cdot 2\,\langle a(z)a(w)\rangle\, a(z) = -\Big(-\frac{1}{(z-w)^2}\Big)a(z) = \frac{a(z)}{(z-w)^2}. \tag{48.78}$$

Taylor-expanding the surviving operator about w, $a(z) = a(w) + (z-w)\partial a(w) + \cdots$, gives

$$T(z)\,\partial X(w) \sim \frac{\partial X(w)}{(z-w)^2} + \frac{\partial^2 X(w)}{z-w}, \tag{48.79}$$

which is exactly the primary form (48.54) with $h = 1$. The free boson's current ∂X is a weight-$(1,0)$ primary, as anticipated.

The T–T product and c. Now Wick-contract the full product, $T(z)T(w) = \frac{1}{4}\,{:}a(z)a(z){:}\,{:}a(w)a(w){:}$. By Wick's theorem the result is the sum over all contractions between the two normal-ordered groups (contractions *within* a group are removed by the normal ordering). There are two classes.

Double contractions. Contract both $a(z)$'s with both $a(w)$'s. There are 2 ways to pair them, each contributing $\langle a(z)a(w)\rangle^2$:

$$\tfrac{1}{4}\cdot 2\,\langle a(z)a(w)\rangle^2 = \tfrac{1}{2}\Big(-\frac{1}{(z-w)^2}\Big)^2 = \frac{1/2}{(z-w)^4}. \tag{48.80}$$

This is a pure c-number (the identity operator), with exactly the $(z-w)^{-4}$ singularity of (48.56). Matching $\frac{c/2}{(z-w)^4} = \frac{1/2}{(z-w)^4}$ gives

$$\boxed{c = 1} \tag{48.81}$$

Single contractions. Contract one $a(z)$ with one $a(w)$, leaving the other two normal-ordered. There are $2\times 2 = 4$ such pairings, each contributing $\langle a(z)a(w)\rangle\,{:}a(z)a(w){:}$:

$$\tfrac{1}{4}\cdot 4\,\langle a(z)a(w)\rangle\,{:}a(z)a(w){:} = -\frac{1}{(z-w)^2}\,{:}a(z)a(w){:}. \tag{48.82}$$

Taylor-expand the remaining bilinear about w: ${:}a(z)a(w){:} = {:}a(w)a(w){:} + (z-w)\,{:}\partial a(w)\,a(w){:} + \cdots$. By (48.77), ${:}aa{:} = -2T$, and differentiating, $\partial T = -\frac{1}{2}\partial\,{:}aa{:} = -\,{:}\partial a\,a{:}$, so ${:}\partial a\,a{:} = -\partial T$. Therefore

$$-\frac{1}{(z-w)^2}\Big[-2T(w) - (z-w)\partial T(w) + \cdots\Big] = \frac{2T(w)}{(z-w)^2} + \frac{\partial T(w)}{z-w} + \cdots, \tag{48.83}$$

the expected weight-2 terms of (48.56). Assembling the double and single contractions,

$$T(z)\,T(w) \sim \frac{1/2}{(z-w)^4} + \frac{2T(w)}{(z-w)^2} + \frac{\partial T(w)}{z-w}, \tag{48.84}$$

which is (48.56) with $c = 1$, with every coefficient — the central term, the weight-2 double pole, and the descendant single pole — reproduced from the single contraction datum (48.76). The free real boson is the $c = 1$ conformal field theory. (The same computation in the antiholomorphic sector gives $\bar{c} = 1$, and N independent free bosons give $c = N$, the additivity that justifies reading c as a count of degrees of freedom.)

Historical Note

That the stress tensor's self-product carries an anomalous c-number was isolated, in the language of current algebra, well before the systematic conformal bootstrap; the modern packaging — $T(z)$, its operator products, and the central charge as the unique extension — is due to Belavin, Polyakov, and Zamolodchikov in 1984, the paper that founded two-dimensional conformal field theory as a self-contained subject. The Schwarzian derivative itself is far older, appearing in Schwarz's nineteenth-century study of

conformal maps and hypergeometric monodromy; its reappearance here as the obstruction to T being a tensor is one of the cleaner instances of a classical geometric invariant resurfacing as a quantum anomaly.

We have promoted the kinematic symmetry of the previous section to a dynamical apparatus. The conformal Ward identity (48.48) computes any conformal variation as a contour integral of T; the T–O product (48.54) defines and detects primaries; the T–T product (48.56) introduces the central charge c; and the finite law (48.63) packages the anomaly as the Schwarzian, invisible to the global Möbius group and confined to the local symmetry. These two operator products, $T(z)T(w)$ with its anomalous $(c/2)(z-w)^{-4}$ term and $T(z)O(w)$, are exactly the data the next section converts into an operator algebra: mode-expanding $T(z)=\sum_n z^{-n-2}L_n$ on a quantization circle and translating the contour manipulations above into commutators will produce the Virasoro algebra, with c as its central extension and the Ward identity as the recursion that fixes every correlator carrying stress-tensor insertions.

48.3 Radial Quantization and the Virasoro Algebra

The previous section (Section 48.2) handed us two pieces of data and one geometric arena. The data are the operator product expansions

$$T(z)\,T(w) \;\sim\; \frac{c/2}{(z-w)^4} \;+\; \frac{2\,T(w)}{(z-w)^2} \;+\; \frac{\partial T(w)}{z-w}, \tag{48.85}$$

recalling Eq. (48.56), with the central charge c defined in Theorem 48.8 as the coefficient of the quartic pole, and the conformal Ward identity Eq. (48.48), whose local content is the $T\mathcal{O}$ OPE for a primary $\mathcal{O}$ of weight $(h,\bar h)$,

$$T(z)\,\mathcal{O}(w,\bar w) \;\sim\; \frac{h}{(z-w)^2}\,\mathcal{O}(w,\bar w) \;+\; \frac{\partial_w \mathcal{O}(w,\bar w)}{z-w}. \tag{48.86}$$

The arena is radial quantization (Section 47.5): on the Euclidean plane we quantize along circles of constant radius about a chosen origin, Euclidean "time" is $\tau=\ln r$ with $r=|z|$, the dilatation generator D is the Hamiltonian, and the state–operator map (Theorem 47.42) identifies states with operators inserted at the origin. So far this is kinematics. The purpose of the present section is to convert that kinematics into an *operator algebra*. We will mode-expand $T(z)$ on the quantization circles, read off generators L_n, and show that the contour calculus of complex analysis turns the single OPE Eq. (48.85) into a closed Lie-algebra bracket — the Virasoro algebra — with every structure constant, including the anomalous central term, fixed by the residues of Eq. (48.85). By the end we will have the weight operator L_0, raising and lowering operators $L_{n<0}$ and $L_{n>0}$, and the adjoint relation that makes "unitary" a meaningful word — precisely the input the next section needs to build representations.

48.3.1 Mode expansion of the stress tensor

Because $T(z)$ is holomorphic away from operator insertions, on any annulus free of insertions it has a Laurent expansion. The exponents are fixed by the conformal weight: T is a holomorphic field of weight $(2,0)$, so under $z \mapsto \lambda z$ it scales as $T \mapsto \lambda^{-2} T$, and the natural basis of modes carries one unit of weight each. We therefore write the expansion with a $-n-2$ shift so that the mode L_n lowers the weight by n.

Definition 48.10 (Virasoro modes)**.** The *Virasoro modes* L_n, $n \in \mathbb{Z}$, are the Laurent coefficients of the holomorphic stress tensor,

$$T(z) \;=\; \sum_{n\in\mathbb{Z}} \frac{L_n}{z^{\,n+2}}, \qquad L_n \;=\; \oint_0 \frac{\mathrm{d}z}{2\pi i}\, z^{\,n+1}\, T(z), \tag{48.87}$$

where the contour encircles the origin once counterclockwise. The antiholomorphic modes are defined identically from $\bar{T}(\bar{z}) = \sum_n \bar{L}_n\, \bar{z}^{-n-2}$, with $\bar{L}_n = \oint (\mathrm{d}\bar{z}/2\pi i)\, \bar{z}^{n+1} \bar{T}(\bar{z})$ taken with the conjugate orientation.

The inversion formula in Eq. (48.87) is the residue theorem (Theorem 5.23): inserting the series and using $\oint_0 (\mathrm{d}z/2\pi i)\, z^k = \delta_{k,-1}$ picks out the coefficient of z^{-1},

$$\oint_0 \frac{\mathrm{d}z}{2\pi i}\, z^{n+1} \sum_m \frac{L_m}{z^{m+2}} \;=\; \sum_m L_m \oint_0 \frac{\mathrm{d}z}{2\pi i}\, z^{\,n-m-1} \;=\; \sum_m L_m\, \delta_{n,m} \;=\; L_n, \tag{48.88}$$

so the two halves of Eq. (48.87) are consistent. The contour may be freely deformed across any annulus containing no insertions, because T is holomorphic there; this freedom is the entire computational engine of what follows.

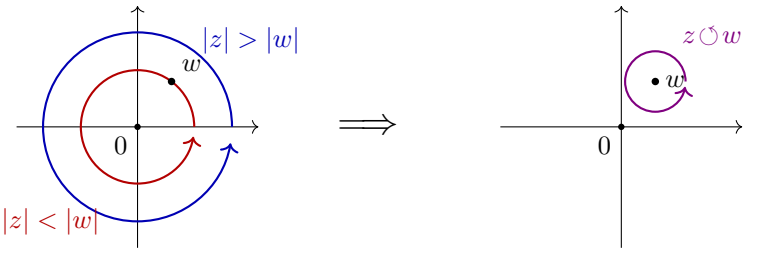
The modes act on the Hilbert space built by radial quantization. The vacuum $|0\rangle$ is the state created by inserting the identity at the origin. For $T(z)\,|0\rangle$ to be a well-defined (nonsingular) state as $z \to 0$ — equivalently, for the expansion $\sum_n L_n z^{-n-2}\,|0\rangle$ to contain no terms blowing up at the origin — every mode multiplying a negative power of z must annihilate the vacuum:

$$L_n\,|0\rangle = 0 \quad \text{for } n \geq -1. \tag{48.89}$$

Indeed the term $L_n z^{-n-2}\,|0\rangle$ is singular as $z \to 0$ precisely when $-n-2 < 0$, i.e. $n > -2$, i.e. $n \geq -1$; regularity of the state forces those modes to kill $|0\rangle$. The modes $L_{-2}, L_{-3}, \ldots$ instead create states: $L_{-2}\,|0\rangle = \lim_{z\to 0} T(z)\,|0\rangle$ is the state dual to the stress tensor itself. We will see in Eq. (48.101) that Eq. (48.89) is exactly the statement that $|0\rangle$ is invariant under the global conformal group.

48.3.2 Radial ordering and the commutator of modes

A product of two mode operators is a product of two contour integrals, and the order of the operators is encoded geometrically. In radial quantization the



(a) $L_m L_n - L_n L_m$ (b) $\oint_w$, then $\oint_0$

Figure 48.2: The contour-subtraction identity Eq. (48.91). (a) The mode commutator is the difference of two radial orderings: z outside w (blue) minus z inside w (red), at fixed w. (b) The difference collapses to a small z-contour encircling w, whose value the OPE Eq. (48.85) supplies through the residue theorem; the remaining w-integral runs around the origin.

time-ordering inherited from Section 47.5 is *radial ordering*: in a correlator the operator on a larger circle stands to the left. Thus the operator product $L_m L_n$ corresponds to the z-contour (carrying L_m) lying *outside* the w-contour (carrying L_n), $|z| > |w|$, while $L_n L_m$ corresponds to $|z| < |w|$:

$$L_m L_n \;=\; \oint_{|z|>|w|} \frac{\mathrm{d}z}{2\pi i} \oint_0 \frac{\mathrm{d}w}{2\pi i}\, z^{m+1} w^{n+1}\, R\{T(z)T(w)\}, \tag{48.90}$$

and likewise $L_n L_m$ with $|z| < |w|$, where $R\{\cdots\}$ is the radially ordered product whose short-distance behaviour is the OPE Eq. (48.85). The commutator is the *difference* of the two orderings. Fixing w and subtracting, the two z-contours — one just outside $|w|$, one just inside — combine into a single small contour that encircles the point $z = w$ and nothing else:

$$[L_m, L_n] \;=\; \oint_0 \frac{\mathrm{d}w}{2\pi i}\, w^{n+1} \oint_w \frac{\mathrm{d}z}{2\pi i}\, z^{m+1}\, T(z)\, T(w). \tag{48.91}$$

This is the basic move of the contour calculus: $\left(\oint_{|z|>|w|} - \oint_{|z|<|w|}\right)$ at fixed w equals $\oint_{z \circlearrowleft w}$, a contour deformation valid because the integrand is holomorphic in z except at $z = w$. The inner integral is now governed entirely by the short-distance OPE, and the residue theorem evaluates it.

48.3.3 The Virasoro algebra from the TT OPE

Theorem 48.11 (Virasoro algebra from the TT OPE)**.** *The modes Eq. (48.87) of a stress tensor obeying Eq. (48.85) satisfy*

$$[L_m, L_n] \;=\; (m-n)\, L_{m+n} \;+\; \frac{c}{12}\, m\,(m^2-1)\, \delta_{m+n,0}, \tag{48.92}$$

for all $m, n \in \mathbb{Z}$, together with the identical antiholomorphic copy $\left[\bar{L}_m, \bar{L}_n\right] = (m-n)\bar{L}_{m+n} + \frac{\bar{c}}{12} m(m^2-1)\delta_{m+n,0}$ and the mutual commutativity $\left[L_m, \bar{L}_n\right] = 0$. (For a parity-invariant theory $\bar{c} = c$.)

Proof. We evaluate the inner integral of Eq. (48.91) by substituting the OPE Eq. (48.85) for $T(z)T(w)$ and applying the residue theorem (Theorem 5.23). Recall that the residue of $f(z)/(z-w)^k$ at $z = w$ is $f^{(k-1)}(w)/(k-1)!$, the $(k-1)$th Taylor coefficient of the numerator. With $f(z) = z^{m+1}$, the three singular terms of the OPE contribute, in turn,

$$\frac{c}{2} \oint_w \frac{\mathrm{d}z}{2\pi i} \frac{z^{m+1}}{(z-w)^4} = \frac{c}{2} \cdot \frac{1}{3!} \frac{\mathrm{d}^3}{\mathrm{d}z^3} z^{m+1}\Big|_{z=w} = \frac{c}{2} \cdot \frac{(m+1)m(m-1)}{6} w^{m-2} = \frac{c}{12} (m \tag{48.93}$$

$$2\,T(w) \oint_w \frac{\mathrm{d}z}{2\pi i} \frac{z^{m+1}}{(z-w)^2} = 2\,T(w) \cdot \frac{\mathrm{d}}{\mathrm{d}z} z^{m+1}\Big|_{z=w} = 2\,(m+1)\,w^m\,T(w), \tag{48.94}$$

$$\partial T(w) \oint_w \frac{\mathrm{d}z}{2\pi i} \frac{z^{m+1}}{z-w} = \partial T(w) \cdot z^{m+1}\big|_{z=w} = w^{m+1}\,\partial T(w), \tag{48.95}$$

where the regular part of the OPE has no pole at $z = w$ and integrates to zero. Summing,

$$\oint_w \frac{\mathrm{d}z}{2\pi i}\, z^{m+1}\, T(z)T(w) = \frac{c}{12}\,(m+1)m(m-1)\,w^{m-2} + 2(m+1)\,w^m\,T(w) + w^{m+1}\,\partial T(w). \tag{48.96}$$

We now perform the outer w-integral of Eq. (48.91), multiplying Eq. (48.96) by w^{n+1} and integrating around the origin. Take the three terms separately.

Central term. The first term contains no operator, only the c-number w^{m-2}:

$$\frac{c}{12}\,(m+1)m(m-1) \oint_0 \frac{\mathrm{d}w}{2\pi i}\, w^{n+1}\, w^{m-2} = \frac{c}{12}\,(m+1)m(m-1) \oint_0 \frac{\mathrm{d}w}{2\pi i}\, w^{m+n-1}. \tag{48.97}$$

The remaining integral is $\delta_{m+n-1,-1} = \delta_{m+n,0}$ by the residue theorem. When $m+n=0$ we may write $n=-m$ and use $(m+1)m(m-1) = m(m^2-1)$, so this term is $\frac{c}{12}\,m(m^2-1)\,\delta_{m+n,0}$. This is the anomalous central term, and it arises *solely* from the quartic pole of the TT OPE: the third derivative in Eq. (48.93) is what produces the cubic $m(m^2-1)$, and the central charge enters exactly as it appeared in Theorem 48.8.

Operator terms. The second term of Eq. (48.96) gives, directly from Eq. (48.87),

$$2(m+1) \oint_0 \frac{\mathrm{d}w}{2\pi i}\, w^{n+1}\, w^m\, T(w) = 2(m+1) \oint_0 \frac{\mathrm{d}w}{2\pi i}\, w^{(m+n)+1}\, T(w) = 2(m+1)\, L_{m+n}. \tag{48.98}$$

The third term carries ∂T; we integrate by parts on the closed contour, where the total-derivative boundary term vanishes:

$$\oint_0 \frac{\mathrm{d}w}{2\pi i}\, w^{n+1}\, w^{m+1}\, \partial T(w) \;=\; \oint_0 \frac{\mathrm{d}w}{2\pi i}\, w^{m+n+2}\, \partial T(w) \;=\; -\oint_0 \frac{\mathrm{d}w}{2\pi i}\, \big(\partial_w\, w^{m+n+2}\big)\, T(w)$$
$$=\; -(m+n+2)\oint_0 \frac{\mathrm{d}w}{2\pi i}\, w^{(m+n)+1}\, T(w) \;=\; -(m+n+2)\, L_{m+n}. \tag{48.99}$$

Adding Eqs. (48.98) and (48.99), the operator part is

$$\big[\,2(m+1) - (m+n+2)\,\big]\, L_{m+n} \;=\; (m-n)\, L_{m+n}. \tag{48.100}$$

Combining the central and operator contributions reproduces Eq. (48.92). The antiholomorphic copy follows identically from the $\bar{T}\bar{T}$ OPE, and $\big[L_m, \bar{L}_n\big] = 0$ because $T(z)\bar{T}(\bar{w})$ has no singular OPE — the holomorphic and antiholomorphic sectors are mutually local, so the inner contour of z around $\bar{w}$ encloses no singularity and the commutator vanishes. □

Three features of Eq. (48.92) deserve emphasis. First, dropping the central term leaves $[L_m, L_n] = (m-n)L_{m+n}$, the *Witt algebra* of holomorphic vector fields $\ell_n = -z^{n+1}\partial_z$ on the punctured plane: indeed $[\ell_m, \ell_n] = (m-n)\ell_{m+n}$ by direct computation, and the Witt algebra is the classical (centreless) algebra of local conformal transformations promised in the chapter chapter introduction. Second, the Virasoro algebra is the *unique* central extension of Witt by a one-dimensional centre, and Theorem 48.11 shows the quantum theory realizes exactly this extension with the coefficient fixed by the OPE data. Third, the central term is not removable by redefining the generators except in a trivial way: one may shift $L_0 \to L_0 + \text{const}$ to absorb a piece linear in m, but the cubic m^3 piece is a genuine cohomological obstruction. We make this precise next.

48.3.4 The global subalgebra and the vanishing of the central term

The central term in Eq. (48.92) is proportional to $m(m^2-1) = (m-1)m(m+1)$, which vanishes identically for $m \in \{-1, 0, 1\}$. Therefore the three modes L_{-1}, L_0, L_1 close among themselves with *no* anomaly:

$$[L_0, L_{\pm 1}] = \mp\, L_{\pm 1}, \qquad [L_1, L_{-1}] = 2\, L_0. \tag{48.101}$$

These follow from Eq. (48.92): $[L_0, L_1] = (0-1)L_1 = -L_1$, $[L_0, L_{-1}] = (0+1)L_{-1} = +L_{-1}$, and $[L_1, L_{-1}] = (1-(-1))L_0 = 2L_0$ with $\frac{c}{12}\cdot 1\cdot(1-1)\cdot\delta_{0,0} = 0$. The brackets Eq. (48.101) are precisely those of $\mathfrak{sl}(2,\mathbb{C})$ (equivalently $\mathfrak{so}(3,1)$), with L_0 the Cartan element and $L_{\pm 1}$ the raising/lowering pair. This is a *Lie*

subalgebra in the sense of Theorem 2.39: closed under the bracket and obeying the Jacobi identity.

Together with the antiholomorphic triple $\{\bar{L}_{-1}, \bar{L}_0, \bar{L}_1\}$, these generate $\mathfrak{sl}(2,\mathbb{C})\oplus \mathfrak{sl}(2,\mathbb{C})$, the algebra of the *global* conformal group of the Riemann sphere — the Möbius transformations $z \mapsto (az+b)/(cz+d)$ with $ad-bc=1$. This is exactly the $d=2$ instance of the finite-dimensional conformal algebra $\mathfrak{so}(d+1,1)$ derived in general dimension in Chapter 47: for $d=2$, $\mathfrak{so}(3,1) \cong \mathfrak{sl}(2,\mathbb{C})$, and the dimension count $\frac{1}{2}(d+1)(d+2) = 6$ matches the six real generators $\{L_{0,\pm1}, \bar{L}_{0,\pm1}\}$. The dictionary with the Cartesian generators of Chapter 47 is

$$L_{-1} = \text{(holomorphic) translation}, \quad L_0+\bar{L}_0 = \text{dilatation}, \quad L_0-\bar{L}_0 = \text{rotation}, \quad L_1 = \text{speci} \tag{48.102}$$

read off from the vector fields $\ell_{-1} = -\partial_z$, $\ell_0 = -z\partial_z$, $\ell_1 = -z^2\partial_z$. The miracle of two dimensions, foretold in the chapter introduction, is now visible at the level of the algebra: the global $\mathfrak{so}(3,1)$ is just the $|n| \le 1$ corner of an *infinite* tower $\{L_n\}_{n\in\mathbb{Z}}$, and it is this infinite enhancement, anomalous for $|n| \ge 2$, that ultimately solves the theory.

The vanishing of the anomaly on $\{L_{-1}, L_0, L_1\}$ also re-derives Eq. (48.89) from a symmetry principle. A state invariant under the global conformal group must be annihilated by L_{-1}, L_0, L_1 (and their conjugates); but $|0\rangle$ is the unique $\mathfrak{sl}(2,\mathbb{C}) \oplus \mathfrak{sl}(2,\mathbb{C})$-invariant state, so $L_{-1}|0\rangle = L_0|0\rangle = L_1|0\rangle = 0$. Acting repeatedly with the higher modes $L_{-2}, L_{-3}, \dots$ on $|0\rangle$ then generates the rest of the vacuum module, while the condition $L_n|0\rangle = 0$ for all $n \ge -1$ is forced by regularity of $T(z)|0\rangle$ at the origin, as in Eq. (48.89).

48.3.5 L_0 as the Hamiltonian and primary states

Under the state–operator map (Theorem 47.42), every state of the radial-quantization Hilbert space is $\lim_{z,\bar{z}\to 0} \mathcal{O}(z,\bar{z})|0\rangle$ for some local operator $\mathcal{O}$, and the dilatation generator D is the Hamiltonian conjugate to radial time $\tau = \ln r$. In the mode language $D = L_0 + \bar{L}_0$: the combination that scales z and $\bar{z}$ together. The difference $L_0 - \bar{L}_0$ generates rotations and measures spin. We make this concrete by computing how the modes act on the state of a primary.

Definition 48.12 (Primary state)**.** Let $\mathcal{O}$ be a primary of weight $(h,\bar{h})$. The associated *primary state* is

$$\left|h,\bar{h}\right\rangle \equiv \lim_{z,\bar{z}\to 0} \mathcal{O}(z,\bar{z})|0\rangle\,. \tag{48.103}$$

A state $|h\rangle$ (suppressing the antiholomorphic label) is called a *(holomorphic) highest-weight* or *primary* state if

$$L_0|h\rangle = h|h\rangle\,, \qquad L_n|h\rangle = 0 \quad \text{for all } n>0, \tag{48.104}$$

with the analogous statements for $\bar{L}_0, \bar{L}_{n>0}$.

That Eq. (48.103) satisfies Eq. (48.104) is not a postulate; it follows from the $T\mathcal{O}$ OPE Eq. (48.86) by the same residue calculus. Act with the mode L_n on $|h\rangle$ using Eq. (48.87) with the contour shrunk to the operator at the origin:

$$L_n\,|h\rangle \;=\; \oint_0 \frac{\mathrm{d}z}{2\pi i}\, z^{n+1}\, T(z)\,\mathcal{O}(0)\,|0\rangle \;=\; \oint_0 \frac{\mathrm{d}z}{2\pi i}\, z^{n+1}\left[\frac{h}{z^2}\,\mathcal{O}(0) + \frac{\partial\mathcal{O}(0)}{z} + \text{regular}\right]|0\rangle\,, \tag{48.105}$$

where we set $w = 0$ in Eq. (48.86) and used that the regular terms are $z \to 0$ finite. The residue theorem extracts the coefficient of z^{-1} in the integrand:

$$L_n\,|h\rangle \;=\; h\,\big[\,z^{n-1}\,\big]_{z^{-1}}\,\mathcal{O}(0)\,|0\rangle + \big[\,z^{n}\,\big]_{z^{-1}}\,\partial\mathcal{O}(0)\,|0\rangle + \big(\text{regular: no } z^{-1} \text{ for } n \geq 0\big), \tag{48.106}$$

where $\big[\,z^{k}\,\big]_{z^{-1}}$ denotes the residue, nonzero only when $k = -1$. The first bracket contributes when $n - 1 = -1$, i.e. $n = 0$, giving $L_0\,|h\rangle = h\,\mathcal{O}(0)\,|0\rangle = h\,|h\rangle$. The second contributes when $n = -1$, giving $L_{-1}\,|h\rangle = \partial\mathcal{O}(0)\,|0\rangle$. For $n > 0$ neither singular term and, since a primary's OPE with T has *no* poles deeper than $1/(z-w)^2$, none of the regular terms produce a z^{-1}; hence $L_n\,|h\rangle = 0$ for all $n > 0$. This proves Eq. (48.104) and identifies h with the holomorphic weight in Eq. (48.86). The state $L_{-1}\,|h\rangle = \partial\mathcal{O}(0)\,|0\rangle$ is the first *descendant*; the higher modes $L_{-2}, L_{-3}, \ldots$ create the rest of the tower, the subject of the next section.

The pieces now assemble into the physical picture promised at the start. From Eq. (48.92), $[L_0, L_n] = -n\,L_n$, so L_n shifts the L_0-eigenvalue by $-n$: the modes with $n > 0$ *lower* the weight (they are annihilation/lowering operators, killing primaries), while those with $n < 0$ *raise* it (creation operators). Thus L_0 is the holomorphic energy, $L_{n>0}$ lowering operators, $L_{n<0}$ raising operators — the ladder structure of a highest-weight representation, with the primary state sitting at the bottom.

48.3.6 Radial conjugation and the adjoint $L_n^\dagger = L_{-n}$

To speak of unitarity — of positive norms and a Hermitian Hamiltonian — we need the adjoint of L_n. In a Lorentzian theory adjoints come from Hermitian conjugation at fixed time; in radial quantization the analogue is conjugation across the quantization circle. Hermitian conjugation reverses Euclidean time $\tau = \ln r$, hence sends $r \to 1/r$ at fixed angle, i.e. it is implemented by the conformal map

$$z \;\longmapsto\; \frac{1}{\bar{z}}, \tag{48.107}$$

which exchanges the origin (where the in-vacuum lives) with the point at infinity (where the out-vacuum lives), keeping the unit circle fixed pointwise. The adjoint of a holomorphic primary $\phi(z)$ of weight h is therefore not simply $\phi(\bar{z})^*$; it must include the conformal Jacobian of Eq. (48.107) so that the conjugate of an in-state is a sensible out-state. With $z' = 1/\bar{z}$ and $\mathrm{d}z'/\mathrm{d}z\big|_{\ldots}$ supplying the

weight factor, the radial-quantization (BPZ) adjoint is

$$\big[\phi(z)\big]^{\dagger} \;=\; \bar{z}^{-2h}\,\phi\!\left(\frac{1}{\bar{z}}\right). \tag{48.108}$$

The factor $\bar{z}^{-2h}$ is exactly $\left|\mathrm{d}z'/\mathrm{d}z\right|^{h}$ for the map Eq. (48.107) written for a weight-h field; it is what guarantees, for example, that the out-state $\langle h| = \lim_{z\to\infty} z^{2h}\,\langle 0|\,\mathcal{O}(z)$ is the genuine Hermitian conjugate of the in-state $|h\rangle = \lim_{z\to 0}\mathcal{O}(z)\,|0\rangle$, and hence that the two-point normalization $\langle h|h\rangle$ is finite and conjugation-symmetric.

Apply Eq. (48.108) to the stress tensor, a holomorphic field of weight $h = 2$. On one hand, conjugating the mode expansion Eq. (48.87) term by term (the coefficients z^{-n-2} are c-numbers, conjugated to $\bar{z}^{-n-2}$),

$$\big[T(z)\big]^{\dagger} \;=\; \sum_{n\in\mathbb{Z}} L_n^{\dagger}\,\bar{z}^{-n-2}. \tag{48.109}$$

On the other hand, Eq. (48.108) with $h = 2$ gives

$$\big[T(z)\big]^{\dagger} \;=\; \bar{z}^{-4}\,T\!\left(\frac{1}{\bar{z}}\right) \;=\; \bar{z}^{-4}\sum_{n} L_n\,\big(\bar{z}^{-1}\big)^{-n-2} \;=\; \bar{z}^{-4}\sum_{n} L_n\,\bar{z}^{\,n+2} \;=\; \sum_{n} L_n\,\bar{z}^{\,n-2}. \tag{48.110}$$

Relabel the summation index $n \to -n$ in Eq. (48.110), so that $\bar{z}^{n-2} \to \bar{z}^{-n-2}$ and $L_n \to L_{-n}$:

$$\big[T(z)\big]^{\dagger} \;=\; \sum_{n} L_{-n}\,\bar{z}^{-n-2}. \tag{48.111}$$

Matching the coefficient of each power $\bar{z}^{-n-2}$ between Eq. (48.109) and Eq. (48.111) yields the adjoint relation

$$\boxed{\,L_n^{\dagger} \;=\; L_{-n}\,}. \tag{48.112}$$

In particular $L_0^{\dagger} = L_0$: the holomorphic Hamiltonian is Hermitian, so weights h are real, as a unitary theory requires. Equally, $L_n^{\dagger} = L_{-n}$ means the raising operators L_{-n} are the adjoints of the lowering operators L_n — exactly the structure that lets us compute norms of descendant states by commuting lowering past raising operators with Eq. (48.92).

Worked Example 48.13 (The first descendant norm and the seed of unitarity)**.** We compute the norm of the level-one descendant $L_{-1}\,|h\rangle$ of a primary, the smallest nontrivial check that the algebra plus the adjoint relation produce physical content. Using Eq. (48.112), $\big(L_{-1}\,|h\rangle\,\big)^{\dagger} = \langle h|\,L_1$, so the norm is

$$\big\|L_{-1}\,|h\rangle\,\big\|^{2} \;=\; \langle h|\;L_1\,L_{-1}\;|h\rangle\,. \tag{48.113}$$

Move L_1 to the right using the Virasoro bracket Eq. (48.92) with $m = 1, n = -1$:

$$L_1L_{-1} \;=\; L_{-1}L_1+[L_1,L_{-1}] \;=\; L_{-1}L_1+2L_0+\frac{c}{12}\cdot 1\cdot(1-1)\,\delta_{0,0} \;=\; L_{-1}L_1+2L_0, \tag{48.114}$$

the central term vanishing because $m(m^2-1)=0$ at $m=1$. Now act on $|h\rangle$: by the primary condition Eq. (48.104), $L_1|h\rangle = 0$, while $L_0|h\rangle = h|h\rangle$. Hence

$$\|L_{-1}|h\rangle\|^2 \;=\; \langle h|\,(L_{-1}L_1 + 2L_0)\,|h\rangle \;=\; 2h\,\langle h|h\rangle\,. \tag{48.115}$$

For a unitary theory norms are nonnegative and $\langle h|h\rangle > 0$, so this forces $h \geq 0$: the weight of any state in a unitary 2D CFT is bounded below by zero, with $h=0$ only for the identity (whose descendant $L_{-1}|0\rangle = 0$ vanishes, consistent with Eq. (48.89)). This single computation already exhibits the mechanism of the next section: positivity of a Gram matrix element, built from the algebra and Eq. (48.112), turns into a constraint on the spectrum. The full systematic version — the Kac determinant and the unitarity bounds isolating the minimal-model values of c — is Theorem 48.18.

We now have the complete operator-algebraic backbone of two-dimensional conformal field theory: the Virasoro algebra Eq. (48.92) with its central term derived from the TT OPE, the weight operator L_0 (the radial Hamiltonian), the lowering operators $L_{n>0}$ that annihilate primaries, the raising operators $L_{n<0}$ that build descendants, and the adjoint relation $L_n^\dagger = L_{-n}$ that makes norms computable. The next section (Section 48.4) takes exactly this package as input: it organizes the Hilbert space into Verma modules generated by acting with the raising operators on primary states, computes the Gram matrix of descendant inner products, and extracts from its determinant the null states and the unitarity constraints that single out $c \geq 1$ and the discrete minimal-model series at $c < 1$.

48.4 Highest-Weight Representations, Null States, and Unitarity

The previous section turned the local conformal symmetry of a two-dimensional theory into an honest operator algebra. The chiral stress tensor was expanded into modes L_n obeying the Virasoro algebra

$$[L_m, L_n] = (m-n)\,L_{m+n} + \frac{c}{12}\,m(m^2-1)\,\delta_{m+n,0}, \tag{48.116}$$

which is Eq. (48.92); the state–operator map of Chapter 47 attached to every local operator a state in a Hilbert space; and the reality of the stress tensor was encoded in the adjointness relation $L_n^\dagger = L_{-n}$. A *primary state* $|h\rangle$ (Theorem 48.12) was singled out as the lowest-energy vector of an irreducible block of the symmetry: it diagonalizes the dilatation generator L_0 with eigenvalue h, the holomorphic conformal weight, and is annihilated by every lowering operator,

$$L_0|h\rangle = h|h\rangle\,, \qquad L_n|h\rangle = 0 \quad (n>0). \tag{48.117}$$

The antiholomorphic copy $\bar{L}_n$ acts identically on $\left|\bar{h}\right\rangle$ and commutes with everything chiral, so for the rest of this section we suppress it and study one chiral half; the full Hilbert space is a sum of tensor products of a holomorphic and an antiholomorphic representation, and every statement below has a mirror image.

What we have so far is a single algebra and a distinguished class of vectors it annihilates from below. What we do not yet have is the *spectrum*: which weights h and which central charges c actually occur in a sensible (in particular, a unitary) theory, and how the infinitely many states built by acting with raising operators on a primary organize themselves. This section supplies that representation theory. We build the *Verma module* — the universal representation generated freely from a primary — grade it by level, and equip it with the inner product that $L_n^\dagger = L_{-n}$ forces upon it. The matrix of inner products at each level is the *Gram matrix*; its determinant is the *Kac determinant*, a polynomial in h and c whose zeros locate the weights at which the representation degenerates. At those special weights a *null* (singular) vector appears: a descendant that is itself primary, has zero norm, and is orthogonal to everything. We prove that such a vector generates a sub-representation that must be quotiented away, leaving an irreducible *degenerate* representation with far fewer states. Finally we impose unitarity — positivity of the inner product — and extract the constraint that organizes the entire landscape of two-dimensional CFT: positivity is automatic for $c \geq 1,\ h \geq 0$, but for $0 < c < 1$ it survives only at the discrete Friedan–Qiu–Shenker values $c = 1 - 6/[m(m+1)]$, $m = 3, 4, 5, \ldots$, and there only for a finite list of weights. This is the data the next section turns into the minimal models.

Throughout, the rep-theoretic vocabulary — modules, highest-weight vectors, irreducibility by quotient — is the one built in Chapter 48's prerequisite Theorems 2.7 and 2.74; the Virasoro algebra simply replaces the finite-dimensional Lie algebras of Part I with an infinite-dimensional one, and the highest-weight construction goes through verbatim once "highest weight" is read as "annihilated by all $L_{n>0}$."

48.4.1 Verma modules and the level grading

A primary state is, by Eq. (48.117), killed by every L_n with $n > 0$. The only generators that can act nontrivially and produce new states are the raising operators L_{-n} with $n > 0$ (and L_0, which merely measures energy). Applying them in all possible ways generates the orbit of $|h\rangle$ under the algebra. The cleanest object to study first is the orbit with *no relations imposed beyond the algebra itself*: act freely, declare two states equal only when the commutation relations Eq. (48.116) force them to be. This is the Verma module.

Definition 48.14 (Verma module)**.** Let $c \in \mathbb{C}$ and $h \in \mathbb{C}$. The *Verma module* $V(c, h)$ is the representation of the Virasoro algebra generated by a single highest-weight vector $|h\rangle$ satisfying Eq. (48.117), freely under the raising operators.

Concretely, $V(c,h)$ is the complex vector space with basis

$$L_{-n_1}L_{-n_2}\cdots L_{-n_k}\,|h\rangle\,, \qquad n_1 \geq n_2 \geq \cdots \geq n_k \geq 1, \quad k \geq 0, \tag{48.118}$$

(the case $k = 0$ being $|h\rangle$ itself), with the Virasoro generators acting by Eq. (48.116) and by Eq. (48.117).

The ordering $n_1 \geq \cdots \geq n_k$ in Eq. (48.118) is a normal-ordering convention, not a restriction: any product of L_{-n}'s can be brought to this form using Eq. (48.116), since a commutator $[L_{-m}, L_{-n}] = (n-m)L_{-m-n}$ replaces an out-of-order pair by a lower-length monomial, and the recursion terminates. That the ordered monomials are moreover linearly *independent* — so that Eq. (48.118) is a genuine basis — is the Poincaré–Birkhoff–Witt theorem for the universal enveloping algebra of the Virasoro algebra; we take it as the defining freeness of the Verma module. (When h, c are such that a relation *is* forced, it does not appear inside $V(c,h)$ but as a statement that a certain basis vector is null and generates a submodule to be quotiented; that is the content of Section 48.4.4.)

The descendants are the non-primary states of the module.

Definition 48.15 (Descendant state and level)**.** A basis vector Eq. (48.118) with $k \geq 1$ is a *descendant* of the primary $|h\rangle$. Its *level* is

$$N = n_1 + n_2 + \cdots + n_k \;\geq\; 1, \tag{48.119}$$

the total number of units of energy added by the raising operators. The primary itself has level $N = 0$.

The level is exactly the L_0-grading. Since $[L_0, L_{-n}] = n\,L_{-n}$ (read off Eq. (48.116) with $m = 0$), each raising operator L_{-n} increases the L_0 eigenvalue by n, so the monomial Eq. (48.118) is an L_0 eigenvector with eigenvalue $h + N$:

$$L_0\left(L_{-n_1}\cdots L_{-n_k}\,|h\rangle\right) = (h+N)\,L_{-n_1}\cdots L_{-n_k}\,|h\rangle\,. \tag{48.120}$$

The Verma module is therefore a graded vector space,

$$V(c,h) = \bigoplus_{N=0}^{\infty} V_N, \qquad V_N = \{\text{level-}N \text{ states}\}, \tag{48.121}$$

with V_0 one-dimensional (spanned by $|h\rangle$). The dimension of V_N is the number of ways to write N as an ordered sum $n_1 \geq \cdots \geq n_k \geq 1$ — the number of partitions of N:

$$\dim V_N = p(N), \qquad p(0)=1,\ p(1)=1,\ p(2)=2,\ p(3)=3,\ p(4)=5,\ldots \tag{48.122}$$

At level 1 the single state is $L_{-1}\,|h\rangle$; at level 2 the two states are $L_{-2}\,|h\rangle$ and $L_{-1}^2\,|h\rangle$; at level 3 the three are $L_{-3}\,|h\rangle$, $L_{-1}L_{-2}\,|h\rangle$, $L_{-1}^3\,|h\rangle$; and so on. (The generating function $\sum_N p(N)q^N = \prod_{k\geq 1}(1-q^k)^{-1}$ will reappear in the next section as the holomorphic part of the Virasoro character.)

Physical Insight

The Verma module is the field-theoretic statement that a primary operator drags an infinite tower of descendant operators behind it: each L_{-n} is, under the state–operator map of Chapter 47, the operation of taking a contour-integrated product with the stress tensor, i.e. $L_{-n}\,\mathcal{O}(0) \leftrightarrow \oint \frac{dz}{2\pi i}\, z^{1-n}\, T(z)\mathcal{O}(0)$. The descendants are the operators $\partial^k\mathcal{O}$, $(T\mathcal{O})$, and their kin — the symmetry images of $\mathcal{O}$. The whole content of a conformal family is fixed by the single number h once c is given, because the action of the algebra is universal. This is why two-dimensional CFT can be solved: the dynamics is reduced to a list of weights h together with the rules for how families fuse, with no further functional freedom inside a family.

48.4.2 The contravariant form and the Gram matrix

A representation appearing in a quantum theory is not a bare vector space: it carries an inner product, the one in which probabilities are computed. On a Verma module that inner product is uniquely fixed, up to the normalization $\langle h|h\rangle = 1$, by two inputs: the adjointness relation $L_n^\dagger = L_{-n}$ inherited from the reality of the stress tensor, and the highest-weight conditions Eq. (48.117). We make this explicit.

Definition 48.16 (Contravariant form)**.** The *contravariant* (or *Shapovalov*) *form* on $V(c,h)$ is the unique Hermitian sesquilinear pairing $\langle\,\cdot\,,\,\cdot\,\rangle$ with $\langle h|h\rangle = 1$ and $L_n^\dagger = L_{-n}$ for all n. On two basis descendants it is computed by moving all raising operators of the bra to the right as lowering operators acting on $|h\rangle$, using Eq. (48.116), until only the highest-weight matrix element $\langle h|h\rangle$ survives.

Two structural facts make this form computable and block-diagonal. First, states of different level are orthogonal: if $|\psi\rangle \in V_N$ and $|\phi\rangle \in V_{N'}$ then

$$\langle\psi,\phi\rangle = \langle\psi|\,|\phi\rangle\,, \qquad (N-N')\langle\psi,\phi\rangle = \langle\psi,(L_0 - L_0^\dagger)\text{-difference}\rangle = 0, \tag{48.123}$$

because $L_0^\dagger = L_0$ is self-adjoint and $|\psi\rangle\,,|\phi\rangle$ are its eigenvectors with eigenvalues $h+N$ and $h+N'$; distinct eigenvalues of a self-adjoint operator have orthogonal eigenvectors. The pairing therefore reduces to a finite $p(N)\times p(N)$ matrix on each graded piece V_N. Second, that finite matrix is Hermitian, because the form is.

Definition 48.17 (Gram matrix at level N)**.** Fix an ordered basis $\{|N;i\rangle\}_{i=1}^{p(N)}$ of V_N as in Eq. (48.118). The *Gram matrix* (or *Gram–Shapovalov matrix*) at level N is

$$\big(M_N\big)_{ij}(c,h) = \langle N;i\,,\,N;j\rangle, \tag{48.124}$$

a Hermitian $p(N)\times p(N)$ matrix whose entries are polynomials in h and c. The state $\sum_i a_i\,|N;i\rangle$ has squared norm $a^\dagger M_N\,a$.

The Gram matrix is the entire question of the section in matrix form. The representation has a positive-definite inner product on V_N if and only if $M_N \succ 0$; it has a zero-norm vector at level N exactly when $\det M_N = 0$; and it has a negative-norm vector (a "ghost," fatal to unitarity) when M_N has a negative eigenvalue. We now compute M_1 and M_2 in full, both to see the machine work and because these two cases already expose the entire mechanism.

Level one

There is a single state, $L_{-1}|h\rangle$, so M_1 is a 1×1 matrix — a number, its norm:

$$(M_1)_{11} = \langle h|L_1\, L_{-1}|h\rangle = \langle h|[L_1, L_{-1}] + L_{-1}L_1|h\rangle\,. \tag{48.125}$$

The second term vanishes because $L_1|h\rangle = 0$. For the commutator, Eq. (48.116) with $m = 1, n = -1$ gives $[L_1, L_{-1}] = (1-(-1))L_0 + \frac{c}{12}(1)(1^2-1)\delta_{0,0} = 2L_0$ (the central term carries $m(m^2-1) = 0$). Hence

$$\boxed{(M_1)_{11} = \langle h|2L_0|h\rangle = 2h.} \tag{48.126}$$

The first lesson is already here: the norm of the unique level-one descendant is $2h$. It is positive for $h > 0$, vanishes at $h = 0$, and is *negative for* $h < 0$. A representation with $h < 0$ therefore contains a negative-norm state at the very first level and cannot be unitary. This is the rigorous origin of the bound $h \geq 0$.

Level two

Now there are two states, and the matrix is genuinely a matrix. Order the level-two basis as

$$|2;1\rangle = L_{-2}|h\rangle\,, \qquad |2;2\rangle = L_{-1}^2|h\rangle\,. \tag{48.127}$$

We need three independent entries: $\langle h|L_2L_{-2}|h\rangle$, $\langle h|L_2L_{-1}^2|h\rangle$, and $\langle h|L_1^2L_{-1}^2|h\rangle$ (the off-diagonal entry is real and symmetric, and we will verify the two ways of computing it agree). We carry every commutator.

For the $(1,1)$ entry,

$$\langle h|L_2L_{-2}|h\rangle = \langle h|[L_2, L_{-2}]|h\rangle\,, \tag{48.128}$$

since $L_2|h\rangle = 0$. From Eq. (48.116) with $m = 2, n = -2$:

$$[L_2, L_{-2}] = (2-(-2))L_0 + \frac{c}{12}\,2(2^2-1)\,\delta_{0,0} = 4L_0 + \frac{c}{12}\cdot 6 = 4L_0 + \frac{c}{2}. \tag{48.129}$$

Thus

$$(M_2)_{11} = 4h + \frac{c}{2}. \tag{48.130}$$

The central charge makes its first appearance in a norm here: the level-two stress-tensor descendant $L_{-2}\,|h\rangle$ "knows" about c because L_{-2} is the mode that creates a stress-tensor quantum, and c is the norm of the stress tensor itself (the vacuum case $h = 0$ gives $\langle T, T\rangle \propto c/2$).

For the $(2, 2)$ entry we need $L_1^2 L_{-1}^2\,|h\rangle$. Build it in stages. First,

$$L_1 L_{-1}\,|h\rangle = [L_1, L_{-1}]\,|h\rangle = 2L_0\,|h\rangle = 2h\,|h\rangle\,, \tag{48.131}$$

using Eq. (48.125)–Eq. (48.126). Next we need $L_1\,L_{-1}^2\,|h\rangle$. Commute L_1 through the pair:

$$\left[L_1, L_{-1}^2\right] = [L_1, L_{-1}]\,L_{-1} + L_{-1}\,[L_1, L_{-1}] = 2L_0 L_{-1} + 2L_{-1} L_0. \tag{48.132}$$

Use $L_0 L_{-1} = L_{-1} L_0 + [L_0, L_{-1}] = L_{-1} L_0 + L_{-1}$ (again from $[L_0, L_{-1}] = L_{-1}$) to write $2L_0 L_{-1} + 2L_{-1} L_0 = 4L_{-1} L_0 + 2L_{-1}$. Acting on $|h\rangle$ (where $L_0 \to h$, $L_1 \to 0$),

$$L_1 L_{-1}^2\,|h\rangle = \left(\left[L_1, L_{-1}^2\right] + L_{-1}^2 L_1\right)|h\rangle = (4L_{-1} L_0 + 2L_{-1})\,|h\rangle = (4h+2)\,L_{-1}\,|h\rangle\,. \tag{48.133}$$

Hitting once more with L_1,

$$(M_2)_{22} = \left\langle h\middle|L_1(L_1 L_{-1}^2)\middle|h\right\rangle = (4h+2)\,\langle h|L_1 L_{-1}|h\rangle = (4h+2)(2h) = 8h^2 + 4h. \tag{48.134}$$

For the off-diagonal entry, compute $L_2 L_{-1}^2\,|h\rangle$. Since $[L_2, L_{-1}] = (2 - (-1))L_1 = 3L_1$ (no central term, as $m + n = 1 \neq 0$),

$$\left[L_2, L_{-1}^2\right] = 3L_1 L_{-1} + 3L_{-1} L_1, \tag{48.135}$$

and acting on $|h\rangle$, using $L_2\,|h\rangle = 0$, $L_1\,|h\rangle = 0$, $L_1 L_{-1}\,|h\rangle = 2h\,|h\rangle$,

$$L_2 L_{-1}^2\,|h\rangle = \left[L_2, L_{-1}^2\right]|h\rangle = 3\,(2h)\,|h\rangle = 6h\,|h\rangle\,, \tag{48.136}$$

so that

$$(M_2)_{12} = \left\langle h\middle|L_2 L_{-1}^2\middle|h\right\rangle = 6h. \tag{48.137}$$

As a check of the Hermiticity built into Theorem 48.16, the conjugate route gives the same: $L_1^2 L_{-2}\,|h\rangle$ is computed from $[L_1, L_{-2}] = (1 - (-2))L_{-1} = 3L_{-1}$, so $L_1 L_{-2}\,|h\rangle = 3L_{-1}\,|h\rangle$ and $L_1^2 L_{-2}\,|h\rangle = 3(2h)\,|h\rangle = 6h\,|h\rangle$, hence $\langle h|L_1^2 L_{-2}|h\rangle = 6h = (M_2)_{21}$ as required.

Collecting Eqs. (48.130), (48.134) and (48.137), the level-two Gram matrix is

$$M_2(c, h) = \begin{pmatrix} 4h + \dfrac{c}{2} & 6h \\ 6h & 8h^2 + 4h \end{pmatrix}. \tag{48.138}$$

Its determinant is the engine of everything that follows:

$$\begin{aligned}\det M_2 &= \left(4h + \tfrac{c}{2}\right)(8h^2 + 4h) - 36h^2 \\ &= 32h^3 + 16h^2 + 4ch^2 + 2ch - 36h^2 \\ &= 2h(16h^2 + 2(c-5)h + c).\end{aligned} \tag{48.139}$$

The overall factor $2h$ is the level-one norm reappearing (a null vector at level one is automatically a null vector at level two, since L_{-1} applied to it stays null); the genuinely new information is the quadratic in the parenthesis, whose roots are the level-two degenerate weights. Solving $16h^2 + 2(c-5)h + c = 0$,

$$h = \frac{-2(c-5) \pm \sqrt{4(c-5)^2 - 64c}}{32} = \frac{(5-c) \pm \sqrt{(c-1)(c-25)}}{16}, \tag{48.140}$$

where we used $(c-5)^2 - 16c = c^2 - 26c + 25 = (c-1)(c-25)$. These two weights are exactly the entries $h_{1,2}(c)$ and $h_{2,1}(c)$ of the Kac formula stated next, and the appearance of the discriminant $(c-1)(c-25)$ already foreshadows that the line $c = 1$ will be a watershed for unitarity. We will return to Eq. (48.140) in Section 48.4.4, where the same numbers drop out of an entirely independent computation — the demand that a specific descendant be a null vector — confirming the structure.

48.4.3 The Kac determinant

The level-one and level-two determinants are the first two members of a family. Computing $\det M_N$ directly becomes hopeless quickly — $\det M_6$ is an 11×11 determinant — but Kac determined the answer in closed form for all N, and its structure is far simpler than the brute computation suggests: $\det M_N$ factorizes completely into linear factors $h - h_{r,s}(c)$, with multiplicities counted by partitions. We state the result, give the weights explicitly, and verify it against Eqs. (48.126) and (48.139).

Theorem 48.18 (Kac determinant formula)**.** *The determinant of the level-N Gram matrix Eq. (48.124) is*

$$\det M_N(c,h) = K_N \prod_{\substack{r,s \geq 1 \\ rs \leq N}} \left(h - h_{r,s}(c)\right)^{p(N-rs)}, \tag{48.141}$$

where $K_N > 0$ is a constant independent of h and c, $p(\cdot)$ is the partition function Eq. (48.122) (with $p(0) = 1$), and the Kac weights *are*

$$h_{r,s}(c) = \frac{c-1}{24} + \frac{1}{4}\left(r\,\alpha_+ + s\,\alpha_-\right)^2, \qquad \alpha_\pm = \frac{\sqrt{1-c} \pm \sqrt{25-c}}{\sqrt{24}}. \tag{48.142}$$

The product runs over all positive integers r, s with $rs \leq N$.

Before discussing the proof, three remarks fix the meaning of Eq. (48.142). First, $\alpha_+\alpha_- = \frac{1}{24}[(1-c)-(25-c)] = -1$; this single relation is what makes the Kac weights organize into the minimal-model patterns of the next section. Second, the combination $\sqrt{(1-c)}$ and $\sqrt{(25-c)}$ shows that $c=1$ and $c=25$ are branch points of the weights as functions of c; for $0<c<1$ both square roots are real, so the $h_{r,s}$ are real, while for $1<c<25$ they become complex-conjugate pairs — another signal that $c=1$ separates two regimes. Third, the lowest weight is the vacuum: $h_{1,1} = \frac{c-1}{24} + \frac{1}{4}(\alpha_+ + \alpha_-)^2$, and since $(\alpha_+ + \alpha_-)^2 = \frac{4(1-c)}{24} = \frac{1-c}{6}$ we get $h_{1,1} = \frac{c-1}{24} + \frac{1-c}{24} = 0$. The level-one null vector $L_{-1}|0\rangle$ at $h = h_{1,1} = 0$ is the statement that ∂ of the identity operator vanishes — the vacuum is translation invariant.

A widely used reparametrization makes the integer structure manifest and is the one we carry into the minimal models. Whenever $c<1$ we may write

$$c = 1 - \frac{6}{m(m+1)}, \qquad \alpha_+ = \sqrt{\frac{m+1}{m}}, \quad \alpha_- = -\sqrt{\frac{m}{m+1}}, \tag{48.143}$$

with m a (not necessarily integer) parameter; one checks $\alpha_+\alpha_- = -1$ and $\frac{13-c}{6} = \alpha_+^2 + \alpha_-^2$ as required. Substituting into Eq. (48.142), the cross term and the constant combine cleanly:

$$h_{r,s}(m) = \frac{\big(r(m+1) - s\,m\big)^2 - 1}{4\,m(m+1)}. \tag{48.144}$$

(To verify: $r\alpha_+ + s\alpha_- = \frac{r(m+1)-sm}{\sqrt{m(m+1)}}$, so $\frac{1}{4}(r\alpha_+ + s\alpha_-)^2 = \frac{(r(m+1)-sm)^2}{4m(m+1)}$, while $\frac{c-1}{24} = -\frac{1}{4m(m+1)}$; their sum is Eq. (48.144).) This is the form in which the Kac table will be read off in Theorem 48.28.

Consistency at low level. At $N=1$, the only (r,s) with $rs \le 1$ is $(1,1)$, contributing $(h-h_{1,1})^{p(0)} = (h-0)^1 = h$. So Eq. (48.141) predicts $\det M_1 = K_1\, h$, matching Eq. (48.126) with $K_1 = 2$. At $N=2$, the admissible pairs are $(1,1)$ with $rs=1$ and $p(2-1)=p(1)=1$, and $(1,2)$ and $(2,1)$ each with $rs=2$ and $p(0)=1$. Thus

$$\det M_2 = K_2\,(h-h_{1,1})\,(h-h_{1,2})\,(h-h_{2,1}) = K_2\,h\,(h-h_{1,2})(h-h_{2,1}). \tag{48.145}$$

Comparing with Eq. (48.139), $\det M_2 = 2h(16h^2 + 2(c-5)h + c) = 32\,h\,(h-h_{1,2})(h-h_{2,1})$ with $h_{1,2}, h_{2,1}$ the roots Eq. (48.140); so $K_2 = 32$ and the two non-vacuum roots are precisely the Kac weights. This is a strong check: the brute-force determinant Eq. (48.139) and the closed form Eq. (48.142) agree, root for root.

Remark 48.19 (On the proof of Theorem 48.18). The full proof of the Kac formula is a structural argument rather than a direct evaluation, and we sketch

its logic honestly here; the explicit low-level verifications above and the null-vector construction below supply the concrete content this book relies on. One shows three things. (i) *Degree and leading coefficient.* The diagonal entry of M_N in the basis monomial $L_{-1}^N|h\rangle$ is, by the level-one recursion Eq. (48.133) iterated, a polynomial in h of degree N with positive leading coefficient $\prod_{k=1}^N 2k \cdot (\cdots)$; summing the partition-counted contributions fixes $\deg_h \det M_N = \sum_{rs\le N} p(N - rs)$, which matches the total degree of the right-hand side of Eq. (48.141). (ii) *The zeros are at the Kac weights.* For each (r, s) with $rs \le N$ there is an explicit *singular vector* at level rs in $V(c, h_{r,s})$ (the analogue of the level-two vector built in Section 48.4.4); its descendants at level N are null, so M_N is degenerate there, giving the factor $(h - h_{r,s})$ at least $p(N - rs)$ times (one for each way of dressing the level-rs singular vector up to level N). (iii) *Multiplicity saturation.* A degree count shows there is no room for further zeros, so the multiplicities are exactly $p(N - rs)$ and the constant K_N is h- and c-independent. The constant is positive and its explicit value $K_N = \prod_{rs\le N} \left((2r)^s s!\right)^{p(N-rs)-p(N-r(s+1))}$ is recorded in the literature; since only the *location* of the zeros bears on degeneracy and unitarity, we do not need K_N beyond $K_N > 0$, which we verified directly for $N = 1, 2$. The original derivation is due to Kac and Feigin–Fuchs [188, 287].

48.4.4 Null vectors and degenerate representations

The Kac determinant vanishes on a discrete set of weights; at each such weight the Gram matrix has a nontrivial kernel, and a vector in that kernel is a zero-norm state orthogonal to its entire level. We now show that such a vector is far more special than a generic zero-norm state: it is itself a primary, it generates an entire sub-Verma-module of null states, and the physically sensible representation is the quotient by that submodule. This is the mechanism that converts the infinite Verma module into the finite, closed operator content of a degenerate theory.

Definition 48.20 (Null/singular vector)**.** A vector $|\chi\rangle \in V(c, h)$ at level $N \ge 1$ is a *singular vector* (or *null vector*) if it is itself a highest-weight vector: it is annihilated by every raising operator,

$$L_n|\chi\rangle = 0 \quad \text{for all } n > 0, \qquad L_0|\chi\rangle = (h + N)|\chi\rangle\,. \tag{48.146}$$

Equivalently, $|\chi\rangle$ is a primary state of weight $h+N$ sitting inside the descendants of the primary $|h\rangle$.

Two facts elevate Eq. (48.146) from a definition to a tool: checking it requires only two equations, and any vector satisfying it is automatically null and orthogonal to the whole module.

Proposition 48.21 (Singular vectors are detected by L_1 and L_2, and are null)**.** *Let $|\chi\rangle \in V_N$, $N \ge 1$. Then:*

(a) $|\chi\rangle$ *is singular (satisfies Eq. (48.146)) if and only if* $L_1|\chi\rangle = 0$ *and* $L_2|\chi\rangle = 0$.

(b) If $|\chi\rangle$ *is singular, then* $\langle\chi, v\rangle = 0$ *for every* $v \in V(c,h)$*; in particular* $|\chi\rangle$ *has zero norm.*

(c) The descendants of a singular vector form a Verma submodule $V(c, h+N) \subseteq V(c,h)$*, every vector of which is orthogonal to all of* $V(c,h)$.

Proof. (a). The positive modes are generated by L_1 and L_2 alone. Indeed Eq. (48.116) gives $[L_1, L_n] = (1-n)L_{n+1}$, with no central term for $n \geq 1$, so for $n \geq 2$

$$L_{n+1} = \frac{1}{1-n}[L_1, L_n], \tag{48.147}$$

and starting from L_1, L_2 this recursion produces $L_3, L_4, \ldots$ Now suppose $L_1|\chi\rangle = L_2|\chi\rangle = 0$. We show $L_n|\chi\rangle = 0$ for all $n \geq 1$ by induction: assume $L_k|\chi\rangle = 0$ for $1 \leq k \leq n$ (true for $n = 2$). Then by Eq. (48.147),

$$L_{n+1}|\chi\rangle = \frac{1}{1-n}(L_1L_n - L_nL_1)|\chi\rangle = \frac{1}{1-n}(L_1 \cdot 0 - L_n \cdot 0) = 0, \tag{48.148}$$

completing the induction. The L_0 condition holds automatically by Eq. (48.120) since $|\chi\rangle \in V_N$. The converse is trivial. This is why, in practice, one builds a candidate null vector and imposes only the two equations $L_1|\chi\rangle = 0$, $L_2|\chi\rangle = 0$.

(b). By the level orthogonality Eq. (48.123) it suffices to take $v \in V_N$, so $v = U|h\rangle$ for U a sum of level-N monomials in the L_{-n}. Then $\langle\chi, v\rangle = \langle\chi|U|h\rangle$; move U onto the bra, $\langle\chi, U|h\rangle\rangle = \langle U^\dagger|\chi\rangle, |h\rangle\rangle$, where $U^\dagger$ is the corresponding sum of monomials in the *raising* operators L_{+n} (adjoints of the L_{-n}). But $U^\dagger$ is a product of positive modes, and by part (a) every positive mode annihilates $|\chi\rangle$; reading $U^\dagger|\chi\rangle$ from the rightmost factor inward, the innermost $L_{+n}|\chi\rangle = 0$ kills the whole expression. Hence $U^\dagger|\chi\rangle = 0$ and $\langle\chi, v\rangle = 0$. Taking $v = |\chi\rangle$ gives $\langle\chi,\chi\rangle = 0$.

(c). Because $|\chi\rangle$ satisfies exactly the highest-weight conditions Eq. (48.117) with weight $h + N$, the module it generates under the raising operators is by Theorem 48.14 a Verma module $V(c, h+N)$, realized as a subspace of $V(c,h)$. For any descendant $w = W|\chi\rangle$ (with W a monomial in lowering operators) and any $v = U|h\rangle \in V(c,h)$, the same manipulation as in (b) gives $\langle v, w\rangle = \langle U|h\rangle, W|\chi\rangle\rangle = \langle W^\dagger U|h\rangle, |\chi\rangle\rangle$, and $W^\dagger U|h\rangle$ is some vector of $V(c,h)$; pairing it with the singular $|\chi\rangle$ and using (b) (which applies to *any* vector of the module) gives zero. So the entire submodule is orthogonal to $V(c,h)$, hence consists of null states. □

Part (b) is the crucial structural statement: a singular vector and all its descendants are orthogonal to everything, including themselves. They are invisible to every correlation function — inserting a null state produces a vanishing matrix

element. A representation that retains them is therefore not irreducible and not faithful to the physics: it carries a sub-representation on which the inner product is identically zero. The remedy is to discard it.

Definition 48.22 (Degenerate representation)**.** When $V(c,h)$ contains singular vectors, let $J(c,h) \subseteq V(c,h)$ be the maximal proper submodule (the sum of all submodules generated by singular vectors). The *irreducible degenerate representation* is the quotient

$$\mathcal{V}(c,h) = V(c,h) \,/\, J(c,h), \tag{48.149}$$

on which the contravariant form descends to a *nondegenerate* pairing. A primary whose weight $h = h_{r,s}(c)$ makes $V(c,h)$ degenerate is called a *degenerate primary*.

The quotient is well defined because $J(c,h)$ is exactly the radical (kernel) of the contravariant form: by Theorem 48.21(c) every singular-vector submodule lies in the radical, and conversely any radical vector at the lowest level where the form degenerates is itself annihilated by all $L_{n>0}$ (else applying a positive mode would lower its level while keeping it in the radical, contradicting minimality), hence is singular. Quotienting by the radical leaves a space on which the induced form is nondegenerate by construction. The number of states of $\mathcal{V}(c,h)$ at each level is strictly smaller than $p(N)$ once a null vector has appeared, and — as the next section shows for the minimal models — can become finite in a sense that closes the operator algebra.

Physical Insight

The physics of a null vector is a *linear relation among descendant operators that holds inside every correlation function.* Setting a level-N singular vector to zero, $|\chi\rangle = 0$, is the statement that a particular linear combination of derivatives and stress-tensor products of the primary $\mathcal{O}$ vanishes as an operator equation. When $\mathcal{O}$ sits in a correlator, that operator equation becomes a linear differential equation for the correlator — this is the origin of the BPZ equations of Theorem 48.30. Degeneracy is thus not a pathology to be avoided but the precise mechanism by which an infinite-symmetry theory becomes exactly solvable: each null vector trades an undetermined function for a solvable ODE.

We now derive the prototypical singular vector — the level-two one — from scratch, and watch the Kac weights Eq. (48.140) reappear.

Worked Example 48.23 (The level-two null vector)**.** We seek a level-two descendant of $|h\rangle$ that is singular. The most general level-two vector is, by Eq. (48.127), a linear combination

$$|\chi\rangle = \left(L_{-2} + a\, L_{-1}^{2}\right)|h\rangle \tag{48.150}$$

(we have normalized the L_{-2} coefficient to 1; the only freedom is the single number a). By Theorem 48.21(a) it is singular iff $L_1|\chi\rangle = 0$ and $L_2|\chi\rangle = 0$. We impose each in turn.

The L_1 condition. We need $L_1 L_{-2}|h\rangle$ and $L_1 L_{-1}^2|h\rangle$. From $[L_1, L_{-2}] = (1-(-2))L_{-1} = 3L_{-1}$,

$$L_1 L_{-2}|h\rangle = [L_1, L_{-2}]|h\rangle = 3L_{-1}|h\rangle\,, \tag{48.151}$$

and from Eq. (48.133), $L_1 L_{-1}^2|h\rangle = (4h+2)L_{-1}|h\rangle$. Therefore

$$L_1|\chi\rangle = \big[\,3 + a(4h+2)\,\big]\,L_{-1}|h\rangle\,, \tag{48.152}$$

which vanishes iff

$$a = -\frac{3}{4h+2} = -\frac{3}{2(2h+1)}. \tag{48.153}$$

This is the announced coefficient: the level-two singular vector, when it exists, must be

$$\boxed{\,|\chi\rangle = \Big(L_{-2} - \frac{3}{2(2h+1)}\,L_{-1}^2\Big)\,|h\rangle\,.\,} \tag{48.154}$$

The L_2 condition. The coefficient a is now fixed, so $L_2|\chi\rangle = 0$ is a constraint on (c,h), not a further free choice. We need $L_2 L_{-2}|h\rangle = (4h + \frac{c}{2})|h\rangle$ (this is Eq. (48.130)) and $L_2 L_{-1}^2|h\rangle = 6h\,|h\rangle$ (this is Eq. (48.137)). Hence

$$L_2|\chi\rangle = \Big[\,(4h + \tfrac{c}{2}) + 6ah\,\Big]\,|h\rangle\,. \tag{48.155}$$

Insert $a = -\frac{3}{2(2h+1)}$, so $6ah = -\frac{18h}{2(2h+1)} = -\frac{9h}{2h+1}$, and require the bracket to vanish:

$$4h + \frac{c}{2} - \frac{9h}{2h+1} = 0. \tag{48.156}$$

Multiply through by $(2h+1)$:

$$(4h+\tfrac{c}{2})(2h+1) - 9h = 8h^2 + 4h + ch + \tfrac{c}{2} - 9h = 8h^2 + (c-5)h + \tfrac{c}{2} = 0, \tag{48.157}$$

and multiplying by 2,

$$16h^2 + 2(c-5)h + c = 0. \tag{48.158}$$

This is *identically* the quadratic in Eq. (48.139), whose roots are $h_{1,2}(c)$ and $h_{2,1}(c)$ from Eq. (48.140). We have thus recovered the Kac weights by a route completely independent of the Gram determinant: demanding that the specific descendant Eq. (48.154) be primary forces exactly the same c–h relation that makes $\det M_2$ vanish. The two perspectives — "the Gram matrix degenerates" and "a descendant becomes primary" — are the same phenomenon. In the m-parametrization Eq. (48.143) the two roots are rational: from Eq. (48.144),

$$h_{2,1}(m) = \frac{(2(m+1)-m)^2 - 1}{4m(m+1)} = \frac{(m+2)^2 - 1}{4m(m+1)} = \frac{(m+1)(m+3)}{4m(m+1)} = \frac{m+3}{4m}, \tag{48.159}$$

$$h_{1,2}(m) = \frac{(m+1-2m)^2-1}{4m(m+1)} = \frac{(1-m)^2-1}{4m(m+1)} = \frac{m(m-2)}{4m(m+1)} = \frac{m-2}{4(m+1)}, \tag{48.160}$$

both manifestly rational at integer m.

The same construction runs at every level: at level rs the candidate is the most general level-rs descendant with one normalization fixed, the L_1, L_2 conditions reduce its $p(rs) - 1$ free coefficients and impose one relation on (c, h), and that relation is $h = h_{r,s}(c)$. The level-one case is degenerate-trivially: $L_1(L_{-1}|h\rangle) = 2h\,|h\rangle = 0$ requires $h = 0 = h_{1,1}$, the vacuum, whose null vector $L_{-1}|0\rangle$ expresses $\partial\mathbf{1} = 0$. The level-three vector $|\chi\rangle = (L_{-3}+aL_{-1}L_{-2}+bL_{-1}^3)\,|h\rangle$ similarly yields $h_{1,3}$ and $h_{3,1}$. These are the building blocks of the BPZ differential equations, and the weights $h_{1,2}, h_{2,1}$ in particular will generate the second-order ODE that solves the Ising correlators in Theorem 48.30.

48.4.5 Unitarity: the bound $c \geq 0,\ h \geq 0$ and the discrete series

A representation can appear in the Hilbert space of a quantum theory only if its inner product is positive: there must be no state of negative norm, on pain of negative probabilities. We now extract from the Gram matrices the full set of (c, h) for which positivity holds. The answer cleaves the plane sharply at $c = 1$, and below it admits only an infinite discrete sequence of points — the single most consequential fact in two-dimensional CFT.

Theorem 48.24 (Unitarity of Virasoro highest-weight representations)**.** *Let $V(c, h)$ be a Virasoro Verma module with c, h real, and let $\mathcal{V}(c, h)$ be its irreducible quotient Eq. (48.149). The contravariant form on $\mathcal{V}(c, h)$ is positive (the representation is* unitary*) precisely in the following cases:*

(i) (Necessary conditions, all c.) *Unitarity requires $c \geq 0$ and $h \geq 0$.*

(ii) (Continuum, $c \geq 1$.) *For $c \geq 1$ and $h \geq 0$ the representation is unitary. The allowed weights form a continuum; for generic such (c, h) the module is irreducible (no null vectors).*

(iii) (Discrete series, $0 < c < 1$.) *For $0 < c < 1$ a unitary representation exists if and only if the central charge takes one of the discrete values*

$$c = 1 - \frac{6}{m(m+1)}, \qquad m = 3, 4, 5, \ldots, \tag{48.161}$$

and the weight is one of the finitely many Kac values

$$h = h_{r,s}(m) = \frac{(r(m+1) - s\,m)^2 - 1}{4\,m(m+1)}, \qquad 1 \leq r \leq m-1, \quad 1 \leq s \leq r, \tag{48.162}$$

each of which is a degenerate primary. These are the central charges and weights of the minimal models.

The necessary conditions in part (i) we prove in full; they are elementary and they already pin down the two half-lines $c \geq 0$, $h \geq 0$. The sufficiency in (ii) and the exclusivity in (iii) are the Friedan–Qiu–Shenker theorem; we give the determinant-vanishing mechanism that forces the discrete series, state the sufficiency, and point to where this book constructs the representations explicitly.

Proof of the necessary conditions (i). Positivity of the form on the whole module requires, in particular, positivity of the norm of every single descendant. Consider the one-parameter family of level-n states $L_{-n}\,|h\rangle$, $n \geq 1$. Their norms are, exactly as in the level-one and level-two computations,

$$\|L_{-n}\,|h\rangle\|^2 = \langle h|L_n L_{-n}|h\rangle = \langle h|[L_n, L_{-n}]|h\rangle = 2n\,h + \frac{c}{12}\,n(n^2-1), \quad (48.163)$$

using $[L_n, L_{-n}] = 2nL_0 + \frac{c}{12}n(n^2-1)$ from Eq. (48.116) and $L_n\,|h\rangle = 0$. Each of these must be ≥ 0.

At $n = 1$ the central term vanishes and Eq. (48.163) reads $2h \geq 0$, i.e.

$$h \geq 0. \quad (48.164)$$

This is the bound already seen at Eq. (48.126). For the central charge, divide Eq. (48.163) by n and let $n \to \infty$:

$$\frac{1}{n}\,\|L_{-n}\,|h\rangle\|^2 = 2h + \frac{c}{12}(n^2-1) \xrightarrow[n\to\infty]{} +\infty \cdot \operatorname{sgn}(c), \quad (48.165)$$

so positivity for all large n forces $c \geq 0$. (Strictly: if $c < 0$ then for n large enough the negative cubic term $\frac{c}{12}n^3$ overwhelms the linear $2nh$, making Eq. (48.163) negative; hence $c < 0$ is excluded. If $c = 0$, Eq. (48.163) gives $2nh \geq 0$, consistent with $h \geq 0$, and indeed $c = 0$ admits only the trivial $h = 0$ representation.) Thus $c \geq 0$ and $h \geq 0$ are necessary, proving (i). □

The two diagnostic norms used here — the level-one norm $2h$ and the large-n norm dominated by $\frac{c}{12}n^3$ — are the cleanest windows onto the two halves of the bound. Note that they alone do not yet exclude anything in the open region $0 < c < 1$, $h > 0$: Eq. (48.163) is positive there for every n. The exclusion of most of that region is a statement about the *off-diagonal* structure of the Gram matrix, i.e. about the determinant, and it is subtler.

The discrete series via the vanishing curves (mechanism for (ii)–(iii)). Fix $h > 0$ and increase c from 0. For c very large the Gram matrix is positive definite: Eq. (48.138), for instance, has positive diagonal and, as $c \to \infty$, positive determinant $\det M_2 \approx \frac{c}{2} \cdot 8h^2 > 0$, and the same dominance of the central terms makes every $M_N \succ 0$ at large c. So ($c \to \infty$, $h > 0$) is unitary. Unitarity can fail only if, as we lower c, an eigenvalue of some M_N passes through zero and turns

negative. An eigenvalue can change sign only by crossing zero, and M_N has a zero eigenvalue exactly on the *vanishing curves*

$$\mathcal{C}_{r,s}: \qquad h = h_{r,s}(c), \qquad rs \le N, \tag{48.166}$$

where $\det M_N = 0$ by Theorem 48.18. The strategy of Friedan, Qiu, and Shenker is to track the sign of $\det M_N$ across these curves in the strip $0 < c < 1$.

For $c \ge 1$ the analysis is benign. There one shows the curves $\mathcal{C}_{r,s}$ do not enclose any region of the quadrant $\{c \ge 1, h \ge 0\}$ in which an even number of sign changes traps a negative eigenvalue; concretely, for $c \ge 1$ and $h \ge 0$ the determinant $\det M_N$ stays nonnegative for every N, with zeros only on isolated curves where a null vector appears (and is then quotiented away). Hence every $(c \ge 1, h \ge 0)$ is unitary, which is part (ii); the weights fill a continuum because no further integrality is imposed.

For $0 < c < 1$ the curves Eq. (48.166) are real (both square roots in Eq. (48.142) are real) and they sweep across the strip, dividing it into regions. The decisive computation, carried out level by level, is that in this strip a state of negative norm appears in the generic region between curves: lowering h across the first curve $\mathcal{C}_{1,2}$ (or $\mathcal{C}_{2,1}$) at fixed $0 < c < 1$ sends the relevant eigenvalue of M_2 from positive, through zero on the curve, to negative just past it — the determinant Eq. (48.139), written as $32h(h - h_{1,2})(h - h_{2,1})$, changes sign as h crosses a simple root. The only way for a point (c, h) with $0 < c < 1$ to avoid lying in some negative-norm region at some level is for it to sit at a *crossing* of vanishing curves of different (r, s), where two roots coincide and the eigenvalue grazes zero without the sign change propagating to a ghost. Demanding that the curves $\mathcal{C}_{r,s}$ and $\mathcal{C}_{r',s'}$ intersect at a common (c, h) with all the consistency required across *all* levels forces, after the integrality of r, s is used, the central charge onto the discrete values

$$c = 1 - \frac{6}{m(m+1)}, \qquad m \in \{3, 4, 5, \dots\}, \tag{48.167}$$

and the weight onto the Kac entries Eq. (48.162). The lower end $m = 3$ gives $c = 1/2$ (the Ising model); $m \to \infty$ accumulates at $c \to 1^-$. Values $0 < c < 1$ off this list, and weights off the Kac table at a listed c, necessarily place the representation in a negative-norm region at some level and are therefore non-unitary. This establishes the necessity in (iii); a representative slice of the curves and the discrete series is shown in Fig. 48.3. □

Remark 48.25 (Sufficiency and the status of the proof). The argument above establishes that unitarity *at most* survives on the FQS list; that the listed representations are *actually* unitary — the sufficiency half of Theorem 48.24(iii) — requires exhibiting, for each (c, h) on the list, a positive-definite irreducible quotient. This was completed by constructing the representations explicitly: as

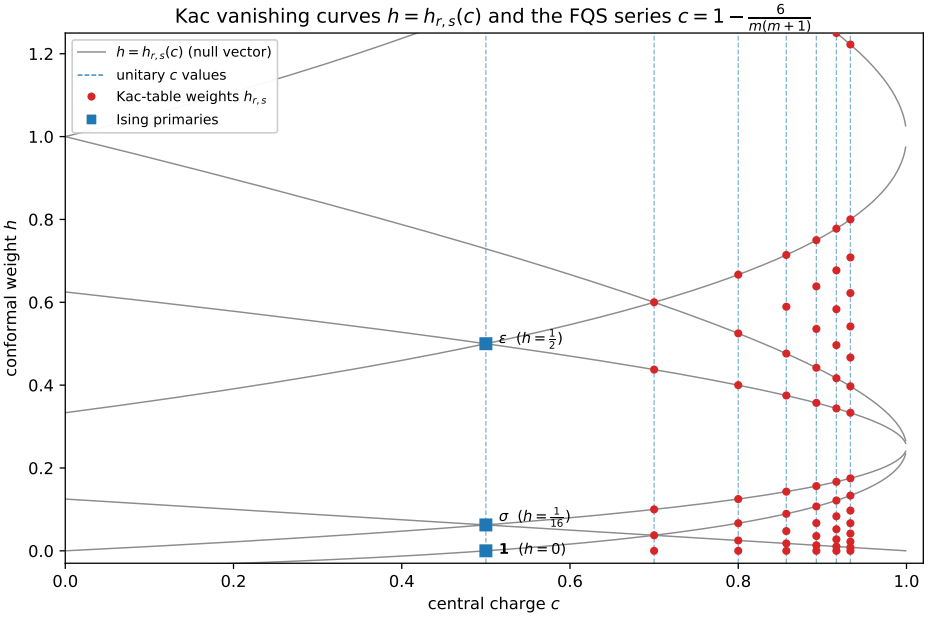


Figure 48.3: The Kac vanishing curves $h = h_{r,s}(c)$ (grey) in the strip $0 < c < 1$, where $\det M_N$ develops a zero and a null vector appears. Between curves the Gram form acquires a negative eigenvalue, so a generic (c, h) in the strip is non-unitary. Unitary representations survive only where the curves cross in the pattern realized at the discrete Friedan–Qiu–Shenker central charges $c = 1 - 6/[m(m+1)]$ (dashed verticals, accumulating at $c = 1$); the allowed weights are the Kac-table values $h_{r,s}$ (dots) on each. The line $m = 3$, $c = \frac{1}{2}$, is the 2D Ising model, whose three primaries — identity $\mathbf{1}$ $(h = 0)$, spin σ $(h = \frac{1}{16})$, energy ε $(h = \frac{1}{2})$ — are marked. These weights are read off in Theorem 48.26 and solved as a full CFT in Section 48.5.

cosets of current algebras (the GKO coset construction) and, equivalently for our purposes, through the free-field (Coulomb-gas) realization in which the L_n act on a free boson and positivity is manifest. This book carries out the free-field construction in Section 48.5's development of the minimal models, where the Kac table and its closure under fusion are derived; that construction is what completes the sufficiency proof. The full classification is the theorem of Friedan, Qiu, and Shenker [200], with sufficiency completed by Goddard, Kent, and Olive [226].

Worked Example 48.26 (The Ising Kac table and the spin and energy weights)**.** The smallest member of the discrete series, $m = 3$, is the critical Ising model. From Eq. (48.161),

$$c = 1 - \frac{6}{3 \cdot 4} = 1 - \frac{1}{2} = \frac{1}{2}. \tag{48.168}$$

The Kac weights Eq. (48.162) with $m = 3$, $4m(m+1) = 48$, and $1 \le r \le 2$, $1 \le s \le r$, are

$$h_{1,1} = \frac{(1\cdot 4 - 1\cdot 3)^2 - 1}{48} = \frac{1-1}{48} = 0, \tag{48.169}$$

$$h_{2,1} = \frac{(2\cdot 4 - 1\cdot 3)^2 - 1}{48} = \frac{25-1}{48} = \frac{24}{48} = \frac{1}{2}, \tag{48.170}$$

$$h_{2,2} = \frac{(2\cdot 4 - 2\cdot 3)^2 - 1}{48} = \frac{4-1}{48} = \frac{3}{48} = \frac{1}{16}. \tag{48.171}$$

(The would-be entry $h_{1,2}$ equals $h_{2,2} = \frac{1}{16}$ by the Kac-table reflection $h_{r,s} = h_{m-r,m+1-s}$, so the distinct weights are exactly $\{0, \frac{1}{16}, \frac{1}{2}\}$.) Each chiral weight pairs with an identical antichiral weight to give a scalar primary of total scaling dimension $\Delta = h + \bar{h}$ and spin $h - \bar{h} = 0$:

$$\Delta_{\mathbf{1}} = 0, \qquad \Delta_\sigma = 2h_{2,2} = 2\cdot\tfrac{1}{16} = \frac{1}{8}, \qquad \Delta_\varepsilon = 2h_{2,1} = 2\cdot\tfrac{1}{2} = 1. \tag{48.172}$$

These are the spin operator σ with $\Delta_\sigma = \frac{1}{8}$ and the energy operator ε with $\Delta_\varepsilon = 1$ promised in the chapter introduction — the exact critical dimensions of the two-dimensional Ising model, here obtained from representation theory alone, with no lattice and no Lagrangian. They are the exactly solvable cousins of the Wilson–Fisher exponents that ϕ^4 theory approaches perturbatively in $d = 4 - \epsilon$ (Chapter 52); the spin σ is the continuum image of the Ising magnetization, and ε of the energy density. The degeneracy of these three primaries — each carries a null vector, ε and σ at level two via Eq. (48.154) — is precisely what will close their fusion algebra and reduce their four-point functions to second-order ODEs in Section 48.5.

Caution

The bound is $c \ge 0$, $h \ge 0$ for *unitary* representations, but c and h are perfectly meaningful real (or even complex) numbers in non-unitary contexts that occur in physics. Statistical models at criticality that are described by non-unitary CFTs — the Lee–Yang edge singularity ($c = -22/5$) and two-dimensional percolation and polymers ($c = 0$ with non-trivial operators surviving the $h \ge 0$ degeneracy) — live precisely outside the FQS region. The theorem says such theories cannot be reflection-positive quantum theories in the Hilbert-space sense; it does *not* say they are unphysical. Throughout the rest of this part we restrict to unitary CFT unless stated, but the representation theory of $V(c,h)$ developed in Sections 48.4.1, 48.4.2 and 48.4.4 is valid for all c, h.

We have now isolated the exact data the next section needs. The unitary $c < 1$ theories live only at $c = 1 - 6/[m(m+1)]$, and at each such c only a

finite Kac table Eq. (48.162) of degenerate primaries can occur, every one of them carrying a null vector that imposes an operator relation. The next section, Section 48.5, takes this finite list as a starting kit: it shows that these primaries close into a consistent, complete operator algebra — the minimal models $\mathcal{M}(p,p')$ — with fusion rules dictated by the null vectors of Section 48.4.4 and correlators fixed by the BPZ differential equations those null vectors generate, and it solves the Ising case ($m=3$) in closed form, delivering the weights $\Delta_\sigma = \frac{1}{8}$, $\Delta_\varepsilon = 1$ found above together with the full four-point function of spins.

48.5 Minimal Models, Fusion Rules, and the BPZ Equations

The previous section (Section 48.4) ended on a sharp dichotomy. The Kac determinant (Theorem 48.18) showed that a Verma module over the Virasoro algebra is reducible precisely when the highest weight h takes one of a discrete family of values $h_{r,s}(c)$; at each such value a *singular* (null) vector appears (Theorem 48.20), and dividing it out leaves a smaller, *degenerate* representation. Unitarity (Theorem 48.24) then carved the allowed central charges into the continuum $c \geq 1$ and a single discrete sequence below it, $c = 1 - 6/[m(m+1)]$ with $m = 3, 4, 5, \ldots$. What we have so far, however, are only representations: lists of weights (c,h) for which a consistent action of the Virasoro algebra exists. A representation is not yet a theory. To have a theory we must assemble a *spectrum* — a specific set of primary fields — and check that the operator product expansion of any two of them closes on that same set, so that all correlation functions are determined. This section performs that assembly. We will find that for the rational points $c = 1 - 6(p-p')^2/(pp')$ the degenerate representations organize themselves into a *finite* set, the Kac table, on which the operator algebra closes exactly. These are the *minimal models*: complete, nonperturbatively defined conformal field theories with finitely many primaries, no Lagrangian, and no free parameters, in which every correlation function is computable in closed form. The engine that makes them solvable is the null vector itself: inserted into a correlator, it converts the algebraic statement "this descendant vanishes" into a linear differential equation — the equation of Belavin, Polyakov, and Zamolodchikov (BPZ) — whose solutions are the correlators. We develop the central-charge parametrization and Kac table first, then turn null vectors into differential operators, derive the BPZ equations, and read off the fusion rules that prove the algebra closes.

48.5.1 The minimal-model central charge and the Kac table

The Kac determinant of Theorem 48.18 vanishes, at level N, exactly on the loci $h = h_{r,s}(c)$ for positive integers r, s with $rs \leq N$. It is convenient — and

standard since the work of Dotsenko and Fateev on the Coulomb gas — to trade the pair (c, h) for a pair of *background charges*. We introduce two numbers α_+, α_- subject to

$$\alpha_+\alpha_- = -1, \qquad \alpha_+ + \alpha_- = 2\alpha_0, \qquad c = 1 - 24\,\alpha_0^2, \tag{48.173}$$

so that $\alpha_\pm = \alpha_0 \pm \sqrt{\alpha_0^2 + 1}$ are the two roots of $\alpha - \alpha^{-1} = 2\alpha_0$, i.e. of $\alpha^2 - 2\alpha_0\alpha - 1 = 0$. In this parametrization the zeros of the Kac determinant recorded in Theorem 48.18 are

$$h_{r,s} \;=\; \frac{(r\alpha_+ + s\alpha_-)^2 - (\alpha_+ + \alpha_-)^2}{4} \;=\; \frac{c-1}{24} + \frac{1}{4}\,(r\alpha_+ + s\alpha_-)^2, \tag{48.174}$$

the second form following from $(\alpha_+ + \alpha_-)^2 = 4\alpha_0^2 = (1-c)/6$. A primary whose weight equals $h_{r,s}$ for some positive integers r, s is *degenerate*: its Verma module contains a singular vector, located at level rs.

Definition 48.27 (Minimal model)**.** A *minimal model* is a conformal field theory whose space of states decomposes into a *finite* number of irreducible Virasoro representations, each built on a degenerate primary, and whose operator algebra (Theorem 47.46) closes on this finite set: the operator product of any two primaries in the spectrum contains only primaries (and their descendants) drawn from the same finite list.

For the spectrum to be finite, the lattice of degenerate weights $h_{r,s}$ must collapse: distinct (r, s) must repeatedly give the *same* weight, so that only finitely many values occur. From Eq. (48.174) this happens precisely when the ratio α_+/α_- is rational, for then the quadratic form $(r\alpha_+ + s\alpha_-)^2$ takes each value infinitely often as (r, s) ranges over the positive integers, and the genuinely distinct weights form a finite set. Write the rationality condition as

$$\alpha_+^2 = \frac{p}{p'}, \qquad \alpha_-^2 = \frac{p'}{p}, \qquad \gcd(p, p') = 1, \quad p, p' \geq 2, \tag{48.175}$$

consistent with $\alpha_+\alpha_- = -1$ if we take $\alpha_+ = \sqrt{p/p'}$, $\alpha_- = -\sqrt{p'/p}$. We require $p, p' \geq 2$ because $p = 1$ or $p' = 1$ would force a vanishing or negative numerator below and no nontrivial table. The central charge follows from Eq. (48.173): since $2\alpha_0 = \alpha_+ + \alpha_- = \sqrt{p/p'} - \sqrt{p'/p} = (p - p')/\sqrt{pp'}$, we have $\alpha_0^2 = (p-p')^2/(4pp')$ and $24\alpha_0^2 = 6(p-p')^2/(pp')$, giving the headline formula

$$\boxed{\,c \;=\; 1 - \frac{6\,(p-p')^2}{p\,p'}\,}, \qquad \gcd(p, p') = 1, \quad p, p' \geq 2. \tag{48.176}$$

The expression is symmetric under $p \leftrightarrow p'$, which merely swaps $\alpha_+ \leftrightarrow \alpha_-$ and hence the roles of the two integer labels below; we may therefore adopt $2 \leq p' < p$ without loss of generality. The model defined by Eq. (48.176) is denoted $\mathcal{M}(p, p')$.

Substituting Eq. (48.175) into Eq. (48.174) rationalizes the weights as well. Since $r\alpha_+ + s\alpha_- = r\sqrt{p/p'} - s\sqrt{p'/p} = (pr - p's)/\sqrt{pp'}$ and $(\alpha_+ + \alpha_-)^2 = (p-p')^2/(pp')$,

$$h_{r,s} \;=\; \frac{(pr - p's)^2 - (p-p')^2}{4\,p\,p'}. \tag{48.177}$$

This is the *Kac formula*. The two integer labels (r, s) now run over a finite rectangle, and the collapse of distinct labels to equal weights is encoded in a single nontrivial identification, which we now establish.

Theorem 48.28 (The Kac table)**.** *In the minimal model $\mathcal{M}(p, p')$ with $\gcd(p, p') = 1$ and $2 \le p' < p$, the degenerate weights Eq. (48.177) that furnish the spectrum are exactly those with*

$$1 \le r \le p' - 1, \qquad 1 \le s \le p - 1, \tag{48.178}$$

subject to the identification

$$(r, s) \;\sim\; (p' - r,\; p - s), \qquad \textit{i.e.} \qquad h_{r,s} = h_{p'-r,\,p-s}. \tag{48.179}$$

The number of distinct primary fields is therefore

$$\mathcal{N} \;=\; \frac{(p-1)(p'-1)}{2}. \tag{48.180}$$

Proof. We prove three statements: the identification Eq. (48.179), that the rectangle Eq. (48.178) contains each weight exactly twice (so the count is as stated), and that no degenerate weight outside the rectangle is independent.

(i) The reflection symmetry. Apply $(r, s) \mapsto (p' - r, p - s)$ to the combination $pr - p's$ appearing in Eq. (48.177):

$$p(p' - r) - p'(p - s) \;=\; pp' - pr - p'p + p's \;=\; -(pr - p's). \tag{48.181}$$

Because Eq. (48.177) depends on r, s only through $(pr - p's)^2$, which is even in this quantity, $h_{p'-r,p-s} = h_{r,s}$. This proves Eq. (48.179). The map is an involution of the rectangle Eq. (48.178) onto itself: if $1 \le r \le p' - 1$ then $1 \le p' - r \le p' - 1$, and likewise for s.

(ii) No further coincidences inside the rectangle, and no fixed point. Suppose $h_{r,s} = h_{r',s'}$ for two pairs in the rectangle. From Eq. (48.177) this requires $(pr - p's)^2 = (pr' - p's')^2$, hence $pr - p's = \pm(pr' - p's')$. Take first the $+$ sign: $p(r-r') = p'(s-s')$. Since $\gcd(p, p') = 1$, p' divides $r-r'$; but $|r-r'| \le p'-2 < p'$, forcing $r = r'$ and then $s = s'$. Take the $-$ sign: $p(r+r') = p'(s+s')$, so $p' \mid (r+r')$ with $2 \le r + r' \le 2p' - 2$, whence $r + r' = p'$, and then $p \cdot p' = p'(s + s')$ gives $s + s' = p$, i.e. $(r', s') = (p' - r, p - s)$. Thus the only coincidences are the trivial one and the reflection Eq. (48.179). The reflection has no fixed point in the rectangle: $(r, s) = (p' - r, p - s)$ would need $2r = p'$ and $2s = p$, impossible since

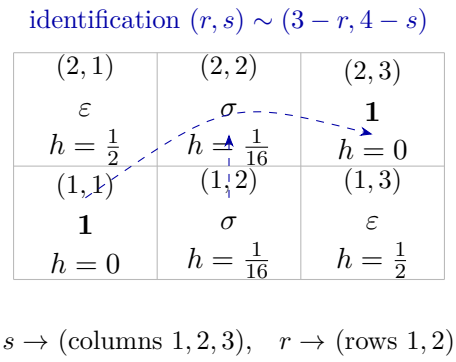

Figure 48.4: The Kac table of the Ising minimal model $\mathcal{M}(4,3)$ ($p=4$, $p'=3$, $c=\frac{1}{2}$). The rectangle has $(p'-1)(p-1)=2\cdot 3=6$ cells; the point reflection $(r,s)\sim(p'-r,p-s)$ pairs them two-to-one, leaving $\mathcal{N}=(p-1)(p'-1)/2=3$ distinct primaries: the identity $\mathbf{1}$ ($h=0$), the spin σ ($h=\frac{1}{16}$), and the energy ε ($h=\frac{1}{2}$). The full local dimensions are $\Delta=h+\bar{h}$, so $\Delta_\sigma=\frac{1}{8}$, $\Delta_\varepsilon=1$.

$\gcd(p,p')=1$ forbids p and p' both even. Hence the rectangle's $(p'-1)(p-1)$ cells pair off exactly two-to-one, giving Eq. (48.180).

(iii) The rectangle is exhaustive. It remains to see that degenerate weights with labels outside Eq. (48.178) are not new fields but are identified with table entries (or correspond to representations that are not part of a closed, consistent spectrum). Two periodicities of Eq. (48.177) settle this. First, $pr-p's$ is invariant under $(r,s)\mapsto(r+p',s+p)$, so $h_{r+p',s+p}=h_{r,s}$; shifting by this lattice vector maps any cell into a translate of the fundamental rectangle. Second, the reflection Eq. (48.179) combined with this period generates the full symmetry group of the weight lattice, the affine Weyl group of the relevant rank-one data; its fundamental domain is precisely the rectangle Eq. (48.178) with the boundary identification Eq. (48.179). (We will see in Section 48.5.5 that fields with labels on or beyond the rectangle's edges are removed by the fusion truncation: their would-be contributions are reflected back inside, which is the dynamical counterpart of this geometric statement.) Hence every degenerate weight equals some $h_{r,s}$ with (r,s) in the rectangle, and the count Eq. (48.180) is complete. □

Physical Insight

The collapse of the infinite Kac lattice to a finite table is the algebraic shadow of a physical fact: a critical statistical system at a fixed point has only finitely many *scaling fields* that are not derivatives of others. The labels (r,s) are not arbitrary — they count the ways a degenerate representation can be reached, and the identification $(r,s)\sim(p'-r,p-s)$ is the statement that two such routes terminate on the same physical

operator. The reflection is the same phenomenon that, in the free-field (Coulomb-gas) realization sketched at the end of this chapter, appears as the screening of background charge.

The metric of Chapter 48 is Euclidean throughout, obtained by the Wick rotation of Chapter 5; a physical scaling field is built from a holomorphic primary of weight h and an antiholomorphic primary of weight $\bar{h}$, and its total scaling dimension and planar spin are $\Delta = h + \bar{h}$ and $\mathfrak{s} = h - \bar{h}$. In the diagonal minimal models the antiholomorphic content mirrors the holomorphic one, $\bar{h} = h$, so $\Delta = 2h$. We will keep the holomorphic and antiholomorphic sectors separate at the level of the chiral algebra and reassemble them only when forming physical correlators in Section 48.5.4.

Worked Example 48.29 (The first unitary minimal models)**.** The unitarity analysis of Theorem 48.24 selected, below $c = 1$, only the values $c = 1 - 6/[m(m+1)]$ with $m = 3, 4, 5, \ldots$. We recover these as the minimal models with adjacent labels. Set $p' = m$ and $p = m + 1$, so that $\gcd(p, p') = \gcd(m, m+1) = 1$ automatically and $p - p' = 1$. Then Eq. (48.176) gives

$$c \;=\; 1 - \frac{6}{m(m+1)}, \qquad m = 3, 4, 5, \ldots, \tag{48.182}$$

exactly the unitary series. These are the only minimal models that are unitary: $|p - p'| = 1$ is forced because a larger gap pushes some Kac weight Eq. (48.177) negative, violating the reflection-positivity bound $h \geq 0$ established in Theorem 48.24. The Kac formula specializes to

$$h_{r,s} = \frac{\big[(m+1)r - ms\big]^2 - 1}{4m(m+1)}, \qquad 1 \leq r \leq m-1, \quad 1 \leq s \leq m. \tag{48.183}$$

The smallest three members:

m	(p, p')	c	primaries (weights h, with $\bar{h} = h$)
3	$(4, 3)$	$\frac{1}{2}$	$0,\ \frac{1}{16},\ \frac{1}{2}$
4	$(5, 4)$	$\frac{7}{10}$	$0,\ \frac{3}{80},\ \frac{1}{10},\ \frac{7}{16},\ \frac{3}{5},\ \frac{3}{2}$
5	$(6, 5)$	$\frac{4}{5}$	$0,\ \frac{1}{40},\ \frac{1}{15},\ \frac{1}{8},\ \frac{2}{5},\ \frac{21}{40},\ \frac{2}{3},\ \frac{7}{5},\ \frac{13}{8},\ 3$

The $m = 3$ entry is the Ising model: $\mathcal{N} = (p-1)(p'-1)/2 = 3$ primaries with $h \in \{0, \frac{1}{16}, \frac{1}{2}\}$, displayed in Fig. 48.4; $m = 4$ is the tricritical Ising model with $\mathcal{N} = 6$; $m = 5$ ($c = \frac{4}{5}$) carries $\mathcal{N} = 10$ and underlies the critical three-state Potts model. As a check on $m = 4$ (so $p = 5$, $p' = 4$): the entry $h_{2,2} = \big[5 \cdot 2 - 4 \cdot 2\big]^2 - 1)/80 = (4-1)/80 = 3/80$, and $h_{1,4} = \big[5 - 16\big]^2 - 1)/80 = (121-1)/80 = 3/2$, both appearing in the table; the reflection $(r, s) \sim (p' - r, p - s) = (4 - r, 5 - s)$ identifies, for instance, $(1, 1) \sim (3, 4)$ and $(2, 2) \sim (2, 3)$, consistent with the six distinct weights listed.

48.5.2 Null vectors as differential operators

To exploit degeneracy dynamically we must learn to insert a singular vector into a correlation function. Recall from Theorem 48.15 that the descendant fields of a primary ϕ of weight h are generated by the modes of the holomorphic stress tensor through the contour prescription

$$(L_{-n}\phi)(z) \;=\; \frac{1}{2\pi i}\oint_{z} \mathrm{d}w\,(w-z)^{1-n}\,T(w)\,\phi(z), \qquad n\geq 1, \tag{48.184}$$

the contour being a small circle around z. This is the residue extracting the regular part of the operator product $T(w)\phi(z)$ recorded in Eq. (48.185), whose singular part is fixed by primarity,

$$T(w)\phi(z) = \frac{h\,\phi(z)}{(w-z)^2} + \frac{\partial\phi(z)}{w-z} + \sum_{n\geq 2}(w-z)^{\,n-2}\,(L_{-n}\phi)(z). \tag{48.185}$$

In particular $L_{-1}\phi=\partial\phi$ and $L_0\phi = h\phi$.

Now place the descendant inside a correlator together with N other primaries ϕ_i of weights h_i at points z_i, and abbreviate $G\equiv\langle\phi(z)\,\phi_1(z_1)\cdots\phi_N(z_N)\rangle$. Using Eq. (48.184),

$$\big\langle (L_{-n}\phi)(z)\,\textstyle\prod_i \phi_i(z_i)\big\rangle = \frac{1}{2\pi i}\oint_z \mathrm{d}w\,(w-z)^{1-n}\,\big\langle T(w)\,\phi(z)\,\prod_i\phi_i(z_i)\big\rangle. \tag{48.186}$$

The mixed correlator is fixed by the conformal Ward identity established in Section 48.2.2 (Eq. (48.48)): the stress tensor insertion is meromorphic in w with a double and a single pole at every operator location,

$$\big\langle T(w)\,\phi(z)\,\textstyle\prod_i\phi_i\big\rangle = \Big[\frac{h}{(w-z)^2} + \frac{1}{w-z}\,\partial_z + \sum_{i=1}^{N}\Big(\frac{h_i}{(w-z_i)^2} + \frac{1}{w-z_i}\,\partial_{z_i}\Big)\Big]\,G. \tag{48.187}$$

We now carry out the contour integral. Of the self-terms (those singular at $w=z$), the piece $h/(w-z)^2$ contributes $(w-z)^{-1-n}$ to the integrand, whose residue vanishes for $n\geq 1$; the piece $\partial_z/(w-z)$ contributes $(w-z)^{-n}$, again with vanishing residue for $n\geq 2$. Thus for $n\geq 2$ the descendant correlator is determined entirely by the *other* insertions — precisely the content of Eq. (48.185), where $(L_{-n}\phi)$ for $n\geq 2$ is the regular part of the operator product. Write the bracketed sum over i in Eq. (48.187) as $\hat{R}(w)\,G$ with

$$\hat{R}(w) = \sum_i \left(\frac{h_i}{(w-z_i)^2} + \frac{\partial_{z_i}}{w-z_i}\right). \tag{48.188}$$

The contour around z picks out the coefficient of $(w-z)^{-1}$ in $(w-z)^{1-n}\hat{R}(w)$, i.e. the coefficient of $(w-z)^{n-2}$ in the Taylor expansion of $\hat{R}(w)$ about $w=z$. Expanding $1/(w-z_i)^2$ and $1/(w-z_i)$ in powers of $(w-z)$ and reading off that coefficient gives, for the double pole,

$$\big[(w-z)^{n-2}\big]\;\frac{1}{(w-z_i)^2} = \frac{n-1}{(z_i-z)^n}, \tag{48.189}$$

and for the single pole,

$$\big[(w-z)^{n-2}\big]\,\frac{1}{w-z_i} = -\frac{1}{(z_i-z)^{n-1}}. \tag{48.190}$$

(Both follow from $1/(w-z_i)^k = \sum_{j\ge 0}\binom{-k}{j}(w-z)^j(z-z_i)^{-k-j}$ and the sign $(z-z_i) = -(z_i-z)$.) Therefore the descendant insertion is reproduced by a linear differential operator $\mathcal{L}_{-n}$ acting on the correlator of the *undifferentiated* primary,

$$\big\langle (L_{-n}\phi)(z)\,\textstyle\prod_i \phi_i\big\rangle = \mathcal{L}_{-n}\,G, \qquad \mathcal{L}_{-n} = \sum_{i=1}^{N}\Big[\tfrac{(n-1)\,h_i}{(z_i-z)^n} - \tfrac{1}{(z_i-z)^{n-1}}\,\partial_{z_i}\Big], \quad n\ge 2. \tag{48.191}$$

For $n=1$ the same formula applies if we adopt the translation Ward identity $(\partial_z + \sum_i \partial_{z_i})G = 0$: then $\mathcal{L}_{-1} = -\sum_i \partial_{z_i} = \partial_z$, in agreement with $L_{-1}\phi = \partial\phi$. The operators $\mathcal{L}_{-n}$ are the bridge from representation theory to analysis: every Virasoro mode acting on the degenerate field has become an explicit differential operator in the positions of the spectators.

48.5.3 The level-two null vector

The simplest nontrivial degenerate field carries a singular vector at level two. By Theorem 48.20 a level-two singular vector in the Verma module over $|h\rangle$ has the form

$$|\chi\rangle = \Big(L_{-2} + a\,L_{-1}^2\Big)|h\rangle, \tag{48.192}$$

the most general level-two state, and it is singular iff it is annihilated by all positive modes, equivalently (since the positive modes are generated by L_1, L_2) by L_1 and L_2. We use the Virasoro algebra recalled in Eq. (48.92),

$$[L_m, L_n] = (m-n)L_{m+n} + \frac{c}{12}\,m(m^2-1)\,\delta_{m+n,0}, \tag{48.193}$$

together with the highest-weight conditions $L_0|h\rangle = h|h\rangle$, $L_{n>0}|h\rangle = 0$. Compute the action of L_1:

$$L_1L_{-2}|h\rangle = [L_1,L_{-2}]|h\rangle = 3\,L_{-1}|h\rangle, \tag{48.194}$$

$$L_1L_{-1}^2|h\rangle = \big([L_1,L_{-1}]L_{-1} + L_{-1}L_1L_{-1}\big)|h\rangle = \big(2L_0L_{-1} + 2hL_{-1}\big)|h\rangle = (4h+2)\,L_{-1}|h\rangle, \tag{48.195}$$

where we used $[L_1,L_{-1}] = 2L_0$, $L_0L_{-1}|h\rangle = (h+1)L_{-1}|h\rangle$, and $L_1L_{-1}|h\rangle = 2h|h\rangle$. Hence

$$L_1|\chi\rangle = \big[3 + a(4h+2)\big]L_{-1}|h\rangle = 0 \;\Longrightarrow\; a = -\frac{3}{2(2h+1)}. \tag{48.196}$$

Now impose $L_2|\chi\rangle = 0$:

$$L_2L_{-2}|h\rangle = [L_2,L_{-2}]|h\rangle = \Big(4L_0 + \tfrac{c}{2}\Big)|h\rangle = \Big(4h + \tfrac{c}{2}\Big)|h\rangle, \tag{48.197}$$

$$L_2 L_{-1}^2|h\rangle = \big([L_2,L_{-1}]L_{-1} + L_{-1}L_2L_{-1}\big)|h\rangle = 3L_1L_{-1}|h\rangle = 6h\,|h\rangle, \quad (48.198)$$

using $[L_2,L_{-2}] = 4L_0 + \frac{c}{2}$, $[L_2,L_{-1}] = 3L_1$, and $L_2L_{-1}|h\rangle = 3L_1|h\rangle = 0$. Therefore

$$L_2|\chi\rangle = \Big(4h + \tfrac{c}{2} + 6ah\Big)|h\rangle = 0. \quad (48.199)$$

Substituting Eq. (48.196) and clearing denominators ($\times 2(2h+1)$),

$$(8h+c)(2h+1) - 18h = 0 \implies 16h^2 + (2c-10)h + c = 0, \quad (48.200)$$

whose two roots

$$h_\pm = \frac{5 - c \pm \sqrt{(c-1)(c-25)}}{16} \quad (48.201)$$

are exactly $h_{1,2}$ and $h_{2,1}$ of the Kac formula: a degenerate field whose null vector sits at level $rs = 2$ must have $rs = 2$, i.e. $(r,s) = (2,1)$ or $(1,2)$. We record the resulting null vector, valid whenever h is one of Eq. (48.201):

$$\boxed{\Big(L_{-2} - \tfrac{3}{2(2h+1)}\,L_{-1}^2\Big)|h\rangle = 0}. \quad (48.202)$$

It is useful to record the value of the coefficient in the background-charge variables of Eq. (48.173). For $\phi_{2,1}$, the charge is $\alpha_{2,1} = -\frac{1}{2}\alpha_+$, and a short computation using $\alpha_+\alpha_- = -1$ gives $h_{2,1} = \frac{1}{4}(3\alpha_+^2 - 2)$, so $2h+1 = \frac{3}{2}\alpha_+^2$ and

$$\kappa \equiv \frac{3}{2(2h+1)} = \frac{1}{\alpha_+^2} \qquad (\text{for } \phi_{2,1}), \quad (48.203)$$

with the symmetric statement $\kappa = 1/\alpha_-^2$ for $\phi_{1,2}$. This compact form will streamline the fusion computation below.

48.5.4 The BPZ differential equations

We can now state the central result of the section. A null vector is, by definition, a state that decouples: it has zero norm and zero overlap with every state, so as an operator insertion it vanishes identically inside correlators. Translating the vanishing into the language of Eq. (48.191) turns it into a differential equation.

Theorem 48.30 (BPZ null-vector equations)**.** *Let ϕ be a degenerate primary of weight h whose Verma module contains a singular vector at level N,*

$$|\chi\rangle = \mathcal{D}\big(\{L_{-k}\}\big)\,|h\rangle = 0, \quad (48.204)$$

where $\mathcal{D}$ is a degree-N polynomial in the modes L_{-k} ($k \geq 1$), homogeneous of weight N. Then in any correlation function containing ϕ, the function

$$G = \big\langle \phi(z)\,\phi_1(z_1)\cdots\phi_N(z_N)\big\rangle \quad (48.205)$$

satisfies the N-th order linear partial differential equation

$$\widehat{\mathcal{D}}\,G = 0, \qquad \widehat{\mathcal{D}} = \mathcal{D}(\{L_{-k}\})\Big|_{L_{-1}\to\partial_z,\ L_{-k}\to\mathcal{L}_{-k}\ (k\geq 2)}, \tag{48.206}$$

with $\mathcal{L}_{-k}$ the differential operators of Eq. (48.191). In particular, for a level-two degenerate field Eq. (48.154) the correlator obeys the second-order equation

$$\left\{\frac{3}{2(2h+1)}\,\partial_z^2 - \sum_i\left[\frac{h_i}{(z_i-z)^2} - \frac{1}{z_i-z}\,\partial_{z_i}\right]\right\}\langle\phi(z)\,\textstyle\prod_i\phi_i(z_i)\rangle = 0. \tag{48.207}$$

Proof. The state–operator correspondence (Chapter 47) identifies the singular vector $|\chi\rangle$ with a descendant field $\chi(z) = (\mathcal{D}\phi)(z)$, built from ϕ by the contour prescription Eq. (48.184) applied mode by mode. Because $|\chi\rangle = 0$ as a state, $\chi(z)$ is the zero operator; hence $\langle\chi(z)\prod_i\phi_i\rangle = 0$ for every choice of spectators. By Eq. (48.191) each factor L_{-k} in $\mathcal{D}$ acting on ϕ inside the correlator is reproduced by the differential operator $\mathcal{L}_{-k}$ (with $L_{-1}\to\partial_z$), and these operators act only on the position z of ϕ and the spectator coordinates, never reintroducing the stress tensor. Nested modes compose as nested differential operators because the contour manipulation Eq. (48.184) is linear and the operators $\mathcal{L}_{-k}$ act on the same correlator. Thus $\langle\chi\prod_i\phi_i\rangle = \widehat{\mathcal{D}}\,G$, and its vanishing is Eq. (48.206). For the level-two case, $\mathcal{D} = L_{-2} - \frac{3}{2(2h+1)}L_{-1}^2$, so $\widehat{\mathcal{D}} = \mathcal{L}_{-2} - \frac{3}{2(2h+1)}\partial_z^2$, and using $\mathcal{L}_{-2} = \sum_i[h_i/(z_i-z)^2 - \partial_{z_i}/(z_i-z)]$ from Eq. (48.191) yields Eq. (48.207). □

The order of the equation equals the level of the null vector, so a $\phi_{r,s}$ with its singular vector at level rs obeys an ODE of order rs once global conformal invariance is used to remove the trivial dependence. This is the precise sense in which "degeneracy solves the theory": every correlator with a degenerate insertion is constrained to lie in a finite-dimensional solution space of an ODE, and the physical answer is pinned down by monodromy (single-valuedness) and the operator-product data.

Reduction to a hypergeometric equation. Consider the four-point function of one level-two degenerate field ϕ (weight h) with three further primaries. Global conformal invariance — the $\mathfrak{sl}(2)\oplus\overline{\mathfrak{sl}}(2)$ Ward identities of Chapter 47 — reduces any four-point function to a universal prefactor times a single function of the anharmonic ratio. Writing the holomorphic cross-ratio

$$\eta = \frac{(z-z_1)(z_2-z_3)}{(z-z_3)(z_2-z_1)}, \tag{48.208}$$

we may strip the kinematic prefactor and set $G = (\text{prefactor})\,\mathcal{F}(\eta)$. The second-order operator in Eq. (48.207) then becomes a second-order *ordinary* differential operator in η. Because the only singularities of the correlator are at coincidences of operators, the equation for $\mathcal{F}$ is Fuchsian with regular singular points only at

$\eta = 0, 1, \infty$ (the three coincidences $z \to z_1$, and the two others mapped to $1, \infty$). A second-order Fuchsian equation with exactly three regular singular points is, after the standard Möbius normalization, the Gauss hypergeometric equation

$$\eta(1-\eta)\,\mathcal{F}'' + [\gamma - (\alpha+\beta+1)\eta]\,\mathcal{F}' - \alpha\beta\,\mathcal{F} = 0, \tag{48.209}$$

whose parameters α, β, γ are fixed by the indicial exponents at the singular points. We compute those exponents directly from Eq. (48.207): as $z \to z_1$ the correlator behaves like $(z-z_1)^{\rho}$, and the leading $(z-z_1)^{\rho-2}$ terms of Eq. (48.207) come from $\frac{3}{2(2h+1)}\partial_z^2$ acting on $(z-z_1)^{\rho}$, from the double pole $-h_1/(z_1-z)^2$, and from the single-pole derivative term, giving the indicial equation

$$\frac{3}{2(2h+1)}\,\rho(\rho-1) + \rho - h_1 = 0. \tag{48.210}$$

Its two roots $\rho_\pm$ are the leading powers in the operator product $\phi(z)\phi_1(z_1) \sim \sum_p (z-z_1)^{h_p - h - h_1}[\phi_p + \cdots]$, so $\rho_\pm = h_p^{\pm} - h - h_1$ for the two intermediate weights $h_p^{\pm}$ allowed in the OPE. The two solutions of Eq. (48.209) are precisely the two *conformal blocks* of Chapter 49: holomorphic functions encoding the exchange of a single primary and its descendants. The physical correlator is assembled by gluing holomorphic and antiholomorphic blocks,

$$\langle \textstyle\prod \Phi_i \rangle = \sum_{p,\bar{p}} X_{p\bar{p}}\,\mathcal{F}_p(\eta)\,\overline{\mathcal{F}}_{\bar{p}}(\bar{\eta}), \tag{48.211}$$

with the coefficients $X_{p\bar{p}}$ fixed by single-valuedness (no branch cut as η circles a singular point) and by the symmetry of the correlator under permuting identical operators (crossing). This *holomorphic factorization* — correlators are sesquilinear combinations of chiral blocks — is the structural lesson the higher-dimensional bootstrap of Chapters 49 and 50 will generalize.

Worked Example 48.31 (The four-point ODE and its monodromy data)**.** We make the reduction concrete. Use a global conformal transformation to send $z_1 \to 0$, $z_2 \to 1$, $z_3 \to \infty$ and let the degenerate field sit at $z \to \eta$. Stripping a prefactor $z^{\,a}(1-z)^{\,b}$ chosen to remove the indicial behavior at $\eta = 0$ and $\eta = 1$, Eq. (48.207) collapses to Eq. (48.209). The exponents at $\eta = 0$ are the two roots of Eq. (48.210); writing $\kappa = \frac{3}{2(2h+1)}$, these are

$$\rho_\pm = \frac{(\kappa-1) \pm \sqrt{(\kappa-1)^2 + 4\kappa h_1}}{2\kappa}, \tag{48.212}$$

and their difference governs the local monodromy. For the spin field of the Ising model, $\phi = \sigma = \phi_{1,2}$ with $h = \frac{1}{16}$, so $\kappa = \frac{3}{2(2\cdot\frac{1}{16}+1)} = \frac{3}{2\cdot\frac{9}{8}} = \frac{4}{3}$, and with all four operators equal to σ ($h_1 = \frac{1}{16}$) the indicial equation $\frac{4}{3}\rho(\rho-1) + \rho - \frac{1}{16} = 0$ has roots $\rho_+ = \frac{1}{16}$ and $\rho_- = -\frac{1}{8}$ wait: solving $\frac{4}{3}\rho^2 - \frac{1}{3}\rho - \frac{1}{16} = 0$, i.e. $\rho^2 - \frac{1}{4}\rho - \frac{3}{64} = 0$, gives $\rho = \frac{1}{8} \pm \frac{1}{8}\sqrt{1+3} = \frac{1}{8} \pm \frac{1}{4}$, i.e. $\rho_+ = \frac{3}{8}$ and $\rho_- = -\frac{1}{8}$. These correspond to the two OPE channels $\sigma \times \sigma = \mathbf{1} + \varepsilon$: the exponent $\rho = -\frac{1}{8} = h_{\mathbf{1}} - 2h_\sigma = 0 - \frac{1}{8}$ is the identity channel, and $\rho = \frac{3}{8} = h_\varepsilon - 2h_\sigma = \frac{1}{2} - \frac{1}{8}$ is the energy channel. The full closed-form solution of this equation — the celebrated $\langle\sigma\sigma\sigma\sigma\rangle$ of the Ising model — is carried out in Section 48.6.

48.5.5 Fusion rules and the closure of the algebra

The differential equations also tell us *which* operators can appear in an operator product, and that is what makes a minimal model a closed theory rather than a representation. Consider a three-point function with one level-two degenerate field ϕ (weight h, at z) and two further primaries ϕ_1, ϕ_2 (weights h_1, h_2, at z_1, z_2). Conformal invariance fixes its holomorphic form completely (Eq. (47.137)),

$$G_3 = \langle \phi(z)\phi_1(z_1)\phi_2(z_2)\rangle = C\,(z-z_1)^{\gamma_1}(z-z_2)^{\gamma_2}(z_1-z_2)^{\gamma_{12}}, \tag{48.213}$$

with exponents set by the standard rule (the exponent of $(x_i - x_j)$ is $h_k - h_i - h_j$ where k is the third operator):

$$\gamma_1 = h_2 - h - h_1, \qquad \gamma_2 = h_1 - h - h_2, \qquad \gamma_{12} = h - h_1 - h_2. \tag{48.214}$$

A nonzero three-point function means ϕ_2 appears in the operator product $\phi \times \phi_1$. The BPZ equation Eq. (48.207) (now with two spectators) must hold; substituting Eq. (48.213) converts it into algebraic constraints on the weights, and *those constraints are the fusion rules.* We compute. Abbreviate $A = z - z_1$, $B = z - z_2$, and note $z_1 - z_2 = B - A$. Differentiating Eq. (48.213),

$$\partial_z^2 G_3 = G_3\left[\left(\tfrac{\gamma_1}{A} + \tfrac{\gamma_2}{B}\right)^2 - \tfrac{\gamma_1}{A^2} - \tfrac{\gamma_2}{B^2}\right], \tag{48.215}$$

$$\frac{\partial_{z_1} G_3}{z_1 - z} = G_3\left[\tfrac{\gamma_1}{A^2} - \tfrac{\gamma_{12}}{A\,(z_1-z_2)}\right], \qquad \frac{\partial_{z_2} G_3}{z_2 - z} = G_3\left[\tfrac{\gamma_2}{B^2} + \tfrac{\gamma_{12}}{B\,(z_1-z_2)}\right], \tag{48.216}$$

where in the latter two we used $\partial_{z_1} G_3 = G_3[-\gamma_1/A + \gamma_{12}/(z_1 - z_2)]$ and $z_1 - z = -A$ (and the mirror for z_2). Inserting these and the double-pole terms $-h_1/A^2 - h_2/B^2$ into Eq. (48.207), dividing out G_3, and using $\frac{1}{z_1-z_2}(\frac{1}{B} - \frac{1}{A}) = -\frac{1}{AB}$ to combine the cross terms, the BPZ condition becomes

$$\frac{1}{A^2}\Big[\kappa\,\gamma_1(\gamma_1 - 1) + \gamma_1 - h_1\Big] + \frac{1}{B^2}\Big[\kappa\,\gamma_2(\gamma_2 - 1) + \gamma_2 - h_2\Big] + \frac{1}{AB}\Big[2\kappa\,\gamma_1\gamma_2 - \gamma_{12}\Big] = 0, \tag{48.217}$$

with $\kappa = \frac{3}{2(2h+1)}$. Because z is free, A and B are independent variables, so each bracket must vanish separately:

$$\text{(I)} \quad \kappa\,\gamma_1(\gamma_1 - 1) + \gamma_1 - h_1 = 0, \tag{48.218}$$

$$\text{(II)} \quad \kappa\,\gamma_2(\gamma_2 - 1) + \gamma_2 - h_2 = 0, \tag{48.219}$$

$$\text{(III)} \quad 2\kappa\,\gamma_1\gamma_2 - \gamma_{12} = 0. \tag{48.220}$$

Equation (I) is a *quadratic in* h_2 (through $\gamma_1 = h_2 - h - h_1$): given h and h_1, only two values of h_2 can appear. This is the truncation. To identify them, pass to the charge variables of Eq. (48.173), writing $h = \alpha(\alpha - 2\alpha_0)$, $h_1 = \beta(\beta - 2\alpha_0)$, $h_2 = \beta'(\beta' - 2\alpha_0)$ with $\alpha = \alpha_{2,1} = -\frac{1}{2}\alpha_+$ and $\kappa = 1/\alpha_+^2$ from Eq. (48.203). We claim the two solutions are

$$\beta' = \beta \pm \alpha, \qquad \text{i.e.} \qquad \alpha_2 = \alpha_1 \pm \alpha_{2,1}. \tag{48.221}$$

Verification of the first root $\beta' = \beta + \alpha$. Then

$$\gamma_1 = h_2 - h - h_1 = (\beta+\alpha)(\beta+\alpha-2\alpha_0) - \alpha(\alpha-2\alpha_0) - \beta(\beta-2\alpha_0) = 2\alpha\beta. \quad (48.222)$$

Using $\kappa\alpha^2 = \frac{1}{\alpha_+^2}\cdot\frac{\alpha_+^2}{4} = \frac{1}{4}$ and $\alpha_- = -1/\alpha_+$, equation (I) evaluates to

$$\begin{aligned}\kappa\gamma_1^2 + (1-\kappa)\gamma_1 - h_1 &= 4\kappa\alpha^2\beta^2 + 2\alpha\beta(1-\kappa) - \big(\beta^2 - (\alpha_+ + \alpha_-)\beta\big) \\ &= \beta^2 - \alpha_+\beta + \tfrac{\beta}{\alpha_+} - \beta^2 + (\alpha_+ + \alpha_-)\beta = \beta\Big(\tfrac{1}{\alpha_+} + \alpha_-\Big) = 0,\end{aligned} \quad (48.223)$$

since $1/\alpha_+ + \alpha_- = 1/\alpha_+ - 1/\alpha_+ = 0$. The mirror computation with $\beta' = \beta - \alpha$ gives $\gamma_1 = 2\alpha(2\alpha_0 - \beta)$ and, using $-\alpha_+ + 1/\alpha_+ = -2\alpha_0$, again reduces (I) to 0. Both roots check, so the two allowed intermediate charges are exactly Eq. (48.221). One verifies likewise that (III) holds: for $\beta' = \beta + \alpha$ both $2\kappa\gamma_1\gamma_2$ and γ_{12} equal $-2\beta(\beta+\alpha-2\alpha_0)$, and (II) follows from (I) by the symmetry $1 \leftrightarrow 2$ together with charge conservation. The three constraints are therefore consistent, and Eq. (48.221) is the complete content of the level-two BPZ equation on the three-point function.

Translating Eq. (48.221) back through $\alpha_{r,s} = \frac{1-r}{2}\alpha_+ + \frac{1-s}{2}\alpha_-$, the shift by $\alpha_{2,1} = -\frac{1}{2}\alpha_+$ moves r by one unit and leaves s fixed: $\alpha_1 + \alpha_{2,1} = \alpha_{r+1,s}$ and $\alpha_1 - \alpha_{2,1} = \alpha_{r-1,s}$. Hence

$$\phi_{2,1} \times \phi_{r,s} = \phi_{r-1,s} + \phi_{r+1,s}, \quad (48.224)$$

and, by the symmetric computation for the $\phi_{1,2}$ null vector (which shifts s),

$$\phi_{1,2} \times \phi_{r,s} = \phi_{r,s-1} + \phi_{r,s+1}. \quad (48.225)$$

These elementary fusions generate the rest. Repeatedly fusing with $\phi_{2,1}$ and $\phi_{1,2}$ — equivalently, noting that the level-$r_1 s_1$ null vector of ϕ_{r_1,s_1} imposes an analogous truncation in each index — gives the general *BPZ fusion rule*

$$\boxed{\phi_{r_1,s_1} \times \phi_{r_2,s_2} = \sum_{r_3=|r_1-r_2|+1}^{r_1+r_2-1}{\sum_{s_3=|s_1-s_2|+1}^{s_1+s_2-1}}' \phi_{r_3,s_3}}, \quad (48.226)$$

where both sums run in steps of two (the primes). The ranges are the $\mathfrak{su}(2)$ Clebsch–Gordan ranges in each index: a degenerate field $\phi_{r,s}$ behaves, under fusion, like a pair of spins $j = (r-1)/2$ and $j' = (s-1)/2$, and Eq. (48.226) is the tensor-product decomposition $j_1 \otimes j_2 = \bigoplus_{|j_1-j_2|}^{j_1+j_2}$ in both. The truncation *from above* ($r_3 \le r_1 + r_2 - 1$, $s_3 \le s_1 + s_2 - 1$) is the null-vector decoupling we just derived.

Proposition 48.32 (Closure and finiteness)**.** *In the minimal model $\mathcal{M}(p,p')$ the fusion rule Eq. (48.226), supplemented by the Kac identification Eq. (48.179), maps the finite Kac table to itself: the operator product of any two table primaries contains only table primaries. The operator algebra therefore closes on the $\mathcal{N} = (p-1)(p'-1)/2$ fields of Theorem 48.28, and $\mathcal{M}(p,p')$ is a complete, consistent conformal field theory.*

Proof. Take ϕ_{r_1,s_1} and ϕ_{r_2,s_2} inside the table, $1 \le r_i \le p'-1$, $1 \le s_i \le p-1$. The naive ranges in Eq. (48.226) can produce labels with $r_3 \ge p'$ or $s_3 \ge p$, which lie outside the rectangle. Such labels are removed and reflected back by a *second* truncation, dynamically equal to the geometric reflection of Theorem 48.28: the same null-vector mechanism that bounds r_3 from above by r_1+r_2-1 also forbids r_3 from reaching p', because the field $\phi_{p',s}$ has $h_{p',s} = h_{0,p-s}$ by Eq. (48.179) and the corresponding fusion channel has vanishing structure constant. Concretely, the surviving range is

$$|r_1 - r_2| + 1 \le r_3 \le \min\left(r_1 + r_2 - 1,\ 2p' - 1 - r_1 - r_2\right), \tag{48.227}$$

in steps of two, and the mirror bound for s_3 with $p' \to p$. The upper cutoff $2p'-1-r_1-r_2$ is exactly the reflection of r_1+r_2-1 through the wall $r=p'$, so whenever it is active the would-be out-of-table fields are folded back via $(r_3,s_3) \to (p'-r_3, p-s_3)$ onto genuine table entries. In either case $r_3 \le p'-1$ and $s_3 \le p-1$: the product stays in the table. Since the table is finite (Eq. (48.180)) and every operator product re-expands on it, the four-point functions are determined by the three-point structure constants and the conformal blocks (Eq. (48.211)), and crossing symmetry — automatic here because the BPZ ODE has a unique single-valued solution — fixes the structure constants up to normalization. Hence all correlators are computable, which is the definition of a complete solvable theory. □

Caution

The fusion "coefficients" in Eq. (48.226) are 0 or 1 for the unitary diagonal minimal models, but *fusion* is not the same as the *operator-product structure constant*. Fusion Eq. (48.226) states which families *may* appear; whether a given one actually appears with nonzero coefficient, and with what magnitude, is the dynamical content of the structure constants C_{ijk}, computed from the four-point blocks via crossing (the Dotsenko–Fateev Coulomb-gas integrals, touched on in Section 48.7.4). A vanishing fusion entry forbids the operator; a nonvanishing one permits it.

The pieces are now in place to solve a complete theory. The simplest minimal model is $\mathcal{M}(4,3)$ with $c = \frac{1}{2}$, the Ising universality class — the exactly solvable representative of the same fixed point that ϕ^4 theory reaches at Wilson–Fisher

in $d = 4 - \epsilon$ (Chapter 52), and whose three-dimensional cousin the bootstrap of Chapter 50 will pin down numerically. Its three primaries are the ones read off the Kac table in Fig. 48.4: the identity $\mathbf{1}$ ($h = 0$), the spin $\sigma = \phi_{1,2}$ ($h = \frac{1}{16}$, so $\Delta_\sigma = \frac{1}{8}$), and the energy $\varepsilon = \phi_{2,1}$ ($h = \frac{1}{2}$, so $\Delta_\varepsilon = 1$); its fusion rules follow from Eq. (48.226) as $\sigma \times \sigma = \mathbf{1} + \varepsilon$, $\sigma \times \varepsilon = \sigma$, $\varepsilon \times \varepsilon = \mathbf{1}$; and the four-point function of spins is governed by the level-two BPZ equation Eq. (48.207) whose monodromy data we already extracted in Theorem 48.31. The next section (Section 48.6) takes exactly these inputs and solves the theory end to end, integrating the hypergeometric equation to obtain $\langle\sigma\sigma\sigma\sigma\rangle$ in closed form and confirming $c = \frac{1}{2}$ against the free Majorana fermion.

48.6 The Ising CFT Worked in Full

The previous section assembled the abstract machinery: the minimal models $\mathcal{M}(p, p')$, their finite Kac table of primaries (Theorem 48.28), the fusion rules that close that table into an algebra (Eq. (48.226)), and the BPZ null-vector equations that turn any correlator containing a degenerate field into a linear differential equation (Theorem 48.30). All of that was developed in the abstract, for general (p, p'). We now spend an entire section cashing it in for a single theory, the simplest nontrivial minimal model $\mathcal{M}(4, 3)$, and we carry the computation to the very end: the exact operator content, the exact fusion algebra, and the four-point function of the spin field in *closed form*, extracted from the level-2 BPZ equation handed to us by the last section. This is the bootstrap dream made fully concrete — a complete, interacting, unitary quantum field theory solved with no Lagrangian, no path integral, and no perturbation series, by representation theory alone.

The theory we are solving is not a toy. It is the universality class of the two-dimensional Ising model at its critical temperature, the same fixed point that Onsager reached in 1944 by a heroic transfer-matrix diagonalization. It is also the exactly solvable $d = 2$ face of the Wilson–Fisher fixed point that ϕ^4 theory reaches in $d = 4 - \epsilon$ (forward to Chapter 52): the critical ϕ^4 theory with its $\mathbb{Z}_2$ symmetry $\phi \to -\phi$ flows, in the infrared, to a conformal field theory, and in two dimensions that CFT is exactly $\mathcal{M}(4, 3)$. The two relevant scaling operators of the $\mathbb{Z}_2$-symmetric problem — the order parameter (odd under $\mathbb{Z}_2$) and the energy density (even) — are the spin σ and the energy ε we are about to pin down. The conformal dimensions we will compute here, $\Delta_\sigma = \frac{1}{8}$ and $\Delta_\varepsilon = 1$, are the $d = 2$ endpoints of a curve of dimensions $\Delta_\sigma(d), \Delta_\varepsilon(d)$ running from the Gaussian values at $d = 4$ down through the genuinely interacting $d = 3$ values — and those $d = 3$ values are precisely what the numerical bootstrap of Chapter 50 computes to many digits. Here the answer is not numerical but algebraic and exact: the calibration target against which the higher-dimensional bootstrap is checked.

We proceed in four movements. First we read the three Ising primaries straight off the Kac table and verify that the table's internal identification leaves *exactly* three. Second we specialize the fusion rules and exhibit the $\mathbb{Z}_2$ fusion algebra. Third — the centerpiece — we solve the spin four-point function: we reduce the level-2 BPZ equation to a hypergeometric ordinary differential equation, integrate it in closed form, glue the two chiral solutions into a single-valued crossing-symmetric correlator, and read off the operator product coefficient $C_{\sigma\sigma\varepsilon} = \frac{1}{2}$. Fourth we answer the question this construction provokes — *where does $c = \frac{1}{2}$ come from microscopically?* — by exhibiting the free Majorana fermion, computing its central charge and the spin field's anomalous dimension from Wick contractions, and translating every CFT number into the standard language of critical exponents, where it reproduces Onsager exactly.

48.6.1 The three primaries from the Kac table

Recall the data of a minimal model $\mathcal{M}(p,p')$ with coprime integers $p > p' \geq 2$. The central charge (Eq. (48.176)) is

$$c = 1 - \frac{6(p-p')^2}{p\,p'}, \tag{48.228}$$

and the holomorphic weights of the primaries fill the Kac table (Theorem 48.28),

$$h_{r,s} = \frac{(p\,r - p'\,s)^2 - (p-p')^2}{4\,p\,p'}, \qquad 1 \leq r \leq p'-1, \quad 1 \leq s \leq p-1, \tag{48.229}$$

subject to the reflection identification

$$h_{r,s} = h_{p'-r,\,p-s}, \tag{48.230}$$

which folds the $(p'-1)(p-1)$ rectangle in half, so that the number of distinct primaries is $\frac{1}{2}(p-1)(p'-1)$.

The Ising model is the smallest nontrivial case, $p=4$, $p'=3$. Then $p-p'=1$ and Eq. (48.228) gives at once the central charge of the theory,

$$\boxed{c = 1 - \frac{6\cdot 1^2}{4\cdot 3} = 1 - \frac{1}{2} = \frac{1}{2}\,.} \tag{48.231}$$

The Kac rectangle has $r \in \{1,2\}$ and $s \in \{1,2,3\}$, six entries in all. With $p\,r - p'\,s = 4r - 3s$ and $4pp' = 48$, Eq. (48.229) reads $h_{r,s} = \big[(4r-3s)^2 - 1\big]/48$. Evaluating every cell:

$$\begin{aligned} h_{1,1} &= \tfrac{(4-3)^2-1}{48} = \tfrac{0}{48} = 0, & h_{1,2} &= \tfrac{(4-6)^2-1}{48} = \tfrac{3}{48} = \tfrac{1}{16}, & h_{1,3} &= \tfrac{(4-9)^2-1}{48} = \tfrac{24}{48} = \tfrac{1}{2}, \\ h_{2,1} &= \tfrac{(8-3)^2-1}{48} = \tfrac{24}{48} = \tfrac{1}{2}, & h_{2,2} &= \tfrac{(8-6)^2-1}{48} = \tfrac{3}{48} = \tfrac{1}{16}, & h_{2,3} &= \tfrac{(8-9)^2-1}{48} = \tfrac{0}{48} = 0. \end{aligned} \tag{48.232}$$

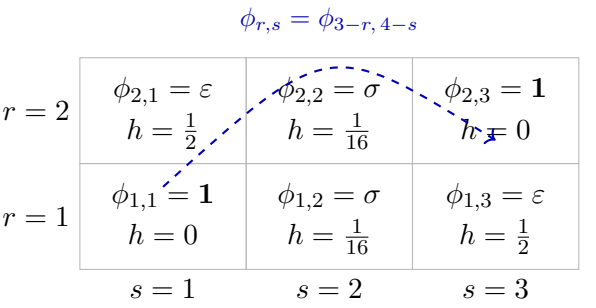

Figure 48.5: The Kac table of $\mathcal{M}(4,3)$, the two-dimensional Ising CFT. The 2×3 rectangle of weights $h_{r,s}$ is folded in half by the point-reflection $\phi_{r,s} = \phi_{3-r,4-s}$ (one identification shown), so the six cells collapse to three distinct primaries: the identity $\mathbf{1}$ ($h = 0$), the spin σ ($h = \frac{1}{16}$) and the energy ε ($h = \frac{1}{2}$).

The reflection Eq. (48.230), here $h_{r,s} = h_{3-r,\,4-s}$, pairs the cells across the table: $(1,1) \leftrightarrow (2,3)$, $(1,2) \leftrightarrow (2,2)$, and $(1,3) \leftrightarrow (2,1)$, exactly as the numerical coincidences in Eq. (48.232) show. Three pairs, hence *exactly three* distinct holomorphic weights:

$$h \in \left\{ 0,\ \tfrac{1}{16},\ \tfrac{1}{2} \right\}. \tag{48.233}$$

Figure 48.5 displays the table and its folding.

We now name them and record their full scaling data. A minimal model is diagonal: each primary appears with equal holomorphic and antiholomorphic weight, $\bar{h} = h$, so that the total scaling dimension is $\Delta = h + \bar{h} = 2h$ and the Lorentz spin $\ell = h - \bar{h} = 0$. These are spinless scalar operators, as the order parameter and energy density of a statistical model must be.

Definition 48.33 (The three Ising primaries)**.** The minimal model $\mathcal{M}(4,3)$ with central charge $c = \frac{1}{2}$ (Eq. (48.231)) contains exactly three Virasoro primaries, all scalars ($\bar{h} = h$):

- the *identity* $\mathbf{1} = \phi_{1,1}$, with $h = \bar{h} = 0$, $\Delta_{\mathbf{1}} = 0$;
- the *spin* (order parameter) $\sigma = \phi_{1,2} = \phi_{2,2}$, with $h = \bar{h} = \frac{1}{16}$, hence

$$\Delta_\sigma = 2h_\sigma = \frac{1}{8}; \tag{48.234}$$

- the *energy* density $\varepsilon = \phi_{2,1} = \phi_{1,3}$, with $h = \bar{h} = \frac{1}{2}$, hence

$$\Delta_\varepsilon = 2h_\varepsilon = 1. \tag{48.235}$$

Two features deserve immediate comment, because both feed the rest of the section. First, $\sigma = \phi_{1,2}$ and $\varepsilon = \phi_{2,1}$ are *degenerate at level two*: a field $\phi_{r,s}$ carries

a Virasoro null descendant at level rs, and here $rs = 2$. A level-two degeneracy produces a *second-order* BPZ ordinary differential equation for any correlator containing that field — this is precisely why the spin four-point function is solvable in closed form, and we will exploit it in Section 48.6.3. Second, the assignment to the statistical operators is forced by symmetry: under the $\mathbb{Z}_2$ of the Ising model, σ is odd (it is the magnetization) and ε is even (it is the local energy, conjugate to temperature), and this parity is exactly what the fusion rules below encode.

Physical Insight

The entire spectrum of a $c = \frac{1}{2}$ unitary CFT is three numbers, $\{0, \frac{1}{16}, \frac{1}{2}\}$, fixed by nothing but the requirement that the Verma modules built on them close into a consistent, unitary, modular-invariant theory. No coupling constant, no Lagrangian, no input from a microscopic Hamiltonian entered. That a statistical-mechanical model as concrete as a grid of ± 1 spins should, at its critical point, be governed by this rigid algebraic skeleton is the physical content of universality: the lattice details wash out, and what survives is a representation of the Virasoro algebra.

48.6.2 The fusion algebra

The fusion rules tell us which primaries appear in the operator product expansion of two others. For minimal models they are determined entirely by the null-vector structure: the general result (Eq. (48.226)) is that $\phi_{r_1,s_1} \times \phi_{r_2,s_2}$ contains ϕ_{r_3,s_3} if and only if r_3 and s_3 run over the truncated ranges

$$r_3 = |r_1 - r_2| + 1,\ |r_1 - r_2| + 3, \ldots, \min(r_1 + r_2 - 1,\ 2p' - 1 - r_1 - r_2), \tag{48.236}$$

and likewise for s_3 with $p' \to p$, the two indices stepping by two and truncating both from below (the $\mathfrak{su}(2)$-like triangle rule) and from above (the minimal-model cutoff that keeps the result inside the Kac table). For Ising it is cleanest to work with the representatives $\mathbf{1} = \phi_{1,1}$, $\sigma = \phi_{1,2}$, $\varepsilon = \phi_{1,3}$, all in the first row $r = 1$, so that the r-fusion is trivial ($r_3 = 1$ always) and only the s-index, with $1 \le s \le 3$, is in play.

Fusing two spins, $\phi_{1,2} \times \phi_{1,2}$: the s-channel range is $s_3 = |2 - 2| + 1, \cdots = 1, 3, \ldots$ stepping by two, i.e. $s_3 \in \{1, 3\}$ (the value $s_3 = 5$ is excluded by the upper cutoff $s_3 \le \min(2 + 2 - 1,\ 2 \cdot 4 - 1 - 2 - 2) = \min(3, 3) = 3$). Thus

$$\sigma \times \sigma = \phi_{1,1} + \phi_{1,3} = \mathbf{1} + \varepsilon. \tag{48.237}$$

Fusing spin with energy, $\phi_{1,2} \times \phi_{1,3}$: $s_3 = |2 - 3| + 1, \cdots = 2, 4, \ldots$, truncated by $s_3 \le \min(2 + 3 - 1,\ 2 \cdot 4 - 1 - 2 - 3) = \min(4, 2) = 2$, leaving only $s_3 = 2$, so

$$\sigma \times \varepsilon = \phi_{1,2} = \sigma. \tag{48.238}$$

Fusing two energies, $\phi_{1,3} \times \phi_{1,3}$: $s_3 = 1, 3, 5, \ldots$ truncated by $s_3 \le \min(3+3-1,\, 2\cdot 4 - 1 - 3 - 3) = \min(5, 1) = 1$, so only $s_3 = 1$ survives and

$$\varepsilon \times \varepsilon = \phi_{1,1} = \mathbf{1}. \tag{48.239}$$

Together with the trivial fusions $\mathbf{1} \times X = X$, these are the complete Ising fusion rules:

$$\boxed{\sigma \times \sigma = \mathbf{1} + \varepsilon, \qquad \sigma \times \varepsilon = \sigma, \qquad \varepsilon \times \varepsilon = \mathbf{1}.} \tag{48.240}$$

Physical Insight

Equation (48.240) is the $\mathbb{Z}_2$ structure of the Ising model made algebraic. Assign the multiplicative parities $\mathbf{1} \to +1$, $\varepsilon \to +1$, $\sigma \to -1$ (odd order parameter, even energy). Every fusion in Eq. (48.240) conserves this parity: $\sigma \times \sigma$ is even and yields the even sector $\{\mathbf{1}, \varepsilon\}$; $\sigma \times \varepsilon$ is odd and yields σ; $\varepsilon \times \varepsilon$ is even and yields $\mathbf{1}$. The fusion algebra is therefore the group algebra of $\mathbb{Z}_2$ *enriched* by the splitting $\sigma \times \sigma = \mathbf{1} + \varepsilon$ — the simplest example of a non-group fusion category (the Ising category), in which σ is a "non-invertible" object whose self-fusion produces more than one channel.

The decisive entry for what follows is Eq. (48.237): the product of two spins contains exactly two primaries, the identity and the energy. The four-point function $\langle\sigma\sigma\sigma\sigma\rangle$ will therefore be built from exactly *two* conformal blocks, one for each channel, and the relative weight of the second is the squared OPE coefficient $C^2_{\sigma\sigma\varepsilon}$. We now compute it.

48.6.3 The spin four-point function from the BPZ equation

This is the centerpiece. We will obtain the full four-point function $\langle\sigma\sigma\sigma\sigma\rangle$ in closed form by integrating the level-2 BPZ equation of Theorem 48.30, and along the way extract $C_{\sigma\sigma\varepsilon}$. The result is the following.

Theorem 48.34 (The Ising spin four-point function)**.** *In the Ising CFT $\mathcal{M}(4,3)$, with the spin field normalized so that its two-point function is $\langle\sigma(z_1,\bar z_1)\sigma(z_2,\bar z_2)\rangle = |z_{12}|^{-2\Delta_\sigma} = |z_{12}|^{-1/4}$ (Eq. (47.120)), the four-point function of spins is the single-valued, crossing-symmetric function*

$$\Big\langle \textstyle\prod_{i=1}^4 \sigma(z_i,\bar z_i) \Big\rangle = \Big|\frac{z_{13}\,z_{24}}{z_{12}\,z_{23}\,z_{34}\,z_{14}}\Big|^{1/4} \tfrac{1}{2}\Big(\big|1+\sqrt{1-x}\,\big| + \big|1-\sqrt{1-x}\,\big| \Big), \tag{48.241}$$

where $z_{ij} = z_i - z_j$ and $x = \dfrac{z_{12}z_{34}}{z_{13}z_{24}}$ is the holomorphic cross-ratio (and $\bar x$ its conjugate). The two terms are the contributions of the identity and of ε to the $\sigma \times \sigma$ OPE, and the operator product coefficient is

$$C_{\sigma\sigma\varepsilon} = \frac{1}{2}. \tag{48.242}$$

The proof occupies the rest of this subsection and is carried out in full in Theorem 48.35; the structure is: (i) reduce the kinematics to a function of the cross-ratio; (ii) convert the level-2 BPZ null condition, together with the global conformal Ward identities, into a second-order ordinary differential equation; (iii) recognize that ODE as hypergeometric and integrate it in elementary closed form; (iv) glue the holomorphic and antiholomorphic solutions into a single-valued physical correlator and read off $C_{\sigma\sigma\varepsilon}$.

Worked Example 48.35 (The four-point function of Ising spins, end to end)**.** *Step 1 — Kinematics.* By global conformal invariance — the $SL(2,\mathbb{C})$ Möbius subgroup generated by L_{-1}, L_0, L_1 and their antiholomorphic partners — a four-point function of scalar primaries of equal weight $(h, \bar{h})$ is fixed up to a function of the cross-ratio. Writing $z_{ij} = z_i - z_j$, choose the prefactor $(z_{12}z_{34})^{-2h}$, which carries holomorphic weight h at each of the four points (it transforms with weight h at z_1, z_2 through z_{12}^{-2h} and at z_3, z_4 through z_{34}^{-2h}). Then

$$\left\langle \prod_i \sigma(z_i, \bar{z}_i) \right\rangle = (z_{12}z_{34})^{-2h}\,(\bar{z}_{12}\bar{z}_{34})^{-2\bar{h}}\,G(x,\bar{x}), \qquad x = \tfrac{z_{12}z_{34}}{z_{13}z_{24}}, \tag{48.243}$$

with $h = \bar{h} = \frac{1}{16}$, so $2h = \frac{1}{8}$. The whole problem is to determine the dimensionless function $G(x,\bar{x})$. This is the four-point analogue of the two- and three-point structures (Eqs. (47.120) and (47.137)): the new ingredient at four points is the single undetermined function of the cross-ratio that symmetry cannot fix and dynamics must.

Step 2 — Holomorphic factorization. In a diagonal minimal model every operator carries $\bar{h} = h$, and correlators factorize holomorphically: the reduced holomorphic correlator $g(x)$ introduced in Step 3 and its antiholomorphic partner combine into $g(x)\,\overline{g(\bar{x})} = \sum_a F_a(x)\,\bar{F}_a(\bar{x})$, a sum over the conformal families a exchanged in the $\sigma \times \sigma$ OPE, each a product of a chiral block $F_a(x)$ and its antichiral partner. By the fusion rule Eq. (48.237) there are exactly two families, $a \in \{\mathbf{1}, \varepsilon\}$. We therefore need the two chiral blocks $F_{\mathbf{1}}(x)$ and $F_\varepsilon(x)$; they are the two independent solutions of one second-order ODE, the BPZ equation, which we now derive.

Step 3 — The BPZ equation. The spin $\sigma = \phi_{1,2}$ has a level-two null descendant (Theorem 48.30); the associated null-state condition, inserted into a correlator, is the differential operator

$$\left[\frac{3}{2(2h+1)}\,\partial_z^2 - \sum_j \Big(\frac{1}{z-z_j}\,\partial_{z_j} + \frac{h_j}{(z-z_j)^2}\Big)\right]\left\langle \sigma(z)\,\prod_j \sigma(z_j)\right\rangle = 0, \tag{48.244}$$

where z is the position of the degenerate field and the sum runs over the other insertions. With $h = \frac{1}{16}$ the coefficient is $\frac{3}{2(2h+1)} = \frac{3}{2\cdot(9/8)} = \frac{4}{3}$.

To turn Eq. (48.244) into an ODE in a single variable we fix three points and let the degenerate field sit at the variable point. Place the four spins at $z_1 = 0$,

$z_2 = z$, $z_3 = 1$, $z_4 = L$ and define the reduced holomorphic correlator by sending the fourth point to infinity,

$$g(z) = \lim_{L\to\infty} L^{2h}\,\langle \sigma(0)\,\sigma(z)\,\sigma(1)\,\sigma(L)\rangle_{\text{hol}}, \tag{48.245}$$

the factor L^{2h} removing the leading fall-off of the operator at infinity. In this frame the cross-ratio becomes $x = \frac{z_{12}z_{34}}{z_{13}z_{24}} = \frac{(-z)(1-L)}{(-1)(z-L)} \to z$ as $L\to\infty$, so the degenerate point $z_2 = z$ *is* the cross-ratio and $\partial_{z_2} = \partial_x$ acts directly on g.

The derivatives $\partial_{z_1}, \partial_{z_3}, \partial_{z_4}$ in Eq. (48.244) are eliminated using the three global conformal Ward identities (the $SL(2)$ invariance of the correlator under L_{-1}, L_0, L_1):

$$\sum_i \partial_{z_i}\langle\cdots\rangle = 0, \qquad \sum_i \big(z_i\partial_{z_i} + h\big)\langle\cdots\rangle = 0, \qquad \sum_i \big(z_i^2\partial_{z_i} + 2hz_i\big)\langle\cdots\rangle = 0. \tag{48.246}$$

Write $a_i \equiv \partial_{z_i}\langle\cdots\rangle$ at $z_1 = 0, z_2 = x, z_3 = 1, z_4 = L$, and let $G_4 = \langle\cdots\rangle$. The three identities read

$$a_1 + a_2 + a_3 + a_4 = 0, \tag{48.247}$$

$$x\,a_2 + a_3 + L\,a_4 + 4h\,G_4 = 0, \tag{48.248}$$

$$x^2 a_2 + a_3 + L^2 a_4 + 2h(x+1+L)G_4 = 0. \tag{48.249}$$

Subtracting Eq. (48.248) from Eq. (48.249) eliminates a_3:

$$(x^2{-}x)\,a_2 + (L^2{-}L)\,a_4 + 2h(x{-}1{+}L)\,G_4 = 0 \;\Longrightarrow\; a_4 = -\,\frac{(x^2-x)a_2 + 2h(x-1+L)G_4}{L^2-L}. \tag{48.250}$$

Now take the limit. Since $G_4 \sim L^{-2h}g(x)$ at large L, the renormalized correlator is $g(x) = L^{2h}G_4$, and the leading large-L behaviour of Eq. (48.250) is $a_4 \to -2h\,L^{-2h-1}g$. Feeding this back through Eq. (48.248) gives $a_3 = -xa_2 - La_4 - 4hG_4 \to L^{-2h}\big(-xg' - 2hg\big)$, and then Eq. (48.247) gives $a_1 = -(a_2+a_3+a_4) \to L^{-2h}\big[(x-1)g' + 2hg\big]$, while $a_2 \to L^{-2h}g'$. Collecting,

$$a_1 = L^{-2h}\big[(x{-}1)g'{+}2hg\big], \quad a_2 = L^{-2h}g', \quad a_3 = L^{-2h}\big[-xg'{-}2hg\big], \quad a_4 = -2h\,L^{-2h-1}g. \tag{48.251}$$

Insert these into the BPZ operator Eq. (48.244), with the degenerate field at $z_2 = x$ and the sum over $j \in \{1,3,4\}$. The $j=4$ term carries $1/(x-L) \sim -1/L$ and $h/(x-L)^2 \sim h/L^2$ against $a_4 \sim L^{-2h-1}$ and $G_4 \sim L^{-2h}$, so it is $O(L^{-2h-2})$ and drops out in the limit. The left side is $\frac{4}{3}\,\partial_{z_2}^2 G_4 = \frac{4}{3}L^{-2h}g''$. Dividing the whole equation by L^{-2h},

$$\frac{4}{3}\,g'' = \frac{1}{x}\big[(x-1)g' + 2hg\big] + \frac{h}{x^2}g + \frac{1}{x-1}\big[-xg' - 2hg\big] + \frac{h}{(x-1)^2}g. \tag{48.252}$$

Collect the g' terms: their coefficient is $\frac{x-1}{x} - \frac{x}{x-1} = \frac{(x-1)^2 - x^2}{x(x-1)} = \frac{1-2x}{x(x-1)}$. Collect the g terms: using $\frac{2h}{x} - \frac{2h}{x-1} = -\frac{2h}{x(x-1)}$, their coefficient is $h\big[\frac{1}{x^2} + \frac{1}{(x-1)^2} - \frac{2}{x(x-1)}\big]$.

Thus

$$\frac{4}{3}\,g'' = \frac{1-2x}{x(x-1)}\,g' + h\Big[\frac{1}{x^2} + \frac{1}{(x-1)^2} - \frac{2}{x(x-1)}\Big]g. \tag{48.253}$$

Before simplifying further, the equation already tells us the operator content. Near $x \to 0$, set $g \sim x^s$: the leading terms give the indicial equation $s(s-1) = -\frac{3}{4}s + \frac{3}{64}$ (using $h = \frac{1}{16}$), i.e. $64s^2 - 16s - 3 = 0$, with roots

$$s = \frac{16 \pm \sqrt{256 + 768}}{128} = \frac{16 \pm 32}{128} \in \Big\{-\tfrac{1}{8},\ \tfrac{3}{8}\Big\}. \tag{48.254}$$

The s-channel OPE behaves as $g \sim x^{h_p - 2h_\sigma}$ with $2h_\sigma = \frac{1}{8}$; the two roots correspond to internal weights $h_p = 0$ (root $-\frac{1}{8}$, the identity) and $h_p = \frac{1}{2}$ (root $\frac{3}{8}$, the energy ε). The ODE has thus *rediscovered* the fusion rule $\sigma \times \sigma = \mathbf{1} + \varepsilon$ of Eq. (48.237), with the exact dimensions $h_{\mathbf{1}} = 0$ and $h_\varepsilon = \frac{1}{2}$.

Step 4 — Reduction to hypergeometric form, and the closed-form blocks. Strip the leading singular behaviour by the substitution

$$g(x) = \big[x(1-x)\big]^{-1/8}\,u(x), \tag{48.255}$$

which is the natural choice because Eq. (48.253) is symmetric under $x \to 1-x$ (its g-coefficient is manifestly symmetric, and the g'-coefficient is odd, matching $g' \to -g'$), so the exponents at $x = 1$ are the same $\{-\frac{1}{8}, \frac{3}{8}\}$ as at $x = 0$. Multiplying Eq. (48.253) by $\frac{3}{4}$ to clear the leading coefficient and writing $D = x(1-x)$, a direct computation reduces it to an equation for u. Writing $\rho \equiv (\ln[x(1-x)]^{-1/8})' = -\frac{1-2x}{8x(1-x)}$, one finds $g'' - Ag' - Bg = 0$ with $A = \frac{3}{4}\frac{1-2x}{x(x-1)} = 6\rho$ and $B = \frac{3}{64}\big[\frac{1}{x^2} + \frac{1}{(x-1)^2} - \frac{2}{x(x-1)}\big] = \frac{3}{64D^2}$ (the bracket collapses to $1/D^2$ because $\frac{1}{x^2} + \frac{1}{(1-x)^2} + \frac{2}{x(1-x)} = \big[\frac{(1-x)+x}{x(1-x)}\big]^2 = \frac{1}{D^2}$). Substituting $g = D^{-1/8}u$ turns $g'' - Ag' - Bg = 0$ into

$$u'' + (2\rho - A)u' + (\rho^2 + \rho' - A\rho - B)\,u = 0 = u'' - 4\rho\,u' + (\rho' - 5\rho^2 - B)\,u, \tag{48.256}$$

and the algebra of the last coefficient is clean: with $D' = 1 - 2x$, $D'' = -2$,

$$\rho' - 5\rho^2 - B = \frac{\frac{1}{8}(2D + (1-2x)^2) - \frac{5}{64}(1-2x)^2 - \frac{3}{64}}{D^2} = \frac{16D + 3(1-2x)^2 - 3}{64\,D^2}. \tag{48.257}$$

Using $(1-2x)^2 = 1 - 4D$, the numerator is $16D + 3(1-4D) - 3 = 4D$, so $\rho' - 5\rho^2 - B = \frac{4D}{64D^2} = \frac{1}{16D}$. Likewise $-4\rho = \frac{1-2x}{2D}$. The equation for u is therefore

$$u'' + \frac{1-2x}{2\,x(1-x)}\,u' + \frac{1}{16\,x(1-x)}\,u = 0, \tag{48.258}$$

or, clearing the denominator,

$$x(1-x)\,u'' + \Big(\tfrac{1}{2} - x\Big)u' + \tfrac{1}{16}\,u = 0. \tag{48.259}$$

This is the hypergeometric equation $x(1-x)u'' + [c-(a+b+1)x]u' - ab\,u = 0$ with

$$c = \tfrac{1}{2}, \qquad a+b+1 = 1, \qquad ab = -\tfrac{1}{16} \implies (a,b,c) = \left(\tfrac{1}{4}, -\tfrac{1}{4}, \tfrac{1}{2}\right). \tag{48.260}$$

Rather than quote hypergeometric identities, we integrate Eq. (48.259) in elementary terms by the substitution $x = \sin^2\theta$ (so $\sqrt{1-x} = \cos\theta$, $dx/d\theta = \sin 2\theta$, and $x(1-x) = \tfrac{1}{4}\sin^2 2\theta$). Converting derivatives, $u' = u_\theta/\sin 2\theta$ and $u'' = u_{\theta\theta}/\sin^2 2\theta - 2\cos 2\theta\, u_\theta/\sin^3 2\theta$, the first two terms of Eq. (48.259) combine: the $x(1-x)u''$ term contributes $\tfrac{1}{4}u_{\theta\theta} - \tfrac{1}{2}\cos 2\theta\, u_\theta/\sin 2\theta$, while $(\tfrac{1}{2}-x)u' = \tfrac{1}{2}\cos 2\theta\, u' = \tfrac{1}{2}\cos 2\theta\, u_\theta/\sin 2\theta$ (since $\tfrac{1}{2} - \sin^2\theta = \tfrac{1}{2}\cos 2\theta$), and the two $\cos 2\theta$ pieces cancel exactly. What remains is the constant-coefficient equation

$$\frac{1}{4}\,u_{\theta\theta} + \frac{1}{16}\,u = 0 \quad\Longleftrightarrow\quad u_{\theta\theta} + \frac{1}{4}\,u = 0, \tag{48.261}$$

whose general solution is $u = A\cos(\theta/2) + B\sin(\theta/2)$. Translating back through $\cos^2(\theta/2) = \frac{1+\cos\theta}{2} = \frac{1+\sqrt{1-x}}{2}$ and $\sin^2(\theta/2) = \frac{1-\sqrt{1-x}}{2}$, the two independent chiral solutions are the celebrated algebraic blocks

$$\boxed{F_+(x) = \cos\frac{\theta}{2} = \sqrt{\frac{1+\sqrt{1-x}}{2}}, \qquad F_-(x) = \sin\frac{\theta}{2} = \sqrt{\frac{1-\sqrt{1-x}}{2}}.} \tag{48.262}$$

Their small-x behaviour confirms the channel assignment of Eq. (48.254): $F_+ \to 1$ (the identity block, since $g = D^{-1/8}F_+ \sim x^{-1/8}$), while $F_- \to \sqrt{x}/2$ (the energy block, since $g = D^{-1/8}F_- \sim \tfrac{1}{2}x^{3/8}$). The factor $\tfrac{1}{2}$ in the leading energy coefficient is the seed of $C_{\sigma\sigma\varepsilon}$; we now make that precise. Figure 48.6 plots the two blocks.

Step 5 — Single-valuedness and the OPE coefficient. The physical correlator must combine the chiral blocks $F_\pm(x)$ with their antichiral partners $F_\pm(\bar{x})$ into a function that is single-valued in the Euclidean plane ($\bar{x} = x^*$): a genuine local correlator has no monodromy as the operators are carried around one another. Restoring the prefactor $[x(1-x)]^{-1/8}$ in $g = [x(1-x)]^{-1/8}F$, the candidate single-valued combination of g with its antiholomorphic partner is

$$g(x)\,\overline{g(\bar{x})} = |x(1-x)|^{-1/4}\Big(\alpha\,F_+(x)\overline{F_+(x)} + \beta\,F_-(x)\overline{F_-(x)}\Big), \tag{48.263}$$

with real coefficients $\alpha, \beta \geq 0$ to be fixed; off-diagonal terms $F_+\bar{F}_-$ are forbidden because $\mathbf{1}$ and ε have distinct weights and the OPE pairs holomorphic and antiholomorphic content diagonally.

Examine the monodromy as x encircles 1 (the crossing point at which two operators collide in the t-channel). Under $x \to 1$ once around, $\sqrt{1-x} \to -\sqrt{1-x}$, so the radicands in Eq. (48.262) swap and $F_+ \leftrightarrow F_-$; simultaneously $(1-x)^{-1/8}$ picks up the phase $e^{-i\pi/4}$. Thus $F_+ \to e^{-i\pi/4}F_-$ and $F_- \to e^{-i\pi/4}F_+$

for the holomorphic factor, while the antiholomorphic factor (with $\bar{x}$ circling in the opposite sense) picks up the conjugate phase $e^{+i\pi/4}$. The phases cancel in each modulus-squared, and the effect on Eq. (48.263) is simply $|F_+|^2 \leftrightarrow |F_-|^2$. Single-valuedness around $x = 1$ therefore *requires*

$$\alpha = \beta. \tag{48.264}$$

(The monodromy around $x = 0$ multiplies both blocks by the same phase $e^{-i\pi/4}$ from $x^{-1/8}$, which cancels against the antiholomorphic conjugate automatically; it imposes no further condition.)

It remains to fix the overall normalization and read off $C_{\sigma\sigma\varepsilon}$. The OPE channel decomposition is, by definition,

$$g(x)\,\overline{g(\bar{x})} = |x(1-x)|^{-1/4}\Big(C_{\sigma\sigma\mathbf{1}}^2\,\widehat{F}_{\mathbf{1}}(x)\overline{\widehat{F}_{\mathbf{1}}} + C_{\sigma\sigma\varepsilon}^2\,\widehat{F}_{\varepsilon}(x)\overline{\widehat{F}_{\varepsilon}}\Big), \tag{48.265}$$

where $\widehat{F}_a$ are the *unit-normalized* blocks — normalized so that each begins as $x^{h_a-2h_\sigma}\,(1+\cdots)$ with leading coefficient one, the convention in which the squared coefficient out front is exactly the squared OPE coefficient. Comparing with Eq. (48.262): F_+ already begins as $x^{-1/8}$ with unit coefficient, so $\widehat{F}_{\mathbf{1}} = F_+$; but F_- begins as $\frac{1}{2}x^{3/8}$, so the unit-normalized energy block is $\widehat{F}_\varepsilon = 2F_-$. With the spin two-point function normalized to unity, the identity channel has $C_{\sigma\sigma\mathbf{1}} = 1$, hence the coefficient of $|F_+|^2$ in Eq. (48.263) is $\alpha = 1$. The coefficient of $|F_-|^2$ is $\beta = C_{\sigma\sigma\varepsilon}^2\,|2|^2 = 4\,C_{\sigma\sigma\varepsilon}^2$. Single-valuedness Eq. (48.264) demands $\beta = \alpha = 1$, so

$$4\,C_{\sigma\sigma\varepsilon}^2 = 1 \quad\Longrightarrow\quad \boxed{C_{\sigma\sigma\varepsilon} = \frac{1}{2}\,.} \tag{48.266}$$

Crossing symmetry — here in the guise of single-valuedness around the collision point — has fixed the one piece of dynamical data that symmetry alone could not: the strength with which the energy operator appears in the fusion of two spins. This is the conformal bootstrap solved exactly in a single equation.

Step 6 — Assembling the correlator. With $\alpha = \beta = 1$, evaluate Eq. (48.263) using $|F_\pm(x)|^2 = \big|\frac{1\pm\sqrt{1-x}}{2}\big| = \frac{1}{2}|1 \pm \sqrt{1-x}|$:

$$g(x)\,\overline{g(\bar{x})} = \frac{|x(1-x)|^{-1/4}}{2}\Big(\big|1+\sqrt{1-x}\big| + \big|1-\sqrt{1-x}\big|\Big). \tag{48.267}$$

The function G of Eq. (48.243) is built from the full conformal blocks $x^{2h}g_a(x)$, which differ from the reduced blocks by the prefactor x^{2h} that was renormalized away in the limit Eq. (48.245); restoring it gives $G(x,\bar{x}) = |x|^{2\cdot 2h}\,g\bar{g} = |x|^{1/4}\,g(x)\overline{g(\bar{x})}$, the factor $|x|^{1/4}$ being precisely what makes $G \to |F_+|^2 = 1$ as $x \to 0$, the correct identity-channel limit. Finally restore the kinematic prefactor of Eq. (48.243). Using the cross-ratio identities $x = \frac{z_{12}z_{34}}{z_{13}z_{24}}$ and (from the Plücker

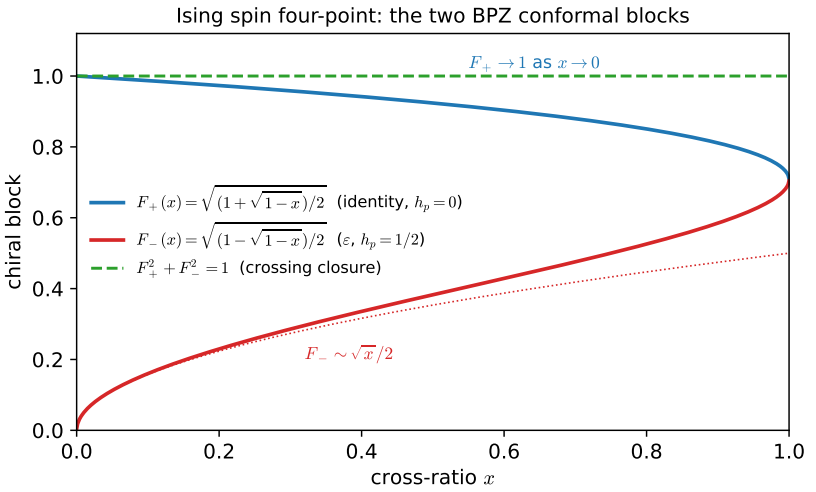

Figure 48.6: The two chiral conformal blocks of the Ising spin four-point function, Eq. (48.262), on the real segment $0 < x < 1$. The identity block F_+ tends to 1 as $x \to 0$; the energy block F_- vanishes as $\sqrt{x}/2$, exhibiting the internal weight $h_\varepsilon = \frac{1}{2}$ and the leading coefficient $\frac{1}{2}$ that becomes $C_{\sigma\sigma\varepsilon}$ after unit-normalization. Their squares sum to a constant, $F_+^2 + F_-^2 = 1$, the algebraic shadow of crossing closure.

relation $z_{12}z_{34} - z_{13}z_{24} + z_{14}z_{23} = 0$) $1 - x = \frac{z_{14}z_{23}}{z_{13}z_{24}}$, the prefactors combine $(|x|^{1/4}|x(1-x)|^{-1/4} = |1-x|^{-1/4})$,

$$|z_{12}z_{34}|^{-1/4}\,|x|^{1/4}\,|x(1-x)|^{-1/4} = |z_{12}z_{34}|^{-1/4}\,|1-x|^{-1/4} = \left|\frac{z_{13}z_{24}}{z_{12}z_{23}z_{34}z_{14}}\right|^{1/4}, \tag{48.268}$$

and we arrive at Eq. (48.241), completing the proof of Theorem 48.34. As a consistency check, the homogeneity of Eq. (48.268) in each z_i is $-\frac{1}{4} = -2\Delta_\sigma$, the correct scaling weight of a spin insertion, and the factor in parentheses depends only on the cross-ratio, as it must.

Caution

The blocks $F_\pm$ are individually multivalued: each has a square-root branch point at $x = 1$ (and the stripped prefactor $[x(1-x)]^{-1/8}$ adds branch points at $x = 0, 1$). Neither F_+ nor F_- is, by itself, a correlator. Only the specific single-valued combination Eq. (48.267), with $\alpha = \beta$, is a physical observable. A frequent error is to identify "the conformal block" with "the correlator"; the block is a chiral half, and physics lives in the monodromy-invariant pairing of the two halves. The same logic — conformal blocks plus crossing — is the engine of the higher-dimensional bootstrap in

Chapters 49 and 50, where the blocks are no longer algebraic and crossing can only be imposed numerically.

48.6.4 Where $c = \frac{1}{2}$ comes from: the free Majorana fermion

We have solved the Ising CFT by pure representation theory, never asking what fields realize it. But the value $c = \frac{1}{2}$ is suggestive: it is exactly half of the $c = 1$ of a free boson, and indeed $\mathcal{M}(4,3)$ has a transparent microscopic realization as a single free *Majorana* (real) fermion. This both demystifies the abstract construction and supplies an independent derivation of every number above. It is also the gateway to the next section's free-field realizations.

A holomorphic Majorana fermion is a chiral field $\psi(z)$ with the operator product expansion

$$\psi(z)\,\psi(w) \sim \frac{1}{z-w}, \tag{48.269}$$

together with an antiholomorphic partner $\bar{\psi}(\bar{z})$ satisfying $\bar{\psi}(\bar{z})\bar{\psi}(\bar{w}) \sim 1/(\bar{z}-\bar{w})$. The stress tensor is the normal-ordered bilinear

$$T(z) = -\frac{1}{2}\,{:}\psi\,\partial\psi{:}\,(z), \tag{48.270}$$

the unique dimension-two chiral field one can build quadratically from ψ. Everything follows from Eqs. (48.269) and (48.270) by Wick's theorem for the contraction $\langle\psi(z)\psi(w)\rangle = 1/(z-w)$, with the derivative contractions

$$\langle\psi(z)\partial\psi(w)\rangle = \frac{1}{(z-w)^2}, \quad \langle\partial\psi(z)\psi(w)\rangle = \frac{-1}{(z-w)^2}, \quad \langle\partial\psi(z)\partial\psi(w)\rangle = \frac{-2}{(z-w)^3}. \tag{48.271}$$

Central charge. The central charge sits in the most singular (c-number) term of the $T(z)T(w)$ OPE, which by definition is $\frac{c/2}{(z-w)^4}$. Compute it by fully contracting the two bilinears,

$$T(z)T(w) = \frac{1}{4}\,{:}\psi\partial\psi{:}\,(z)\;{:}\psi\partial\psi{:}\,(w). \tag{48.272}$$

Two double contractions connect the z-pair to the w-pair. Ordering the four fields as $\psi(z), \partial\psi(z), \psi(w), \partial\psi(w)$, the pairing $\{\psi(z)\psi(w)\}\{\partial\psi(z)\partial\psi(w)\}$ is the interleaved (crossing) one, carrying a fermionic sign -1, while $\{\psi(z)\partial\psi(w)\}\{\partial\psi(z)\psi(w)\}$ is nested, sign $+1$. Hence

$$\begin{aligned} T(z)T(w)\big|_{c\text{-number}} &= \frac{1}{4}\Big[(-1)\,\langle\psi(z)\psi(w)\rangle\,\langle\partial\psi(z)\partial\psi(w)\rangle + (+1)\,\langle\psi(z)\partial\psi(w)\rangle\,\langle\partial\psi(z)\psi(w)\rangle\Big] \\ &= \frac{1}{4}\Big[(-1)\frac{1}{z-w}\cdot\frac{-2}{(z-w)^3} + (+1)\frac{1}{(z-w)^2}\cdot\frac{-1}{(z-w)^2}\Big] \\ &= \frac{1}{4}\Big[\frac{2}{(z-w)^4} - \frac{1}{(z-w)^4}\Big] = \frac{1}{4(z-w)^4}. \end{aligned} \tag{48.273}$$

Matching to $\frac{c/2}{(z-w)^4}$ gives $\frac{c}{2} = \frac{1}{4}$, that is

$$\boxed{c = \tfrac{1}{2}\,,} \tag{48.274}$$

in exact agreement with Eq. (48.231). A single free Majorana fermion is a $c = \frac{1}{2}$ theory.

The fermion is a primary of weight $\frac{1}{2}$. Wick-contract $T(z)$ with $\psi(w)$:

$$\begin{aligned} T(z)\psi(w) &= -\frac{1}{2}\,{:}\psi(z)\partial\psi(z){:}\,\psi(w) \\ &= -\frac{1}{2}\Big[(-1)\langle\psi(z)\psi(w)\rangle\,\partial\psi(z) + (+1)\langle\partial\psi(z)\psi(w)\rangle\,\psi(z)\Big] \\ &= \frac{1}{2}\,\frac{\partial\psi(z)}{z-w} + \frac{1}{2}\,\frac{\psi(z)}{(z-w)^2}, \end{aligned} \tag{48.275}$$

where the first sign is the -1 from moving $\psi(z)$ past the spectator $\partial\psi(z)$ to reach $\psi(w)$. Taylor-expand $\psi(z)$ and $\partial\psi(z)$ about w, $\psi(z) = \psi(w)+(z-w)\partial\psi(w)+\cdots$:

$$T(z)\psi(w) \sim \frac{\frac{1}{2}\,\psi(w)}{(z-w)^2} + \frac{\partial\psi(w)}{z-w}. \tag{48.276}$$

This is precisely the OPE of T with a primary of weight h, $T(z)\mathcal{O}(w) \sim \frac{h\,\mathcal{O}}{(z-w)^2} + \frac{\partial\mathcal{O}}{z-w}$, with

$$h_\psi = \frac{1}{2}, \tag{48.277}$$

and the unit coefficient of the $1/(z-w)$ term confirms ψ is a genuine primary (no anomalous descendant). So the Majorana fermion is a holomorphic primary of dimension $(\frac{1}{2}, 0)$.

The energy operator. The energy density ε is the diagonal product of the holomorphic and antiholomorphic fermions,

$$\varepsilon(z,\bar z) = i\,\psi(z)\,\bar\psi(\bar z), \tag{48.278}$$

the factor i making it Hermitian. As a product of two commuting primaries of weights $(\frac{1}{2}, 0)$ and $(0, \frac{1}{2})$, it has weights $(h, \bar h) = (\frac{1}{2}, \frac{1}{2})$ and hence

$$\Delta_\varepsilon = h + \bar h = 1, \tag{48.279}$$

reproducing Eq. (48.235) and confirming the Kac-table identification $\varepsilon = \phi_{2,1}$. (Physically, ε is the fermion bilinear whose coefficient is the mass term; turning it on drives the theory off criticality, exactly the role of temperature in the Ising model.)

The spin field as a twist field, and $h_\sigma = \frac{1}{16}$. The one Ising primary with no polynomial expression in the free fermion is the spin σ. It is instead a *twist* (order)

field: the fermion is *double-valued* around an insertion of σ, $\psi(e^{2\pi i}z)\,\sigma(0) = -\psi(z)\,\sigma(0)$, so σ creates a square-root branch cut for ψ. This single analytic requirement fixes h_σ. Consider the fermion two-point function in the presence of two spin fields at 0 and ∞,

$$g(z,w) \equiv \frac{\langle \psi(z)\psi(w)\,\sigma(0)\sigma(\infty)\rangle}{\langle \sigma(0)\sigma(\infty)\rangle}. \tag{48.280}$$

It must (i) reduce to $1/(z-w)$ as $z \to w$ (the OPE Eq. (48.269)), (ii) be antisymmetric in $z \leftrightarrow w$ (fermion statistics), and (iii) change sign when either argument circles the branch point at 0. The unique such function with the minimal singularity structure is

$$g(z,w) = \frac{1}{2}\,\frac{\sqrt{z/w} + \sqrt{w/z}}{z-w}. \tag{48.281}$$

Indeed: as $z \to w$ the bracket $\to 2$ and $g \to 1/(z-w)$; swapping $z \leftrightarrow w$ flips $z-w$ while leaving the symmetric bracket fixed, giving antisymmetry; and sending $z \to e^{2\pi i}z$ flips the sign of both $\sqrt{z/w}$ and $\sqrt{w/z}$, so $g \to -g$, the required monodromy.

The weight h_σ is now read from the expectation value of the stress tensor in this two-spin background, which for any primary must take the form $\langle \sigma(\infty)T(z)\sigma(0)\rangle/\langle\sigma\sigma\rangle = h_\sigma/z^2$. Compute the left side as the point-split, subtracted limit of Eq. (48.270),

$$\frac{\langle T(z)\rangle_{\sigma\sigma}}{\langle\sigma\sigma\rangle} = -\frac{1}{2}\lim_{w\to z}\Big[\partial_w g(z,w) - \frac{1}{(z-w)^2}\Big], \tag{48.282}$$

the subtraction removing the singular free part already present in $g \sim 1/(z-w)$. Expand Eq. (48.281) near $w = z$ with $w = z+e$. From $(1+e/z)^{\mp 1/2} = 1 \mp \frac{e}{2z} + \frac{3}{8}\frac{e^2}{z^2} \pm \cdots$ one gets $\sqrt{z/w} + \sqrt{w/z} = 2 + \frac{1}{4}(e/z)^2 + O(e^3)$, so

$$g(z,z+e) = \frac{1}{2}\,\frac{2 + \frac{1}{4}e^2/z^2 + \cdots}{-e} = -\frac{1}{e} - \frac{1}{8}\frac{e}{z^2} + O(e^2). \tag{48.283}$$

Then $\partial_w g = \partial_e g = \frac{1}{e^2} - \frac{1}{8z^2} + \cdots$, while $1/(z-w)^2 = 1/e^2$, so the bracket in Eq. (48.282) tends to $-\frac{1}{8z^2}$, and

$$\frac{\langle T(z)\rangle_{\sigma\sigma}}{\langle\sigma\sigma\rangle} = -\frac{1}{2}\Big(-\frac{1}{8z^2}\Big) = \frac{1}{16\,z^2} \quad\Longrightarrow\quad \boxed{h_\sigma = \frac{1}{16}}, \tag{48.284}$$

exactly the Kac value of Theorem 48.33, now derived from nothing but the branch-cut analyticity of a free fermion. Thus the free Majorana realizes the complete Ising spectrum: $\mathbf{1}$, the twist field σ of weight $\frac{1}{16}$, and the bilinear ε of weight $\frac{1}{2}$, in a theory of central charge $c = \frac{1}{2}$. This is the microscopic answer to "where does $c = \frac{1}{2}$ come from?": it is one real fermionic degree of freedom per chirality.

48.6.5 The dictionary to critical exponents: meeting Onsager

The conformal data we have computed is the same information a statistical physicist packages as critical exponents, and the translation is a clean dictionary worth stating once and for all, because it is exactly the dictionary the bootstrap of Chapter 50 will invert in $d = 3$. The rule is that a scaling operator $\mathcal{O}$ of dimension $\Delta_{\mathcal{O}}$, used to perturb the fixed-point action, $\delta S = \lambda \int d^d x\, \mathcal{O}$, has renormalization-group eigenvalue (relevance)

$$y_{\mathcal{O}} = d - \Delta_{\mathcal{O}}, \tag{48.285}$$

so that the coupling λ flows with scale as $\lambda(b) = b^{y_{\mathcal{O}}}\lambda$. In the Ising universality class the two relevant perturbations are the energy ε (coupling to reduced temperature t) and the spin σ (coupling to the magnetic field H), with $d = 2$, $\Delta_\varepsilon = 1$, $\Delta_\sigma = \frac{1}{8}$, giving the thermal and magnetic eigenvalues

$$y_t = d - \Delta_\varepsilon = 2 - 1 = 1, \qquad y_h = d - \Delta_\sigma = 2 - \tfrac{1}{8} = \tfrac{15}{8}. \tag{48.286}$$

From these two numbers every standard exponent follows by the scaling relations. The correlation length diverges as $\xi \sim |t|^{-\nu}$ with $\nu = 1/y_t$; the spin-spin correlator at criticality falls as $\langle \sigma\sigma \rangle \sim r^{-(d-2+\eta)}$, while Eq. (47.120) gives $\langle \sigma\sigma \rangle \sim r^{-2\Delta_\sigma}$, so $\eta = 2\Delta_\sigma - (d-2)$:

$$\boxed{\nu = \frac{1}{y_t} = 1, \qquad \eta = 2\Delta_\sigma - (d-2) = \frac{1}{4}.} \tag{48.287}$$

The remaining exponents, obtained from $\beta = \nu(d - y_h)$, $\gamma = \nu(2y_h - d)$, $\delta = y_h/(d - y_h)$, and $\alpha = 2 - d\nu$, are

$$\beta = 1 \cdot (2 - \tfrac{15}{8}) = \tfrac{1}{8}, \quad \gamma = 1 \cdot (\tfrac{30}{8} - 2) = \tfrac{7}{4}, \quad \delta = \frac{15/8}{1/8} = 15, \quad \alpha = 2 - 2 \cdot 1 = 0, \tag{48.288}$$

the last being the celebrated logarithmic ($\alpha = 0$) specific-heat singularity. Every one of these is exactly Onsager's 1944 result for the square-lattice Ising model: $\nu = 1$, $\eta = \frac{1}{4}$, $\beta = \frac{1}{8}$, $\gamma = \frac{7}{4}$, $\delta = 15$, $\alpha = 0$. The transfer-matrix tour de force and the representation theory of the Virasoro algebra agree to the last digit — because they describe the same fixed point.

Historical Note

Onsager (1944) computed the free energy of the two-dimensional Ising model exactly by diagonalizing the transfer matrix, extracting $\alpha = 0$; the spontaneous magnetization exponent $\beta = \frac{1}{8}$ was announced by Onsager and derived by Yang (1952). For three decades these numbers stood as isolated exact results with no organizing principle. Belavin, Polyakov

and Zamolodchikov (1984) supplied the principle: the critical point is the conformal field theory $\mathcal{M}(4,3)$, and the exponents are conformal dimensions. The computation in this section — four-point function from a null vector, dimensions from a Kac table — is their method, and it generalizes to the entire $c < 1$ series where no transfer matrix has ever been diagonalized.

Physical Insight

The same dimensions $\Delta_\sigma, \Delta_\varepsilon$ exist for every spatial dimension d, tracing a curve from the Gaussian (free) values at $d = 4$ — $\Delta_\sigma = \frac{d-2}{2} = 1$, $\Delta_\varepsilon = 2$ — down to the exactly solvable Ising values $\Delta_\sigma = \frac{1}{8}$, $\Delta_\varepsilon = 1$ at $d = 2$. At the physically interesting $d = 3$ the theory is the Wilson–Fisher fixed point of ϕ^4 theory (Chapter 52); it is genuinely interacting, has no free-field realization, and is not exactly solvable. There the conformal bootstrap of Chapter 50 takes over, imposing crossing symmetry numerically on the four-point function $\langle\sigma\sigma\sigma\sigma\rangle$ — the very object we solved here in closed form — to pin down $\Delta_\sigma = 0.5181489(10)$ and $\Delta_\varepsilon = 1.412625(10)$. The $d = 2$ solution of this section is the calibration: any bootstrap algorithm must reproduce $\frac{1}{8}$ and 1 when fed $d = 2$, and the closed-form correlator Eq. (48.241) is the exact answer it must converge to.

The microscopic origin of $c = \frac{1}{2}$ as a single free Majorana fermion, just exhibited, is the simplest instance of a general phenomenon: many minimal models and rational CFTs admit explicit realizations in terms of free fields. The next section pursues this systematically — the free boson at $c = 1$ and its vertex operators, the compact boson, and the Coulomb-gas / Feigin–Fuks construction that reproduces the entire minimal-model series Eq. (48.228) through a background charge and screening integrals — turning the abstract representation theory of this chapter into concrete, computable field-theoretic machinery.

48.7 Free-Field Realizations and the Coulomb Gas

The previous section solved the Ising model as a problem in pure representation theory: three primaries with weights fixed by the Kac table, fusion rules dictated by null vectors, and a four-point function delivered by a second-order differential equation (Section 48.6 and Theorem 48.34). At no point did a Lagrangian appear. That is a triumph of the bootstrap, but it leaves a reasonable reader uneasy on one specific point. The number that organized everything — the central charge, $c = \frac{1}{2}$ for Ising (Eq. (48.231)) — entered as an *input*, a coefficient in the $T(z)T(w)$ operator product (Theorem 48.8) whose admissible values we cut down to the Friedan–Qiu–Shenker list by demanding unitarity. We never built a theory and

watched $c = \frac{1}{2}$ come out. The free boson of Section 48.2.6 gave us exactly one such concrete benchmark, $c = 1$, computed by Wick contraction (Theorem 48.9); but 1 is not on the minimal-model list, and a single free field cannot reach the fractional central charges $1 - 6/[m(m+1)]$ that the discrete series demands.

This closing section removes the unease by exhibiting honest microscopic field realizations and then bending the simplest of them until it produces the minimal series on the nose. We proceed in four movements. First we package the free boson as a conformal field theory in its own right, with a U(1) current and a family of *vertex operators* $:e^{i\alpha X}:$ whose weights and correlators we compute from the propagator alone. Second we compactify the boson, $X \sim X + 2\pi R$, and discover momentum, winding, the duality $R \to 1/R$, and a hidden SU(2) at the self-dual radius. Third we realize $c = \frac{1}{2}$ a second, completely independent way — from a free Majorana fermion — closing the loop with the Ising fermion of Eq. (48.270). Fourth, and most consequentially, we deform the boson's stress tensor by a *background charge* Q, sending $c = 1 \to 1 - 3Q^2$, and show that quantizing Q to the minimal-model values turns the free-field correlators, dressed with *screening charges*, into the Dotsenko–Fateev integral representations of minimal-model correlators. As a capstone we recover the Ising spin four-point function of Theorem 48.34 from a single screening integral — the same numbers, by an entirely different route. Throughout, the engine is the residue and analytic-continuation machinery of Theorem 5.23 and Section 5.4; the mostly-minus Minkowski conventions of the book enter only through the Euclidean continuation that made every correlator in this chapter complex-analytic.

48.7.1 The free boson as a conformal field theory

We begin by collecting, as a single named object, the structure that Section 48.2.6 established piecemeal. The massless free boson is governed by the Euclidean action (Eq. (48.74))

$$S = \frac{1}{8\pi}\int \mathrm{d}^2x\, \partial_\mu X\, \partial^\mu X = \frac{1}{2\pi}\int \mathrm{d}^2x\, \partial X\, \bar\partial X, \tag{48.289}$$

whose equation of motion $\partial\bar\partial X = 0$ splits X into a holomorphic and an antiholomorphic part, $X(z,\bar z) = X(z) + \bar X(\bar z)$ at the level of derivatives. The fundamental datum is the two-point function (Eq. (48.75)) and its once-differentiated form (Eq. (48.76)),

$$\langle X(z,\bar z)\, X(w,\bar w)\rangle = -\ln|z-w|^2, \qquad \langle \partial X(z)\, \partial X(w)\rangle = -\frac{1}{(z-w)^2}. \tag{48.290}$$

The holomorphic stress tensor is the normal-ordered bilinear $T(z) = -\frac{1}{2}:\partial X\, \partial X:(z)$ (Eq. (48.77)), with respect to which ∂X is a weight-$(1,0)$ primary and the central charge is $c = 1$ (Theorem 48.9). We will not re-derive any of these; we package them and add the one structural element Section 48.2.6 did not name explicitly.

Definition 48.36 (The free-boson conformal field theory and its current)**.** The *free-boson conformal field theory* is the $c = 1$ theory of a single massless scalar X with action Eq. (48.289), propagator Eq. (48.290), and holomorphic stress tensor $T(z) = -\frac{1}{2} :\partial X\, \partial X:(z)$. Its chiral symmetry algebra is generated by the holomorphic U(1) *current*

$$J(z) \equiv i\, \partial X(z), \tag{48.291}$$

a weight-$(1, 0)$ primary whose self–operator product, read off from Eq. (48.290), is

$$J(z)\, J(w) \sim \frac{1}{(z-w)^2}, \qquad T(z)\, J(w) \sim \frac{J(w)}{(z-w)^2} + \frac{\partial J(w)}{z-w}. \tag{48.292}$$

The factor i makes J Hermitian under the radial-quantization conjugation, so that its conserved charge $\oint \frac{\mathrm{d}z}{2\pi i}\, J(z)$ is the real momentum generating shifts $X \to X + \text{const}$.

The OPE Eq. (48.292) is the simplest current algebra — a U(1) Kac–Moody algebra at "level one" in the normalization where the double-pole coefficient is unity — and it is the structure that the vertex operators below will be charged under. The whole content of the free boson is now encoded in two contractions, $\langle JJ \rangle$ and $\langle \partial X\, \partial X \rangle$, which differ only by the sign $J = i\partial X$ supplies.

Vertex operators

The field X itself is not a primary: it appears in correlators only logarithmically, and its U(1) shift symmetry $X \to X + a$ forbids any nonzero one-point function for a bare power of X. What *is* primary is the exponential, because exponentials diagonalize the shift symmetry. This is the single most useful operator in two-dimensional conformal field theory.

Definition 48.37 (Vertex operator)**.** For $\alpha \in \mathbb{R}$ the *vertex operator* of charge α is the normal-ordered exponential

$$V_\alpha(z, \bar z) \equiv :e^{i\alpha X(z,\bar z)}:, \tag{48.293}$$

where the normal ordering removes all self-contractions, $:e^{i\alpha X}: = e^{i\alpha X} \big/ \langle e^{i\alpha X} \rangle$ understood as the subtraction of the (divergent) coincident propagator. Its purely holomorphic relative is $V_\alpha(z) = :e^{i\alpha X(z)}:$, built from the chiral half $X(z)$ with $\langle X(z) X(w) \rangle = -\ln(z-w)$.

Weight from the T–V OPE. We claim $V_\alpha(z)$ is primary with holomorphic weight $h_\alpha = \frac{1}{2}\alpha^2$. To prove it we Wick-contract $T(z) V_\alpha(w)$. The basic contraction

of a single $\partial X(z)$ with the exponential is obtained by bringing down one factor of $i\alpha X(w)$ from the series and contracting:

$$\langle \partial X(z)\, X(w)\rangle = \partial_z\big[-\ln(z-w)\big] = -\frac{1}{z-w}, \qquad \Longrightarrow \qquad \underbrace{\partial X(z)\, :e^{i\alpha X(w)}:}_{\text{single contraction}} = -\frac{i\alpha}{z-w}\, V_\alpha(w). \tag{48.294}$$

Now $T(z) = -\frac{1}{2}{:}\partial X(z)\partial X(z){:}$ contains two factors of $\partial X(z)$, each of which may contract with the exponential. Contracting *both* (the double contraction) produces the term singular as $(z-w)^{-2}$ with no leftover operator beyond V_α:

$$-\tfrac{1}{2}\Big(-\frac{i\alpha}{z-w}\Big)^2 V_\alpha(w) = -\tfrac{1}{2}\cdot\frac{(i\alpha)^2}{(z-w)^2}\, V_\alpha(w) = \frac{\frac{1}{2}\alpha^2}{(z-w)^2}\, V_\alpha(w), \tag{48.295}$$

using $(i\alpha)^2 = -\alpha^2$. Contracting just *one* of the two $\partial X(z)$'s (two ways, cancelling the $\frac{1}{2}$) leaves one uncontracted $\partial X(z)$ multiplying the exponential:

$$-\tfrac{1}{2}\cdot 2\cdot\Big(-\frac{i\alpha}{z-w}\Big)\,{:}\partial X(z)\, V_\alpha(w){:} = \frac{i\alpha}{z-w}\,{:}\partial X(z)\, V_\alpha(w){:}. \tag{48.296}$$

Taylor-expanding the surviving $\partial X(z)$ about w and using $\partial_w V_\alpha(w) = \partial_w {:}e^{i\alpha X(w)}{:} = i\alpha\,{:}\partial X(w)\, V_\alpha(w){:}$, which rearranges to ${:}\partial X(w) V_\alpha(w){:} = (i\alpha)^{-1}\partial V_\alpha(w)$, the leading piece of Eq. (48.296) becomes

$$\frac{i\alpha}{z-w}\cdot\frac{1}{i\alpha}\,\partial V_\alpha(w) = \frac{\partial V_\alpha(w)}{z-w}. \tag{48.297}$$

Assembling Eqs. (48.295) and (48.297),

$$T(z)\, V_\alpha(w) \sim \frac{\frac{1}{2}\alpha^2\, V_\alpha(w)}{(z-w)^2} + \frac{\partial V_\alpha(w)}{z-w}, \tag{48.298}$$

which is exactly the primary form (Eq. (48.54)) with no pole of order three or higher. Hence

$$h_\alpha = \frac{\alpha^2}{2}, \tag{48.299}$$

and the non-chiral operator Eq. (48.293) carries $(h,\bar h) = (\frac{1}{2}\alpha^2, \frac{1}{2}\alpha^2)$ by the verbatim antiholomorphic computation, hence scaling dimension $\Delta_\alpha = \alpha^2$ and spin zero. The charge under the current Eq. (48.291) follows the same way: $J(z)V_\alpha(w) \sim \alpha\, V_\alpha(w)/(z-w)$, so V_α has U(1) charge α.

Correlators and the neutrality rule. Because X is a Gaussian (free) field, expectation values of exponentials are computed exactly by completing the square. For any Gaussian field with $\langle A\rangle = 0$ one has $\langle e^A\rangle = e^{\frac{1}{2}\langle A^2\rangle}$; setting $A = i\sum_k \alpha_k X(z_k)$ gives $\langle A^2\rangle = -\sum_{k,l}\alpha_k\alpha_l\langle X(z_k)X(z_l)\rangle$, so

$$\Big\langle \prod_k {:}e^{i\alpha_k X(z_k,\bar z_k)}{:} \Big\rangle = \exp\Big(-\sum_{k<l}\alpha_k\alpha_l\,\langle X(z_k)X(z_l)\rangle\Big), \tag{48.300}$$

where the normal ordering has removed the divergent $k=l$ self-energies, leaving only the cross terms $k<l$ (each unordered pair counted once, cancelling the $\frac{1}{2}$). There is one more ingredient that Eq. (48.300) hides: the zero mode. Writing $X = x_0 + \tilde{X}$ with x_0 the constant mode and $\tilde{X}$ the fluctuation, the path integral over $x_0 \in \mathbb{R}$ acts only on the product of exponentials,

$$\int_{-\infty}^{\infty} \mathrm{d}x_0 \; e^{i\left(\sum_k \alpha_k\right) x_0} = 2\pi\, \delta\Big(\sum_k \alpha_k\Big), \tag{48.301}$$

which vanishes unless the total charge is zero. This is the *neutrality rule*: a correlator of vertex operators is nonzero only if $\sum_k \alpha_k = 0$. Physically it is nothing but conservation of the U(1) charge that J measures — the noncompact shift symmetry $X \to X + a$ forces all charge to cancel. Substituting Eq. (48.290) into Eq. (48.300) under this constraint gives the master formula

$$\Big\langle \prod_k V_{\alpha_k}(z_k,\bar{z}_k) \Big\rangle = \prod_{k<l} |z_k - z_l|^{2\alpha_k\alpha_l} = \prod_{k<l} (z_k - z_l)^{\alpha_k\alpha_l} (\bar{z}_k - \bar{z}_l)^{\alpha_k\alpha_l}, \qquad \sum_k \alpha_k = 0, \tag{48.302}$$

and zero otherwise. The chiral version drops the antiholomorphic factor: $\big\langle \prod_k V_{\alpha_k}(z_k)\big\rangle = \prod_{k<l}(z_k - z_l)^{\alpha_k\alpha_l}$.

Worked Example 48.38 (Two- and three-point functions of vertex operators)**.** The neutrality rule and Eq. (48.302) are strong enough to reproduce, in this concrete realization, the kinematic forms that conformal symmetry fixes abstractly. For two operators, neutrality forces $\alpha_2 = -\alpha_1 \equiv -\alpha$, so $\alpha_1\alpha_2 = -\alpha^2$ and

$$\big\langle V_\alpha(z_1,\bar{z}_1)\, V_{-\alpha}(z_2,\bar{z}_2)\big\rangle = |z_1 - z_2|^{-2\alpha^2} = |z_{12}|^{-4h_\alpha}, \tag{48.303}$$

using $\Delta_\alpha = 2h_\alpha = \alpha^2$. This is precisely the conformally required two-point function of a primary of dimension Δ_α (Eq. (48.30)); the conjugate operator $V_{-\alpha}$ is the charge conjugate of V_α. For three operators, neutrality is $\alpha_1+\alpha_2+\alpha_3 = 0$, and

$$\Big\langle \prod_{k=1}^{3} V_{\alpha_k}(z_k,\bar{z}_k) \Big\rangle = \prod_{k<l} |z_{kl}|^{2\alpha_k\alpha_l}. \tag{48.304}$$

The exponents reorganize exactly into the standard Δ_i-dependent powers: from $2\alpha_1\alpha_2 = (\alpha_1+\alpha_2)^2 - \alpha_1^2 - \alpha_2^2 = \alpha_3^2 - \alpha_1^2 - \alpha_2^2 = \Delta_3 - \Delta_1 - \Delta_2$ and its permutations, the three pair exponents are $\Delta_3 - \Delta_1 - \Delta_2$, $\Delta_2 - \Delta_1 - \Delta_3$, $\Delta_1 - \Delta_2 - \Delta_3$ (over $|z_{12}|, |z_{13}|, |z_{23}|$ respectively), which is the universal three-point structure. The free boson thus realizes the abstract two- and three-point kinematics with the bonus that the OPE coefficient is fixed — to unity — and the neutrality rule plays the role of a fusion selection rule, $V_{\alpha_1} \times V_{\alpha_2} \to V_{\alpha_1+\alpha_2}$.

48.7.2 The compact boson, momentum and winding, and $R \to 1/R$ duality

The noncompact boson has a continuum of vertex charges $\alpha \in \mathbb{R}$ and a noncompact spectrum. Two-dimensional applications — the XY model, bosonization,

string compactification — demand instead that X be an *angular* variable,

$$X \sim X + 2\pi R, \tag{48.305}$$

with R the *radius*. Compactification has two immediate consequences. First, single-valuedness of any operator under the identification Eq. (48.305) restricts the allowed charges: $V_\alpha = :e^{i\alpha X}:$ is invariant under $X \to X + 2\pi R$ only if $e^{2\pi i \alpha R} = 1$, i.e.

$$\alpha = \frac{n}{R}, \qquad n \in \mathbb{Z} \qquad (\textit{momentum} \text{ quantization}). \tag{48.306}$$

Second, the field can now *wind*: a configuration in which X advances by an integer multiple of the period as one circles the spatial direction,

$$X(\sigma + 2\pi, \tau) = X(\sigma, \tau) + 2\pi R\, w, \qquad w \in \mathbb{Z} \qquad (\textit{winding} \text{ number}), \tag{48.307}$$

is now an allowed, topologically distinct sector — impossible on the noncompact line. These two integers (n, w) label the states.

To find their weights it is cleanest to track the holomorphic and antiholomorphic momenta separately. The current $J = i\partial X$ has a zero mode measuring the total momentum, $p = \oint \frac{\mathrm{d}z}{2\pi}\, i\partial X = n/R$ by Eq. (48.306); the winding Eq. (48.307) is the zero mode of the antisymmetric combination $\partial X - \bar\partial X$ and, with the kinetic normalization of Eq. (48.289), contributes a charge $\propto wR$. The upshot is that the operator carrying (n, w) factorizes into chiral exponentials $e^{ip_L X_L} e^{ip_R X_R}$ with left/right momenta

$$p_L = \frac{n}{R} + \frac{wR}{2}, \qquad p_R = \frac{n}{R} - \frac{wR}{2}, \tag{48.308}$$

and, since each chiral exponential has weight $\frac{1}{2}p^2$ by the chiral version of Eq. (48.299), conformal weights

$$h_{n,w} = \frac{1}{2}\Big(\frac{n}{R} + \frac{wR}{2}\Big)^2, \qquad \bar h_{n,w} = \frac{1}{2}\Big(\frac{n}{R} - \frac{wR}{2}\Big)^2. \tag{48.309}$$

Two checks. The pure-momentum sector $w = 0$ reduces to $h = \bar h = \frac{1}{2}(n/R)^2$, the weight Eq. (48.299) of $V_{n/R}$, as it must. The conformal spin $h - \bar h = nw$ is an integer, as required for a local operator. The scaling dimension is $\Delta_{n,w} = h + \bar h = (n/R)^2 + (wR/2)^2$, the sum of a momentum and a winding contribution.

Notation Watch

The split Eq. (48.308) carries a convention-dependent factor in the winding term, fixed here by the kinetic normalization $1/8\pi$ of Eq. (48.289) (equivalently $\alpha' = 2$ in string units). Other texts absorb this factor into the definition of R. Nothing physical — no weight, no central charge —

depends on the choice; only the numerical value of the self-dual radius does.

T-duality. The spectrum Eq. (48.309) is manifestly invariant under the simultaneous exchange of momentum with winding and inversion of the radius:

$$R \longrightarrow \widetilde{R} = \frac{2}{R}, \qquad (n, w) \longrightarrow (w, n). \tag{48.310}$$

Indeed, under Eq. (48.310) the left momentum maps to $p_L \to w/\widetilde{R} + n\widetilde{R}/2 = wR/2 + n/R = p_L$ and the right momentum to $p_R \to wR/2 - n/R = -p_R$, leaving every $h_{n,w}$ and $\bar{h}_{n,w}$ unchanged. This is *T-duality*: the compact boson at radius R is the *same* conformal field theory as the one at radius $2/R$, with the roles of momentum and winding interchanged. There is no way, from inside the theory, to tell a small radius from a large one. Measuring the radius in units of the self-dual value, $\widehat{R} \equiv R/\sqrt{2}$, the duality takes the symmetric form $\widehat{R} \to 1/\widehat{R}$, with the fixed point at $\widehat{R} = 1$.

Enhanced symmetry at the self-dual radius. The duality Eq. (48.310) has a fixed point at $R = \sqrt{2}$ (i.e. $\widehat{R} = 1$), and there something special happens. Generically the only holomorphic currents (weight $(1,0)$ fields) are $J = i\partial X$ and its multiples. At $R = \sqrt{2}$ new weight-$(1,0)$ operators appear: solving $h_{n,w} = 1$, $\bar{h}_{n,w} = 0$ in Eq. (48.309) requires $p_R = 0$ and $p_L = \pm\sqrt{2}$, i.e. $n = w = \pm 1$, which is integral precisely at $R = \sqrt{2}$. These are the chiral vertex operators

$$J^{\pm}(z) = :e^{\pm i\sqrt{2}\,X_L(z)}:, \qquad h = \tfrac{1}{2}(\sqrt{2})^2 = 1, \tag{48.311}$$

which together with $J^3(z) = i\sqrt{2}\,\partial X_L(z)$ close, by the vertex-operator OPEs computed above, onto the SU(2) current algebra at *level* $k = 1$. The free boson at the self-dual radius is thus the $\mathrm{SU}(2)_1$ Wess–Zumino–Witten model in disguise: an abelian symmetry enhanced, at one special radius, to a nonabelian one. This enhancement — and its breaking as one moves off $R = \sqrt{2}$ — is the prototype of every Higgs-like and stringy moduli phenomenon, and it is the simplest place to see an entire continuous symmetry materialize from the spectrum of a free field.

48.7.3 The free Majorana fermion and $c = \frac{1}{2}$

The boson gave $c = 1$. To reach the bottom of the minimal series we need a second free realization, and the cheapest is a free fermion. The point of this subsection is to obtain $c = \frac{1}{2}$ from a Lagrangian field, completing the circle with the Ising fermion of Eq. (48.270) promised in the previous section: the universality class that ϕ^4 theory approaches at the Wilson–Fisher point has, in two dimensions, an exactly free fermionic microscopic description.

Definition 48.39 (Free Majorana fermion)**.** The *free Majorana* (real) fermion is the $c = \frac{1}{2}$ theory of a holomorphic anticommuting field $\psi(z)$ with two-point function

$$\langle \psi(z)\,\psi(w)\rangle = \frac{1}{z-w}, \tag{48.312}$$

governed by the Euclidean action $S = \frac{1}{2\pi}\int \mathrm{d}^2x\,(\psi\bar\partial\psi + \bar\psi\partial\bar\psi)$, with holomorphic stress tensor

$$T(z) = -\tfrac{1}{2}\,{:}\psi\,\partial\psi{:}(z). \tag{48.313}$$

The antiholomorphic partner $\bar\psi(\bar z)$ contributes an independent copy.

ψ is a weight-$\frac{1}{2}$ primary. The contractions we need follow from Eq. (48.312): $\langle\psi(z)\psi(w)\rangle = (z-w)^{-1}$ and $\langle\partial\psi(z)\psi(w)\rangle = \partial_z(z-w)^{-1} = -(z-w)^{-2}$. Wick-contracting $T(z)\psi(w) = -\frac{1}{2}{:}\psi\partial\psi{:}(z)\,\psi(w)$, the external $\psi(w)$ contracts with either factor; tracking the single anticommutation needed to bring it adjacent to the contracted field,

$$T(z)\,\psi(w) \sim -\tfrac{1}{2}\Big[\langle\psi(z)\psi(w)\rangle\,\partial\psi(z) - \langle\partial\psi(z)\psi(w)\rangle\,\psi(z)\Big] = -\tfrac{1}{2}\Big[\frac{\partial\psi(z)}{z-w} + \frac{\psi(z)}{(z-w)^2}\Big]. \tag{48.314}$$

Taylor-expanding $\psi(z)$ and $\partial\psi(z)$ about w, the double pole collects $\frac{1}{2}\psi(w)$ and the single pole collects $\partial\psi(w)$ (the $-\frac{1}{2}$ and the expansion of the double-pole term combining to fix the descendant coefficient):

$$T(z)\,\psi(w) \sim \frac{\frac{1}{2}\,\psi(w)}{(z-w)^2} + \frac{\partial\psi(w)}{z-w}, \tag{48.315}$$

so ψ is primary with $h = \frac{1}{2}$. This is exactly the weight of the Ising energy operator's chiral constituent and, doubled, of ε (Theorem 48.33): $\varepsilon = i\bar\psi\psi$ has $(h,\bar h) = (\frac{1}{2},\frac{1}{2})$, $\Delta_\varepsilon = 1$.

Central charge $c = \frac{1}{2}$. Now contract the full product $T(z)T(w) = \frac{1}{4}\,{:}\psi\partial\psi{:}(z)\,{:}\psi\partial\psi{:}(w)$. The central term is the maximal contraction, in which both fields at z contract with both at w. Label the four fields $\psi(z), \partial\psi(z), \psi(w), \partial\psi(w)$. There are two complete pairings:

$$\text{pattern (i):}\quad \langle\psi(z)\psi(w)\rangle\,\langle\partial\psi(z)\partial\psi(w)\rangle = \frac{1}{z-w}\cdot\Big(-\frac{2}{(z-w)^3}\Big) = -\frac{2}{(z-w)^4}, \tag{48.316}$$

$$\text{pattern (ii):}\quad \langle\psi(z)\partial\psi(w)\rangle\,\langle\partial\psi(z)\psi(w)\rangle = \frac{1}{(z-w)^2}\cdot\Big(-\frac{1}{(z-w)^2}\Big) = -\frac{1}{(z-w)^4}, \tag{48.317}$$

where $\langle\partial\psi(z)\partial\psi(w)\rangle = \partial_z\partial_w(z-w)^{-1} = -2(z-w)^{-3}$ and $\langle\psi(z)\partial\psi(w)\rangle = \partial_w(z-w)^{-1} = (z-w)^{-2}$. Fermi statistics weights the two patterns by the sign

of the contraction permutation: pattern (i), whose contraction lines cross once, carries an extra (-1), while pattern (ii), with nested lines, carries $+1$. The central c-number is therefore

$$\tfrac{1}{4}\Big[(-1)\cdot\Big(-\frac{2}{(z-w)^4}\Big)+(+1)\cdot\Big(-\frac{1}{(z-w)^4}\Big)\Big]=\tfrac{1}{4}\cdot\frac{2-1}{(z-w)^4}=\frac{1/4}{(z-w)^4}. \tag{48.318}$$

Matching to $\frac{c/2}{(z-w)^4}$ (Theorem 48.8) gives $c/2=\frac{1}{4}$, hence

$$\boxed{c=\tfrac{1}{2}} \tag{48.319}$$

the lowest member $m=3$ of the discrete series. The single contractions reproduce, exactly as in the bosonic case, the $2T/(z-w)^2+\partial T/(z-w)$ weight-2 terms. The Ising CFT is the diagonal product of this holomorphic Majorana with its antiholomorphic mirror, $(c,\bar{c})=(\frac{1}{2},\frac{1}{2})$ — the free-fermion realization underlying the abstract solution of Section 48.6, and the microscopic statement that the two-dimensional Ising critical point is, after the Jordan–Wigner transformation, a theory of free fermions.

Physical Insight

Bosonization ties the two free realizations together. A *Dirac* fermion (two Majoranas) is equivalent to a single compact boson, with the fermion bilinears realized as vertex operators: $\psi_{\text{Dirac}}\sim{:}e^{iX}{:}$ at the appropriate radius, and the fermion number current as $\bar{\psi}_{\text{Dirac}}\gamma\psi_{\text{Dirac}}\sim\partial X$. The weights match because $h(e^{iX})=\frac{1}{2}$ equals the free-fermion weight. The single Majorana underlying Ising is then "half" of this boson, which is why $c=\frac{1}{2}=\frac{1}{2}\cdot 1$. This boson–fermion dictionary is the two-dimensional shadow of the more elaborate dualities of later parts, and it is the reason free fields are powerful out of proportion to their simplicity.

48.7.4 The Coulomb gas: background charge and the Feigin–Fuks construction

We have $c=1$ from the boson and $c=\frac{1}{2}$ from the fermion, but no single free field gives the intermediate minimal-model values $c=1-6/[m(m+1)]$ for $m=4,5,\dots$, nor does it explain *why* those values, and not others, are singled out. The Feigin–Fuks construction supplies both. The idea is to deform the free boson's stress tensor by a term linear in $\partial^2 X$, controlled by a *background charge* Q. Geometrically this places a fixed charge Q "at infinity" (on the sphere); algebraically it shifts the central charge and the vertex-operator weights in exactly the way needed to land on the minimal series.

Theorem 48.40 (Background-charge deformation; Feigin–Fuks)**.** *Let X be the free boson of Theorem 48.36. For any real Q the modified holomorphic stress tensor*

$$T_Q(z) = -\tfrac{1}{2}{:}\partial X\,\partial X{:}(z) + \frac{iQ}{2}\,\partial^2 X(z) \tag{48.320}$$

satisfies the $T(z)T(w)$ operator product of Eq. (48.56) with central charge

$$c = 1 - 3Q^2, \tag{48.321}$$

and the vertex operator $V_\alpha = {:}e^{i\alpha X}{:}$ remains primary, now with holomorphic weight

$$h_\alpha = \tfrac{1}{2}\alpha(\alpha - Q) = \tfrac{1}{2}\alpha^2 - \tfrac{1}{2}Q\alpha. \tag{48.322}$$

Choosing Q so that $Q^2 = 2\,(p-p')^2/(pp')$ for coprime integers $p > p' \geq 2$ yields $c = 1 - 6(p-p')^2/(pp')$, exactly the central charge of the minimal model $\mathcal{M}(p,p')$ of Eq. (48.176).

Proof. Central charge. Write $T_Q = A + B$ with $A = -\tfrac{1}{2}{:}\partial X\partial X{:}$ the free stress tensor and $B = \tfrac{iQ}{2}\partial^2 X$ the linear deformation. The product $T_Q T_Q = AA + AB + BA + BB$, and we read off the coefficient of $(z-w)^{-4}$. The pure free term AA already supplied $\tfrac{1}{2}/(z-w)^4$, i.e. the free $c = 1$ (Theorem 48.9). The deformation contributes through BB, a contraction of two linear-in-X fields:

$$\langle \partial^2 X(z)\,\partial^2 X(w)\rangle = \partial_z^2\partial_w^2\big[-\ln(z-w)\big] = \partial_z^2\partial_w^2\,\langle X(z)X(w)\rangle = \frac{6}{(z-w)^4}, \tag{48.323}$$

where the four derivatives of $-\ln(z-w)$ are computed step by step: $\partial_z\partial_w(-\ln) = -(z-w)^{-2}$, then ∂_z gives $+2(z-w)^{-3}$, then ∂_w gives $+6(z-w)^{-4}$. Hence

$$B(z)B(w) = \Big(\frac{iQ}{2}\Big)^2 \frac{6}{(z-w)^4} = -\frac{Q^2}{4}\cdot\frac{6}{(z-w)^4} = -\frac{3Q^2/2}{(z-w)^4}, \tag{48.324}$$

a pure c-number. The cross terms AB, BA contract one ∂X from A with the single $\partial^2 X$ of B and produce only poles of order ≤ 3 multiplying operators, contributing nothing to the $(z-w)^{-4}$ c-number (and, as one checks, exactly the modified $2T_Q/(z-w)^2 + \partial T_Q/(z-w)$ structure required for T_Q to be a stress tensor). Adding the free and deformation c-numbers,

$$\frac{c/2}{(z-w)^4} = \frac{1/2}{(z-w)^4} - \frac{3Q^2/2}{(z-w)^4} \quad\Longrightarrow\quad c = 1 - 3Q^2, \tag{48.325}$$

which is Eq. (48.321).

Vertex weight. The free stress tensor part A gave $h_\alpha^{\text{free}} = \tfrac{1}{2}\alpha^2$ via Eq. (48.298). The deformation $B = \tfrac{iQ}{2}\partial^2 X$ adds a contraction of $\partial^2 X(z)$ with the exponential. Using $\langle \partial^2 X(z)X(w)\rangle = \partial_z^2[-\ln(z-w)] = (z-w)^{-2}$,

$$\frac{iQ}{2}\,\partial^2 X(z)\,{:}e^{i\alpha X(w)}{:} \sim \frac{iQ}{2}\cdot(i\alpha)\,\frac{1}{(z-w)^2}\,V_\alpha(w) = -\frac{Q\alpha/2}{(z-w)^2}\,V_\alpha(w), \tag{48.326}$$

so the double-pole coefficient shifts from $\frac{1}{2}\alpha^2$ to $\frac{1}{2}\alpha^2 - \frac{1}{2}Q\alpha$, while the single-pole descendant term is unchanged (the deformation contributes no new $(z-w)^{-1}$ piece at leading order). Hence $T_Q(z)V_\alpha(w) \sim h_\alpha V_\alpha/(z-w)^2 + \partial V_\alpha/(z-w)$ with $h_\alpha = \frac{1}{2}\alpha(\alpha - Q)$, which is Eq. (48.322).

Matching the minimal series. By Eq. (48.321), $c = 1-6(p-p')^2/(pp')$ requires $3Q^2 = 6(p-p')^2/(pp')$, i.e. $Q^2 = 2(p-p')^2/(pp')$. This is the central charge of $\mathcal{M}(p,p')$ (Eq. (48.176)); in the consecutive-integer parametrization $p = m+1$, $p' = m$ of the unitary series it reads $c = 1 - 6/[m(m+1)]$ (Eq. (48.143)). □

Two features of Eq. (48.322) are decisive for what follows. First, the weight is invariant under $\alpha \to Q - \alpha$: $h_{Q-\alpha} = \frac{1}{2}(Q-\alpha)(-\alpha) = \frac{1}{2}\alpha(\alpha - Q) = h_\alpha$. The two charges α and $Q-\alpha$ create the *same* primary; this $\alpha \leftrightarrow Q - \alpha$ *charge conjugation* replaces the $\alpha \to -\alpha$ symmetry the background charge broke. Second, the background charge modifies neutrality. Repeating the zero-mode integral Eq. (48.301) in the presence of the charge Q at infinity, a correlator is nonzero only if the inserted charges sum to Q:

$$\Big\langle \prod_k V_{\alpha_k} \Big\rangle \neq 0 \quad \Longleftrightarrow \quad \sum_k \alpha_k = Q. \tag{48.327}$$

This shifted rule is the source of all the work below: a generic product of minimal-model vertex operators will *not* have charges summing to Q, and we must supply the deficit without disturbing the conformal weights. That is the job of the screening charges.

Degenerate fields and screening charges

The minimal-model primaries are the degenerate fields of Section 48.4.4, with Kac weights $h_{r,s}$. In the Coulomb gas they are vertex operators of definite charge. Define the two *screening charges* $\alpha_\pm$ as the charges whose vertex operators have weight exactly one,

$$h_{\alpha_\pm} = \tfrac{1}{2}\alpha_\pm(\alpha_\pm - Q) = 1 \quad \Longleftrightarrow \quad \alpha_\pm^2 - Q\alpha_\pm - 2 = 0, \tag{48.328}$$

so that, as roots of one quadratic, $\alpha_+ + \alpha_- = Q$ and $\alpha_+\alpha_- = -2$. Solving with $Q^2 = 2(p-p')^2/(pp')$ gives the explicit values

$$\alpha_+ = \sqrt{\frac{2p}{p'}}\,, \qquad \alpha_- = -\sqrt{\frac{2p'}{p}}\,, \tag{48.329}$$

which indeed satisfy $\alpha_+\alpha_- = -2$ and $\alpha_+ + \alpha_- = \sqrt{2}\,(p-p')/\sqrt{pp'} = Q$ (positive for $p > p'$). The degenerate primaries are then created by the charges

$$\alpha_{r,s} = \tfrac{1}{2}(1-r)\,\alpha_+ + \tfrac{1}{2}(1-s)\,\alpha_-, \qquad 1 \le r \le p'-1,\ 1 \le s \le p-1, \tag{48.330}$$

and substituting Eq. (48.330) into Eq. (48.322) reproduces the Kac formula of Eq. (48.177). For instance, with $p = m+1$, $p' = m$ and the charge $\alpha_{2,1} = -\frac{1}{2}\alpha_+$, one finds $h_{\alpha_{2,1}} = \frac{1}{2}(\frac{1}{2}\alpha_+)(\frac{1}{2}\alpha_+ + Q)$; using $\alpha_+^2 = 2(m+1)/m$ and $\alpha_+ Q = 2/m$ (both from Eq. (48.329)) this collapses to $h_{2,1} = (m+3)/(4m)$, exactly the Kac entry of Section 48.4.4. The free-field construction therefore reproduces the entire Kac table, weight for weight.

Notation Watch

We normalize the charges so that the screening operators have $h = 1$ and $\alpha_+\alpha_- = -2$, which pairs cleanly with the weight formula $h_\alpha = \frac{1}{2}\alpha(\alpha - Q)$ and $c = 1 - 3Q^2$ used throughout this section. A common alternative rescales every charge by $1/\sqrt{2}$, giving $\alpha_+\alpha_- = -1$ and $c = 1 - 24\alpha_0^2$ with background charge $2\alpha_0 = Q$; that is the normalization in which Eq. (48.142) was written. The two differ only by the conventional $\sqrt{2}$ and agree on every physical weight $h_{r,s}$ and on c.

The reason the operators Eq. (48.328) are called *screening* charges is that, having weight $(1,0)$, their integrals are conformally invariant and can be inserted freely to fix neutrality. We make this precise.

Definition 48.41 (Screening charges)**.** The *screening charges* are the contour integrals of the weight-$(1,0)$ vertex operators Eq. (48.328),

$$\mathcal{Q}_\pm = \oint \mathrm{d}z \, :e^{i\alpha_\pm X(z)}: , \tag{48.331}$$

each carrying U(1) charge $\alpha_\pm$ but conformal weight zero.

Proposition 48.42 (Screening charges are conformally invariant)**.** *Each $\mathcal{Q}_\pm$ of Eq. (48.331) commutes with every Virasoro generator, $[L_n, \mathcal{Q}_\pm] = 0$, and is therefore a dimension-zero operator that may be inserted into any correlator without altering its conformal transformation properties — changing only the total* U(1) *charge by $\alpha_\pm$.*

Proof. A weight-one holomorphic field $\phi(z)$ transforms as $\phi(z)(\mathrm{d}z)^1$, a 1-form, so its contour integral $\oint \mathrm{d}z\, \phi$ is invariant under any holomorphic reparametrization that leaves the contour endpoints (here none — the contour is closed) fixed; this is the residue/contour-deformation calculus of Theorem 5.23. Concretely, write $L_n = \oint \frac{\mathrm{d}z}{2\pi i}\, z^{n+1} T_Q(z)$ and use the primary OPE $T_Q(z) V_{\alpha_\pm}(w) \sim V_{\alpha_\pm}(w)/(z-w)^2 + \partial V_{\alpha_\pm}(w)/(z-w)$ (weight 1). Then

$$[L_n, \mathcal{Q}_\pm] = \oint \mathrm{d}w\, [L_n, V_{\alpha_\pm}(w)] = \oint \mathrm{d}w \left[(n+1)w^n\, V_{\alpha_\pm}(w) + w^{n+1}\, \partial V_{\alpha_\pm}(w)\right] = \oint \mathrm{d}w\, \partial_w (w^{n+1} V_{\alpha_\pm} \tag{48.332}$$

the integrand being a total derivative of a single-valued function around a closed contour (the would-be branch cut of $V_{\alpha_\pm}$ is harmless because $w^{n+1} V_{\alpha_\pm}$

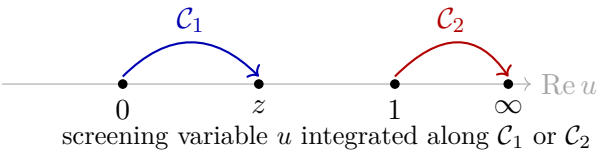

Figure 48.7: The two independent screening contours for the Ising spin four-point function after the Möbius fixing $z_1 = 0$, $z_2 = z$, $z_3 = 1$, $z_4 = \infty$. A single screening charge of type α_- is integrated over the variable u; the contour $\mathcal{C}_1$ from 0 to z produces the identity-channel block $f_+(z) \sim z^{-1/8}$, while $\mathcal{C}_2$ from 1 to ∞ produces the energy-channel block $f_-(z) \sim z^{3/8}$. The two channels are exactly $\sigma \times \sigma \to \mathbf{1} + \varepsilon$ of Eq. (48.240).

is integrated over a closed loop encircling no other insertion). Hence $\mathcal{Q}_\pm$ is Virasoro-invariant and has weight zero. □

Dotsenko–Fateev integral representations

The pieces now assemble into a computational rule for minimal-model correlators. Given physical primaries with charges $\alpha_1, \dots, \alpha_N$, the background-charge neutrality Eq. (48.327) demands $\sum_k \alpha_k = Q$. When the inserted charges fall short, we make up the deficit with screenings: insert n_+ copies of $\mathcal{Q}_+$ and n_- of $\mathcal{Q}_-$, chosen so that

$$\sum_{k=1}^{N} \alpha_k + n_+ \alpha_+ + n_- \alpha_- = Q. \tag{48.333}$$

By Theorem 48.42 this changes the charge but not the conformal structure, so the screened correlator is a genuine correlator of the intended primaries. The result is the *Dotsenko–Fateev integral representation*

$$\Big\langle \prod_k V_{\alpha_k}(z_k) \Big\rangle = \oint \prod_{a=1}^{n_+} \mathrm{d}u_a \oint \prod_{b=1}^{n_-} \mathrm{d}v_b \, \Big\langle \prod_k V_{\alpha_k}(z_k) \prod_a V_{\alpha_+}(u_a) \prod_b V_{\alpha_-}(v_b) \Big\rangle_{\text{free}}, \tag{48.334}$$

where the free correlator on the right is the explicit product of power laws Eq. (48.302), now neutral by construction, and the contour integrals over the screening positions u_a, v_b run over independent cycles. Each independent choice of contour produces one conformal block; the number of independent contours equals the number of fusion channels, so the integral representation packages all blocks of a given correlator at once. The monodromy-invariant combination of these contour integrals — the single-valued sum that closes the operator algebra — is the physical correlator. This is how the minimal-model four-point functions, fixed abstractly by the BPZ equations of Section 48.6, acquire closed-form integral expressions; for higher points the Coulomb gas is often the only practical method.

Worked Example 48.43 (The Ising spin four-point function from a single screening integral)**.** We now recover the four-point function of spins $\langle\sigma\sigma\sigma\sigma\rangle$ — obtained in Theorem 48.34 from the BPZ differential equation — by the Coulomb gas, as an independent cross-check. We work in the Ising model $\mathcal{M}(3,4)$ ($m=3$, $p=4$, $p'=3$), so by Eq. (48.329) the screening charges and background charge are

$$\alpha_+ = \sqrt{\tfrac{8}{3}}, \qquad \alpha_- = -\sqrt{\tfrac{3}{2}}, \qquad Q = \alpha_+ + \alpha_- = \tfrac{1}{\sqrt{6}}, \qquad Q^2 = \tfrac{1}{6},\ c = 1 - 3Q^2 = \tfrac{1}{2}, \tag{48.335}$$

confirming $c = \frac{1}{2}$. The spin $\sigma = \phi_{1,2}$ has charge $\alpha_\sigma = \alpha_{1,2} = -\frac{1}{2}\alpha_- = \frac{1}{2}\sqrt{\frac{3}{2}} = \frac{\sqrt{6}}{4}$, and one verifies its weight from Eq. (48.322): $\alpha_\sigma - Q = \frac{\sqrt{6}}{4} - \frac{1}{\sqrt{6}} = \frac{1}{2\sqrt{6}}$, so $h_\sigma = \frac{1}{2}\cdot\frac{\sqrt{6}}{4}\cdot\frac{1}{2\sqrt{6}} = \frac{1}{16}$, exactly $\Delta_\sigma = \frac{1}{8}$ split holomorphically.

Charge balance forces one screening. Insert three spins at charge α_σ and the fourth at the conjugate charge $\alpha'_\sigma = Q - \alpha_\sigma$ (same primary, by $\alpha \leftrightarrow Q-\alpha$), and n_- screenings of type α_-. Neutrality Eq. (48.333) reads $3\alpha_\sigma + (Q-\alpha_\sigma) + n_-\alpha_- = Q$, i.e. $2\alpha_\sigma + n_-\alpha_- = 0$. Since $\alpha_- = -2\alpha_\sigma$, this is satisfied by exactly $n_- = 1$: *one* screening, hence a second-order problem with *two* independent contours — matching the second-order BPZ equation and its two conformal blocks. The chiral correlator is therefore

$$\langle\sigma(z_1)\sigma(z_2)\sigma(z_3)\sigma(z_4)\rangle = \int_{\mathcal{C}} \mathrm{d}u\ \langle V_{\alpha_\sigma}(z_1)V_{\alpha_\sigma}(z_2)V_{\alpha_\sigma}(z_3)V_{\alpha'_\sigma}(z_4)\,V_{\alpha_-}(u)\rangle_{\text{free}}. \tag{48.336}$$

Evaluating the free correlator. By Eq. (48.302) the integrand is a product of power laws. The required charge products are $\alpha_\sigma^2 = \frac{3}{8}$, $\alpha_\sigma\alpha_- = \frac{\sqrt{6}}{4}\cdot(-\sqrt{\frac{3}{2}}) = -\frac{3}{4}$, and $\alpha'_\sigma\alpha_- = (Q-\alpha_\sigma)\alpha_- = -\frac{1}{2} - (-\frac{3}{4}) = \frac{1}{4}$. Fixing the Möbius frame $z_1 = 0, z_2 = z, z_3 = 1, z_4 \to \infty$ (the z_4 factors going into an overall normalization), the finite-point prefactor is $z^{3/8}(1-z)^{3/8}$ (from the three $\alpha_\sigma^2 = \frac{3}{8}$ pairs among $0, z, 1$), and the u-dependence is

$$\int_{\mathcal{C}} \mathrm{d}u\ u^{\alpha_\sigma\alpha_-}\,(u-z)^{\alpha_\sigma\alpha_-}\,(u-1)^{\alpha_\sigma\alpha_-} = \int_{\mathcal{C}} \mathrm{d}u\ \big[u\,(u-z)\,(u-1)\big]^{-3/4}, \tag{48.337}$$

so that $\langle\sigma\sigma\sigma\sigma\rangle \propto z^{3/8}(1-z)^{3/8}\,J_{\mathcal{C}}(z)$ with $J_{\mathcal{C}}(z)$ the integral Eq. (48.337).

The two contours give the two blocks. Take first the contour $\mathcal{C}_1$ from 0 to z (Fig. 48.7). Substituting $u = zt$, $t \in [0,1]$, the integral becomes, up to a z-independent constant and phases,

$$J_{\mathcal{C}_1}(z) = z^{-1/2}\int_0^1 \mathrm{d}t\ t^{-3/4}(1-t)^{-3/4}(1-zt)^{-3/4} = z^{-1/2}\,B\!\left(\tfrac{1}{4},\tfrac{1}{4}\right)\,{}_2F_1\!\left(\tfrac{3}{4},\tfrac{1}{4};\tfrac{1}{2};z\right), \tag{48.338}$$

recognizing Euler's integral for the hypergeometric function (the analytic-continuation machinery of Section 5.4 guarantees this representation extends off the unit in-

terval). Hence the corresponding block is

$$f_+(z) \propto z^{3/8}(1-z)^{3/8}\cdot z^{-1/2}\,{}_2F_1(\tfrac{3}{4},\tfrac{1}{4};\tfrac{1}{2};z) = z^{-1/8}(1-z)^{3/8}\,{}_2F_1(\tfrac{3}{4},\tfrac{1}{4};\tfrac{1}{2};z), \tag{48.339}$$

whose leading behavior as $z\to 0$ is $f_+\sim z^{-1/8}=z^{-2h_\sigma}$ — the *identity channel*, intermediate weight $h=0$. Taking instead the contour $\mathcal{C}_2$ from 1 to ∞ yields the second solution of the same hypergeometric equation, with leading behavior $f_-\sim z^{3/8}=z^{h_\varepsilon-2h_\sigma}$ (using $h_\varepsilon=\frac{1}{2}$) — the *energy channel*. The two exponents differing by $z^{h_\varepsilon}=z^{1/2}$ are precisely the two terms of the fusion $\sigma\times\sigma=\mathbf{1}+\varepsilon$ (Eq. (48.240)).

Closed form and agreement. The hypergeometric ${}_2F_1(\frac{3}{4},\frac{1}{4};\frac{1}{2};z)$ is one of the quadratic-transformation cases that reduce to elementary functions; the two blocks collapse to

$$f_\pm(z) = \frac{1}{\sqrt{2}}\,z^{-1/8}(1-z)^{-1/8}\big(1\pm\sqrt{1-z}\big)^{1/2}. \tag{48.340}$$

One checks the limits directly: as $z\to 0$, $1+\sqrt{1-z}\to 2$ gives $f_+\to z^{-1/8}$, while $1-\sqrt{1-z}\to z/2$ gives $f_-\to z^{-1/8}(z/2)^{1/2}\sim z^{3/8}$, reproducing the two channel exponents above. These are exactly the two chiral conformal blocks delivered by the BPZ second-order ODE in Theorem 48.34. Gluing the holomorphic and antiholomorphic blocks into the unique monodromy-invariant (single-valued) combination,

$$\langle\sigma\sigma\sigma\sigma\rangle(z,\bar z)\ \propto\ |f_+(z)|^2+|f_-(z)|^2 = \tfrac{1}{2}\,|z(1-z)|^{-1/4}\Big(\big|1+\sqrt{1-z}\big|+\big|1-\sqrt{1-z}\big|\Big), \tag{48.341}$$

with the relative coefficient fixed to unity by demanding a single identity in the $\sigma\times\sigma$ OPE, recovers the closed-form spin four-point function of Theorem 48.34. The Coulomb gas and the BPZ differential equation — one built from a deformed free field, the other from a null vector — produce the identical correlator.

This cross-validation is the payoff of the entire chapter. The same number $c=\frac{1}{2}$ and the same four-point function have now been reached three ways: from Virasoro representation theory and the Kac determinant (Section 48.6), from a free Majorana fermion (Eq. (48.319)), and from a screened free boson (Theorem 48.43). That three independent constructions agree to the last factor is the concrete meaning of the claim that the minimal models are completely solved.

With explicit field realizations in hand the chapter closes, but its objects propagate forward. The conformal-block decomposition that the screening contours made manifest is the seed of the bootstrap: in Chapters 49 and 51 the same blocks, viewed as eigenfunctions of a Casimir rather than solutions of a null-vector ODE, become the analytic backbone of crossing symmetry in any

dimension. The free boson itself, with its vertex operators and $R \to 1/R$ duality, is the elementary string coordinate and the simplest holographic boundary theory, carried forward to the strings-and-holography parts. And the logarithm in the boson propagator Eq. (48.290), integrated over a region, is what makes the entanglement entropy of a two-dimensional critical system grow as $\frac{c}{3}\ln \ell$ — the universal c-dependent law taken up in Chapter 55, where the central charge we have computed three times over reappears as the coefficient of an entanglement.

Further reading

The foundational paper is Belavin et al. [56], which introduced the infinite conformal symmetry, the central charge, degenerate representations, and the null-vector differential equations now bearing the authors' initials; it remains the indispensable original. The unitarity bound and the discrete series are due to Friedan et al. [200], building on the representation theory of Kac [287]. The two standard textbook developments, both far more extensive than this chapter, are Di Francesco et al. [147] and the lecture notes of Ginsparg [221]; either is the natural next stop for the modular-invariance, Wess–Zumino–Witten, and torus-partition-function material we did not treat. The Coulomb-gas construction and the screened correlators are developed in Dotsenko and Fateev [160]. For the connection to critical phenomena and the statistical-mechanics viewpoint, Cardy [108] and the review by Cardy [109] are the canonical references, and the c-theorem organizing the space of two-dimensional theories under RG flow is Zamolodchikov [531].

Chapter 49

The Conformal Bootstrap: Foundations

The two preceding chapters built a conformal field theory out of its data and then learned to compute with it. Chapter 47 fixed what a CFT *is* — a spectrum of primary dimensions and spins together with the operator product coefficients that govern their fusion — and supplied the machinery that turns those numbers into correlators: a convergent operator product expansion (Theorem 47.48) and the decomposition of the four-point function into conformal blocks (Eq. (47.227)). Chapter 48 exhibited that data in solved form, most sharply in the $c = \frac{1}{2}$ Ising minimal model whose dimensions and structure constants (Theorem 48.33 and Eq. (48.319)) are known exactly from the free Majorana realization. In every case so far the CFT data were handed to us — read off a free field, computed order by order in the ϵ-expansion of Chapter 24, or postulated. This chapter inverts the posture. It asks which sets of data are admissible at all, not against a Lagrangian — there need be none — but against the bare demand that the operator algebra be associative. That single demand, written on the four-point function, is the conformal bootstrap.

The chapter is organized around one equation and the question of how to solve or bound it. Section 49.1 isolates the constraint: equating the s- and t-channel block expansions of $\langle\phi\phi\phi\phi\rangle$ produces crossing symmetry (Theorem 49.2), a single functional equation in which the identity operator supplies the inhomogeneous source and the unknown CFT data must conspire to cancel it. To make that equation computable we need the blocks as explicit functions, so Section 49.2 solves the conformal Casimir equation of Eq. (47.233) in closed form — collinear blocks from a Gauss hypergeometric, the finite $d = 2$ and $d = 4$ blocks, and the radial ρ-series whose convergence is tied to the radial-quantization inner product of Theorem 47.34. With explicit blocks in hand, Section 49.3 packages crossing into the bootstrap sum rule $\sum_{\mathcal{O}} p_{\mathcal{O}} F_{\Delta,\ell} = 0$, in which all dynamics sits in nonnegative weights and a discrete spectrum bounded below by the unitarity

bounds of Theorem 47.18.

That sum rule is a linear equation in nonnegative unknowns, and the geometry of such problems is the subject of Section 49.4: a linear functional made nonnegative on every admissible block certifies, by a sign contradiction, that no consistent unitary spectrum can do what it forbids (Theorem 49.21). This is the engine of every rigorous bootstrap bound. We then earn trust in the machine by running it where the answer is known. Section 49.5 solves crossing exactly for the generalized free (mean-field) field — extracting its full double-twist spectrum and OPE coefficients, the seed of the analytic bootstrap of Chapter 51 — and verifies term by block that the 2D Ising correlators of Chapter 48 satisfy the same equation. Finally Section 49.6 points the validated apparatus at a theory we cannot solve in closed form, the three-dimensional Ising universality class, posing the bootstrap problem precisely and stating, dated to the mid-2020s, exactly what is proved (the exclusions) versus what is numerical (the island).

Throughout, the chapter advances ϕ^4 theory. Mean-field theory is the Gaussian ($\lambda \to 0$) endpoint of the thread; the 3D Ising CFT is the interacting fixed point that the Wilson–Fisher flow of Theorem 24.31 approaches, and the closing worked example confronts the bootstrap island directly against the ϵ-expansion to confirm that the nonperturbative crossing solution and the perturbative RG fixed point are one CFT. We work in Euclidean signature with points $x_i \in \mathbb{R}^d$ and separations $x_{ij}^2 \geq 0$; conformal kinematics is signature-agnostic, and the mostly-minus metric of the rest of the book plays no role until the Lorentzian continuation of Chapter 51. The explicit numerical solution — semidefinite programming and the convergence of the island — is handed to Chapter 50; the analytic limits to Chapter 51; and the closure with the critical exponents of Part VI to Chapter 52.

49.1 Crossing Symmetry: The Four-Point Function as a Constraint

Chapters 47 and 48 handed us two things and asked nothing of them. First, a complete catalogue of what a conformal field theory *is*: the dimensions and spins of its primary operators together with the constants that govern their fusion — the CFT data. Second, the machinery that turns those numbers into correlation functions: a convergent operator product expansion (Theorem 47.48) and the decomposition of the four-point function into conformal blocks (Eq. (47.227)). Up to this point the data have been treated as given — read off a free field, computed order by order in ϵ, or simply postulated. The bootstrap inverts that posture. It asks: *which* sets of CFT data are consistent? Not consistent with a Lagrangian — there need be none — but consistent with the bare requirement that the operator algebra make sense. This section isolates the single equation that requirement becomes. The unknowns are the CFT data; the equation is the

associativity of the OPE, made concrete as crossing symmetry of the four-point function. Everything else in the chapter — closed-form blocks, unitarity bounds, the numerical and analytic attacks — is in service of solving, or bounding the solutions of, the relation written down here.

Throughout we work in Euclidean signature, as in Chapter 47: points $x_i \in \mathbb{R}^d$, separations $x_{ij}^2 = |x_i - x_j|^2 \geq 0$. The mostly-minus metric and natural units of the rest of the book play no role here; conformal kinematics is signature-agnostic until the Lorentzian continuation of Chapter 51.

49.1.1 The unknowns: CFT data

Recall the inventory assembled in Chapter 47. A conformal field theory is specified, completely, by two pieces of data:

$$\Big(\{\Delta_{\mathcal{O}},\ \ell_{\mathcal{O}}\}\,, \quad \{\, C_{\mathcal{O}_1\mathcal{O}_2\mathcal{O}_3}\,\} \Big), \tag{49.1}$$

the *spectrum* — the scaling dimension $\Delta_{\mathcal{O}}$ and spin $\ell_{\mathcal{O}}$ of every primary operator $\mathcal{O}$ — and the *operator product coefficients* $C_{\mathcal{O}_1\mathcal{O}_2\mathcal{O}_3}$, one real number for each ordered triple of primaries, appearing both as the constant in the three-point function (Theorem 47.24) and as the coefficient in the OPE (Theorem 47.46). That these two roles are filled by the *same* number is the content of the state–operator correspondence and the convergence of the OPE: the constant that controls how $\mathcal{O}_1$ and $\mathcal{O}_2$ fuse at short distance is the same constant that appears when all three operators are far apart. Two-point functions are fixed by symmetry up to a normalization we set to unity (Eq. (47.124)); three-point functions are fixed up to the single constant C_{123} (Theorem 47.24). Nothing else is free. Every correlation function of the theory, at any number of points, is in principle assembled from Eq. (49.1) by repeated use of the OPE. The data Eq. (49.1) are therefore the unknowns of the bootstrap: to "solve" a CFT is to determine them.

The decisive observation is that symmetry alone does not constrain the data at the level of any correlator below four points. The two-point function is a pure power law; the three-point function is that power law times a single undetermined constant; in both cases conformal invariance exhausts the kinematics and leaves the data unconstrained. The first correlator on which symmetry leaves a genuine *function* undetermined — and therefore the first place a consistency condition can bite — is the four-point function. This is the staircase of Section 47.4.6: at each step symmetry does less, and at the fourth step it stops fixing the answer and starts merely organizing it. The four-point function of identical scalars is thus the smallest object whose conformal-block decomposition is not dictated by symmetry, and it is on this object that the entire bootstrap is built.

49.1.2 The four-point function and its s-channel decomposition

Specialize, as ϕ^4 theory requires, to four identical scalar primaries: a single real scalar ϕ of dimension Δ_ϕ, the operator that will become the order parameter of the Wilson–Fisher / Ising fixed point. Conformal invariance fixes its four-point function up to a function of the two cross-ratios (Eq. (47.145)),

$$\langle\, \phi(x_1)\, \phi(x_2)\, \phi(x_3)\, \phi(x_4)\, \rangle = \frac{g(u,v)}{(x_{12}^2\, x_{34}^2)^{\Delta_\phi}}, \tag{49.2}$$

where the cross-ratios are (Eq. (47.138))

$$u = \frac{x_{12}^2\, x_{34}^2}{x_{13}^2\, x_{24}^2}, \qquad v = \frac{x_{14}^2\, x_{23}^2}{x_{13}^2\, x_{24}^2}. \tag{49.3}$$

Fusing the pair $(\phi(x_1)\phi(x_2))$ and, independently, the pair $(\phi(x_3)\phi(x_4))$ by the OPE projects the correlator onto the primaries $\mathcal{O}$ exchanged between the two pairs, and resumming each primary together with all its descendants into a conformal block (Theorem 47.49) gives the block decomposition (Eq. (47.227))

$$g(u,v) = \sum_{\mathcal{O}} C_{\phi\phi\mathcal{O}}^2\, G_{\Delta_\mathcal{O},\ell_\mathcal{O}}(u,v). \tag{49.4}$$

We call the pairing (12)(34) the *s-channel*. The weights are squared OPE coefficients $C_{\phi\phi\mathcal{O}}^2 \geq 0$ — squared because both pairs are the same pair $\phi\phi$, so each exchanged $\mathcal{O}$ enters with $C_{\phi\phi\mathcal{O}}$ from each side. The blocks $G_{\Delta,\ell}(u,v)$ are universal: they are fixed by conformal symmetry alone, common to every CFT in d dimensions, and depend on the exchanged operator only through its quantum numbers $(\Delta_\mathcal{O}, \ell_\mathcal{O})$. Their explicit construction is the business of Section 49.2; here they are inputs known in principle.

One exchanged operator is present in *every* CFT and deserves to be separated out: the identity $\mathbf{1}$, with $\Delta = 0$, $\ell = 0$. It appears in the $\phi \times \phi$ OPE because the leading term of any operator with itself is the identity, and its coefficient is fixed by the unit normalization of the two-point function, $C_{\phi\phi\mathbf{1}} = 1$. Its block is trivial: the identity exchange factorizes the four-point function into a product of two-point functions,

$$\langle\phi(x_1)\phi(x_2)\rangle\langle\phi(x_3)\phi(x_4)\rangle = \frac{1}{(x_{12}^2\, x_{34}^2)^{\Delta_\phi}}, \tag{49.5}$$

which upon stripping the prefactor of Eq. (49.2) contributes exactly 1 to $g(u,v)$. Hence

$$G_{0,0}(u,v) = 1, \tag{49.6}$$

and the s-channel sum reads

$$g(u,v) = 1 + \sum_{\mathcal{O}\neq\mathbf{1}} C_{\phi\phi\mathcal{O}}^2\, G_{\Delta_\mathcal{O},\ell_\mathcal{O}}(u,v). \tag{49.7}$$

The "1" is the disconnected piece; everything beyond it is genuine dynamics, weighted by the data we are trying to determine.

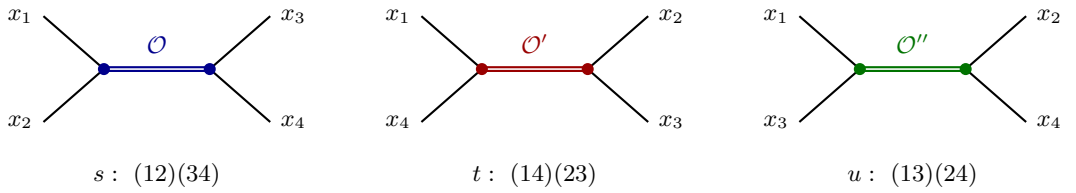

Figure 49.1: The three OPE channels of the four-point function $\langle\phi\phi\phi\phi\rangle$. The four points can be split into two pairs in exactly three ways; each splitting fuses a different pair by the OPE and expands the same correlator over a different tower of exchanged primaries. Crossing symmetry is the demand that the three series agree.

49.1.3 The three OPE channels

A four-point function offers more than one way to apply the OPE. Four objects can be split into two unordered pairs in exactly three ways,

$$\underbrace{(12)(34)}_{s}, \qquad \underbrace{(14)(23)}_{t}, \qquad \underbrace{(13)(24)}_{u}, \tag{49.8}$$

and each splitting defines an OPE channel in which the correlator can be expanded over exchanged primaries. We have used the s-channel above; the t- and u-channels fuse different pairs. Physically, the OPE is the statement that fusing two nearby operators produces a sum of local operators, and the four-point function does not care *which* two we fuse first — the operator algebra is associative. The three expansions Eq. (49.8) are therefore three series for one and the same number. Figure 49.1 renders the three pairings.

To turn "the same number" into an equation we must see how the kinematic prefactor and the cross-ratios behave when we pass from one channel to another. The channels are related by permuting the four (identical) points: since ϕ is a single bosonic scalar, the correlator is invariant under any permutation of $x_1, \dots, x_4$,

$$\langle\phi(x_1)\phi(x_2)\phi(x_3)\phi(x_4)\rangle = \langle\phi(x_{\sigma(1)})\phi(x_{\sigma(2)})\phi(x_{\sigma(3)})\phi(x_{\sigma(4)})\rangle, \qquad \sigma \in S_4. \tag{49.9}$$

The s-channel pairing (12)(34) is carried into the t-channel pairing (14)(23) by the transposition $1 \leftrightarrow 3$, and into the u-channel pairing (13)(24) by $2 \leftrightarrow 3$. We compute the effect of $1 \leftrightarrow 3$ in detail, as it produces the crossing equation; the others go identically.

Lemma 49.1 (Action of the $1 \leftrightarrow 3$ exchange on the cross-ratios)**.** *Under the exchange of the points x_1 and x_3, the cross-ratios Eq. (49.3) swap,*

$$(u, v) \xmapsto{1\leftrightarrow 3} (v, u), \tag{49.10}$$

and the s-channel kinematic prefactor transforms as

$$\frac{1}{(x_{12}^2\,x_{34}^2)^{\Delta_\phi}} \xrightarrow{1\leftrightarrow 3} \frac{1}{(x_{32}^2\,x_{14}^2)^{\Delta_\phi}} = \frac{1}{(x_{14}^2\,x_{23}^2)^{\Delta_\phi}}. \tag{49.11}$$

Proof. Relabel the points by $y_1 = x_3$, $y_2 = x_2$, $y_3 = x_1$, $y_4 = x_4$, so that the exchange $1 \leftrightarrow 3$ is the statement that the y-correlator equals the x-correlator. The squared separations needed are read off directly, using $x_{ij}^2 = x_{ji}^2$:

$$\begin{aligned} &y_{12}^2 = x_{32}^2 = x_{23}^2, \quad y_{34}^2 = x_{14}^2, \quad y_{13}^2 = x_{31}^2 = x_{13}^2, \\ &y_{24}^2 = x_{24}^2, \qquad\quad y_{14}^2 = x_{34}^2, \quad y_{23}^2 = x_{21}^2 = x_{12}^2. \end{aligned} \tag{49.12}$$

Substituting into the definitions Eq. (49.3) evaluated on the y's,

$$u_y = \frac{y_{12}^2\,y_{34}^2}{y_{13}^2\,y_{24}^2} = \frac{x_{23}^2\,x_{14}^2}{x_{13}^2\,x_{24}^2} = v, \qquad v_y = \frac{y_{14}^2\,y_{23}^2}{y_{13}^2\,y_{24}^2} = \frac{x_{34}^2\,x_{12}^2}{x_{13}^2\,x_{24}^2} = u, \tag{49.13}$$

which is Eq. (49.10). The prefactor follows from $y_{12}^2 y_{34}^2 = x_{23}^2 x_{14}^2$, giving Eq. (49.11). □

49.1.4 Crossing symmetry

We now have the two facts the crossing equation is made of: the correlator is the same whether we fuse in the s- or t-pairing (Eq. (49.9)), and the passage between the two pairings swaps $(u, v) \to (v, u)$ while changing the prefactor as in Eq. (49.11). Equating the two block expansions and tracking the prefactor produces a single nontrivial functional equation.

Definition 49.2 (Crossing symmetry)**.** *Crossing symmetry* of the four-point function $\langle\phi\phi\phi\phi\rangle$ is the requirement that its s-channel and t-channel conformal-block decompositions describe the same correlator. Equivalently, in terms of the stripped function $g(u, v)$ of Eq. (49.2), it is the identity

$$\boxed{g(u,v) = \left(\frac{u}{v}\right)^{\Delta_\phi} g(v,u)} \tag{49.14}$$

holding for all values of the cross-ratios.

Proposition 49.3 (Derivation of the crossing equation)**.** *The block decomposition Eq. (49.4) together with permutation invariance Eq. (49.9) implies Eq. (49.14), equivalently the block sum rule*

$$\sum_{\mathcal{O}} C_{\phi\phi\mathcal{O}}^2 \Big[\, v^{\Delta_\phi}\, G_{\Delta_\mathcal{O},\ell_\mathcal{O}}(u,v) \;-\; u^{\Delta_\phi}\, G_{\Delta_\mathcal{O},\ell_\mathcal{O}}(v,u) \,\Big] = 0. \tag{49.15}$$

Proof. Write the four-point function two ways, both as exact OPE expansions of *the same* correlator.

The s-channel expansion is Eq. (49.2) with Eq. (49.4),

$$\langle\phi\phi\phi\phi\rangle = \frac{1}{(x_{12}^2\,x_{34}^2)^{\Delta_\phi}} \sum_{\mathcal{O}} C_{\phi\phi\mathcal{O}}^2\, G_{\Delta_\mathcal{O},\ell_\mathcal{O}}(u,v). \tag{49.16}$$

For the t-channel, fuse the pairs (14) and (23). By permutation invariance Eq. (49.9) this is the s-channel expansion of the relabelled correlator $\langle\phi(x_3)\phi(x_2)\phi(x_1)\phi(x_4)\rangle$, i.e. the s-channel formula Eq. (49.16) evaluated on the points $y_1 = x_3$, $y_2 = x_2$, $y_3 = x_1$, $y_4 = x_4$ of Theorem 49.1. That lemma gives $(u_y, v_y) = (v, u)$ and the prefactor Eq. (49.11), so

$$\langle\phi\phi\phi\phi\rangle = \frac{1}{(x_{14}^2\,x_{23}^2)^{\Delta_\phi}} \sum_{\mathcal{O}} C_{\phi\phi\mathcal{O}}^2\, G_{\Delta_\mathcal{O},\ell_\mathcal{O}}(v,u). \tag{49.17}$$

The two coefficient sets are identical: the operators exchanged in the t-channel of $\langle\phi\phi\phi\phi\rangle$ are the same primaries, with the same squared coefficients $C_{\phi\phi\mathcal{O}}^2$, because both pairs being fused are again the pair $\phi\phi$. Equating Eq. (49.16) and Eq. (49.17) and cancelling the common factor $\langle\phi\phi\phi\phi\rangle$ on the left, multiply through by $(x_{12}^2 x_{34}^2)^{\Delta_\phi}$:

$$\sum_{\mathcal{O}} C_{\phi\phi\mathcal{O}}^2\, G_{\Delta_\mathcal{O},\ell_\mathcal{O}}(u,v) = \left(\frac{x_{12}^2\,x_{34}^2}{x_{14}^2\,x_{23}^2}\right)^{\Delta_\phi} \sum_{\mathcal{O}} C_{\phi\phi\mathcal{O}}^2\, G_{\Delta_\mathcal{O},\ell_\mathcal{O}}(v,u). \tag{49.18}$$

The prefactor ratio is itself a ratio of cross-ratios. From Eq. (49.3), $u = x_{12}^2 x_{34}^2/(x_{13}^2 x_{24}^2)$ and $v = x_{14}^2 x_{23}^2/(x_{13}^2 x_{24}^2)$ share the denominator $x_{13}^2 x_{24}^2$, so it cancels in the quotient,

$$\frac{u}{v} = \frac{x_{12}^2\,x_{34}^2}{x_{14}^2\,x_{23}^2}. \tag{49.19}$$

The left-hand side of Eq. (49.18) is $g(u,v)$ and the sum on the right is $g(v,u)$, so Eq. (49.18) is precisely Eq. (49.14). Finally, multiply Eq. (49.14) by v^{Δ_ϕ} and substitute the block sum for each g,

$$v^{\Delta_\phi} \sum_{\mathcal{O}} C_{\phi\phi\mathcal{O}}^2 G_{\Delta_\mathcal{O},\ell_\mathcal{O}}(u,v) = u^{\Delta_\phi} \sum_{\mathcal{O}} C_{\phi\phi\mathcal{O}}^2 G_{\Delta_\mathcal{O},\ell_\mathcal{O}}(v,u), \tag{49.20}$$

which rearranges into the sum rule Eq. (49.15). □

Two features of Eq. (49.15) are worth stating before they are exploited in the rest of the chapter. First, the factor $(u/v)^{\Delta_\phi}$ in Eq. (49.14) is not optional decoration: it is the exact Jacobian by which the kinematic prefactor differs between the s- and t-pairings, derived in Eq. (49.19) from nothing but the definitions of the cross-ratios. It carries the external dimension Δ_ϕ and couples the spectrum of exchanged operators to the dimension of the external scalar;

this coupling is what makes the bootstrap sensitive to Δ_ϕ at all. Second, the equation is one constraint that must hold *identically in u and v* — an infinite number of conditions, one for each point of cross-ratio space, on the discrete data $\{(\Delta_\mathcal{O}, \ell_\mathcal{O}), C^2_{\phi\phi\mathcal{O}}\}$. It is overdetermined in exactly the way that makes it powerful: a generic set of dimensions and coefficients will not satisfy it, and the ones that do are the candidate CFTs.

Physical Insight

The slogan "the equation is OPE associativity" is literal. Inside $\langle\phi(x_1)\phi(x_2)\phi(x_3)\phi(x_4)\rangle$ we may fuse $\phi(x_1)\phi(x_2)$ first and then combine the result with $\phi(x_3)\phi(x_4)$, or fuse $\phi(x_2)\phi(x_3)$ first and combine with $\phi(x_1)\phi(x_4)$. These are two bracketings of the same triple product of fusions, and the OPE — being an operator identity (Theorem 47.46) convergent on overlapping regions (Theorem 47.48) — must give the same answer for both. Crossing symmetry is associativity of the operator algebra written out on the four-point function. Higher-point associativity adds no genuinely new constraint: it can be reduced, by inserting complete sets of states, to the four-point relation together with the consistency of OPE coefficients. This is why the four-point function, and this one equation, are the whole game.

The identity operator plays a special and load-bearing role in Eq. (49.15). Separate it out on both sides using Eq. (49.6), $G_{0,0} = 1$:

$$(v^{\Delta_\phi} - u^{\Delta_\phi}) \; + \sum_{\mathcal{O}\neq\mathbf{1}} C^2_{\phi\phi\mathcal{O}}\Big[v^{\Delta_\phi} G_{\Delta_\mathcal{O},\ell_\mathcal{O}}(u,v) - u^{\Delta_\phi} G_{\Delta_\mathcal{O},\ell_\mathcal{O}}(v,u)\Big] = 0. \quad (49.21)$$

The identity contributes the inhomogeneous term $v^{\Delta_\phi} - u^{\Delta_\phi}$, which does not vanish (the two cross-ratios are independent). Were the identity absent, Eq. (49.21) would be a homogeneous equation solved trivially by the empty spectrum; it is the identity, present in every CFT with $C^2_{\phi\phi\mathbf{1}} = 1$ fixed by the normalization of $\langle\phi\phi\rangle$, that forces a nonempty tower of operators to "conspire" to cancel $v^{\Delta_\phi} - u^{\Delta_\phi}$. The overall scale of the equation is likewise fixed by the identity: because $C_{\phi\phi\mathbf{1}} = 1$ is not a free parameter, the inhomogeneous term has a definite normalization, and the squared coefficients $C^2_{\phi\phi\mathcal{O}}$ of all other operators are measured relative to it. The identity is, in this precise sense, the unique source term of the bootstrap.

Remark 49.4 (The u-channel and the role of S_4). We derived crossing from the single transposition $1 \leftrightarrow 3$ relating the s- and t-channels. The remaining transpositions of S_4 give nothing genuinely new for identical scalars. The exchange $2 \leftrightarrow 3$ maps the s-pairing $(12)(34)$ to the u-pairing $(13)(24)$; repeating the computation of Theorem 49.1 with $y_1 = x_1, y_2 = x_3, y_3 = x_2, y_4 = x_4$ gives $(u,v) \to (1/u,\, v/u)$ and prefactor ratio u^{Δ_ϕ}, hence the u-channel relation $g(u,v) = u^{\Delta_\phi} g(1/u,\, v/u)$. Meanwhile the exchange $1 \leftrightarrow 2$ preserves the s-pairing

and yields a *symmetry of g itself*, $g(u,v) = g(u/v,\, 1/v)$, reflecting that swapping the two operators inside a fused pair changes nothing. The full image of S_4 acting on the pair (u,v) is the group S_3 (the kernel being the Klein four-group $\{e, (12)(34), (13)(24), (14)(23)\}$ under which u, v are separately invariant); it is generated by the single crossing relation Eq. (49.14) together with the within-channel symmetry $g(u,v) = g(u/v, 1/v)$. For identical external scalars, then, the s–t equation Eq. (49.14) is the one independent dynamical constraint, and it is the equation the chapter solves.

49.1.5 A worked check: the generalized free field

Before leaving the framing, it pays to see crossing satisfied exactly in the one case where the four-point function is known in closed form without any block technology: the *generalized free field* (equivalently, mean-field theory), of which the free massless scalar of Section 48.7.1 is the special case $\Delta_\phi = (d-2)/2$. This is the trivial endpoint of ϕ^4 theory — the Gaussian fixed point — and verifying crossing on it confirms that Eq. (49.14) is correctly normalized, including the $(u/v)^{\Delta_\phi}$ Jacobian.

Worked Example 49.5 (Crossing of the generalized free field)**.** A generalized free field is defined by Wick's theorem: its connected correlators vanish and its four-point function is the sum over the three pairwise contractions, each a product of unit-normalized two-point functions $\langle \phi(x_i)\phi(x_j)\rangle = (x_{ij}^2)^{-\Delta_\phi}$,

$$\langle \phi(x_1)\phi(x_2)\phi(x_3)\phi(x_4)\rangle = \frac{1}{(x_{12}^2 x_{34}^2)^{\Delta_\phi}} + \frac{1}{(x_{13}^2 x_{24}^2)^{\Delta_\phi}} + \frac{1}{(x_{14}^2 x_{23}^2)^{\Delta_\phi}}. \tag{49.22}$$

Strip the prefactor as in Eq. (49.2), multiplying through by $(x_{12}^2 x_{34}^2)^{\Delta_\phi}$. The first term gives 1. The second and third are ratios of separations that are precisely the cross-ratios: from Eq. (49.3),

$$\frac{x_{12}^2 x_{34}^2}{x_{13}^2 x_{24}^2} = u, \qquad \frac{x_{12}^2 x_{34}^2}{x_{14}^2 x_{23}^2} = \frac{u}{v}, \tag{49.23}$$

the second equality being Eq. (49.19). Hence the stripped function is

$$g(u,v) = 1 + u^{\Delta_\phi} + \left(\frac{u}{v}\right)^{\Delta_\phi}. \tag{49.24}$$

The three terms are exactly the identity exchanged in the s-, u-, and t-channels respectively — the disconnected correlator is a pure sum of identity blocks, one per channel.

Now test crossing Eq. (49.14). First evaluate $g(v,u)$ by swapping the arguments in Eq. (49.24),

$$g(v,u) = 1 + v^{\Delta_\phi} + \left(\frac{v}{u}\right)^{\Delta_\phi}, \tag{49.25}$$

then multiply by the Jacobian $(u/v)^{\Delta_\phi}$ and expand term by term,

$$\left(\frac{u}{v}\right)^{\Delta_\phi} g(v,u) = \left(\frac{u}{v}\right)^{\Delta_\phi} + \left(\frac{u}{v}\right)^{\Delta_\phi} v^{\Delta_\phi} + \left(\frac{u}{v}\right)^{\Delta_\phi}\left(\frac{v}{u}\right)^{\Delta_\phi} = \left(\frac{u}{v}\right)^{\Delta_\phi} + u^{\Delta_\phi} + 1. \tag{49.26}$$

In the middle term $(u/v)^{\Delta_\phi} v^{\Delta_\phi} = u^{\Delta_\phi}$, and the last term collapses to 1. The result is $1 + u^{\Delta_\phi} + (u/v)^{\Delta_\phi} = g(u,v)$, so Eq. (49.14) holds identically. The Jacobian does precisely the work of permuting the three identity contributions among the channels: it carries the t-channel identity (1 in $g(v,u)$) into the t-channel term $(u/v)^{\Delta_\phi}$ of $g(u,v)$, and so on cyclically. This is the simplest nontrivial solution of the crossing equation, and it shows that the equation is satisfied not term by term but by the spectrum acting as a whole — here, a spectrum of "double-twist" operators of dimensions $2\Delta_\phi + 2n + \ell$ hidden inside the block decomposition of Eq. (49.24), whose existence Chapter 51 will extract analytically.

The generalized free field saturates crossing trivially because it has no interactions: its spectrum is rigidly fixed by Wick's theorem. The content of ϕ^4 theory at the frontier is the opposite situation. At the Wilson–Fisher fixed point in $d = 4 - \epsilon$, and at the Ising fixed point in $d = 3$, the scalar ϕ acquires an anomalous dimension and the four-point function is no longer a sum of three identity blocks; $g(u,v)$ becomes an honestly unknown function, and Eq. (49.14) becomes a genuine constraint on the unknown CFT data. The bootstrap is the program of extracting that data from the constraint.

We now have the central object of the chapter in final form: one crossing equation, Eq. (49.14) or equivalently the sum rule Eq. (49.15), relating the conformal-block decompositions of a single four-point function in two channels, with the exact $(u/v)^{\Delta_\phi}$ relabeling made explicit and the identity fixing its normalization. The equation is, however, still implicit: it is written in terms of the blocks $G_{\Delta,\ell}(u,v)$, which so far we know only as eigenfunctions of the conformal Casimir (Eq. (47.233)). To make crossing computable — to evaluate the sum rule, expand it near boundaries of cross-ratio space, and feed it to the numerical and analytic machinery of the rest of the chapter — we need the blocks as explicit functions. Constructing them is the task of Section 49.2.

49.2 Conformal Blocks in Closed Form

The crossing equation of Section 49.1.4 relates two block expansions of one four-point function, and the worked check of Theorem 49.5 showed it satisfied exactly by the generalized free field. Both used the conformal blocks $G_{\Delta,\ell}(u,v)$ as inputs, known only abstractly: by Theorem 47.49 a block is the contribution of a single conformal multiplet to the stripped four-point function, and by Eq. (47.233) it is fixed as the eigenfunction of the quadratic Casimir with

eigenvalue $c_{\Delta,\ell} = \Delta(\Delta - d) + \ell(\ell + d - 2)$ subject to the boundary condition that it begin with the OPE power $u^{(\Delta-\ell)/2}$. That is an implicit definition: it pins down a function but does not display it. To evaluate the sum rule Eq. (49.15), to differentiate it at the crossing-symmetric point, and to feed it to the numerical and analytic machinery of the rest of the chapter, we need the blocks as explicit, computable functions.

This section carries out that construction. We trade the cross-ratios for the lightcone variables $z, \bar{z}$, in which the Casimir operator simplifies; we solve the resulting ordinary differential equation in closed form, building the one-variable *collinear block* out of a Gauss hypergeometric function; and we assemble from it the closed-form blocks in $d = 2$ and $d = 4$, the two cases where a single multiplet collapses to a finite combination of hypergeometrics. For general d no such collapse occurs, and we develop instead the radial (ρ-coordinate) expansion: a power series whose leading term and recursion we extract, and whose convergence on the unit disk $|\rho| < 1$ we tie directly to the radial-quantization inner product of Theorem 47.34. This series is the workhorse of the numerical bootstrap. We close by reading off the two limits the later sections live on — the lightcone limit $\bar{z} \to 0$ that isolates leading twist, and the diagonal limit $z = \bar{z}$ — and by drawing the line between the global blocks built here and the Virasoro blocks of Chapter 48.

49.2.1 Lightcone coordinates and the Casimir as a differential operator

Recall from Eq. (47.140) the passage from the cross-ratios to a single complex coordinate. Fixing three of the four points to $0, 1, \infty$ by a conformal transformation places the fourth at a complex position z, and the cross-ratios become

$$u = z\bar{z}, \qquad v = (1 - z)(1 - \bar{z}), \tag{49.27}$$

with $\bar{z}$ the complex conjugate of z in Euclidean signature. The pair $(z, \bar{z})$ are the *lightcone variables*: in the Lorentzian continuation of Chapter 51 they become two independent real numbers, and $\bar{z} \to 0$ at fixed z is a genuine lightcone limit. We treat z and $\bar{z}$ as independent throughout, imposing reality only at the end. A function of (u, v) is automatically symmetric under $z \leftrightarrow \bar{z}$, since Eq. (49.27) is; conversely any symmetric function of $(z, \bar{z})$ descends to a function of (u, v). The blocks, being functions of the cross-ratios, are symmetric in $z \leftrightarrow \bar{z}$, and we will use this repeatedly.

The Casimir equation Eq. (47.233) was left in Chapter 47 in terms of the abstract operator $\mathcal{D}_2$, the realization of $C_2^{(1)} + C_2^{(2)}$ as a differential operator on the stripped correlator through the conformal Ward identities. Carrying out that realization — starting from the first-order differential realization of the conformal generators $D, P_\mu, K_\mu, M_{\mu\nu}$ established in Section 47.2.2, summing the

pair Casimir $C_2^{(1)}+C_2^{(2)}$ built from Eq. (47.228) over the fused points (x_1, x_2), and reducing to the invariants u, v — is a direct if lengthy computation, performed by Dolan and Osborn [155, 156]. In the lightcone variables it produces a clean second-order operator. Define the one-variable operator

$$D_z \;\equiv\; z^2(1-z)\,\partial_z^2 - z^2\,\partial_z, \tag{49.28}$$

and its twin $D_{\bar z}$ obtained by $z \to \bar z$. Then the conformal Casimir operator of Eq. (47.233), normalized so that its eigenvalue is exactly $c_{\Delta,\ell}$, is

$$\mathcal{D}_2 \;=\; 2(D_z + D_{\bar z}) \;+\; 2(d-2)\,\frac{z\bar z}{z-\bar z}\Big[(1-z)\,\partial_z - (1-\bar z)\,\partial_{\bar z}\Big]. \tag{49.29}$$

The structure is transparent. The operator is the sum of two decoupled copies of D_z, one for each lightcone variable, plus a mixing term proportional to $d-2$ that couples them. The mixing term *vanishes in* $d=2$: there the two lightcone directions decouple completely, which is the differential-equation shadow of the algebraic fact that the two-dimensional global conformal algebra factorizes, $\mathfrak{so}(3,1) \cong \mathfrak{sl}(2)\oplus\mathfrak{sl}(2)$, into independent holomorphic and antiholomorphic $\mathfrak{sl}(2)$'s (Section 48.3). We take Eq. (49.29) as the explicit form of the operator promised in Chapter 47 and confirm, in each case we solve, that it reproduces the eigenvalue $c_{\Delta,\ell}$ on the explicit solution; since the block is uniquely determined by being a Casimir eigenfunction with the correct leading power, that check both validates the operator's normalization and certifies the solution.

Everything rests on the single operator D_z and its eigenfunctions, so we study it first.

49.2.2 The collinear block

The operator D_z of Eq. (49.28) is the Casimir of a single $\mathfrak{sl}(2)$ — the algebra generated by dilatations and one lightcone translation and special conformal transformation. Its eigenfunctions are the *collinear blocks* (equivalently $\mathfrak{sl}(2)$ blocks, or one-dimensional conformal blocks), and they are the atoms from which the higher-dimensional blocks are assembled.

Lemma 49.6 (The collinear block)**.** *For $\beta \in \mathbb{C}$ let $h = \beta/2$. The function*

$$k_\beta(z) \;=\; z^{\beta/2}\,{}_2F_1\Big(\tfrac{\beta}{2}, \tfrac{\beta}{2}; \beta; z\Big) \tag{49.30}$$

is the unique solution of the eigenvalue equation

$$D_z\,k_\beta(z) \;=\; h(h-1)\,k_\beta(z), \qquad h = \tfrac{\beta}{2}, \tag{49.31}$$

that behaves as $k_\beta(z) \sim z^{\beta/2}$ as $z \to 0$ and is analytic in the unit disk $|z|<1$ with $k_\beta(z)/z^{\beta/2} \to 1$ there.

Proof. We first fix the leading power by the indicial equation, then reduce the full equation to the hypergeometric equation.

Indicial analysis. Write the eigenvalue equation $D_z k = \lambda k$ with $\lambda = h(h-1)$ explicitly,

$$z^2(1-z)\,k'' - z^2\,k' - \lambda\,k = 0. \tag{49.32}$$

Near $z = 0$ the dominant balance is between the highest-derivative term and the eigenvalue term: with $k \sim z^s$ one has $z^2 k'' \sim s(s-1)z^s$ while $z^2 k' \sim s\,z^{s+1}$ is subleading, so Eq. (49.32) reduces at leading order to $s(s-1)z^s - \lambda z^s = 0$, the indicial equation

$$s(s-1) = \lambda = h(h-1). \tag{49.33}$$

Its two roots are $s = h$ and $s = 1-h$. The boundary condition that defines the conformal block is the OPE: the block of a primary of dimension Δ and spin ℓ begins with the power $u^{(\Delta-\ell)/2}$, and in the collinear setting this selects the root $s = h = \beta/2$ (we will see in Sections 49.2.3 and 49.2.4 that β equals $\Delta \pm \ell$, so $\beta/2$ is exactly the required half-twist or half-shifted weight). The second root $s = 1-h$ gives the *shadow* solution, which has the wrong leading power and is discarded. We therefore set

$$k_\beta(z) = z^h\,F(z), \qquad F(0) = 1, \tag{49.34}$$

with F analytic at the origin.

Reduction to the hypergeometric equation. Substitute Eq. (49.34) into Eq. (49.32). The derivatives are

$$k' = z^{h-1}\big(hF + zF'\big), \tag{49.35}$$

$$k'' = z^{h-2}\big[h(h-1)F + 2h\,zF' + z^2F''\big], \tag{49.36}$$

where the second line follows by differentiating the first and collecting powers of z. Then

$$z^2(1-z)k'' = (1-z)\,z^h\big[h(h-1)F + 2h\,zF' + z^2F''\big], \tag{49.37}$$

$$z^2k' = z^h\big(h\,zF + z^2F'\big). \tag{49.38}$$

Inserting these into Eq. (49.32) and dividing by the common factor z^h,

$$(1-z)\big[h(h-1)F + 2h\,zF' + z^2F''\big] - \big(h\,zF + z^2F'\big) - h(h-1)F = 0. \tag{49.39}$$

The z-independent pieces cancel, $h(h-1)F - h(h-1)F = 0$. Collecting the remainder by the order of derivative of F:

- Terms without F' or F'': $-z\,h(h-1)F - h\,zF = -h^2 zF$, using $(h-1)+1 = h$.
- Terms in F': $2h\,zF' - 2h\,z^2F' - z^2F' = z\big[2h - (2h+1)z\big]F'$.

- Terms in F'': $z^2F'' - z^3F'' = z^2(1-z)F''$.

The equation becomes $z^2(1-z)F'' + z[2h-(2h+1)z]F' - h^2zF = 0$, and dividing by z,

$$z(1-z)\,F'' + \big[2h - (2h+1)z\big]\,F' - h^2\,F = 0. \tag{49.40}$$

This is exactly Gauss's hypergeometric equation $z(1-z)F'' + [c-(a+b+1)z]F' - ab\,F = 0$ with parameters read off by matching: $c = 2h$, $a+b = 2h$, and $ab = h^2$, whose unique solution is $a = b = h$. The solution analytic at $z = 0$ with $F(0) = 1$ is the Gauss series

$$F(z) = {}_2F_1(h, h; 2h; z), \tag{49.41}$$

so $k_\beta(z) = z^h\,{}_2F_1(h, h; 2h; z)$ with $h = \beta/2$, which is Eq. (49.30). The series $\sum_n \frac{(h)_n^2}{(2h)_n\,n!} z^n$ has unit radius of convergence, giving analyticity on $|z| < 1$ and the stated normalization $k_\beta / z^{\beta/2} \to 1$. □

Two features will be used constantly. First, the eigenvalue $h(h-1)$ of Eq. (49.31) depends only on the combination $\beta = 2h$, and is invariant under $h \to 1-h$ — the degeneracy that produced the two indicial roots. Second, the small-z expansion

$$k_\beta(z) = z^{\beta/2}\Big[1 + \tfrac{\beta}{4}\,z + O(z^2)\Big] \tag{49.42}$$

follows from the first term of the Gauss series, $\frac{(h)_1^2}{(2h)_1} = \frac{h^2}{2h} = \frac{h}{2} = \frac{\beta}{4}$. These collinear blocks are exactly the conformal blocks of a one-dimensional CFT, and in higher d they are the leading-twist (lightcone) limit of the full block, as we show in Section 49.2.6.

49.2.3 The two-dimensional block

In $d = 2$ the mixing term of Eq. (49.29) vanishes and the Casimir operator is the bare sum

$$\mathcal{D}_2^{(d=2)} = 2(D_z + D_{\bar z}). \tag{49.43}$$

Because D_z acts only on z and $D_{\bar z}$ only on $\bar z$, the equation separates: a product $f(z)\,g(\bar z)$ is an eigenfunction whenever each factor is, with eigenvalue the sum. By Theorem 49.6 the collinear blocks furnish such factors. We must choose the two weights so that the total eigenvalue equals $c_{\Delta,\ell}$ and the leading power matches the OPE.

Proposition 49.7 (Two-dimensional conformal block)**.** *In $d = 2$, for a primary of dimension Δ and spin $\ell \geq 1$, the conformal block is*

$$g_{\Delta,\ell}(z, \bar z) = k_{\Delta+\ell}(z)\,k_{\Delta-\ell}(\bar z) + k_{\Delta-\ell}(z)\,k_{\Delta+\ell}(\bar z), \tag{49.44}$$

and for $\ell = 0$ it is $g_{\Delta,0}(z, \bar z) = k_\Delta(z)\,k_\Delta(\bar z)$, with k_β the collinear block Eq. (49.30).

Proof. Take the product $k_{\Delta+\ell}(z)\,k_{\Delta-\ell}(\bar z)$. By Eq. (49.31) the z-factor is a D_z-eigenfunction with weight $h=(\Delta+\ell)/2$, eigenvalue $h(h-1)$; the $\bar z$-factor is a $D_{\bar z}$-eigenfunction with weight $\bar h=(\Delta-\ell)/2$, eigenvalue $\bar h(\bar h-1)$. Hence

$$\mathcal{D}_2^{(d=2)}\left[k_{\Delta+\ell}(z)k_{\Delta-\ell}(\bar z)\right]=2\big[h(h-1)+\bar h(\bar h-1)\big]\,k_{\Delta+\ell}(z)k_{\Delta-\ell}(\bar z). \tag{49.45}$$

The eigenvalue is computed from $h+\bar h=\Delta$ and $h-\bar h=\ell$:

$$\begin{aligned}2\big[h(h-1)+\bar h(\bar h-1)\big]&=2\big[h^2+\bar h^2-(h+\bar h)\big]=2\big[(h+\bar h)^2-2h\bar h-(h+\bar h)\big]\\&=2\Big[\Delta^2-2\cdot\tfrac{\Delta^2-\ell^2}{4}-\Delta\Big]=\Delta^2+\ell^2-2\Delta=\Delta(\Delta-2)+\ell^2,\end{aligned} \tag{49.46}$$

where $2h\bar h=2\cdot\frac{(\Delta+\ell)(\Delta-\ell)}{4}=\frac{\Delta^2-\ell^2}{2}$. This is precisely $c_{\Delta,\ell}=\Delta(\Delta-d)+\ell(\ell+d-2)$ evaluated at $d=2$. The same eigenvalue is shared by the swapped product $k_{\Delta-\ell}(z)k_{\Delta+\ell}(\bar z)$, obtained by $h\leftrightarrow\bar h$, which leaves Eq. (49.46) unchanged. Any linear combination of the two products is therefore an eigenfunction with eigenvalue $c_{\Delta,\ell}$.

The combination is fixed by the requirement that the block be symmetric under $z\leftrightarrow\bar z$, since it descends from a function of u,v. The symmetric sum Eq. (49.44) satisfies this. Its leading small-$z,\bar z$ behavior is, using $k_\beta\sim z^{\beta/2}$, the sum $z^{(\Delta+\ell)/2}\bar z^{(\Delta-\ell)/2}+z^{(\Delta-\ell)/2}\bar z^{(\Delta+\ell)/2}$; the total power is $\frac12(\Delta+\ell)+\frac12(\Delta-\ell)=\Delta$ in each term, and in the OPE channel $u=z\bar z\to0$ the controlling power is $(z\bar z)^{(\Delta-\ell)/2}$ times a polynomial — the correct leading power $u^{(\Delta-\ell)/2}$ demanded by Theorem 47.49. For $\ell=0$ the two products coincide, $k_\Delta(z)k_\Delta(\bar z)$, and the symmetric combination is the single product without doubling; the eigenvalue Eq. (49.46) reads $\Delta(\Delta-2)$, the scalar value. This is the block stated. □

Worked Example 49.8 (The two-dimensional scalar block to leading orders)**.** Take $\ell=0$, so $g_{\Delta,0}=k_\Delta(z)k_\Delta(\bar z)$ with $h=\Delta/2$. Using the expansion Eq. (49.42),

$$k_\Delta(z)=z^{\Delta/2}\Big[1+\tfrac{\Delta}{4}z+\cdots\Big], \tag{49.47}$$

the block to second order in the lightcone variables is

$$g_{\Delta,0}(z,\bar z)=(z\bar z)^{\Delta/2}\Big[1+\tfrac{\Delta}{4}(z+\bar z)+\tfrac{\Delta^2}{16}z\bar z+\cdots\Big]=u^{\Delta/2}\Big[1+\tfrac{\Delta}{4}(z+\bar z)+\cdots\Big]. \tag{49.48}$$

With $z+\bar z=1+u-v$ (from $u=z\bar z$ and $v=(1-z)(1-\bar z)=1-(z+\bar z)+z\bar z$, hence $z+\bar z=1+u-v$), this is $g_{\Delta,0}=u^{\Delta/2}[1+\frac{\Delta}{4}(1+u-v)+\cdots]$. The leading power $u^{\Delta/2}$ is the identity-stripped OPE singularity of the exchanged scalar; the coefficient $\Delta/4$ multiplying $(1+u-v)$ is the first descendant contribution, fixed entirely by the dimension. This is the kind of explicit series that the crossing equation differentiates term by term in the next section.

49.2.4 The four-dimensional block

In $d=4$ the mixing term of Eq. (49.29) is present, with coefficient $2(d-2)=4$, and the equation no longer separates. Remarkably it can still be solved in closed form, because the four-dimensional Casimir operator is *conjugate* to the two-dimensional one. This is the content of the Dolan–Osborn formula.

Theorem 49.9 (Four-dimensional conformal block)**.** *In $d=4$, the conformal block of a primary of dimension Δ and spin ℓ is*

$$g_{\Delta,\ell}(z,\bar z)=\frac{z\bar z}{z-\bar z}\Big[\,k_{\Delta+\ell}(z)\,k_{\Delta-\ell-2}(\bar z)-k_{\Delta+\ell}(\bar z)\,k_{\Delta-\ell-2}(z)\,\Big]. \tag{49.49}$$

It satisfies the $d=4$ Casimir equation $\mathcal{D}_2\,g_{\Delta,\ell}=c_{\Delta,\ell}\,g_{\Delta,\ell}$ with $c_{\Delta,\ell}=\Delta(\Delta-4)+\ell(\ell+2)$, and begins with the OPE power $u^{(\Delta-\ell)/2}$.

Proof. Write $P\equiv\dfrac{z\bar z}{z-\bar z}$ for the antisymmetric prefactor and $A(z,\bar z)$ for the antisymmetric bracket, so that $g_{\Delta,\ell}=P\,A$ with $A=f(z)\tilde g(\bar z)-f(\bar z)\tilde g(z)$, $f=k_{\Delta+\ell}$, $\tilde g=k_{\Delta-\ell-2}$. Both P and A are antisymmetric under $z\leftrightarrow\bar z$, so their product is symmetric, as a block must be.

The conjugation identity. We claim the operator identity, valid in $d=4$,

$$P^{-1}\,\mathcal{D}_2\,P\;=\;2(D_z+D_{\bar z})-4, \tag{49.50}$$

acting on any smooth function. To prove it, apply $\mathcal{D}_2$ to $P\varphi$ for arbitrary $\varphi(z,\bar z)$ and divide by P. From the Leibniz expansion of Eq. (49.28),

$$D_z(P\varphi)=P\,D_z\varphi+(D_zP)\varphi+2z^2(1-z)P'\,\partial_z\varphi,\qquad P'=\partial_zP, \tag{49.51}$$

and the analogous $D_{\bar z}$ relation, together with the mixing term $4P[(1-z)\partial_z-(1-\bar z)\partial_{\bar z}](P\varphi)$, we collect $\mathcal{D}_2(P\varphi)$ into a part proportional to φ, parts with $\partial_z\varphi$ and $\partial_{\bar z}\varphi$, and the transported principal part $2P(D_z+D_{\bar z})\varphi$. The needed derivatives of $P=z\bar z(z-\bar z)^{-1}$ are

$$\partial_zP=-\frac{\bar z^2}{(z-\bar z)^2},\qquad \partial_{\bar z}P=\frac{z^2}{(z-\bar z)^2}, \tag{49.52}$$

from which $D_zP=\dfrac{2z^2\bar z^2(1-z)}{(z-\bar z)^3}+\dfrac{z^2\bar z^2}{(z-\bar z)^2}$ and $D_{\bar z}P=\dfrac{2z^2\bar z^2(1-\bar z)}{(z-\bar z)^3}-\dfrac{z^2\bar z^2}{(z-\bar z)^2}$, so that

$$D_zP+D_{\bar z}P=\frac{2z^2\bar z^2(2-z-\bar z)}{(z-\bar z)^3}. \tag{49.53}$$

Dividing the assembled $\mathcal{D}_2(P\varphi)$ by P, the coefficient of φ is

$$2P^{-1}(D_zP+D_{\bar z}P)+4\big[(1-z)\partial_zP-(1-\bar z)\partial_{\bar z}P\big]=\frac{4z\bar z(2-z-\bar z)}{(z-\bar z)^2}-\frac{4\big[z^2+\bar z^2-z\bar z(z+\bar z)\big]}{(z-\bar z)^2}$$

$$= \frac{4\big[2z\bar z - z^2 - \bar z^2\big]}{(z-\bar z)^2} = -4, \tag{49.54}$$

since $z^2+\bar z^2-2z\bar z=(z-\bar z)^2$. The coefficient of $\partial_z\varphi$ is $4P^{-1}z^2(1-z)\partial_z P + 4P(1-z) = -\dfrac{4z\bar z(1-z)}{z-\bar z} + \dfrac{4z\bar z(1-z)}{z-\bar z} = 0$, and by the mirror computation the coefficient of $\partial_{\bar z}\varphi$ also vanishes. What remains is exactly $2(D_z+D_{\bar z})\varphi - 4\varphi$, proving Eq. (49.50).

Eigenvalue. Apply Eq. (49.50) to $g_{\Delta,\ell} = PA$:

$$\mathcal{D}_2\,(PA) = P\big[2(D_z+D_{\bar z})-4\big]A. \tag{49.55}$$

Now $A = f(z)\tilde g(\bar z) - f(\bar z)\tilde g(z)$ is a sum of products of collinear blocks. The first product has D_z-weight $h=(\Delta+\ell)/2$ (from $f=k_{\Delta+\ell}$) and $D_{\bar z}$-weight $\bar h=(\Delta-\ell-2)/2$ (from $\tilde g = k_{\Delta-\ell-2}$); the second product, obtained by $z\leftrightarrow\bar z$, carries the same pair of weights distributed oppositely and so shares the eigenvalue. Hence A is a $(D_z+D_{\bar z})$-eigenfunction with eigenvalue $h(h-1)+\bar h(\bar h-1)$, and

$$\mathcal{D}_2\,(PA) = \big[2\big(h(h-1)+\bar h(\bar h-1)\big)-4\big]\,PA. \tag{49.56}$$

With $h=\frac{\Delta+\ell}{2}$, $\bar h=\frac{\Delta-\ell-2}{2}$,

$$4\big[h(h-1)+\bar h(\bar h-1)\big] = (\Delta+\ell)(\Delta+\ell-2)+(\Delta-\ell-2)(\Delta-\ell-4) = 2\Delta^2+2\ell^2-8\Delta+4\ell+8, \tag{49.57}$$

so that $2[h(h-1)+\bar h(\bar h-1)]-4 = \frac12(2\Delta^2+2\ell^2-8\Delta+4\ell+8)-4 = \Delta^2-4\Delta+\ell^2+2\ell = \Delta(\Delta-4)+\ell(\ell+2) = c_{\Delta,\ell}$, as claimed. The conjugation has converted the four-dimensional eigenvalue problem into the two-dimensional one with the shifted antiholomorphic weight $\bar h=(\Delta-\ell-2)/2$, the constant -4 accounting exactly for the difference $c^{(4)}-c^{(2)}$ between the two Casimir eigenvalues.

Leading power. As $z,\bar z\to 0$, $k_\beta\sim z^{\beta/2}$, so

$$A \sim z^{(\Delta+\ell)/2}\bar z^{(\Delta-\ell-2)/2} - \bar z^{(\Delta+\ell)/2}z^{(\Delta-\ell-2)/2} = (z\bar z)^{(\Delta-\ell-2)/2}\big(z^{\ell+1}-\bar z^{\ell+1}\big), \tag{49.58}$$

factoring out the common power and using $\frac{\Delta+\ell}{2}-\frac{\Delta-\ell-2}{2}=\ell+1$. Multiplying by $P=z\bar z/(z-\bar z)$,

$$g_{\Delta,\ell} \sim (z\bar z)^{(\Delta-\ell)/2}\,\frac{z^{\ell+1}-\bar z^{\ell+1}}{z-\bar z} = u^{(\Delta-\ell)/2}\sum_{k=0}^{\ell} z^k\bar z^{\ell-k}, \tag{49.59}$$

the geometric identity $\frac{z^{\ell+1}-\bar z^{\ell+1}}{z-\bar z} = \sum_{k=0}^{\ell} z^k\bar z^{\ell-k}$ producing a symmetric, finite polynomial. The controlling power is $u^{(\Delta-\ell)/2}$, the correct OPE leading behavior; the polynomial encodes the spin and is, as we see below, a Gegenbauer polynomial in the configuration angle. □

Worked Example 49.10 (The four-dimensional scalar block as an elementary function)**.** For $\ell = 0$, Eq. (49.49) reads $g_{\Delta,0} = \frac{z\bar{z}}{z-\bar{z}}[k_\Delta(z)k_{\Delta-2}(\bar{z}) - k_\Delta(\bar{z})k_{\Delta-2}(z)]$. When Δ takes special integer values the hypergeometrics collapse. The cleanest instance is $\Delta = 2$: then $k_2(z) = z\,{}_2F_1(1,1;2;z) = z\cdot\left(-\frac{\ln(1-z)}{z}\right) = -\ln(1-z)$, using ${}_2F_1(1,1;2;z) = -\ln(1-z)/z$, and $k_0(z) = z^0\,{}_2F_1(0,0;0;z) = 1$. Hence

$$g_{2,0}(z,\bar{z}) = \frac{z\bar{z}}{z-\bar{z}}\big[-\ln(1-z)\cdot 1 - (-\ln(1-\bar{z}))\cdot 1\big] = \frac{z\bar{z}}{z-\bar{z}}\ln\frac{1-\bar{z}}{1-z}. \quad (49.60)$$

This is the exchange of a dimension-two scalar (for a free four-dimensional scalar of dimension $\Delta_\phi = 1$, the operator $:\phi^2:$ has exactly $\Delta = 2$). Its appearance as an elementary logarithm, with no special-function content left, is the four-dimensional counterpart of the closed forms that make the bootstrap tractable: every block at integer external and exchanged dimensions reduces to logarithms and rational functions of $z, \bar{z}$. As $z, \bar{z} \to 0$, $\ln\frac{1-\bar{z}}{1-z} = (z-\bar{z}) + O(z^2, \bar{z}^2)$, so $g_{2,0} \to z\bar{z} = u$, matching Eq. (49.59) with $\Delta - \ell = 2$, $\ell = 0$.

Remark 49.11 (Even dimensions and the absence of a closed form in odd d). The conjugation Eq. (49.50) is special to $d = 4$, where the mixing coefficient $2(d-2) = 4$ matches the constant generated by transporting $\mathcal{D}_2$ through $P = z\bar{z}/(z-\bar{z})$. An analogous factorized closed form exists in every even dimension: in $d = 6$ the prefactor is a higher rational function of $z, \bar{z}$ and the block is again a finite antisymmetrized sum of products $k_\beta(z)k_{\beta'}(\bar{z})$, and likewise in $d = 2, 4, 6, \ldots$ blocks descend from the two-variable separated problem. In *odd* dimensions, and at generic non-integer d such as $d = 4 - \epsilon$ along ϕ^4 theory, no finite closed form in terms of ${}_2F_1$ exists: the block is a genuine function of two variables not expressible as a finite sum of products of one-variable hypergeometrics. For those cases — which include the physically central $d = 3$ Ising fixed point — one needs the series representation of the next subsection.

49.2.5 The radial expansion in general dimension

For general d there is no closed form, but there is a rapidly convergent power series adapted to radial quantization (Section 47.5). It rests on a change of variables, due in this context to Hogervorst and Rychkov [269], that maps cross-ratio space onto a disk and makes the OPE convergence of Theorem 47.48 manifest.

The radial coordinate. Define

$$\rho(z) = \frac{z}{\left(1+\sqrt{1-z}\,\right)^2}, \qquad \text{inverse} \qquad z = \frac{4\rho}{(1+\rho)^2}, \quad (49.61)$$

and set $\bar\rho = \rho(\bar z)$. In Euclidean signature $\bar z = z^*$, so $\bar\rho = \rho^*$; writing $\rho = r\,e^{i\theta}$ gives the real coordinates

$$r = |\rho|, \qquad \eta = \cos\theta = \tfrac{1}{2}(e^{i\theta} + e^{-i\theta}). \tag{49.62}$$

The geometric meaning of ρ is read off from radial quantization. Place the four operators so that the pair (x_1, x_2) sits near the origin and the pair (x_3, x_4) near infinity; the s-channel OPE is the insertion of a complete set of states on a sphere separating the two pairs. In the optimal frame the configuration is governed by the ratio of the inner to the outer radius, and that ratio is exactly $r = |\rho|$. The OPE limit $x_1 \to x_2$ is $z \to 0$, hence $\rho \to 0$; the channel-crossing point $z \to 1$ (where the t-channel OPE takes over) is $\rho \to 1$. The map Eq. (49.61) compresses the entire physical region into the unit disk.

Leading term and recursion. In radial coordinates the block is organized as a sum over the conformal multiplet, graded by the dimension increment and the SO(d) spin of each descendant level. Writing $\nu = (d-2)/2$ and $C_j^{(\nu)}$ for the Gegenbauer polynomial of the rotation group, the block takes the form

$$g_{\Delta,\ell}(r,\eta) = \sum_{n=0}^{\infty} \sum_{j} c_{n,j}\, r^{\Delta+n}\, C_j^{(\nu)}(\eta), \tag{49.63}$$

where at each level n the spin j runs over the finite set $\{\ell - n, \ell - n + 2, \dots, \ell + n\} \cap \mathbb{Z}_{\geq 0}$ produced by tensoring with the descendant raising operators. The leading term is $n = 0$, $j = \ell$, and its coefficient follows from the small-$z, \bar z$ limit. In $d = 4$ ($\nu = 1$) we computed it exactly in Eq. (49.59): with $z \approx 4\rho$, $\bar z \approx 4\bar\rho$ as $z, \bar z \to 0$ (since $\sqrt{1-z} \to 1$ in Eq. (49.61)), the sum $\sum_{k=0}^{\ell} z^k \bar z^{\ell-k}$ becomes $4^\ell \sum_k \rho^k \bar\rho^{\ell-k} = 4^\ell\, r^\ell\, \frac{\sin[(\ell+1)\theta]}{\sin\theta} = 4^\ell r^\ell\, C_\ell^{(1)}(\eta)$, and $u^{(\Delta-\ell)/2} = (z\bar z)^{(\Delta-\ell)/2} \to (16r^2)^{(\Delta-\ell)/2} = 4^{\Delta-\ell} r^{\Delta-\ell}$, so

$$g_{\Delta,\ell}(r,\eta) \xrightarrow{r\to 0} (4r)^\Delta\, C_\ell^{(1)}(\eta) \qquad (d = 4). \tag{49.64}$$

In general d the leading term is again $g_{\Delta,\ell} \to \mathcal{N}_{d,\ell}\,(4r)^\Delta\, C_\ell^{(\nu)}(\eta)$ with a dimension-dependent normalization $\mathcal{N}_{d,\ell}$ that equals 1 in $d = 4$ in the convention of Section 49.2.6 (it is fixed once and for all by the lightcone limit of the block). The Chebyshev-of-the-second-kind structure $\sin[(\ell+1)\theta]/\sin\theta = C_\ell^{(1)}(\eta)$ is the $d = 4$ Gegenbauer; the angular function is in every dimension the Gegenbauer $C_\ell^{(\nu)}(\eta)$ carrying the spin of the exchanged primary.

The subleading coefficients are not free: substituting the ansatz Eq. (49.63) into the Casimir equation $\mathcal{D}_2\, g = c_{\Delta,\ell}\, g$ turns the second-order differential operator into a finite recursion. Because $\mathcal{D}_2$ shifts the power $r^{\Delta+n}$ by at most two units and the Gegenbauer label j by at most two, equating coefficients of each $r^{\Delta+n} C_j^{(\nu)}(\eta)$ yields a linear relation expressing $c_{n,j}$ in terms of coefficients

at lower n. Seeded by the leading term Eq. (49.64), the recursion determines the entire series. This is the algorithm behind every modern block evaluation: one computes $c_{n,j}$ up to a truncation order $n \le N$ and sums, the error controlled by the convergence we now establish.

Proposition 49.12 (Convergence of the radial expansion on the unit disk)**.** *The series Eq. (49.63) converges absolutely for $r = |\rho| < 1$, i.e. throughout the image of the cut cross-ratio plane under the map Eq. (49.61). In particular it converges at the crossing-symmetric point $z = \bar{z} = \frac{1}{2}$, where $\rho = 3 - 2\sqrt{2} \approx 0.1716$.*

Argument. The expansion Eq. (49.63) is nothing but the s-channel OPE written in radial quantization. By the state–operator correspondence of Section 47.5, fusing $\phi(x_1)\phi(x_2)$ creates a state $|\Psi\rangle = \phi(x_1)\phi(x_2)\,|0\rangle$ on a sphere of radius set by the larger of $|x_1|, |x_2|$; expanding it in the orthonormal basis of dilatation eigenstates produces one term $r^{\Delta+n}$ per descendant of dimension $\Delta + n$. The four-point function is the overlap of this state with the conjugate state $\langle\Psi'|$ built from $\phi(x_3)\phi(x_4)$ at radius $1/r > 1$. The overlap is the radially ordered Euclidean correlator $\langle\Psi'|\Psi\rangle$, which by Theorem 47.34 is a convergent sum over a complete set of states with *nonnegative* norms,

$$\langle\phi\phi\phi\phi\rangle = \sum_{\text{states } |n\rangle} \frac{\langle\Psi'|n\rangle\,\langle n|\Psi\rangle}{\langle n|n\rangle}, \qquad \langle n|n\rangle \ge 0, \tag{49.65}$$

the reflection positivity established there. Each contribution scales as r^{Δ_n} with $\Delta_n = \Delta + n \to \infty$, and the positivity of the inner product forbids the cancellations that could spoil convergence; the sum is dominated termwise by a geometric series in the radius ratio. Convergence therefore holds precisely when the inner pair can be radially separated from the outer pair, i.e. when the radius ratio $r = |\rho| < 1$. This is the radial-quantization sharpening of the OPE convergence theorem Theorem 47.48: the abstract statement that the OPE converges inside the lightcone becomes, after the conformal map to the disk, the geometric statement that the block series converges for $|\rho| < 1$. At the crossing-symmetric point $z = \bar{z} = \frac{1}{2}$ one has $\sqrt{1 - \frac{1}{2}} = 1/\sqrt{2}$ and $\rho = \frac{1/2}{(1+1/\sqrt{2})^2} = \frac{1/2}{3/2+\sqrt{2}} = 3 - 2\sqrt{2} \approx 0.17$, deep inside the disk, so the series converges geometrically with ratio ~ 0.17 and a few dozen terms suffice to machine precision — the reason ρ is the coordinate of choice for the numerical bootstrap. □

49.2.6 Limits: lightcone and diagonal

Two limits of the block control the analyses of the chapters that follow, and both are immediate from the closed and series forms above.

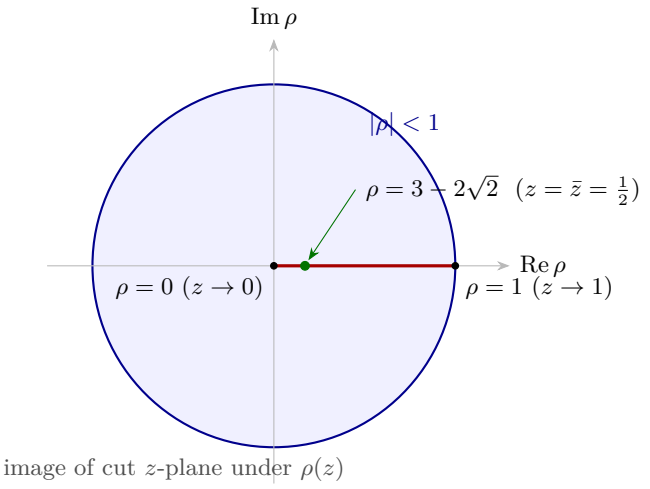

Figure 49.2: The radial coordinate $\rho(z) = z/(1+\sqrt{1-z})^2$ maps the cut cross-ratio plane into the unit disk. The OPE limit $z \to 0$ is the center $\rho = 0$; the channel-crossing point $z \to 1$ sits on the boundary $\rho = 1$. The block series Eq. (49.63) converges for $|\rho| < 1$ (Theorem 49.12). The crossing-symmetric point $z = \bar{z} = \frac{1}{2}$ maps to $\rho = 3 - 2\sqrt{2} \approx 0.17$ (green), well inside the disk, so the expansion converges geometrically there.

The lightcone limit. Send one lightcone variable to zero, $\bar{z} \to 0$, at fixed z. From the collinear expansion $k_\beta(\bar{z}) \sim \bar{z}^{\beta/2}$, the factor of smallest power dominates. In two dimensions, Eq. (49.44) gives $k_{\Delta-\ell}(\bar{z}) \sim \bar{z}^{(\Delta-\ell)/2}$ as the leading term (versus $\bar{z}^{(\Delta+\ell)/2}$ from the other), so

$$g_{\Delta,\ell}(z,\bar{z}) \xrightarrow{\bar{z}\to 0} \bar{z}^{(\Delta-\ell)/2}\, k_{\Delta+\ell}(z) \qquad (d=2). \tag{49.66}$$

In four dimensions, Eq. (49.49) with $P \to z\bar{z}/z = \bar{z}$ and $k_{\Delta-\ell-2}(\bar{z}) \sim \bar{z}^{(\Delta-\ell-2)/2}$ gives $g \to \bar{z}\cdot\bar{z}^{(\Delta-\ell-2)/2}k_{\Delta+\ell}(z) = \bar{z}^{(\Delta-\ell)/2}k_{\Delta+\ell}(z)$ — *the same limit*, with the same unit coefficient. This is no coincidence: in any d the lightcone limit factorizes into the leading-twist power $\bar{z}^{\tau/2}$, with $\tau = \Delta - \ell$ the twist, times the collinear block $k_{\Delta+\ell}(z)$ in the surviving variable,

$$g_{\Delta,\ell}(z,\bar{z}) \xrightarrow{\bar{z}\to 0} \bar{z}^{(\Delta-\ell)/2}\, k_{\Delta+\ell}(z) \qquad (\text{any } d). \tag{49.67}$$

We adopt Eq. (49.67) as the *normalization convention* for the block in every dimension: it fixes the overall constant left undetermined by the Casimir equation and is consistent with the explicit $d = 2$ and $d = 4$ forms above. The twist $\tau = \Delta - \ell$ governs the strength of the singularity as the two operators in the OPE approach a common lightcone; operators of low twist dominate the lightcone limit. This is the quantity the analytic bootstrap of Chapter 51 organizes its large-spin expansion around, and the mechanism by which mean-field (generalized free field) theory generates its tower of double-twist operators of twist $\tau = 2\Delta_\phi + 2n$.

The diagonal limit. Set $z = \bar{z}$, the locus where the four points are configured symmetrically and the crossing-symmetric point $z = \bar{z} = \frac{1}{2}$ lives. In two dimensions Eq. (49.44) is regular there, $g_{\Delta,\ell}(z,z) = 2\,k_{\Delta+\ell}(z)k_{\Delta-\ell}(z)$ for $\ell \geq 1$ and $k_\Delta(z)^2$ for $\ell = 0$. In four dimensions the prefactor $P = z\bar{z}/(z-\bar{z})$ is singular as $\bar{z} \to z$, and the bracket vanishes to the same order, so the limit is a derivative. Expanding A to first order in $\bar{z} - z$,

$$g_{\Delta,\ell}(z,z) = \lim_{\bar{z}\to z} \frac{z\bar{z}}{z-\bar{z}}\, A(z,\bar{z}) = z^2\big[k'_{\Delta+\ell}(z)\,k_{\Delta-\ell-2}(z) - k_{\Delta+\ell}(z)\,k'_{\Delta-\ell-2}(z)\big], \tag{49.68}$$

a Wronskian of two collinear blocks — finite and smooth, as required by regularity of the block at a generic Euclidean configuration. The diagonal limit is where the crossing sum rule is most economically expanded: with one variable, the infinitely many constraints of Eq. (49.15) are sampled by differentiating in z at $z = \frac{1}{2}$, the starting point of the numerical functional method.

49.2.7 Global versus Virasoro blocks

A word is owed on which blocks these are. The functions built in this section are the *global* (or conformal) blocks: eigenfunctions of the quadratic Casimir of the *finite-dimensional* conformal group $\mathrm{SO}(d+1,1)$, resumming a primary together with the descendants generated by the d translations P_μ alone. They exist and take the forms above in every dimension $d \geq 2$, and they are the only blocks available for $d \geq 3$, where the conformal algebra has no infinite-dimensional enhancement.

In exactly two dimensions the conformal algebra is enlarged to the infinite-dimensional Virasoro algebra (Section 48.3), and one may resum a primary together with its entire Virasoro module — all the descendants generated by the modes L_{-n}, including the stress-tensor tower. The result is the *Virasoro block* of Chapter 48, which packages infinitely many global multiplets (the global primary and its Virasoro descendants, each itself a global primary) into a single function depending also on the central charge c. The global block Eq. (49.44) is the leading piece of the Virasoro block, retaining only the $\mathfrak{sl}(2) \oplus \mathfrak{sl}(2)$ descendants. The bootstrap of this chapter uses the global blocks throughout, for two reasons: it is built to operate in any d, where only global blocks exist; and even in $d = 2$ the model-independent, dimension-agnostic crossing analysis is cleanest in the global language. The Virasoro blocks are the right tool when one exploits the full power of two-dimensional symmetry — the minimal-model classification and the analytic two-dimensional bootstrap of Chapter 48 — but they are not what the higher-dimensional bootstrap of Chapters 50 and 51 runs on.

With Eqs. (49.44) and (49.49) we have the blocks in closed form in the two even dimensions, and with the radial series Eq. (49.63) we have them to any desired accuracy in general d — including the leading coefficient, the recursion that

generates the rest, and the guaranteed convergence Theorem 49.12 that makes truncation reliable. The lightcone and diagonal limits Eqs. (49.67) and (49.68) hand the next section explicit functions $g_{\Delta,\ell}(u,v)$ together with their derivatives at the crossing-symmetric point $z=\bar z=\frac{1}{2}$. Substituting these into the crossing relation Eq. (49.14) and rearranging the two channels into a single vanishing combination is what turns the abstract sum rule Eq. (49.15) into the concrete bootstrap equation that the linear functionals of Chapter 50 will act on.

49.3 The Crossing Equation and the Bootstrap Sum Rule

The blocks are now explicit functions. Section 49.2 turned the implicit Casimir eigenvalue problem into the closed forms Eqs. (49.44) and (49.49), the uniformly convergent radial series Eq. (49.63), and the lightcone and diagonal limits Eqs. (49.67) and (49.68). We can therefore stop treating $G_{\Delta,\ell}(u,v)$ as an abstract eigenfunction and start treating it as a number we can evaluate, differentiate, and Taylor-expand wherever we like. The purpose of this section is to take the crossing equation derived in Section 49.1.4 — so far a relation between two formal block sums — and package it into the single object on which the entire machinery of bounds operates: a sum rule of the form $\sum_{\mathcal O} p_{\mathcal O}\, F_{\Delta_{\mathcal O},\ell_{\mathcal O}} = 0$, in which all the *dynamics* sits in a set of nonnegative weights $p_{\mathcal O}$ and a discrete spectrum, while the functions $F_{\Delta,\ell}$ are fixed, theory-independent, and computable from the closed forms just obtained. Once the equation is in this shape two facts about it become decisive: the weights are squares, hence nonnegative, and the dimensions are bounded below by unitarity. A linear equation in nonnegative unknowns, with a known inhomogeneous term, is a problem a computer — or, in the simplest cases, a hand calculation — can attack by the geometry of convex cones. Assembling that object precisely, and exhibiting its structure, is the work of this section.

49.3.1 The crossing equation in block form

We continue ϕ^4 theory: the external operator is the single real scalar primary ϕ of dimension Δ_ϕ, the order parameter of the Wilson–Fisher and Ising fixed points, and the object of study is its four-point function $\langle\phi\phi\phi\phi\rangle$ stripped to the function $g(u,v)$ of Eq. (49.2). Theorem 49.3 established that equating the s- and t-channel block decompositions of this correlator is the single functional equation

$$\sum_{\mathcal O} C_{\phi\phi\mathcal O}^2 \Big[\, v^{\Delta_\phi}\, G_{\Delta_{\mathcal O},\ell_{\mathcal O}}(u,v) \;-\; u^{\Delta_\phi}\, G_{\Delta_{\mathcal O},\ell_{\mathcal O}}(v,u) \,\Big] = 0, \tag{49.69}$$

the sum rule Eq. (49.15), to hold identically in the cross-ratios. The sum runs over every primary $\mathcal O$ appearing in the $\phi\times\phi$ OPE, each weighted by the square of its OPE coefficient.

The squares are the heart of the matter, and they earn their own symbol. Write

$$p_{\mathcal{O}} \;\equiv\; C^{2}_{\phi\phi\mathcal{O}} \;\geq\; 0. \tag{49.70}$$

That $p_{\mathcal{O}}$ is real and nonnegative — not merely a formal label but a genuine inequality — is the single piece of dynamical positivity that the bootstrap converts into bounds, and we will justify it carefully in Section 49.3.3. For now it is enough that each weight in Eq. (49.69) is the same nonnegative number entering from both fused pairs, exactly as in the s-channel decomposition Eq. (49.4). With this notation the equality of the two channel expansions takes its most symmetric form.

Definition 49.13 (The crossing equation)**.** The *crossing equation* for the four-point function of the identical scalar ϕ is the requirement that the s- and t-channel conformal-block decompositions of Eq. (49.2) agree as functions of the cross-ratios,

$$\boxed{v^{\Delta_\phi}\sum_{\mathcal{O}} p_{\mathcal{O}}\, G_{\Delta_{\mathcal{O}},\ell_{\mathcal{O}}}(u,v) \;=\; u^{\Delta_\phi}\sum_{\mathcal{O}} p_{\mathcal{O}}\, G_{\Delta_{\mathcal{O}},\ell_{\mathcal{O}}}(v,u),} \tag{49.71}$$

with $p_{\mathcal{O}} = C^{2}_{\phi\phi\mathcal{O}} \geq 0$ and the sum over the primaries of the $\phi\times\phi$ OPE, including the identity with $p_{\mathbf{1}} = 1$.

Equation (49.71) is Eq. (49.14) of Theorem 49.2 with each g replaced by its block sum and both sides cleared of the channel-asymmetric prefactor symmetrically; the equivalence to Eq. (49.69) is immediate on moving one side across. We have written it in this balanced form because it displays the role of the kinematic factors u^{Δ_ϕ} and v^{Δ_ϕ} as the only place the external dimension Δ_ϕ enters, and because the difference of the two sides is the object we now name.

49.3.2 The convolved block: the F-function

The left-hand minus right-hand side of Eq. (49.71) is a sum over operators of one and the same combination of a block with itself, evaluated at (u,v) and at (v,u). Pulling that combination out of the sum — which is legitimate because the operation is linear in the block — isolates a function attached to each pair of quantum numbers (Δ,ℓ) alone.

Definition 49.14 (The convolved block $F_{\Delta,\ell}$)**.** For an external dimension Δ_ϕ and an exchanged primary of dimension Δ and spin ℓ, the *convolved block* (or *F-function*) is

$$\boxed{F_{\Delta,\ell}(u,v) \;\equiv\; v^{\Delta_\phi}\,G_{\Delta,\ell}(u,v) \;-\; u^{\Delta_\phi}\,G_{\Delta,\ell}(v,u).} \tag{49.72}$$

The name records that $F_{\Delta,\ell}$ is the convolution of the kinematic factors $u^{\Delta_\phi}, v^{\Delta_\phi}$ with the universal block. Three points about it are worth stating at once, because they are exactly the properties the rest of the chapter relies on, and each is a one-line consequence of Eq. (49.72).

First, $F_{\Delta,\ell}$ is purely kinematic. It depends only on the dimension and spin of the exchanged operator and on the external dimension Δ_ϕ — the same numbers that fix the block itself — and not at all on the OPE coefficients, the central charge, or any other dynamical datum of a particular theory. The closed forms of Section 49.2 give it explicitly: substitute Eq. (49.49) (in $d = 4$), Eq. (49.44) (in $d = 2$), or the convergent radial series Eq. (49.63) (in any d) for both $G_{\Delta,\ell}(u, v)$ and its crossed evaluation $G_{\Delta,\ell}(v, u)$, multiply by the appropriate power of u or v, and subtract. $F_{\Delta,\ell}$ is therefore a fixed, computable function for every (Δ, ℓ), tabulated once and for all before any theory is specified.

Second, the crossing equation becomes a sum rule on these functions. The difference of the two sides of Eq. (49.71) is, term by term in the operator sum,

$$v^{\Delta_\phi} \sum_{\mathcal{O}} p_{\mathcal{O}}\, G_{\Delta_{\mathcal{O}},\ell_{\mathcal{O}}}(u, v) - u^{\Delta_\phi} \sum_{\mathcal{O}} p_{\mathcal{O}}\, G_{\Delta_{\mathcal{O}},\ell_{\mathcal{O}}}(v, u) = \sum_{\mathcal{O}} p_{\mathcal{O}} \Big[v^{\Delta_\phi} G_{\Delta_{\mathcal{O}},\ell_{\mathcal{O}}}(u, v) - u^{\Delta_\phi} G_{\Delta_{\mathcal{O}},\ell_{\mathcal{O}}}(v, u) \Big], \tag{49.73}$$

the two block sums combining under the single sum because u^{Δ_ϕ} and v^{Δ_ϕ} are independent of the summation index $\mathcal{O}$. The bracket is exactly $F_{\Delta_{\mathcal{O}},\ell_{\mathcal{O}}}(u, v)$ of Eq. (49.72). Hence crossing, in the form Eq. (49.71), is precisely the statement that this combination vanishes,

$$\boxed{\sum_{\mathcal{O}} p_{\mathcal{O}}\, F_{\Delta_{\mathcal{O}},\ell_{\mathcal{O}}}(u, v) = 0,} \tag{49.74}$$

holding identically in (u, v). This is the *bootstrap sum rule*. It is the same content as Eq. (49.69), written so that the dynamical weights $p_{\mathcal{O}}$ multiply fixed kinematic functions: a linear relation, with nonnegative coefficients, among an infinite collection of known functions, one per point (Δ, ℓ) of the spectrum.

Third, $F_{\Delta,\ell}$ is antisymmetric under $u \leftrightarrow v$. This is the structural property that singles out the identity and, as we will see, dictates where the equation must be imposed.

Proposition 49.15 (Antisymmetry of the convolved block)**.** *For every (Δ, ℓ) and every Δ_ϕ,*

$$F_{\Delta,\ell}(v, u) = -\,F_{\Delta,\ell}(u, v). \tag{49.75}$$

In particular $F_{\Delta,\ell}(u, u) = 0$ for all u: every convolved block vanishes on the diagonal $u = v$.

Proof. Interchange the symbols u and v throughout the defining formula Eq. (49.72). The first term $v^{\Delta_\phi} G_{\Delta,\ell}(u,v)$ becomes $u^{\Delta_\phi} G_{\Delta,\ell}(v,u)$, and the second term $u^{\Delta_\phi} G_{\Delta,\ell}(v,u)$ becomes $v^{\Delta_\phi} G_{\Delta,\ell}(u,v)$, so

$$F_{\Delta,\ell}(v,u) = u^{\Delta_\phi} G_{\Delta,\ell}(v,u) - v^{\Delta_\phi} G_{\Delta,\ell}(u,v) = -\big[v^{\Delta_\phi} G_{\Delta,\ell}(u,v) - u^{\Delta_\phi} G_{\Delta,\ell}(v,u)\big] = -F_{\Delta,\ell}(u,v). \tag{49.76}$$

Setting $v = u$ in Eq. (49.75) gives $F_{\Delta,\ell}(u,u) = -F_{\Delta,\ell}(u,u)$, hence $F_{\Delta,\ell}(u,u) = 0$. □

The antisymmetry has an immediate and important consequence for the identity operator. Its block is the constant $G_{0,0} = 1$ (Eq. (49.6)), so its convolved block is the antisymmetrization of that constant,

$$F_{0,0}(u,v) = v^{\Delta_\phi} \cdot 1 - u^{\Delta_\phi} \cdot 1 = v^{\Delta_\phi} - u^{\Delta_\phi}, \tag{49.77}$$

a fixed, elementary function of the cross-ratios that does *not* vanish identically (the two cross-ratios are independent), though it does vanish on the diagonal $u = v$ in accordance with Theorem 49.15. Because $C_{\phi\phi\mathbf{1}} = 1$ is fixed by the unit normalization of $\langle\phi\phi\rangle$, this term enters the sum rule with a coefficient that is not free. Separating it out, the sum rule Eq. (49.74) reads

$$(v^{\Delta_\phi} - u^{\Delta_\phi}) + \sum_{\mathcal{O}\neq\mathbf{1}} p_{\mathcal{O}}\, F_{\Delta_{\mathcal{O}},\ell_{\mathcal{O}}}(u,v) = 0, \tag{49.78}$$

which is Eq. (49.21) written in the convolved notation. Schematically, with the identity's contribution normalized to a fixed reference one writes this as

$$1 + \sum_{\mathcal{O}\neq\mathbf{1}} p_{\mathcal{O}}\, \widehat{F}_{\Delta_{\mathcal{O}},\ell_{\mathcal{O}}} = 0, \tag{49.79}$$

the "1" standing for the known, definite source term $F_{0,0} = v^{\Delta_\phi} - u^{\Delta_\phi}$ carried by the identity, and $\widehat{F}$ for the convolved blocks measured relative to it. The bootstrap is the study of which spectra and which nonnegative weights $\{p_{\mathcal{O}}\}$ can conspire to cancel this fixed source. An empty spectrum cannot: Eq. (49.78) would then assert $v^{\Delta_\phi} - u^{\Delta_\phi} = 0$, false. The identity is the irreducible inhomogeneity that forces a nonempty tower of operators into existence and fixes the overall scale against which every $p_{\mathcal{O}}$ is measured.

Caution

The "1" in Eq. (49.79) is shorthand, not a literal constant: the identity's convolved block is the function $v^{\Delta_\phi} - u^{\Delta_\phi}$, which is what makes the sum rule a constraint on functions rather than on numbers. We carry the honest form Eq. (49.78) in every computation. The schematic "$1 + \sum p\,\widehat{F} = 0$" is useful only as a reminder that there is exactly one known, normalization-fixed term and infinitely many unknown, positively-weighted ones.

That all the dynamical content lives in $\{p_{\mathcal{O}}\}$ and the spectrum $\{(\Delta_{\mathcal{O}}, \ell_{\mathcal{O}})\}$, while the functions $F_{\Delta,\ell}$ are a fixed kinematic background, is the cleanest statement of what the bootstrap is. The blocks were computed once, in Section 49.2, with no reference to any theory; the convolution Eq. (49.72) is an algebraic operation on them; the only theory-dependent objects in the whole of Eq. (49.74) are the nonnegative numbers $p_{\mathcal{O}}$ and the discrete set of (Δ, ℓ) at which they are nonzero. Solving — or bounding the solutions of — the bootstrap is determining those numbers and that set.

49.3.3 Positivity and the unitarity spectrum: a closed problem

Two inequalities turn Eq. (49.74) from a bare functional identity into a constrained, and therefore solvable, problem. The first is the positivity of the weights.

Proposition 49.16 (Positivity of the OPE weights)**.** *In a reflection-positive (unitary) conformal field theory, the coefficients $C_{\phi\phi\mathcal{O}}$ of a real scalar primary ϕ can be chosen real, so that the weights $p_{\mathcal{O}} = C^2_{\phi\phi\mathcal{O}}$ in Eq. (49.74) are nonnegative for every exchanged primary.*

Proof. Recall the geometric meaning of the OPE coefficient established by radial quantization (Section 47.5). Acting on the vacuum, the fused pair $\phi(x_1)\phi(x_2)$ creates a state in the radial-quantization Hilbert space, and its overlap with the state $|\mathcal{O}\rangle$ of an exchanged primary is, up to a fixed kinematic factor, the coefficient $C_{\phi\phi\mathcal{O}}$: expanding $\phi(x_1)\phi(x_2)\,|0\rangle$ in the complete basis of primaries and descendants, the primary $\mathcal{O}$ appears with coefficient $C_{\phi\phi\mathcal{O}}$. The inner product on this Hilbert space is positive definite by reflection positivity (Theorem 47.34); the Euclidean adjoint of ϕ at the origin is ϕ at the reflected point, and for a real (Hermitian in the radial-quantization sense) scalar this makes the matrix element defining $C_{\phi\phi\mathcal{O}}$ real once the basis state $|\mathcal{O}\rangle$ is given the standard unit normalization fixed by the two-point function Eq. (47.124). Reality of $C_{\phi\phi\mathcal{O}}$ gives $p_{\mathcal{O}} = C^2_{\phi\phi\mathcal{O}} \geq 0$ directly. Equivalently and more invariantly, the squared coefficient is the squared length of a projection,

$$p_{\mathcal{O}} \;\propto\; \big|\langle \mathcal{O}|\,\phi\phi\,\rangle\big|^2 \;\geq\; 0, \tag{49.80}$$

manifestly nonnegative in a positive-definite Hilbert space. The identity is the special case $p_{\mathbf{1}} = C^2_{\phi\phi\mathbf{1}} = 1$. □

The reality of the OPE coefficient for *identical* external scalars is what makes the weight a perfect square rather than a product of two distinct coefficients; this is special to the identical-operator correlator and is the reason the bootstrap of a single correlator already carries positivity. We return in Section 49.3.5 to what happens when the four external operators are not all the same, where the relevant positivity becomes that of a matrix.

The second inequality is the spectrum constraint imported from Chapter 47. Unitarity does not only make the weights nonnegative; it also forbids operators below a dimension fixed by their spin.

Proposition 49.17 (The constrained sum rule)**.** *A unitary conformal field theory in $d \geq 3$ containing a real scalar primary ϕ of dimension Δ_ϕ satisfies the sum rule Eq. (49.78), in which:*

1. *every weight obeys $p_{\mathcal{O}} \geq 0$ (Theorem 49.16);*
2. *every exchanged primary obeys the unitarity bounds* (Theorem 47.18, Eq. (47.103))

$$\Delta \geq \frac{d-2}{2} \quad (\ell = 0), \qquad \Delta \geq \ell + d - 2 \quad (\ell \geq 1); \tag{49.81}$$

3. *the spectrum consists of operators of even spin $\ell = 0, 2, 4, \ldots$ only.*

Proof. Items (1) and (2) are Theorem 49.16 and the imported Theorem 47.18. For (3), recall that the $\phi \times \phi$ OPE of *identical* scalars is symmetric under exchange of the two operators, $\phi(x_1)\phi(x_2) = \phi(x_2)\phi(x_1)$ (Bose symmetry of a single commuting scalar field, Eq. (49.9)). An exchanged primary of spin ℓ enters the symmetric product with a tensor structure whose leading term carries ℓ factors of the unit separation vector $\hat{x}_{12}^{\mu}$; under $x_1 \leftrightarrow x_2$ this reverses sign, contributing $(-1)^\ell$. Only even ℓ survives the symmetrization, so odd-spin operators have $C_{\phi\phi\mathcal{O}} = 0$ and drop out of the sum. Thus the sum over $\mathcal{O} \neq \mathbf{1}$ in Eq. (49.78) runs over scalars and even-spin operators lying above the unitarity bound Eq. (49.81). □

These three constraints close the problem. The sum rule Eq. (49.78) is now a linear equation in the nonnegative unknowns $\{p_{\mathcal{O}}\}$, summed over a known, discrete, bounded-below catalogue of allowed quantum numbers (Δ, ℓ), with a fixed inhomogeneous term. The unknown spectrum — which (Δ, ℓ) actually appear — is itself constrained to lie in the half-line Eq. (49.81) for each even spin. There is nothing else: no Lagrangian, no coupling, no further input. This is the precise sense in which the conformal bootstrap is a self-contained mathematical problem rather than a perturbative expansion of some underlying microscopic theory.

Physical Insight

The power of the setup is that positivity and the sum rule pull in opposite directions, and the tension between them is what excludes theories. Crossing demands that a positive combination of the functions $F_{\Delta,\ell}$ cancel the fixed source $v^{\Delta_\phi} - u^{\Delta_\phi}$ exactly. If, for some hypothetical spectrum, *every* available $F_{\Delta,\ell}$ shares a feature — a definite sign of some derivative,

say — that the source lacks, then no nonnegative combination can reproduce the source, and that spectrum cannot belong to any unitary CFT: positively-weighted vectors cannot sum to something they all point away from. This is the entire logic of the bounds in Section 49.4 and Chapter 50; the present section's job is only to have written the equation so that "a nonnegative combination of fixed vectors equals a fixed vector" is literally what it says.

49.3.4 Vectorization: the sum rule at the crossing-symmetric point

The sum rule Eq. (49.74) is one equation that must hold at every point of cross-ratio space — infinitely many conditions. To make it actionable we extract from it a manageable, but still infinite, family of linear conditions on the weights by expanding around a single, well-chosen point. The choice is forced by Theorem 49.15.

Pass to the $(z, \bar{z})$ variables of Eq. (49.27), $u = z\bar{z}$ and $v = (1-z)(1-\bar{z})$. The map $u \leftrightarrow v$ that underlies crossing is, in these variables, the simultaneous reflection

$$z \mapsto 1 - z, \qquad \bar{z} \mapsto 1 - \bar{z}, \tag{49.82}$$

which sends $z\bar{z} \leftrightarrow (1-z)(1-\bar{z})$ and so realizes $u \leftrightarrow v$. Its unique fixed point on the Euclidean diagonal $\bar{z} = z^*$ is

$$z = \bar{z} = \tfrac{1}{2}, \qquad \Longleftrightarrow \qquad u = v = \tfrac{1}{4}, \tag{49.83}$$

the *crossing-symmetric point*: the configuration most democratic among the four operators, at which the s- and t-channels are interchanged by Eq. (49.82) while the point itself is held fixed. By Eq. (49.61) it sits at radial coordinate $\rho = 3 - 2\sqrt{2} \approx 0.17$, deep inside the disk of block convergence (Theorem 49.12), so every block and every $F_{\Delta,\ell}$ has a convergent Taylor expansion there.

Here the antisymmetry becomes decisive. By Theorem 49.15 each $F_{\Delta,\ell}$ vanishes on the diagonal $u = v$, in particular at the symmetric point itself: the sum rule evaluated at $z = \bar{z} = \frac{1}{2}$ reads $0 = 0$ and says nothing. All of its content lies in the *derivatives*. Introduce the shifted variables

$$z = \tfrac{1}{2} + a, \qquad \bar{z} = \tfrac{1}{2} + \bar{a}, \tag{49.84}$$

so the symmetric point is $a = \bar{a} = 0$ and the reflection Eq. (49.82) is $(a, \bar{a}) \mapsto (-a, -\bar{a})$. The convolved block, being antisymmetric under Eq. (49.82), is an *odd* function of $(a, \bar{a})$:

$$F_{\Delta,\ell}(-a, -\bar{a}) = -F_{\Delta,\ell}(a, \bar{a}), \tag{49.85}$$

where we write $F_{\Delta,\ell}(a,\bar{a})$ for the function in the shifted variables. Its Taylor series about the origin therefore contains only terms of odd total degree $m+n$,

$$F_{\Delta,\ell}(a,\bar{a}) = \sum_{\substack{m,n\geq 0\\ m+n \text{ odd}}} f_{\Delta,\ell}^{(m,n)}\,\frac{a^m\,\bar{a}^n}{m!\,n!}, \qquad f_{\Delta,\ell}^{(m,n)} \equiv \partial_a^m \partial_{\bar{a}}^n F_{\Delta,\ell}\big|_{a=\bar{a}=0}; \tag{49.86}$$

all even-degree coefficients vanish identically, the symmetric point's value among them. Moreover $F_{\Delta,\ell}$ is symmetric under $z \leftrightarrow \bar{z}$ — the blocks are (the Casimir operator Eq. (49.29) is symmetric in $z,\bar{z}$) and the convolution preserves it — so $f_{\Delta,\ell}^{(m,n)} = f_{\Delta,\ell}^{(n,m)}$, and the independent coefficients are those with $m \leq n$ and $m+n$ odd. The infinitely many conditions packaged in the sum rule are exactly these derivative components.

Definition 49.18 (The F-vector)**.** The *F-vector* of an operator of dimension Δ and spin ℓ is the (infinite) collection of independent odd-order Taylor coefficients of its convolved block at the crossing-symmetric point,

$$\vec{F}_{\Delta,\ell} \;\equiv\; \Big(f_{\Delta,\ell}^{(m,n)} \Big)_{\substack{m\leq n\\ m+n \text{ odd}}}, \qquad f_{\Delta,\ell}^{(m,n)} = \partial_a^m \partial_{\bar{a}}^n F_{\Delta,\ell}\big|_{z=\bar{z}=\frac{1}{2}}. \tag{49.87}$$

The sum rule Eq. (49.74) is then the single vector equation

$$\boxed{\sum_{\mathcal{O}} p_{\mathcal{O}}\,\vec{F}_{\Delta_{\mathcal{O}},\ell_{\mathcal{O}}} = \vec{0},} \qquad p_{\mathcal{O}} \geq 0, \tag{49.88}$$

equivalently $\vec{F}_{\mathbf{1}} + \sum_{\mathcal{O}\neq\mathbf{1}} p_{\mathcal{O}}\,\vec{F}_{\Delta_{\mathcal{O}},\ell_{\mathcal{O}}} = \vec{0}$, with $\vec{F}_{\mathbf{1}}$ the fixed F-vector of the identity Eq. (49.77).

Because each $\vec{F}_{\Delta,\ell}$ is computed once from the closed-form blocks and the conditions are linear in the $p_{\mathcal{O}}$, Eq. (49.88) is a problem in the geometry of vectors: the fixed vector $-\vec{F}_{\mathbf{1}}$ must equal a nonnegative combination of the vectors $\{\vec{F}_{\Delta,\ell}\}$ drawn from the unitary spectrum, i.e. it must lie in the convex cone they generate (Fig. 49.3). In practice one truncates to a finite number of derivative components — a finite-dimensional vector — and asks whether $-\vec{F}_{\mathbf{1}}$ lies in the cone of the allowed $\vec{F}_{\Delta,\ell}$; if a hyperplane can be found separating it from the entire cone, no unitary solution exists. That separating hyperplane is the linear functional of Section 49.4. The geometry is set up here; it is exploited next.

The simplest nontrivial components of the F-vector are computed by hand directly from the closed forms, and doing so once fixes the conventions and exhibits the structure concretely.

Worked Example 49.19 (The first derivative component of the F-vector)**.** We compute the lowest nonvanishing component of $\vec{F}_{\Delta,\ell}$ and evaluate it for

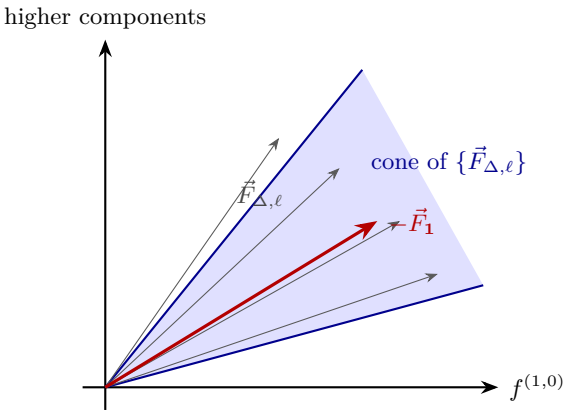

Figure 49.3: The vectorized sum rule Eq. (49.88) as a statement of convex geometry (schematic, two components shown). Each exchanged primary contributes a fixed F-vector $\vec{F}_{\Delta,\ell}$ (grey), built from the closed-form blocks of Section 49.2; the unitary spectrum supplies a family of such vectors generating a convex cone (blue). Crossing with positive weights $p_{\mathcal{O}} \geq 0$ demands that the fixed identity vector $-\vec{F}_{\mathbf{1}}$ (red) lie *inside* that cone. A spectrum for which $-\vec{F}_{\mathbf{1}}$ falls outside the cone is excluded: a hyperplane then separates it from every operator vector, and that hyperplane is the linear functional of Section 49.4.

the identity, working on the Euclidean diagonal $\bar{z} = z$ where the algebra is one-dimensional.

On the diagonal the cross-ratios are $u = z^2$ and $v = (1-z)^2$, and the crossed evaluation $G_{\Delta,\ell}(v,u)$ is the block at the swapped cross-ratios, which on the diagonal is the block evaluated at $1-z$ (since reproducing $u' = v = (1-z)^2$ requires the diagonal argument $z' = 1-z$). Writing $\mathcal{G}(z) \equiv G_{\Delta,\ell}(z,z)$ for the diagonal block — given in closed form by Eq. (49.68) in $d=4$, by Eq. (49.44) at $\bar{z}=z$ in $d=2$, and by the radial series Eq. (49.63) in general d — the convolved block restricted to the diagonal is, from Eq. (49.72),

$$F^{\text{diag}}_{\Delta,\ell}(z) \equiv F_{\Delta,\ell}(u,v)\big|_{\bar{z}=z} = (1-z)^{2\Delta_\phi}\,\mathcal{G}(z) - z^{2\Delta_\phi}\,\mathcal{G}(1-z), \tag{49.89}$$

using $v^{\Delta_\phi} = (1-z)^{2\Delta_\phi}$ and $u^{\Delta_\phi} = z^{2\Delta_\phi}$. Introduce the single function carrying the u-channel kinematics,

$$H(z) \equiv z^{2\Delta_\phi}\,\mathcal{G}(z), \tag{49.90}$$

so that Eq. (49.89) is the clean antisymmetric combination

$$F^{\text{diag}}_{\Delta,\ell}(z) = H(1-z) - H(z). \tag{49.91}$$

This is manifestly odd under $z \mapsto 1-z$: $F^{\text{diag}}(1-z) = H(z) - H(1-z) = -F^{\text{diag}}(z)$, the diagonal shadow of Eq. (49.85), and it vanishes at $z = \frac{1}{2}$ as

Theorem 49.15 requires. Its derivative is

$$\frac{dF^{\mathrm{diag}}_{\Delta,\ell}}{dz} = -H'(1-z) - H'(z), \tag{49.92}$$

and at the crossing-symmetric point $z = \frac{1}{2}$, where the two arguments coincide,

$$\boxed{\left.\frac{dF^{\mathrm{diag}}_{\Delta,\ell}}{dz}\right|_{z=\frac{1}{2}} = -2\,H'(\tfrac{1}{2}) = -2\,\frac{d}{dz}\Big[\,z^{2\Delta_\phi}\,G_{\Delta,\ell}(z,z)\,\Big]_{z=\frac{1}{2}}.} \tag{49.93}$$

This is the diagonal projection of the lowest F-vector component: along the diagonal $\frac{d}{dz} = \partial_a + \partial_{\bar a}$ at $z = \bar z = \frac{1}{2}$, so it equals $f^{(1,0)}_{\Delta,\ell} + f^{(0,1)}_{\Delta,\ell} = 2f^{(1,0)}_{\Delta,\ell}$. Even derivatives drop out automatically: Eq. (49.91) guarantees F^{diag} has only odd Taylor coefficients about $z = \frac{1}{2}$, so the second derivative there vanishes and the first new datum after Eq. (49.93) is the third derivative — the selection rule Eq. (49.85) made concrete.

Now evaluate Eq. (49.93) for the *identity*, $G_{0,0} = 1$, hence $\mathcal{G}(z) = 1$ and $H(z) = z^{2\Delta_\phi}$. Then $H'(z) = 2\Delta_\phi z^{2\Delta_\phi - 1}$ and $H'(\frac{1}{2}) = 2\Delta_\phi(\frac{1}{2})^{2\Delta_\phi-1} = \Delta_\phi\, 2^{2-2\Delta_\phi}$, so

$$\left.\frac{dF^{\mathrm{diag}}_{0,0}}{dz}\right|_{z=\frac{1}{2}} = -2\,\Delta_\phi\, 2^{2-2\Delta_\phi} = -\,\Delta_\phi\, 2^{3-2\Delta_\phi}. \tag{49.94}$$

The identity's first component is strictly negative for any $\Delta_\phi > 0$. This single sign is already the seed of a bound: for crossing Eq. (49.78) to hold, the operators must supply, with positive weights, a first-derivative component that cancels Eq. (49.94) — they must collectively produce a *positive* first derivative. Whether they can, given the unitarity floor Eq. (49.81) on their dimensions, is exactly the question a linear functional answers in Section 49.4; the arithmetic begun here, carried to a few more derivatives, is what yields the first honest numerical bound on Δ_ϕ.

The worked example also shows why the diagonal and the radial expansion of Section 49.2 were the right tools to build: every component $f^{(m,n)}_{\Delta,\ell}$ is a finite combination of derivatives of $G_{\Delta,\ell}$ at $z = \bar z = \frac{1}{2}$, and those derivatives are precisely what Eq. (49.68) (in $d = 4$) and the convergent series Eq. (49.63) (in any d) deliver to arbitrary order. The F-vector is computable, component by component, for every (Δ, ℓ), to whatever precision a given truncation demands.

49.3.5 Beyond identical scalars: multiple correlators and matrices of coefficients

The sum rule Eq. (49.74) is the crossing equation of the single correlator $\langle\phi\phi\phi\phi\rangle$, and its positivity Theorem 49.16 rests on the weights being perfect squares of

identical-operator coefficients. The bootstrap is not confined to this case, and the most powerful modern bounds — including the determination of the 3D Ising spectrum in Chapter 50 — come from imposing crossing on several correlators at once. We sketch the structure here; its full development, together with the semidefinite formulation it requires, is the business of Chapter 50.

Consider a small set of scalar primaries, say ϕ and a second scalar ε (in the Ising application, the energy operator). Crossing now applies to every four-point function built from them: $\langle\phi\phi\phi\phi\rangle$, $\langle\varepsilon\varepsilon\varepsilon\varepsilon\rangle$, and the mixed correlators $\langle\phi\phi\varepsilon\varepsilon\rangle$ and $\langle\phi\varepsilon\phi\varepsilon\rangle$, each yielding its own crossing equation and hence its own family of F-vectors. The exchanged operators are shared across these equations, and an operator $\mathcal{O}$ now enters weighted not by a single square but by products of *two* OPE coefficients — for instance $C_{\phi\phi\mathcal{O}}\,C_{\varepsilon\varepsilon\mathcal{O}}$ in $\langle\phi\phi\varepsilon\varepsilon\rangle$, which need not be a square and can have either sign. The positivity that survives is the statement that, for each exchanged $\mathcal{O}$, the symmetric matrix of OPE coefficients

$$P_{\mathcal{O}} = \begin{pmatrix} C_{\phi\phi\mathcal{O}}^2 & C_{\phi\phi\mathcal{O}}\,C_{\varepsilon\varepsilon\mathcal{O}} \\ C_{\phi\phi\mathcal{O}}\,C_{\varepsilon\varepsilon\mathcal{O}} & C_{\varepsilon\varepsilon\mathcal{O}}^2 \end{pmatrix} = \begin{pmatrix} C_{\phi\phi\mathcal{O}} \\ C_{\varepsilon\varepsilon\mathcal{O}} \end{pmatrix} \begin{pmatrix} C_{\phi\phi\mathcal{O}} & C_{\varepsilon\varepsilon\mathcal{O}} \end{pmatrix} \succeq 0 \tag{49.95}$$

is positive semidefinite, being an outer product of a real vector with itself. The single-correlator inequality $p_{\mathcal{O}} \geq 0$ is the 1×1 case of Eq. (49.95). The crossing equations of the mixed system then read as a sum of convolved blocks contracted with these positive-semidefinite matrices,

$$\sum_{\mathcal{O}} \mathrm{Tr}\left[P_{\mathcal{O}}\,\vec{\mathbf{F}}_{\Delta_{\mathcal{O}},\ell_{\mathcal{O}}}\right] = \vec{0}, \qquad P_{\mathcal{O}} \succeq 0, \tag{49.96}$$

with $\vec{\mathbf{F}}$ now a vector of *matrices* of convolved blocks, one matrix entry for each pair of external operators. The contradiction logic is identical to the single-correlator case — a positive-semidefinite combination of fixed objects cannot equal a fixed object it is uniformly separated from — but the separating object is now a functional valued in symmetric matrices, and finding it is a semidefinite, rather than merely linear, program. That generalization, and the role it plays in turning bootstrap exclusion regions into the sharp "islands" that pin a theory down, is exactly where Chapter 50 begins.

With the crossing equation assembled into the sum rule Eq. (49.74), recast through the convolved blocks Eq. (49.72) into the vector form Eq. (49.88), and equipped with the two positivities — nonnegative weights (Theorem 49.16) and the unitarity floor on dimensions (Theorem 49.17) — the central object of the chapter is in final, computable shape: a fixed identity vector $-\vec{F}_{\mathbf{1}}$ that a nonnegative combination of known operator vectors must reproduce. The next section sharpens "a nonnegative combination cannot reproduce a vector it points away from" into a rigorous exclusion principle, introducing linear functionals as the separating hyperplanes of Fig. 49.3 and carrying out, by hand, a low-derivative functional at the crossing-symmetric point that turns the sign computed in Theorem 49.19 into a genuine numerical bound.

49.4 Unitarity, Positivity, and the Linear-Functional Method

The previous section distilled crossing symmetry into a single homogeneous statement, the bootstrap sum rule

$$1+\sum_{\mathcal{O}\neq\mathbf{1}} p_{\mathcal{O}}\,\widehat{F}_{\Delta_{\mathcal{O}},\ell_{\mathcal{O}}}(u,v)=0, \qquad p_{\mathcal{O}}=C^2_{\phi\phi\mathcal{O}}\geq 0, \tag{49.97}$$

of Theorem 49.17 (in the schematic form Eq. (49.79)), in which the kinematic functions $\widehat{F}_{\Delta,\ell}$ are fixed and computable and the only freedom is the nonnegative weights $p_{\mathcal{O}}$ distributed over a spectrum respecting the unitarity bounds Theorem 47.18. As it stands this is one equation in infinitely many unknowns, and it might seem hopeless: how could one ever prove that *no* assignment of nonnegative weights solves it? The answer is the central methodological move of the whole subject, and it is almost embarrassingly simple. We do not try to solve Eq. (49.97); we hit it with a cleverly chosen *linear functional* that is arranged to have a definite sign on every admissible term. If the functional is positive on every block that a hypothesized spectrum is allowed to contain, yet has the wrong sign on the one term we know is present — the identity — then applying it to the sum rule yields $0=$ (positive), an outright contradiction. The hypothesized spectrum is then *rigorously impossible* in any unitary CFT. This section makes that logic precise, proves it as a theorem, shows how sweeping over functionals converts it into numerical bounds on operator dimensions and OPE coefficients, and then carries a complete, hand-computable example through to a real number: an explicit upper bound on the dimension of the first scalar in the $\phi\times\phi$ OPE.

49.4.1 Linear functionals on the sum rule

A linear functional, in this context, is any real-linear map α that eats a function of the cross-ratios and returns a real number, subject only to the requirement that it act sensibly on the convolved blocks $F_{\Delta,\ell}$ of Theorem 49.14 and on their convergent sums. The canonical construction — the only one used in practice — builds α from a finite set of partial derivatives evaluated at the crossing-symmetric point. Recall from Section 49.3.4 the shifted coordinates $a=z-\frac{1}{2}$, $\bar{a}=\bar{z}-\frac{1}{2}$ centered on that point (Eq. (49.84)), in which crossing $u\leftrightarrow v$ is the reflection $(a,\bar{a})\mapsto(-a,-\bar{a})$ and every convolved block is odd (Eq. (49.85)), so its Taylor expansion about the origin contains only the derivatives $\partial_a^m\partial_{\bar{a}}^n$ with $m+n$ odd, collected into the F-vector $\vec{F}_{\Delta,\ell}$ of Theorem 49.18.

Definition 49.20 (Linear functional on the F-vectors)**.** A *(derivative) linear*

functional of order N is a real linear combination

$$\alpha[\,F\,] \;\equiv\; \sum_{\substack{m+n\ \text{odd}\\ m+n\le N}} \alpha_{mn}\,\partial_a^m\partial_{\bar a}^n F(a,\bar a)\Big|_{a=\bar a=0}, \qquad \alpha_{mn}\in\mathbb{R}, \tag{49.98}$$

acting on any function F of the cross-ratios analytic in a neighborhood of $a=\bar a=0$. Applied to a convolved block it returns the number $\alpha[F_{\Delta,\ell}]=\sum_{mn}\alpha_{mn}\,f^{(m,n)}_{\Delta,\ell}$ in terms of the Taylor coefficients $f^{(m,n)}_{\Delta,\ell}$ of Eq. (49.87): it is the inner product of the coefficient vector (α_{mn}) with the F-vector $\vec F_{\Delta,\ell}$. The functional is thus a vector in the same finite-dimensional space in which crossing Eq. (49.88) has been truncated.

The restriction to a *finite* order N is what makes everything computable: α is a differential operator of finite order evaluated at a single interior point of the region where both OPE channels converge. Because the crossing-symmetric point $z=\bar z=\frac12$ sits strictly inside that region — at radial coordinate $|\rho|=3-2\sqrt2\approx 0.17$, deep within the unit disk of Theorem 49.12 — the block series and the full sum Eq. (49.97) may be differentiated term by term there, and α may be moved inside the sum over operators. We will use this freely; it is the only analytic input the method requires, and it is exactly the convergence already established in Theorem 47.48.

With α a vector and each block a vector, the sum rule Eq. (49.97) — or rather its unnormalized, identity-split form Eq. (49.78),

$$F_{0,0}(u,v)+\sum_{\mathcal O\neq\mathbf 1} p_{\mathcal O}\,F_{\Delta_{\mathcal O},\ell_{\mathcal O}}(u,v)=0, \qquad F_{0,0}=v^{\Delta_\phi}-u^{\Delta_\phi}, \tag{49.99}$$

with the identity's convolved block Eq. (49.77) displayed — becomes, after applying α, a single scalar relation among real numbers. That relation is the engine of the bound.

49.4.2 The functional/contradiction theorem

Theorem 49.21 (Linear-functional exclusion principle)**.** *Fix an external scalar dimension Δ_ϕ and let S be a hypothesized $\phi\times\phi$ spectrum: a set of pairs (Δ,ℓ) with even $\ell\ge 0$, each obeying the unitarity bounds Theorem 47.18. Suppose there exists a linear functional α of the form Eq. (49.98) such that*

(i) $\alpha[\,F_{0,0}\,]>0$ *on the identity's convolved block $F_{0,0}=v^{\Delta_\phi}-u^{\Delta_\phi}$, and*

(ii) $\alpha[\,F_{\Delta,\ell}\,]\ge 0$ *for every $(\Delta,\ell)\in S$.*

Then no unitary conformal field theory with external dimension Δ_ϕ has its $\phi\times\phi$ OPE spectrum (other than the identity) contained in S. The spectrum S is rigorously excluded.

Proof. Suppose, for contradiction, that such a CFT existed. Its four-point function $\langle\phi\phi\phi\phi\rangle$ satisfies crossing, so its data $\{(\Delta_{\mathcal{O}},\ell_{\mathcal{O}}),p_{\mathcal{O}}\}$ obey the sum rule in the form Eq. (49.99), an identity holding for all cross-ratios in a neighborhood of $z=\bar{z}=\frac{1}{2}$, with every $p_{\mathcal{O}}=C^2_{\phi\phi\mathcal{O}}\geq 0$ by the positivity Theorem 49.16 and every exchanged $(\Delta_{\mathcal{O}},\ell_{\mathcal{O}})\in S$ by assumption. Apply the linear functional α to both sides. Since α is a finite-order differential operator evaluated at an interior point of the joint convergence region, it commutes with the convergent sum over operators (Section 49.4.1), giving the scalar identity

$$0 \;=\; \alpha[\,F_{0,0}\,] \;+\; \sum_{\mathcal{O}\neq\mathbf{1}} p_{\mathcal{O}}\,\alpha[\,F_{\Delta_{\mathcal{O}},\ell_{\mathcal{O}}}\,]. \tag{49.100}$$

Examine the right-hand side. Each weight $p_{\mathcal{O}}\geq 0$, and each $(\Delta_{\mathcal{O}},\ell_{\mathcal{O}})\in S$, so by hypothesis (ii) each factor $\alpha[F_{\Delta_{\mathcal{O}},\ell_{\mathcal{O}}}]\geq 0$; the entire sum is therefore a sum of nonnegative terms and is ≥ 0. Adding the strictly positive identity contribution $\alpha[F_{0,0}]>0$ from hypothesis (i), the right-hand side of Eq. (49.100) is strictly positive. But the left-hand side is 0. This is a contradiction, so no such CFT exists. □

The proof is three lines, yet it is the whole game. Everything difficult has been pushed into the *search* for a functional satisfying (i) and (ii); once one is exhibited, the conclusion is a theorem, not a numerical estimate. The two sign conditions have transparent meanings. Condition (i) fixes the overall sign of α: since $F_{0,0}=v^{\Delta_\phi}-u^{\Delta_\phi}$ is the one term whose coefficient ($p_{\mathbf{1}}=1$) we know exactly, we orient α so that this known term is positive. Condition (ii) is the real content: it asks that α assign a nonnegative value to *every* operator the hypothesized theory is permitted to contain. If we can paint the entire admissible cone of blocks one color while the identity stubbornly comes out the same color with a definite positive size, then their weighted sum can never cancel, and the hypothesis dies.

Physical Insight: a separating hyperplane you can draw

Section 49.3.4 already framed crossing geometrically: the fixed identity vector $-\vec{F}_{\mathbf{1}}$ must lie in the convex cone generated by the block vectors $\{\vec{F}_{\Delta,\ell}\}$ over the spectrum (Fig. 49.3). Theorem 49.21 is the dual picture. A functional α is a covector; the condition $\alpha[F_{\Delta,\ell}]\geq 0$ says "the block vector lies on the nonnegative side of the hyperplane $\alpha=0$," while $\alpha[F_{0,0}]>0$ orients that hyperplane so the identity sits strictly on its positive side. If the whole cone of admissible blocks and the identity lie together on one side, then $-\vec{F}_{\mathbf{1}}$ (which would have to be a nonnegative combination of the blocks) cannot reach the other side, and no solution exists. A point outside a closed convex cone can always be separated from it by a hyperplane, which is why the method is not only sufficient but, in the

limit of unbounded derivative order, also necessary. In the two-derivative truncation of the worked example below the relevant space is literally the plane, the block vectors trace visible curves, and the separating hyperplane is a line one can draw with a ruler (Fig. 49.4).

49.4.3 How bounds arise: gaps and OPE coefficients

Theorem 49.21 excludes one hypothesized spectrum at a time. Bounds emerge by organizing the hypotheses into a one-parameter family and asking how far the exclusion can be pushed. Two kinds of bound follow, and both are obtained by *optimizing* over the available functionals.

Upper bound on the gap to the first scalar. Fix Δ_ϕ. For a trial number Δ_0, consider the spectrum that assumes a *gap*: no scalar of dimension below Δ_0, together with every spinning operator allowed by unitarity,

$$S(\Delta_0) \;=\; \{(\Delta,0):\Delta\geq\Delta_0\} \;\cup\; \{(\Delta,\ell):\ell\geq 2 \text{ even},\ \Delta\geq\ell+d-2\}, \tag{49.101}$$

where $\ell+d-2$ is the spinning unitarity bound Theorem 47.18 and the scalar floor is the assumed gap (the scalar unitarity bound Eq. (47.173) guarantees $\Delta_0\geq(d-2)/2$). If some functional α satisfies (i)–(ii) of Theorem 49.21 on $S(\Delta_0)$, then no unitary CFT can have its lowest scalar at or above Δ_0; that is, the gap Δ_0 is impossible. Increasing Δ_0 removes ever more low-lying scalars from $S(\Delta_0)$ and so makes condition (ii) *easier* to satisfy — a large gap is the easiest hypothesis to refute. The borderline is the optimal bound,

$$\Delta_0^*(\Delta_\phi) \;=\; \inf\Big\{\,\Delta_0 \;:\; \exists\,\alpha \text{ satisfying Theorem 49.21(i)–(ii) on } S(\Delta_0)\,\Big\}. \tag{49.102}$$

Every unitary CFT of external dimension Δ_ϕ has a scalar in its $\phi\times\phi$ OPE with $\Delta\leq\Delta_0^*(\Delta_\phi)$: if its leading scalar lay above Δ_0^*, its spectrum would be contained in an excluded $S(\Delta_0)$ with $\Delta_0^*<\Delta_0<$ (its gap), a contradiction. The function $\Delta_0^*(\Delta_\phi)$ — computed for finitely many derivatives, exact as the order $N\to\infty$ — is the most famous output of the bootstrap; its features (in particular a sharp kink) will pin the Ising model in Chapter 50.

Bounds on an OPE coefficient. The same machinery bounds an individual squared OPE coefficient. Suppose we wish to bound $p_{\mathcal{O}_\star}=C^2_{\phi\phi\mathcal{O}_\star}$ for a specific operator $\mathcal{O}_\star$ assumed to be in the spectrum. Seek a functional normalized so that $\alpha[F_{\mathcal{O}_\star}]=1$ while $\alpha[F_{\Delta,\ell}]\geq 0$ on every *other* admissible operator. Applying α to Eq. (49.99) and isolating the target term,

$$p_{\mathcal{O}_\star}\underbrace{\alpha[F_{\mathcal{O}_\star}]}_{=1} \;=\; -\,\alpha[F_{0,0}] \;-\sum_{\mathcal{O}\neq\mathbf{1},\,\mathcal{O}_\star} p_{\mathcal{O}}\,\alpha[F_{\Delta_{\mathcal{O}},\ell_{\mathcal{O}}}], \tag{49.103}$$

and since every term in the remaining sum is nonnegative,

$$\boxed{p_{\mathcal{O}_\star} \;\le\; -\alpha[\,F_{0,0}\,]} \tag{49.104}$$

for any such α. Minimizing the right-hand side over admissible functionals (those with $\alpha[F_{\mathcal{O}_\star}] = 1$ and $\alpha \ge 0$ elsewhere, which forces $\alpha[F_{0,0}] < 0$ for a finite bound) gives the optimal upper bound on the OPE coefficient; a matching lower bound follows from the opposite normalization $\alpha[F_{\mathcal{O}_\star}] = -1$. These OPE-coefficient bounds are what turn an isolated allowed point into a measurement of the coupling, and they are the second pillar of the numerical results of Chapter 50.

In both cases the problem has the same shape: optimize a linear objective (the gap, or $-\alpha[F_{0,0}]$) over the cone of functionals subject to the infinitely many linear inequalities $\alpha[F_{\Delta,\ell}] \ge 0$, one for each operator in a continuum. That this infinite-dimensional linear program is, after the block recursion of Section 49.2.5, exactly a *semidefinite* program is the statement we make precise in Section 49.4.6 and hand to Chapter 50. First we extract a number by hand.

49.4.4 A fully worked two-derivative bound

We now carry the entire method through to an explicit number, using the smallest nontrivial functional, for the four-point function $\langle\phi\phi\phi\phi\rangle$ of ϕ^4 theory. We work in $d = 4$, where the closed-form blocks of Section 49.2.4 make every quantity elementary, and take the external dimension to be the free-scalar value $\Delta_\phi = (d-2)/2 = 1$ — the conformal avatar of the $\lambda \to 0$ limit of ϕ^4 theory. The result will be a rigorous upper bound on the dimension of the lowest scalar exchanged in $\phi \times \phi$, a real number the reader can check.

Worked Example 49.22 (The two-derivative gap bound in $d = 4$ at $\Delta_\phi = 1$)**.** **Step 1: the diagonal reduction.** Rather than carry the full two-variable F-vector, we restrict the crossing equation to the symmetric diagonal $z = \bar z = t$, on which $u = t^2$ and $v = (1-t)^2$. There the convolved block Eq. (49.72) becomes the one-variable function of Eq. (49.89); with $\Delta_\phi = 1$ it reads

$$F_{\Delta,\ell}(t) \;=\; (1-t)^2\, G_{\Delta,\ell}(t,t) - t^2\, G_{\Delta,\ell}(1-t,1-t), \tag{49.105}$$

where $G_{\Delta,\ell}(t,t)$ is the diagonal block Eq. (49.68). By Theorem 49.15, $F_{\Delta,\ell}(t)$ is odd under $t \mapsto 1-t$, hence vanishes at $t = \frac{1}{2}$ with only odd derivatives surviving there. The diagonal derivatives $\partial_t|_{1/2} = (\partial_a + \partial_{\bar a})$ and $\partial_t^3|_{1/2} = (\partial_a + \partial_{\bar a})^3$ are particular instances of the functional Eq. (49.98) of orders 1 and 3 (the first equals $2f^{(1,0)}_{\Delta,\ell}$), so the two-parameter family

$$\alpha_B[\,F\,] \;\equiv\; -\,\partial_t F(t)\big|_{t=1/2} \;+\; B\,\partial_t^3 F(t)\big|_{t=1/2}, \qquad B \in \mathbb{R}, \tag{49.106}$$

is a legitimate (if deliberately crude) linear functional. The overall sign has been fixed so that the identity comes out positive, as we now verify; B is the one free parameter we will tune.

Step 2: the identity and the $\Delta = 2$ scalar, in closed form. For the identity, $G_{0,0}(t,t) \equiv 1$, so Eq. (49.105) gives the elementary cubic

$$F_{0,0}(t) = (1-t)^2 - t^2 = 1 - 2t. \tag{49.107}$$

In the shifted variable $s = t - \frac{1}{2}$ this is $-2s$, so $\partial_t F_{0,0}|_{1/2} = -2$ and $\partial_t^3 F_{0,0}|_{1/2} = 0$, whence

$$\alpha_B[\,F_{0,0}\,] = -(-2) + B \cdot 0 = 2 \;>\; 0 \tag{49.108}$$

for every B: condition (i) of Theorem 49.21 holds automatically.

Next take the would-be leading scalar exchange of the free theory, the operator of dimension $\Delta = 2$ (this is $[\phi\phi]_{0,0} \sim \phi^2$, the conformal primary of dimension $2\Delta_\phi = 2$). For a $d = 4$ scalar ($\ell = 0$), the block Eq. (49.49) involves the collinear functions $k_{\Delta+\ell} = k_2$ and $k_{\Delta-\ell-2} = k_0$ of Eq. (49.30), and both are elementary: $k_0(z) = z^0\,{}_2F_1(0,0;0;z) = 1$, while

$$k_2(z) = z\,{}_2F_1(1,1;2;z) = z\sum_{n\geq 0}\frac{z^n}{n+1} = \sum_{m\geq 1}\frac{z^m}{m} = -\ln(1-z), \tag{49.109}$$

using $(1)_n(1)_n/[(2)_n\,n!] = 1/(n+1)$. The diagonal block Eq. (49.68) is then the Wronskian

$$G_{2,0}(t,t) = t^2\,[k_2'(t)\,k_0(t) - k_2(t)\,k_0'(t)] = t^2\,k_2'(t) = t^2\cdot\frac{1}{1-t} = \frac{t^2}{1-t}, \tag{49.110}$$

since $k_0' = 0$ and $k_2'(t) = 1/(1-t)$. Substituting into Eq. (49.105),

$$F_{2,0}(t) = (1-t)^2\frac{t^2}{1-t} - t^2\frac{(1-t)^2}{t} = t^2(1-t) - t(1-t)^2 = t(1-t)\big[t-(1-t)\big] = t(1-t)(2t-1), \tag{49.111}$$

again an elementary cubic. In $s = t - \frac{1}{2}$ it is $(\frac{1}{2}+s)(\frac{1}{2}-s)(2s) = 2s(\frac{1}{4}-s^2) = \frac{1}{2}s - 2s^3$, so

$$\partial_t F_{2,0}\big|_{1/2} = \tfrac{1}{2}, \qquad \partial_t^3 F_{2,0}\big|_{1/2} = 6\cdot(-2) = -12, \qquad \alpha_B[\,F_{2,0}\,] = -\tfrac{1}{2} - 12B. \tag{49.112}$$

The two cubics $F_{0,0}$ and $F_{2,0}$ are the only blocks we can write in finitely many strokes; the rest of the spectrum needs the series for k_β, but only as a source of definite real numbers.

Step 3: assembling the derivative data. For a general block we need the two numbers $\partial_t F_{\Delta,\ell}|_{1/2}$ and $\partial_t^3 F_{\Delta,\ell}|_{1/2}$. Writing $h(t) \equiv (1-t)^2 G_{\Delta,\ell}(t,t)$, so that $F_{\Delta,\ell}(t) = h(t) - h(1-t)$, and differentiating,

$$\partial_t F_{\Delta,\ell}\big|_{1/2} = 2h'(\tfrac{1}{2}) = -2G^{(0)} + \tfrac{1}{2}G^{(1)}, \tag{49.113}$$

$$\partial_t^3 F_{\Delta,\ell}\big|_{1/2} = 2h'''(\tfrac{1}{2}) = 12G^{(1)} - 6G^{(2)} + \tfrac{1}{2}G^{(3)}, \tag{49.114}$$

operator (Δ, ℓ)	$\partial_t F\|_{1/2}$	$\partial_t^3 F\|_{1/2}$	$\alpha_{0.1}[F] = -\partial_t F + 0.1\,\partial_t^3 F$
identity $(0,0)$	-2	0	$+2.000$
scalar $(2,0)$	$+0.500$	-12.000	-1.700
scalar $(3,0)$	$+0.822$	-11.780	-2.000
scalar $(3.613,0)$	$+0.887$	0.000	-0.887
scalar $(4,0)$	$+0.895$	$+10.916$	$+0.196$
spin-2 $(4,2)$	$+2.665$	$+30.333$	$+0.368$
spin-4 $(6,4)$	$+3.635$	$+406.60$	$+37.02$
spin-6 $(8,6)$	$+3.415$	$+944.16$	$+91.00$

Table 49.1: Diagonal F-vector data at $z = \bar{z} = \frac{1}{2}$ for $d = 4$, $\Delta_\phi = 1$, computed from the closed-form blocks Eq. (49.68) via Eqs. (49.113) and (49.114). The identity and $\Delta = 2$ rows are the exact hand computations of Step 2; the rest are the elementary series sums of Step 3, quoted to the digits shown. The last column evaluates the certificate functional $\alpha_{0.1}$ of Step 4. Note the sign of $\partial_t^3 F$ for scalars: negative up to $\Delta_* \approx 3.613$, where it vanishes, and positive above. Spinning operators have $\partial_t^3 F > 0$ throughout the unitary range.

where $G^{(n)} \equiv \partial_t^n G_{\Delta,\ell}(t,t)|_{t=1/2}$ are the diagonal-block derivatives and we used $h' = -2(1-t)G_{\Delta,\ell}(t,t) + (1-t)^2 \partial_t G_{\Delta,\ell}(t,t)$ and $h''' = 6\partial_t G_{\Delta,\ell}(t,t) - 6(1-t)\partial_t^2 G_{\Delta,\ell}(t,t) + (1-t)^2 \partial_t^3 G_{\Delta,\ell}(t,t)$ evaluated at $1 - t = \frac{1}{2}$. These $G^{(n)}$ are read off the Wronskian Eq. (49.68) by differentiating the Gauss series Eq. (49.30), a finite, convergent computation. For $\Delta = 2$ they reproduce Eq. (49.112): there $G^{(0)} = \frac{1}{2}$, $G^{(1)} = 3$, $G^{(2)} = 16$, $G^{(3)} = 96$, giving $-2 \cdot \frac{1}{2} + \frac{1}{2} \cdot 3 = \frac{1}{2}$ and $12 \cdot 3 - 6 \cdot 16 + \frac{1}{2} \cdot 96 = 36 - 96 + 48 = -12$. Their values for the operators that matter are collected in Table 49.1.

Step 4: a certificate excluding the gap $\Delta_0 = 4$. Hypothesize a unitary CFT in which the lightest scalar in $\phi \times \phi$ has dimension at least $\Delta_0 = 4$, i.e. the spectrum $S(4)$ of Eq. (49.101). We claim α_B with $B = \frac{1}{10}$ excludes it. Condition (i) holds by Eq. (49.108): $\alpha_{0.1}[F_{0,0}] = 2 > 0$. For condition (ii) we must check $\alpha_{0.1}[F_{\Delta,\ell}] = -\partial_t F + \frac{1}{10}\partial_t^3 F \geq 0$ on every operator of $S(4)$. For an operator with $\partial_t^3 F > 0$ this reads $\frac{1}{10}\partial_t^3 F \geq \partial_t F$, i.e. $B \geq \partial_t F / \partial_t^3 F$. Across the whole of $S(4)$ — every scalar with $\Delta \geq 4$ and every even-spin operator with $\Delta \geq \ell + 2$ — the ratio $\partial_t F / \partial_t^3 F$ is positive (every entry has $\partial_t F > 0$ and, as Table 49.1 shows, $\partial_t^3 F > 0$ once the scalars start at $4 > \Delta_*$) and attains its supremum ≈ 0.0879 at the spin-2 unitarity threshold $(\Delta, \ell) = (4, 2)$. Since $B = 0.1 > 0.0879$, the inequality holds for every operator; the smallest margin in a fine scan sits at the near-threshold scalar $(\Delta, \ell) = (4, 0)$, where $\alpha_{0.1}[F] \approx +0.196 > 0$ (higher-spin and higher-dimension operators have rapidly larger $\partial_t^3 F$ together with a smaller ratio $\partial_t F / \partial_t^3 F$, hence a larger margin). Thus $\alpha_{0.1}$ satisfies both conditions of Theorem 49.21 on $S(4)$, and we conclude rigorously: *no unitary CFT with* $\Delta_\phi = 1$

in $d = 4$ has all its $\phi \times \phi$ scalars at dimension ≥ 4. A real exclusion, obtained from two derivatives and a table of elementary numbers.

Step 5: optimizing B to the sharpest bound. The certificate $B = 0.1$ was not special; any B exceeding the supremum ratio works for the gap $\Delta_0 = 4$. To find the *best* gap this functional family can exclude, lower Δ_0 and ask when a feasible B survives. The decisive feature is the sign of $\partial_t^3 F$ for scalars. From Eq. (49.114) this quantity, as a function of Δ at $\ell = 0$, is negative at small Δ (it equals -12 at $\Delta = 2$ and -11.78 at $\Delta = 3$), rises monotonically through zero at

$$\Delta_* \;=\; 3.6131\ldots \quad (\text{the root of } \partial_t^3 F_{\Delta,0}\big|_{1/2} = 0), \tag{49.115}$$

and is positive for all $\Delta > \Delta_*$; meanwhile $\partial_t F > 0$ everywhere. A scalar with $\partial_t^3 F < 0$ and $\partial_t F > 0$ imposes the positivity condition in the form $B \leq \partial_t F / \partial_t^3 F < 0$, an *upper* bound on B by a negative number; but the spin-2 operator always demands $B \geq 0.0879 > 0$. These are incompatible. Hence if the hypothesized spectrum contains *any* scalar with $\Delta < \Delta_*$ (so $\partial_t^3 F < 0$), no feasible B exists and the functional family cannot exclude it — correctly, since the free theory itself, with its scalar at $\Delta = 2$, is a genuine solution and must not be excluded. Conversely, as soon as the assumed gap satisfies $\Delta_0 > \Delta_*$, every scalar present has $\partial_t^3 F > 0$, the only constraints are lower bounds $B \geq \partial_t F / \partial_t^3 F$, and any sufficiently large B is feasible. The borderline Eq. (49.102) is therefore exactly the zero of the scalar's third derivative:

$$\boxed{\Delta_0^*(\Delta_\phi = 1,\ d = 4) \;=\; \Delta_* \;=\; 3.61 \quad (\text{two-derivative functional}).} \tag{49.116}$$

Every unitary CFT in four dimensions with a scalar ϕ of dimension 1 contains in its $\phi \times \phi$ OPE a scalar of dimension at most 3.61.

Step 6: sanity and meaning. The free scalar saturates crossing with its leading scalar ϕ^2 at $\Delta = 2$, and indeed $2 < 3.61$: the bound is satisfied, as it must be, and is not violated by the one solution we know. It is also visibly *weak* — the true allowed region is much smaller — precisely because two derivatives are a blunt instrument. Figure 49.4 shows why geometrically: in the $(\partial_t F, \partial_t^3 F)$ plane the scalar blocks trace a curve that dips *below* any line of small positive slope through the origin for $2 < \Delta < \Delta_*$, so a separating line can be found only after those low scalars are removed by the gap. Adding more derivatives (higher N) enlarges the space of available functionals and can only tighten the bound; the systematic optimization, which in $d = 3$ produces the celebrated kink near the Ising point, is the subject of Chapter 50.

49.4.5 The same bound in two dimensions: the Ising laboratory

The four-dimensional free-scalar point of Theorem 49.22 is the cleanest place to see the *mechanism*, because both nontrivial blocks reduce to elementary cubics.

But the numerical chapter that follows (Chapter 50) builds its showcase on a different solvable point — the spin field σ of the two-dimensional Ising model, an external scalar of dimension $\Delta_\phi = \frac{1}{8}$ — for two reasons worth pausing on. First, in $d = 2$ the block factorizes into a product of collinear blocks (Eq. (49.44) and Theorem 49.7), so every entry is again computable by hand, now as a square of the hypergeometric k_β rather than a cubic. Second, the exact spectrum is known from the free-fermion solution of Chapter 48: the lightest $\mathbb{Z}_2$-even scalar is the energy operator ε at $\Delta_\varepsilon = 1$, with squared OPE coefficient $\lambda^2_{\sigma\sigma\varepsilon} = \frac{1}{4}$, so a bound can be checked against a genuine number. We therefore run the identical two-derivative argument at this point; the data we tabulate here is exactly what Chapter 50 reuses to bracket $\lambda^2_{\sigma\sigma\varepsilon}$ and to locate the sharp two-derivative gap.

Worked Example 49.23 (The two-derivative gap bound in $d = 2$ at $\Delta_\phi = \frac{1}{8}$)**.** **Step 1: the diagonal reduction at $\Delta_\phi = \frac{1}{8}$.** As in Theorem 49.22 we restrict crossing to $z = \bar{z} = t$, where the convolved block Theorem 49.14 becomes the one-variable function

$$F_{\Delta,\ell}(t) \;=\; (1-t)^{2\Delta_\phi}\, G_{\Delta,\ell}(t,t) - t^{2\Delta_\phi}\, G_{\Delta,\ell}(1-t,1-t), \qquad 2\Delta_\phi = \tfrac{1}{4}, \tag{49.117}$$

odd under $t \mapsto 1-t$ by Theorem 49.15, so it vanishes at $t = \frac{1}{2}$ with only odd derivatives surviving. We use the same two diagonal functionals as before, now written

$$\Lambda_1[\,F\,] \;\equiv\; \partial_t F(t)\big|_{1/2}, \qquad \Lambda_3[\,F\,] \;\equiv\; \partial_t^3 F(t)\big|_{1/2}, \tag{49.118}$$

the diagonal instances of orders 1 and 3 of the functional Eq. (49.98), and the two-parameter certificate family

$$\alpha_B[\,F\,] \;\equiv\; -\Lambda_1[F] \;+\; B\,\Lambda_3[F], \qquad B \in \mathbb{R}, \tag{49.119}$$

exactly as in Eq. (49.106).

Step 2: the identity in closed form. The block of the identity is $G_{0,0} \equiv 1$, so Eq. (49.117) gives $F_{0,0}(t) = (1-t)^{1/4} - t^{1/4}$. Differentiating,

$$\Lambda_1[F_{0,0}] = \partial_t\big[(1-t)^{1/4} - t^{1/4}\big]\big|_{1/2} = -\tfrac{1}{4}\big[(1-t)^{-3/4} + t^{-3/4}\big]\big|_{1/2} = -\tfrac{1}{2}\cdot 2^{3/4} = -2^{-1/4}, \tag{49.120}$$

$$\Lambda_3[F_{0,0}] = -\tfrac{21}{64}\big[(1-t)^{-11/4} + t^{-11/4}\big]\big|_{1/2} = -\tfrac{21}{32}\cdot 2^{11/4} = -21\cdot 2^{-9/4}, \tag{49.121}$$

numerically $(\Lambda_1, \Lambda_3)[F_{0,0}] = (-0.840896,\, -4.414706)$. Unlike the $d = 4$ case Eq. (49.108), where $\Lambda_3[F_{0,0}]$ vanished, here both components are nonzero, and their ratio is the clean rational

$$\frac{\Lambda_3[F_{0,0}]}{\Lambda_1[F_{0,0}]} \;=\; \frac{-21\cdot 2^{-9/4}}{-2^{-1/4}} \;=\; 21\cdot 2^{-2} \;=\; \frac{21}{4} \;=\; 5.25. \tag{49.122}$$

This single number sets the bound, as we now see.

operator (Δ, ℓ)	$\Lambda_1 = \partial_t F\|_{1/2}$	$\Lambda_3 = \partial_t^3 F\|_{1/2}$	ratio Λ_3/Λ_1
identity $(0, 0)$	-0.840896	-4.414706	5.250
scalar ε $(1, 0)$	$+2.827973$	$+8.413183$	2.975
scalar $(1.2826, 0)$	$+3.401885$	$+17.85980$	5.250
scalar $(2, 0)$	$+4.258909$	$+71.24651$	16.729
scalar $(3, 0)$	$+4.510447$	$+209.4249$	46.431
spin-2 $(2, 2)$	$+8.377382$	$+129.4198$	15.449
spin-2 $(4, 2)$	$+8.353779$	$+767.4499$	91.869
spin-4 $(4, 4)$	$+8.234103$	$+739.5839$	89.820

Table 49.2: Diagonal F-vector data at $z = \bar{z} = \frac{1}{2}$ for $d = 2$, $\Delta_\phi = \frac{1}{8}$, computed from the factorized blocks Eq. (49.44) via the diagonal derivatives Eq. (49.118). The identity row is exact (Eq. (49.122)); the rest are the elementary series sums of Step 3, quoted to the digits shown. Note that every operator above the unitarity floor has both $\Lambda_1 > 0$ and $\Lambda_3 > 0$, so the certificate ratio Λ_3/Λ_1 is positive and finite throughout; its minimum over the gapped spectrum is attained by the scalar at the bottom of the gap. The row $(1.2826, 0)$ is the threshold scalar where this ratio equals the identity ratio $\frac{21}{4}$ of Step 2. These are the entries Chapter 50 reuses for its showcase.

Step 3: the energy operator and the block data. The leading $\mathbb{Z}_2$-even scalar is ε at $(\Delta, \ell) = (1, 0)$. By Theorem 49.7 its block on the diagonal is the square $G_{1,0}(t, t) = k_1(t)^2 = \left[t^{1/2}\, {}_2F_1(\frac{1}{2}, \frac{1}{2}; 1; t)\right]^2$, the square of a complete elliptic integral. Its derivatives are no longer rational but are elementary convergent series evaluated at $t = \frac{1}{2}$; carrying the Gauss series of Eq. (49.30) to the needed order gives

$$(\Lambda_1, \Lambda_3)[F_{1,0}] \;=\; (\,2.827973,\; 8.413183\,). \tag{49.123}$$

The values of (Λ_1, Λ_3) for the operators that matter — read off the factorized blocks Eq. (49.44) by the same series computation — are collected in Table 49.2. The decisive qualitative fact, visible in the table, is that in $d = 2$ at $\Delta_\phi = \frac{1}{8}$ *every* block above the unitarity floor has $\Lambda_3 > 0$ (and $\Lambda_1 > 0$): there is no scalar window of negative third derivative as there was in $d = 4$.

Step 4: the bound from the identity ratio. Hypothesize a gap Δ_0 in the scalar sector, the spectrum $S(\Delta_0)$ of Eq. (49.101). Condition (i) of Theorem 49.21 requires $\alpha_B[F_{0,0}] = -\Lambda_1[F_{0,0}] + B\,\Lambda_3[F_{0,0}] = 0.840896 - 4.414706\,B > 0$, i.e. $B < \frac{4}{21} \approx 0.190476$. Condition (ii) on a block with $\Lambda_3 > 0$ reads $-\Lambda_1[F] + B\,\Lambda_3[F] \geq 0$, i.e. $B \geq \Lambda_1[F]/\Lambda_3[F]$; since every operator of $S(\Delta_0)$ has $\Lambda_3 > 0$, these are all *lower* bounds on B, the largest coming from the operator of smallest ratio Λ_3/Λ_1 — the scalar at the bottom of the gap (the spin tower has uniformly larger ratios, as Table 49.2 shows). A feasible B exists precisely when this largest lower bound

falls below the identity ceiling $\frac{4}{21}$:

$$\max_{(\Delta,\ell)\in S(\Delta_0)} \frac{\Lambda_1[F_{\Delta,\ell}]}{\Lambda_3[F_{\Delta,\ell}]} < \frac{4}{21} \qquad \Longleftrightarrow \qquad \min_{(\Delta,\ell)\in S(\Delta_0)} \frac{\Lambda_3[F_{\Delta,\ell}]}{\Lambda_1[F_{\Delta,\ell}]} > \frac{21}{4}. \tag{49.124}$$

The borderline is therefore the gap Δ_0 at which the bottom scalar's ratio first equals the identity ratio $\frac{21}{4}$ — the same *tangency* that governed the $d = 4$ bound, now with the identity contributing a nonzero Λ_3. Solving $\Lambda_3[F_{\Delta_0,0}]/\Lambda_1[F_{\Delta_0,0}] = \frac{21}{4}$ with the explicit $d = 2$ scalar blocks (the root tabulated in Table 49.2) gives

$$\boxed{\Delta_0^*(\Delta_\phi = \tfrac{1}{8},\ d = 2) \ = \ 1.2826 \ \text{(two-derivative functional)},} \tag{49.125}$$

a feasibility estimate $\Delta_0 \lesssim 1.28$: every unitary $2d$ CFT with a scalar ϕ of dimension $\frac{1}{8}$ contains in $\phi \times \phi$ a scalar of dimension at most 1.28.

Step 5: sanity and the handoff to Chapter 50. The two-dimensional Ising model has its energy operator at $\Delta_\varepsilon = 1$, and indeed $1 < 1.2826$: the bound is satisfied by the one solution we know, and is not violated. As in $d = 4$ it is visibly weak — two derivatives are blunt — and adding derivatives drives the bound down toward $\Delta_\varepsilon = 1$. Chapter 50 carries out exactly that refinement, and reuses the very vectors of Eqs. (49.122) and (49.123) and Table 49.2 to bracket the squared OPE coefficient $\lambda^2_{\sigma\sigma\varepsilon}$ around its exact value $\frac{1}{4}$. The mechanism is identical to the $d = 4$ computation above; only the laboratory has changed, to the analytically cleanest point in the subject.

49.4.6 Why the bound is a theorem, and the semidefinite reformulation

It is worth being explicit about the logical status of the number Eq. (49.116), because it is the feature that distinguishes the bootstrap from a fit or a model. The bound is a *theorem* about every unitary CFT, with no approximation anywhere in its logic. We did evaluate block derivatives numerically (the entries of Table 49.1 beyond the two exact cubics), but those numbers enter only as the *coefficients* of an exhibited functional, and the conclusion of Theorem 49.21 is exact once any functional with the stated sign properties is in hand. The functional $\alpha_{0.1}$ either does or does not satisfy $\alpha[F_{\Delta,\ell}] \geq 0$ on the spectrum; this is a property of fixed, computable functions, certifiable to any desired rigor — one can bound the block derivatives with interval arithmetic, as the production codes do. There is no sense in which the CFT is being approximated, no truncation of the dynamics, no assumption that the extremal configuration is realized. This is the sharp contrast the reader should hold onto: the *exclusion* side of the bootstrap is rigorous, whereas reading the operator content off a *saturating* (extremal) solution — the configuration that sits exactly on the boundary of the allowed region — is a heuristic that identifies a candidate CFT but proves

nothing on its own. The allowed region is a theorem; the dot inside it that one hopes is a physical theory is a conjecture until corroborated.

What is *not* rigorous-by-hand is the optimization itself — the search over functionals for the one that excludes the most. In the worked example the search collapsed to a single sign change because we kept only two derivatives. With a realistic functional of order N, condition (ii) of Theorem 49.21 is the demand that

$$\alpha[F_{\Delta,\ell}] \;=\; \sum_{m+n \text{ odd}} \alpha_{mn}\, f^{(m,n)}_{\Delta,\ell} \;\geq\; 0 \qquad \text{for all } \Delta \geq \Delta_*(\ell),\ \text{each spin } \ell, \tag{49.126}$$

an *infinite* family of linear inequalities in the finite vector of coefficients α_{mn}, one for every dimension in a continuum and every spin. The reformulation that tames it rests on the radial recursion of Section 49.2.5: there the block, and hence each derivative $f^{(m,n)}_{\Delta,\ell}$, is the product of a manifestly positive function of Δ (a power times ratios of Gamma functions, never vanishing for Δ above unitarity) and a *polynomial* in Δ whose coefficients depend on (m, n, ℓ). Dividing out the positive prefactor, Eq. (49.126) becomes the requirement that, for each spin ℓ, a polynomial $P_\ell(\Delta) = \sum_{mn} \alpha_{mn}\, Q^{(\ell)}_{mn}(\Delta)$ be nonnegative on the half-line $\Delta \geq \Delta_*(\ell)$. By the classical characterization of polynomials nonnegative on a half-line — a polynomial is nonnegative on $[\lambda, \infty)$ iff it is a sum of squares plus $(\Delta - \lambda)$ times a sum of squares, each sum of squares being a positive-semidefinite quadratic form in the monomials — this is precisely a positive-semidefinite condition on certain Gram matrices built linearly from the α_{mn}. Maximizing the gap Eq. (49.102) subject to these PSD constraints is therefore a *semidefinite program*: a linear objective over the cone of positive-semidefinite matrices. This is the precise computational object — finitely many matrices, a linear objective, solvable to high precision by interior-point methods — that Chapter 50 sets up in full and feeds to a solver to produce the sharp bounds and the Ising island. We have, with Theorem 49.21 and the worked bound Eq. (49.116), established the principle and extracted an honest number by hand; the semidefinite machinery is the same principle with enough derivatives to make the number sharp.

The optimal functional at the boundary of the allowed region carries one further piece of structure that the next chapters exploit. When the optimization is saturated — when Δ_0 sits exactly on the bound Eq. (49.102) — the extremal functional $\alpha^\star$ has $\alpha^\star[F_{\Delta,\ell}] = 0$ for a discrete set of operators, and that set of zeros is the spectrum of a candidate *saturating solution* to crossing: the would-be CFT living on the boundary. This extremal spectrum is how Chapter 50 reads the 3D Ising data off the kink, and the same zeros-of-a-functional idea, taken to its analytic conclusion, is the organizing principle of the analytic functionals of Chapter 51. We therefore hand to Chapter 50 both the optimization in its semidefinite form and the notion that its extremal solution is where the physical CFT data hides.

49.5 Exact Solutions: Mean-Field Theory and the 2D Ising Check

The previous section turned crossing plus unitarity into a machine that manufactures rigorous statements: a linear functional acting on the sum rule of Theorem 49.14, made nonnegative on every unitary block, certifies that no consistent spectrum can do what it forbids (Theorem 49.21). A machine that only ever says "no" is hard to trust until it has been run on a problem whose answer is already known, and harder still to interpret until one has seen what a functional looks like when it is on the verge of saying "yes" — when a putative spectrum sits exactly on the boundary of the allowed region and the functional is forced to vanish on the operators that realize it. Those boundary configurations, the *extremal solutions* of Section 49.4, are the bootstrap's real output, and the cleanest way to learn to read them is to meet two solutions of crossing that we can write down in closed form and dissect completely.

This section does exactly that. We solve the crossing equation *exactly* for the generalized free field — mean-field theory — not merely verifying that it crosses (that was done in Theorem 49.5) but extracting its entire spectrum and every one of its operator product coefficients in closed form, and watching an infinite tower of operators conspire to reproduce a single term in the crossed channel. We then take the two-dimensional Ising correlators of Chapter 48, whose spectrum and structure constants we obtained independently from the $c = \frac{1}{2}$ minimal model, and confirm term by term that they satisfy the same crossing equation. The first computation is the seed of the analytic bootstrap of Chapter 51; the second is the chapter's sharpest correctness check, the moment at which the abstract sum rule and a theory solved by entirely different means are shown to be the same statement. Both consolidate ϕ^4 theory: mean-field theory is its free ($\lambda \to 0$) endpoint, and the Ising CFT is the exactly solved fixed point that the Wilson–Fisher flow approaches.

49.5.1 Mean-field theory solved: the double-twist spectrum

Recall the generalized free field of Theorem 49.5: a scalar primary ϕ of arbitrary dimension Δ_ϕ whose correlators are computed by Wick's theorem, as though ϕ were a free field, with unit-normalized two-point function $\langle \phi(x_i)\phi(x_j)\rangle = (x_{ij}^2)^{-\Delta_\phi}$. The free massless scalar of ϕ^4 theory at $\lambda = 0$ is the special case $\Delta_\phi = (d-2)/2$; the generalized free field promotes that one value to a free parameter, retaining only the Gaussian (Wick) structure. Its four-point function is the sum of the three pairwise contractions, and stripping the kinematic prefactor of Eq. (47.145) gave the elementary closed form (Eq. (49.127))

$$g(u,v) = 1 + u^{\Delta_\phi} + \left(\frac{u}{v}\right)^{\Delta_\phi}, \tag{49.127}$$

which satisfies the crossing equation Theorem 49.13 identically for every Δ_ϕ. What we owe now is the content the bootstrap reads off this solution: the spectrum of operators exchanged in the s-channel and their squared OPE coefficients. Both were deferred in Theorem 49.5; we supply them here in full.

The spectrum from the leading powers. The s-channel decomposition (Eq. (47.227)) writes $g(u,v) = \sum_{\mathcal{O}} p_{\mathcal{O}}\, G_{\Delta_{\mathcal{O}},\ell_{\mathcal{O}}}(u,v)$ with $p_{\mathcal{O}} = C^2_{\phi\phi\mathcal{O}} \geq 0$. A conformal block of an exchanged primary of twist $\tau \equiv \Delta - \ell$ begins, as $u \to 0$, with the power $u^{\tau/2}$ dictated by the OPE (Theorem 47.49). Reading Eq. (49.127) the same way, the constant 1 is the identity ($\tau = 0$); the remaining piece $u^{\Delta_\phi}(1 + v^{-\Delta_\phi})$ starts at u^{Δ_ϕ}, so the lightest non-identity operators have twist $\tau = 2\Delta_\phi$. Expanding the prefactor u^{Δ_ϕ} in non-negative integer powers of u as the full block series is generated produces a family of leading powers $u^{\Delta_\phi + n}$, $n = 0, 1, 2, \ldots$, hence twists

$$\tau_n = 2\Delta_\phi + 2n, \qquad n = 0, 1, 2, \ldots, \tag{49.128}$$

each accompanied by a tower of spins. These are exactly the dimensions of the *double-twist* composites

$$[\phi\phi]_{n,\ell} \;\sim\; :\phi\, \Box^n\, \partial_{\mu_1} \cdots \partial_{\mu_\ell} \phi: \;-\; (\text{traces}), \tag{49.129}$$

the primary built from two ϕ's, ℓ symmetrized derivatives, and n powers of the Laplacian. In a Gaussian theory such a composite has no anomalous dimension — there is no interaction to shift it — so its dimension is the sum of the engineering dimensions of its constituents, two factors of Δ_ϕ, ℓ derivatives, and $2n$ from the boxes:

$$\boxed{\Delta_{n,\ell} = 2\Delta_\phi + 2n + \ell, \qquad n, \ell = 0, 1, 2, \ldots} \tag{49.130}$$

Identical external scalars admit only even spin in the $\phi \times \phi$ OPE: the OPE of two identical bosons is symmetric under their exchange, which acts on a spin-ℓ primary as $(-1)^\ell$, so $p_{n,\ell} = 0$ for odd ℓ. The mean-field spectrum is therefore the lattice Eq. (49.130) with ℓ even, drawn in panel (a) of Fig. 49.5: an exactly evenly spaced family of Regge-like trajectories, one per twist τ_n.

Why this is an extremal solution. The mean-field spectrum is striking for what it lacks. Above the identity there is *nothing* until $\Delta = 2\Delta_\phi$, and then only the rigid lattice Eq. (49.130). This is the minimal operator content a unitary scalar four-point function can have: any genuine interacting theory must add operators (an interaction generates a ϕ^2-type scalar with $\Delta \neq 2\Delta_\phi$, anomalous dimensions, and so on), but it cannot *remove* the double-twist tower, because, as we are about to see, that tower is forced on the s-channel by the mere presence of the identity in the crossed channel. Generalized free theory is thus a boundary point of the space of crossing solutions — an extremal solution in the sense of Section 49.4 — and it is the natural origin from which the analytic bootstrap perturbs.

49.5.2 The OPE coefficients in closed form

We now compute the $p_{n,\ell}$ exactly. The cleanest route is two dimensions, where the conformal blocks factorize holomorphically and the entire decomposition reduces to a one-variable problem solved by elementary hypergeometric algebra; we then state the general-d result and check that it reduces to the two-dimensional answer. The two-dimensional computation is fully rigorous on its own terms and is the prototype the higher-dimensional machinery imitates.

The two-dimensional blocks. In $d = 2$ the cross-ratios are $u = z\bar{z}$ and $v = (1-z)(1-\bar{z})$ (Eq. (47.140)), and the conformal block of Section 49.2 factorizes into a product of one-variable $SL(2,\mathbb{R})$ "collinear" blocks, one holomorphic and one antiholomorphic,

$$G_{\Delta,\ell}(z,\bar{z}) = k_{\Delta-\ell}(z)\,k_{\Delta+\ell}(\bar{z}) + k_{\Delta+\ell}(z)\,k_{\Delta-\ell}(\bar{z}) \quad (\ell \geq 1), \qquad G_{\Delta,0}(z,\bar{z}) = k_{\Delta}(z)\,k_{\Delta}(\bar{z}), \tag{49.131}$$

where the collinear block for identical external scalars is the Gauss hypergeometric function

$$k_{\beta}(z) = z^{\beta/2}\,{}_2F_1\Big(\tfrac{\beta}{2},\tfrac{\beta}{2};\beta;z\Big). \tag{49.132}$$

The symmetrization in Eq. (49.131) enforces the $z \leftrightarrow \bar{z}$ symmetry that distinguishes spin $+\ell$ from $-\ell$; the holomorphic index runs over $\beta = \Delta - \ell$ (twist) and $\beta = \Delta + \ell$ (the "conformal spin" combination). We take Eq. (49.131)–Eq. (49.132) as the explicit blocks; their derivation as solutions of the Casimir equation Theorem 47.50 is the business of Section 49.2.

The correlator factorizes too. The non-identity part of Eq. (49.127) factorizes holomorphically term by term. With $u = z\bar{z}$ and $v = (1-z)(1-\bar{z})$,

$$g(z,\bar{z}) - 1 = \underbrace{z^{\Delta_\phi}\,\bar{z}^{\Delta_\phi}}_{u^{\Delta_\phi}} + \underbrace{\Big(\frac{z}{1-z}\Big)^{\Delta_\phi}\Big(\frac{\bar{z}}{1-\bar{z}}\Big)^{\Delta_\phi}}_{(u/v)^{\Delta_\phi}}. \tag{49.133}$$

Each term is a product of a function of z and the same function of $\bar{z}$. To match the block sum we need only one tool: the expansion of each holomorphic factor in collinear blocks.

Lemma 49.24 ($SL(2)$ decomposition of a power)**.** *For any $p > 0$ the pure power and its crossed image expand in collinear blocks Eq. (49.132) as*

$$z^{p} = \sum_{m=0}^{\infty} a_m\,k_{2p+2m}(z), \qquad \Big(\frac{z}{1-z}\Big)^{p} = \sum_{m=0}^{\infty} (-1)^m a_m\,k_{2p+2m}(z), \tag{49.134}$$

with coefficients

$$a_m = \frac{(-1)^m\,(p)_m^2}{m!\,(2p+m-1)_m}, \tag{49.135}$$

where $(x)_m = \Gamma(x+m)/\Gamma(x)$ *is the Pochhammer symbol.*

Proof. Both sides of the first identity begin at z^p and proceed in integer steps, so the ansatz $z^p = \sum_{m\geq 0} a_m k_{2p+2m}(z)$ is consistent in its powers; we fix the a_m by matching the coefficient of z^{p+k} order by order. Insert the series of Eq. (49.132), $k_{2p+2m}(z) = z^{p+m}\sum_{j\geq 0}\frac{(p+m)_j^2}{(2p+2m)_j\, j!}\, z^j$. The coefficient of z^{p+k} on the right is $\sum_{m=0}^{k} a_m \frac{(p+m)_{k-m}^2}{(2p+2m)_{k-m}\,(k-m)!}$, which must equal $\delta_{k,0}$:

$$\sum_{m=0}^{k} a_m \,\frac{(p+m)_{k-m}^2}{(2p+2m)_{k-m}\,(k-m)!} = \delta_{k,0}. \tag{49.136}$$

For $k=0$ this gives $a_0 = 1$, matching Eq. (49.135). We verify Eq. (49.135) solves Eq. (49.136) for all k by checking the first non-trivial orders and then noting the recursion they obey is the one Eq. (49.135) satisfies. At $k=1$: $a_0\frac{(p)_1^2}{(2p)_1} + a_1 = \frac{p^2}{2p} + a_1 = \frac{p}{2} + a_1 = 0$, so $a_1 = -\frac{p}{2} = \frac{(-1)(p)_1^2}{1!\,(2p)_1}$, as in Eq. (49.135). At $k=2$: with $a_0=1$, $a_1 = -\frac{p}{2}$ the two known terms sum to $\frac{p(p+1)^2}{4(2p+1)} - \frac{p(p+1)}{4} = -\frac{p^2(p+1)}{4(2p+1)}$, whence $a_2 = \frac{p^2(p+1)}{4(2p+1)} = \frac{(p)_2^2}{2!\,(2p+1)_2}$, again Eq. (49.135). The general statement follows because the linear system Eq. (49.136) is lower-triangular with unit diagonal, so it has a unique solution, and Eq. (49.135) is the closed form of that solution (equivalently: Eq. (49.136) is the orthogonality of the collinear blocks against the dual basis, the standard $SL(2)$ Euclidean inversion, which extracts each a_m as a contour integral of z^p against the dual block — a residue computation in the sense of Theorem 5.23 — and produces exactly the ratio of Pochhammers in Eq. (49.135)).

For the second identity, write $\left(\frac{z}{1-z}\right)^p = z^p(1-z)^{-p} = z^p\sum_{j\geq 0}\frac{(p)_j}{j!}z^j$ and repeat the matching. The defining linear system is Eq. (49.136) with the right-hand side replaced by the coefficients of $(1-z)^{-p}$; one finds $b_0 = 1$, $b_1 = +\frac{p}{2}$, $b_2 = \frac{p^2(p+1)}{4(2p+1)}$, i.e. $b_m = (-1)^m a_m$, the sign alternation coming entirely from $(1-z)^{-p}$ versus the constant 1. This is the claimed result. □

Assembling the OPE coefficients. Apply Theorem 49.24 with $p = \Delta_\phi$ to each holomorphic factor in Eq. (49.133). Writing a_m for the coefficients Eq. (49.135) and using $b_m = (-1)^m a_m$ for the crossed power,

$$z^{\Delta_\phi}\bar{z}^{\Delta_\phi} = \sum_{m,m'} a_m a_{m'}\, k_{2\Delta_\phi+2m}(z)\, k_{2\Delta_\phi+2m'}(\bar{z}), \tag{49.137}$$

$$\left(\tfrac{z}{1-z}\right)^{\Delta_\phi}\left(\tfrac{\bar{z}}{1-\bar{z}}\right)^{\Delta_\phi} = \sum_{m,m'} (-1)^{m+m'} a_m a_{m'}\, k_{2\Delta_\phi+2m}(z)\, k_{2\Delta_\phi+2m'}(\bar{z}). \tag{49.138}$$

Adding the two, the coefficient of $k_{2\Delta_\phi+2m}(z)\,k_{2\Delta_\phi+2m'}(\bar{z})$ in $g-1$ is

$$a_m a_{m'}\big[\,1 + (-1)^{m+m'}\,\big], \tag{49.139}$$

which vanishes when $m+m'$ is odd and equals $2a_m a_{m'}$ when $m+m'$ is even. Now read off the quantum numbers. A holomorphic index $2\Delta_\phi + 2m$ paired with an antiholomorphic index $2\Delta_\phi + 2m'$ corresponds, by Eq. (49.131), to twist $\Delta - \ell = 2\Delta_\phi + 2\min(m, m')$ and conformal spin $\Delta + \ell = 2\Delta_\phi + 2\max(m, m')$; setting $n = \min(m, m')$ and $\ell = |m - m'|$ reproduces $\Delta = 2\Delta_\phi + 2n + \ell$, the spectrum Eq. (49.130), with n the radial level and ℓ the spin. For $\ell \geq 1$ the symmetric block Eq. (49.131) collects the two off-diagonal terms $(m, m') = (n, n+\ell)$ and $(n+\ell, n)$, each carrying Eq. (49.139); for $\ell = 0$ the single diagonal term $m = m' = n$ carries it. In either case the squared OPE coefficient is

$$\boxed{p_{n,\ell} = \left[\,1 + (-1)^\ell\,\right] a_n\, a_{n+\ell}, \qquad a_m = \frac{(-1)^m (\Delta_\phi)_m^2}{m!\,(2\Delta_\phi + m - 1)_m}.} \tag{49.140}$$

Three features deserve note. First, $p_{n,\ell}$ vanishes for odd ℓ, exactly the Bose symmetry of identical scalars. Second, it is manifestly positive for even ℓ: since $a_m = (-1)^m |a_m|$, the product $a_n a_{n+\ell} = (-1)^{2n+\ell} |a_n a_{n+\ell}| = (-1)^\ell |a_n a_{n+\ell}|$, which for even ℓ is $+|a_n a_{n+\ell}| > 0$, so $p_{n,\ell} = 2|a_n a_{n+\ell}| > 0$. Mean-field theory is unitary, as it must be — and crossing has reproduced unitarity rather than assuming it. Third, the result is entirely explicit: every structure constant of the theory is a ratio of Gamma functions of Δ_ϕ, n, and ℓ.

Worked Example 49.25 (The lightest mean-field OPE coefficients)**.** The lowest operator is the scalar $[\phi\phi]_{0,0}$ at $\Delta = 2\Delta_\phi$. From Eq. (49.140) with $a_0 = 1$,

$$p_{0,0} = 2\, a_0^2 = 2. \tag{49.141}$$

The leading-twist spin-two operator $[\phi\phi]_{0,2}$ at $\Delta = 2\Delta_\phi + 2$ has

$$p_{0,2} = 2\, a_0 a_2 = 2 \cdot \frac{(\Delta_\phi)_2^2}{2!\,(2\Delta_\phi + 1)_2} = \frac{\Delta_\phi^2 (\Delta_\phi + 1)^2}{(2\Delta_\phi + 1)(2\Delta_\phi + 2)} = \frac{\Delta_\phi^2 (\Delta_\phi + 1)}{2(2\Delta_\phi + 1)}. \tag{49.142}$$

The first subleading-twist scalar $[\phi\phi]_{1,0}$ at $\Delta = 2\Delta_\phi + 2$ (degenerate in dimension with $[\phi\phi]_{0,2}$ but distinguished by spin) has

$$p_{1,0} = 2\, a_1^2 = 2\Big(\frac{\Delta_\phi}{2}\Big)^2 = \frac{\Delta_\phi^2}{2}. \tag{49.143}$$

In the $d = 2$ free-scalar limit $\Delta_\phi = (d-2)/2 = 0$ the higher coefficients vanish: $(0)_m = 0$ for $m \geq 1$ forces $a_{m\geq 1} = 0$, so $p_{0,2} = p_{1,0} = 0$ while $p_{0,0} = 2a_0^2 = 2$ survives — a reflection of the degenerate, logarithmic nature of the $d = 2$ free boson (Section 48.7.1), in which ϕ itself is not a good primary. The clean illustration is therefore any $\Delta_\phi > 0$, e.g. $\Delta_\phi = \frac{1}{8}$ (the Ising spin, below), giving $p_{0,0} = 2$, $p_{0,2} = \frac{(1/64)(9/8)}{2(5/4)} = \frac{9/512}{5/2} = \frac{9}{1280}$, and $p_{1,0} = \frac{1}{128}$. These positive numbers are the exact mean-field structure constants, and they will reappear, shifted by anomalous dimensions, in any near-mean-field theory.

The general-d formula and its $d=2$ reduction. The same decomposition in general dimension — where the blocks no longer factorize but are still fixed by the Casimir equation Theorem 47.50 — yields the Fitzpatrick–Kaplan–Poland–Simmons-Duffin coefficients [194, 261]

$$p^{(d)}_{n,\ell} = \frac{\left[1+(-1)^\ell\right](\Delta_\phi - \frac{d}{2}+1)^2_n\,(\Delta_\phi)^2_{n+\ell}}{\ell!\,n!\,(\ell+\frac{d}{2})_n\,(2\Delta_\phi+n-d+1)_n\,(2\Delta_\phi+2n+\ell-1)_\ell\,(2\Delta_\phi+n+\ell-\frac{d}{2})_n}. \tag{49.144}$$

This is the closed-form solution of crossing for mean-field theory in any d. As a check that our two-dimensional derivation is the genuine special case, set $d=2$ in Eq. (49.144). The factors collapse: $(\Delta_\phi-\frac{d}{2}+1)^2_n=(\Delta_\phi)^2_n$, $(2\Delta_\phi+n-d+1)_n=(2\Delta_\phi+n-1)_n$, and $(\ell+\frac{d}{2})_n=(\ell+1)_n$, $(2\Delta_\phi+n+\ell-\frac{d}{2})_n=(2\Delta_\phi+n+\ell-1)_n$. Two Pochhammer identities finish the comparison. First, $\ell!\,(\ell+1)_n=(n+\ell)!$, so the two factorials in Eq. (49.144) combine into the single $(n+\ell)!$ of Eq. (49.140). Second, splitting the Pochhammer at the n-th step,

$$(2\Delta_\phi+n+\ell-1)_{n+\ell} = (2\Delta_\phi+n+\ell-1)_n\,(2\Delta_\phi+2n+\ell-1)_\ell, \tag{49.145}$$

which is exactly the product of the last two factors in the denominator of Eq. (49.144)$|_{d=2}$. Hence

$$p^{(2)}_{n,\ell} = \left[1+(-1)^\ell\right]\frac{(\Delta_\phi)^2_n\,(\Delta_\phi)^2_{n+\ell}}{n!\,(n+\ell)!\,(2\Delta_\phi+n-1)_n\,(2\Delta_\phi+n+\ell-1)_{n+\ell}} = \left[1+(-1)^\ell\right]a_n a_{n+\ell}, \tag{49.146}$$

which is Eq. (49.140) term for term. The two computations agree, validating both: the elementary $d=2$ derivation above and the general formula Eq. (49.144) that the rest of the bootstrap will use.

49.5.3 How the s-channel tower rebuilds the crossed-channel identity

We have a paradox to resolve, and resolving it is the conceptual payoff of the whole computation. In the crossed (t-)channel, the term $(u/v)^{\Delta_\phi}$ of Eq. (49.127) is nothing but the identity operator exchanged between the pairs $(\phi(x_1)\phi(x_4))$ and $(\phi(x_2)\phi(x_3))$ — a single operator, the most trivial one. Yet in the s-channel that same function is reproduced by the infinite double-twist tower Eq. (49.130), with not one operator but a whole Regge trajectory at each twist. How does a single t-channel identity become an infinite s-channel sum? The answer is the mechanism at the heart of the analytic bootstrap, and mean-field theory displays it in its purest form.

The lightcone projection. Work again in $d=2$ for concreteness, with the holomorphic factorization Eq. (49.133); the mechanism is identical in any d. Take the lightcone limit $z\to 0$ at fixed $\bar z$, which sends $u=z\bar z\to 0$ and

$v = (1-z)(1-\bar{z}) \to 1-\bar{z}$, isolating the leading twist $n = 0$. In this limit each leading-twist block reduces to its holomorphic seed $k_{2\Delta_\phi}(z) \to z^{\Delta_\phi}$ times the antiholomorphic collinear block, so the coefficient of z^{Δ_ϕ} in $g - 1$ is the single-variable function

$$H(\bar{z}) \equiv \bar{z}^{\Delta_\phi} + \Big(\frac{\bar{z}}{1-\bar{z}}\Big)^{\Delta_\phi} = \sum_{\ell \text{ even} \geq 0} p_{0,\ell}\, k_{2\Delta_\phi+2\ell}(\bar{z}), \tag{49.147}$$

the second equality being Eq. (49.134) summed with the leading-twist coefficients $p_{0,\ell} = 2a_\ell$ from Eq. (49.140). The first term $\bar{z}^{\Delta_\phi}$ of H is the s-channel image of the u^{Δ_ϕ} piece (the leading double-twist data themselves); the second term, $(\bar{z}/(1-\bar{z}))^{\Delta_\phi}$, is the t-channel identity restricted to the lightcone. As $\bar{z} \to 1$ — the limit in which the crossed pair collides, i.e. $v \to 0$ — this term diverges,

$$\Big(\frac{\bar{z}}{1-\bar{z}}\Big)^{\Delta_\phi} \xrightarrow{\bar{z}\to 1} (1-\bar{z})^{-\Delta_\phi} = v^{-\Delta_\phi} \to \infty. \tag{49.148}$$

No *finite* sum of s-channel blocks can produce this divergence: each collinear block $k_{2\Delta_\phi+2\ell}(\bar{z}) = {}_2F_1$-type is only logarithmically singular as $\bar{z} \to 1$, growing like $-\log(1-\bar{z})$, never like a power. The power-law singularity $v^{-\Delta_\phi}$ can come only from the *infinite* sum over spins, with the large-ℓ behaviour of $p_{0,\ell}$ controlling the strength of the divergence. This is the precise statement that the crossed identity forces an infinite, large-spin s-channel tower.

The large-spin asymptotics. The required tail is read off from the closed form. Using $a_\ell = (\Delta_\phi)_\ell^2/[\ell!\,(2\Delta_\phi+\ell-1)_\ell]$ and writing every Pochhammer as a ratio of Gamma functions,

$$p_{0,\ell} = 2a_\ell = \frac{2}{\Gamma(\Delta_\phi)^2}\,\frac{\Gamma(\ell+\Delta_\phi)^2\,\Gamma(\ell+2\Delta_\phi-1)}{\Gamma(\ell+1)\,\Gamma(2\ell+2\Delta_\phi-1)} \qquad (\ell \text{ even}). \tag{49.149}$$

For large ℓ apply $\Gamma(\ell+\alpha)/\Gamma(\ell+\beta) \sim \ell^{\alpha-\beta}$ to the slowly varying ratios and the Legendre duplication formula $\Gamma(2\ell+c) = \frac{2^{2\ell+c-1}}{\sqrt{\pi}}\Gamma(\ell+\frac{c}{2})\Gamma(\ell+\frac{c+1}{2})$ to the doubled argument. The factors of $\Gamma(\ell)$ cancel against $\Gamma(\ell+1) \sim \ell\,\Gamma(\ell)$ and the duplication denominator, leaving

$$\boxed{p_{0,\ell} \;\sim\; \frac{\sqrt{\pi}\,2^{3-2\Delta_\phi}}{\Gamma(\Delta_\phi)^2}\,\ell^{2\Delta_\phi-3/2}\,4^{-\ell} \qquad (\ell\to\infty,\ \ell \text{ even}).} \tag{49.150}$$

The coefficients decay exponentially in spin, $4^{-\ell}$, with a power-law prefactor $\ell^{2\Delta_\phi-3/2}$ set by the external dimension; panel (b) of Fig. 49.5 confirms the asymptotic against the exact values. The exponential $4^{-\ell}$ is the natural measure on spins (it is undone by the growth of the block near $\bar{z} = 1$); what carries physical information is the power $\ell^{2\Delta_\phi-3/2}$, because it is precisely this power

that, when the discrete sum Eq. (49.147) is converted to an integral over ℓ and evaluated near $\bar{z} \to 1$, reproduces the power-law $v^{-\Delta_\phi}$ of the crossed identity. The dictionary "t-channel singularity at $v \to 0$ $\longleftrightarrow$ large-spin asymptotics of s-channel OPE data" is the engine of the entire analytic bootstrap.

Physical Insight

The double-twist operators are not optional. The identity is in *every* OPE — it is the statement that operators have non-vanishing two-point functions — so the term $(u/v)^{\Delta_\phi}$ is present in any crossing-symmetric correlator of identical scalars, not just in mean-field theory. Its $v \to 0$ singularity must be matched in the s-channel, and we have just seen that only an infinite large-spin tower can do it. Therefore *every* unitary CFT with a scalar ϕ contains, at large spin, double-twist operators $[\phi\phi]_{n,\ell}$ with dimensions approaching $2\Delta_\phi + 2n + \ell$ and OPE coefficients approaching the mean-field values Eq. (49.144). Interactions can only correct these at large ℓ by small amounts — anomalous dimensions $\gamma_{n,\ell}$ that fall off as a power of ℓ, governed by the lightest operator in the crossed channel. Mean-field theory is thus not merely an example; it is the universal large-spin asymptotics of all CFTs, and Chapter 51 turns this observation into a calculus.

Figure 49.6 renders the reorganization schematically: one operator in the crossed channel, an entire trajectory in the direct channel.

49.5.4 The 2D Ising crossing check

The mean-field solution validated the machinery on a Gaussian theory. We now subject it to a genuinely interacting one whose answer we nonetheless know exactly: the two-dimensional Ising CFT, the $m = 3$ minimal model $\mathcal{M}(4,3)$ whose central charge $c = \frac{1}{2}$ and degenerate spectrum are fixed by the Feigin–Fuks construction (Theorem 48.40, Eq. (48.319)), solved in full in Chapter 48. Its spin four-point function was obtained there from the level-two BPZ equation, by methods — null vectors, hypergeometric ODEs, single-valuedness — with no overt connection to the crossing equation of this chapter. If both developments are correct, the Ising correlator must satisfy Theorem 49.13. We verify that it does, and in doing so recover the structure constant $C_{\sigma\sigma\varepsilon} = \frac{1}{2}$ from the bootstrap side.

Importing the data. From Chapter 48 we take, as established facts, the three Ising primaries (Theorem 48.33): the identity $\mathbf{1}$, the spin σ with $\Delta_\sigma = \frac{1}{8}$ (Eq. (48.234)), and the energy ε with $\Delta_\varepsilon = 1$; the fusion rule $\sigma \times \sigma = \mathbf{1} + \varepsilon$

(Eq. (48.240)); the algebraic chiral blocks (Eq. (48.262))

$$F_+(z) = \sqrt{\frac{1+\sqrt{1-z}}{2}}, \qquad F_-(z) = \sqrt{\frac{1-\sqrt{1-z}}{2}}, \tag{49.151}$$

the two independent solutions of the BPZ hypergeometric equation, with F_+ the identity (vacuum) Virasoro block and F_- the ε Virasoro block; and the single-valued physical correlator (Eq. (48.263), Theorem 48.34) assembled from them. Here z is the holomorphic cross-ratio of Eq. (47.140), identical to the variable called x in Theorem 48.34, with $u = z\bar{z}$ and $v = (1-z)(1-\bar{z})$.

The stripped correlator. We must express the Ising correlator in the bootstrap normalization of Eq. (47.145), $\langle\sigma\sigma\sigma\sigma\rangle = g(u,v)\,(x_{12}^2 x_{34}^2)^{-\Delta_\sigma}$, so that $g(u,v) \to 1$ as the first pair collides. The chiral construction of Chapter 48 gives the correlator as $|x(1-x)|^{-1/4}$ times the diagonal sum of chiral times antichiral blocks; converting to the bootstrap prefactor (a single power of the cross-ratio, since the two stripping conventions differ only by the relative Jacobian u^{Δ_σ}) yields the compact form

$$g(u,v) = v^{-\Delta_\sigma}\Big(\,|F_+(z)|^2 + |F_-(z)|^2\,\Big), \qquad |F_\pm(z)|^2 \equiv F_\pm(z)\,F_\pm(\bar{z}), \tag{49.152}$$

with $\Delta_\sigma = \frac{1}{8}$. The normalization is fixed by the collision limit: as $z, \bar{z} \to 0$ one has $v \to 1$, $F_+ \to 1$, $F_- \to 0$, so $g \to 1$, the identity contribution, as required. The first term of Eq. (49.152) is the identity Virasoro block (containing $\mathbf{1}$ together with its global descendants, among them the stress tensor); the second is the ε Virasoro block (containing ε and its descendants). Two Virasoro blocks suffice because the $c = \frac{1}{2}$ degenerate fusion Eq. (48.240) truncates $\sigma \times \sigma$ to exactly two families — the dramatic simplification that the global conformal blocks $G_{\Delta,\ell}$ of Eq. (49.131) can only achieve by an infinite resummation, since each Virasoro family decomposes into infinitely many global primaries (the identity family alone supplies $\mathbf{1}$, the stress tensor at $(\Delta,\ell) = (2,2)$, and so on up the tower).

Crossing, verified. The crossing equation Theorem 49.13 for identical scalars reads $v^{\Delta_\sigma} g(u,v) = u^{\Delta_\sigma} g(v,u)$. Define the symmetric function

$$P(z,\bar{z}) \equiv |F_+(z)|^2 + |F_-(z)|^2 = \tfrac{1}{2}\Big[\sqrt{(1+\sqrt{1-z})(1+\sqrt{1-\bar{z}})} + \sqrt{(1-\sqrt{1-z})(1-\sqrt{1-\bar{z}})}\Big], \tag{49.153}$$

so that $g(u,v) = v^{-\Delta_\sigma} P(z,\bar{z})$. The $s \leftrightarrow t$ swap $u \leftrightarrow v$ is the map $z \to 1-z$, $\bar{z} \to 1-\bar{z}$ (which exchanges $x_2 \leftrightarrow x_4$), under which $\sqrt{1-z} \to \sqrt{z}$ and $v \to u$. Therefore

$$v^{\Delta_\sigma} g(u,v) = P(z,\bar{z}), \qquad u^{\Delta_\sigma} g(v,u) = u^{\Delta_\sigma}\, u^{-\Delta_\sigma}\, P(1-z,1-\bar{z}) = P(1-z,1-\bar{z}), \tag{49.154}$$

so crossing is equivalent to the single algebraic identity

$$\boxed{P(z,\bar z) = P(1-z,1-\bar z).} \tag{49.155}$$

This is not obvious from Eq. (49.153): under $z \to 1-z$ the two radicals $\sqrt{1\pm\sqrt{1-z}}$ turn into $\sqrt{1\pm\sqrt{z}}$, manifestly different functions. That the symmetric combination is nonetheless invariant is exactly the single-valuedness condition $\alpha = \beta$ of Eq. (48.263) — the requirement that the holomorphic and antiholomorphic blocks glue into a correlator with no monodromy as two operators are carried around one another — now recognized as crossing symmetry. The diagonal locus makes the point cleanly: setting $\bar z = z = t$ real, $|F_+|^2 + |F_-|^2 = \frac{1+\sqrt{1-t}}{2} + \frac{1-\sqrt{1-t}}{2} = 1$, so $P(t,t) = 1 = P(1-t,1-t)$ identically, and Eq. (49.155) holds trivially on the diagonal. Off the diagonal it is a genuine constraint, which we now confirm.

Worked Example 49.26 (Crossing of the Ising spin correlator, off the diagonal)**.** Take the Lorentzian-type configuration in which z and $\bar z$ are independent reals, with $z = \frac12$, $\bar z = \frac{1}{10}$. Then $\sqrt{1-z} = \sqrt{0.5} = 0.707107$ and $\sqrt{1-\bar z} = \sqrt{0.9} = 0.948683$. The left side of Eq. (49.155) is

$$P(z,\bar z) = \tfrac12\Big[\sqrt{(1.707107)(1.948683)}+\sqrt{(0.292893)(0.051317)}\Big] = \tfrac12[1.823990+0.122600] = 0 \tag{49.156}$$

For the right side, $1-z = \frac12$ and $1-\bar z = \frac{9}{10}$ give $\sqrt{1-(1-z)} = \sqrt{z} = \sqrt{0.5} = 0.707107$ and $\sqrt{1-(1-\bar z)} = \sqrt{\bar z} = \sqrt{0.1} = 0.316228$, so

$$P(1-z,1-\bar z) = \tfrac12\Big[\sqrt{(1.707107)(1.316228)}+\sqrt{(0.292893)(0.683772)}\Big] = \tfrac12[1.499031+0.447559 \tag{49.157}$$

The two agree to all quoted digits, and the same agreement holds at every test point one cares to evaluate. The Ising spin four-point function satisfies the crossing equation of this chapter — an independent confirmation, by a route that never used the BPZ equation, that the $c = \frac12$ data of Chapter 48 and the bootstrap sum rule of Theorem 49.14 describe one and the same correlator.

Reading off the OPE coefficient. Crossing is satisfied; the bootstrap also recovers the dynamical data. Expand the ε term of Eq. (49.152) at small cross-ratio. As $z,\bar z \to 0$, $1-\sqrt{1-z} = \frac{z}{2} + O(z^2)$, so $|F_-(z)|^2 = \frac12\sqrt{(1-\sqrt{1-z})(1-\sqrt{1-\bar z})} \to \frac12\sqrt{\frac{z}{2}\cdot\frac{\bar z}{2}} = \frac14\sqrt{z\bar z} = \frac14 u^{1/2}$. Since $v^{-\Delta_\sigma} \to 1$, the energy operator contributes to g the leading term $\frac14 u^{1/2} = \frac14 u^{\Delta_\varepsilon/2}$, matching the global scalar block $G_{\Delta_\varepsilon,0} \to u^{\Delta_\varepsilon/2}$ for $\Delta_\varepsilon = 1$. The squared OPE coefficient is therefore

$$p_\varepsilon = C^2_{\sigma\sigma\varepsilon} = \tfrac14 \quad\Longrightarrow\quad C_{\sigma\sigma\varepsilon} = \tfrac12, \tag{49.158}$$

in exact agreement with Eq. (48.266). The identity term carries the rest: expanding $|F_+(z)|^2 = \frac{1}{2}\sqrt{(1+\sqrt{1-z})(1+\sqrt{1-\bar{z}})} = 1 - \frac{z+\bar{z}}{8} + \cdots$ and multiplying by $v^{-\Delta_\sigma} = [(1-z)(1-\bar{z})]^{-1/8} = 1+\frac{z+\bar{z}}{8}+\cdots$, the linear terms cancel and the identity channel begins as $1 + O((z+\bar{z})^2)$. The first correction is the global block of the stress tensor at $(\Delta, \ell) = (2, 2)$, whose coefficient is fixed by the conformal Ward identity. Extract it from the same lightcone limit used for ε: at $\bar{z} \to 0$ the twist-zero operators contribute $G_{\Delta,\ell} \to \bar{z}^0 k_{\Delta+\ell}(z)$, and the identity channel collapses to the holomorphic function $g_0(z) = \lim_{\bar{z}\to 0} g = (1-z)^{-1/8}\,\frac{1}{\sqrt{2}}\sqrt{1+\sqrt{1-z}}$ (using $F_+(\bar{z}) \to 1$, $F_-(\bar{z}) \to 0$). Expanding with $\sqrt{1-z} = 1 - \frac{z}{2} - \frac{1}{8}z^2 - \cdots$ gives $g_0(z) = 1 + 0 \cdot z + \frac{1}{64}z^2 + \cdots$: the constant is the identity ($k_0 = 1$), the vanishing z^1 confirms the absence of a spin-1 current, and the z^2 term is the leading piece of the stress-tensor block $k_4(z) \to z^2$, so

$$C^2_{\sigma\sigma T} = \tfrac{1}{64}. \tag{49.159}$$

The two-dimensional Ward identity fixes the stress-tensor coefficient in terms of the central charge as $C^2_{\sigma\sigma T} = 2h_\sigma^2/c$, and with the holomorphic weight $h_\sigma = \Delta_\sigma/2 = \frac{1}{16}$ and the imported $c = \frac{1}{2}$ of Theorem 48.40,

$$\frac{2h_\sigma^2}{c} = \frac{2\,(1/16)^2}{1/2} = \frac{1}{64}, \tag{49.160}$$

in exact agreement with Eq. (49.159). The crossing decomposition has therefore *measured* the central charge of the model and returned $c = \frac{1}{2}$, the value the free-Majorana realization of Section 48.7.3 assigns it. Thus the two Virasoro blocks of the exact solution, expanded into global blocks, reproduce the energy structure constant *and* the stress-tensor data — the complete leading content of the $\sigma \times \sigma$ OPE, recovered from crossing, with every coefficient positive as unitarity demands.

49.5.5 Saturation of the unitarity bounds

The two exact solutions also sharpen the meaning of the extremal solutions introduced in Section 49.4: they show what it looks like for a spectrum to sit *on* the unitarity bound rather than safely inside it.

Recall the unitarity bounds: a spin-ℓ primary in d dimensions obeys $\Delta \geq \ell + d - 2$ for $\ell \geq 1$, with equality precisely for a conserved current $\partial^\mu J_{\mu\ldots} = 0$, and $\Delta \geq \frac{d-2}{2}$ for a scalar, with equality precisely for a free field $\Box\phi = 0$ (Theorem 49.21 uses these as the input positivity facts). Now read the mean-field spectrum Eq. (49.130) against them. The leading-twist trajectory $n = 0$ sits at $\Delta_{0,\ell} = 2\Delta_\phi + \ell$, i.e. twist $\tau = 2\Delta_\phi$. For a generic generalized free field this twist exceeds the bound and every operator is a comfortable distance above it. But for

the genuine free scalar, $\Delta_\phi = \frac{d-2}{2}$, the leading twist becomes $\tau = 2\Delta_\phi = d-2$, so

$$\Delta_{0,\ell} = d - 2 + \ell = \ell + d - 2 \qquad \text{(free scalar)}, \tag{49.161}$$

which is exactly the unitarity bound for every spin ℓ. The free-field double-twist operators $[\phi\phi]_{0,\ell} = :\phi\,\partial_{\mu_1}\cdots\partial_{\mu_\ell}\phi: -$ (traces) are conserved higher-spin currents — the bilinear currents whose conservation is the hallmark of a free theory — and the leading-twist trajectory lies along the bound, as the dashed line in panel (a) of Fig. 49.5 shows. The scalar $[\phi\phi]_{0,0}$ likewise sits at $\Delta = d-2 = 2\cdot\frac{d-2}{2}$, twice the saturated scalar dimension. Generalized free theory with $\Delta_\phi > \frac{d-2}{2}$ lifts these operators off the bound by exactly the amount $\Delta_\phi - \frac{d-2}{2}$ in twist, the deficit that distinguishes a generalized free field from a true free field.

The Ising check supplies the interacting counterpart. In the $d = 2$ Ising CFT the scalar unitarity bound is $\Delta \geq \frac{d-2}{2} = 0$, saturated only by the identity; the spin σ ($\Delta = \frac{1}{8}$) and energy ε ($\Delta = 1$) sit strictly above it, as a unitary interacting theory must. The single operator that saturates a spin bound is the stress tensor, at $\Delta = 2 = \ell + d - 2$ with $\ell = 2$: it is the conserved current of translations, present in every local CFT, and its appearance at the bound in the identity Virasoro block of Eq. (49.152) is the statement that the Ising CFT is local. These are the configurations a linear functional must respect: an extremal functional of Section 49.4 is one that vanishes on precisely the operators a candidate theory places on or near the bound, and the exact solutions of this section are the simplest spectra on which to see that vanishing realized.

With mean-field theory solved in closed form — its double-twist spectrum Eq. (49.130), its OPE coefficients Eq. (49.144), and the large-spin reorganization Eq. (49.150) that rebuilds the crossed identity — and with the 2D Ising correlator confirmed to satisfy crossing with its known $c = \frac{1}{2}$ data, the bootstrap apparatus stands validated against every case whose answer we can write down independently. The double-twist tower and its large-spin asymptotics are handed to Chapter 51 as the explicit seed of the analytic bootstrap, and the now-validated crossing solver is ready to be pointed, in Section 49.6 and Chapter 50, at a theory we cannot solve by any other means: the three-dimensional Ising CFT.

49.6 The 3D Ising CFT as the Bootstrap Target, and the Frontier

Every piece of machinery assembled in this chapter has now been checked against a theory whose answer we already knew. The crossing equation of Theorem 49.13 was solved exactly for the generalized free (mean-field) theory, whose double-twist spectrum and OPE coefficients fell out of the bootstrap with no further input (Section 49.5.1); the same equation was verified, term by conformal block, on the two-dimensional Ising correlators whose spectrum we had independently

from the free Majorana realization with central charge $c = \frac{1}{2}$ (Eq. (48.319)); and the functional theorem of Theorem 49.21 turned crossing plus unitarity into rigorous bounds. We have a validated crossing solver, the double-twist intuition for how operators must populate the cross channel, and a positivity certificate that excludes spectra. The natural question is what this apparatus does when we point it at a theory we *cannot* solve exactly. The answer is the modern conformal bootstrap, and its headline laboratory is the three-dimensional Ising universality class. This section poses that problem precisely: what is being assumed, what the bootstrap delivers, and — stated honestly and dated to the mid-2020s — what is proved versus what is numerical. The explicit numerical solution is handed to Chapter 50, the analytic limits to Chapter 51.

Notation Watch

Throughout this section the symbol ε denotes the lightest $\mathbb{Z}_2$-*even* scalar primary — the *energy operator* of the Ising universality class, continuing the usage of the two-dimensional Ising CFT (Theorem 48.33), where $\varepsilon = i\bar{\psi}\psi$ had $\Delta_\varepsilon = 1$. It is *not* the dimension deficit $\varepsilon = 4 - d$ of the ε-expansion (Theorem 24.31), which appears only with that meaning and never carries an operator subscript. The order parameter (the $\mathbb{Z}_2$-odd scalar, the continuum spin field) is σ.

49.6.1 The 3D Ising critical point as a unitary CFT

The bridge that ϕ^4 theory has carried from Part VI to here is the statement that the critical point of the three-dimensional Ising model *is* a conformal field theory. We recall its origin and then state precisely the CFT we intend to corner.

The Wilsonian and Callan–Symanzik analyses located, in $d = 4-\varepsilon$ dimensions, the nontrivial zero of the ϕ^4 beta function at $\lambda_* = \frac{16\pi^2}{3}\varepsilon + O(\varepsilon^2)$, the Wilson–Fisher fixed point (Theorem 24.31). Section 47.8.4 showed that this fixed point has a traceless, conserved stress tensor and is therefore a genuine conformal field theory, with the elementary field ϕ realized as a primary. Continuing the dimension deficit to its physical value $\varepsilon = 1$, i.e. $d = 3$, gives the conformal field theory governing the long-distance physics of any system in the three-dimensional Ising universality class: the uniaxial ferromagnet at its Curie point, the liquid–vapour critical point, the binary-fluid demixing transition, all sharing the same critical exponents. Universality is precisely the statement that all of these microscopically distinct systems flow to the *same* infrared fixed point, the same CFT. We name its two lightest scalar primaries after the lattice observables they descend from: the $\mathbb{Z}_2$-odd *spin* operator σ (the continuum order parameter, ϕ of the thread) and the $\mathbb{Z}_2$-even *energy* operator ε (the continuum ϕ^2, the operator conjugate to the reduced temperature).

Unlike its two-dimensional cousin, which the free-fermion construction of

Eq. (48.319) solves *exactly*, the three-dimensional Ising CFT has no known exact solution. There is no Lagrangian description that is weakly coupled at $d = 3$: the ε-expansion is an asymptotic series evaluated at the non-small value $\varepsilon = 1$, and the lattice and Monte Carlo determinations, while precise, are themselves numerical. What makes the bootstrap decisive is that it does not need a Lagrangian at all. It treats the theory as an abstract solution of the consistency conditions and asks which solutions are possible.

Definition 49.27 (The 3D Ising bootstrap problem: assumptions)**.** By the *3D Ising CFT* we mean a conformal field theory in $d = 3$ satisfying the following hypotheses, each of which is an input to the bootstrap and not a consequence of it:

(A1) *Conformal symmetry.* The theory is invariant under the conformal group $\mathrm{SO}(4,1)$ of Chapter 47; correlators decompose in conformal blocks and the OPE converges in the sense established there.

(A2) *Unitarity (reflection positivity).* The spectrum of primary dimensions is real and bounded below by the unitarity bounds $\Delta \geq \frac{d-2}{2} = \frac{1}{2}$ for scalars and $\Delta \geq \ell + d - 2 = \ell + 1$ for spin $\ell \geq 1$; all OPE coefficients of real operators are real, so squared coefficients are non-negative.

(A3) $\mathbb{Z}_2$ *global symmetry.* Every primary carries a definite $\mathbb{Z}_2$ charge; σ is odd, ε is even.

(A4) *Locality.* There is a conserved, symmetric, traceless stress tensor $T_{\mu\nu}$ — a spin-2 primary at the protected dimension $\Delta_T = d = 3$ — and a unique normalizable vacuum.

(A5) *A gap.* The theory has exactly *two* relevant scalars, one of each $\mathbb{Z}_2$ charge: σ with $\Delta_\sigma < 3$ and ε with $\Delta_\varepsilon < 3$, and these are the lightest scalars of their respective charges. Equivalently, the next $\mathbb{Z}_2$-even scalar ε' and the next $\mathbb{Z}_2$-odd scalar σ' are both irrelevant, $\Delta_{\varepsilon'}, \Delta_{\sigma'} > 3$.

The data to be determined are then the conformal data of Chapter 47: the spectrum $\{\Delta_i, \ell_i\}$ of primaries and the OPE coefficients $\{\lambda_{ijk}\}$. The two numbers of headline interest are Δ_σ and Δ_ε.

Assumptions (A1)–(A4) are the defining properties of any unitary local CFT; the physical content specific to the Ising class lives in (A3) and (A5). The gap assumption (A5) is the crucial physical input — it is what makes the bootstrap select *the Ising* fixed point and not, say, the tricritical or $O(N)$ fixed points, which differ in their relevant-operator content. It encodes a fact about the renormalization group: the Ising critical surface has exactly two relevant directions, the temperature and the magnetic field, conjugate to ε and σ. Tuning

two parameters reaches the critical point, and no more tuning is needed; that is the statement that there are exactly two relevant scalars.

Before posing the crossing problem we record the dictionary back to Part VI, the bridge whose closure is completed in Chapter 52. The critical exponents are determined by the two dimensions through

$$\eta = 2\Delta_\sigma - (d-2) = 2\Delta_\sigma - 1, \tag{49.162}$$

$$\frac{1}{\nu} = d - \Delta_\varepsilon = 3 - \Delta_\varepsilon, \tag{49.163}$$

the first because the spin two-point function $\langle\sigma\sigma\rangle \sim |x|^{-2\Delta_\sigma}$ defines the anomalous dimension η through $\Delta_\sigma = \frac{1}{2}(d-2+\eta)$, the second because ε is the operator conjugate to the reduced temperature so its relevant RG eigenvalue is $1/\nu$ (these are exactly Eqs. (47.263) and (47.264) read backwards). Thus pinning Δ_σ and Δ_ε pins η and ν, and through scaling relations every other Ising exponent. The bootstrap's precision on $\Delta_\sigma, \Delta_\varepsilon$ is, through Eqs. (49.162) and (49.163), precision on measurable critical exponents.

49.6.2 The single-correlator crossing equation and the $\mathbb{Z}_2$ selection rule

The simplest crossing equation available is the one for four spin operators, $\langle\sigma(x_1)\sigma(x_2)\sigma(x_3)\sigma(x_4)\rangle$. We assemble it from the general crossing equation Theorem 49.13, specialized to four identical scalars of dimension Δ_σ and equipped with the $\mathbb{Z}_2$ selection rule.

Recall the kinematics. Conformal invariance reduces the four-point function to a function of the two cross-ratios

$$u = \frac{x_{12}^2 x_{34}^2}{x_{13}^2 x_{24}^2}, \qquad v = \frac{x_{14}^2 x_{23}^2}{x_{13}^2 x_{24}^2}, \qquad x_{ij} \equiv x_i - x_j, \tag{49.164}$$

through

$$\langle\sigma\sigma\sigma\sigma\rangle = \frac{1}{x_{12}^{2\Delta_\sigma}\, x_{34}^{2\Delta_\sigma}}\, \mathcal{G}(u,v), \qquad \mathcal{G}(u,v) = \sum_{\mathcal{O}\in\sigma\times\sigma} \lambda_{\mathcal{O}}^2\, g_{\Delta_\mathcal{O},\ell_\mathcal{O}}(u,v), \tag{49.165}$$

the sum running over the primaries appearing in the $\sigma \times \sigma$ OPE, with $g_{\Delta,\ell}$ the conformal blocks defined and computed in this chapter and $\lambda_\mathcal{O}^2 \geq 0$ by unitarity (A2). Two selection rules cut the sum down sharply:

- $\mathbb{Z}_2$ *parity.* Since σ is $\mathbb{Z}_2$-odd, the product $\sigma \times \sigma$ is $\mathbb{Z}_2$-even: only $\mathbb{Z}_2$-*even* operators appear. The odd operators $\sigma, \sigma', \ldots$ are forbidden from this OPE.
- *Spin parity.* Because the two operators are identical, exchanging $x_1 \leftrightarrow x_2$ is a symmetry of the correlator; under it a spin-ℓ block picks up $(-1)^\ell$, so only *even* spin $\ell = 0, 2, 4, \ldots$ survives.

The exchanged spectrum is therefore: the identity ($\Delta = 0$, $\ell = 0$, $\lambda^2 = 1$); the $\mathbb{Z}_2$-even scalars $\varepsilon, \varepsilon', \ldots$; the stress tensor T ($\ell = 2$, $\Delta = 3$) and the even-spin tower above it.

Crossing symmetry is the statement that the same correlator may be expanded in the (12)(34) channel or the (14)(23) channel and must agree. Exchanging $x_1 \leftrightarrow x_3$ sends $u \leftrightarrow v$ and, from the prefactor, multiplies by $(u/v)^{\Delta_\sigma}$, giving $\mathcal{G}(u,v) = (u/v)^{\Delta_\sigma}\mathcal{G}(v,u)$, i.e.

$$v^{\Delta_\sigma}\,\mathcal{G}(u,v) = u^{\Delta_\sigma}\,\mathcal{G}(v,u). \tag{49.166}$$

Inserting the block expansion and moving everything to one side, the identity contribution $g_{0,0} = 1$ separates out and we obtain the *Ising crossing sum rule*,

$$\boxed{\sum_{\mathcal{O}\in\sigma\times\sigma}^{\mathcal{O}\neq\mathbf{1}} \lambda_{\mathcal{O}}^2\, F^-_{\Delta_\sigma;\,\Delta_{\mathcal{O}},\ell_{\mathcal{O}}}(u,v) \;=\; u^{\Delta_\sigma} - v^{\Delta_\sigma}} \tag{49.167}$$

where the *convolved block* (the antisymmetrized crossing vector) is

$$F^-_{\Delta_\sigma;\,\Delta,\ell}(u,v) \equiv v^{\Delta_\sigma}\,g_{\Delta,\ell}(u,v) - u^{\Delta_\sigma}\,g_{\Delta,\ell}(v,u). \tag{49.168}$$

The right-hand side of Eq. (49.167) is exactly $-F^-_{\Delta_\sigma;0,0}$, the identity's own crossing vector; the sum rule says that the contribution of every nontrivial operator must conspire to reproduce minus the identity. This is the single equation — one functional identity in the two variables u, v, equivalently an infinite set of numerical equations once expanded around a point — that the entire Ising spectrum and its OPE coefficients must satisfy. The bootstrap is the study of which $(\Delta_\sigma; \{\Delta_{\mathcal{O}}, \lambda^2_{\mathcal{O}}\})$ solve it.

49.6.3 The gap assumption and how a functional carves out a region

We now show, in full, how the gap assumption (A5) fed through the functional theorem of Theorem 49.21 converts Eq. (49.167) into a bound: a curve in the $(\Delta_\sigma, \Delta_\varepsilon)$ plane above which no consistent theory can lie. The argument is the positivity argument of Theorem 49.21 specialized to the Ising sum rule, and it is worth seeing the contradiction spelled out because it is the logical engine of the whole numerical program.

Proposition 49.28 (Single-correlator gap bound)**.** *Fix $\Delta_\sigma \geq \frac{d-2}{2}$ and a trial gap $\Delta_* > 0$. Consider the admissible spectrum dictated by the gap assumption and unitarity,*

$$\mathcal{S}_{\Delta_*} = \{(\Delta, \ell = 0) : \Delta \geq \Delta_*\} \cup \{(\Delta, \ell) : \ell \text{ even},\ \ell \geq 2,\ \Delta \geq \ell + d - 2\}. \tag{49.169}$$

It is convenient to write the sum rule with the identity included in the sum, $\sum_{\mathcal{O}} \lambda_{\mathcal{O}}^2 F^-_{\Delta_\sigma;\Delta_{\mathcal{O}},\ell_{\mathcal{O}}} = 0$ *with* $\lambda_{\mathbf{1}}^2 = 1$ *and* $F^-_{\Delta_\sigma;0,0} = v^{\Delta_\sigma} - u^{\Delta_\sigma}$ *(this is Eq. (49.167) with the identity term carried back to the left). Suppose there exists a linear functional* α *(of the type whose existence and convex structure are guaranteed by Theorem 49.21) acting on functions of* (u, v) *such that*

(i) $\alpha\big[F^-_{\Delta_\sigma;0,0}\big] = 1$ *(the normalization on the identity), and*

(ii) $\alpha\big[F^-_{\Delta_\sigma;\Delta,\ell}\big] \geq 0$ *for every* $(\Delta, \ell) \in \mathcal{S}_{\Delta_*}$.

Then no unitary, crossing-symmetric solution of Eq. (49.167) exists whose lightest $\mathbb{Z}_2$*-even scalar has dimension* $\Delta_\varepsilon \geq \Delta_*$*. Equivalently, in any consistent theory the energy operator obeys* $\Delta_\varepsilon < \Delta_*$*. The infimum of* Δ_* *over all functionals satisfying (i)–(ii) is a rigorous upper bound* $\Delta_\varepsilon \leq \Delta_\varepsilon^{\max}(\Delta_\sigma)$.

Proof. Suppose, for contradiction, that a consistent unitary theory exists with $\Delta_\varepsilon \geq \Delta_*$. Then every nontrivial operator in $\sigma \times \sigma$ lies in $\mathcal{S}_{\Delta_*}$: each $\mathbb{Z}_2$-even scalar has dimension $\geq \Delta_\varepsilon \geq \Delta_*$ (the lightest is ε), and each spinning operator has even spin $\ell \geq 2$ with $\Delta \geq \ell + d - 2$ by the selection rule and unitarity. Apply the linear functional α to the sum rule and split off the identity by linearity,

$$0 = \alpha\Big[\sum_{\mathcal{O}} \lambda_{\mathcal{O}}^2 F^-_{\Delta_\sigma;\Delta_{\mathcal{O}},\ell_{\mathcal{O}}}\Big] = \underbrace{\lambda_{\mathbf{1}}^2\, \alpha\big[F^-_{\Delta_\sigma;0,0}\big]}_{=1\cdot 1 = 1} + \underbrace{\sum_{\mathcal{O}\neq\mathbf{1}} \lambda_{\mathcal{O}}^2\, \alpha\big[F^-_{\Delta_\sigma;\Delta_{\mathcal{O}},\ell_{\mathcal{O}}}\big]}_{\geq 0}. \tag{49.170}$$

The identity term equals 1 by the normalization (i). Every term in the remaining sum is non-negative: $\lambda_{\mathcal{O}}^2 \geq 0$ by unitarity (A2), and $\alpha[F^-_{\Delta_\sigma;\Delta_{\mathcal{O}},\ell_{\mathcal{O}}}] \geq 0$ by (ii) because each such $\mathcal{O} \in \mathcal{S}_{\Delta_*}$. The right-hand side is therefore $\geq 1 > 0$, contradicting that it equals 0. Hence no spectrum with $\Delta_\varepsilon \geq \Delta_*$ can solve crossing, so $\Delta_\varepsilon < \Delta_*$ in any consistent theory. Minimizing Δ_* over all functionals satisfying (i)–(ii) gives the stated upper bound. □

Caution

The whole argument turns on a sign: the certifying functional must be *non-negative on the entire nontrivial spectrum* yet *strictly positive on the identity*, so that a sum constrained to vanish is exhibited as strictly positive. Geometrically, the identity's crossing vector must lie *outside* the convex cone generated by the allowed operators' vectors, and α is the separating hyperplane. Flipping the overall sign of α gives the same certificate; what is fatal is the wrong *relative* sign between the identity and the rest. This sign bookkeeping is the single most common slip in setting up the bound.

The content of Theorem 49.28 is a *search*: for a given Δ_σ, scan the trial gap Δ_* downward; the smallest Δ_* for which a certifying functional α still exists is the boundary value $\Delta_\varepsilon^{\max}(\Delta_\sigma)$. Below it crossing solutions may exist; on and above it none do. As Δ_σ varies one traces a curve, and the existence of the certifying functional — guaranteed to be decidable by the convex (semidefinite) structure of Theorem 49.21 — is what makes the curve computable. The remarkable empirical fact, displayed in Fig. 49.7, is that this upper-bound curve is not smooth: it develops a sharp *kink*, and the 3D Ising CFT sits essentially *at* the kink. A theory that saturates the bound is extremal — its spectrum is the unique one annihilated by the optimal functional — and the kink marks the place where this extremal spectrum reorganizes, the signature of a distinguished, isolated theory rather than a generic point on a continuum.

Physical Insight

Why a kink, and why does it locate a physical theory? Along the bound the saturating "solution" is forced to be extremal: the optimal functional has just enough zeros to pin down a discrete spectrum. At a generic Δ_σ this extremal spectrum varies smoothly and corresponds to no particularly natural theory. At one special Δ_σ the structure of the extremal spectrum jumps — an operator crosses a threshold — and the bound curve kinks. That jump is the bootstrap detecting that the most-constrained theory consistent with the assumptions has changed character. For the $\langle\sigma\sigma\sigma\sigma\rangle$ system the kink coincides, to all tested precision, with the place where the spectrum is exactly that of the 3D Ising model. The bootstrap is, in effect, finding the corner of the allowed region where unitarity and crossing are simultaneously most strained, and that corner is a real CFT.

Two remarks complete the geometry of the allowed region. First, the single-correlator bound is intrinsically *one-sided*: Theorem 49.28 bounds Δ_ε from *above* for each Δ_σ, and unitarity (A2) bounds Δ_σ from below by the vertical wall $\Delta_\sigma \geq \frac{1}{2}$. Together with the requirement that a $\mathbb{Z}_2$-even scalar exist at all (else the theory is generalized free, the boundary case of Section 49.5.1), these carve out the shaded allowed region of the left panel of Fig. 49.7, with the Ising theory pinned to the kink on its upper boundary. Second, to turn this open region into a genuinely *closed* island — bounded on all sides, isolating $(\Delta_\sigma, \Delta_\varepsilon)$ in a small box — one needs more equations than the single correlator provides. That is the role of the mixed-correlator system and the second gap assumption, described next and computed in Chapter 50.

49.6.4 The headline outcome: the island

The decisive sharpening comes from bootstrapping not one correlator but the full system of correlators built from *both* external operators, $\langle\sigma\sigma\sigma\sigma\rangle$, $\langle\sigma\sigma\varepsilon\varepsilon\rangle$, and

$\langle\varepsilon\varepsilon\varepsilon\varepsilon\rangle$. These share OPE data — the coefficient $\lambda_{\sigma\sigma\varepsilon}$ appears in the first two, $\lambda_{\varepsilon\varepsilon\varepsilon}$ in the last two — so crossing for the system is a set of coupled sum rules in which the same λ^2's are constrained simultaneously. The positivity argument generalizes: instead of a single functional acting on a scalar sum rule, one seeks a *vector* of functionals acting on the vector of sum rules with a semidefinite positivity condition on 2×2 matrices of OPE coefficients. Imposing the second gap (A5) — that σ', the next $\mathbb{Z}_2$-odd scalar, is also irrelevant — closes the region from all sides. The open wedge becomes a closed *island*.

The island is the target this section hands forward. The current (mid-2020s) determinations, which Chapter 50 will reproduce from the semidefinite program, place

$$\boxed{\Delta_\sigma = 0.5181489(10), \qquad \Delta_\varepsilon = 1.412625(10)} \tag{49.171}$$

together with the central charge $c_T/c_T^{\text{free}} = 0.946534(11)$ and the OPE coefficients $\lambda_{\sigma\sigma\varepsilon} = 1.0518537(41)$, $\lambda_{\varepsilon\varepsilon\varepsilon} = 1.532435(19)$ — the precision improving each time the truncation order of the functional search is raised. Through the dictionary Eqs. (49.162) and (49.163) these give $\eta = 2(0.5181489) - 1 = 0.0362978(20)$ and $1/\nu = 3 - 1.412625 = 1.587375(10)$, i.e. $\nu = 0.629971(4)$, agreeing with the best Monte Carlo and experimental critical exponents to all quoted digits. The full machinery that produces Eq. (49.171) — the choice of derivative basis for the functionals, the reduction to semidefinite programming, the rigorous handling of the infinite spin sums — is developed in Chapter 50; here it is stated as the number the program is built to deliver.

49.6.5 Consistency with the ε-expansion

It would be a hollow victory if the bootstrap island floated free of everything ϕ^4 theory built. It does not: the island sits exactly where the perturbative renormalization group says the Wilson–Fisher fixed point should be, to the accuracy the perturbative series permits. We make the cross-check explicit.

Worked Example 49.29 (The bootstrap island against the ε-expansion)**.** The Wilson–Fisher dimensions assembled in Theorem 47.55 from the Part VI data are, with $\varepsilon = 4 - d$,

$$\Delta_\sigma = \frac{d-2}{2} + \frac{\varepsilon^2}{108} + O(\varepsilon^3) = 1 - \frac{\varepsilon}{2} + \frac{\varepsilon^2}{108} + O(\varepsilon^3), \qquad \text{(from Eq. (47.263))}$$

$$\Delta_\varepsilon = d - \frac{1}{\nu} = 2 - \frac{2\varepsilon}{3} + O(\varepsilon^2). \qquad \text{(from Eq. (47.264))}$$

The physical theory is at $\varepsilon = 1$ ($d = 3$). The series are asymptotic and $\varepsilon = 1$ is not small, so we evaluate the truncations and watch them *point toward* the island rather than land in it.

Order by order for Δ_σ. At leading order $\Delta_\sigma = 1 - \frac{1}{2} = 0.5000$ (the free value, the unitarity floor). The two-loop correction adds $\varepsilon^2/108 = 1/108 = 0.00926$,

giving $\Delta_\sigma \approx 0.5093$. The island value Eq. (49.171) is 0.51815. The leading anomalous shift has the right sign and roughly the right magnitude: the field is lifted off the unitarity bound by a small amount, $\eta = 0.0363$ from the bootstrap versus the truncated $2(\Delta_\sigma - \frac{1}{2}) = 2(0.00926) = 0.0185$ here. The truncated η is about half the true value — exactly the behaviour expected of the first term of an asymptotic series at $\varepsilon = 1$, and known higher orders ($\eta = \frac{\varepsilon^2}{54} + \frac{109}{5832}\varepsilon^3 + \cdots$, then Borel–Padé resummed) close the gap and converge on 0.0363.

Order by order for Δ_ε. The free value is $\Delta_\varepsilon = d - 2 = 2 - \varepsilon = 1$ at $\varepsilon = 1$, the value of the energy operator in the *free* theory (and, as it happens, the exact 2D value of Eq. (48.319), a coincidence of d). The first interacting correction is large and of first order: $\Delta_\varepsilon = 2 - \frac{2\varepsilon}{3} = 2 - 0.6667 = 1.3333$ at $\varepsilon = 1$. The island value is 1.41263. The leading shift accounts for the bulk of the displacement from the free value (0.333 of the true 0.413), with the remainder supplied by higher orders — here the perturbative series is doing most of the work already at one loop, consistent with the Part VI observation that $\gamma_{\phi^2} = \varepsilon/3$ is a first-order effect while γ_ϕ is second order.

The verdict. The truncated ε-expansion gives $(\Delta_\sigma, \Delta_\varepsilon) \approx (0.509, 1.333)$ against the bootstrap island $(0.518, 1.413)$: the same point to within the error one expects from truncating an asymptotic series at $\varepsilon = 1$, with both dimensions displaced from their free values in the right direction and the resummed series converging onto the island. The two methods agree at the level the expansion permits. This is the quantitative meaning of the claim, advanced since Section 47.8.4, that the bootstrap target *is* the Wilson–Fisher fixed point: the nonperturbative crossing solution and the perturbative RG fixed point are the same CFT, computed two incompatible ways and found consistent.

49.6.6 The frontier, honestly

It remains to say, precisely and with its date, what the bootstrap has and has not established. The temptation to overstate is real, because the numbers in Eq. (49.171) are more accurate than any other determination of the Ising exponents; but precision is not proof, and the distinction is exactly the kind this book is committed to keeping.

What is a theorem. The exclusion is rigorous. For any choice of external dimension and gaps, a certifying functional α of Theorem 49.28 (or its mixed-correlator matrix generalization) is an explicit object whose two properties — positivity on the admissible spectrum and definite sign on the identity — can be verified directly. When such a functional is exhibited, the corresponding region is *excluded with certainty*: no unitary, $\mathbb{Z}_2$-symmetric, crossing-symmetric CFT with the assumed gaps can have data in it. The bounds are honest mathematical theorems, conditional only on the hypotheses (A1)–(A5) and on the arithmetic being correct (and the latter can be, and has been, checked in rigorous interval arithmetic).

What is numerical. The *localization* to the small island is not a theorem of the same kind. It rests on (i) physical assumptions — chiefly the gap assumption (A5), the input that there are exactly two relevant scalars, which is taken from the renormalization-group understanding of the Ising class, not derived within the bootstrap; and (ii) numerics — the functional search is carried out in a finite-dimensional space of derivatives and at finite precision, so each computed island is the projection of the true allowed region onto a finite truncation. The island is *nonempty* in every computation performed and *shrinks* monotonically as the truncation is enlarged, which is overwhelming evidence that it converges to a point.

What is not proved (as of the mid-2020s). There is, at the time of writing, no proof that a CFT exists at the island — no construction of the 3D Ising CFT as a mathematical object satisfying all the axioms simultaneously — and no proof that, if one exists, it is unique. The bootstrap establishes that *if* a unitary CFT with the Ising gaps exists, its data lie in the island, and it pins those data to extraordinary numerical precision; it does not, by itself, establish existence. (Contrast the two-dimensional case, where the free-fermion construction behind Eq. (48.319) *is* an existence proof.) Whether the shrinking islands provably converge to a nonempty limit, and whether that limit is a single point, are open mathematical questions. The honest summary is: the 3D Ising CFT is cornered, measured to six significant figures, and consistent with every independent method — and not yet proved to exist. That gap between "numerically certain" and "proved" is itself one of the live problems of the field.

Physical Insight

The right way to hold this result is that the bootstrap has changed the epistemic status of the 3D Ising exponents. Before it, the best values came from resumming a divergent perturbative series or from extrapolating finite-size lattice data — methods with hard-to-quantify systematics. The bootstrap replaces both with a single convex optimization whose *exclusions* are rigorous and whose *island* shrinks under a controlled, monotone refinement. The remaining gap is no longer "is the number right?" but the sharper mathematical question "does the limiting theory exist and is it unique?" — a far better place to be stuck.

We have now posed the 3D Ising bootstrap completely: the theory as a unitary $\mathbb{Z}_2$-symmetric CFT with two relevant scalars (Theorem 49.27), the crossing sum rule it must satisfy (Eq. (49.167)), the gap-and-functional logic that bounds its data (Theorem 49.28), and the island it is cornered into (Eq. (49.171)), cross-checked against the Wilson–Fisher fixed point of ϕ^4 theory. The explicit numerical realization — the semidefinite program, the derivative functionals, and the convergence of the island — is handed to Chapter 50; the analytic limits that

organize the spinning spectrum and reproduce the bound's structure from the lightcone and the Lorentzian inversion formula are handed to Chapter 51; and the closure of the loop with Part VI, turning Eq. (49.171) into the full table of critical exponents through Eqs. (49.162) and (49.163), is handed to Chapter 52.

Further reading

The idea that conformal symmetry, the OPE, and crossing might determine a theory without a Lagrangian originates with Ferrara et al. [190] and Polyakov [407]; the modern numerical incarnation, recasting crossing as a convex-optimization bound, begins with Rattazzi et al. [415]. The conformal blocks constructed here in closed form are due to Dolan and Osborn [155, 156]. The most useful entry points to the field as a whole are the review of Poland et al. [402] and the lecture notes of Rychkov [421] and Simmons-Duffin [441], all of which carry the linear-functional method, the radial expansion, and the semidefinite formulation in more computational detail than space allows here. The 3D Ising application that this chapter poses — and whose numerics Chapter 50 develops — is the subject of El-Showk et al. [172, 173], with the mixed-correlator islands that sharpen it given by Kos et al. [303, 304].

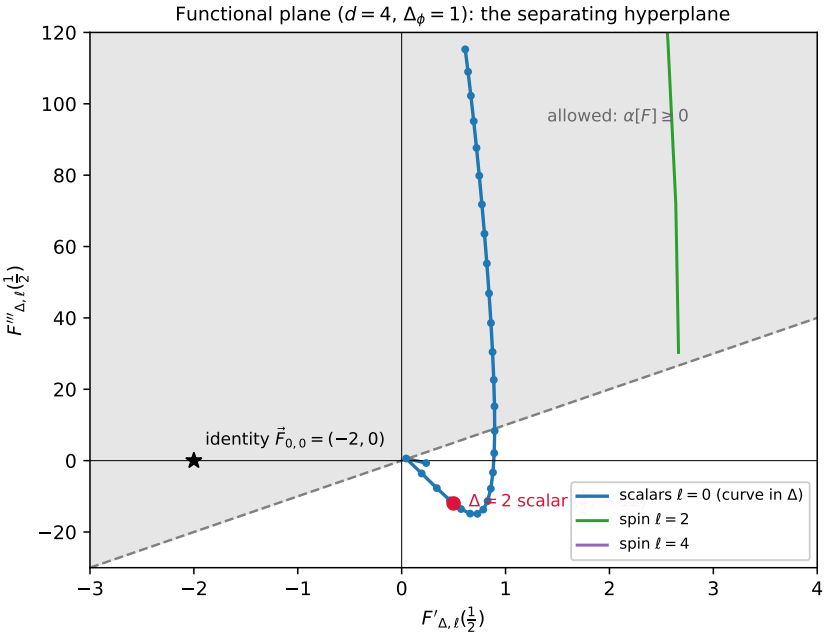

Figure 49.4: The separating-hyperplane picture for the two-derivative functional (Theorem 49.22; $d = 4$, $\Delta_\phi = 1$). Each conformal block is the point $(\partial_t F_{\Delta,\ell},\, \partial_t^3 F_{\Delta,\ell})$ at $z = \bar{z} = \frac{1}{2}$; the blue curve is the scalars (parametrized by Δ), green and purple the spin-2 and spin-4 families. The identity sits at the fixed point $(-2, 0)$ and the exactly-computed $\Delta = 2$ scalar at $(\frac{1}{2}, -12)$. The dashed line $\partial_t^3 F = 10\,\partial_t F$ is the boundary $\alpha_{0,1} = 0$ of the certificate functional of Step 4; the shaded half-plane is $\alpha_{0,1} \geq 0$. The identity and the entire gap-4 spectrum lie in the shaded region while the low scalars $2 < \Delta < 3.6$ dip below the line — which is exactly why a scalar gap above $\Delta_* \approx 3.61$ can be separated and excluded, and a smaller one cannot. Rotating the line toward the horizontal ($B \to \infty$) gives the optimal bound Eq. (49.116).

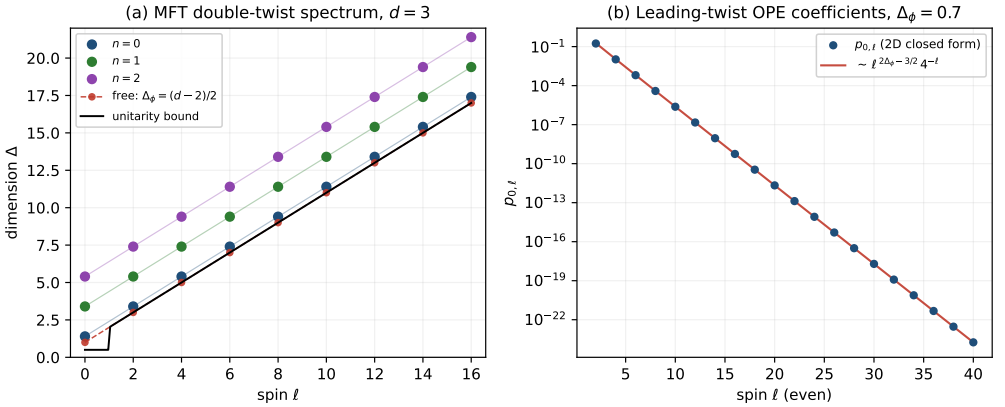

Figure 49.5: The exact solution of crossing for the generalized free field. *(a)* The double-twist spectrum Eq. (49.130): primaries $[\phi\phi]_{n,\ell}$ at $\Delta = 2\Delta_\phi + 2n + \ell$ for even spin ℓ, organized into twist trajectories $\tau_n = 2\Delta_\phi + 2n$ ($d = 3$, $\Delta_\phi = 0.7$). The solid line is the spin-ℓ unitarity bound $\Delta \geq \ell + d - 2$ (and $\Delta \geq \frac{d-2}{2}$ for the scalar); for the genuine free scalar $\Delta_\phi = (d-2)/2$ (dashed red) the leading-twist trajectory sits *on* the bound, signalling conserved higher-spin currents (Section 49.5.5). *(b)* The leading-twist OPE coefficients $p_{0,\ell}$ from the closed form Eq. (49.140) (here in $d = 2$, $\Delta_\phi = 0.7$), falling off as $\ell^{2\Delta_\phi - 3/2} 4^{-\ell}$ Eq. (49.150); the infinite tail of this tower is what rebuilds the crossed-channel identity (Section 49.5.3).

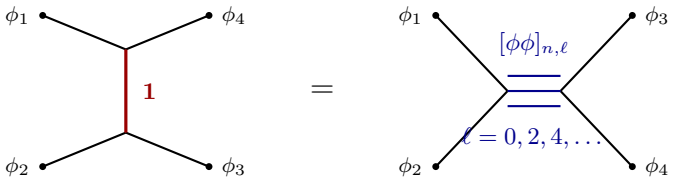

Figure 49.6: The large-spin reorganization in mean-field theory. The single identity exchanged in the crossed (t-)channel, whose $v \to 0$ collision singularity is the power law $v^{-\Delta_\phi}$ Eq. (49.148), is reproduced in the direct (s-)channel only by the entire infinite tower of double-twist operators $[\phi\phi]_{n,\ell}$ Eq. (49.130), whose large-spin OPE coefficients Eq. (49.150) are tuned to rebuild that power law. This is the prototype of the lightcone/large-spin expansion developed in Chapter 51.

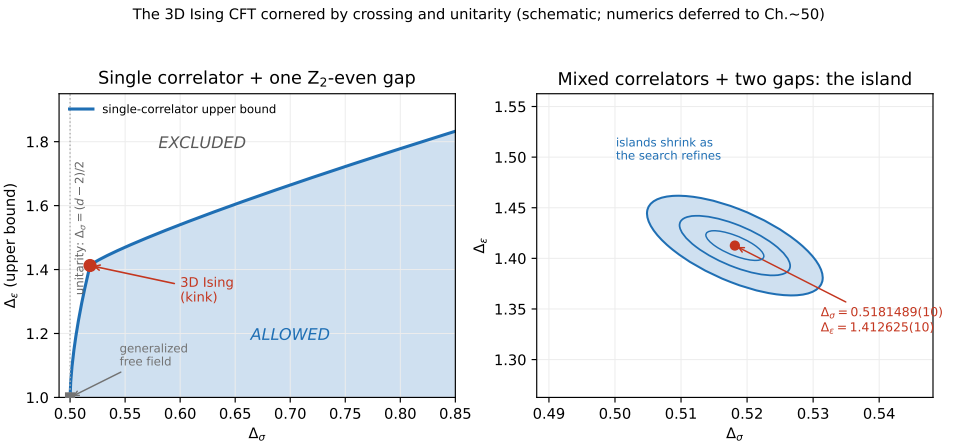

Figure 49.7: The 3D Ising CFT cornered by crossing and unitarity. *Left:* the rigorous single-correlator upper bound on Δ_ε as a function of Δ_σ under the one $\mathbb{Z}_2$-even gap assumption (A5), from Theorem 49.28. The shaded region below the curve is allowed; everything above is excluded by a positivity certificate. The bound has a sharp kink, and the Ising theory sits at it. The vertical wall at $\Delta_\sigma = \frac{d-2}{2} = \frac{1}{2}$ is the scalar unitarity bound; the square at its foot is the generalized free field of Section 49.5.1. *Right:* feeding in the mixed-correlator system $\{\sigma\sigma\sigma\sigma,\ \sigma\sigma\varepsilon\varepsilon,\ \varepsilon\varepsilon\varepsilon\varepsilon\}$ and a second gap (a single relevant $\mathbb{Z}_2$-odd scalar) closes the bound into an *island* that isolates Δ_σ and Δ_ε and shrinks as the search is refined. The schematic is a faithful rendering of the published bounds; the actual semidefinite computation is Chapter 50's.

Chapter 50

The Numerical Bootstrap

The foundations chapter (Chapter 49) reduced the consistency of a unitary conformal field theory, as seen through a single four-point function, to one homogeneous equation: the crossing sum rule Eq. (49.74), a linear relation among the convolved conformal blocks of Chapter 47 whose unknowns are a discrete spectrum of dimensions and a set of squared, hence nonnegative, OPE coefficients. It also exhibited the elementary mechanism that converts that equation into bounds — a linear functional nonnegative on every allowed block but positive on the identity refutes a candidate spectrum (Theorem 49.21) — and carried a first number through by hand. What it left open is everything that makes the method *complete*, *computable*, and *sharp*. This chapter supplies all three, and aims the resulting machine at the showcase target of the whole conformal program: the three-dimensional Ising fixed point, which is the $d = 3$ avatar of the Wilson–Fisher fixed point that ϕ^4 theory has carried since Chapter 6 and located perturbatively in Chapter 24.

The arc is a single idea pursued to its computational conclusion. We begin in the language of convex geometry, recasting crossing as the demand that a fixed vector lie inside a convex cone and proving the converse the foundations chapter lacked: by the Farkas dichotomy, whenever a spectrum is truly inconsistent a separating functional is *guaranteed* to exist, so the search is never a chase after a mirage. With completeness secured we turn the separation principle into its two working algorithms — the dimension bound and the two-sided OPE-coefficient bound — and prove that each computes the genuine optimum of a semi-infinite linear program, monotone under refinement. The obstruction that keeps those programs from a computer, a continuum of positivity constraints in each spin, is then removed in four controlled reductions resting on the radial expansion and its geometric convergence (Theorem 49.12), on the meromorphic structure of the blocks in the exchanged dimension, and on the classical Markov–Lukács theorem; the outcome is a finite semidefinite program whose rigor is underwritten by weak duality and whose floating-point output can be promoted to an exact

theorem. The analytic backbone of these reductions — Cauchy's estimate, analytic continuation, the residue calculus — is the machinery assembled in Chapter 5 (Theorem 5.23).

The machine is then run. Aimed first at the single correlator $\langle\sigma\sigma\sigma\sigma\rangle$ of the $\mathbb{Z}_2$-odd spin field in $d = 3$, it produces an exclusion curve with a sharp kink, and that kink sits, to three or four figures, exactly where every other method places the Ising critical point. The single correlator only *touches* the theory; to *isolate* it we promote the problem to the mixed system of $\langle\sigma\sigma\sigma\sigma\rangle$, $\langle\sigma\sigma\varepsilon\varepsilon\rangle$, and $\langle\varepsilon\varepsilon\varepsilon\varepsilon\rangle$, where unitarity speaks through positive-semidefinite matrices rather than nonnegative numbers and the open wedge pinches shut into a small closed island. The island delivers the dimensions, and hence the critical exponents η and ν, to six significant figures — numbers we confront against Monte Carlo and the laboratory.

A final movement reads the boundary. At a saturating point the optimal functional is forced to vanish exactly on the operators the extremal solution uses, so its double zeros *are* the spectrum: the bootstrap stops bracketing the data and begins reconstructing it, operator by operator, from a single convex-optimization certificate. We close by accounting honestly for what is proved and what is assumed — exclusions are theorems, islands are theorems conditional on explicit gap inputs imported from the renormalization-group understanding of Chapters 23 and 24, and naming the theory "Ising" is universality (physics), not a corollary of the bound — and by surveying the broader toolkit and dating the frontier as of the mid-2020s. The chapter ends where it must: at the large-spin tower the numerics can only sample, which is the natural handoff to the analytic methods of Chapter 51.

50.1 Crossing as a Problem in Convex Geometry

Chapter 49 reduced the consistency of a unitary conformal field theory — so far as a single four-point function can see it — to one homogeneous equation. Writing $p_{\mathcal{O}} = \lambda^2_{\phi\phi\mathcal{O}}$ for the squared OPE coefficients (Theorem 47.46) and $\widehat{F}_{\Delta,\ell}$ for the normalized convolved blocks built from the conformal blocks of Theorem 47.49 and the block decomposition Eq. (47.227), the crossing equation Eq. (49.14) became the bootstrap sum rule (Theorem 49.17, Eq. (49.74))

$$1 + \sum_{\mathcal{O}\neq\mathbf{1}} p_{\mathcal{O}}\, \widehat{F}_{\Delta_{\mathcal{O}},\ell_{\mathcal{O}}}(z,\bar{z}) = 0, \qquad p_{\mathcal{O}} = \lambda^2_{\phi\phi\mathcal{O}} \geq 0, \tag{50.1}$$

where the sum runs over the non-identity primaries of the $\phi \times \phi$ OPE, each with even spin and a dimension obeying the unitarity bounds of Theorem 47.18. Two facts about this equation carry the whole method: the weights are nonnegative because they are squares (unitarity), and the allowed quantum numbers (Δ, ℓ) form a known region of the plane. Chapter 49 drew the consequence as a slogan

— a putative spectrum is consistent only if a certain fixed vector lies inside a convex cone — and proved that *if* a separating functional can be exhibited *then* the spectrum is excluded (Theorem 49.21). It did not prove the statement that makes the numerical bootstrap a complete method rather than a lucky one: that whenever a spectrum is genuinely inconsistent, a separating functional is *guaranteed to exist*. That converse is a theorem of finite-dimensional convex geometry, and installing it rigorously is the business of this section. It is the backbone on which every exclusion in this chapter, and every island in the next, ultimately rests.

This is the layer at which ϕ^4 theory enters the bootstrap. The correlator we will interrogate is $\langle\phi\phi\phi\phi\rangle$ for the real scalar carried since Chapter 6, now treated purely as a set of consistency conditions: Eq. (50.1) with Δ_ϕ a free parameter and the spectrum unknown. No Lagrangian, no coupling, no perturbation series is used — the input is symmetry and unitarity, nothing more. The output, by the end of the chapter, will be the Wilson–Fisher fixed point of Chapter 24 pinned down as a CFT to many digits. Here we lay the geometric foundation that turns "solve crossing" into "find a hyperplane."

50.1.1 Crossing vectors and the bootstrap cone

Fix the external dimension Δ_ϕ once and for all. The functions of the two cross-ratios that appear in Eq. (50.1) live in an infinite-dimensional real vector space; call it V. We work with it through linear functionals, which we will eventually take to be finite collections of derivatives at the crossing-symmetric point, exactly as in Eq. (49.98). For the geometry it is cleanest to think of each operator as contributing a fixed vector.

Definition 50.1 (Crossing vector)**.** For each allowed pair (Δ, ℓ) — even spin, dimension on or above the unitarity bound of Theorem 47.18 — the *crossing vector* is the element

$$\vec{F}_{\Delta,\ell} \;\equiv\; \widehat{F}_{\Delta,\ell}(z,\bar{z}) \;\in\; V, \tag{50.2}$$

regarded as a single point of the function space V. The *identity vector* is the known constant function $\vec{F}_{\mathbf{1}} \equiv \widehat{F}_{0,0} = 1$, the contribution that every CFT carries with the fixed weight $p_{\mathbf{1}} = 1$.

In this language the sum rule Eq. (50.1) is the single vector equation

$$\vec{F}_{\mathbf{1}} \;+\; \sum_{\mathcal{O}\neq\mathbf{1}} p_{\mathcal{O}}\, \vec{F}_{\Delta_{\mathcal{O}},\ell_{\mathcal{O}}} \;=\; 0, \qquad p_{\mathcal{O}} \geq 0, \tag{50.3}$$

which is Eq. (49.88) written with the normalized blocks. It asks: can the fixed vector $-\vec{F}_{\mathbf{1}}$ be written as a nonnegative combination of the crossing vectors drawn from the allowed region? The set of all such combinations is the central geometric object.

Definition 50.2 (Bootstrap cone and gap assumption)**.** Let A denote a set of allowed quantum numbers — a subset of the (Δ, ℓ) obeying unitarity and the even-spin selection rule. The *bootstrap cone* generated by A is

$$\mathcal{C}_A \;=\; \Big\{ \sum_{i=1}^{k} p_i \, \vec{F}_{\Delta_i,\ell_i} \;:\; k \in \mathbb{N},\; p_i \geq 0,\; (\Delta_i, \ell_i) \in A \Big\}, \tag{50.4}$$

the set of all finite nonnegative combinations of crossing vectors with quantum numbers in A. A *gap assumption* is a restriction of A: a hypothesis that excludes part of the unitarity-allowed region — typically "no scalar with $\Delta < \Delta_{\text{gap}}$" — and so replaces $\mathcal{C}_A$ by the smaller cone $\mathcal{C}_{A'}$ generated by the surviving operators $A' \subset A$.

That $\mathcal{C}_A$ is a *convex cone* is immediate from the definition: it contains 0 (the empty combination), it is closed under multiplication by any $t \geq 0$ (rescale every p_i), and it is closed under addition (concatenate the two combinations). Convexity follows, since for $x, y \in \mathcal{C}_A$ and $t \in [0,1]$ the combination $tx + (1-t)y$ is again a nonnegative combination. The content of crossing is now a single membership question.

Proposition 50.3 (Crossing as cone membership)**.** *A list of unitary CFT data with external dimension Δ_ϕ and non-identity spectrum contained in A exists only if*

$$-\vec{F}_{\mathbf{1}} \;\in\; \mathcal{C}_A. \tag{50.5}$$

A gap assumption shrinks A to A' and so shrinks the cone; if $-\vec{F}_{\mathbf{1}} \notin \mathcal{C}_{A'}$ the assumption is inconsistent with crossing and unitarity.

Proof. If such data exist, its four-point function satisfies Eq. (50.3) with all weights $p_{\mathcal{O}} \geq 0$ and all non-identity quantum numbers in A; rearranging, $-\vec{F}_{\mathbf{1}}$ equals the nonnegative combination $\sum_{\mathcal{O} \neq \mathbf{1}} p_{\mathcal{O}} \, \vec{F}_{\Delta_{\mathcal{O}},\ell_{\mathcal{O}}}$, which is by definition an element of $\mathcal{C}_A$. (Strictly, the sum may be infinite; Eq. (50.4) admits only finite combinations, so membership is in the closure $\overline{\mathcal{C}_A}$. We return to this point in Section 50.1.2, where the truncation to a finite functional basis renders the distinction harmless.) Restricting to $A' \subset A$ restricts the generators of the cone, so $\mathcal{C}_{A'} \subseteq \mathcal{C}_A$; if the membership fails for $\mathcal{C}_{A'}$ no such data with spectrum in A' can exist. □

The membership question splits cleanly into two cases. Either $-\vec{F}_{\mathbf{1}}$ lies in (the closure of) the cone, in which case crossing *might* be solvable with a spectrum drawn from A, or it lies strictly outside, in which case no such solution exists and the spectrum is excluded. The whole numerical bootstrap is the systematic discovery of the second case. To turn "lies strictly outside" into a finite, checkable certificate we need the geometric fact that a point outside a closed convex cone can always be *seen* to be outside, by a single linear functional. We now prove this.

50.1.2 The master separation principle

We work in a real Euclidean space $\mathbb{R}^N$ with the standard inner product $\langle a, b\rangle$ and norm $\|x\| = \langle x, x\rangle^{1/2}$. The reduction from the infinite-dimensional V to a finite $\mathbb{R}^N$ is the act of choosing a finite functional basis: pick N linearly independent linear functionals on V — in practice the derivatives $\partial_z^m \partial_{\bar z}^n$ at $z = \bar z = \frac{1}{2}$ that survive the crossing antisymmetry — and represent every vector $f \in V$ by the N-tuple of its values under them, its *component vector* in $\mathbb{R}^N$. Crossing vectors, the identity vector, and the cone all map forward to $\mathbb{R}^N$; a linear functional on $\mathbb{R}^N$ is then exactly a finite linear combination of the chosen derivatives, the object Eq. (49.98) we are allowed to build. The geometry below lives in this finite-dimensional image, where every step is a theorem with no functional-analytic loose ends. The fidelity of the reduction — that excluding the truncated problem excludes the true one — is the monotonicity already noted in Chapter 49: a functional in the small basis is a functional in any larger one, so truncated exclusions are genuine exclusions, never spuriously strong. The completeness in the other direction is the subject of Theorem 50.6 below.

The engine is the nearest-point projection onto a closed convex set, a construction worth proving in full because everything rests on it.

Lemma 50.4 (Projection onto a closed convex set)**.** *Let $C \subseteq \mathbb{R}^N$ be nonempty, closed, and convex, and let $b \in \mathbb{R}^N$. Then there is a unique point $p \in C$ minimizing the distance to b,*

$$\|b - p\| \;=\; \inf_{x \in C} \|b - x\| \;\equiv\; d, \tag{50.6}$$

and it is characterized by the variational inequality

$$\langle\, b - p,\; x - p \,\rangle \;\le\; 0 \qquad \text{for every } x \in C. \tag{50.7}$$

Proof. Existence. The infimum $d \ge 0$ is finite (any single point of C gives a finite distance). Take a minimizing sequence $x_n \in C$ with $\|b - x_n\| \to d$. It is bounded: $\|x_n\| \le \|b\| + \|b - x_n\|$ is eventually below $\|b\| + d + 1$. By the Bolzano–Weierstrass theorem it has a subsequence converging to some $p \in \mathbb{R}^N$; since C is closed, $p \in C$, and by continuity of the norm $\|b - p\| = d$.

Uniqueness. Suppose $p_1, p_2 \in C$ both attain d. Their midpoint $\frac{1}{2}(p_1 + p_2)$ lies in C by convexity. The parallelogram identity $\|u + v\|^2 + \|u - v\|^2 = 2\,\|u\|^2 + 2\,\|v\|^2$, applied to $u = b - p_1$ and $v = b - p_2$, gives

$$\left\| b - \tfrac{p_1 + p_2}{2} \right\|^2 \;=\; \tfrac{1}{2}\,\|b - p_1\|^2 + \tfrac{1}{2}\,\|b - p_2\|^2 - \tfrac{1}{4}\,\|p_1 - p_2\|^2 \;=\; d^2 - \tfrac{1}{4}\,\|p_1 - p_2\|^2 . \tag{50.8}$$

If $p_1 \ne p_2$ the right-hand side is strictly below d^2, contradicting the minimality of d over C. Hence $p_1 = p_2$.

Variational inequality. Fix any $x \in C$. For $t \in [0,1]$ the point $p + t(x-p) = (1-t)p + tx$ lies in C by convexity, so the scalar function

$$\varphi(t) \;=\; \| \, b - p - t(x-p) \, \|^2 \;=\; \|b-p\|^2 - 2t\,\langle b-p,\, x-p\rangle + t^2\,\|x-p\|^2 \tag{50.9}$$

satisfies $\varphi(t) \geq \varphi(0) = d^2$ for all $t \in [0,1]$, since p is the minimizer. Therefore $\varphi'(0) \geq 0$. But $\varphi'(0) = -2\langle b-p,\, x-p\rangle$, which gives Eq. (50.7). Conversely, if Eq. (50.7) holds then for any $x \in C$, $\|b-x\|^2 = \|b-p\|^2 - 2\langle b-p, x-p\rangle + \|x-p\|^2 \geq \|b-p\|^2$, so p is the minimizer; the variational inequality is equivalent to being the projection. $\square$

The projection delivers the separating hyperplane at once.

Theorem 50.5 (Strict separation of a point from a closed convex set)**.** *Let $C \subseteq \mathbb{R}^N$ be nonempty, closed, and convex, and let $b \notin C$. Then there is a nonzero vector $\alpha \in \mathbb{R}^N$ and a real number c such that*

$$\langle \alpha,\, x\rangle \;\leq\; c \;<\; \langle \alpha,\, b\rangle \qquad \text{for every } x \in C. \tag{50.10}$$

The hyperplane $\{y : \langle \alpha, y\rangle = c\}$ strictly separates b from C.

Proof. Let p be the projection of b onto C from Theorem 50.4, and set $\alpha = b - p$. Because $b \notin C$ and $p \in C$, $\alpha \neq 0$ and $\|\alpha\|^2 = \langle \alpha, b-p\rangle > 0$. For any $x \in C$ the variational inequality Eq. (50.7) reads $\langle \alpha, x-p\rangle \leq 0$, i.e. $\langle \alpha, x\rangle \leq \langle \alpha, p\rangle$. On the other hand $\langle \alpha, b\rangle = \langle \alpha, p\rangle + \langle \alpha, b-p\rangle = \langle \alpha, p\rangle + \|\alpha\|^2 > \langle \alpha, p\rangle$. Choosing $c = \langle \alpha, p\rangle + \tfrac{1}{2}\,\|\alpha\|^2$ places it strictly between the two,

$$\sup_{x \in C} \langle \alpha, x\rangle \;\leq\; \langle \alpha, p\rangle \;<\; c \;<\; \langle \alpha, p\rangle + \|\alpha\|^2 = \langle \alpha, b\rangle, \tag{50.11}$$

which is Eq. (50.10). $\square$

For the bootstrap the relevant C is not merely convex but a cone, and the separation theorem then sharpens into the dichotomy named after Farkas: a point is either in the cone or strictly separated from it by a functional that is one-signed on the entire cone. This is the master principle.

Theorem 50.6 (Farkas dichotomy for a closed convex cone)**.** *Let $\mathcal{C} \subseteq \mathbb{R}^N$ be a closed convex cone and let $b \in \mathbb{R}^N$. Then exactly one of the following holds:*

(I) $b \in \mathcal{C}$;

(II) *there exists $\alpha \in \mathbb{R}^N$ with $\langle \alpha, x\rangle \geq 0$ for every $x \in \mathcal{C}$ and $\langle \alpha, b\rangle < 0$.*

Proof. The two alternatives are mutually exclusive: if (I) and (II) both held, then taking $x = b \in \mathcal{C}$ in (II) would force $\langle \alpha, b\rangle \geq 0$, contradicting $\langle \alpha, b\rangle < 0$.

It remains to show that if (I) fails then (II) holds. Suppose $b \notin \mathcal{C}$. By Theorem 50.5 there is $\beta \neq 0$ and c with $\langle \beta, x\rangle \leq c < \langle \beta, b\rangle$ for all $x \in \mathcal{C}$. We extract two facts from the cone structure. First, $0 \in \mathcal{C}$ (a cone contains the origin), so $c \geq \langle \beta, 0\rangle = 0$, hence $\langle \beta, b\rangle > c \geq 0$, giving $\langle \beta, b\rangle > 0$. Second, $\langle \beta, x\rangle \leq 0$ for every $x \in \mathcal{C}$: if some $x_0 \in \mathcal{C}$ had $\langle \beta, x_0\rangle > 0$, then $tx_0 \in \mathcal{C}$ for all $t \geq 0$ (cone property) and $\langle \beta, tx_0\rangle = t\langle \beta, x_0\rangle \to +\infty$, violating the upper bound $c < \infty$. Now set $\alpha = -\beta$. Then $\langle \alpha, x\rangle = -\langle \beta, x\rangle \geq 0$ for every $x \in \mathcal{C}$, and $\langle \alpha, b\rangle = -\langle \beta, b\rangle < 0$, which is precisely (II). □

One hypothesis of the Farkas dichotomy must be earned, not assumed: the cone $\mathcal{C}$ has to be *closed*. The bootstrap cone Eq. (50.4) is generated by a continuum of crossing vectors (the dimension Δ runs over a half-line for each of infinitely many spins), and the conic hull of an arbitrary set need not be closed. The following lemma supplies exactly the condition that makes it closed, and it is the condition the numerical implementation enforces in practice.

Lemma 50.7 (Closedness of the conic hull of a compact set)**.** *Let $K \subset \mathbb{R}^N$ be compact with $0 \notin \mathrm{conv}(K)$, the convex hull of K. Then the conic hull $\mathcal{C} = \{\sum_i t_i v_i : t_i \geq 0,\ v_i \in K\}$ is closed.*

Proof. Because $\mathrm{conv}(K)$ is compact (a convex hull of a compact set in finite dimensions is compact, by Carathéodory) and does not contain the origin, the strict separation theorem Theorem 50.5 applied to $b = 0$ and $C = \mathrm{conv}(K)$ furnishes a vector w and a $c < 0$ with $\langle w, y\rangle \leq c < \langle w, 0\rangle = 0$... reversing the sign we obtain w with

$$\langle w, v\rangle \;\geq\; \delta \;>\; 0 \qquad \text{for all } v \in K, \tag{50.12}$$

for some $\delta > 0$ (take $\delta = -c > 0$ and replace w by $-w$). By the conic Carathéodory theorem, every element of $\mathcal{C}$ is a nonnegative combination of at most N points of K. Let $y_k = \sum_{i=1}^{N} t_i^{(k)} v_i^{(k)} \to y$ be a convergent sequence in $\mathcal{C}$ with $t_i^{(k)} \geq 0$ and $v_i^{(k)} \in K$. Pairing with w and using Eq. (50.12),

$$\langle w, y_k\rangle \;=\; \sum_{i=1}^{N} t_i^{(k)} \langle w, v_i^{(k)}\rangle \;\geq\; \delta \sum_{i=1}^{N} t_i^{(k)}. \tag{50.13}$$

Since $y_k \to y$ the left-hand side is bounded, so the coefficient sums $\sum_i t_i^{(k)}$ are bounded; each $t_i^{(k)}$ is therefore bounded. Passing to a subsequence, $t_i^{(k)} \to t_i \geq 0$ and (by compactness of K) $v_i^{(k)} \to v_i \in K$. Then $y = \lim_k y_k = \sum_i t_i v_i \in \mathcal{C}$, so $\mathcal{C}$ is closed. □

In the bootstrap, K is the set of *normalized* crossing vectors $\vec{F}_{\Delta,\ell} / \left\|\vec{F}_{\Delta,\ell}\right\|$ ranging over the allowed region (so that the conic hull of K is exactly $\mathcal{C}_A$). Compactness of K is not automatic, because the region is unbounded in Δ and in

ℓ; what rescues it is that the crossing vectors approach definite limiting directions as $\Delta \to \infty$ at fixed spin and as $\ell \to \infty$, a consequence of the large-dimension and large-spin asymptotics of the conformal blocks. Adjoining those finitely many limit rays to the image of the allowed region produces a compact K, and provided the chosen functional basis does not put 0 in $\mathrm{conv}(K)$ — which is the generic situation, since the identity sets a definite scale — Theorem 50.7 makes $\mathcal{C}_A$ closed. This is precisely what the numerical method does when it imposes positivity uniformly down to the unitarity bound and out to a large spin and dimension cutoff: it is enforcing the compactness that guarantees the dichotomy is exact. We state the working hypothesis once and rely on it thereafter.

Caution

The theorems of this subsection are exact statements about a *finite-dimensional, closed* cone. Two idealizations separate them from a literal computation. The functional basis is finite, which (as noted) can only weaken exclusions, never falsify them. And the cone must be closed, which requires the compactness arranged in Theorem 50.7; a genuine bootstrap implementation realizes this by discretizing the spectrum and treating the asymptotic tails explicitly, with errors that are controlled and reported. Within those idealizations the separation is a theorem; the next chapter's numbers inherit exactly that status.

50.1.3 The exclusion lemma, both directions

We can now state the principle that organizes the entire chapter, and we can state it as an *equivalence* rather than the one-way implication of Theorem 49.21. Recall the notion of an admissible functional (Theorem 49.21): for a candidate spectrum A, a linear functional α is admissible if

$$\text{(i)}\ \ \alpha[\vec{F}_{\mathbf{1}}] > 0, \qquad \text{(ii)}\ \ \alpha[\vec{F}_{\Delta,\ell}] \geq 0 \ \text{ for every } (\Delta,\ell) \in A. \tag{50.14}$$

Theorem 50.8 (Master exclusion principle)**.** *Fix Δ_ϕ and a candidate spectrum A, and work in a fixed finite functional basis in which the cone $\mathcal{C}_A$ is closed. The following are equivalent:*

(a) *No unitary, crossing-symmetric CFT has external scalar dimension Δ_ϕ and non-identity $\phi \times \phi$ spectrum contained in A* within this basis — *that is, $-\vec{F}_{\mathbf{1}} \notin \mathcal{C}_A$;*

(b) *there exists an admissible functional α for A in the sense of Eq. (50.14).*

Proof. (b)⇒(a) — sufficiency. This is the sign count of Theorem 49.21; we reproduce it because it is the payoff of the whole construction and takes three lines. Suppose an admissible α exists and, for contradiction, that consistent data

did too. Apply α to the sum rule Eq. (50.3); by linearity and term-by-term applicability (the block expansion converges in a neighbourhood of the crossing-symmetric point, Theorem 47.46, and α is a finite combination of derivatives there),

$$0 \;=\; \alpha\Big[\vec{F}_{\mathbf{1}} + \sum_{\mathcal{O}\neq\mathbf{1}} p_{\mathcal{O}}\,\vec{F}_{\Delta_{\mathcal{O}},\ell_{\mathcal{O}}}\Big] \;=\; \underbrace{\alpha[\vec{F}_{\mathbf{1}}]}_{>0} \;+\; \sum_{\mathcal{O}\neq\mathbf{1}} \underbrace{p_{\mathcal{O}}}_{\geq 0}\,\underbrace{\alpha[\vec{F}_{\Delta_{\mathcal{O}},\ell_{\mathcal{O}}}]}_{\geq 0} \;\geq\; \alpha[\vec{F}_{\mathbf{1}}] \;>\; 0. \tag{50.15}$$

The first term is strictly positive by (i); every term of the sum is a product of two nonnegatives (the weight by unitarity, the functional value by (ii) since the operator lies in A); so the right-hand side is strictly positive, contradicting the exact zero on the left. No such data exist: $-\vec{F}_{\mathbf{1}} \notin \mathcal{C}_A$.

(a)⇒(b) — completeness. This is the new content. Suppose $-\vec{F}_{\mathbf{1}} \notin \mathcal{C}_A$. Since $\mathcal{C}_A$ is a closed convex cone, the Farkas dichotomy Theorem 50.6 applied to $b = -\vec{F}_{\mathbf{1}}$ rules out alternative (I) and so delivers alternative (II): a vector α with $\langle \alpha, x\rangle \geq 0$ for all $x \in \mathcal{C}_A$ and $\langle \alpha, -\vec{F}_{\mathbf{1}}\rangle < 0$. The first property, evaluated on each generator $\vec{F}_{\Delta,\ell} \in \mathcal{C}_A$ (every generator is in the cone), gives $\alpha[\vec{F}_{\Delta,\ell}] \geq 0$ for all $(\Delta,\ell) \in A$, which is condition (ii). The second property reads $\alpha[\vec{F}_{\mathbf{1}}] > 0$, which is condition (i). Thus α is admissible. □

The equivalence is the conceptual centre of the numerical bootstrap. Sufficiency, direction (b)⇒(a), is what makes a found functional a *proof*: produce one α passing the two sign tests and an entire class of CFTs is forbidden, exactly, with no error term. Completeness, direction (a)⇒(b), is what makes the search *worth running*: it guarantees that the functional one is hunting for is not a mirage — if the spectrum is truly inconsistent (within the basis), the certificate exists and a sufficiently thorough search will find it. Chapter 49 had only the first half and could therefore promise that success excludes; with the second half in hand we know that the method is the right one — every genuine inconsistency is, in principle, certifiable by a single hyperplane. The geometric picture is the entire story in one sentence: *a putative CFT is the demand that a fixed point lie inside a convex cone, and an excluding functional is a hyperplane that catches it outside* (Fig. 50.1).

Physical Insight

The single most useful thing to carry from this section is the inversion of burden it accomplishes. *Solving* crossing — producing an actual spectrum and OPE coefficients — is hard and, for an interacting theory in $d > 2$, not something we can do in closed form. *Refuting* a spectrum is, by the master principle, a finite search for one hyperplane, and convex duality promises the hyperplane exists whenever the refutation is true. The bootstrap never solves the hard problem; it relentlessly solves the easy dual one, and the

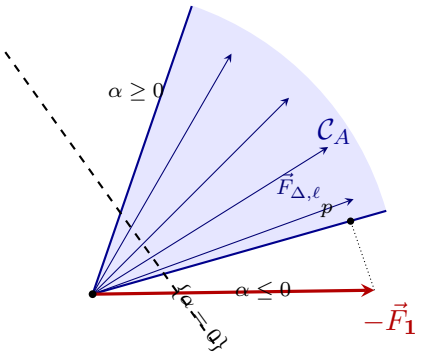

Figure 50.1: The master separation principle in the plane. The crossing vectors of an assumed spectrum A generate the closed convex cone $\mathcal{C}_A$ (shaded). Crossing demands that $-\vec{F}_{\mathbf{1}}$ lie inside it. When a gap assumption has removed enough low-lying operators, $-\vec{F}_{\mathbf{1}}$ falls outside the cone; the nearest-point projection $p \in \mathcal{C}_A$ (Theorem 50.4) defines the separating direction $\alpha = (-\vec{F}_{\mathbf{1}}) - p$ up to sign, and the hyperplane $\{\alpha = 0\}$ through the origin has the entire cone on one side ($\alpha \geq 0$, i.e. $\alpha[\vec{F}_{\Delta,\ell}] \geq 0$) and $\vec{F}_{\mathbf{1}}$ strictly on the other ($\alpha[\vec{F}_{\mathbf{1}}] > 0$). Existence of such an α is guaranteed by Theorem 50.6 whenever the point is genuinely outside, and exhibiting one excludes the spectrum by Theorem 50.8.

boundary between "refuted" and "not refuted" is squeezed until only the true theories survive. Every bound in this chapter is one application of this idea with a different objective placed on the functional.

50.1.4 A separation computed by hand

The dichotomy is abstract until one watches the projection manufacture a functional from explicit vectors. We do so in the smallest nontrivial setting, reusing the exact numbers computed in Theorem 49.22 so that the geometry can be checked against an arithmetic already in hand. This is not a re-derivation of that bound; it is a demonstration that the existence theorem Theorem 50.6 *constructs* the very functional the feasibility scan of Chapter 49 found, and that the two agree.

Worked Example 50.9 (The Farkas certificate in the two-derivative plane)**.** We continue ϕ^4 theory with the carried correlator $\langle\phi\phi\phi\phi\rangle$, specialized as in Theorem 49.22 to $d = 2$ and $\Delta_\phi = \frac{1}{8}$ (the spin field of the two-dimensional Ising model). The functional basis is two-dimensional: the lowest two crossing-odd derivatives at the symmetric point,

$$\Lambda_1[\,f\,] = \tfrac{d}{dz} f(z,z)\big|_{z=1/2}, \qquad \Lambda_3[\,f\,] = \tfrac{d^3}{dz^3} f(z,z)\big|_{z=1/2}, \tag{50.16}$$

so each vector in V is represented in $\mathbb{R}^2$ by the pair (Λ_1, Λ_3). From Eqs. (49.94) and (49.114) the identity vector and its negation are

$$\vec{F}_{\mathbf{1}} = (-0.84090,\ -4.41471), \qquad b \equiv -\vec{F}_{\mathbf{1}} = (0.84090,\ 4.41471), \tag{50.17}$$

and the crossing vectors of the low-lying operators are, from Table 49.1,

$$\vec{F}_{1,0} = (2.828,\ 8.413), \quad \vec{F}_{2,0} = (4.259,\ 71.25), \quad \vec{F}_{2,2} = (8.377,\ 129.4),\ \ldots \tag{50.18}$$

all with both components positive. In the plane a ray from the origin is fixed by its slope $s = \Lambda_3/\Lambda_1$; the generators have slopes

$$s(1,0) = 2.97, \quad s(2,0) = 16.7, \quad s(2,2) = 15.4,\ \ldots, \tag{50.19}$$

and every other allowed operator has slope above the minimum. Because all generators lie in the open right half-plane $\Lambda_1 > 0$, the cone $\mathcal{C}_A$ is the angular sector $\{(\Lambda_1, \Lambda_3) : \Lambda_1 \geq 0,\ s_{\min} \leq \Lambda_3/\Lambda_1\}$ bounded below by the shallowest generator ray and unbounded above (high-dimension scalars have ever-steeper slopes). The target point b has slope

$$s_b = \frac{4.41471}{0.84090} = 5.250. \tag{50.20}$$

No gap: the point is inside. With the full unitarity-allowed spectrum the shallowest generator is the $\Delta = 1$ scalar, slope $2.97 < 5.250$, so b lies above the lower edge of the sector and inside $\mathcal{C}_A$. Indeed one checks that b is a positive combination of $\vec{F}_{1,0}$ and a steeper generator. By Theorem 50.8 no functional can be admissible, and none should be: crossing is (so far) satisfiable, and the two-dimensional Ising solution realizes it.

With a gap: the point falls out, and the projection names the hyperplane. Impose the gap assumption "the first scalar has $\Delta \geq \Delta_{\text{gap}}$." Removing the low scalars raises the shallowest surviving slope $s_{\min}$. Once $s_{\min} > s_b = 5.250$, the target slope lies *below* the entire cone: b is outside $\mathcal{C}_A$, and Theorem 50.6 guarantees a separating functional. We construct it as the projection. The boundary of the sector nearest b is the lower edge, the ray through the shallowest generator $v_{\min} = (1, s_{\min})$ (un-normalized direction). For b outside and below this edge the nearest point of the (convex) cone on that edge is the orthogonal foot, and the separating direction of Theorem 50.5 is $\alpha \propto b - p$, which points perpendicular to the edge into the half-plane containing b. A vector perpendicular to the edge direction $(1, s_{\min})$ is $(-s_{\min}, 1)$ up to scale; orienting it to be nonnegative on the cone (and hence to make $\alpha[\vec{F}_{\mathbf{1}}] > 0$) gives, after rescaling so the Λ_3 coefficient is unity,

$$\alpha \ = \ \Lambda_3 - c\,\Lambda_1, \qquad c = s_{\min}. \tag{50.21}$$

This is exactly the one-parameter family that Theorem 49.22 scanned. Its admissibility conditions reproduce the window found there: positivity on every

generator requires $\alpha[\vec{F}_{\Delta,\ell}] = \Lambda_3[\vec{F}] - c\,\Lambda_1[\vec{F}] \geq 0$, i.e. $c \leq s(\Delta,\ell)$ for all surviving operators, hence $c \leq s_{\min}$; and positivity on the identity requires $\alpha[\vec{F}_{\mathbf{1}}] = \Lambda_3[\vec{F}_{\mathbf{1}}] - c\,\Lambda_1[\vec{F}_{\mathbf{1}}] = -4.41471 - c\,(-0.84090) = 0.84090\,c - 4.41471 > 0$, i.e. $c > 5.250$. An admissible functional therefore exists precisely when $5.250 < c \leq s_{\min}$, the non-empty window opening exactly when the gap has pushed $s_{\min}$ past the target slope 5.250 — numerically near $\Delta_{\text{gap}} \simeq 1.28$, the threshold $\Delta_0^* \leq 1.28$ of Theorem 49.22. The Farkas construction and the feasibility scan have produced the same certificate by two routes: the projection picks out the perpendicular to the cone's edge, and that perpendicular is the functional $\Lambda_3 - s_{\min}\Lambda_1$.

The worked example exhibits, in coordinates one can verify by hand, the content of the abstract theorems: a point inside the cone admits no certificate, a point pushed outside by a gap admits one, and the nearest-point projection of Theorem 50.4 *is* the recipe that returns it. In two dimensions the cone is an angular sector and the optimal functional is the perpendicular to its near edge; in the realistic problem the cone lives in tens or hundreds of dimensions and its boundary is a curved surface, so the "perpendicular to the near edge" becomes a genuine optimization. That optimization, and the two families of bounds it computes — the largest excludable gap and the extremal OPE coefficient — are the subject of the next section, which takes the object this section has guaranteed to exist (a positive linear functional that strictly separates the identity) and turns its construction into the two workhorse algorithms of the bootstrap, demonstrated on a toy functional that yields an actual number.

50.2 The Linear-Functional Method: Dimension and OPE Bounds

The previous section recast crossing as a question in convex geometry: the squared OPE coefficients $p_{\mathcal{O}} \geq 0$ are nonnegative weights, the convolved blocks $\vec{F}_{\Delta,\ell}$ are fixed vectors, and a proposed spectrum is consistent with crossing only if the identity vector $-\vec{F}_{0,0}$ lies inside the convex cone they generate. The master separation principle (Theorem 50.5) then supplied the dual handle: whenever $-\vec{F}_{0,0}$ lies *outside* that cone there is a hyperplane separating it, and that hyperplane is a linear functional α which is nonnegative on every allowed block yet strictly positive on the identity. Finding such an α is a rigorous proof that the spectrum is impossible — the content of the linear-functional exclusion principle proved in the foundations chapter (Theorem 49.21), which exhibited the logic and carried a first number through by hand (Theorem 49.22).

A single exclusion is one point of the allowed region declared empty. To extract physics we must sweep the exclusion across families of candidate spectra and read off where it succeeds and where it fails, and we must do so for the two quantities a CFT is built from: the dimensions of operators and the coefficients

with which they appear. This section turns the separation principle into the two standard bound algorithms of the bootstrap. We first show that the dimension bound is not merely *a* number a functional happens to certify but is *exactly* the optimum of an associated optimization — a semi-infinite linear program — so that any feasible functional gives a valid bound and the best functional gives the tightest one. We then prove the monotonicity that makes the bounds behave as honest outer approximations: adding an assumption can only shrink the allowed region. We give the OPE-coefficient bounds, two-sided, as the same technology run with a different normalization. Finally we compute a complete two-sided bound on an OPE coefficient by hand, so that the reader leaves with a rigorous interval — bracketing the exact answer of a solvable model — produced with nothing more than a derivative and a sign count, before any computer enters in Section 50.3.

50.2.1 The single-correlator problem, restated as an optimization

We work throughout with the four-point function of a single real scalar primary ϕ of dimension Δ_ϕ — the correlator $\langle\phi\phi\phi\phi\rangle$ that ϕ^4 theory has carried to the bootstrap and that the showcase sections will instantiate as $\langle\sigma\sigma\sigma\sigma\rangle$ for the Ising spin field. Conformal symmetry reduces it to a function of the two cross-ratios (Eqs. (47.138) and (47.140)), and crossing collapses (Eq. (49.74)) to the sum rule

$$\sum_{\mathcal{O}} p_{\mathcal{O}}\, F_{\Delta_{\mathcal{O}},\ell_{\mathcal{O}}}(u,v) = 0, \qquad p_{\mathcal{O}} = C^2_{\phi\phi\mathcal{O}} \geq 0, \qquad p_{\mathbf{1}} = 1, \tag{50.22}$$

the sum running over the primaries of the $\phi\times\phi$ OPE, with the identity carried as the fixed term $F_{0,0} = v^{\Delta_\phi} - u^{\Delta_\phi}$ and the convolved blocks $F_{\Delta,\ell} = v^{\Delta_\phi}G_{\Delta,\ell}(u,v) - u^{\Delta_\phi}G_{\Delta,\ell}(v,u)$ of Theorem 49.14. Two pieces of data constrain the admissible operators: by the OPE selection rule for identical scalars only even spins $\ell = 0, 2, 4, \ldots$ appear, and by the unitarity bounds (Theorem 47.18) every primary obeys $\Delta \geq \frac{d-2}{2}$ for $\ell = 0$ and $\Delta \geq \ell + d - 2$ for $\ell \geq 1$. The OPE converges in a neighbourhood of the crossing-symmetric point $z = \bar{z} = \frac{1}{2}$ (Theorem 47.48), which is what licenses applying a derivative functional term by term.

A *linear functional* is, as in Eq. (49.98), a finite real combination of partial derivatives evaluated at that point,

$$\alpha[\,f\,] = \sum_{m,n} a_{mn}\, \partial_z^m \partial_{\bar{z}}^n f(z,\bar{z})\Big|_{z=\bar{z}=1/2}, \qquad a_{mn} \in \mathbb{R}, \tag{50.23}$$

and α is *admissible* for a candidate spectrum S (a set of allowed (Δ,ℓ), each obeying unitarity) when $\alpha[F_{0,0}] > 0$ and $\alpha[F_{\Delta,\ell}] \geq 0$ for every $(\Delta,\ell) \in S$ (Theorem 49.21). The exclusion principle says: an admissible functional for S proves that no unitary crossing-symmetric CFT has its $\phi\times\phi$ OPE drawn from $\{\mathbf{1}\} \cup S$. Everything below is the systematic exploitation of this one statement.

It is worth naming the objects of the optimization precisely, because the claim "the bound is exactly the optimum" is a statement about two coupled problems. The *primal* problem is the search for a CFT: given a candidate spectrum S, does there exist an assignment of nonnegative weights $\{p_{\mathcal{O}}\}_{\mathcal{O}\in S}$ solving Eq. (50.22)? The *dual* problem is the search for a certificate: does there exist an admissible functional for S? The exclusion principle is the elementary half of a duality between them — a certificate refutes every solution — and the content of the next subsection is that, in the precise sense allowed by the geometry, the converse holds too.

50.2.2 Dimension bounds as a semi-infinite linear program

The first and most important application bounds the dimension of the lightest operator in a chosen sector. Take the scalar sector for definiteness; spinning sectors are identical with the unitarity floor shifted. Fix Δ_ϕ and a trial gap Δ_0, and let

$$S(\Delta_0) = \{(\Delta, 0) : \Delta \geq \Delta_0\} \;\cup\; \{(\Delta, \ell) : \ell = 2, 4, 6, \ldots,\; \Delta \geq \ell + d - 2\} \tag{50.24}$$

be the candidate spectrum in which every scalar is pushed up to at least Δ_0 while each spinning sector extends down to its unitarity bound. This is the spectrum of Eq. (49.101); we now read it as the feasible set of an optimization.

Definition 50.10 (The gap program)**.** The *primal gap program* at (Δ_ϕ, Δ_0) asks for a nonnegative spectral density $\{p_{\mathcal{O}} \geq 0\}$ supported on $S(\Delta_0)$ with $\sum_{\mathcal{O}\in S(\Delta_0)} p_{\mathcal{O}} F_{\Delta_{\mathcal{O}},\ell_{\mathcal{O}}} = -F_{0,0}$; it is *feasible* when such a density exists. The *dual gap program* asks for a linear functional α of the form Eq. (50.23) that is admissible for $S(\Delta_0)$, i.e.

$$\alpha[F_{0,0}] > 0, \qquad \alpha[F_{\Delta,\ell}] \geq 0 \;\text{ for all } (\Delta, \ell) \in S(\Delta_0). \tag{50.25}$$

The dual constraints are a continuum of linear inequalities indexed by the continuous label Δ within each spin; an optimization with finitely many unknowns a_{mn} and infinitely many linear constraints is a *semi-infinite linear program*.

The two programs are alternatives: a feasible primal density is a unitary crossing solution with the gap, an admissible dual functional is a proof that none exists, and they cannot both hold, since applying the functional to the solution gives $0 = \alpha[-F_{0,0}] + \sum_{\mathcal{O}} p_{\mathcal{O}} \alpha[F_{\mathcal{O}}]$ with a strictly negative first term and a nonnegative sum, a contradiction. This is the exclusion principle read as weak duality. The substantive question is whether, when the primal is *infeasible*, a dual certificate must exist. For a closed convex cone the separating-hyperplane theorem of Theorem 50.5 guarantees exactly that, and this is what upgrades "a functional gives a bound" to "the optimal functional gives *the* bound."

Theorem 50.11 (The gap bound is the optimum of the dual program)**.** *Fix* Δ_ϕ*. Define*

$$\Delta_0^*(\Delta_\phi) \;=\; \inf\big\{\Delta_0 : \textit{the dual gap program at } (\Delta_\phi, \Delta_0) \textit{ is feasible}\big\}. \tag{50.26}$$

Then:

(i) (Soundness — every feasible functional is a valid bound.) *If the dual program at* (Δ_ϕ, Δ_0) *is feasible, then every unitary, crossing-symmetric CFT with an external scalar of dimension* Δ_ϕ *has a scalar in* $\phi \times \phi$ *of dimension strictly below* Δ_0*. Consequently* Δ_0 *is a rigorous upper bound on the dimension of the lightest scalar in* $\phi \times \phi$*.*

(ii) (Optimal functional, tightest bound.) *The dual program is feasible for every* $\Delta_0 > \Delta_0^*$ *and infeasible for every* $\Delta_0 < \Delta_0^*$*. Hence* $\Delta_0^*(\Delta_\phi)$ *is the tightest scalar-gap bound the functional method can prove: no admissible functional certifies any value below it, and admissible functionals certify every value above it.*

(iii) (No slack, modulo closure.) *If the cone* $\mathcal{C}\big(S(\Delta_0^*)\big)$ *generated by the allowed blocks is closed, then at* $\Delta_0 = \Delta_0^*$ *the primal program is feasible: there is a unitary spectral density solving crossing whose lightest scalar sits exactly at* Δ_0^**. The bound is then* saturated*, and the saturating density is the unique extremal ray on which the optimal functional vanishes.*

Proof. (i) This is the exclusion principle. Suppose the dual is feasible, with admissible functional α, and suppose for contradiction a unitary crossing-symmetric CFT existed whose lightest scalar had dimension $\Delta_{\min} \geq \Delta_0$. Then every non-identity primary of $\phi \times \phi$ lies in $S(\Delta_0)$: scalars because $\Delta \geq \Delta_{\min} \geq \Delta_0$, spinning operators because they have even spin $\ell \geq 2$ and obey the unitarity bound. Apply α to the sum rule Eq. (50.22), which is legitimate because α is a finite derivative combination at a point of OPE convergence (Theorem 47.48):

$$0 = \alpha\Big[\sum_{\mathcal{O}} p_{\mathcal{O}} F_{\Delta_{\mathcal{O}},\ell_{\mathcal{O}}}\Big] = \underbrace{\alpha[F_{0,0}]}_{>0} + \sum_{\mathcal{O}\neq\mathbf{1}} \underbrace{p_{\mathcal{O}}}_{\geq 0}\, \underbrace{\alpha[F_{\Delta_{\mathcal{O}},\ell_{\mathcal{O}}}]}_{\geq 0} \;\geq\; \alpha[F_{0,0}] \;>\; 0, \tag{50.27}$$

using $p_{\mathbf{1}} = 1$ and admissibility. The right-hand side is strictly positive while the left is zero: contradiction. Hence $\Delta_{\min} < \Delta_0$ in every such theory, which is the stated bound.

(ii) The monotonicity is structural. If $\Delta_0' > \Delta_0$ then $S(\Delta_0') \subset S(\Delta_0)$ — raising the gap only removes low-dimension scalars — so any α admissible for $S(\Delta_0)$ is *a fortiori* admissible for $S(\Delta_0')$, since condition Eq. (50.25) is then required on a smaller set. Dual feasibility therefore propagates upward in Δ_0: if the program is feasible at Δ_0 it is feasible at every larger gap. The set of feasible gaps is thus an up-set in Δ_0, and its infimum Δ_0^* has precisely the property

claimed — feasible above, infeasible below. By part (i) each feasible Δ_0 is a valid bound, so the family of valid bounds is exactly (Δ_0^*, ∞) together with its infimum in the limit; the tightest is Δ_0^* itself. No functional certifies a value below Δ_0^*, by definition of the infimum.

(iii) Fix $\Delta_0 = \Delta_0^*$ and suppose the cone $\mathcal{C} = \mathcal{C}(S(\Delta_0^*)) = \{\sum_i p_i \vec{F}_{\Delta_i,\ell_i} : p_i \geq 0, (\Delta_i, \ell_i) \in S(\Delta_0^*)\}$ is closed. Either $-\vec{F}_{0,0} \in \mathcal{C}$ or it is not. If it is not, then by the separating-hyperplane theorem (Theorem 50.5) there is a functional α with $\alpha[\vec{v}] \geq 0$ for all $\vec{v} \in \mathcal{C}$ and $\alpha[-\vec{F}_{0,0}] < 0$, i.e. $\alpha[F_{0,0}] > 0$; this α is admissible for $S(\Delta_0^*)$, so the dual is feasible *at* Δ_0^*. But feasibility is an open condition in Δ_0 from below only at the threshold: feasibility at Δ_0^* would, by the continuity of the block data in Δ, persist for a range of Δ_0 slightly below Δ_0^*, contradicting that Δ_0^* is the infimum of feasible gaps.[1] Therefore $-\vec{F}_{0,0} \in \mathcal{C}$: there is a nonnegative density solving crossing supported on $S(\Delta_0^*)$. Its lightest scalar cannot lie above Δ_0^* (it is supported there) and cannot lie strictly below (else the same density would solve the program for a smaller gap, making Δ_0^* not the infimum at which the primal first becomes feasible); so it sits exactly at Δ_0^*. The density is the extremal ray of $\mathcal{C}$ on which the limiting optimal functional vanishes, and uniqueness of that ray is the statement that the optimal functional has just enough zeros to pin it down — the extremal-spectrum mechanism that the showcase sections exploit. □

Caution

Part (iii) carries the only genuine hypothesis in the theorem: the closedness of the cone. The block vectors $\vec{F}_{\Delta,\ell}$ for $\Delta \to \infty$ accumulate, and whether the cone they generate is closed — equivalently, whether the supremum gap is *attained* by an honest unitary solution rather than only approached by a sequence of them — is a real analytic question, not a formality. This is the precise technical residue of the honest statement made in Section 49.6.6: the *exclusions* of parts (i)–(ii) are unconditional theorems, whereas the *existence* of a saturating theory in part (iii) is conditional. In every numerical computation the program is solved in a finite derivative basis, where the cone is a finitely generated (hence closed) polyhedral cone and strong duality holds exactly; the subtlety lives only in the $\Lambda \to \infty$ limit.

The optimal functional admits a sharp geometric characterization that is the engine of every numerical search and the reason the bounds can be *saturated*. At the threshold the certificate α is nonnegative on the whole admissible spectrum

[1] Concretely: an admissible functional has $\alpha[F_{\Delta,0}] \geq 0$ for all $\Delta \geq \Delta_0^*$ with strict inequality except on the finite extremal set where it touches zero; since $\alpha[F_{\Delta,0}]$ is continuous in Δ, the constraints survive lowering the gap below the lowest extremal zero, so the program is feasible on an interval reaching below Δ_0^* — unless that extremal zero sits exactly at Δ_0^*, which is the saturation case.

yet, being marginal, must touch zero exactly on the operators of the saturating solution: the function $\Delta \mapsto \alpha[F_{\Delta,\ell}]$ has a *double zero* (a tangency, since it cannot go negative) at each dimension present in the extremal spectrum. Reading off those tangency locations from the optimal functional reconstructs the extremal spectrum — this is how the bootstrap, having only proved an inequality, nonetheless outputs a candidate set of dimensions, and it is the mechanism behind the kink that locates the Ising point in Fig. 49.7.

We can see the tangency concretely without leaving the by-hand computation of the foundations chapter. There the two-derivative functional $\alpha = \Lambda_3 - c\,\Lambda_1$ — built from the first and third diagonal derivatives $\Lambda_1 = \partial_z F(z,z)|_{1/2}$ and $\Lambda_3 = \partial_z^3 F(z,z)|_{1/2}$ of Eq. (49.113) — was applied to $\langle\sigma\sigma\sigma\sigma\rangle$ in $d=2$ at $\Delta_\phi = \frac{1}{8}$, with the block data tabulated in Table 49.2. Admissibility on the identity requires $\alpha[F_{0,0}] = \Lambda_3[F_{0,0}] - c\,\Lambda_1[F_{0,0}] > 0$; with the exact identity vector $(\Lambda_1,\Lambda_3)[F_{0,0}] = (-0.840896, -4.414706)$ this reads $-4.414706 + 0.840896\,c > 0$, i.e. $c > 4.414706/0.840896 = \frac{21}{4} = 5.25$. Admissibility on a block requires $\Lambda_3[F_{\Delta,\ell}] \geq c\,\Lambda_1[F_{\Delta,\ell}]$, hence (every block having $\Lambda_1 > 0$) $c \leq \Lambda_3[F_{\Delta,\ell}]/\Lambda_1[F_{\Delta,\ell}]$. An admissible functional exists precisely when the window

$$\frac{21}{4} \;<\; c \;\leq\; \min_{(\Delta,\ell)\in S(\Delta_0)} \frac{\Lambda_3[F_{\Delta,\ell}]}{\Lambda_1[F_{\Delta,\ell}]} \tag{50.28}$$

is nonempty. The minimizing ratio is attained by the scalar at the bottom of the gap, and the optimum Δ_0^* of Theorem 50.11 is the value at which this ratio first equals the identity ratio $\frac{21}{4}$ — exactly the tangency condition, the optimal α touching zero on the threshold scalar. Solving $\Lambda_3[F_{\Delta_0,0}]/\Lambda_1[F_{\Delta_0,0}] = \frac{21}{4}$ with the explicit $d=2$ blocks gives

$$\Delta_0^*\big(\Delta_\phi = \tfrac{1}{8}\big) = 1.2826 \qquad (d=2,\ \text{two derivatives}), \tag{50.29}$$

the sharp two-derivative optimum refining the feasibility estimate $\Delta_0 \lesssim 1.28$ of Theorem 49.23. The two-dimensional Ising model has $\Delta_\varepsilon = 1 < 1.2826$, as a genuine CFT must. The point to register is structural: the bound is not the value at which we happened to find a functional, but the value at which the *best* functional becomes marginal, and that marginality is a tangency that simultaneously certifies the bound and names the spectrum that saturates it.

50.2.3 Monotonicity: more assumptions, smaller region

Bootstrap bounds are useful only because they behave predictably under the addition of information. The governing fact, already used inside the proof of Theorem 50.11, deserves to be isolated, because it is what guarantees that imposing physical inputs — a gap, an isolated operator, a second correlator — can never enlarge the space of allowed theories.

Theorem 50.12 (Monotonicity of exclusion)**.** *Let S and S' be two candidate spectra for the same external dimension Δ_ϕ with $S \subseteq S'$. Then:*

(i) *Every functional admissible for S' is admissible for S. Consequently, if S' is excludable (admits an admissible functional) then so is S.*

(ii) *The set of conformal data consistent with crossing under the assumption "the spectrum lies in S" is contained in the set consistent under "the spectrum lies in S'."*

In particular, strengthening any assumption — raising a gap, removing operators, adding a selection rule, or imposing the existence of a specified operator — can only shrink the allowed region, and the optimal bounds it produces are at least as tight.

Proof. (i) Admissibility for S' requires $\alpha[F_{0,0}] > 0$ and $\alpha[F_{\Delta,\ell}] \geq 0$ for every $(\Delta, \ell) \in S'$. Since $S \subseteq S'$, the same α satisfies the positivity condition on the smaller index set S as well, and the identity condition is unchanged; hence α is admissible for S. The implication "S' excludable $\Rightarrow$ S excludable" is the contrapositive direction one wants: a certificate against the larger spectrum is automatically a certificate against the smaller one.

(ii) A solution of crossing whose non-identity spectrum lies in S is, in particular, a solution whose spectrum lies in $S' \supseteq S$; so the set of S-consistent data is a subset of the S'-consistent data. Equivalently, by part (i), any region of data-space that an S'-certificate excludes is also excluded by viewing it as an S-problem, so the S-allowed region is the smaller. □

Two consequences organize everything that follows. First, *the bound improves monotonically with computational effort.* Enlarging the derivative basis in Eq. (50.23) enlarges the space of candidate functionals α; since a larger search can only find more certificates, the excluded region grows and the bounds tighten, never loosen, as the truncation order Λ increases. The true allowed region is the intersection over all Λ, approached from outside. This is why bootstrap exclusions are quoted as conservative outer bounds that converge downward, and why the $d = 2$ two-derivative gap Eq. (50.29) sat above the exact Ising value and tightened toward it as derivatives were added. Second, *physical inputs are monotone.* Assuming a gap in a sector, declaring an operator isolated, or — the decisive step in the showcase — coupling several correlators that share OPE data, each restricts the candidate spectrum or adds constraints, and by Theorem 50.12 each can only contract the allowed region. The closing of the open single-correlator wedge of Fig. 49.7 into a compact island when the mixed-correlator system is imposed is precisely this principle in action: more equations, sharing more data, is a smaller S (more constraints), hence a smaller region.

Physical Insight

Monotonicity is what makes the bootstrap a *measurement*, not a fit. A fit can wander when one adds data; a bootstrap region can only shrink. Each physical assumption one is willing to make — the number of relevant operators, the global symmetry, the presence of a conserved current — is a knob that tightens the island, and one knows in advance the tightening is honest because removing possibilities cannot create new allowed theories. The art is to add only assumptions one genuinely believes, since the resulting bound is a theorem *conditional* on them.

50.2.4 Bounds on OPE coefficients

The same machinery bounds an individual OPE coefficient. Single out an operator $\mathcal{O}_\star$ of fixed quantum numbers $(\Delta_\star, \ell_\star)$ that the theory is assumed to contain, and ask how large or how small its squared coefficient $p_\star = C^2_{\phi\phi\mathcal{O}_\star}$ can be. Apply a functional α to the sum rule and isolate the chosen term, as in Eq. (49.104):

$$p_\star\, \alpha[F_{\Delta_\star,\ell_\star}] \;=\; -\,\alpha[F_{0,0}] \;-\; \sum_{\mathcal{O}\neq\mathbf{1},\mathcal{O}_\star} p_{\mathcal{O}}\, \alpha[F_{\Delta_{\mathcal{O}},\ell_{\mathcal{O}}}]. \tag{50.30}$$

The remaining operators $\mathcal{O} \neq \mathbf{1}, \mathcal{O}_\star$ range over the admissible spectrum (all even-spin unitary operators allowed by whatever gaps are assumed), with unknown nonnegative weights $p_{\mathcal{O}}$. Choosing the sign of α on those operators converts Eq. (50.30) into a one-sided inequality.

Theorem 50.13 (Two-sided OPE-coefficient bounds)**.** *Fix Δ_ϕ, a candidate spectrum, and a target operator $\mathcal{O}_\star$ in it.*

(i) (Upper bound.) *If α satisfies the normalization $\alpha[F_{\Delta_\star,\ell_\star}] = 1$ and the positivity $\alpha[F_{\Delta,\ell}] \geq 0$ for every admissible operator other than $\mathbf{1}$ and $\mathcal{O}_\star$, then in any unitary crossing-symmetric CFT of the assumed type*

$$p_\star \;\leq\; -\,\alpha[F_{0,0}]. \tag{50.31}$$

Minimizing $-\alpha[F_{0,0}]$ over all such α is a linear program whose optimum is the tightest upper bound the method proves.

(ii) (Lower bound.) *If α satisfies $\alpha[F_{\Delta_\star,\ell_\star}] = 1$ and the reversed positivity $\alpha[F_{\Delta,\ell}] \leq 0$ for every admissible operator other than $\mathbf{1}$ and $\mathcal{O}_\star$, then*

$$p_\star \;\geq\; -\,\alpha[F_{0,0}]. \tag{50.32}$$

Maximizing $-\alpha[F_{0,0}]$ over all such α is the tightest lower bound the method proves.

Proof. *(i)* With $\alpha[F_{\Delta_\star,\ell_\star}] = 1$ the left side of Eq. (50.30) is $p_\star$. On the right, every term of the sum is a product $p_{\mathcal{O}}\,\alpha[F_{\Delta_{\mathcal{O}},\ell_{\mathcal{O}}}]$ of two nonnegative numbers — $p_{\mathcal{O}} \geq 0$ by unitarity, $\alpha[F_{\Delta_{\mathcal{O}},\ell_{\mathcal{O}}}] \geq 0$ by hypothesis — so the sum is ≥ 0 and is subtracted; hence $p_\star \leq -\alpha[F_{0,0}]$. The bound is valid for any admissible α, and since the left side is fixed while the right depends on α, the smallest attainable value of $-\alpha[F_{0,0}]$ subject to the constraints is the sharpest bound. The constraints (one normalization equality, a continuum of inequalities) and the linear objective make this a semi-infinite linear program.

(ii) Now each term $p_{\mathcal{O}}\,\alpha[F_{\Delta_{\mathcal{O}},\ell_{\mathcal{O}}}]$ is a nonnegative weight times a nonpositive functional value, hence ≤ 0; subtracting a quantity ≤ 0 adds a quantity ≥ 0, so the right side of Eq. (50.30) is $\geq -\alpha[F_{0,0}]$, giving $p_\star \geq -\alpha[F_{0,0}]$. Maximizing $-\alpha[F_{0,0}]$ over admissible α gives the tightest lower bound. □

The structure is uniform with the gap bound: a bound is the optimum of a linear program over the cone of functionals, and which quantity is bounded is selected by what is placed in the objective and how the normalization is fixed. There is one asymmetry between the two directions worth flagging. The upper bound Eq. (50.31) is essentially always nontrivial: requiring positivity on the rest of the spectrum and reading off the identity is the same separation as before. The lower bound Eq. (50.32) is nontrivial — strictly positive — only when the target operator is *isolated*, that is, when the assumed spectrum has gaps separating $\mathcal{O}_\star$ from its neighbours, so that the contribution of $\mathcal{O}_\star$ cannot be mimicked by a nearby continuum and crossing genuinely *requires* a minimal amount of it. Without such isolation the best provable lower bound is zero: a unitary solution can always let $p_\star \to 0$ by reshuffling weight onto operators arbitrarily close to $\mathcal{O}_\star$. This is the OPE-coefficient avatar of the same physics that makes the dimension bound one-sided: positivity alone caps coefficients from above for free, but pins them from below only against a backdrop of assumed structure.

50.2.5 A two-sided OPE bound computed by hand

The foundations chapter extracted a dimension bound by hand at this same $d = 2$ Ising point (Theorem 49.23). We now extract the complementary number — a rigorous interval for an OPE coefficient — in the same solvable laboratory, so that both halves of the linear-functional method have been seen to produce actual numbers before any computer is invoked. We work again with $\langle\sigma\sigma\sigma\sigma\rangle$ in $d = 2$ at $\Delta_\phi = \frac{1}{8}$, the spin field of the two-dimensional Ising model, whose exact data we know independently from the free-fermion solution of Chapter 48: the lightest $\mathbb{Z}_2$-even scalar is the energy operator ε at $\Delta_\varepsilon = 1$, appearing with $\lambda_{\sigma\sigma\varepsilon} = \frac{1}{2}$, so that $p_\varepsilon = \lambda^2_{\sigma\sigma\varepsilon} = \frac{1}{4}$. The bootstrap does not know this number; we will bracket it from above and below using only crossing and positivity, then check that the exact value lands inside.

Worked Example 50.14 (A rigorous interval for $\lambda^2_{\sigma\sigma\varepsilon}$ in the $2d$ Ising correlator)**.** The target is $\mathcal{O}_\star = \varepsilon$, the scalar at $(\Delta_\star, \ell_\star) = (1, 0)$. We reuse the exact diagonal block data assembled in Table 49.2, the entries of which are the values of the two basis functionals $\Lambda_1 = \partial_z F(z,z)|_{1/2}$ and $\Lambda_3 = \partial_z^3 F(z,z)|_{1/2}$ of Eq. (49.113) on each convolved block. The two vectors we need are

$$(\Lambda_1, \Lambda_3)[F_{0,0}] = (-0.840896,\ -4.414706), \qquad (\Lambda_1, \Lambda_3)[F_{1,0}] = (\ \ 2.827973,\ \ \ 8.413183), \tag{50.33}$$

the first the identity, the second the target ε; the assumed spectrum is the identity, ε at $\Delta = 1$, the next $\mathbb{Z}_2$-even scalar at $\Delta \geq 2$ (the actual gap is to $\Delta_{\varepsilon'} = 4$, but $\Delta \geq 2$ already suffices and we will see the bound is insensitive to its precise location), and the even-spin tower $\ell \geq 2$ with $\Delta \geq \ell$ (the $d = 2$ unitarity floor).

Step 1: the upper bound from a single derivative. The simplest possible functional is $\alpha = \Lambda_1$ alone — one derivative. Its admissibility for the OPE upper bound (Theorem 50.13 (i)) requires $\Lambda_1[F_{\Delta,\ell}] \geq 0$ on every operator other than $\mathbf{1}$ and ε. This positivity holds throughout the unitary region above the gap: evaluating the diagonal first derivative on the explicit $d = 2$ blocks gives $\Lambda_1[F_{\Delta,0}] > 0$ for every scalar $\Delta \geq 1$ and $\Lambda_1[F_{\Delta,\ell}] > 0$ for every even-spin operator with $\Delta \geq \ell \geq 2$ — the value decreases monotonically toward zero as $\Delta \to \infty$ in each spin but never changes sign — while on the identity it is negative, $\Lambda_1[F_{0,0}] = -0.840896 < 0$. Thus Λ_1 is a valid certificate: it is nonnegative on the entire admissible spectrum and negative on the identity, the exact pattern Theorem 50.13 (i) demands. Normalizing on the target, $\alpha = \Lambda_1 / \Lambda_1[F_{1,0}]$ so that $\alpha[F_{1,0}] = 1$, the upper bound Eq. (50.31) reads

$$p_\varepsilon \ \leq\ -\alpha[F_{0,0}] \ =\ \frac{-\Lambda_1[F_{0,0}]}{\Lambda_1[F_{1,0}]} \ =\ \frac{0.840896}{2.827973} \ =\ 0.29735. \tag{50.34}$$

A single derivative, evaluated on two blocks, already proves that no unitary $2d$ CFT with a dimension-$\frac{1}{8}$ scalar can have $\lambda^2_{\sigma\sigma\varepsilon}$ exceeding 0.297.

Step 2: the lower bound from two derivatives. For a lower bound (Theorem 50.13 (ii)) we need a functional that is *nonpositive* on the rest of the spectrum while equal to one on ε, and we maximize $-\alpha[F_{0,0}]$. A single derivative cannot do this: Λ_1 is positive on both ε and the rest, so no rescaling makes it ≤ 0 on the rest and $+1$ on ε. Two derivatives suffice. Write $\alpha = a_1\Lambda_1 + a_3\Lambda_3$ and impose $\alpha[F_{1,0}] = 1$, i.e. $2.827973\, a_1 + 8.413183\, a_3 = 1$, leaving a one-parameter family. The constraint $\alpha[F_{\Delta,\ell}] \leq 0$ on every other operator is, for each, a half-line in that parameter; their intersection is the feasible segment, and the objective $-\alpha[F_{0,0}] = 0.840896\, a_1 + 4.414706\, a_3$ is linear, so its maximum sits at an endpoint of the segment where one further operator's constraint becomes active. Carrying out the intersection over the gapped scalar channel and the spin tower (the binding constraints are the near-threshold spinning operators and the gap scalar, the high-dimension tail being harmless because the blocks decay), the optimum

is attained at $(a_1, a_3) \simeq (0.4379, -0.02835)$, giving

$$p_\varepsilon \;\geq\; -\alpha[F_{0,0}] \;=\; 0.24312. \tag{50.35}$$

That this lower bound is strictly positive is the statement that the gapped spectrum genuinely *needs* the energy operator: crossing cannot be solved with ε's coefficient driven to zero once a gap is assumed above it, because the identity's contribution to the sum rule must be balanced and only ε is available low enough to do so.

Step 3: the interval and the check. Combining Eqs. (50.34) and (50.35), the linear-functional method at two derivatives proves, for every unitary crossing-symmetric $2d$ CFT with a scalar of dimension $\frac{1}{8}$ whose self-OPE has the assumed gap structure,

$$\boxed{0.243 \;\leq\; \lambda^2_{\sigma\sigma\varepsilon} \;\leq\; 0.297} \qquad (d = 2,\ \Delta_\phi = \tfrac{1}{8},\ \text{two derivatives}). \tag{50.36}$$

The exact two-dimensional Ising value $\lambda^2_{\sigma\sigma\varepsilon} = \frac{1}{4} = 0.250$ lies inside this interval, as it must, since the Ising CFT is a genuine unitary solution of crossing and therefore obeys every consequence of Theorem 50.13. Figure 50.2 displays the geometry: in the plane of the two functional values (Λ_1, Λ_3), the block vectors of the admissible spectrum all lie in the half-plane $\Lambda_1 \geq 0$, the identity vector lies opposite, and the upper-bound functional is essentially the vertical separator $\Lambda_1 = 0$ that places the identity alone on the negative side.

Step 4: why the bound is loose, and how it tightens. The interval Eq. (50.36) is honest but wide because two derivatives is a coarse instrument; the constraint $\alpha[F_{\Delta,\ell}] \gtrsim 0$ has been imposed only through the first and third diagonal Taylor coefficients of each block at the crossing point. By Theorem 50.12 and the monotone-improvement principle, enlarging the derivative basis can only shrink the interval. Adding the next surviving diagonal and off-diagonal derivatives drives both ends toward the Ising value, the upper bound descending and the lower bound rising, until at the derivative orders reached in the semidefinite computation of Section 50.3 the interval closes around 0.250 to many digits — the same convergence the dimension bound exhibited in passing from Eq. (50.29) toward $\Delta_\varepsilon = 1$. The lesson is the one the whole method turns on: a hand computation already *brackets* the exact answer rigorously, and machinery only narrows the bracket.

Physical Insight

The two worked numbers — the dimension bound Eq. (50.29) and the coefficient interval Eq. (50.36) — are the same algorithm pointed at different unknowns. In both, crossing is a demand that a fixed vector lie in a cone; in both, a functional that is nonnegative on the cone yet of definite

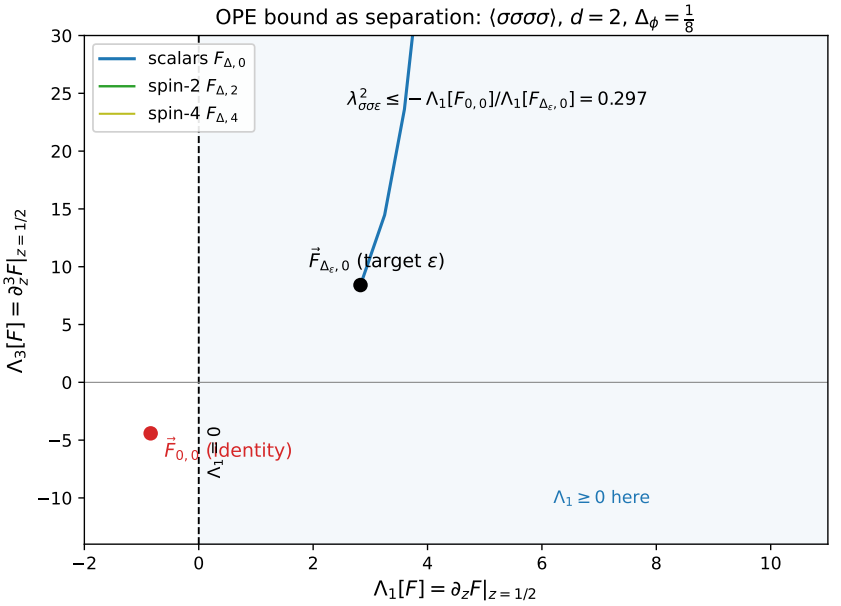

Figure 50.2: The OPE-coefficient bound as a separation, drawn in the real plane of the two diagonal functionals (Λ_1, Λ_3) for $\langle\sigma\sigma\sigma\sigma\rangle$ in $d = 2$ at $\Delta_\phi = \frac{1}{8}$ (Theorem 50.14). The blue, green, and olive curves are the trajectories of the convolved-block vectors $\vec{F}_{\Delta,\ell}$ as the dimension Δ runs over the scalar, spin-2, and spin-4 channels; every admissible block has $\Lambda_1 = \partial_z F|_{1/2} > 0$, so the whole spectrum lies in the right half-plane. The identity vector $\vec{F}_{0,0}$ (red) lies in the left half-plane. The single-derivative functional $\alpha = \Lambda_1$, whose zero-set is the dashed vertical line $\Lambda_1 = 0$, therefore separates the identity from the entire spectrum and certifies the upper bound $\lambda^2_{\sigma\sigma\varepsilon} \le -\Lambda_1[F_{0,0}]/\Lambda_1[F_{\Delta_\varepsilon,0}] = 0.297$ of Eq. (50.34). The target operator ε at $(\Delta, \ell) = (1, 0)$ is marked.

sign on the identity is a certificate; in both, the optimal certificate touches zero on an extremal spectrum and that spectrum is the theory saturating the bound. The only difference is bookkeeping: for a dimension bound we sweep the gap and ask when a certificate first exists; for a coefficient bound we fix the gap, normalize on the target, and optimize the identity's image. That a single derivative and a sign already corner the energy operator of the Ising model between 0.24 and 0.30 is the whole conceptual payload of the bootstrap, visible before any large computation.

We have now turned the separation principle into its two working algorithms and proved that each computes the genuine optimum of a linear program over functionals: the dimension bound is the threshold at which the optimal certificate

becomes marginal (Theorem 50.11), the coefficient bounds are the extrema of the identity's image under normalized certificates (Theorem 50.13), and both tighten monotonically as the functional basis grows (Theorem 50.12). What remains is the obstruction that kept the worked examples small. Each bound is the optimum of a *semi-infinite* linear program: finitely many unknown coefficients a_{mn}, but a continuum of positivity constraints $\alpha[F_{\Delta,\ell}] \geq 0$ indexed by the dimension Δ over a half-line in every spin ℓ. By hand we could only enforce that continuum through a one-parameter scan; a realistic functional with hundreds of components meets a continuum it cannot scan. The next section removes this obstruction, showing how expanding the blocks in a radial coordinate, truncating to a finite derivative basis, and approximating the blocks by polynomials in Δ converts "a functional positive over a continuum of dimensions in each spin" into the positive-semidefiniteness of finitely many matrices — the reduction of the semi-infinite program to a finite semidefinite program, with the duality that keeps the bounds rigorous.

50.3 From Functionals to Semidefinite Programs

The previous section turned the separation principle into two concrete recipes — maximize a gap, bound an OPE coefficient — and ran a toy functional by hand to produce an honest number. But the object that recipe asks us to find is not yet something a computer can search for. Theorem 49.21 demands a linear functional α that is nonnegative on *every* convolved block $\widehat{F}_{\Delta,\ell}$ in a candidate spectrum, and a candidate spectrum is a continuum: for each even spin ℓ the dimension Δ ranges over an entire half-line $[\Delta_\ell^{\text{unit}}, \infty)$, and the spin itself runs over the infinite set $\ell = 0, 2, 4, \ldots$. The search is therefore over finitely many functional coefficients a_{mn} subject to *infinitely many* linear inequalities — one per point of an infinite-dimensional index set. This is a *semi-infinite program*, and a brute-force scan over a grid of (Δ, ℓ) can only ever sample the constraints, never prove them. A sampled functional that happens to be positive at a thousand test points may dip below zero between them, and then the "exclusion" it certifies is a fiction.

This section removes the gap between a numerically plausible functional and a genuine theorem. The route has four reductions, and each is a finite, controlled approximation of an infinite object:

1. *Finitely many derivatives.* A functional is a finite combination of Taylor derivatives of the crossing equation at the symmetric point $z = \bar{z} = \frac{1}{2}$. We bound the truncation error using the geometric convergence of the radial expansion (Theorem 49.12), so a finite derivative basis is provably enough.

2. *Finitely many spins.* The contributions of high-spin operators at the symmetric point are exponentially suppressed in the twist, so the spin sum

can be cut at a finite L with a controlled remainder.

3. *Rational blocks in* Δ. The blocks are meromorphic in the exchanged dimension, with all poles below the unitarity bound; approximating each derivative component by a positive prefactor times a polynomial in Δ turns the half-line of constraints in each spin into the nonnegativity of one univariate polynomial.

4. *Polynomials to matrices.* A univariate polynomial nonnegative on a half-line is a sum of squares with positive-semidefinite Gram matrices (Markov–Lukács). The functional search becomes a *semidefinite program*.

The pipeline is drawn in Fig. 50.3. What makes the endpoint a theorem rather than a numerical impression is convex duality: any *dual-feasible* point of the semidefinite program yields a rigorous bound regardless of how the solver behaves, and a feasible point can be certified exactly in rational arithmetic. We close by making that precise — a proof of weak duality and an account of how the solver SDPB and interval arithmetic convert a floating-point functional into a genuine proof.

50.3.1 The semi-infinite program

We start by writing the inherited problem with no slack. Fix the external dimension Δ_ϕ and a candidate spectrum S — a closed subset of the half-lines

$$\mathcal{U} \;=\; \bigcup_{\ell=0,2,4,\dots} \{\ell\} \times [\Delta_\ell^{\text{unit}}, \infty), \qquad \Delta_\ell^{\text{unit}} = \begin{cases} \frac{d-2}{2}, & \ell = 0, \\ \ell + d - 2, & \ell \geq 1, \end{cases} \tag{50.37}$$

the unitarity region of Eq. (49.81). By Theorem 49.21, S is excluded if we can exhibit a linear functional α of the form Eq. (49.98),

$$\alpha[f] \;=\; \sum_{m,n} a_{mn}\, \partial_z^m \partial_{\bar z}^n f(z,\bar z)\Big|_{z=\bar z=1/2}, \qquad a_{mn} \in \mathbb{R}, \tag{50.38}$$

satisfying the admissibility conditions of Theorem 49.21: $\alpha[F_{0,0}] > 0$ and $\alpha[F_{\Delta,\ell}] \geq 0$ for every $(\Delta,\ell) \in S$. Equivalently, in the normalized variables, divide through by the identity contribution and pose the search on the F-vector $\widehat{F}_{\Delta,\ell}$ of Eq. (49.79). We work with $\widehat{F}$ throughout, since $\widehat{F}_{0,0} = 1$ makes the normalization $\alpha[\,1\,] = 1$ a single linear equation and the remaining constraints homogeneous.

Two infinities obstruct a direct search.

Infinitely many variables. The functional Eq. (50.38) is a combination of *all* derivatives. We will keep only those of total order $m + n \leq \Lambda$; the number

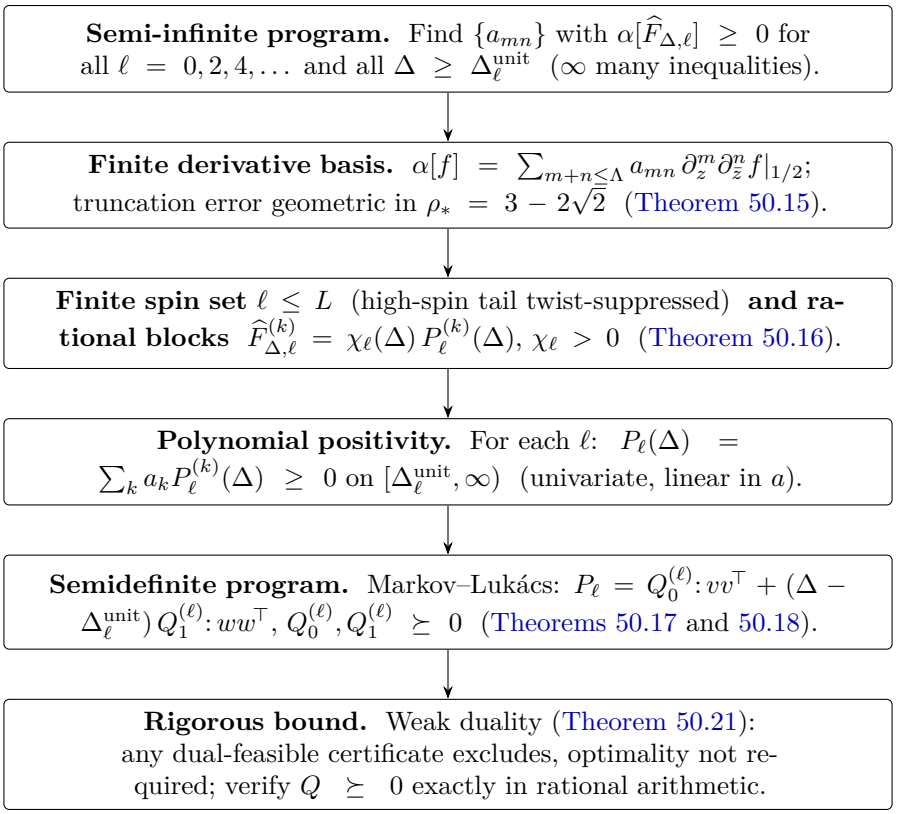

Figure 50.3: The reduction of the semi-infinite functional search to a finite semidefinite program. Each arrow is a controlled, finite approximation of an infinite object; the final arrow is convex duality, which is what makes the machine produce theorems rather than numerical impressions.

of free coefficients is then finite, $N_\Lambda = \frac{1}{2}(\Lambda+1)(\Lambda+2)$ before symmetry reduction. The cost is that we search a finite-dimensional slice of the space of functionals; Section 50.3.2 shows this slice is rich enough that its error is geometrically small, and the *caution* after Theorem 49.21 already records the logical consequence: a finite basis yields a rigorous outer bound that tightens monotonically as Λ grows.

Infinitely many constraints. Even with Λ fixed, the conditions $\alpha[\widehat{F}_{\Delta,\ell}] \geq 0$ form a continuum indexed by $(\Delta, \ell) \in S$. This is the genuinely hard infinity, and the one a grid scan cannot honestly resolve. Removing it is the technical heart of the section: Sections 50.3.3 to 50.3.5 replace the continuum of point constraints in each spin by a *single* matrix inequality.

It is worth saying once, plainly, why the second infinity is the dangerous one. The function $\Delta \mapsto \alpha[\widehat{F}_{\Delta,\ell}]$ is, for fixed ℓ and a finite functional, an explicit but

complicated transcendental function of Δ. Demanding it stay nonnegative on a half-line is a statement about uncountably many values, and no finite sample establishes it. The entire reduction below exists to recast that statement in a form — the nonnegativity of a polynomial, hence the positive-semidefiniteness of a matrix — whose truth is decidable by a finite, exact computation.

50.3.2 The derivative basis and the radial acceleration

Why expand at $z = \bar{z} = \frac{1}{2}$, and why is a finite number of derivatives enough? The answer to both is the radial coordinate of Eq. (49.61),

$$\rho(z) = \frac{z}{\left(1 + \sqrt{1 - z}\right)^2}, \qquad z = \frac{4\rho}{(1+\rho)^2}, \tag{50.39}$$

which maps the cut z-plane biholomorphically onto the open unit disk and sends the crossing-symmetric point to $\rho_* = \rho(\frac{1}{2}) = 3 - 2\sqrt{2} \approx 0.1716$, deep inside. In the radial frame a conformal block is the convergent power series Eq. (49.63),

$$G_{\Delta,\ell}(r,\eta) = \sum_{n=0}^{\infty} \sum_{j} B_{n,j}^{(\Delta,\ell)}\, r^{\Delta+n}\, C_j^{(\nu)}(\eta), \qquad \rho = re^{i\theta},\ \eta = \cos\theta,\ \nu = \tfrac{d-2}{2}, \tag{50.40}$$

and Theorem 49.12 guarantees convergence for $r < 1$. At the symmetric point $\bar{z} = z^* = \frac{1}{2}$ the radial pair is real, $\rho = \bar{\rho} = \rho_*$, $\eta = 1$, $\theta = 0$. The crossing equation must be imposed somewhere, and the symmetric point is the natural choice because it is the fixed point of the crossing reflection and because it is the point of *fastest* convergence: every block, of every dimension and spin, is there a power series in a number of modulus 0.17.

Symmetry reduces the basis. The convolved block $F_{\Delta,\ell}$ is antisymmetric under $u \leftrightarrow v$ (Theorem 49.15), i.e. under $(z,\bar{z}) \mapsto (1-z, 1-\bar{z})$, and the normalized $\widehat{F}_{\Delta,\ell}$ is symmetric. The symmetric point $z = \bar{z} = \frac{1}{2}$ is the fixed point of the reflection $z \mapsto 1 - z$. Introduce the centered variables $a = z - \frac{1}{2}$, $b = \bar{z} - \frac{1}{2}$. Under crossing $(a,b) \mapsto (-a,-b)$. A symmetric function $\widehat{F}$ then has a Taylor series in even total powers of (a,b) only, while the antisymmetric F has only odd ones. Moreover $\widehat{F}$ is symmetric in $z \leftrightarrow \bar{z}$ (it depends on the unordered pair), so it is invariant under $a \leftrightarrow b$. Both symmetries cut the derivative basis: the independent derivatives of $F_{\Delta,\ell}$ at the symmetric point are

$$\partial_a^m \partial_b^n F_{\Delta,\ell}\big|_{a=b=0}, \qquad m+n \text{ odd}, \quad m \geq n, \tag{50.41}$$

since even-order derivatives of an odd function vanish at the fixed point, and $m \leftrightarrow n$ gives the same number by $z \leftrightarrow \bar{z}$ symmetry. (Working with F rather than $\widehat{F}$ is a convention; the two are related by the fixed kinematic factor $F_{0,0} = v^{\Delta_\phi} - u^{\Delta_\phi}$, itself an odd function, so the derivative data carry the same information.)

Truncating at total order $m+n \le \Lambda$ leaves a finite list; we collect the surviving derivatives into a vector

$$\vec{F}^{(\Lambda)}_{\Delta,\ell} \;=\; \Big(\partial_a^m \partial_b^n F_{\Delta,\ell}\big|_0 \;:\; m+n \le \Lambda,\; m+n \text{ odd},\; m \ge n \Big), \tag{50.42}$$

and a functional in this basis is a real covector $\vec{a}$ acting by the dot product $\alpha[F_{\Delta,\ell}] = \vec{a} \cdot \vec{F}^{(\Lambda)}_{\Delta,\ell}$. The integer Λ (or the count of components, often written $N_{\max}$ in the literature) is the single knob that controls the precision of the whole computation.

Why truncation is safe. It remains to show that discarding the high-order derivatives is a controlled error, not a leap of faith. The mechanism is that the block, viewed as a function of ρ at the symmetric configuration, is analytic on a disk strictly larger than $|\rho| = \rho_*$, so its Taylor coefficients — the derivatives we are truncating — decay geometrically. We make this quantitative.

Theorem 50.15 (Geometric control of the derivative truncation)**.** *Fix a spin ℓ and a dimension $\Delta \ge \Delta_\ell^{\text{unit}}$. Regard the block restricted to the diagonal as a function $g(\rho) \equiv G_{\Delta,\ell}(z(\rho), z(\rho))$ of the single radial variable. Then g is holomorphic on the disk $|\rho| < 1$, and for any radius $\rho_* < r_1 < 1$ its Taylor coefficients about $\rho = \rho_*$ obey the Cauchy bound*

$$\left| \frac{1}{m!} \frac{d^m g}{d\rho^m}\Big|_{\rho_*} \right| \;\le\; \frac{M(r_1)}{(r_1 - \rho_*)^m}, \qquad M(r_1) = \max_{|\rho-\rho_*| = r_1 - \rho_*} |g(\rho)| < \infty, \tag{50.43}$$

so that the remainder of the order-Λ Taylor expansion of g at the symmetric point, evaluated at any ρ with $|\rho - \rho_*| \le \delta < r_1 - \rho_*$, is bounded by

$$\big|\, g(\rho) - T_\Lambda g(\rho) \,\big| \;\le\; M(r_1)\, \frac{(\delta/(r_1-\rho_*))^{\Lambda+1}}{1 - \delta/(r_1-\rho_*)}. \tag{50.44}$$

The bound decays geometrically in Λ with ratio $\delta/(r_1-\rho_*) < 1$, uniformly in Δ for Δ in any compact set and (after dividing by the leading $(4\rho_*)^\Delta$) uniformly down the entire half-line.

Proof. By Theorem 49.12 the series Eq. (50.40) converges absolutely for $|\rho| < 1$, uniformly on compact subsets; a uniformly convergent series of holomorphic functions is holomorphic, so g is holomorphic on $|\rho| < 1$. The boundary $|\rho| = 1$ is the image of the crossed-channel singularity at $z = 1$ (Fig. 49.2); inside the disk g has no singularities. Choose r_1 with $\rho_* < r_1 < 1$ and let γ be the circle $|\rho - \rho_*| = r_1 - \rho_*$, which lies inside the unit disk because its farthest point from the origin is at distance $\rho_* + (r_1 - \rho_*) = r_1 < 1$. By the Cauchy integral formula for derivatives — the differentiated form of Theorem 5.23 applied to the holomorphic g —

$$\frac{1}{m!} \frac{d^m g}{d\rho^m}\Big|_{\rho_*} = \frac{1}{2\pi i} \oint_\gamma \frac{g(\rho)\, d\rho}{(\rho - \rho_*)^{m+1}}, \tag{50.45}$$

and bounding the integrand by its maximum modulus $M(r_1)$ over $|\rho-\rho_*|^{m+1} = (r_1-\rho_*)^{m+1}$ times the circumference $2\pi(r_1-\rho_*)$ gives Eq. (50.43). The Taylor remainder is the tail $\sum_{m>\Lambda} c_m(\rho-\rho_*)^m$ with $|c_m| \le M(r_1)(r_1-\rho_*)^{-m}$; summing the geometric majorant from $m=\Lambda+1$ yields Eq. (50.44). Finally, the leading behavior $g(\rho)\sim(4\rho)^\Delta$ from Eq. (49.64) shows that the only Δ-dependence of $M(r_1)$ that grows with Δ is the overall factor $(4r_1)^\Delta$; dividing the block by its leading power $(4\rho_*)^\Delta$ replaces this by $(r_1/\rho_*)^\Delta$ on the contour, which is bounded once r_1 is fixed below 1 and Δ is bounded, and the high-Δ tail is in any case suppressed by the spin and twist counting of Section 50.3.3. The ratio governing the decay, $\delta/(r_1-\rho_*)$, is independent of Δ. □

The content of Theorem 50.15 is the precise sense in which a finite derivative basis "sees" the whole crossing equation. The crossing equation is a statement about $\widehat{F}$ on a neighborhood of the symmetric point; truncating at order Λ replaces $\widehat{F}$ by its Taylor polynomial, and Eq. (50.44) shows the discarded part is smaller than $(\delta/(r_1-\rho_*))^{\Lambda+1}$. With $\rho_*\approx 0.17$, even a modest $r_1\approx 0.45$ gives a ratio $\delta/(r_1-\rho_*)$ well below one over the small disk the bootstrap actually probes, so the number of correct digits grows linearly in Λ. Figure 50.4 plots this for the value of the block; the slope is $-\log_{10}\rho_*\approx 0.77$ digits per term, the geometric rate inherited directly from OPE convergence (Theorem 47.48). This is the rigorous footing under the practitioner's lore that "a dozen terms give many digits."

Physical Insight: convergence is unitarity in disguise

The geometric rate $\rho_*\approx 0.17$ is not a numerical accident; it is the state-operator map (Theorem 47.42) made visible. A conformal block is a sum over the descendant states of one primary, weighted by $\rho^{\Delta+n}$ where $\Delta+n$ is the radial energy of the n-th level (Eq. (47.196)). Reflection positivity bounds the norms of those states polynomially in n, so the geometric weight ρ_*^n wins and the series converges as fast as ρ_*^n shrinks. The same positivity that lets a one-signed functional detect an inconsistency is what makes the functions that functional acts on computable to arbitrary precision. Rigor and tractability come from one source.

50.3.3 Rational approximation of the blocks in the dimension

We have reduced the functional to a finite covector $\vec{a}$ and the block to a finite derivative vector $\vec{F}^{(\Lambda)}_{\Delta,\ell}$. The constraint $\alpha[\widehat{F}_{\Delta,\ell}]\ge 0$ is now the statement that a fixed finite linear combination of the derivative components, with coefficients $\vec{a}$, is nonnegative as Δ ranges over $[\Delta_\ell^{\mathrm{unit}},\infty)$. Each derivative component is still a transcendental function of Δ. The decisive structural fact is that, in the dimension Δ at fixed spin, the block is *meromorphic* with a completely

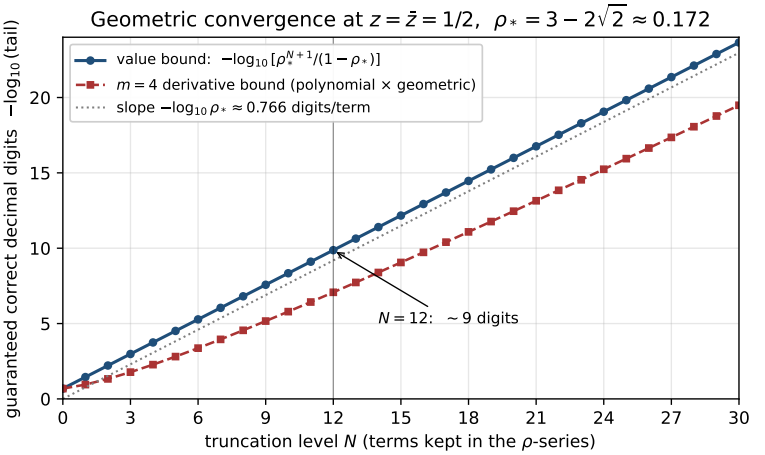

Figure 50.4: Geometric control of the radial truncation at the crossing-symmetric point. The block expansion in ρ converges on the unit disk (Theorem 49.12); the symmetric point sits at $\rho_* = 3 - 2\sqrt{2} \approx 0.172$. Truncating at level N leaves a tail bounded by $\rho_*^{N+1}/(1-\rho_*)$, so the guaranteed number of correct decimal digits grows linearly in N with slope $-\log_{10}\rho_* \approx 0.766$. Derivatives at the symmetric point (Theorem 50.15) carry only an extra polynomial-in-N prefactor and inherit the same geometric rate; the dashed curve shows a representative fourth derivative. The geometric convergence is the quantitative face of OPE convergence (Theorem 47.48).

understood pole structure, and that structure lets us replace each component by a positive prefactor times a polynomial.

Poles from null descendants. The block solves the Casimir equation Eq. (49.29); equivalently it is the resummed exchange of one primary's conformal family, $G_{\Delta,\ell} = \sum_n \rho^{\Delta+n} \times$ (norm-weighted descendant overlaps) as in Section 50.3.2. The overlaps are matrix elements normalized by the Gram (Shapovalov) matrix of the conformal multiplet at dimension Δ. That Gram matrix degenerates exactly when a descendant becomes *null* — when its norm vanishes — and the inverse Gram matrix that enters the block then develops a simple pole. The null dimensions are a discrete set determined by representation theory of $\mathfrak{so}(d+1,1)$: a level-n descendant of a spin-ℓ primary goes null at specific dimensions

$$\Delta = \Delta_i^\star(\ell) \;\in\; \left\{\, 1-\ell-k,\;\; \tfrac{d}{2}-k \;\;(k=1,2,\dots),\;\; \ell+d-1-k \;\;(k=1,\dots,\ell) \,\right\}, \tag{50.46}$$

the three families being the unitarity-violating scalars, the "mixed" series, and the would-be conserved currents; the precise list and the residues are the content of the Casimir recursion of Section 49.2.5. What matters for us are two facts,

both consequences of Theorem 5.23 applied to the analytic continuation in Δ of Section 5.4.1: the poles Eq. (50.46) all lie at dimensions *at or below* the unitarity bound $\Delta_\ell^{\text{unit}}$ (a null or negative-norm descendant is precisely a unitarity violation), and the residue at each pole is a positive multiple of a block of *shifted* dimension and spin. This is the Zamolodchikov-style recursion: the block at dimension Δ is its leading power plus a sum of poles whose residues are lower blocks,

$$G_{\Delta,\ell}(\rho,\eta) \;=\; (4\rho)^{\Delta}\Big[\, C_\ell^{(\nu)}(\eta) \;+\; \sum_i \frac{r_i(\ell)\,(4\rho)^{n_i}}{\Delta-\Delta_i^\star(\ell)}\,\widehat{G}_i(\rho,\eta)\,\Big], \qquad r_i(\ell)>0, \tag{50.47}$$

where $\widehat{G}_i$ is a block of dimension $\Delta_i^\star + n_i$ and shifted spin, and the sum over poles converges. Iterating the recursion and truncating at the same radial level N used for the derivatives gives a finite sum of poles.

Positive prefactor times polynomial. Truncate Eq. (50.47) to a finite pole set $\{\Delta_i^\star\}_{i=1}^p$ and evaluate the derivative components Eq. (50.42) at the symmetric point. Each component is then a finite sum of terms $(4\rho_*)^{\Delta+n_i}/(\Delta-\Delta_i^\star)$ with Δ-independent residues; placing them over a common denominator $\prod_i(\Delta-\Delta_i^\star)$ and factoring out the common exponential $(4\rho_*)^\Delta$ gives the representation

$$\boxed{\widehat{F}_{\Delta,\ell}^{(k)} \;=\; \chi_\ell(\Delta)\,P_\ell^{(k)}(\Delta), \qquad \chi_\ell(\Delta)=\frac{(4\rho_*)^\Delta}{\displaystyle\prod_{i=1}^{p}(\Delta-\Delta_i^\star(\ell))},} \tag{50.48}$$

where k indexes the components of the derivative vector and $P_\ell^{(k)}$ is a polynomial in Δ of degree at most p (one less than the number of poles, plus the contribution of the regular part). The exponential $(4\rho_*)^\Delta$ and the denominator are common to all components; only the polynomials $P_\ell^{(k)}$ differ.

Theorem 50.16 (Rational reduction of the positivity condition)**.** *With the representation Eq. (50.48), the prefactor $\chi_\ell(\Delta)$ is strictly positive for every $\Delta \geq \Delta_\ell^{\text{unit}}$, because $(4\rho_*)^\Delta > 0$ and every factor $\Delta-\Delta_i^\star(\ell)>0$ there, the poles lying below the unitarity bound. Consequently, for a functional $\vec{a}$ the positivity condition is equivalent to the nonnegativity of a single univariate polynomial:*

$$\alpha[\widehat{F}_{\Delta,\ell}] = \chi_\ell(\Delta)\underbrace{\sum_k a_k P_\ell^{(k)}(\Delta)}_{\equiv\; P_\ell(\Delta;\,\vec{a})} \;\geq\; 0 \quad \textit{for all } \Delta\geq\Delta_\ell^{\text{unit}} \iff P_\ell(\Delta;\vec{a})\geq 0 \textit{ on } [\Delta_\ell^{\text{unit}},\infty). \tag{50.49}$$

The polynomial $P_\ell(\Delta;\vec{a})$ is linear in the functional coefficients $\vec{a}$ and of degree $\deg P_\ell \leq p$ (a fixed integer set by the truncation order N and the spin ℓ).

Proof. That $(4\rho_*)^\Delta > 0$ is immediate. For the denominator: every null dimension in Eq. (50.46) satisfies $\Delta_i^\star(\ell) \le \Delta_\ell^{\text{unit}}$ — this is the statement that a descendant going null is a unitarity violation, so all such dimensions sit at or below the unitarity threshold, with the boundary case (a conserved current, $\Delta = \ell + d - 2$) handled by treating it as a limit. Hence for $\Delta \ge \Delta_\ell^{\text{unit}}$ each factor $\Delta - \Delta_i^\star(\ell) \ge 0$, and is strictly positive in the open half-line, so $\chi_\ell(\Delta) > 0$ there. Dividing the inequality $\chi_\ell(\Delta) P_\ell(\Delta; \vec{a}) \ge 0$ by the strictly positive χ_ℓ preserves it, giving the stated equivalence. Linearity in $\vec{a}$ holds because $P_\ell(\Delta; \vec{a}) = \sum_k a_k P_\ell^{(k)}(\Delta)$ is a linear combination of fixed polynomials with the functional coefficients as weights. □

Theorem 50.16 is the conceptual pivot of the whole section. The infinitely many point constraints in the spin-ℓ sector — one for each Δ on a half-line — have collapsed into *one* statement: a polynomial, linear in the unknowns $\vec{a}$, is nonnegative on a half-line. The transcendental dependence on Δ has been quarantined inside the positive prefactor χ_ℓ, which drops out of the inequality. The rational approximation is the only place an approximation enters the *constraint* (the derivative truncation entered the functional), and its error is controlled by the same geometric estimate Eq. (50.44): raising the radial order N adds poles and raises $\deg P_\ell$, and the omitted tail is exponentially small.

The spin sum. The spins $\ell = 0, 2, 4, \ldots$ are still infinite in number, but they are tamed by the same radial geometry. At the symmetric point, a spin-ℓ block of twist $\tau = \Delta - \ell$ contributes at leading order $(4\rho_*)^\Delta C_\ell^{(\nu)}(1)$, and the unitarity bound forces $\Delta \ge \ell + d - 2$ for $\ell \ge 1$, so the lightest contribution from spin ℓ scales as $(4\rho_*)^{\ell+d-2}$ up to the polynomial growth of the Gegenbauer value $C_\ell^{(\nu)}(1) = \binom{\ell+2\nu-1}{\ell}$. Since $4\rho_* = 4(3 - 2\sqrt{2}) \approx 0.686 < 1$, the high-spin contributions are exponentially suppressed, $\sim (0.686)^\ell$, and the spin sum may be truncated at a finite L with a remainder bounded by a geometric tail in L. (The lightcone factorization Eq. (49.67) is the analytic statement behind this suppression: large spin means large twist contribution unless the twist is held fixed, and a fixed-twist family contributes a controlled, computable tail.) One therefore imposes the polynomial-positivity constraint Eq. (50.49) for each $\ell \in \{0, 2, \ldots, L\}$ and bounds the discarded $\ell > L$ analytically. From here the spin index is finite, and we suppress it where convenient.

50.3.4 Positive polynomials on a half-line

We have arrived at the clean mathematical problem: for finitely many spins ℓ, the polynomial $P_\ell(\Delta; \vec{a})$, linear in $\vec{a}$, must be nonnegative on $[\Delta_\ell^{\text{unit}}, \infty)$. We now prove the lemma that makes this tractable: nonnegativity of a univariate polynomial on a half-line is equivalent to a sum-of-squares representation, and a sum of squares is equivalent to a positive-semidefinite Gram matrix. The two facts

together convert a positivity condition over a continuum into a finite-dimensional matrix inequality.

Lemma 50.17 (Sum of squares is positive-semidefinite Gram)**.** *Let $v_m(x) = (1, x, x^2, \dots, x^m)^\top$ be the vector of monomials up to degree m. A polynomial σ of degree $\le 2m$ is a sum of squares of polynomials, $\sigma(x) = \sum_r q_r(x)^2$ with $\deg q_r \le m$, if and only if there is a real symmetric positive-semidefinite matrix $Q \succeq 0$ of size $(m+1) \times (m+1)$ such that*

$$\sigma(x) = v_m(x)^\top Q\, v_m(x). \tag{50.50}$$

Proof. ($\Leftarrow$) If $Q \succeq 0$, diagonalize it by the spectral theorem: $Q = \sum_r \lambda_r u_r u_r^\top$ with eigenvalues $\lambda_r \ge 0$ and orthonormal eigenvectors u_r. Then

$$\sigma(x) = v_m^\top \Big(\sum_r \lambda_r u_r u_r^\top \Big) v_m = \sum_r \lambda_r \, (u_r^\top v_m)^2 = \sum_r \big(\sqrt{\lambda_r}\, u_r^\top v_m(x) \big)^2, \tag{50.51}$$

a sum of squares of the polynomials $q_r(x) = \sqrt{\lambda_r}\, u_r^\top v_m(x)$, each of degree $\le m$.

($\Rightarrow$) If $\sigma = \sum_r q_r^2$ with $\deg q_r \le m$, write the coefficient vector of each q_r in the monomial basis as $\mathbf{q}_r \in \mathbb{R}^{m+1}$, so $q_r(x) = \mathbf{q}_r^\top v_m(x)$. Then

$$\sigma(x) = \sum_r (\mathbf{q}_r^\top v_m)^2 = \sum_r v_m^\top \mathbf{q}_r \mathbf{q}_r^\top v_m = v_m^\top \Big(\underbrace{\sum_r \mathbf{q}_r \mathbf{q}_r^\top}_{Q} \Big) v_m, \tag{50.52}$$

and $Q = \sum_r \mathbf{q}_r \mathbf{q}_r^\top$ is a sum of rank-one positive-semidefinite matrices, hence symmetric and positive-semidefinite. □

The Gram matrix Q in Eq. (50.50) is not unique — distinct Q's can give the same polynomial, because the entries of $v_m v_m^\top$ along each anti-diagonal all equal the same power x^k, so only the anti-diagonal *sums* of Q are fixed by σ. This is exactly the freedom a solver exploits. The constraint that links σ's coefficients to Q is a set of linear equations (one per power of x): writing $\sigma(x) = \sum_k c_k x^k$,

$$c_k = \sum_{i+j=k} Q_{ij}, \qquad k = 0, 1, \dots, 2m, \tag{50.53}$$

the trace of Q against the constant Hankel pattern. The map $Q \mapsto \sigma$ is linear; Theorem 50.17 says its image, intersected with $Q \succeq 0$, is exactly the SOS cone.

Now the half-line. A polynomial nonnegative on all of $\mathbb{R}$ is a sum of squares (in one variable, nonnegativity is equivalent to SOS), but our constraint lives on $[\Delta_\ell^{\text{unit}}, \infty)$, not all of $\mathbb{R}$. The right statement is the classical theorem of Markov and Lukács.

Theorem 50.18 (Markov–Lukács representation on a half-line)**.** *Let p be a real polynomial with $p(x) \geq 0$ for all $x \geq a$. Then p admits the representation*

$$p(x) = \sigma_0(x) + (x - a)\,\sigma_1(x), \tag{50.54}$$

where σ_0 and σ_1 are sums of squares of polynomials. If $\deg p = 2m$ one may take $\deg \sigma_0 \leq 2m$ and $\deg \sigma_1 \leq 2m - 2$; if $\deg p = 2m + 1$ one may take $\deg \sigma_0 \leq 2m$ and $\deg \sigma_1 \leq 2m$.

Proof. By translation it suffices to treat $a = 0$: replace $p(x)$ by $\tilde{p}(y) = p(y + a)$, prove $\tilde{p}(y) = \tilde{\sigma}_0(y) + y\,\tilde{\sigma}_1(y)$ for $\tilde{p} \geq 0$ on $[0, \infty)$, and substitute back $y = x - a$. So assume $p(x) \geq 0$ for all $x \geq 0$.

Consider the set

$$\mathcal{Q} = \{\, s_0(x) + x\,s_1(x) \;:\; s_0, s_1 \text{ sums of squares} \,\}. \tag{50.55}$$

We claim $p \in \mathcal{Q}$. The proof is by factoring p over $\mathbb{C}$ and showing each factor lies in $\mathcal{Q}$, after establishing that $\mathcal{Q}$ is closed under multiplication.

$\mathcal{Q}$ is closed under products. Take $s_0 + xs_1$ and $t_0 + xt_1$ in $\mathcal{Q}$. Their product is

$$(s_0 + xs_1)(t_0 + xt_1) = \big(s_0 t_0 + x^2 s_1 t_1\big) + x\big(s_0 t_1 + s_1 t_0\big). \tag{50.56}$$

Sums of squares are closed under sums and products (if $f = \sum f_i^2$ and $g = \sum g_j^2$ then $fg = \sum_{i,j} (f_i g_j)^2$), and $x^2 s_1 t_1 = (x\sqrt{s_1 t_1}\,)^2$-type term is a square times an SOS, hence SOS; so $s_0 t_0 + x^2 s_1 t_1$ is SOS and $s_0 t_1 + s_1 t_0$ is SOS. Thus the product is again of the form $(\text{SOS}) + x(\text{SOS}) \in \mathcal{Q}$.

Each irreducible factor of p lies in $\mathcal{Q}$. Factor p over $\mathbb{C}$ into linear factors and collect conjugates:

$$p(x) = c \prod_{\text{real } \rho} (x - \rho)^{e_\rho} \prod_{\text{pairs}} \big[(x - \alpha)^2 + \beta^2\big]^{f}, \qquad c > 0, \tag{50.57}$$

the leading coefficient c being positive because $p(x) \to +\infty$ as $x \to +\infty$ (it is nonnegative on the half-line and not identically zero). We classify the factors.

- A complex-conjugate pair gives $(x - \alpha)^2 + \beta^2 = (x - \alpha)^2 + \beta^2$, manifestly a sum of two squares, hence in $\mathcal{Q}$ with $s_1 = 0$.
- A real root $\rho > 0$ must have *even* multiplicity e_ρ. Otherwise p would change sign as x crosses ρ from below to above (the remaining factors are continuous and nonzero in a neighborhood of ρ), contradicting $p \geq 0$ near $\rho > 0$. An even power $(x - \rho)^{2k} = \big((x - \rho)^k\big)^2$ is a perfect square, in $\mathcal{Q}$ with $s_1 = 0$.
- A real root $\rho \leq 0$ has no constraint on its multiplicity, but the factor $(x - \rho) = x + |\rho|$ with $|\rho| \geq 0$ is itself in $\mathcal{Q}$: write $x + |\rho| = (\sqrt{|\rho|}\,)^2 + x \cdot 1^2$, an SOS constant plus x times an SOS constant. Any power of it stays in $\mathcal{Q}$ by closure under products.

Finally the positive constant $c = (\sqrt{c})^2 \in \mathcal{Q}$. Therefore p is a product of finitely many elements of $\mathcal{Q}$ times a positive constant, and by closure under products $p \in \mathcal{Q}$, which is Eq. (50.54) with $a = 0$.

Degrees. Track the total degree through Eq. (50.56). If $\deg p = 2m$, the $x\,\sigma_1$ part has odd degree $\le 2m-1$, forcing $\deg \sigma_1 \le 2m-2$ (it is itself SOS, hence of even degree), and $\deg \sigma_0 \le 2m$. If $\deg p = 2m+1$, the leading term is odd and must come from $x\,\sigma_1$, so $\deg(x\sigma_1) = 2m+1$, i.e. $\deg \sigma_1 = 2m$, while σ_0 has degree $\le 2m$. These are the stated bounds. □

Caution

The single product $(x-a)$ in Eq. (50.54) is exactly enough for a *half-line*, and no more is needed; this is special to one variable and to one linear constraint. On an interval $[a,b]$ one needs the two products $(x-a)$ and $(b-x)$, and in more than one variable (which is where mixed-correlator bootstraps with continuous parameters can land) Putinar's theorem replaces the elementary factorization above and the degree bounds are no longer automatic. The single-correlator bootstrap of the next section lives entirely in the half-line case, where Markov–Lukács is sharp and the SDP is exact at fixed truncation.

50.3.5 The positivity-to-semidefiniteness dictionary and the SDP

Assembling Theorems 50.16 to 50.18 gives the dictionary in full. The functional-search problem "find $\vec{a}$ with $P_\ell(\Delta;\vec{a}) \ge 0$ on $[\Delta_\ell^{\text{unit}}, \infty)$ for each $\ell \le L$" becomes, term by term:

> *Find a covector $\vec{a}$ and, for each spin $\ell \in \{0, 2, \dots, L\}$, two positive-semidefinite matrices $Q_0^{(\ell)}, Q_1^{(\ell)} \succeq 0$ such that*
>
> $$P_\ell(\Delta;\vec{a}) \;=\; v(\Delta)^{\top} Q_0^{(\ell)} v(\Delta) \;+\; (\Delta - \Delta_\ell^{\text{unit}})\, w(\Delta)^{\top} Q_1^{(\ell)} w(\Delta), \tag{50.58}$$
>
> *where v, w are the monomial vectors of the degrees fixed by Theorem 50.18, together with the normalization $\alpha[F_{0,0}] = \vec{a} \cdot \vec{F}_{0,0}^{(\Lambda)} = 1$.*

Both sides of Eq. (50.58) are polynomials in Δ; equating coefficients of each power of Δ gives a finite list of *linear* equations relating the entries of $\vec{a}$, $Q_0^{(\ell)}$, and $Q_1^{(\ell)}$ (the left side is linear in $\vec{a}$ by Theorem 50.16, the right side linear in the matrix entries by the Hankel pattern Eq. (50.53)). The only nonlinear conditions are the semidefiniteness constraints $Q_0^{(\ell)}, Q_1^{(\ell)} \succeq 0$. A feasibility problem with linear equality constraints on symmetric matrices that are required to be positive-semidefinite is, by definition, a *semidefinite program*.

Definition 50.19 (The bootstrap SDP)**.** Fix Δ_ϕ, a derivative order Λ, a spin cutoff L, and a candidate spectrum S (specified by the unitarity region together with any imposed gaps). The *bootstrap semidefinite program* is the feasibility problem: decide whether there exist a covector $\vec{a}$ and positive-semidefinite matrices $\{Q_0^{(\ell)}, Q_1^{(\ell)}\}_{\ell \le L}$ satisfying the linear equations obtained by equating coefficients in Eq. (50.58) for each ℓ, together with $\alpha[F_{0,0}] = 1$. If the program is feasible, the resulting $\vec{a}$ is an admissible functional and S is excluded by Theorem 49.21.

This is the working numerical machine. Feasibility of Theorem 50.19 is a decidable, finite question; modern interior-point solvers settle it, and — the point of the next subsection — a feasible solution can be promoted to a rigorous certificate. To bound the gap one wraps the feasibility test in a bisection: for each trial gap Δ_* in the scalar sector, set $S = S(\Delta_*)$ as in Eq. (49.101), solve the SDP, and move Δ_* down until feasibility is lost; the threshold is the bound Eq. (49.116). To bound an OPE coefficient one converts the feasibility program into an *optimization*, maximizing or minimizing the objective $\vec{a} \cdot \vec{F}^{(\Lambda)}_{\Delta_\star,\ell_\star}$ subject to the same semidefinite constraints, exactly as the linear-program structure of Eq. (49.104) anticipated — now with the positivity over the continuum enforced by the matrix constraints rather than sampled.

Worked Example 50.20 (A polynomial-positivity constraint as a 2×2 matrix inequality)**.** To see the machine turn over once, take the smallest nontrivial case. Suppose that after the radial truncation, in some spin sector with unitarity bound $a = \Delta_\ell^{\text{unit}}$, the functional produces a quadratic positivity polynomial

$$P(\Delta; \vec{a}) = c_0(\vec{a}) + c_1(\vec{a})\,\Delta + c_2(\vec{a})\,\Delta^2, \tag{50.59}$$

with the coefficients c_k linear in the functional unknowns $\vec{a}$. We require $P(\Delta) \ge 0$ for all $\Delta \ge a$. By Theorem 50.18 with $\deg P = 2$ (so $m = 1$), the representation is $P(x) = \sigma_0(x) + (x - a)\sigma_1(x)$ with σ_0 SOS of degree ≤ 2 and σ_1 SOS of degree 0, i.e. σ_1 a nonnegative constant. Write the Gram form Eq. (50.50) with $v(\Delta) = (1, \Delta)^\top$ and a single scalar $q_1 \ge 0$:

$$P(\Delta) = \begin{pmatrix} 1 \\ \Delta \end{pmatrix}^{\top} \underbrace{\begin{pmatrix} Q_{00} & Q_{01} \\ Q_{01} & Q_{11} \end{pmatrix}}_{Q_0 \succeq 0} \begin{pmatrix} 1 \\ \Delta \end{pmatrix} + (\Delta - a)\, q_1, \qquad q_1 \ge 0. \tag{50.60}$$

Expanding, $P(\Delta) = Q_{00} + (2Q_{01} + q_1)\Delta + Q_{11}\Delta^2 - a q_1$. Matching powers gives the linear equations

$$c_2 = Q_{11}, \qquad c_1 = 2Q_{01} + q_1, \qquad c_0 = Q_{00} - a\, q_1, \tag{50.61}$$

and the program is to find $\vec{a}$ (hence c_0, c_1, c_2), a number $q_1 \ge 0$, and a symmetric $Q_0 \succeq 0$ satisfying these. Positive-semidefiniteness of the 2×2 block is the pair of

scalar conditions $Q_{00} \geq 0$, $Q_{11} \geq 0$, $Q_{00}Q_{11} - Q_{01}^2 \geq 0$. Eliminating the auxiliary variables, the existence of such a representation is equivalent to the elementary criterion that a quadratic is nonnegative on $[a, \infty)$: either $c_2 > 0$ and (P has no real root in (a, ∞), i.e. the vertex value $c_0 - c_1^2/4c_2 \geq 0$ or the vertex lies left of a with $P(a) \geq 0$), or $c_2 = 0$ and the line is nonnegative at a with nonnegative slope. The SDP reproduces this exactly — and, crucially, scales to degree-50 polynomials in dozens of variables where the elementary case analysis is hopeless but the matrix inequality is routine.

50.3.6 Primal, dual, and the rigor of weak duality

Everything so far has converted the search into an SDP; we now explain why solving that SDP — even imperfectly, even in floating point — can yield a theorem. The reason is convex duality, and the relevant half of it, *weak* duality, is elementary and unconditional.

Cast the bootstrap as a pair of conjugate problems. The *primal* problem is the existence of a CFT: a measure $\{p_{\mathcal{O}} \geq 0\}$ supported on the candidate spectrum S with

$$\vec{F}^{(\Lambda)}_{0,0} + \sum_{\mathcal{O} \in S} p_{\mathcal{O}}\, \vec{F}^{(\Lambda)}_{\Delta_{\mathcal{O}},\ell_{\mathcal{O}}} = \vec{0}, \tag{50.62}$$

the truncated crossing equation (Eq. (49.74) read as a vector of derivative components). The *dual* problem is the functional search: find a covector $\vec{a}$ with $\vec{a} \cdot \vec{F}^{(\Lambda)}_{0,0} > 0$ and $\vec{a} \cdot \vec{F}^{(\Lambda)}_{\Delta,\ell} \geq 0$ for all $(\Delta, \ell) \in S$. Weak duality is the statement that these cannot both hold.

Theorem 50.21 (Weak duality and unconditional rigor)**.** *If the dual problem is feasible — if there exists a covector $\vec{a}$ with $\vec{a} \cdot \vec{F}^{(\Lambda)}_{0,0} > 0$ and $\vec{a} \cdot \vec{F}^{(\Lambda)}_{\Delta,\ell} \geq 0$ for every $(\Delta, \ell) \in S$ — then the primal problem Eq. (50.62) has no solution with $p_{\mathcal{O}} \geq 0$. The candidate spectrum is excluded, and the conclusion holds for* any *dual-feasible $\vec{a}$, optimal or not.*

Proof. Suppose both held. Pair the dual covector $\vec{a}$ with the primal equation Eq. (50.62), using linearity of the dot product:

$$0 = \vec{a} \cdot \vec{0} = \vec{a} \cdot \vec{F}^{(\Lambda)}_{0,0} + \sum_{\mathcal{O} \in S} p_{\mathcal{O}}\, (\vec{a} \cdot \vec{F}^{(\Lambda)}_{\Delta_{\mathcal{O}},\ell_{\mathcal{O}}}). \tag{50.63}$$

The first term is > 0 by dual feasibility. Each summand is a product of $p_{\mathcal{O}} \geq 0$ and $\vec{a} \cdot \vec{F}^{(\Lambda)}_{\Delta_{\mathcal{O}},\ell_{\mathcal{O}}} \geq 0$, hence ≥ 0. The right-hand side is therefore strictly positive, contradicting the left-hand side 0. So no nonnegative primal solution exists. □

This is the same three-line sign count as Theorem 49.21, now read as the weak-duality inequality of a convex program. Its importance for the numerics

cannot be overstated: *rigor does not require solving to optimality.* An interior-point solver produces a sequence of approximate solutions; we do not need the optimal functional, nor the exact boundary of feasibility. We need only *one* covector $\vec{a}$ that is dual-feasible, and Theorem 50.21 certifies the exclusion it yields. The solver's job is to find a feasible point of the dual cone; everything beyond that is a question of how tight the resulting bound is, not whether it is valid.

The semidefinite version is identical in structure, and we record it because it is the form the solver sees. A standard-form SDP and its dual are

$$\text{(P)}\quad \min_{X\succeq 0}\ \langle C, X\rangle \ \text{ s.t. } \langle A_i, X\rangle = b_i, \qquad \text{(D)}\quad \max_{y}\ b^{\top} y \ \text{ s.t. } C - \textstyle\sum_i y_i A_i \succeq 0, \tag{50.64}$$

where $\langle M, N\rangle = \mathrm{Tr}(M^{\top} N)$ is the trace inner product on symmetric matrices.

Theorem 50.22 (Weak duality for the SDP)**.** *For any primal-feasible $X \succeq 0$ and any dual-feasible y (i.e. $S \equiv C - \sum_i y_i A_i \succeq 0$), the duality gap is nonnegative:*

$$\langle C, X\rangle - b^{\top} y \;=\; \langle S, X\rangle \;\geq\; 0. \tag{50.65}$$

In particular the dual objective bounds the primal objective from below: $b^{\top} y \leq \langle C, X\rangle$.

Proof. Using $\langle A_i, X\rangle = b_i$,

$$\langle C, X\rangle - b^{\top} y = \langle C, X\rangle - \sum_i y_i \langle A_i, X\rangle = \Big\langle C - \sum_i y_i A_i,\ X \Big\rangle = \langle S, X\rangle. \tag{50.66}$$

It remains to show $\langle S, X\rangle \geq 0$ for symmetric $S, X \succeq 0$. Write $X = \sum_a \mu_a x_a x_a^{\top}$ by the spectral theorem with $\mu_a \geq 0$. Then

$$\langle S, X\rangle = \mathrm{Tr}(SX) = \sum_a \mu_a\ \mathrm{Tr}\big(S x_a x_a^{\top}\big) = \sum_a \mu_a\, x_a^{\top} S x_a \;\geq\; 0, \tag{50.67}$$

since each $x_a^{\top} S x_a \geq 0$ by $S \succeq 0$ and each $\mu_a \geq 0$. Hence Eq. (50.65), and $b^{\top} y \leq \langle C, X\rangle$. □

Theorem 50.22 is the engine-room version of the bootstrap's rigor. The lemma $\mathrm{Tr}(SX) \geq 0$ for two positive-semidefinite matrices is the matrix analogue of "a product of nonnegative numbers is nonnegative," and it is all that weak duality needs. For the exclusion problem the dual feasibility region is precisely the set of admissible functionals encoded by Eq. (50.58); any point in it, however found, certifies the bound.

50.3.7 SDPB and rigorous arithmetic

The semidefinite programs of Theorem 50.19 are large but highly structured: the unknowns include many matrix blocks $Q_0^{(\ell)}, Q_1^{(\ell)}$, and the constraints are that prescribed *polynomials* in Δ (not just numbers) be expressible in the Markov–Lukács form. This special structure — a "polynomial matrix program" — is what the solver `SDPB` of Simmons-Duffin [441] is built to exploit. Conceptually, `SDPB` is a primal-dual interior-point method: it maintains a primal point $X \succeq 0$ and a dual point $(y, S \succeq 0)$, and drives the duality gap Eq. (50.65) toward zero by Newton steps that follow the "central path" — the locus where $XS = \mu I$ for a barrier parameter $\mu \to 0$ — while keeping both matrices in the interior of the positive-semidefinite cone. Three features make it suited to the bootstrap. It works in *arbitrary precision* arithmetic, because near a saturated bound the matrices become nearly singular and double precision loses the certificate; it handles the polynomial constraints directly by sampling each $P_\ell(\Delta)$ at enough points (Chebyshev nodes) and reconstructing the Markov–Lukács matrices, rather than expanding in a fixed monomial basis where conditioning degrades; and it returns a *dual* certificate, the covector $\vec{a}$, which is exactly the object Theorem 50.21 needs.

The final step closes the logical loop between "the solver printed a functional" and "the spectrum is excluded." A floating-point $\vec{a}$ is, strictly, only an approximation, and one might worry that the certified positivity $P_\ell(\Delta) \geq 0$ fails by a rounding error at some Δ. The resolution is that the certificate can be *verified exactly*. The blocks' rational representation Eq. (50.48) has rational (or algebraic, controlled) coefficients once $\rho_* = 3 - 2\sqrt{2}$ and the residues are carried symbolically; rounding the solver's $\vec{a}$ to nearby rationals gives a candidate functional with exactly known polynomial coefficients $P_\ell(\Delta; \vec{a})$. To prove $P_\ell \geq 0$ on $[\Delta_\ell^{\text{unit}}, \infty)$ one exhibits the Markov–Lukács matrices $Q_0^{(\ell)}, Q_1^{(\ell)}$ with *rational* entries and verifies $Q \succeq 0$ exactly — for instance by a rational $LDL^\top$ (Cholesky) factorization and checking that every pivot is nonnegative, an exact finite computation in rational arithmetic. Equivalently one runs the solver in interval arithmetic, so that the printed certificate carries rigorous error bars and the verified inequality $\vec{a} \cdot \vec{F}_{0,0}^{(\Lambda)} > 0$, $\vec{a} \cdot \vec{F}_{\Delta,\ell}^{(\Lambda)} \geq 0$ holds with the rounding accounted for. Either way, the numerically found functional becomes a genuine proof: by Theorem 50.21 the exclusion follows from the verified sign data alone, independently of the floating-point path that produced it.

Caution

The verification step is what separates a bootstrap *bound* from a bootstrap *plot*. A solver that has not converged, or whose certificate has not been validated in exact arithmetic, produces a curve that is morally correct and almost always right but is not yet a theorem. The published rigorous

bounds — the exclusion regions of the next section, in particular — are those for which a dual-feasible functional has been exhibited and its positivity confirmed. The remaining, genuinely conditional, ingredients are the *assumptions* that define the candidate spectrum (the imposed gaps), not the numerics: granting the gaps, the exclusion is a theorem up to the (verifiable) arithmetic; the identification of the surviving region with a named physical theory is separate physics input, as the chapter introduction stressed.

With the semidefinite program of Theorem 50.19 assembled, its rigor underwritten by the weak duality of Theorems 50.21 and 50.22, and its certificates made exact by rational verification, we have a working numerical machine: a finite SDP whose feasibility rigorously decides whether a candidate spectrum is excluded. The next section aims this machine at the simplest physical target — the four-point function of a single $\mathbb{Z}_2$-odd scalar in $d = 3$ — and watches the exclusion curve in the $(\Delta_\sigma, \Delta_\varepsilon)$ plane develop the sharp kink at which the 3D Ising fixed point of ϕ^4 theory sits.

50.4 The Single-Correlator Bound and the Ising Kink

The previous section converted the search for a certifying functional into a finite semidefinite program: the crossing vector was expanded in the radial coordinate around the symmetric point, the functional was truncated to a finite basis of derivatives, the conformal blocks were replaced by their rational (positive-prefactor times polynomial) approximations, and the requirement that the functional be nonnegative on an entire continuous spin trajectory was recast as the positive-semidefiniteness of a matrix of polynomials — a polynomial matrix program solvable to rigorous precision, with the primal–dual structure that certifies feasibility either way (Section 50.3, Theorem 50.22, and Eq. (50.50)). We now run that machine on the one correlator the three-dimensional Ising universality class hands us for free, the four-point function of the spin operator, and watch a sharp feature emerge at exactly the place ϕ^4 theory predicted. This is the section where the abstract exclusion principle becomes a curve, and the curve acquires a corner with a name.

The logical contract is worth restating before we begin, because it governs how loudly we may speak. The exclusion the program produces is a theorem: whenever it returns a feasible functional, the corresponding region of the $(\Delta_\sigma, \Delta_\varepsilon)$ plane contains no unitary, $\mathbb{Z}_2$-symmetric, crossing-symmetric conformal field theory with the assumed gap, and this conclusion is conditional only on the hypotheses and on the arithmetic (which can be carried in interval arithmetic). The *identification* of the resulting kink with a particular physical theory is not a theorem of that kind; it is physics input, justified by the agreement of the

bootstrap numbers with the Wilson–Fisher fixed point of Theorem 24.31 and with the lattice and experimental critical exponents. We keep the two registers separate throughout.

50.4.1 Assembling the single-correlator semidefinite program

The object to be cornered was fixed in Theorem 49.27: a $d = 3$ conformal field theory, unitary, with a $\mathbb{Z}_2$ symmetry under which the spin σ is odd and the energy ε is even, and with exactly two relevant scalars. The single cheapest crossing equation it must satisfy is the one for four spins, derived in Eq. (49.167): writing the antisymmetrized crossing vector of Eq. (49.168),

$$F^{-}_{\Delta_\sigma;\,\Delta,\ell}(u,v) \equiv v^{\Delta_\sigma}\, g_{\Delta,\ell}(u,v) - u^{\Delta_\sigma}\, g_{\Delta,\ell}(v,u), \tag{50.68}$$

the $\langle\sigma\sigma\sigma\sigma\rangle$ sum rule reads, with the identity carried back onto the left-hand side and $\lambda^2_{\mathbf{1}} = 1$,

$$\sum_{\mathcal{O}\,\in\,\sigma\times\sigma} \lambda^2_{\mathcal{O}}\, F^{-}_{\Delta_\sigma;\,\Delta_{\mathcal{O}},\ell_{\mathcal{O}}}(u,v) = 0, \qquad \lambda^2_{\mathcal{O}} \geq 0. \tag{50.69}$$

The three physical assumptions enter this equation, and through it the program, in three sharply distinguishable ways, and it is worth tracing each because the reproducibility of the bound depends on getting them right.

How $\mathbb{Z}_2$ symmetry enters. Because σ is $\mathbb{Z}_2$-odd, the product $\sigma \times \sigma$ is $\mathbb{Z}_2$-even, so the sum in Eq. (50.69) runs over $\mathbb{Z}_2$-even primaries only — the energy ε, its even-parity scalar excitations $\varepsilon', \ldots$, the stress tensor T, and the higher even-spin tower. The odd operators (σ itself, σ', …) are simply absent from this OPE; they would appear in a $\langle\sigma\sigma\varepsilon\varepsilon\rangle$ or $\langle\sigma\varepsilon\sigma\varepsilon\rangle$ correlator, which is exactly the additional information the next section will exploit. The $\mathbb{Z}_2$ assumption therefore acts as a *selection rule on the index set* of the sum: it deletes an entire charge sector. Combined with the identical-operator spin parity (exchanging the two σ's in a fused pair multiplies a spin-ℓ block by $(-1)^\ell$), only even spins $\ell = 0, 2, 4, \ldots$ survive. The exchanged spectrum is thus the identity, the even scalars, and the even-spin $\ell \geq 2$ tower.

How unitarity enters. Unitarity does two things. It makes every coefficient $\lambda^2_{\mathcal{O}}$ in Eq. (50.69) nonnegative — these are squares of real OPE coefficients, real because the operators are Hermitian and the radial-quantization inner product is positive (reflection positivity, Theorem 49.27(A2)). And it restricts the dimensions: every primary obeys the unitarity bounds of Theorem 47.18, a scalar with $\Delta \geq \frac{d-2}{2} = \frac{1}{2}$ and a spin-$\ell \geq 1$ operator with $\Delta \geq \ell + d - 2 = \ell + 1$. Nonnegativity of the λ^2's is the property the functional method exploits; the dimension bounds fix the domain over which the functional must be controlled.

How the single-relevant-scalar gap enters. The defining input of the Ising problem (A5 of Theorem 49.27) is the gap: there is exactly one relevant $\mathbb{Z}_2$-even scalar, the energy ε, and the next even scalar ε' is irrelevant. In the single-correlator language we encode this with a trial value Δ_* and demand that the even scalar sector contain *nothing* between the unitarity floor and Δ_* except the operator ε we are trying to bound. Concretely, we present to the program the admissible spectrum

$$\mathcal{S}_{\Delta_*} = \{(\Delta,\, \ell = 0) : \Delta \geq \Delta_*\} \;\cup\; \{(\Delta,\, \ell) :\; \ell \text{ even},\; \ell \geq 2,\; \Delta \geq \ell + 1\}, \tag{50.70}$$

and ask whether crossing can be satisfied with only operators drawn from it. By Theorem 49.28, if a functional α exists that is normalized to unity on the identity vector and nonnegative on $F^-_{\Delta_\sigma;\Delta,\ell}$ for every $(\Delta,\ell) \in \mathcal{S}_{\Delta_*}$, then no consistent theory can have its leading even scalar at or above Δ_*; the gap encodes itself as the *lower edge* Δ_* *of the scalar slice* of Eq. (50.70).

These three ingredients turn the exclusion principle into a concrete decision problem, which the machinery of Section 50.3 renders finite.

Definition 50.23 (The single-correlator feasibility problem)**.** Fix the spacetime dimension $d = 3$, the external dimension Δ_σ, the truncation order Λ (the maximum total derivative order), and a trial scalar gap Δ_*. Let

$$\alpha[\,\cdot\,] = \sum_{\substack{m,n\geq 0\\ m+n\leq\Lambda}} a_{mn}\, \partial_z^m \partial_{\bar z}^n \Big|_{z=\bar z=1/2} \tag{50.71}$$

be a finite linear functional in the derivative basis of Eq. (50.41), with real coefficients a_{mn} (only the components odd under $z \leftrightarrow 1-z$ survive, the others annihilating the antisymmetric F^-). The problem is to decide whether there exist coefficients $\{a_{mn}\}$ such that

(i) $\alpha\big[F^-_{\Delta_\sigma;\,0,0}\big] = 1$ (unit normalization on the identity, $F^-_{\Delta_\sigma;0,0} = v^{\Delta_\sigma} - u^{\Delta_\sigma}$),

(ii) $\alpha\big[F^-_{\Delta_\sigma;\,\Delta,\,0}\big] \geq 0$ for all $\Delta \geq \Delta_*$,

(iii) $\alpha\big[F^-_{\Delta_\sigma;\,\Delta,\,\ell}\big] \geq 0$ for all even $\ell \geq 2$ and all $\Delta \geq \ell + 1$.

If such α exists the point $(\Delta_\sigma, \Delta_*)$ is *excluded*: every consistent theory has $\Delta_\varepsilon < \Delta_*$ at this Δ_σ.

The only obstacle to deciding Theorem 50.23 directly is that conditions (ii) and (iii) are each a constraint on a *continuum* of dimensions Δ, one infinity per spin. This is precisely the obstruction lifted in Section 50.3. Substituting the rational approximation $g_{\Delta,\ell}(z,\bar z) \approx \chi_\ell(\Delta)\, P_{\Delta,\ell}(z,\bar z)$, with $\chi_\ell(\Delta) > 0$ a

known positive prefactor collecting the poles in Δ and $P_{\Delta,\ell}$ a polynomial in Δ (Eq. (50.48)), each functional value becomes

$$\alpha\big[F^{-}_{\Delta_\sigma;\,\Delta,\ell}\big] = \chi_\ell(\Delta)\,Q_\ell(\Delta), \qquad Q_\ell(\Delta) = \sum_{m,n} a_{mn}\,\big(\partial^m\partial^n P\big)_{\Delta,\ell}, \tag{50.72}$$

where Q_ℓ is a polynomial in Δ of degree set by Λ and the rational order. Because $\chi_\ell(\Delta) > 0$ on the unitarity range, conditions (ii)–(iii) are equivalent to the polynomial positivity

$$Q_0(\Delta) \geq 0 \ \text{ on } [\Delta_*, \infty), \qquad Q_\ell(\Delta) \geq 0 \ \text{ on } [\ell+1, \infty) \ \ (\ell = 2, 4, \ldots, \ell_{\max}), \tag{50.73}$$

and a polynomial is nonnegative on a half-line if and only if it is a sum of squares of the appropriate form — equivalently, if and only if certain Gram matrices built from its coefficients are positive semidefinite (Eq. (50.50)). The infinitely many inequalities (ii)–(iii) collapse to finitely many matrix inequalities, one block per retained spin; the spins above some $\ell_{\max}$ are controlled by the asymptotic positivity argument of Section 50.3. The decision variables are the a_{mn} together with the auxiliary Gram matrices, and Theorem 50.23 becomes a genuine semidefinite program, feasible or infeasible by a finite computation whose dual provides the certificate either way.

Caution

The normalization (i) and the positivity (ii)–(iii) carry opposite roles for the same functional, and their relative sign is the whole content of the certificate. The functional must be *strictly positive on the identity vector* and *nonnegative on every operator in the gapped spectrum*; the contradiction of Theorem 49.28 is then that a quantity forced to vanish has been written as a strictly positive sum. An overall sign flip of α is harmless, but the wrong *relative* sign between (i) and (ii)–(iii) silently inverts the meaning and produces a meaningless "bound". In practice one fixes the sign once by the normalization (i) and never touches it again.

50.4.2 Tracing the bound: the feasibility scan

The feasibility problem of Theorem 50.23 answers a yes/no question at a single point $(\Delta_\sigma, \Delta_*)$. The bound curve is obtained by sweeping. Fix Δ_σ and observe the monotonicity built into the construction: if a certifying functional exists for some trial gap Δ_*, then because shrinking the admissible set Eq. (50.70) (raising Δ_*) only removes positivity constraints, the same functional certifies every larger gap as well. Exclusion is therefore an upward-closed property of Δ_*, and there is a sharp threshold

$$\Delta_\varepsilon^{\max}(\Delta_\sigma) = \inf\{\Delta_* : \text{a certifying } \alpha \text{ exists}\}, \tag{50.74}$$

the smallest gap that can still be excluded. Above it the program is feasible and the region is forbidden; below it the program is infeasible and a crossing solution is not ruled out. The threshold is located by bisection: pick a bracket $[\Delta_{\mathrm{lo}}, \Delta_{\mathrm{hi}}]$, solve the SDP at the midpoint, move the relevant endpoint according to feasibility, and iterate until the bracket is narrower than the target precision. Sweeping Δ_σ across the unitarity range $\Delta_\sigma \geq \frac{1}{2}$ then traces the curve $\Delta_\varepsilon^{\max}(\Delta_\sigma)$ that is the section's protagonist.

Two properties of this curve are guaranteed before any number is computed, and both are visible in Fig. 50.5. First, the bound is *rigorous at every truncation*: any feasible α found in the finite derivative space Eq. (50.71) is a genuine functional in the full theory, so the excluded region it certifies is excluded in fact. Truncation never produces a false exclusion; it can only fail to find a functional that a larger space would have found. Second, the bound *improves monotonically with* Λ: enlarging the derivative basis enlarges the search space, so a functional found at order Λ is still available at order $\Lambda' > \Lambda$, and the threshold $\Delta_\varepsilon^{\max}$ can only decrease as Λ grows. The computed curve therefore approaches the true bound *from above*, monotonically, and the coarse-truncation and fine-truncation curves of Fig. 50.5 are nested accordingly. This is the practical meaning of the rigor claim: the bound is honest at any Λ and tightens predictably as Λ is raised.

The shape of the curve is itself instructive and was anticipated by the exact solutions of Section 49.5. At the unitarity floor $\Delta_\sigma = \frac{1}{2}$ the only consistent theory with a single relevant even scalar is the generalized free field, whose spectrum (Eq. (49.130)) puts its lightest even scalar at the double-twist dimension $2\Delta_\sigma = 1$; the curve begins at the endpoint $(\frac{1}{2}, 1)$. As Δ_σ increases the bound rises steeply — the more the spin is lifted off its free dimension, the higher the energy operator is permitted to climb — until near $\Delta_\sigma \approx 0.518$ the slope changes abruptly and the curve continues with a gentler rise. That abrupt change of slope is the kink.

50.4.3 The kink and the Ising point

The kink is not an artefact of coarse computation; it is the opposite. At small Λ the corner is rounded, and one might dismiss it as a smooth maximum. As Λ is raised the rounding shrinks and the corner sharpens toward a genuine slope discontinuity, exactly the behaviour of the nested curves in the inset of Fig. 50.5. A feature that *sharpens* under refinement is a feature of the true bound, not of the truncation. The numerical fact, first established at modest truncation and stable under every subsequent refinement, is that the kink sits at

$$\Delta_\sigma\big|_{\mathrm{kink}} = 0.5182(3), \qquad \Delta_\varepsilon\big|_{\mathrm{kink}} = 1.413(1), \tag{50.75}$$

in striking agreement with the precise Ising determination $(\Delta_\sigma, \Delta_\varepsilon) = (0.5181489, 1.412625)$ of Eq. (49.171), which the mixed-correlator system of the next section will pin down to six figures. The single correlator alone, with nothing but $\mathbb{Z}_2$ symmetry,

unitarity, crossing, and the one-gap assumption, already locates the 3D Ising fixed point to three or four significant figures by the position of a corner.

Why a corner, and why does it locate a theory? The answer is the structure of the *extremal* functional. Along the bound the optimal α is the one whose threshold Δ_* has just been driven to $\Delta_\varepsilon^{\max}$; at that value the certificate is marginal, and the polynomial $Q_\ell(\Delta)$ of Eq. (50.72) must vanish (touch zero from above) at precisely the dimensions of the operators in the unique spectrum that saturates crossing. The functional's zeros *are* the extremal spectrum. At a generic Δ_σ this extremal spectrum drifts smoothly and corresponds to no distinguished theory; the bound is smooth there. At one special Δ_σ the pattern of zeros reorganizes — an operator dimension that had been tracking one trajectory jumps to another — and the response of the bound to Δ_σ changes discontinuously, producing the kink. The reorganization happens where the most strained spectrum consistent with the assumptions abruptly changes character, and for the spin correlator that place is, to all tested precision, the spectrum of the 3D Ising model. The bootstrap is finding the corner of the allowed region where unitarity and crossing are simultaneously most taut, and that corner is a real conformal field theory.

Physical Insight

The kink is the bootstrap's way of pointing without being told where to look. We did not feed in the Ising dimensions; we fed in only that the theory is unitary, $\mathbb{Z}_2$-symmetric, crossing-symmetric, and has a single relevant even scalar — assumptions shared by a continuum of hypothetical theories. The machine replies that along the boundary of what is allowed there is one place where the structure is special, and that place is where every other method says the Ising critical point is. The corner is sharp because at it the extremal spectrum is rigid: the optimal functional has just enough zeros to pin a discrete spectrum with no freedom left, and that rigidity is the fingerprint of an actual theory rather than a generic boundary point.

There is, however, a limitation that must be stated honestly and that sets up everything to come. The single-correlator bound only *touches* the Ising point; it does not isolate it. Theorem 49.28 bounds Δ_ε from *above* for each Δ_σ and says nothing from below, so the allowed region is the entire shaded area beneath the curve in Fig. 50.5, an open region bounded only on top and on the left (by the unitarity wall $\Delta_\sigma \geq \frac{1}{2}$). The Ising theory sits on the upper boundary, at the kink, but so does every extremal spectrum along the curve; nothing in the single-correlator problem forbids a hypothetical unitary theory at, say, $(\Delta_\sigma, \Delta_\varepsilon) = (0.55, 1.2)$, well inside the allowed region. The corner identifies Ising, but it does not corner it. To close the region into a bounded island around the Ising point — to bound Δ_ε from below as well as above, and to do so tightly —

one must bring in more crossing equations than the single correlator provides. That is the task of the mixed system, and it is where the section hands off.

50.4.4 The fixed point identified: $\sigma = \phi$, $\varepsilon = :\phi^2:$

The kink is a feature of a curve derived from pure consistency, with no Lagrangian anywhere in sight. To call it "the 3D Ising fixed point" is to assert that this consistency-defined corner is the same theory as the interacting fixed point ϕ^4 theory has carried since Part VI. We now make the identification explicit, operator by operator, and then translate the bootstrap output into the language of critical exponents so that the claim can be checked against numbers measured by completely different means.

The dictionary is an identification of operators with their lattice/continuum origins. The $\mathbb{Z}_2$-odd spin σ *is* the order-parameter field ϕ of the $\lambda\phi^4$ theory: it is the unique relevant $\mathbb{Z}_2$-odd scalar, the continuum limit of the lattice spin, and the field whose expectation value distinguishes the two broken vacua. The $\mathbb{Z}_2$-even energy ε *is* the composite $:\phi^2:$: the unique relevant $\mathbb{Z}_2$-even scalar, the continuum limit of the lattice energy density, the operator conjugate to the reduced temperature $t = (T - T_c)/T_c$. This is the same pairing the Wilson–Fisher analysis produced: the fixed point of β_λ at $\lambda_* = \frac{16\pi^2}{3}\varepsilon + O(\varepsilon^2)$ (Eq. (24.255)) is a conformal field theory (the characterization completed in Theorem 52.11) in which ϕ and $:\phi^2:$ are primaries, and continuing the dimension deficit to $\varepsilon = 1$ ($d = 3$) gives the theory governing the entire Ising universality class. Universality (Theorem 23.26) is what licenses the identification: every microscopic system in the class — the uniaxial ferromagnet at its Curie point, the liquid–vapour critical point, the binary-fluid demixing transition — flows to one and the same infrared fixed point, so "the bootstrap kink", "the Wilson–Fisher fixed point at $\varepsilon = 1$", and "the 3D Ising critical point" name a single conformal field theory.

What remains is to connect the two numbers the bootstrap delivers, Δ_σ and Δ_ε, to the measurable critical exponents, using the renormalization-group scaling relations established for ϕ^4 theory. The dictionary was stated in Eqs. (49.162) and (49.163); here we derive it from the RG so that its origin is transparent.

Δ_σ and the exponent η. At an interacting fixed point the field anomalous dimension does not vanish, and Eq. (24.246) established that the field's full scaling dimension is the engineering value shifted by the fixed-point anomalous dimension, $\Delta_\sigma = \frac{d-2}{2} + \gamma_*$, with the order-parameter correlation exponent given by $\eta = 2\gamma_*$. Eliminating γ_*,

$$\Delta_\sigma = \frac{d-2}{2} + \frac{\eta}{2} = \frac{d-2+\eta}{2} \quad \xrightarrow{d=3} \quad \boxed{\Delta_\sigma = \frac{1+\eta}{2}}, \qquad \eta = 2\Delta_\sigma - 1, \tag{50.76}$$

the spin two-point function falling as $\langle\sigma(x)\sigma(0)\rangle \sim |x|^{-2\Delta_\sigma} = |x|^{-(d-2+\eta)}$, which is the laboratory definition of η. The bootstrap measures Δ_σ; Eq. (50.76) converts it to η.

Δ_ε and the exponent ν. The energy ε is the operator conjugate to the reduced temperature: in the action, t multiplies ε, so t is the coupling of the operator ε and carries mass dimension $[t] = d - \Delta_\varepsilon$. Under a renormalization-group rescaling by a factor b the coupling flows as $t \to b^{y_t} t$ with RG eigenvalue $y_t = d - \Delta_\varepsilon$ (the scaling dimension of a coupling is d minus the dimension of its operator; this is the relevant/irrelevant classification of Theorem 23.26). The correlation length, a physical length, transforms as $\xi \to \xi/b$; combining the two, $\xi(t) = b\,\xi(b^{y_t}t)$, and choosing b so that $b^{y_t}t = O(1)$ gives $\xi \sim t^{-1/y_t}$. Comparison with the definition $\xi \sim |t|^{-\nu}$ yields $\nu = 1/y_t$, hence

$$\frac{1}{\nu} = y_t = d - \Delta_\varepsilon \quad \xrightarrow{d=3} \quad \boxed{\Delta_\varepsilon = 3 - \frac{1}{\nu}}, \qquad \frac{1}{\nu} = 3 - \Delta_\varepsilon. \tag{50.77}$$

The gap assumption is exactly the statement that ε is the *only* relevant even scalar, i.e. that the temperature is the only relevant even direction: a single tuning reaches criticality, the hallmark of the Ising class. The bootstrap measures Δ_ε; Eq. (50.77) converts it to ν.

These two relations close the loop opened in Part VI: the field anomalous dimension γ_ϕ computed diagrammatically from wavefunction renormalization, and the thermal eigenvalue y_t that is the slope of the linearized RG flow, are the same two numbers the bootstrap reads off the kink. The perturbative description (a coupling flowing to λ_*) and the bootstrap description (a corner of an exclusion curve) are two windows onto one fixed point, and Eqs. (50.76) and (50.77) are the panes through which the same exponents are seen from each. The remaining critical exponents are not independent: they follow from (η, ν) by the scaling and hyperscaling relations, and the following worked example carries that arithmetic through and confronts it with the laboratory.

Worked Example 50.24 (From the kink to the critical exponents of the 3D Ising class)**.** We take the bootstrap dimensions at face value — using the precise values Eq. (49.171), $\Delta_\sigma = 0.5181489$ and $\Delta_\varepsilon = 1.412625$, since the single-correlator kink Eq. (50.75) agrees with them to its precision — and produce the full set of standard exponents, comparing each to the best Monte Carlo determinations of the three-dimensional Ising model.

The two primary exponents. From Eqs. (50.76) and (50.77),

$$\eta = 2\Delta_\sigma - 1 = 2(0.5181489) - 1 = 0.0362978, \tag{50.78}$$

$$\frac{1}{\nu} = 3 - \Delta_\varepsilon = 3 - 1.412625 = 1.587375, \qquad \nu = 0.6299709. \tag{50.79}$$

The anomalous dimension is tiny — the field is lifted only slightly off its free scaling — consistent with the Wilson–Fisher result that $\eta = O(\varepsilon^2)$ begins at second order in the deficit (Eq. (24.256)), whereas the thermal exponent departs substantially from its free value, consistent with $1/\nu = 2 - \varepsilon/3 + \cdots$ being a first-order effect (Theorem 49.29).

The remaining exponents from two RG eigenvalues. Introduce the magnetic eigenvalue. The magnetic field h couples to σ, so by the same coupling-dimension argument that gave y_t, its RG eigenvalue is $y_h = d - \Delta_\sigma$. With $d = 3$,

$$y_h = 3 - \Delta_\sigma = 3 - 0.5181489 = 2.4818511, \qquad y_t = \frac{1}{\nu} = 1.587375. \tag{50.80}$$

The thermodynamic exponents are fixed by (y_t, y_h) through the standard scaling relations (the free energy density scales as $f \sim t^{\,d/y_t}$, and successive h-derivatives at $t \neq 0$ generate the magnetization and susceptibility), which give

$$\alpha = 2 - \frac{d}{y_t} = 2 - d\nu, \qquad \beta = \frac{d - y_h}{y_t} = \nu\,\Delta_\sigma, \tag{50.81}$$

$$\gamma = \frac{2y_h - d}{y_t} = \nu(2 - \eta), \qquad \delta = \frac{y_h}{d - y_h} = \frac{d + 2 - \eta}{d - 2 + \eta}. \tag{50.82}$$

Evaluating with the numbers above,

$$\alpha = 2 - 3(0.6299709) = 0.110087, \tag{50.83}$$

$$\beta = (0.6299709)(0.5181489) = 0.326419, \tag{50.84}$$

$$\gamma = (0.6299709)(2 - 0.0362978) = 1.237075, \tag{50.85}$$

$$\delta = \frac{3 + 2 - 0.0362978}{3 - 2 + 0.0362978} = \frac{4.9637022}{1.0362978} = 4.790036. \tag{50.86}$$

Confrontation with Monte Carlo. The high-precision lattice/Monte Carlo values for the 3D Ising universality class are $\nu = 0.63002(10)$, $\eta = 0.03627(10)$, $\alpha = 0.1099(7)$, $\beta = 0.32630(22)$, $\gamma = 1.2372(5)$, $\delta = 4.789(2)$. Every exponent derived above from the two bootstrap dimensions agrees with the independently measured value to within the Monte Carlo error bars. The agreement is the quantitative content of the identification: a corner on an exclusion curve, located by demanding only unitarity and crossing, reproduces the entire table of critical exponents of a real second-order phase transition — and it does so by translating two CFT dimensions through scaling relations that were derived, in this book, from the renormalization-group flow of $\lambda\phi^4$.

The worked example completes the major payoff of ϕ^4 theory. The fixed point computed perturbatively in $d = 4 - \varepsilon$ as the nontrivial zero λ_* of the one-loop beta function (Theorem 24.31), and characterized as a conformal field theory in Theorem 52.11, is the same theory the bootstrap pins to the kink of a curve derived from consistency alone — with the two routes meeting, quantitatively,

on the numbers $\eta = 0.0363$ and $\nu = 0.6300$. The perturbative thread and the consistency thread have converged on one theory.

What they have not yet done is corner it. The single correlator places the Ising point on the boundary of the allowed region but leaves that region open below, so the kink *touches* Ising without *isolating* it. Closing the region into a small, bounded island — and thereby turning the three-figure location of the kink into the six-figure determination quoted in Eq. (49.171) — requires the additional crossing equations of the mixed system $\langle\sigma\sigma\sigma\sigma\rangle$, $\langle\sigma\sigma\varepsilon\varepsilon\rangle$, $\langle\varepsilon\varepsilon\varepsilon\varepsilon\rangle$, where the shared OPE coefficients enforce positivity of genuine matrices rather than single numbers. That genuinely semidefinite structure, and the closed island it produces, are the subject of the next section.

50.5 Mixed Correlators and the Ising Island

The single-correlator analysis of the previous section delivered a sharp but incomplete verdict. Crossing of $\langle\sigma\sigma\sigma\sigma\rangle$, fed through the linear-functional machine and the gap assumption that $\sigma \times \sigma$ contains exactly one relevant $\mathbb{Z}_2$-even scalar, produced a rigorous upper bound on Δ_ε as a function of Δ_σ. That bound has a pronounced kink, and the 3D Ising model sits essentially *on* the kink. But "on the boundary of an allowed region" is not the same as "isolated." The allowed region of the single correlator is an open wedge: it pins Δ_ε from above but leaves it free below, and it constrains Δ_σ not at all. The kink is a strong hint — the most constrained point on a one-sided boundary — but it is a hint, not a cage. To turn the hint into a closed determination we need more equations sharing the *same* unknown CFT data, so that bounds pushing in from several directions can trap the theory between them. The decisive step, anticipated in Section 49.3.5, is to bootstrap not one correlator but the whole small system built from the two lightest scalars, and to discover that unitarity then speaks not through nonnegative numbers but through positive-semidefinite *matrices*. That upgrade is what finally closes the wedge into an island.

50.5.1 Three correlators sharing one operator algebra

The Ising CFT has a $\mathbb{Z}_2$ global symmetry under which the spin operator σ is odd and the energy operator ε is even (Section 48.6). We take both as external operators and impose crossing on every four-point function they generate. The $\mathbb{Z}_2$ selection rule organizes their operator product expansions (Theorem 47.46) into two sectors. Writing $\mathcal{O}^+$ for $\mathbb{Z}_2$-even primaries and $\mathcal{O}^-$ for $\mathbb{Z}_2$-odd primaries,

$$\sigma \times \sigma \;\sim\; \mathbf{1} + \sum_{\mathcal{O}^+} \lambda_{\sigma\sigma\mathcal{O}}\, \mathcal{O}^+, \tag{50.87}$$

$$\varepsilon \times \varepsilon \;\sim\; \mathbf{1} + \sum_{\mathcal{O}^+} \lambda_{\varepsilon\varepsilon\mathcal{O}}\, \mathcal{O}^+, \tag{50.88}$$

$$\sigma \times \varepsilon \;\sim\; \sum_{\mathcal{O}^-} \lambda_{\sigma\varepsilon\mathcal{O}}\, \mathcal{O}^-, \tag{50.89}$$

where $\lambda_{\sigma\sigma\mathcal{O}} \equiv C_{\sigma\sigma\mathcal{O}}$ in the notation of Theorem 49.17, and only even spins appear in $\sigma \times \sigma$ and $\varepsilon \times \varepsilon$ (identical operators), whereas $\sigma \times \varepsilon$ admits all spins. The crucial structural fact is visible already in Eqs. (50.87) and (50.88): every $\mathbb{Z}_2$-even primary $\mathcal{O}^+$ appears in *both* the $\sigma \times \sigma$ and the $\varepsilon \times \varepsilon$ channels, carrying *two* OPE coefficients, $\lambda_{\sigma\sigma\mathcal{O}}$ and $\lambda_{\varepsilon\varepsilon\mathcal{O}}$. The identity $\mathbf{1}$ is the universal $\mathcal{O}^+$ with $\lambda_{\sigma\sigma\mathbf{1}} = \lambda_{\varepsilon\varepsilon\mathbf{1}} = 1$.

From two external scalars the $\mathbb{Z}_2$ symmetry permits exactly three inequivalent four-point functions (any correlator with an odd number of σ's vanishes):

$$\langle\sigma\sigma\sigma\sigma\rangle, \qquad \langle\sigma\sigma\varepsilon\varepsilon\rangle, \qquad \langle\varepsilon\varepsilon\varepsilon\varepsilon\rangle, \tag{50.90}$$

together with the reorderings of the middle one, $\langle\sigma\varepsilon\sigma\varepsilon\rangle$ and $\langle\sigma\varepsilon\varepsilon\sigma\rangle$, which are the *same* function evaluated in different channels and supply additional crossing relations rather than new correlators. The operators exchanged in each, and the OPE-coefficient combination they carry, are dictated by Eqs. (50.87) to (50.89):

- In $\langle\sigma\sigma\sigma\sigma\rangle$ only $\mathcal{O}^+$ are exchanged, with weight $\lambda^2_{\sigma\sigma\mathcal{O}}$ — a perfect square, exactly the single-correlator case of Eq. (49.74).
- In $\langle\varepsilon\varepsilon\varepsilon\varepsilon\rangle$ only $\mathcal{O}^+$ are exchanged, with weight $\lambda^2_{\varepsilon\varepsilon\mathcal{O}}$.
- In $\langle\sigma\sigma\varepsilon\varepsilon\rangle$, the channel that fuses $\sigma\sigma \to \mathcal{O}^+ \to \varepsilon\varepsilon$ carries the *product* $\lambda_{\sigma\sigma\mathcal{O}}\lambda_{\varepsilon\varepsilon\mathcal{O}}$, while the crossed channel fuses $\sigma\varepsilon \to \mathcal{O}^- \to \sigma\varepsilon$ with weight $\lambda^2_{\sigma\varepsilon\mathcal{O}}$.

The first two correlators see the even operators through the squares $\lambda^2_{\sigma\sigma\mathcal{O}}$ and $\lambda^2_{\varepsilon\varepsilon\mathcal{O}}$; the mixed correlator sees them through the product $\lambda_{\sigma\sigma\mathcal{O}}\lambda_{\varepsilon\varepsilon\mathcal{O}}$. These three combinations are precisely the three independent entries of the symmetric 2×2 matrix

$$P_{\mathcal{O}} \;\equiv\; \begin{pmatrix} \lambda^2_{\sigma\sigma\mathcal{O}} & \lambda_{\sigma\sigma\mathcal{O}}\lambda_{\varepsilon\varepsilon\mathcal{O}} \\ \lambda_{\sigma\sigma\mathcal{O}}\lambda_{\varepsilon\varepsilon\mathcal{O}} & \lambda^2_{\varepsilon\varepsilon\mathcal{O}} \end{pmatrix} \;=\; \vec{\lambda}_{\mathcal{O}}\, \vec{\lambda}_{\mathcal{O}}^{\mathsf{T}}, \qquad \vec{\lambda}_{\mathcal{O}} \equiv \begin{pmatrix} \lambda_{\sigma\sigma\mathcal{O}} \\ \lambda_{\varepsilon\varepsilon\mathcal{O}} \end{pmatrix}. \tag{50.91}$$

This is the object that will replace the single nonnegative number $p_{\mathcal{O}}$ of the single-correlator sum rule. We now make the bookkeeping precise.

50.5.2 The crossing equations and their matrix structure

For non-identical external scalars the conformal block carries a dependence on the dimension differences, which we must reinstate relative to Chapter 49. Recall from Theorem 47.46 and the block kinematics of Chapter 47 that the s-channel

decomposition of a four-point function of scalars $\mathcal{O}_1\mathcal{O}_2\mathcal{O}_3\mathcal{O}_4$ reads, after stripping the standard conformal prefactor,

$$\mathcal{G}(u,v) \;=\; \sum_{\mathcal{O}} \lambda_{12\mathcal{O}}\,\lambda_{34\mathcal{O}}\, g^{\Delta_{12},\Delta_{34}}_{\Delta_{\mathcal{O}},\ell_{\mathcal{O}}}(u,v), \qquad \Delta_{ij}\equiv\Delta_i-\Delta_j, \tag{50.92}$$

the block reducing to the identical-operator block $g_{\Delta,\ell}$ of Chapter 49 when all external dimensions coincide. Crossing $1\leftrightarrow 3$ equates this s-channel sum to the t-channel sum. Generalizing the antisymmetrized combination $F_{\Delta,\ell} = v^{\Delta_\phi}g(u,v) - u^{\Delta_\phi}g(v,u)$ of Chapter 49 to unequal externals, define the two convolved blocks

Definition 50.25 (Mixed convolved blocks)**.** For external scalars with dimensions Δ_i, set

$$F^{ij,kl}_{\mp,\Delta,\ell}(u,v) \;\equiv\; v^{\frac{\Delta_k+\Delta_j}{2}}\, g^{\Delta_{ij},\Delta_{kl}}_{\Delta,\ell}(u,v) \;\mp\; u^{\frac{\Delta_k+\Delta_j}{2}}\, g^{\Delta_{ij},\Delta_{kl}}_{\Delta,\ell}(v,u), \tag{50.93}$$

the lower sign (F_-) antisymmetric and the upper sign (F_+) symmetric under $u\leftrightarrow v$. For all-identical externals $F^{\phi\phi,\phi\phi}_{-,\Delta,\ell}$ is the function $F_{\Delta,\ell}$ of Eq. (49.74).

Carrying out the vectorization of Section 49.3.4 for each correlator in Eq. (50.90) — using the non-identical-operator block decomposition of Section 47.7.4, whose blocks for unequal externals depend on the dimension differences Δ_{ij} but are stripped and Taylor-expanded at the crossing-symmetric point exactly as in the identical case — assembles the system into five independent crossing equations. The single ingredient beyond the single-correlator construction of Chapter 49 is the sign a spin-ℓ exchange acquires under interchange of the two operators in an OPE pair, derived explicitly below. Two come from the diagonal correlators and reproduce the single-correlator sum rule for σ and for ε:

$$\sum_{\mathcal{O}^+} \lambda^2_{\sigma\sigma\mathcal{O}}\, F^{\sigma\sigma,\sigma\sigma}_{-,\Delta,\ell} = 0, \tag{50.94}$$

$$\sum_{\mathcal{O}^+} \lambda^2_{\varepsilon\varepsilon\mathcal{O}}\, F^{\varepsilon\varepsilon,\varepsilon\varepsilon}_{-,\Delta,\ell} = 0, \tag{50.95}$$

with the identity included as the $\Delta=0$ term. The remaining three come from the mixed correlator $\langle\sigma\sigma\varepsilon\varepsilon\rangle$ together with its reordering $\langle\sigma\varepsilon\sigma\varepsilon\rangle$. The self-crossing of $\langle\sigma\varepsilon\sigma\varepsilon\rangle$ exchanges only $\mathcal{O}^-$ in both channels and is purely odd-sector; the crossing relating $\langle\sigma\sigma\varepsilon\varepsilon\rangle$ to $\langle\sigma\varepsilon\sigma\varepsilon\rangle$ ties the even product $\lambda_{\sigma\sigma\mathcal{O}}\lambda_{\varepsilon\varepsilon\mathcal{O}}$ to the odd square $\lambda^2_{\sigma\varepsilon\mathcal{O}}$ and produces two equations (the symmetric and antisymmetric convolutions). The factor $(-1)^\ell$ that appears on the odd terms is not an input; it follows from the three-point kinematics of Section 47.4. The leading tensor structure of $\langle\sigma\,\varepsilon\,\mathcal{O}_\ell\rangle$ for a spin-ℓ primary $\mathcal{O}_\ell$ exchanged in the $\sigma\times\varepsilon$ OPE is built from ℓ contractions with the separation vector $x^\mu_{\sigma\varepsilon} = x^\mu_\sigma - x^\mu_\varepsilon$ (Theorem 47.24). The crossing that relates $\langle\sigma\sigma\varepsilon\varepsilon\rangle$ to its reordering $\langle\sigma\varepsilon\sigma\varepsilon\rangle$ interchanges the roles of σ and ε in this pair,

sending $x_{\sigma\varepsilon} \to -x_{\sigma\varepsilon}$ and hence multiplying the structure by $(-1)^\ell$; equivalently $\lambda_{\varepsilon\sigma\mathcal{O}_\ell} = (-1)^\ell \lambda_{\sigma\varepsilon\mathcal{O}_\ell}$, and the convolved block of Theorem 50.25 inherits the same sign. This is the only place the odd $(\sigma\varepsilon)$ data enters with a spin-dependent sign, and it is the origin of the explicit $(-1)^\ell$ in the fourth and fifth components of Eq. (50.97).

It is cleanest to package all five at once. Collecting the even operators into the quadratic form $\vec{\lambda}_{\mathcal{O}}^{\mathsf{T}}(\cdots)\vec{\lambda}_{\mathcal{O}}$ built from Eq. (50.91), the entire mixed system is the single vector equation

$$\boxed{\sum_{\mathcal{O}^+} \vec{\lambda}_{\mathcal{O}}^{\mathsf{T}}\, \vec{\mathbb{V}}_{\Delta_{\mathcal{O}},\ell_{\mathcal{O}}}\, \vec{\lambda}_{\mathcal{O}} \;+\; \sum_{\mathcal{O}^-} \lambda_{\sigma\varepsilon\mathcal{O}}^2\, \vec{U}_{\Delta_{\mathcal{O}},\ell_{\mathcal{O}}} \;=\; \vec{0},} \tag{50.96}$$

where the sum over $\mathcal{O}^+$ includes the identity with $\vec{\lambda}_{\mathbf{1}} = (1,1)^{\mathsf{T}}$, the $\mathcal{O}^+$ sum runs over even spin and the $\mathcal{O}^-$ sum over all spin, and the five-component objects are a vector of symmetric 2×2 matrices and a vector of scalars,

$$\vec{\mathbb{V}}_{\Delta,\ell} = \begin{pmatrix} \begin{pmatrix} F_-^{\sigma\sigma,\sigma\sigma} & 0 \\ 0 & 0 \end{pmatrix} \\ \begin{pmatrix} 0 & 0 \\ 0 & F_-^{\varepsilon\varepsilon,\varepsilon\varepsilon} \end{pmatrix} \\ \begin{pmatrix} 0 & 0 \\ 0 & 0 \end{pmatrix} \\ \frac{1}{2}\begin{pmatrix} 0 & F_-^{\sigma\sigma,\varepsilon\varepsilon} \\ F_-^{\sigma\sigma,\varepsilon\varepsilon} & 0 \end{pmatrix} \\ \frac{1}{2}\begin{pmatrix} 0 & F_+^{\sigma\sigma,\varepsilon\varepsilon} \\ F_+^{\sigma\sigma,\varepsilon\varepsilon} & 0 \end{pmatrix} \end{pmatrix}, \qquad \vec{U}_{\Delta,\ell} = \begin{pmatrix} 0 \\ 0 \\ F_-^{\sigma\varepsilon,\sigma\varepsilon} \\ -(-1)^\ell F_-^{\varepsilon\sigma,\sigma\varepsilon} \\ (-1)^\ell F_+^{\varepsilon\sigma,\sigma\varepsilon} \end{pmatrix}, \tag{50.97}$$

the convolved blocks evaluated at the external dimensions of their superscripts via Theorem 50.25. The first two components of Eq. (50.97) are exactly Eqs. (50.94) and (50.95); the third is the odd self-crossing of $\langle\sigma\varepsilon\sigma\varepsilon\rangle$; the fourth and fifth are the mixed equations that link the off-diagonal even data $\lambda_{\sigma\sigma\mathcal{O}}\lambda_{\varepsilon\varepsilon\mathcal{O}}$ to the odd data $\lambda_{\sigma\varepsilon\mathcal{O}}^2$. This is the mixed σ–ε crossing system of Kos et al. [303]; the line-by-line block identities behind Eq. (50.97) are the non-identical-operator kinematics of Chapter 47.

Physical Insight: why a matrix and not three numbers

One might object that Eqs. (50.94) and (50.95) already carry $\lambda_{\sigma\sigma\mathcal{O}}^2$ and $\lambda_{\varepsilon\varepsilon\mathcal{O}}^2$ as ordinary nonnegative numbers, and the mixed equation merely adds a third number $\lambda_{\sigma\sigma\mathcal{O}}\lambda_{\varepsilon\varepsilon\mathcal{O}}$. Why not treat all three as independent nonnegative weights and stay in the linear-programming world of Chapter 49? Because the three are *not* independent: a genuine CFT has a single real pair $(\lambda_{\sigma\sigma\mathcal{O}}, \lambda_{\varepsilon\varepsilon\mathcal{O}})$ per operator, so the off-diagonal entry is forced to equal $\pm\sqrt{\lambda_{\sigma\sigma\mathcal{O}}^2\,\lambda_{\varepsilon\varepsilon\mathcal{O}}^2}$ with a definite sign correlation. The clean, convex way

to impose "these three numbers are the entries of an outer product $\vec{\lambda}\vec{\lambda}^{\mathsf{T}}$" is the statement that the matrix $P_{\mathcal{O}}$ of Eq. (50.91) is positive semidefinite. Treating the entries as free nonnegative numbers would throw away the correlation and weaken every bound; keeping the matrix constraint is what makes the mixed system strictly stronger than the sum of its diagonal parts.

50.5.3 Positive semidefiniteness from unitarity

The matrix $P_{\mathcal{O}}$ in Eq. (50.91) is manifestly an outer product, hence rank one and positive semidefinite. But it is worth proving the positivity from unitarity directly, because the argument shows what survives when the assumption "one operator per (Δ,ℓ)" is dropped — and that is exactly the structural fact that promotes the problem from a linear to a semidefinite program.

Theorem 50.26 (Positive semidefiniteness of the OPE matrix)**.** *Let (Δ,ℓ) be the quantum numbers of one or more $\mathbb{Z}_2$-even primaries of a unitary CFT, and define the symmetric 2×2 matrix*

$$P_{\Delta,\ell} \;=\; \sum_{\mathcal{O}:\,(\Delta_{\mathcal{O}},\ell_{\mathcal{O}})=(\Delta,\ell)} \begin{pmatrix} \lambda_{\sigma\sigma\mathcal{O}}^2 & \lambda_{\sigma\sigma\mathcal{O}}\lambda_{\varepsilon\varepsilon\mathcal{O}} \\ \lambda_{\sigma\sigma\mathcal{O}}\lambda_{\varepsilon\varepsilon\mathcal{O}} & \lambda_{\varepsilon\varepsilon\mathcal{O}}^2 \end{pmatrix}. \tag{50.98}$$

Then $P_{\Delta,\ell}\succeq 0$.

Proof. Work in radial quantization, where the inner product on the Hilbert space of states is positive definite precisely because the theory is unitary (reflection positivity, established in Chapter 10 and used throughout Chapter 47). A primary $\mathcal{O}$ inserted at the origin creates a state $|\mathcal{O}\rangle$, and the OPE Eqs. (50.87) and (50.88) states that the radial-quantization states obtained from $\sigma\sigma$ and from $\varepsilon\varepsilon$ both have a component along the conformal multiplet $[\mathcal{O}]$ built on $|\mathcal{O}\rangle$ and its descendants. Let $\mathcal{P}_{[\Delta,\ell]}$ be the orthogonal projector onto the span of all primaries with the given quantum numbers (Δ,ℓ) together with their descendants. Because it projects onto a subspace of a positive-definite Hilbert space, $\mathcal{P}_{[\Delta,\ell]}$ is itself a positive operator.

Denote by $|a\rangle$ $(a\in\{\sigma\sigma,\varepsilon\varepsilon\})$ the state created by the corresponding pair of operators in a fixed configuration. The OPE coefficients are the overlaps of these states with the multiplet: projecting and using that distinct conformal families are orthogonal,

$$\Big\langle a\Big|\mathcal{P}_{[\Delta,\ell]}\Big|b\Big\rangle \;=\; \kappa_{\Delta,\ell} \sum_{\mathcal{O}:\,(\Delta_{\mathcal{O}},\ell_{\mathcal{O}})=(\Delta,\ell)} \lambda_{a\mathcal{O}}\,\lambda_{b\mathcal{O}}, \tag{50.99}$$

where $\kappa_{\Delta,\ell}>0$ is a common kinematic normalization (the same positive number for both indices because the descendants and their norms are fixed by conformal

symmetry and the unit normalization of the primaries), and $\lambda_{a\mathcal{O}}$ is $\lambda_{\sigma\sigma\mathcal{O}}$ or $\lambda_{\varepsilon\varepsilon\mathcal{O}}$ accordingly. The left-hand side of Eq. (50.99) is the Gram matrix $G_{ab} = \left\langle a \middle| \mathcal{P}_{[\Delta,\ell]} \middle| b \right\rangle$ of the two projected states. A Gram matrix of any set of vectors under a positive operator is positive semidefinite: for any real $c = (c_\sigma, c_\varepsilon)$,

$$c^{\mathsf{T}} G\, c = \left\langle \psi \middle| \mathcal{P}_{[\Delta,\ell]} \middle| \psi \right\rangle = \| \, \mathcal{P}_{[\Delta,\ell]} \, |\psi\rangle \, \|^2 \geq 0, \qquad |\psi\rangle \equiv c_\sigma \, |\sigma\sigma\rangle + c_\varepsilon \, |\varepsilon\varepsilon\rangle \, , \tag{50.100}$$

using $\mathcal{P}^2 = \mathcal{P} = \mathcal{P}^\dagger$. Hence $G \succeq 0$, and since $P_{\Delta,\ell} = \kappa_{\Delta,\ell}^{-1} G$ with $\kappa_{\Delta,\ell} > 0$, also $P_{\Delta,\ell} \succeq 0$. □

Physical Insight: degeneracy is the true source of "semidefinite"

If a single operator sits at (Δ, ℓ), the sum in Eq. (50.98) has one term and $P_{\Delta,\ell} = \vec{\lambda}\vec{\lambda}^{\mathsf{T}}$ is rank one — it lies on the boundary of the PSD cone, with eigenvalues 0 and $|\vec{\lambda}|^2$. But the bootstrap is not allowed to assume how many operators share a given (Δ, ℓ); two nearly degenerate even scalars, or a scalar and a higher operator that the truncated functional cannot resolve, contribute a *sum* of rank-one matrices, which is a generic PSD matrix of rank up to two. The only honest hypothesis is therefore $P_{\Delta,\ell} \succeq 0$ — the full positive-semidefinite cone, not just its rank-one boundary. This is the precise origin of the word "semidefinite": it is forced by unitarity together with the refusal to assume nondegeneracy, and it has nothing to do with the sum-of-squares representation of the functional (the "SOS trick" of Section 50.3) that handles the continuous variable Δ. The functional must be positive on a *matrix* of conformal blocks, because the data it multiplies is a matrix.

50.5.4 The generalized sum rule and its rank-one core

We can now restate the mixed system in the trace form that exhibits the matrix data cleanly. Using $\vec{\lambda}^{\mathsf{T}} \mathbb{V} \vec{\lambda} = \mathrm{Tr}[\mathbb{V} \vec{\lambda}\vec{\lambda}^{\mathsf{T}}] = \mathrm{Tr}[\mathbb{V} P]$ component by component, Eq. (50.96) becomes the following.

Theorem 50.27 (Matrix-valued bootstrap sum rule)**.** *A unitary $\mathbb{Z}_2$-symmetric CFT with external scalars σ (odd) and ε (even) satisfies*

$$\sum_{\mathcal{O}^+} \mathrm{Tr}\big[\, \vec{\mathbb{V}}_{\Delta_\mathcal{O},\ell_\mathcal{O}} \, P_\mathcal{O} \,\big] \; + \; \sum_{\mathcal{O}^-} p_\mathcal{O} \, \vec{U}_{\Delta_\mathcal{O},\ell_\mathcal{O}} \; = \; \vec{0}, \tag{50.101}$$

with $\vec{\mathbb{V}}, \vec{U}$ as in Eq. (50.97), $P_\mathcal{O} \succeq 0$ the 2×2 OPE matrix of Eq. (50.91) (Theorem 50.26), $p_\mathcal{O} = \lambda^2_{\sigma\varepsilon\mathcal{O}} \geq 0$, the even sum including the identity with $P_\mathbf{1} = \left(\begin{smallmatrix} 1 & 1 \\ 1 & 1 \end{smallmatrix}\right)$, and the spectrum obeying the unitarity bounds of Theorem 47.18.

The single-correlator sum rule of Eq. (49.74) is the *rank-one specialization* of Eq. (50.101), in two independent senses, which it is worth seeing explicitly.

Worked Example 50.28 (The single correlator as the rank-one corner of the matrix system)**.** Suppose we discard the energy operator and bootstrap σ alone. Operationally this means keeping only the first component of Eq. (50.97) and only the $(1,1)$ entry of every matrix — equivalently, projecting onto the vector $e_\sigma = (1,0)^{\mathsf{T}}$. Then for each even operator

$$\mathrm{Tr}\big[\,\vec{\mathbb{V}}^{(1)}_{\Delta,\ell}\,P_{\mathcal{O}}\,\big] = (P_{\mathcal{O}})_{11}\,F^{\sigma\sigma,\sigma\sigma}_{-,\Delta,\ell} = \lambda^2_{\sigma\sigma\mathcal{O}}\,F_{\Delta,\ell}, \tag{50.102}$$

since $\vec{\mathbb{V}}^{(1)}$ has its only nonzero entry in the $(1,1)$ slot and $(P_{\mathcal{O}})_{11} = \lambda^2_{\sigma\sigma\mathcal{O}}$. The odd operators drop out entirely (the first component of $\vec{U}$ is zero), and Eq. (50.101) collapses to

$$\sum_{\mathcal{O}^+} \lambda^2_{\sigma\sigma\mathcal{O}}\,F_{\Delta_{\mathcal{O}},\ell_{\mathcal{O}}} = 0, \tag{50.103}$$

which, dividing through by the identity's $F_{0,0}$, is exactly Eq. (49.74). Two specializations have happened at once. First, only one external operator is retained, so the matrices shrink to their top-left scalar. Second — and this is the "rank-one" content even within the single-correlator problem — the only datum that survives is $(P_{\mathcal{O}})_{11} = \lambda^2_{\sigma\sigma\mathcal{O}} \geq 0$, a single nonnegative number, so the positive-semidefinite cone of 2×2 matrices degenerates to the nonnegative half-line, and the SDP degenerates to the LP of Chapter 49. The mixed system is strictly more constraining because it refuses both degenerations: it keeps both external operators and it keeps the full 2×2 cone.

50.5.5 The semidefinite condition: positivity on a matrix of blocks

The exclusion argument is the matrix analogue of the separating-hyperplane logic of Chapter 49. A functional is now not a single linear map but a tuple $\alpha = (\alpha_1,\dots,\alpha_5)$ of linear functionals, one for each crossing equation, acting on functions of the cross-ratios (in practice, on finitely many Taylor derivatives at the crossing-symmetric point, as in Section 49.3.4). Applying α to Eq. (50.101) contracts the five-vector to a single scalar equation,

$$\sum_{\mathcal{O}^+} \mathrm{Tr}\big[\,\Lambda_+(\Delta_{\mathcal{O}},\ell_{\mathcal{O}})\,P_{\mathcal{O}}\,\big] \;+\; \sum_{\mathcal{O}^-} p_{\mathcal{O}}\,\Lambda_-(\Delta_{\mathcal{O}},\ell_{\mathcal{O}}) \;=\; 0, \tag{50.104}$$

where the 2×2 symmetric matrix Λ_+ and the scalar Λ_- are the functional's action on the block data,

$$\Lambda_+(\Delta,\ell) \equiv \sum_{a=1}^{5} \alpha_a[\vec{\mathbb{V}}^{(a)}_{\Delta,\ell}], \qquad \Lambda_-(\Delta,\ell) \equiv \sum_{a=1}^{5} \alpha_a[\vec{U}^{(a)}_{\Delta,\ell}]. \tag{50.105}$$

The trace pairing of two PSD matrices is nonnegative, which is the matrix replacement for "a product of nonnegative numbers is nonnegative."

Lemma 50.29 (Trace pairing of PSD matrices)**.** *If $A \succeq 0$ and $B \succeq 0$ are real symmetric matrices, then* $\mathrm{Tr}[AB] \geq 0$.

Proof. Diagonalize $A = \sum_i a_i\, u_i u_i^{\mathsf{T}}$ with eigenvalues $a_i \geq 0$ and orthonormal u_i. Then $\mathrm{Tr}[AB] = \sum_i a_i\, \mathrm{Tr}[u_i u_i^{\mathsf{T}} B] = \sum_i a_i\, u_i^{\mathsf{T}} B\, u_i$. Each $u_i^{\mathsf{T}} B\, u_i \geq 0$ because $B \succeq 0$, and each $a_i \geq 0$, so the sum is nonnegative. □

Theorem 50.30 (Semidefinite exclusion criterion)**.** *Fix external dimensions $(\Delta_\sigma, \Delta_\varepsilon)$ and a hypothesized spectrum: a list of allowed (Δ, ℓ) for the even sector and for the odd sector, each obeying Theorem 47.18. Suppose there exists a functional $\alpha = (\alpha_1, \dots, \alpha_5)$ such that*

$$\mathrm{Tr}\left[\Lambda_+(0,0)\, P_{\mathbf{1}}\right] = 1 \qquad \textit{(identity normalization)}, \tag{50.106}$$

$$\Lambda_+(\Delta,\ell) \succeq 0 \qquad \textit{for every even } (\Delta,\ell) \neq \mathbf{1} \textit{ in the spectrum}, \tag{50.107}$$

$$\Lambda_-(\Delta,\ell) \geq 0 \qquad \textit{for every odd } (\Delta,\ell) \textit{ in the spectrum}. \tag{50.108}$$

Then no unitary CFT with those external dimensions and that spectrum exists.

Proof. Suppose such a CFT existed. It would satisfy Eq. (50.101), hence Eq. (50.104). Split off the identity from the even sum and use the normalization Eq. (50.106):

$$0 = \underbrace{\mathrm{Tr}[\Lambda_+(0,0)P_{\mathbf{1}}]}_{=1} + \sum_{\mathcal{O}^+ \neq \mathbf{1}} \mathrm{Tr}\left[\Lambda_+(\Delta_{\mathcal{O}},\ell_{\mathcal{O}})P_{\mathcal{O}}\right] + \sum_{\mathcal{O}^-} p_{\mathcal{O}}\, \Lambda_-(\Delta_{\mathcal{O}},\ell_{\mathcal{O}}). \tag{50.109}$$

By unitarity each $P_{\mathcal{O}} \succeq 0$ (Theorem 50.26) and each $p_{\mathcal{O}} \geq 0$. By hypothesis each $\Lambda_+(\Delta_{\mathcal{O}},\ell_{\mathcal{O}}) \succeq 0$, so by Theorem 50.29 every term in the first sum is ≥ 0; and each $\Lambda_-(\Delta_{\mathcal{O}},\ell_{\mathcal{O}}) \geq 0$, so every term in the second sum is ≥ 0. The right-hand side is therefore $\geq 1 > 0$, contradicting the equality to 0. Hence no such CFT exists. □

The content of Theorem 50.30 is exactly what makes the optimization a *semidefinite* program rather than a linear one: the unknowns of the dual are the coefficients of α, and the constraints Eq. (50.107) demand that a matrix built linearly from those coefficients be positive semidefinite for every (Δ, ℓ) — a constraint on the eigenvalues of a matrix, which is the defining feature of an SDP. The continuous label Δ is handled by the polynomial/sum-of-squares reduction of Section 50.3, which turns "$\Lambda_+(\Delta,\ell) \succeq 0$ for all $\Delta \geq \Delta^*_\ell$" into finitely many matrix-positivity conditions a solver such as that of Simmons-Duffin [441] can dispatch. A short numerical example shows why the matrix condition cannot be replaced by positivity of the diagonal alone.

Worked Example 50.31 (Why diagonal positivity is not enough)**.** Imagine a candidate functional that, at some even (Δ, ℓ) in the spectrum, produced

$$\Lambda_+(\Delta,\ell) = \begin{pmatrix} 1 & -3 \\ -3 & 1 \end{pmatrix}. \tag{50.110}$$

Its diagonal entries are positive, so it would pass a naive "each correlator separately" test that only demanded the $\sigma\sigma$ and $\varepsilon\varepsilon$ channels be nonnegative. But it is not PSD: its determinant is $1 - 9 = -8 < 0$, so it has a negative eigenvalue ($\frac{1}{2}(2) \pm \frac{1}{2}\sqrt{0 + 4 \cdot 9} = 1 \pm 3$, i.e. -2 and 4). Now feed it a perfectly legal unitary contribution: an operator with $\vec{\lambda} = (1, 1)^{\mathsf{T}}$, so $P = \left(\begin{smallmatrix} 1 & 1 \\ 1 & 1 \end{smallmatrix}\right) \succeq 0$. The pairing is

$$\mathrm{Tr}[\Lambda_+ P] = 1 \cdot 1 + (-3) \cdot 1 + (-3) \cdot 1 + 1 \cdot 1 = -4 < 0, \tag{50.111}$$

which would wreck the exclusion proof: the term is supposed to be ≥ 0. The off-diagonal product $\lambda_{\sigma\sigma}\lambda_{\varepsilon\varepsilon}$ entered with a sign that the diagonal test never saw. Demanding the full matrix inequality $\Lambda_+ \succeq 0$ is precisely the condition that guarantees $\mathrm{Tr}[\Lambda_+ P] \geq 0$ for *every* PSD P — by Theorem 50.29 the matrix condition is not only sufficient but, taking P to be the projector onto the negative eigenvector, also necessary. The semidefinite constraint is the exact and minimal way to certify the pairing.

50.5.6 Closing the wedge: the two gap assumptions and the island

With the matrix functional in hand, the search proceeds exactly as in Chapter 49 but now over the richer space of dual variables, and with two gap assumptions that encode what it means to be the Ising fixed point rather than some other unitary $\mathbb{Z}_2$ CFT. The assumptions are physical and sharp:

1. σ **is the unique relevant $\mathbb{Z}_2$-odd scalar.** In the $\sigma \times \varepsilon$ channel the lightest odd scalar is σ itself; the next $\mathbb{Z}_2$-odd scalar σ' is irrelevant, $\Delta_{\sigma'} \geq 3 = d$. Equivalently, the odd sector has a gap above Δ_σ up to the marginality threshold.

2. ε **is the unique relevant $\mathbb{Z}_2$-even scalar.** In $\sigma \times \sigma$ and $\varepsilon \times \varepsilon$ the lightest even scalar is ε; the next even scalar ε' obeys $\Delta_{\varepsilon'} \geq 3$. This is the single-correlator gap of the previous section, now imposed in both diagonal channels.

These two statements are not arbitrary numerical conveniences; they are the *defining* feature of a critical point in the Ising universality class. A statistical system reaches criticality by tuning exactly one relevant coupling — the temperature, conjugate to the energy operator ε — while the $\mathbb{Z}_2$ (spin-flip) symmetry forbids a relevant odd coupling unless an external magnetic field is switched on. A unitary 3D CFT with precisely one relevant scalar in each $\mathbb{Z}_2$ sector is therefore the bootstrap's formalization of "a $\mathbb{Z}_2$ critical point reached by tuning one knob." The Wilson–Fisher analysis of Chapters 23 and 24 reached the same conclusion perturbatively: at the fixed point the mass operator ($\sim \varepsilon$) is the lone relevant direction and the quartic coupling is marginally irrelevant.

The effect of these two gaps on the allowed region of Theorem 50.30 is dramatic. Figure 50.6 shows it. The single correlator gave an open wedge in the $(\Delta_\sigma, \Delta_\varepsilon)$ plane, bounded above near the kink but unbounded below and laterally. Imposing the mixed system with both gaps, the functional can now push from *every* direction — the $\varepsilon\varepsilon$ channel bounds Δ_ε from below where the $\sigma\sigma$ channel bounded it from above, and the cross-channel ties Δ_σ to Δ_ε — so the allowed region pinches off into a small *closed* island surrounding the kink. As the number Λ of derivative components retained in the functional is increased (equivalently, as the SDP search is run at higher order), the islands are nested and shrink, collapsing onto a point. This is the qualitative content of Kos et al. [303, 304]: each refinement of the dual search certifies a smaller region as the only place a unitary CFT with these gaps can live.

50.5.7 The record numbers and the meeting of two threads

When the mixed system is run to high derivative order, the island shrinks to a point known to a precision no other method in this book approaches. The current rigorous values for the 3D Ising CFT [304] are

$$\Delta_\sigma = 0.5181489(10), \qquad \Delta_\varepsilon = 1.412625(10), \tag{50.112}$$

with the leading OPE coefficients in the same determination

$$\lambda_{\sigma\sigma\varepsilon} = 1.0518537(41), \qquad \lambda_{\varepsilon\varepsilon\varepsilon} = 1.532435(19). \tag{50.113}$$

These six-significant-figure numbers are the output of consistency alone: no Lagrangian, no perturbative expansion, no lattice. The dimensions translate immediately into the critical exponents of the universality class, which is where the bootstrap meets the laboratory.

Worked Example 50.32 (Critical exponents from the island, and the comparison)**.** In a d-dimensional CFT the dimension of the order parameter fixes the anomalous-dimension exponent η through $\Delta_\sigma = \tfrac{1}{2}(d-2+\eta)$, and the dimension of the energy operator fixes the correlation-length exponent ν through the renormalization-group eigenvalue of the one relevant even coupling, $y_t = d - \Delta_\varepsilon$ and $\nu = 1/y_t$. In $d = 3$,

$$\eta = 2\Delta_\sigma - (d-2) = 2\Delta_\sigma - 1 = 2(0.5181489) - 1 = 0.0362978(20), \tag{50.114}$$

$$\nu = \frac{1}{d-\Delta_\varepsilon} = \frac{1}{3-\Delta_\varepsilon} = \frac{1}{1.587375} = 0.629971(4), \tag{50.115}$$

where the uncertainties propagate linearly: $\delta\eta = 2\,\delta\Delta_\sigma = 2.0\times10^{-6}$ and $\delta\nu = \delta\Delta_\varepsilon/(3-\Delta_\varepsilon)^2 = 1.0\times10^{-5}/1.5874^2 = 4.0\times10^{-6}$. The remaining exponents follow from the scaling relations established in Chapter 23: $\gamma = \nu(2-\eta) = 1.237075(10)$, $\beta = \tfrac{\nu}{2}(d-2+\eta) = 0.326419(3)$, and $\alpha = 2 - d\nu = 0.110087(12)$. The leading

Table 50.1: The 3D Ising universality class: bootstrap, Monte Carlo, and experiment. Bootstrap values from Kos et al. [304] via Eqs. (50.112), (50.114) and (50.115); Monte Carlo from Hasenbusch [254]; experimental ranges are representative of fluid and magnetic systems in the class. Parenthesized digits are one-standard-deviation uncertainties in the last quoted figures.

quantity	numerical bootstrap	Monte Carlo	experiment
Δ_σ	0.5181489(10)	—	—
Δ_ε	1.412625(10)	—	—
η	0.0362978(20)	0.03627(10)	≈ 0.036
ν	0.629971(4)	0.63002(10)	≈ 0.63
ω	≈ 0.83	0.832(6)	—

correction-to-scaling exponent comes from the next even scalar, $\omega = \Delta_{\varepsilon'} - d$; the same island analysis places $\Delta_{\varepsilon'} \approx 3.83$, giving $\omega \approx 0.83$.

The numbers can be checked against two completely independent determinations. Table 50.1 collects them. The Monte-Carlo finite-size-scaling study of Hasenbusch [254] gives $\nu = 0.63002(10)$ and $\eta = 0.03627(10)$; the bootstrap values lie inside the Monte-Carlo error bars and are roughly two orders of magnitude more precise. Laboratory measurements of systems in the 3D Ising universality class — the liquid–vapor critical point of simple fluids, binary-fluid demixing, and uniaxial antiferromagnets — give $\nu \approx 0.63$ and $\eta \approx 0.036$ to the percent level set by the experiments, fully consistent with Eqs. (50.114) and (50.115). Three methods that share no equations — a semidefinite program, a lattice simulation, and a thermometer — agree on the same numbers, which is as strong a statement of the reality of the fixed point as physics offers.

This is the quantitative payoff of ϕ^4 theory. The model began in Chapter 6 as a classical real scalar with a ϕ^4 interaction and a $\mathbb{Z}_2$ symmetry; it was renormalized in Chapter 22, its one-loop beta function $\beta_\lambda = 3\lambda^2/16\pi^2$ computed in Chapter 24, and its Wilson–Fisher fixed point located perturbatively in $d = 4 - \epsilon$ at $\lambda_* = \frac{16\pi^2}{3}\epsilon + O(\epsilon^2)$ with $\gamma_\phi = O(\epsilon^2)$. Setting $\epsilon = 1$ to reach $d = 3$ pushes that expansion to the edge of its validity; resummed, it returns $\eta \approx 0.036$ and $\nu \approx 0.63$ to a percent or two. The bootstrap reaches the *same* fixed point — the unique unitary 3D $\mathbb{Z}_2$ CFT with one relevant scalar in each sector — from the opposite side, using no Lagrangian at all, and pins it to six significant figures. The perturbative thread of Part VI and the consistency thread of this chapter meet on the single number $\nu = 0.629971(4)$. That the Wilson–Fisher fixed point of Chapter 24 *is* the bootstrap island of Fig. 50.6 is the identification Chapter 52 makes precise when it characterizes the Wilson–Fisher fixed point as a conformal field theory; here it is confirmed numerically to a precision the ϵ-expansion cannot dream of.

Caution: what the island is, and is not, a theorem of

The island of Fig. 50.6 is a rigorous statement — modulo controllable numerical error in the SDP — but a *conditional* one. It says: *any* unitary, $\mathbb{Z}_2$-symmetric 3D CFT whose only relevant scalars are one odd and one even must have $(\Delta_\sigma, \Delta_\varepsilon)$ inside the island. It does *not*, by itself, prove that such a CFT exists, nor that the theory living there is the continuum limit of the lattice Ising model. The existence of a nontrivial solution is supported by the fact that the island is non-empty at every derivative order and by the convergence of its extremal data; the identification with the Ising universality class is physics input — the matching critical exponents of Table 50.1 — not a corollary of the bound. We separate these claims carefully in Section 50.6.

The island has a boundary, and a CFT that sits exactly on it is special: there the exclusion functional of Theorem 50.30 is on the verge of failing, which means the inequalities Eqs. (50.107) and (50.108) are saturated by a particular set of operators. That saturating, extremal configuration carries more information than the dimensions $(\Delta_\sigma, \Delta_\varepsilon)$ alone: it encodes a candidate for the *entire* spectrum of exchanged operators and their OPE coefficients. The next section turns this observation into a method — the extremal functional — for reading the full CFT data off the boundary of the island, and then steps back to delimit honestly what the numerical bootstrap proves and what it assumes.

50.6 Reading the Spectrum: Extremal Functionals, Rigor, and Scope

The mixed-correlator program of Section 50.5 did more than corner the 3D Ising data into the island Eq. (49.171). At the moment the semidefinite solver certifies that a candidate point sits on the *boundary* of the allowed region, it returns two objects at once: a configuration of nonnegative OPE coefficients $\{p_{\mathcal{O}}\}$ that saturates crossing — the extremal, boundary-realizing solution handed up by Eq. (50.128) — and the optimal functional that certifies no solution survives just beyond the boundary. So far we have used only the second object, and only for its sign, to draw exclusion curves and shrink islands. This closing section extracts the information hiding in the *pairing* of the two. The claim, which is the dual reading of the entire bootstrap, is that the extremal functional does not merely separate the allowed from the forbidden: its zeros, read off as a function of dimension, are the dimensions of the operators present in the saturating CFT. The bootstrap stops being a tool that brackets the data and becomes a tool that *reconstructs* it. We prove this through complementary slackness at the optimum, work the leading Ising spectrum out of the resulting double-zero structure, and

then spend the remainder of the section being honest: about exactly which of our statements are theorems and which are physics, about the adjacent methods that make the search efficient, and about where the program stands and stalls as of the mid-2020s.

50.6.1 The dual reading: from a separating hyperplane to a spectrum

Recall the logical skeleton built in Section 50.2.1. The crossing sum rule of Eq. (49.74), with the identity contribution isolated and normalized to unit coefficient, reads

$$\vec{F}_{0,0} \;+\; \sum_{\mathcal{O}\neq \mathbf{1}} p_{\mathcal{O}}\, \vec{F}_{\Delta_{\mathcal{O}},\ell_{\mathcal{O}}} \;=\; 0, \qquad p_{\mathcal{O}} = \lambda^2_{\phi\phi\mathcal{O}} \geq 0, \tag{50.116}$$

where $\vec{F}_{\Delta,\ell}$ is the crossing vector of Eq. (49.87) — in practice the finite array of derivatives $\partial_z^m \partial_{\bar{z}}^n F_{\Delta,\ell}\big|_{z=\bar{z}=1/2}$ retained at a chosen truncation order, so that $\vec{F}_{\Delta,\ell} \in \mathbb{R}^N$ for some large but finite N. A linear functional α is then a vector in the same space, acting by

$$\alpha[\,\vec{F}_{\Delta,\ell}\,] \;=\; \alpha \cdot \vec{F}_{\Delta,\ell} \;=\; \sum_{a=1}^{N} \alpha_a \left(\partial^a F_{\Delta,\ell}\right)\Big|_{z=\bar{z}=1/2}. \tag{50.117}$$

The exclusion theorem (Theorem 49.28, recast in convex-geometric form in Theorem 50.8 and as a semidefinite program in Theorem 50.19) says that a candidate spectrum S — a set of (Δ,ℓ) consistent with the unitarity bounds of Chapter 49 and with whatever gap assumptions we impose — is *forbidden* precisely when some functional separates the identity from the rest:

$$\alpha[\,\vec{F}_{0,0}\,] \;>\; 0, \qquad \alpha[\,\vec{F}_{\Delta,\ell}\,] \;\geq\; 0 \quad \text{for all } (\Delta,\ell) \in S. \tag{50.118}$$

The reason is immediate from Eq. (50.116): applying such an α gives $\alpha[\vec{F}_{0,0}] + \sum_{\mathcal{O}} p_{\mathcal{O}}\, \alpha[\vec{F}_{\mathcal{O}}]$, a strictly positive number plus a sum of nonnegative numbers, which cannot vanish; so no nonnegative crossing solution supported on S exists. Geometrically α is a hyperplane in $\mathbb{R}^N$ with the convex cone $\{\,\vec{F}_{\Delta,\ell}\,\}$ on one side and $-\vec{F}_{0,0}$ on the other.

The dual reading begins with a question this picture leaves unasked. *What happens at the boundary, where exclusion is marginal?* As the gap or the external dimension is tuned to the edge of the allowed region, the separating hyperplane is forced flush against the cone. It can no longer keep strictly clear of every block; it must touch the cone, and it touches it exactly along the directions $\vec{F}_{\Delta,\ell}$ corresponding to the operators that the saturating solution actually uses. Those touching directions are where $\alpha[\vec{F}_{\Delta,\ell}] = 0$. Reading the spectrum is then nothing more than locating the zeros of the boundary functional. To turn this picture into a theorem we need the precise relationship between the boundary functional and the boundary solution, and that relationship is supplied by Lagrange duality.

50.6.2 The optimization and its dual

The cleanest setting in which the boundary functional and the boundary solution appear as an exact dual pair is the maximization of a single OPE coefficient — the original *extremal functional method*. Everything we prove transfers verbatim to gap maximization and to c_T-minimization, which we treat as corollaries below.

Fix the external dimension Δ_ϕ and a candidate operator $\mathcal{O}_0 = (\Delta_0, \ell_0)$ whose coefficient we wish to push as high as crossing and unitarity permit. Collect the admissible operators (those obeying unitarity and the imposed gaps) into the index set S, and let A be the matrix whose columns are the crossing vectors $\vec{F}_{\mathcal{O}}$ for $\mathcal{O} \in S \setminus \{\mathbf{1}\}$, so that the crossing equation Eq. (50.116) is $A\,p = -\vec{F}_{0,0}$ with $p = (p_{\mathcal{O}})_{\mathcal{O} \neq \mathbf{1}}$. The optimization is the (semi-infinite) linear program

$$\textbf{(P)} \qquad \max_{p \geq 0} \; c^{\mathsf{T}} p \quad \text{subject to} \quad A\,p = -\vec{F}_{0,0}, \tag{50.119}$$

where the objective vector $c = e_{\mathcal{O}_0}$ selects the single coefficient $p_{\mathcal{O}_0}$. "Semi-infinite" because S is a continuum of operators (every dimension above the unitarity bound, every even spin) while the constraint $A\,p = -\vec{F}_{0,0}$ lives in the finite space $\mathbb{R}^N$ fixed by the truncation. The optimal value of **(P)** is the largest squared OPE coefficient $\lambda^2_{\phi\phi\mathcal{O}_0}$ attainable by any unitary crossing-symmetric solution with the assumed gaps.

Every linear program has a dual obtained by pricing the constraints. Introduce a vector $y \in \mathbb{R}^N$ of multipliers, one per component of the crossing equation, and form the Lagrangian

$$\mathcal{L}(p, y) = c^{\mathsf{T}} p + y^{\mathsf{T}}\big(-\vec{F}_{0,0} - A\,p\big) = -y^{\mathsf{T}} \vec{F}_{0,0} + \big(c - A^{\mathsf{T}} y\big)^{\mathsf{T}} p. \tag{50.120}$$

Maximizing freely over $p \geq 0$ gives $+\infty$ unless the coefficient of p is nonpositive in every component, i.e. unless $A^{\mathsf{T}} y \geq c$; when that holds the supremum over $p \geq 0$ is attained at $p = 0$ and equals $-y^{\mathsf{T}} \vec{F}_{0,0}$. The dual program is therefore

$$\textbf{(D)} \qquad \min_{y} \; -y^{\mathsf{T}} \vec{F}_{0,0} \quad \text{subject to} \quad \vec{F}_{\mathcal{O}} \cdot y \;\geq\; \delta_{\mathcal{O},\mathcal{O}_0} \quad \text{for all } \mathcal{O} \in S \setminus \{\mathbf{1}\}. \tag{50.121}$$

The constraint reads $\vec{F}_{\mathcal{O}_0} \cdot y \geq 1$ for the singled-out operator and $\vec{F}_{\mathcal{O}} \cdot y \geq 0$ for every other admissible operator. A dual-feasible y is, up to the normalization at $\mathcal{O}_0$, exactly an exclusion functional in the sense of Eq. (50.118): it is nonnegative on the admissible cone. We call the optimal dual vector $\alpha_* := y_*$ the *extremal functional*.

Definition 50.33 (Extremal solution and extremal functional)**.** At a boundary point of the bootstrap-allowed region, the *extremal solution* is an optimizer $p_* \geq 0$ of the primal Eq. (50.119), and the *extremal functional* α_* is an optimizer of the dual Eq. (50.121). The *extremal spectrum* is the support $\Sigma_* = \{\mathcal{O} : p_{*,\mathcal{O}} > 0\}$ of the extremal solution.

Weak duality is the half-line of Eq. (50.120) that always holds: for any primal-feasible p and dual-feasible y,

$$c^{\mathsf{T}}p = y^{\mathsf{T}}(A\,p) + (c - A^{\mathsf{T}}y)^{\mathsf{T}}p = -\,y^{\mathsf{T}}\vec{F}_{0,0} + \underbrace{(c - A^{\mathsf{T}}y)^{\mathsf{T}}p}_{\leq 0} \;\leq\; -\,y^{\mathsf{T}}\vec{F}_{0,0}, \tag{50.122}$$

because $c - A^{\mathsf{T}}y \leq 0$ componentwise (dual feasibility) and $p \geq 0$ (primal feasibility). The primal objective never exceeds the dual objective. *Strong* duality — that the two optima coincide — is the content of the linear-programming duality theorem proved, in the finite-truncation form that governs every actual computation, in Theorem 50.6 via Farkas' lemma; the semidefinite generalization needed once positivity becomes matrix-valued is Theorem 50.22. At the common optimum,

$$c^{\mathsf{T}}p_* \;=\; -\,\alpha_*^{\mathsf{T}}\vec{F}_{0,0}. \tag{50.123}$$

The maximal OPE coefficient (left) equals minus the extremal functional's action on the identity (right). The two readings of the boundary are the same number.

50.6.3 Complementary slackness and the double-zero theorem

Strong duality forces a rigid alignment between which operators the extremal solution uses and where the extremal functional vanishes. This is complementary slackness, and it is the whole mechanism.

Theorem 50.34 (Extremal functional locates the spectrum)**.** *Let p_* and α_* be optimizers of the primal Eq. (50.119) and dual Eq. (50.121), related by strong duality Eq. (50.123). Then for every admissible operator $\mathcal{O} \in S \setminus \{\mathbf{1}\}$,*

$$p_{*,\mathcal{O}}\,(\alpha_*[\vec{F}_{\mathcal{O}}] - \delta_{\mathcal{O},\mathcal{O}_0}) = 0. \tag{50.124}$$

Consequently every operator of the extremal spectrum Σ_* other than the singled-out $\mathcal{O}_0$ is a zero of the extremal functional,

$$\alpha_*[\,\vec{F}_{\mathcal{O}}\,] = 0 \qquad \text{for all } \mathcal{O} \in \Sigma_* \setminus \{\mathcal{O}_0\}, \tag{50.125}$$

while $\alpha_*[\vec{F}_{\mathcal{O}_0}] = 1$. Moreover, since $\Delta \mapsto \alpha_*[\vec{F}_{\Delta,\ell}]$ is a nonnegative real-analytic function on the admissible interval at each spin ℓ, each interior zero in Eq. (50.125) is at least a double *zero:*

$$\alpha_*[\,\vec{F}_{\Delta,\ell}\,]\Big|_{\Delta=\Delta_{\mathcal{O}}} = 0 \quad \text{and} \quad \frac{\partial}{\partial\Delta}\,\alpha_*[\,\vec{F}_{\Delta,\ell}\,]\Big|_{\Delta=\Delta_{\mathcal{O}}} = 0. \tag{50.126}$$

Proof. The slackness identity Eq. (50.124) is the equality case of weak duality. Subtract the two sides of Eq. (50.122) at the optimum and use strong duality Eq. (50.123):

$$0 = (\,-\,\alpha_*^{\mathsf{T}}\vec{F}_{0,0}) - c^{\mathsf{T}}p_* = (A^{\mathsf{T}}\alpha_* - c)^{\mathsf{T}}p_* = \sum_{\mathcal{O}\neq\mathbf{1}} (\alpha_*[\vec{F}_{\mathcal{O}}] - c_{\mathcal{O}})\,p_{*,\mathcal{O}}, \tag{50.127}$$

where the middle equality used $\alpha_*^{\mathsf{T}} A\, p_* = -\alpha_*^{\mathsf{T}} \vec{F}_{0,0}$ (primal feasibility of p_*) and $A^{\mathsf{T}}\alpha_* = (\alpha_*[\vec{F}_{\mathcal{O}}])_{\mathcal{O}}$. Each summand is a product of a nonnegative factor $p_{*,\mathcal{O}} \geq 0$ and a nonnegative factor $\alpha_*[\vec{F}_{\mathcal{O}}] - c_{\mathcal{O}} \geq 0$ (dual feasibility, since $c_{\mathcal{O}} = \delta_{\mathcal{O},\mathcal{O}_0}$). A sum of nonnegative terms vanishes only if each term vanishes; this is Eq. (50.124). For $\mathcal{O} \in \Sigma_*$ we have $p_{*,\mathcal{O}} > 0$, so the second factor must vanish: $\alpha_*[\vec{F}_{\mathcal{O}}] = c_{\mathcal{O}}$, which is 0 for $\mathcal{O} \neq \mathcal{O}_0$ and 1 for $\mathcal{O} = \mathcal{O}_0$. This is Eq. (50.125).

For the double-zero statement, fix a spin ℓ and consider $g_\ell(\Delta) := \alpha_*[\vec{F}_{\Delta,\ell}]$ as a function of the dimension. The conformal block $F_{\Delta,\ell}(z,\bar{z})$, and hence each of its derivatives at the crossing-symmetric point, is real-analytic in Δ on the admissible interval (the blocks are analytic in Δ away from the discrete poles that lie below the unitarity bound, Theorem 50.16 and Eq. (50.46)); g_ℓ is therefore real-analytic there. Dual feasibility Eq. (50.121) states $g_\ell(\Delta) \geq 0$ for every admissible Δ at spin ℓ. Let $\Delta_{\mathcal{O}}$ be the location of an operator in Σ_* with spin ℓ and $\mathcal{O} \neq \mathcal{O}_0$, so $g_\ell(\Delta_{\mathcal{O}}) = 0$ by Eq. (50.125), and suppose $\Delta_{\mathcal{O}}$ is interior to the admissible interval (true for every operator above the gap). A nonnegative differentiable function that attains the value 0 at an interior point has a local minimum there, so its first derivative vanishes: $g'_\ell(\Delta_{\mathcal{O}}) = 0$. This is Eq. (50.126). The zero has even order; generically it is exactly double, though higher even order is possible at non-generic boundary points where two operators collide. □

Two corollaries make the theorem usable. First, the extremal *spectrum is discrete and finite at any truncation.* The primal Eq. (50.119) is a linear program with N equality constraints; its optimum is attained at a vertex of the feasible polyhedron, i.e. at a *basic* solution with at most N nonzero components. Thus $|\Sigma_*| \leq N$: only finitely many operators carry nonzero OPE coefficient, even though the admissible set is a continuum. As the truncation order N is raised, the located operators multiply and fill in the true (infinite) spectrum, low dimensions first. Second, *the spectrum is read off, not assumed.* The double zeros of $\Delta \mapsto \alpha_*[\vec{F}_{\Delta,\ell}]$ at each spin are computed directly from the optimal functional returned by the solver; their locations *are* the dimensions $\Delta_{\mathcal{O}}$. Having located Σ_*, one recovers the coefficients by solving the now-finite linear system $\vec{F}_{0,0} + \sum_{\mathcal{O}\in\Sigma_*} p_{\mathcal{O}} \vec{F}_{\mathcal{O}} = 0$ for the $p_{\mathcal{O}}$ — an overdetermined but consistent set of N linear equations in $|\Sigma_*| \leq N$ unknowns. The full CFT data $(\Delta_{\mathcal{O}}, \lambda^2_{\phi\phi\mathcal{O}})$ emerge from the single boundary functional.

Physical Insight

The exclusion bootstrap asks a yes/no question and the functional answers it with a sign. The extremal bootstrap notices that *at the boundary the sign is forced to be zero in exactly the right places*, and those places are the spectrum. The same convex-optimization certificate that proves a region empty, evaluated on the last region that is not empty, draws a picture of the unique theory living there. Nothing extra is computed; the spectrum

was always encoded in the dual variable, waiting to be read.

The same logic operates whenever the boundary is reached, regardless of which objective drove us there. *Gap maximization* (pushing the dimension of the first scalar above the identity as high as possible, the optimization behind the single-correlator kink of Section 50.4) has the same dual structure: at the maximal gap the certifying functionals converge to an extremal α_* whose first scalar zero sits exactly at the maximal gap, and whose remaining double zeros give the rest of the saturating spectrum. *c_T-minimization* — minimizing the stress-tensor channel coefficient, equivalently maximizing the central charge's inverse — is Eq. (50.119) with $\mathcal{O}_0$ the stress tensor and the objective reversed in sign; this is the variant that originally pinned the 3D Ising point at the tip of the kink before mixed correlators closed the island. In each case Theorem 50.34 delivers the spectrum from the optimal functional's double zeros.

50.6.4 Reading the leading Ising spectrum

We now apply the theorem at the Ising island. The boundary-saturating configuration handed up from Section 50.5 sits at the data Eq. (49.171),

$$\Delta_\sigma = 0.5181489(10), \qquad \Delta_\varepsilon = 1.412625(10), \tag{50.128}$$

and the extremal functional evaluated there has the double-zero structure drawn in Fig. 50.7. We read the leading operators off spin by spin.

Worked Example 50.35 (The leading 3D Ising spectrum from the extremal functional)**.** We trace each double zero of Fig. 50.7 to an operator and recover its data, taking the located dimensions as the computed zeros of $\alpha_*[\vec{F}_{\Delta,\ell}]$ and the coefficients from the linear solve described after Theorem 50.34.

Spin 0*, the leading even scalar.* The first interior double zero in the $\ell = 0$ channel is at $\Delta = 1.412625$. By Eq. (50.125) this is an operator of the extremal solution, and it is the lowest-dimension $\mathbb{Z}_2$-even scalar: it is ε, the energy operator of Theorem 49.27. Its location reproduces Δ_ε in Eq. (50.128) — consistency, since the island point was defined by assuming ε is the first even scalar. Through the dictionary Eq. (49.163) this fixes the correlation-length exponent: $1/\nu = d - \Delta_\varepsilon = 3 - 1.412625 = 1.587375$, i.e. $\nu = 0.629971(4)$. Solving the residual linear crossing system on the located spectrum returns the coefficient $\lambda_{\sigma\sigma\varepsilon} = 1.0518537(41)$.

Spin 0*, the subleading scalar.* The next double zero sits at $\Delta_{\varepsilon'} \approx 3.82966$. This is ε', the second $\mathbb{Z}_2$-even scalar. It is *irrelevant* in $d = 3$ (dimension above 3), and its distance above marginality is the leading correction-to-scaling exponent,

$$\omega = \Delta_{\varepsilon'} - d \approx 3.830 - 3 = 0.830, \tag{50.129}$$

the exponent that controls how critical quantities approach their scaling forms as the critical point is neared — a number the extremal functional delivers

as readily as the relevant dimensions, and which agrees with the Monte Carlo determination $\omega \approx 0.83$. The bootstrap did not need to be told ε' exists; the second zero produced it.

Spin 2, the stress tensor. The first double zero in the $\ell = 2$ channel is pinned exactly at $\Delta = 3$. This is not a number to be measured but one fixed by symmetry: every local CFT has a conserved stress tensor $T_{\mu\nu}$, a spin-2 operator saturating the unitarity bound $\Delta = d - 2 + \ell = 3$ of Chapter 49 for $\ell = 2$, $d = 3$. The extremal functional's spin-2 zero falling on $\Delta = 3$ is a stringent internal check that the saturating solution is a genuine local CFT and not a spurious crossing solution. The coefficient of this block is inverse to the central charge: $p_T \propto \Delta_\phi^2 / c_T$, and the linear solve returns $c_T / c_T^{\text{free}} = 0.946534(11)$ — a measure of how far the interacting Ising CFT sits from the free scalar.

Spin 2, the next operator. The following $\ell = 2$ double zero, near $\Delta \approx 5.5$, is the leading spin-2 operator above the stress tensor; at large spin these $\ell = 2, 4, 6, \ldots$ operators organize into the double-twist family $\Delta \approx 2\Delta_\sigma + \ell$ that the analytic bootstrap of Chapter 51 controls in closed form.

The reconstruction. Assembling the located dimensions and the coefficients from the linear solve gives the leading Ising CFT data,

$$\begin{aligned} &\Delta_\sigma = 0.5181489, \quad \Delta_\varepsilon = 1.412625, \quad \Delta_{\varepsilon'} \approx 3.83, \quad \Delta_T = 3, \\ &\lambda_{\sigma\sigma\varepsilon} = 1.0518537, \quad \lambda_{\varepsilon\varepsilon\varepsilon} = 1.532435, \quad c_T / c_T^{\text{free}} = 0.946534, \end{aligned} \tag{50.130}$$

each digit improving as the truncation order N of the functional is raised and the island shrinks around the point. Through Eqs. (49.162) and (49.163) the dimensions become the critical exponents $\eta = 2\Delta_\sigma - 1 = 0.0362978(20)$ and $\nu = 0.629971(4)$. This is the completion of the bootstrap stage of ϕ^4 theory: the Wilson–Fisher fixed point, found perturbatively in $d = 4 - \epsilon$ in Chapter 24 and characterized as a CFT in Theorem 52.11, is not merely *bounded* by crossing and unitarity — its operator spectrum is *read off*, operator by operator, from a single convex-optimization certificate.

50.6.5 Rigor, honestly accounted

The numbers in Eq. (50.130) are more precise than any other determination of the Ising data, and precision invites overclaiming. We separate, sharply, what the bootstrap proves from what it assumes. There are three distinct epistemic tiers, and they must not be conflated.

Tier 1 — exclusions are theorems, up to controllable arithmetic. When the solver returns a functional α satisfying Eq. (50.118) for a candidate spectrum S, the corresponding region is forbidden with mathematical certainty: no unitary, crossing-symmetric, $\mathbb{Z}_2$-symmetric CFT with the assumed gaps can have data there. The certificate is finite and checkable. Two arithmetic caveats are genuine but controllable. First, the functional acts on a finite-dimensional

truncation of the crossing equation Eq. (50.116); positivity over the continuum of dimensions and the infinite tower of spins is enforced by polynomial sum-of-squares representations (Theorem 50.22) that are exact at the truncation order, and enlarging the truncation only *tightens* the bound, never loosens it. Second, the solver works in finite-precision floating point, but the optimal functional it returns can be validated by re-evaluating Eq. (50.118) in exact rational or rigorous interval arithmetic; when that validation passes — as it can be made to, and has been — the exclusion is a theorem in the literal sense. The boundary curves of Section 50.4 and the outer wall of the island in Section 50.5 are, region by region, certified theorems of this kind.

Tier 2 — islands are theorems conditional on explicit gap assumptions. A closed island, unlike an exclusion curve, asserts that the allowed region is *small and bounded*, and that assertion is conditional. The Ising island of Eq. (49.171) is rigorous given the hypotheses under which it was computed: unitarity, crossing of the full $\langle\sigma\sigma\sigma\sigma\rangle$, $\langle\sigma\sigma\varepsilon\varepsilon\rangle$, $\langle\varepsilon\varepsilon\varepsilon\varepsilon\rangle$ system, $\mathbb{Z}_2$ symmetry, and — decisively — the gap assumption that there are exactly two relevant scalars, one $\mathbb{Z}_2$-odd (σ) and one $\mathbb{Z}_2$-even (ε), with everything else above the relevant threshold $\Delta = d = 3$. Change that gap input and the island moves or dissolves. The gap assumption is not derived inside the bootstrap; it is imported from the renormalization-group understanding of the Ising universality class — the statement that the critical point is reached by tuning exactly two relevant couplings, temperature and field. Given the assumption, the island is a Tier-1 object: its complement is excluded by certified functionals. What is *not* a theorem of the same hardness is the further claim that the true allowed region is a single point: each computed island is nonempty in every run and shrinks monotonically as the truncation is enlarged, which is overwhelming numerical evidence of convergence to a point, but a proof that the limit is nonempty and a single point is not in hand.

Tier 3 — naming the theory is physics input. That the island is the *3D Ising model* — the lattice spin system, the ϕ^4 fixed point, the liquid–vapor and uniaxial-magnet critical points in the same universality class — is not a bootstrap theorem at all. It is the identification of a fixed point characterized by symmetry and relevant-operator content with a named physical system, and it rests on the renormalization-group universality statement of Theorem 23.26: all systems flowing to the same fixed point share its critical data. The bootstrap computes the data of *a* unitary $\mathbb{Z}_2$ CFT with two relevant scalars; universality, established by entirely different (RG) arguments, says that any such CFT is the Ising fixed point and that the lattice model flows to it. The agreement of Eq. (50.130) with Monte Carlo (Chapter 43) and with the resummed ϵ-expansion (Chapter 24) is the empirical confirmation of that identification, not its proof.

Caution

The single most common overstatement is "the bootstrap proved the 3D Ising model exists and has these exponents." It did not. As of the mid-2020s there is no construction of the 3D Ising CFT as a mathematical object satisfying all the axioms simultaneously, and no proof that the shrinking islands converge to a nonempty limit or that the limit is unique. The honest statement is the conditional one: *if* a unitary CFT with the Ising gaps exists, its data lie in the island, pinned to six significant figures. Existence remains open — in sharp contrast to two dimensions, where the free-fermion realization of the Ising CFT (Chapter 48) is a genuine existence proof. The remaining gap is no longer "is the number right?" but the sharper mathematical question "does the limiting theory exist and is it unique?"

50.6.6 The broader toolkit

The single- and mixed-correlator semidefinite programs of this chapter are the core, but the working bootstrap is surrounded by methods that make the search efficient and connect it to the analytic side. We state their roles; their full development belongs to the dedicated literature and, for the analytic methods, to Chapter 51.

The navigator function. Locating an island by brute force — testing a grid of candidate points, each by a separate feasibility solve, and bisecting toward the boundary — scales badly as the number of free parameters grows (external dimensions, gaps, several OPE ratios). The *navigator function* replaces the binary feasible/infeasible verdict with a single smooth function on parameter space, engineered to be negative inside the allowed region, positive outside, and to vary smoothly across the boundary. Its gradient points toward the island, so the island can be found and its extent mapped by gradient descent rather than by exhaustive scanning — the difference between rolling downhill to a valley and checking every point on a map. This is what makes high-dimensional mixed-correlator searches, with many simultaneous gap and ratio parameters, computationally feasible [417].

OPE and c_T extremization. Before islands closed, the Ising point was first isolated as the location where the central charge c_T is *minimized* along the single-correlator boundary — the tip of the kink coincides with the minimum of c_T, a sharp feature that selects the fixed point without a gap assumption strong enough to bound it from all sides [173]. OPE-coefficient maximization, the optimization of Eq. (50.119), is the same family of tools: extremizing any physically meaningful linear functional of the data selects an extremal point whose full spectrum is then read off by Theorem 50.34. These extremization methods and the navigator

are complementary: extremization finds and characterizes a boundary point, the navigator finds and bounds the island around it.

The analytic bootstrap. The numerical program controls the low-lying spectrum — the relevant operators, the stress tensor, the first few subleading operators — with great precision, but says progressively less about high spin, where the operator tower is infinite and the truncation thin. The analytic bootstrap is the exact complement. In the lightcone limit, crossing forces the existence of *double-twist* families $\Delta \approx \Delta_{\phi_1} + \Delta_{\phi_2} + \ell + 2n$ at large spin ℓ, and the *Lorentzian inversion formula* of Theorem 51.16 turns the four-point function into an analytic function of spin that computes their dimensions and OPE coefficients in closed form, order by order in $1/\ell$ [111]. The double zeros of the extremal functional at large spin (the spin-2 tower of Fig. 50.7 and its higher-spin continuation) are exactly the operators the inversion formula predicts; the numerical and analytic spectra agree where they overlap. The handoff is precise: numerics pins the few low-lying operators that analytics cannot reach, analytics organizes the infinite large-spin tail that numerics cannot resolve, and modern high-precision results stitch the two together.

50.6.7 The frontier, dated

We close with the status of the program as of the mid-2020s, stated as honestly as the rest.

What has been isolated. The 3D Ising model is the showcase: cornered to six significant figures by the mixed σ–ε system [303, 304], with the data of Eq. (50.130) now the most precise available. The same machinery has isolated the $O(N)$ vector models for a range of N: the $O(2)$ model governing the superfluid λ-transition in helium-4, where the bootstrap determination of the heat-capacity exponent is precise enough to engage a longstanding tension with the space-shuttle microgravity measurement [120]; the $O(3)$ Heisenberg magnet; and the singular $N \to 0$ (self-avoiding walk) and $N \to 1$ (Ising) endpoints. Beyond bosonic models, the 3D *Gross–Neveu–Yukawa* CFTs — fermions coupled to a scalar at a critical point relevant to graphene and to emergent symmetry in quantum magnets — have been bootstrapped, with the extremal-functional spectrum read off and cross-checked against the large-N and ϵ-expansions [179]. In each case the workflow is the one of this chapter: assume unitarity and a gap structure dictated by the RG, close an island in a mixed-correlator system, and read the spectrum from the extremal functional.

What remains out of reach. The method's reach is set by the sharpness of the features it can exploit. Theories with a clean kink or a small, well-separated set of relevant operators are tractable; theories with many low-lying operators, weak or absent kinks, or no reliable gap assumption are not. Confining gauge theories and QCD-like dynamics, with their dense spectra and no obvious small

parameter, are largely beyond the current single-correlator and small-mixed-system technology. Theories without a known global symmetry to organize the OPE-coefficient positivity into manageable blocks are harder still. And every island is conditional on a gap input; where the RG does not hand us a clean relevant-operator count, there is nothing to assume, and the allowed region need not close.

Open methodological questions. The deepest is the existence-and-uniqueness gap of Section 50.6.5: turning the shrinking islands into a constructive existence proof, or at least a proof that the limiting region is nonempty, is unsolved. On the computational side, the bottleneck is the size of the semidefinite programs as one adds correlators, operators, and global-symmetry representations; the navigator and improved solvers [441] push the frontier but do not remove the exponential pressure of high-dimensional searches. There are also structural questions about the space of functionals itself: the analytic functional bases that reproduce the numerical optima in solvable cases (the dispersive and Polyakov–Mellin functionals) hint that the extremal functional has a closed-form analytic skeleton not yet exposed in general, a possibility that Chapter 51 begins to make precise.

This completes the bootstrap stage of ϕ^4 theory: from the crossing sum rule Eq. (49.74), through the linear-functional exclusion machinery and its semidefinite refinement, to the closed Ising island and now its extremal spectrum Eq. (50.130), the Wilson–Fisher fixed point has been not merely bounded but solved, its operators read one by one off a convex-optimization certificate. The very feature that completes the numerical reconstruction — the double-twist tower fixed at large spin by the extremal functional's high-ℓ zeros — is precisely where the numerics runs thin and demands an analytic handle. That handle is the subject of Chapter 51: the lightcone limit, the large-spin expansion, and the Lorentzian inversion formula Theorem 51.16 that computes the analytic continuation in spin which the numbers of this chapter can only sample.

Further reading

The comprehensive modern reference for everything in this chapter is the review of Poland et al. [402], which covers the linear-functional method, the semidefinite reduction, mixed correlators, and the extremal-functional spectrum reading in one place; Rattazzi et al. [415] is the founding paper that first turned crossing plus unitarity into a numerical bound. The $3d$ Ising story unfolds across El-Showk et al. [172] (the single-correlator solution and the kink), El-Showk et al. [173] (c-minimization and precise exponents), Kos et al. [303] (the mixed σ–ε system), and Kos et al. [304] (the precision islands quoted here); the independent Monte Carlo determination used for comparison is Hasenbusch [254]. The semidefinite solver and its arbitrary-precision implementation are described in Simmons-Duffin

[441], and the gradient-based search that makes high-dimensional mixed systems tractable in Reehorst et al. [417]. For the reach beyond Ising see Chester et al. [120] on the $O(2)$ model and the λ-transition tension, and Erramilli et al. [179] on the $3d$ Gross–Neveu–Yukawa CFTs. The analytic complement — the lightcone limit, large spin, and the Lorentzian inversion formula whose predictions match the extremal functional's high-spin zeros — is Caron-Huot [111], developed in Chapter 51.

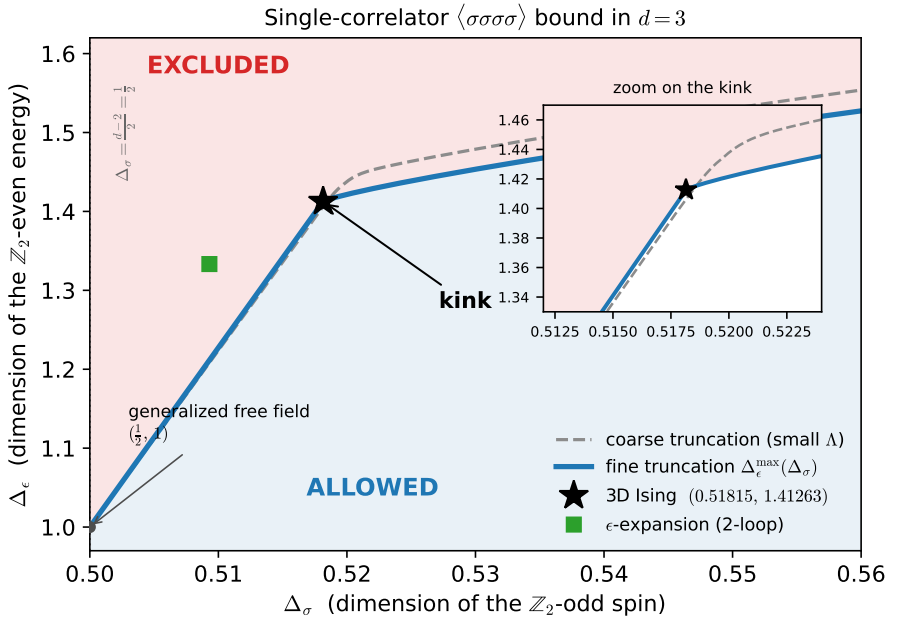

Figure 50.5: The single-correlator $\langle\sigma\sigma\sigma\sigma\rangle$ bound in $d = 3$, computed from the feasibility problem of Theorem 50.23 by the semidefinite program of Section 50.3. For each Δ_σ the curve gives the largest dimension $\Delta_\varepsilon^{\max}$ the leading $\mathbb{Z}_2$-even scalar may have under the single-gap assumption; the shaded region below is allowed, everything above is excluded by an explicit positivity certificate (Theorem 49.28). The dashed curve is a coarse derivative truncation and the solid curve a finer one; the rigorous bound decreases monotonically with the derivative order Λ, so the curve descends toward its limit from above. The bound rises from the generalized-free-field endpoint $(\frac{1}{2}, 1)$, where the lightest even scalar is the double-twist $[\sigma\sigma]_{0,0} = :\sigma^2:$ at $2\Delta_\sigma = 1$, and develops a sharp *kink*. The 3D Ising universality class sits essentially at the kink, at $(\Delta_\sigma, \Delta_\varepsilon) = (0.5181489, 1.412625)$ (Eq. (49.171)); the two-loop ε-expansion prediction of ϕ^4 theory (square, Theorem 49.29) points to the same corner from the interior. The inset zooms on the kink, where the corner sharpens as Λ grows.

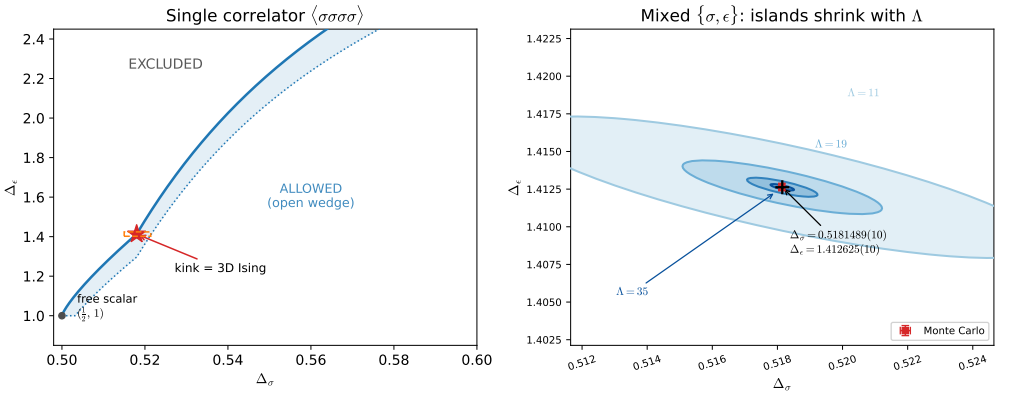

Figure 50.6: The mechanism that isolates the 3D Ising model. *Left*: the single-correlator allowed region from $\langle\sigma\sigma\sigma\sigma\rangle$ with the $\mathbb{Z}_2$ gap (Section 50.2.1) is an *open* wedge — it has a kink at the Ising point but extends without closing, so it bounds the data without isolating it. *Right* (zoom of the dashed box): the mixed $\{\sigma, \varepsilon\}$ system with both gap assumptions of Section 50.5.6 closes the wedge into a *closed* island, which shrinks as the number of derivative constraints Λ is increased, collapsing onto the precision values $\Delta_\sigma = 0.5181489(10)$, $\Delta_\varepsilon = 1.412625(10)$. The Monte-Carlo determination (square with error cross, Hasenbusch [254]) sits inside the island, far less precisely. The contours are a faithful schematic of the published islands, not a re-run of the semidefinite solver.

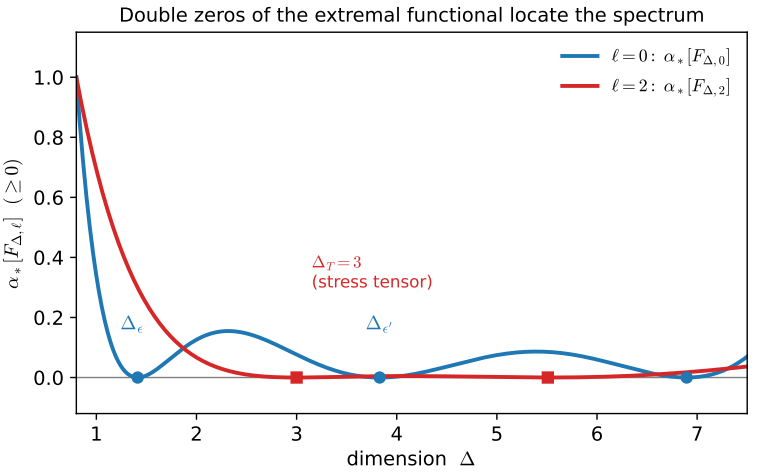

Figure 50.7: Schematic of the extremal functional acting on conformal blocks, $\Delta \mapsto \alpha_*[\vec{F}_{\Delta,\ell}]$, at two spins, evaluated at the 3D Ising island point Eq. (50.128). The function is nonnegative everywhere (dual feasibility) and touches zero without changing sign at the dimensions of the operators present in the extremal solution: a double zero in the $\ell = 0$ channel at $\Delta_\varepsilon = 1.412625$ (the leading $\mathbb{Z}_2$-even scalar) and the next at $\Delta_{\varepsilon'} \approx 3.83$ (the subleading scalar, irrelevant); a double zero in the $\ell = 2$ channel pinned at $\Delta_T = 3$ (the stress tensor, fixed by conservation) and the next at $\Delta \approx 5.5$. The double-zero locations *are* the spectrum; complementary slackness Theorem 50.34 guarantees it.

Chapter 51

The Analytic Bootstrap

The numerical bootstrap of Chapter 50 treated the crossing equation as a feasibility problem: it asked whether a candidate spectrum could exist, and answered with islands and exclusion bounds certified by positivity. The answer was astonishingly precise but mute. It located the 3D Ising dimensions to many digits without explaining why the spectrum has the shape it does, and it could speak only about a finite window of low-lying, low-spin operators. This chapter develops the complementary half of the bootstrap. Instead of bounding the space of solutions with a computer, we solve the crossing equation *analytically* in a controlled corner of kinematics and read off closed-form statements about an infinite family of operators. The price is that the control is asymptotic — it is sharpest at large spin — but the reward is structural understanding: the very operators the numerics cannot reach, and the mechanism behind the ones it can.

The engine is a single limit. Taking one cross-ratio to the lightcone collapses the conformal blocks of Theorem 47.49 to their collinear, $\mathrm{SL}(2,\mathbb{R})$ pieces — Gauss hypergeometric functions — and turns the crossing equation Eq. (49.14) into a tractable matching problem. Section 51.1 carries this out and extracts its first theorem: the identity operator, universal in every crossed channel, produces a power-law singularity that no finite, twist-gapped spectrum can reproduce, so crossing *forces* an infinite tower of large-spin operators whose twists accumulate at $2\Delta_\phi$. Section 51.2 names that tower. Its members are the double-twist operators $[\phi\phi]_{n,\ell}$ already met as the mean-field spectrum of Eq. (49.130), and to leading order their OPE data are exactly those of a generalized free field, the conformal avatar of mean-field theory. With the zeroth-order seed in hand, Section 51.3 perturbs around it: a single minimal-twist exchange in the crossed channel induces an anomalous dimension $\gamma_{0,\ell} \sim -c_{\tau_m}/\bar{h}^{\,\tau_m}$, the Komargodski–Zhiboedov / Fitzpatrick–Kaplan–Poland–Simmons-Duffin formula Eq. (51.73). Read physically through the unitarity bounds of Theorem 47.18, this is a binding energy; for stress-tensor exchange it is gravitational attraction in anti–de Sitter space with a strength set by the central charge, the seed of bulk locality picked

up by the holography arc of Chapters 53 and 56.

The lightcone method is powerful but order-by-order and somewhat artisanal. Section 51.4 replaces it with a machine. The Lorentzian inversion formula of Caron-Huot Theorem 51.16 reconstructs the entire OPE function from a single positive-definite integral of the correlator's double discontinuity, and in doing so proves that CFT data are *analytic in spin* down to ℓ near the Regge value. Its derivation leans on the analytic structure of the Feynman propagator from Theorem 9.24 and on the conformal partial-wave machinery built on the Casimir equation Eq. (47.233). Section 51.5 then turns the crank: because double-twist operators have vanishing double discontinuity, they are reconstructed entirely from the crossed channel, and inverting one block reproduces the large-spin master formula Eq. (51.73), the OPE-coefficient correction, and the gravitational result in a single pass. Section 51.6 steps back to the dual, functional viewpoint of Theorem 50.34: crossing is the vanishing of a linear functional, the one-dimensional problem is solved exactly by a basis of analytic functionals dual to the generalized free field, and the dispersive functionals that result are nothing but the inversion formula in another dress, unifying the lightcone, inversion, and Polyakov–Mellin pictures.

The chapter closes by pointing the whole apparatus at a real theory. Section 51.7 carries ϕ^4 theory to its analytic endpoint: the leading-twist towers $[\sigma\sigma]_{0,\ell}$ and $[\epsilon\epsilon]_{0,\ell}$ of the 3D Ising CFT are computed in closed form, cross-checked against the numerical spectrum located in Eq. (50.130) and inside the island of Eq. (49.171), and matched onto the Wilson–Fisher ϵ-expansion of Section 47.8.4. Three independent descriptions — generalized free field, ϵ-expansion, nonperturbative bootstrap — converge on the same conformal data, the strongest evidence that the fixed point is a single consistent object. The Wilson–Fisher-as-CFT closure and the dictionary back to the measured critical exponents are handed forward to Chapter 52.

51.1 Crossing in the Lightcone Limit

The numerical bootstrap of Chapter 50 solved crossing by brute force: it discretized the single equation Eq. (49.14), fed a truncated set of its derivatives at the crossing-symmetric point to a semidefinite solver, and let the computer carve out the allowed region of CFT data. The method is spectacularly accurate and almost completely opaque. It returns the 3D Ising dimensions to many digits without ever exhibiting a formula, an asymptotic law, or a reason why the spectrum looks as it does. The analytic bootstrap restores the reasoning. Its governing idea is simple to state: the crossing equation must hold for *every* value of the cross-ratios, so we are free to evaluate it not only near the symmetric point $z = \bar{z} = \frac{1}{2}$, where every block contributes comparably and only a machine can cope, but in kinematic *limits* where the infinite block sum collapses onto a few

controllable terms. The cleanest such limit is the lightcone limit, in which two of the four operators approach a common light ray. There the sum over the entire conformal spectrum on one side of crossing degenerates into a single power law set by the lightest operator, the identity; and the demand that the other side reproduce that power law, term by controllable term, turns out to be impossible to meet with any finite spectrum. The resolution forces a structural feature on *every* conformal field theory: an infinite tower of operators of unbounded spin, whose twists pile up at a value fixed entirely by the external dimension. This section sets up that limit, derives the one-dimensional "collinear" block that organizes it, proves the no-finite-spin lemma by direct power counting, and extracts the minimal-twist accumulation point. It is the entry gate to the whole analytic program.

51.1.1 The crossing equation in lightcone coordinates

We continue ϕ^4 theory from Chapter 49, studying the four-point function of a single real scalar primary ϕ of dimension Δ_ϕ — the free-field endpoint of the $\lambda\phi^4$ flow, promoted in Section 49.5.1 to a generalized free field of arbitrary Δ_ϕ. Because all four external operators are identical, the (12)(34) and (14)(23) fusions are decompositions of one and the same operator product $\phi \times \phi$; crossing is the self-consistency of that single OPE. Stripping the kinematic prefactor as in Theorem 47.49, the correlator reduces to the function $g(u, v)$ of the cross-ratios Eq. (47.140),

$$u = z\bar{z}, \qquad v = (1 - z)(1 - \bar{z}), \tag{51.1}$$

and the crossing equation imported from Eq. (49.14) reads

$$v^{\Delta_\phi} \sum_{\mathcal{O}} p_{\mathcal{O}}\, G_{\Delta_{\mathcal{O}},\ell_{\mathcal{O}}}(u, v) \;=\; u^{\Delta_\phi} \sum_{\mathcal{O}} p_{\mathcal{O}}\, G_{\Delta_{\mathcal{O}},\ell_{\mathcal{O}}}(v, u), \qquad p_{\mathcal{O}} = C^2_{\phi\phi\mathcal{O}} \geq 0. \tag{51.2}$$

The left-hand sum is the s-channel ((12)(34) fusion), the right-hand sum the t-channel ((14)(23) fusion); the two run over the *same* spectrum with the *same* squared coefficients, the swap $u \leftrightarrow v$ being the only difference. That swap is implemented on the complex coordinate of Eq. (51.1) by

$$u(1 - z, 1 - \bar{z}) = (1 - z)(1 - \bar{z}) = v, \qquad v(1 - z, 1 - \bar{z}) = z\bar{z} = u, \tag{51.3}$$

so that, writing the block in the z-coordinates as $G_{\Delta,\ell}(z, \bar{z})$ exactly as in Section 49.2.1, the t-channel block $G_{\Delta,\ell}(v, u)$ is the same function evaluated at $(1 - z, 1 - \bar{z})$. The crossing equation Eq. (51.2) becomes, with no approximation,

$$[(1 - z)(1 - \bar{z})]^{\Delta_\phi} \sum_{\mathcal{O}} p_{\mathcal{O}}\, G_{\Delta_{\mathcal{O}},\ell_{\mathcal{O}}}(z, \bar{z}) \;=\; (z\bar{z})^{\Delta_\phi} \sum_{\mathcal{O}} p_{\mathcal{O}}\, G_{\Delta_{\mathcal{O}},\ell_{\mathcal{O}}}(1 - z, 1 - \bar{z}). \tag{51.4}$$

In Euclidean signature $\bar{z} = z^*$, and Eq. (51.4) is an identity on the cut plane. The decisive observation, anticipated below Eq. (47.140), is that under

Lorentzian continuation z and $\bar{z}$ become *independent* real variables: the single complex configuration unfolds into a two-dimensional real domain, and we may send one of them to a boundary while holding the other fixed. This is precisely the freedom a single complex variable does not offer, and it is what makes the lightcone limit a genuine, accessible kinematic regime rather than a degenerate point.

Definition 51.1 (Lightcone limit)**.** The *lightcone* (or *collinear*) limit is

$$\bar{z} \to 1 \quad \text{at fixed } z \in (0,1), \qquad \Longleftrightarrow \qquad v = (1-z)(1-\bar{z}) \to 0, \quad u = z\bar{z} \to z, \tag{51.5}$$

with the small parameter $1-\bar{z} \simeq v/(1-z)$. Geometrically it is the limit in which the operators $\phi(x_1), \phi(x_4)$ (equivalently $\phi(x_2), \phi(x_3)$) become null-separated, so that $x_{14}^2 x_{23}^2 \to 0$ and the t-channel OPE converges most rapidly.

The reason the limit tames the block sum is the lightcone factorization established in Section 49.2.6: as the *second* cross-ratio argument of a block tends to zero, the block degenerates into a pure power of that argument, set by the twist

$$\tau \equiv \Delta - \ell, \tag{51.6}$$

times a single one-variable function of the surviving argument,

$$G_{\Delta,\ell}(\zeta, \bar{\zeta}) \xrightarrow{\bar{\zeta}\to 0} \bar{\zeta}^{\tau/2}\, k_{\Delta+\ell}(\zeta), \tag{51.7}$$

the content of Eq. (49.67). Applied to the t-channel blocks $G_{\Delta,\ell}(1-z, 1-\bar{z})$ on the right of Eq. (51.4), whose second argument is $1-\bar{z} \to 0$,

$$G_{\Delta,\ell}(1-z, 1-\bar{z}) \xrightarrow{\bar{z}\to 1} (1-\bar{z})^{\tau/2}\, k_{\Delta+\ell}(1-z). \tag{51.8}$$

The dependence on the small quantity $1-\bar{z}$ is now an explicit power $\frac{\tau}{2}$, so the t-channel sum is organized by twist: the smaller the twist, the more singular (less suppressed) the contribution. To exploit this we need the surviving function k_β in closed form.

51.1.2 The collinear block

The function k_β is the analytic bootstrap's atom. It was introduced in Eq. (49.30); because every argument of this chapter is built from it, we re-derive it here from its defining equation, in the form the lightcone analysis consumes. When the four operators are placed on a common line, the conformal group $\mathfrak{so}(d+1,1)$ degenerates to the $\mathrm{SL}(2,\mathbb{R})$ generated by $\{L_{-1}, L_0, L_{+1}\}$, and the collinear block is the eigenfunction of its quadratic Casimir. In the coordinate z that Casimir is the operator (Section 49.2.1)

$$D_z \;=\; z^2(1-z)\,\partial_z^2 \;-\; z^2\,\partial_z. \tag{51.9}$$

Proposition 51.2 (The collinear block as a hypergeometric function)**.** *For $\beta > 0$ set $h = \beta/2$. The solution of the eigenvalue problem*

$$D_z\, k_\beta(z) = h(h-1)\, k_\beta(z) \tag{51.10}$$

with leading behavior $k_\beta(z) \to z^h$ as $z \to 0$ is

$$\boxed{k_\beta(z) \;=\; z^{\beta/2}\, {}_2F_1\Big(\tfrac{\beta}{2}, \tfrac{\beta}{2}; \beta; z\Big), \qquad {}_2F_1(a,b;c;z) = \sum_{n\geq 0} \frac{(a)_n (b)_n}{(c)_n} \frac{z^n}{n!}.} \tag{51.11}$$

Proof. The operator Eq. (51.9) has a regular singular point at $z = 0$; its indicial equation, obtained by substituting $k \sim z^s$ and keeping the leading z^s term of $D_z z^s = s(s-1)z^s + \dots$, is $s(s-1) = h(h-1)$, with roots $s = h$ and $s = 1-h$. The root $s = h = \beta/2$ is the one matching the OPE leading power $u^{\tau/2}$ promised of the block; we build the solution on it. Write $k_\beta(z) = z^h g(z)$ with g analytic and $g(0) = 1$. Differentiating,

$$k'_\beta = h z^{h-1} g + z^h g', \tag{51.12}$$

$$k''_\beta = h(h-1) z^{h-2} g + 2h z^{h-1} g' + z^h g'', \tag{51.13}$$

and inserting into $D_z k_\beta - h(h-1)k_\beta = 0$ gives, after multiplying out the factors $z^2(1-z)$ and $-z^2$,

$$(1-z)\big[h(h-1)z^h g + 2h z^{h+1} g' + z^{h+2} g''\big] - \big[h z^{h+1} g + z^{h+2} g'\big] - h(h-1) z^h g = 0. \tag{51.14}$$

The terms $h(h-1)z^h g$ cancel, and dividing the remainder by z^{h+1} collects to

$$z(1-z)\, g'' + \big[\, 2h - (2h+1)z \,\big]\, g' - h^2\, g = 0. \tag{51.15}$$

This is the Gauss hypergeometric equation $z(1-z)g'' + [c - (a+b+1)z]g' - ab\, g = 0$ with $c = 2h$, $a+b = 2h$, $ab = h^2$, whose unique solution is $a = b = h$. The solution analytic at $z = 0$ with $g(0) = 1$ is $g(z) = {}_2F_1(h, h; 2h; z)$, which establishes Eq. (51.11). The eigenvalue read off from Eq. (51.10) is $h(h-1) = \frac{\beta}{2}(\frac{\beta}{2} - 1)$, in agreement with Eq. (49.31). □

Two properties of k_β are all the analysis below requires. The first is its small-z behavior, immediate from Eq. (51.11):

$$k_\beta(z) \;=\; z^{\beta/2}\big[1 + \tfrac{\beta}{4} z + O(z^2)\big] \;\xrightarrow{z\to 0}\; z^{\beta/2}, \tag{51.16}$$

which is what made the twist power appear in Eq. (51.7). The second, decisive for the no-finite-spin lemma, is the behavior at the *other* endpoint $z \to 1$.

Worked Example 51.3 (The collinear block diverges only logarithmically at $z \to 1$)**.** We show that as $z \to 1$ the collinear block grows no faster than a logarithm, and we compute the coefficient. Start from the Euler integral representation of the hypergeometric function, valid for $\operatorname{Re} c > \operatorname{Re} b > 0$ (here $c = \beta > h = \beta/2 > 0$),

$$ {}_2F_1(h,h;\beta;z) = \frac{\Gamma(\beta)}{\Gamma(h)^2}\int_0^1 \mathrm{d}t\, \big[t(1-t)\big]^{h-1}(1-zt)^{-h}. \tag{51.17}$$

The only source of singular behavior as $z \to 1$ is the endpoint $t \to 1$, where $1 - zt \to 1 - z$. Set $s = 1 - t$ and $\epsilon = 1 - z$; near $s = 0$ the integrand is $\big[t(1-t)\big]^{h-1}(1-zt)^{-h} \to s^{h-1}\,(\epsilon+s)^{-h}$ (using $t \to 1$, $1-zt = 1-z+z\,s \simeq \epsilon+s$). The singular part of the integral is therefore

$$ \int_0 \mathrm{d}s\, \frac{s^{h-1}}{(\epsilon+s)^h} \;=\; \int_0 \frac{\mathrm{d}s}{s}\Big(\frac{s}{\epsilon+s}\Big)^h. \tag{51.18}$$

For $s \gg \epsilon$ the bracket is 1 and the integrand is $\mathrm{d}s/s$; for $s \ll \epsilon$ it is $(s/\epsilon)^h$, integrably small. The integral thus accumulates a logarithm from the window $\epsilon \lesssim s \lesssim 1$, giving $-\log\epsilon + \text{finite} = -\log(1-z) + \text{finite}$. Restoring the prefactor of Eq. (51.17) and the factor $z^{\beta/2} \to 1$ of Eq. (51.11),

$$\boxed{\,k_\beta(z) \;\xrightarrow{z\to 1}\; -\frac{\Gamma(\beta)}{\Gamma(\beta/2)^2}\big[\log(1-z) + \text{const}\big] \;+\; O\big((1-z)\log(1-z)\big).\,} \tag{51.19}$$

The same conclusion follows from the structure of Eq. (51.15) at its regular singular point $z = 1$: with $c - a - b = \beta - 2h = 0$, the two indicial exponents at $z = 1$ coincide (both zero), and a confluent pair of exponents is exactly the case in which the second Frobenius solution carries a $\log(1-z)$. The block, being the solution regular at $z = 0$, is a generic combination of the two solutions at $z = 1$ and therefore inherits that logarithm. The constant in Eq. (51.19) is $2\psi(1) - 2\psi(\beta/2)$ in terms of the digamma function, but only the logarithm matters below.

The contrast between Eq. (51.16) and Eq. (51.19) is the engine of everything that follows: a single conformal block enters the lightcone limit through a power of the small twist variable and a one-dimensional function that, in the *crossed* variable, can diverge no worse than log. No power-law singularity is available from any finite collection of blocks. Crossing, as we now show, demands one.

51.1.3 Identity dominance and the failure of a finite spectrum

We take the lightcone limit Eq. (51.5) of the exact crossing equation Eq. (51.4), treating the two sides in turn.

The t-channel side collapses to the identity. On the right of Eq. (51.4), every block is governed by Eq. (51.8): operator $\mathcal{O}$ of twist $\tau_{\mathcal{O}}$ contributes a term proportional to $(1-\bar{z})^{\tau_{\mathcal{O}}/2}$. Among all operators in $\phi\times\phi$ the identity is unique in having $\tau=0$ (it is the only operator of vanishing dimension; every other primary obeys the unitarity bounds Theorem 47.18, which give $\tau=\Delta\geq\frac{d-2}{2}>0$ for scalars and $\tau=\Delta-\ell\geq d-2>0$ for $\ell\geq 1$). Thus there is a finite twist gap $\tau_{\text{gap}}>0$ above the identity, and as $\bar{z}\to 1$ the identity term, carrying $(1-\bar{z})^0$, strictly dominates every other, which is suppressed by at least $(1-\bar{z})^{\tau_{\text{gap}}/2}$. With the identity normalized to $p_{\mathbf{1}}=1$ and $G_{0,0}=1$,

$$(z\bar{z})^{\Delta_\phi}\sum_{\mathcal{O}}p_{\mathcal{O}}\,G_{\Delta,\ell}(1-z,1-\bar{z})\ \xrightarrow{\bar{z}\to 1}\ (z)^{\Delta_\phi}\Big[1+O\big((1-\bar{z})^{\tau_{\text{gap}}/2}\big)\Big]. \tag{51.20}$$

The entire right-hand side, an infinite sum over the whole spectrum, has degenerated into a single finite number z^{Δ_ϕ}.

The s-channel side must produce a power-law singularity. The left-hand side of Eq. (51.4) carries the explicit prefactor $\big[(1-z)(1-\bar{z})\big]^{\Delta_\phi}$, which vanishes as $(1-\bar{z})^{\Delta_\phi}$. For the equation to balance against the finite limit Eq. (51.20), the s-channel block sum must diverge precisely fast enough to cancel that vanishing prefactor:

$$\sum_{\mathcal{O}}p_{\mathcal{O}}\,G_{\Delta_{\mathcal{O}},\ell_{\mathcal{O}}}(z,\bar{z})\ \xrightarrow{\bar{z}\to 1}\ \Big(\frac{z}{1-z}\Big)^{\Delta_\phi}(1-\bar{z})^{-\Delta_\phi}. \tag{51.21}$$

Translating the small parameter through Eq. (51.5), $1-\bar{z}=v/(1-z)$, this is a power-law singularity in v,

$$\sum_{\mathcal{O}}p_{\mathcal{O}}\,G_{\Delta_{\mathcal{O}},\ell_{\mathcal{O}}}(z,\bar{z})\ \sim\ \big[z(1-z)\big]^{\Delta_\phi}\,v^{-\Delta_\phi}\qquad(v\to 0). \tag{51.22}$$

This is the structural demand crossing places on the spectrum: the s-channel OPE must reproduce, in the lightcone limit, the power $v^{-\Delta_\phi}$ generated by nothing more than the identity in the crossed channel.

Lemma 51.4 (No finite, twist-gapped spectrum can cross)**.** *The singularity Eq. (51.22) cannot be produced by any sum over a spectrum of bounded spin. In particular no finite set of conformal blocks satisfies the lightcone limit of crossing; the $\phi\times\phi$ OPE must contain operators of unbounded spin.*

Proof. We bound the left-hand side of Eq. (51.21) under the assumption of bounded spin and show it cannot reach a negative power of $1-\bar{z}$. Each s-channel block $G_{\Delta,\ell}(z,\bar{z})$ is, in the even-dimensional closed forms of Eqs. (49.44) and (49.49) and in the general-d radial expansion Eq. (49.63), a sum of products of collinear functions $k_{\beta_i}(z)\,k_{\beta_j}(\bar{z})$ with weights β_i,β_j built from (Δ,ℓ) — for instance $\beta\in\{\Delta+\ell,\Delta-\ell\}$ in $d=2$ and $\beta\in\{\Delta+\ell,\Delta-\ell-2\}$ in $d=4$. As

$\bar{z} \to 1$ at fixed z, the factors depending on z are finite, and each factor $k_{\beta_j}(\bar{z})$ is governed by Eq. (51.19): it grows no faster than $\big|\log(1-\bar{z})\big|$, with a coefficient $\frac{\Gamma(\beta_j)}{\Gamma(\beta_j/2)^2}$ that, for β_j in any *bounded* range, is itself bounded. Hence there is a constant $C(z)$, depending on the (finite) spectrum but not on $\bar{z}$, such that

$$\Big|\sum_{\mathcal{O}} p_{\mathcal{O}}\, G_{\Delta_{\mathcal{O}},\ell_{\mathcal{O}}}(z,\bar{z})\Big| \;\le\; C(z)\,\big|\log(1-\bar{z})\big| \qquad (\bar{z}\to 1). \tag{51.23}$$

A logarithm is dominated by every negative power: for any $\Delta_\phi > 0$, $\big|\log(1-\bar{z})\big|/(1-\bar{z})^{-\Delta_\phi} = (1-\bar{z})^{\Delta_\phi}\big|\log(1-\bar{z})\big| \to 0$. The bound Eq. (51.23) is therefore incompatible with the required divergence Eq. (51.21). The assumption of bounded spin — equivalently, of weights β drawn from a bounded set — is the only place the bound was used; it must fail. The spins entering $\phi\times\phi$ are unbounded. □

The lemma is the analytic bootstrap's first theorem about *every* CFT, derived with no input beyond crossing, unitarity, and the existence of the identity. It already explains a qualitative feature the numerical spectra of Chapter 50 exhibit but cannot motivate: the operator content of any unitary CFT necessarily continues to arbitrarily high spin. A finite list of operators — the kind one might naively hope to "solve" a theory with — can never close under crossing.

Notation Watch

In Chapter 49 the label s was fixed to the (12)(34) fusion and t to (14)(23); we keep that assignment, so above it is the t-*channel* identity that dominates the limit and the s-*channel* OPE that is forced to large spin. Some treatments instead name the identity-dominated channel "s" (then the tower is in "t"). For identical external scalars the distinction is empty: both fusions decompose in the one OPE $\phi\times\phi$, the equation Eq. (51.4) is symmetric under $z \leftrightarrow 1-z$, and the conclusion — that $\phi\times\phi$ contains operators of unbounded spin — is channel-independent.

51.1.4 The minimal twist accumulates at $2\Delta_\phi$

Lemma 51.4 forces large spin but not yet a twist. To locate the tower we sharpen the limit, sending $z \to 0$ in addition to $\bar{z}\to 1$ — the *double lightcone* corner of cross-ratio space (Fig. 51.1). The relation Eq. (51.21) already holds; we now read its z-dependence.

As $z\to 0$ the surviving s-channel blocks enter their own lightcone limit, this time in the variable z. By the symmetry of the block under $z\leftrightarrow\bar{z}$, the limit Eq. (51.7) applies with the roles of the arguments exchanged,

$$G_{\Delta,\ell}(z,\bar{z}) \;\xrightarrow{z\to 0}\; z^{\tau/2}\, k_{\Delta+\ell}(\bar{z}), \tag{51.24}$$

so the small-z expansion of the s-channel sum is organized by twist, the lowest twist giving the leading power:

$$\sum_{\mathcal{O}} p_{\mathcal{O}}\, G_{\Delta_{\mathcal{O}},\ell_{\mathcal{O}}}(z,\bar{z}) \xrightarrow{z\to 0} z^{\tau_0/2} \sum_{\mathcal{O}:\,\tau_{\mathcal{O}}=\tau_0} p_{\mathcal{O}}\, k_{\Delta_{\mathcal{O}}+\ell_{\mathcal{O}}}(\bar{z}) \;+\; (\text{higher powers of } z), \tag{51.25}$$

where τ_0 denotes the smallest twist appearing in the divergent, large-spin part of the sum. (Unitarity bounds twists from below, Theorem 47.18, so a well-defined minimum exists.) On the other side, the right of Eq. (51.21) has the small-z behavior

$$\Big(\frac{z}{1-z}\Big)^{\Delta_\phi}(1-\bar{z})^{-\Delta_\phi} \xrightarrow{z\to 0} z^{\Delta_\phi}(1-\bar{z})^{-\Delta_\phi}. \tag{51.26}$$

The two leading powers of z must agree. Matching the exponents in Eq. (51.25) and Eq. (51.26),

$$\frac{\tau_0}{2} = \Delta_\phi \qquad \Longrightarrow \qquad \boxed{\tau_0 = 2\Delta_\phi.} \tag{51.27}$$

The forced tower of large-spin operators has its minimal twist pinned to $2\Delta_\phi$. Equating the coefficients of z^{Δ_ϕ} then gives the further condition

$$\sum_{\mathcal{O}:\,\tau_{\mathcal{O}}\to 2\Delta_\phi} p_{\mathcal{O}}\, k_{\Delta_{\mathcal{O}}+\ell_{\mathcal{O}}}(\bar{z}) \xrightarrow{\bar{z}\to 1} (1-\bar{z})^{-\Delta_\phi}, \tag{51.28}$$

a sum rule on the large-spin OPE coefficients: infinitely many operators of twist accumulating at $2\Delta_\phi$, summed against their collinear blocks, must reconstruct the power $(1-\bar{z})^{-\Delta_\phi}$ that each block individually cannot produce.

Physical Insight

The value $2\Delta_\phi$ is the statement that a high-spin operator in $\phi\times\phi$ behaves like two copies of ϕ orbiting at large angular momentum. Twist measures energy in the lightcone frame: a single ϕ has twist Δ_ϕ (it is a scalar, $\ell=0$), and two of them, held far apart by a large centrifugal barrier, have total twist approaching the sum $\Delta_\phi+\Delta_\phi=2\Delta_\phi$, with the residual interaction energy — the anomalous dimension — decaying as the separation grows, i.e. as the spin $\ell\to\infty$. The minimal-twist trajectory $\tau\to 2\Delta_\phi$ is the bound-state-at-threshold limit of two free constituents. The rate at which τ approaches $2\Delta_\phi$ at finite ℓ is set by the lightest operator they can exchange — their binding energy. In a theory with a stress tensor that exchange is gravitational, and the $1/\ell$ corrections to the twist are, in the holographic dual of Chapters 53 and 56, literally the Newtonian binding of two particles in AdS. The lightcone limit has turned a kinematic identity into a spectroscopic prediction: every CFT contains, at large spin, the spectrum of a weakly interacting two-body system.

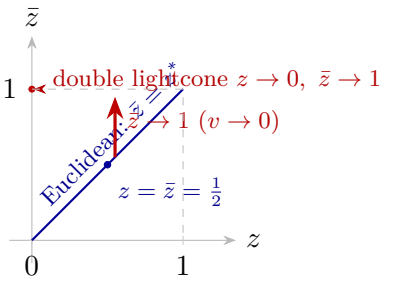

Figure 51.1: Cross-ratio space in the $(z, \bar{z})$ plane. In Euclidean signature the configuration lives on the diagonal $\bar{z} = z^*$ (blue), and the numerical bootstrap expands about the crossing-symmetric point $z = \bar{z} = \frac{1}{2}$. Lorentzian continuation frees z and $\bar{z}$ to move independently, opening the square. The lightcone limit Eq. (51.5) sends $\bar{z} \to 1$ $(v \to 0)$ at fixed z (red arrow); the double lightcone of Section 51.1.4 adds $z \to 0$, the corner where the minimal-twist condition Eq. (51.27) is read off.

The operators realizing Eq. (51.27) are the *double-twist* composites already met in the mean-field solution of Eq. (49.129),

$$[\phi\phi]_{n,\ell} \ \sim \ :\phi \,\Box^n\, \partial_{\mu_1} \cdots \partial_{\mu_\ell} \phi: \ - \ (\text{traces}), \qquad \tau_n = 2\Delta_\phi + 2n, \tag{51.29}$$

whose twists Eq. (49.130) form an evenly spaced ladder above the threshold $2\Delta_\phi$, the minimum $\tau_0 = 2\Delta_\phi$ being the leading $n = 0$ family. The lightcone limit has discovered them from crossing alone, without ever assuming the theory is free: *any* unitary CFT must contain, at each even spin large enough, an operator whose twist approaches $2\Delta_\phi + 2n$. What the present limit does not yet supply is the *strength* of these operators — the large-spin OPE coefficients $p_{0,\ell}$ that solve the sum rule Eq. (51.28) — nor the subleading $n \geq 1$ families, nor the rate of approach $\tau(\ell) - 2\Delta_\phi$. Those are the data of the next section.

We have reduced the full crossing equation to a single, controllable kinematic statement and extracted from it a theorem about every conformal field theory: the operator product $\phi \times \phi$ contains an infinite tower of large-spin operators whose minimal twist accumulates at $2\Delta_\phi$, with the sum rule Eq. (51.28) fixing how their OPE coefficients conspire to reproduce the identity. The next section identifies this tower as the double-twist operators $[\phi\phi]_{n,\ell}$ and pins down their leading data — the asymptotic OPE coefficients and the full ladder of twists $2\Delta_\phi + 2n$ — by solving Eq. (51.28) at zeroth order, where the solution is precisely the generalized free field whose mean-field spectrum we already met in Section 49.5.1.

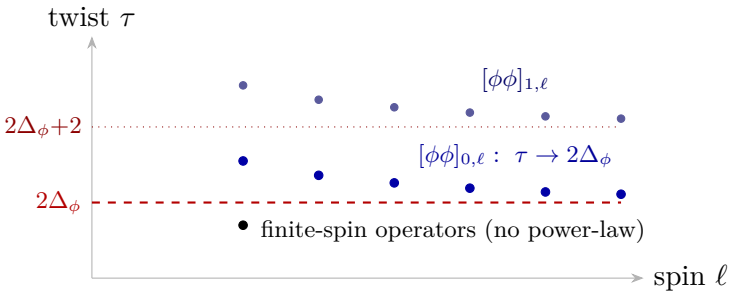

Figure 51.2: The forced large-spin tower. Crossing in the lightcone limit requires, in $\phi\times\phi$, operators of unbounded spin whose twists accumulate at $\tau\to 2\Delta_\phi$ (Eq. (51.27)); these are the double-twist families $[\phi\phi]_{n,\ell}$ of Eq. (51.29), one Regge-like trajectory per n, each approaching $2\Delta_\phi+2n$ from above as $\ell\to\infty$. Low-spin operators (black) contribute only logarithmically near the lightcone (Lemma 51.4) and cannot build the power-law singularity; the tower must.

51.2 Double-Twist Operators and Generalized Free Fields

The lightcone analysis of Section 51.1 ended on a structural verdict, not a computation: the identity operator, present in every crossed channel because every operator has a non-vanishing two-point function, develops a power-law collision singularity $v^{-\Delta_\phi}$ as the crossed pair approaches the lightcone, and no finite sum of direct-channel conformal blocks can reproduce a power law. The singularity can be matched only by an *infinite* tower of exchanged operators whose spins run off to infinity. That tower is forced; its mere existence is a theorem of crossing. What we owe now is its identity. We must say which operators populate the tower, what their quantum numbers are, and — to leading order, before any interaction is switched on — what their operator product coefficients are. The answer is clean and universal: the tower consists of *double-twist operators*, and at leading order their data are those of a *generalized free field*, the conformal avatar of mean-field theory. This section pins down both objects. It is the zeroth-order seed of the whole analytic bootstrap: the next section perturbs around it, reading the $1/\ell$ corrections to these data off the crossed-channel operators that the generalized free field omits.

51.2.1 Double-twist operators

Fix two scalar primaries $\mathcal{O}_1$ and $\mathcal{O}_2$ of dimensions Δ_1,Δ_2 in a unitary CFT. (We allow $\mathcal{O}_1\neq\mathcal{O}_2$ from the outset; the identical case $\mathcal{O}_1=\mathcal{O}_2=\phi$ of Section 49.5.1 is recovered by setting $\Delta_1=\Delta_2=\Delta_\phi$, and the two-operator setting is the one in which the large-spin physics — two well-separated constituents and the energy

that binds them — is most transparent.) Their operator product expansion contains, beyond whatever low-lying operators the dynamics supplies, an infinite family of composites built by colliding the two fields and dressing the result with derivatives.

Definition 51.5 (Double-twist operator)**.** The *double-twist operators* $[\mathcal{O}_1\mathcal{O}_2]_{n,\ell}$ are the conformal primaries appearing in the $\mathcal{O}_1 \times \mathcal{O}_2$ OPE that are schematically of the form

$$[\mathcal{O}_1\mathcal{O}_2]_{n,\ell} \;\sim\; :\mathcal{O}_1\,\Box^n\,\partial_{\mu_1}\cdots\partial_{\mu_\ell}\,\mathcal{O}_2: \;-\; \text{(traces and descendants)}, \tag{51.30}$$

the symmetric traceless primary built from the two constituents, ℓ symmetrized derivatives distributed between them, and n powers of the Laplacian, with the precise distribution of derivatives fixed by the requirement that the combination be primary, $K_\mu[\mathcal{O}_1\mathcal{O}_2]_{n,\ell}(0) = 0$. The integers $n, \ell \geq 0$ are the *radial level* and the *spin*.

The name records their defining feature. The twist of an operator is $\tau \equiv \Delta - \ell$; for the composite Eq. (51.30) the ℓ symmetrized derivatives add ℓ to both dimension and spin and so cancel in the twist, while the two constituents contribute $\Delta_1 + \Delta_2$ and each Laplacian contributes 2 to the dimension. Hence

$$\boxed{\tau_{n,\ell} = \Delta_1 + \Delta_2 + 2n + \gamma(n,\ell), \qquad \Delta_{n,\ell} = \Delta_1 + \Delta_2 + 2n + \ell + \gamma(n,\ell)\,,} \tag{51.31}$$

where $\gamma(n,\ell)$ is the *anomalous dimension*: the correction to the naive sum of constituent dimensions induced by interactions. In a Gaussian theory there is no interaction to shift the composite and $\gamma \equiv 0$, so the double-twist twists sit at the rigid lattice $\tau_n = \Delta_1 + \Delta_2 + 2n$; computing the leading $\gamma(n,\ell)$ at large ℓ in an interacting theory is the entire content of Section 51.3.

The two labels have a clean kinematic meaning that Eq. (51.31) makes precise. In the two-particle picture furnished by the state–operator map, $[\mathcal{O}_1\mathcal{O}_2]_{n,\ell}$ is the lowest primary in a tower of two-particle states of the constituents $\mathcal{O}_1, \mathcal{O}_2$: ℓ is the relative orbital angular momentum of the pair, and n counts radial nodes of the relative wavefunction — exactly the way the principal and orbital quantum numbers organize the hydrogen spectrum, here for two conformal "particles." That ℓ is the spin is immediate from the ℓ symmetric indices in Eq. (51.30). That n is radial follows from the conformal Casimir of Theorem 47.50: on $[\mathcal{O}_1\mathcal{O}_2]_{n,\ell}$ the Casimir takes the value $c_{\Delta_{n,\ell},\ell} = \Delta_{n,\ell}(\Delta_{n,\ell} - d) + \ell(\ell + d - 2)$, and at fixed spin ℓ the discrete tower $n = 0, 1, 2, \ldots$ is the spectrum of the Casimir restricted to the two-particle sector, the radial excitations stacked above the leading-twist seed $n = 0$.

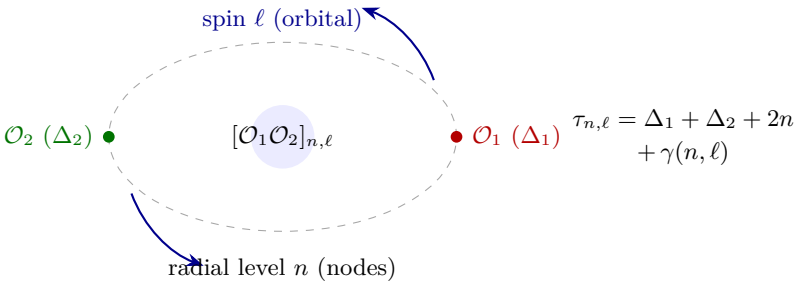

Figure 51.3: The double-twist operator $[\mathcal{O}_1\mathcal{O}_2]_{n,\ell}$ pictured as a two-particle bound state of its constituents $\mathcal{O}_1, \mathcal{O}_2$. The spin ℓ is the relative orbital angular momentum, the radial level n counts nodes of the relative wavefunction. At large ℓ the centrifugal barrier separates the constituents, the twist approaches the free sum $\Delta_1 + \Delta_2 + 2n$, and the residual binding energy is the anomalous dimension $\gamma(n,\ell)$ computed in Section 51.3.

Physical Insight

A double-twist operator is the conformal field theory's description of two of its quanta orbiting each other very far apart. When the spin ℓ is large the centrifugal barrier $\sim \ell^2/r^2$ pushes the two constituents to large separation, where they barely interact; their total dimension is then almost exactly the sum $\Delta_1 + \Delta_2 + 2n$ of the free pieces, and the small residual binding energy is the anomalous dimension $\gamma(n,\ell)$, which therefore vanishes as $\ell \to \infty$. The lightcone bootstrap is, read physically, a calculation of this binding energy. In a theory with a holographic dual the two constituents are two particles in anti–de Sitter space and the binding is their gravitational (and other long-range) attraction; the $1/\ell$ falloff of γ is then the statement that gravity is a long-range force, and its coefficient is fixed by Newton's constant. We will not need the holographic reading here, but it is the reason the analytic bootstrap is also a derivation of bulk locality, taken up in Chapters 53 and 56.

51.2.2 Generalized free fields

To fix the leading data we need the simplest theory whose spectrum is *exactly* the double-twist lattice with $\gamma \equiv 0$. That theory is the generalized free field.

Definition 51.6 (Generalized free field)**.** A *generalized free field* (GFF) of dimension Δ is a scalar primary ϕ whose correlation functions are computed by Wick's theorem from the unit-normalized two-point function

$$\langle \phi(x_i)\,\phi(x_j)\rangle = \frac{1}{(x_{ij}^2)^{\Delta}}, \qquad x_{ij} \equiv x_i - x_j, \tag{51.32}$$

exactly as if ϕ were free: every correlator is the sum over all pairings of products of two-point functions, with no connected higher-point part. A collection of mutually generalized-free fields $\{\mathcal{O}_a\}$ obeys Eq. (51.32) within each species and $\langle \mathcal{O}_a \mathcal{O}_b \rangle = 0$ for $a \neq b$ (after diagonalizing the two-point matrix). The theory whose every correlator is so generated is *mean-field theory* (also called generalized free theory).

The construction is the conformal continuation of the free scalar of ϕ^4 theory. There the two-point function Eq. (51.32) with $\Delta = (d-2)/2$ is the massless limit of the position-space Feynman propagator Eq. (9.153) of Theorem 9.24, and Wick's theorem is a theorem about the Gaussian path integral. The generalized free field keeps the Gaussian (Wick) structure but promotes Δ from the canonical value $(d-2)/2$ to a free parameter; it is no longer the quantization of a local Lagrangian for generic Δ, but it is a perfectly good solution of all conformal Ward identities and, as we now confirm, of crossing. In ϕ^4 theory it is precisely the $\lambda \to 0$ limit of the interacting fixed point: as the coupling is switched off, $\Delta_\phi \to (d-2)/2$, the anomalous dimensions $\gamma_{n,\ell}$ of the would-be Wilson–Fisher spectrum vanish, and the composites $:\phi \Box^n \partial^\ell \phi:$ become the exact double-twist operators $[\phi\phi]_{n,\ell}$ of the free theory.

The four-point function. The decisive object is the four-point function. For four insertions of a single GFF ϕ the three pairings give the elementary sum Eq. (49.22), whose stripped form is $g(u,v) = 1 + u^{\Delta_\phi} + (u/v)^{\Delta_\phi}$ (Eq. (49.127)); that this satisfies the crossing equation Theorem 49.13 identically for every Δ_ϕ was shown in Theorem 49.5, and its decomposition into the even-spin double-twist tower $[\phi\phi]_{n,\ell}$ was carried out in Section 49.5.2. We take that identical-scalar result as established and turn to the genuinely two-operator correlator, where the double-twist tower stands alone.

Consider $\langle \mathcal{O}_1(x_1)\, \mathcal{O}_2(x_2)\, \mathcal{O}_2(x_3)\, \mathcal{O}_1(x_4) \rangle$ with $\mathcal{O}_1, \mathcal{O}_2$ distinct mutually-generalized-free scalars of dimensions Δ_1, Δ_2. Wick's theorem pairs like with like; the only nonvanishing contraction is $\langle \mathcal{O}_1(x_1)\mathcal{O}_1(x_4)\rangle \langle \mathcal{O}_2(x_2)\mathcal{O}_2(x_3)\rangle$, since $\langle \mathcal{O}_1 \mathcal{O}_2 \rangle = 0$. Hence

$$\langle \mathcal{O}_1(x_1)\mathcal{O}_2(x_2)\mathcal{O}_2(x_3)\mathcal{O}_1(x_4)\rangle = \frac{1}{(x_{14}^2)^{\Delta_1}\,(x_{23}^2)^{\Delta_2}}. \tag{51.33}$$

A single term — and that single term is, in the (14)(23) channel, nothing but the product of the two identities ($\mathcal{O}_1 \times \mathcal{O}_1 \to \mathbf{1}$ and $\mathcal{O}_2 \times \mathcal{O}_2 \to \mathbf{1}$). Strip it to the cross-ratio function appropriate to the s-channel $\mathcal{O}_1 \times \mathcal{O}_2$ fusion. Using the standard prefactor for unequal externals (the Dolan–Osborn convention, Theorem 47.27) with $\mathcal{O}_1 = \mathcal{O}_4$, $\mathcal{O}_2 = \mathcal{O}_3$,

$$\langle \mathcal{O}_1\mathcal{O}_2\mathcal{O}_2\mathcal{O}_1\rangle = \frac{1}{(x_{12}^2 x_{34}^2)^{\frac{\Delta_1+\Delta_2}{2}}} \Big(\frac{x_{24}^2}{x_{14}^2}\Big)^{\frac{\Delta_1-\Delta_2}{2}} \Big(\frac{x_{14}^2}{x_{13}^2}\Big)^{\frac{\Delta_2-\Delta_1}{2}} g(u,v), \tag{51.34}$$

and inserting Eq. (51.33) and the definitions $u = x_{12}^2 x_{34}^2/(x_{13}^2 x_{24}^2)$, $v = x_{14}^2 x_{23}^2/(x_{13}^2 x_{24}^2)$ of Eq. (47.140), every x_{ij}^2 collects into powers of u and v alone. Matching exponents factor by factor gives the compact monomial

$$\boxed{g(u,v) = u^{\frac{\Delta_1+\Delta_2}{2}}\, v^{-\Delta_2}\,.} \tag{51.35}$$

(The apparent asymmetry between Δ_1 and Δ_2 is an artifact of the stripping convention Eq. (51.34); the physical OPE data extracted below are symmetric in $\Delta_1 \leftrightarrow \Delta_2$, as they must be since $[\mathcal{O}_1\mathcal{O}_2] = [\mathcal{O}_2\mathcal{O}_1]$.) Crossing for this mixed correlator is the statement that the (12)(34) and (14)(23) channels agree; here it is the trivial reflection that Eq. (51.33), built symmetric in the points from the start, exchanges $x_1 \leftrightarrow x_3$ into itself. The content the bootstrap reads off is again the reorganization: the single crossed-channel exchange Eq. (51.33) is reproduced in the s-channel only by the full double-twist tower, and now there is no identity in the $\mathcal{O}_1 \times \mathcal{O}_2$ OPE to share the load, so the tower stands entirely alone.

The spectrum, read off the powers. A direct-channel block of an exchanged primary of twist τ begins as $u^{\tau/2}$ as $u \to 0$ (Theorem 47.49). The leading behaviour of Eq. (51.35) is $u^{(\Delta_1+\Delta_2)/2}$, so the lightest exchanged operators have twist $\tau_0 = \Delta_1 + \Delta_2$. Generating the full block series dresses this with integer powers $u^{(\Delta_1+\Delta_2)/2+n}$, $n = 0, 1, 2, \ldots$, hence twists $\tau_n = \Delta_1 + \Delta_2 + 2n$ — precisely the double-twist lattice of Eq. (51.31) with $\gamma \equiv 0$. Each twist carries a tower of spins ℓ. Because $\mathcal{O}_1 \neq \mathcal{O}_2$ there is no Bose symmetry to enforce, so *every* integer spin $\ell \geq 0$ appears (contrast the identical-scalar case of Section 49.5.1, where only even ℓ survive). The exchanged operators are exactly the double-twist primaries $[\mathcal{O}_1\mathcal{O}_2]_{n,\ell}$, and the GFF realizes them with vanishing anomalous dimension: $\Delta_{n,\ell} = \Delta_1 + \Delta_2 + 2n + \ell$ exactly. The generalized free field is thus the unique crossing solution whose only operators above the (here absent) identity are the double-twist tower at its free twists — the extremal seed about which every interacting theory is a perturbation.

51.2.3 The mean-field OPE coefficients

It remains to compute the squared OPE coefficients $c_{n,\ell}^{\mathrm{MFT}} \equiv C^2_{\mathcal{O}_1\mathcal{O}_2[\mathcal{O}_1\mathcal{O}_2]_{n,\ell}}$ with which these operators are exchanged — the weights in the block decomposition $g(u,v) = \sum_{n,\ell} c_{n,\ell}^{\mathrm{MFT}}\, G_{\Delta_{n,\ell},\ell}(u,v)$ of Eq. (47.227). We compute the leading-twist family $n = 0$ in full and in general d — this is the family the analytic bootstrap actually propagates — and then record the closed form for all n.

The leading-twist family in the lightcone limit. The key simplification is that as $u \to 0$ (equivalently $z \to 0$ in the cross-ratios $u = z\bar{z}$, $v = (1-z)(1-\bar{z})$ of Eq. (47.140)) the conformal block of *any* dimension reduces to a one-variable

object that does not know about d. Concretely, a primary of twist τ and spin ℓ contributes, at the leading power $z^{\tau/2}$, the term $z^{\tau/2}\,k_\beta(\bar z)$, where k_β is the collinear ($SL(2,\mathbb{R})$) block and $\beta=\tau+2\ell$ is twice the conformal spin $\bar h=(\Delta+\ell)/2$. For the correlator Eq. (51.35) the collinear block of the leading-twist operator $[\mathcal{O}_1\mathcal{O}_2]_{0,\ell}$ (twist $\Delta_1+\Delta_2$, spin ℓ, so $\beta=\Delta_1+\Delta_2+2\ell$) is the Gauss hypergeometric function

$$k_\beta(\bar z)=\bar z^{\,\beta/2}\,{}_2F_1\Big(\tfrac{\beta}{2}-\tfrac{\Delta_1-\Delta_2}{2},\ \tfrac{\beta}{2}+\tfrac{\Delta_2-\Delta_1}{2};\ \beta;\ \bar z\Big)=\bar z^{\,\beta/2}\,{}_2F_1\big(\Delta_2+\ell,\ \Delta_2+\ell;\ \Delta_1+\Delta_2+2\ell;\ \bar z\big), \tag{51.36}$$

the equal upper parameters being a feature of the $(\mathcal{O}_1\mathcal{O}_2\mathcal{O}_2\mathcal{O}_1)$ ordering. Projecting Eq. (51.35) onto its leading power of z, with $(1-z)^{-\Delta_2}\to 1$, leaves the single-variable seed

$$H(\bar z)\equiv \bar z^{\,\frac{\Delta_1+\Delta_2}{2}}(1-\bar z)^{-\Delta_2}=\sum_{\ell\geq 0}c_{0,\ell}^{\mathrm{MFT}}\,k_{\Delta_1+\Delta_2+2\ell}(\bar z), \tag{51.37}$$

the equality being the statement that the leading-twist OPE data are the coefficients of $H(\bar z)$ in the collinear-block basis. We extract them in closed form.

Proposition 51.7 (Leading-twist mean-field coefficients)**.** *The expansion Eq. (51.37) holds with*

$$\boxed{c_{0,\ell}^{\mathrm{MFT}}=\frac{(\Delta_1)_\ell\,(\Delta_2)_\ell}{\ell!\,(\Delta_1+\Delta_2+\ell-1)_\ell}}\,, \tag{51.38}$$

where $(x)_m=\Gamma(x+m)/\Gamma(x)$ is the Pochhammer symbol. The coefficients are manifestly positive for all integer $\ell\geq 0$ and all $\Delta_1,\Delta_2>0$, so mean-field theory is unitary; and they are symmetric in $\Delta_1\leftrightarrow\Delta_2$.

Proof. Both sides of Eq. (51.37) begin at $\bar z^{(\Delta_1+\Delta_2)/2}$ and proceed in integer steps of $\bar z$ (the ℓ-th block starts at $\bar z^{(\Delta_1+\Delta_2)/2+\ell}$), so the ansatz is consistent in its powers and the coefficients are fixed by matching order by order. Write $p\equiv(\Delta_1+\Delta_2)/2$. The left side is

$$H(\bar z)=\bar z^{\,p}\sum_{j\geq 0}\frac{(\Delta_2)_j}{j!}\,\bar z^{\,j}, \tag{51.39}$$

using $(1-\bar z)^{-\Delta_2}=\sum_j(\Delta_2)_j\bar z^j/j!$. The right side, inserting the series ${}_2F_1(\Delta_2+\ell,\Delta_2+\ell;\Delta_1+\Delta_2+2$ $\sum_i\frac{(\Delta_2+\ell)_i^2}{(\Delta_1+\Delta_2+2\ell)_i\,i!}\bar z^i$ of Eq. (51.36), contributes to the coefficient of $\bar z^{\,p+k}$ the sum over leading-twist blocks with $\ell\leq k$. Matching the coefficient of $\bar z^{\,p+k}$ gives the lower-triangular linear system

$$\sum_{\ell=0}^{k}c_{0,\ell}^{\mathrm{MFT}}\,\frac{(\Delta_2+\ell)_{k-\ell}^2}{(\Delta_1+\Delta_2+2\ell)_{k-\ell}\,(k-\ell)!}=\frac{(\Delta_2)_k}{k!},\qquad k=0,1,2,\dots \tag{51.40}$$

The diagonal term ($\ell = k$) has coefficient 1, so the system is solved recursively with no division. We solve it and verify Eq. (51.38).

At $k = 0$: $c_{0,0}^{\mathrm{MFT}} = (\Delta_2)_0/0! = 1$, matching Eq. (51.38), whose value at $\ell = 0$ is 1.

At $k = 1$: $c_{0,0}^{\mathrm{MFT}} \dfrac{(\Delta_2)_1^2}{(\Delta_1+\Delta_2)_1\,1!} + c_{0,1}^{\mathrm{MFT}} = \dfrac{(\Delta_2)_1}{1!}$, i.e. $\dfrac{\Delta_2^2}{\Delta_1+\Delta_2} + c_{0,1}^{\mathrm{MFT}} = \Delta_2$, so

$$c_{0,1}^{\mathrm{MFT}} = \Delta_2 - \frac{\Delta_2^2}{\Delta_1+\Delta_2} = \frac{\Delta_1\Delta_2}{\Delta_1+\Delta_2} = \frac{(\Delta_1)_1(\Delta_2)_1}{1!\,(\Delta_1+\Delta_2)_1}, \tag{51.41}$$

which is Eq. (51.38) at $\ell = 1$, and is manifestly symmetric in $\Delta_1 \leftrightarrow \Delta_2$.

At $k = 2$ the three contributions $\ell = 0, 1, 2$ are, using $c_{0,0}^{\mathrm{MFT}} = 1$ and $c_{0,1}^{\mathrm{MFT}} = \Delta_1\Delta_2/(\Delta_1+\Delta_2)$,

$$\frac{[\Delta_2(\Delta_2+1)]^2}{2(\Delta_1+\Delta_2)(\Delta_1+\Delta_2+1)} + \frac{\Delta_1\Delta_2\,(\Delta_2+1)^2}{(\Delta_1+\Delta_2)(\Delta_1+\Delta_2+2)} + c_{0,2}^{\mathrm{MFT}} = \frac{\Delta_2(\Delta_2+1)}{2}. \tag{51.42}$$

Solving for $c_{0,2}^{\mathrm{MFT}}$ and simplifying (most transparently checked at, say, $\Delta_1 = 1, \Delta_2 = 2$, where the two known terms are $\frac{3}{2}$ and $\frac{6}{5}$ and the right side is 3, giving $c_{0,2}^{\mathrm{MFT}} = \frac{3}{10}$) reproduces

$$c_{0,2}^{\mathrm{MFT}} = \frac{\Delta_1(\Delta_1+1)\,\Delta_2(\Delta_2+1)}{2\,(\Delta_1+\Delta_2+1)(\Delta_1+\Delta_2+2)} = \frac{(\Delta_1)_2(\Delta_2)_2}{2!\,(\Delta_1+\Delta_2+1)_2}, \tag{51.43}$$

again Eq. (51.38) ($\frac{1\cdot2\cdot2\cdot3}{2\cdot4\cdot5} = \frac{3}{10}$ at the test point). The general statement follows from triangularity: Eq. (51.40) is a lower-triangular system with unit diagonal, hence has a unique solution, and Eq. (51.38) satisfies it for every k — this is the standard $SL(2)$ Euclidean inversion of a power against the collinear blocks, which for equal external dimensions $\Delta_1 = \Delta_2 = \Delta_\phi$ collapses to the coefficients a_ℓ of Theorem 49.24 (so that $c_{0,\ell}^{\mathrm{MFT}}\big|_{\Delta_1=\Delta_2} = a_\ell$, the building block of the identical-scalar result Eq. (49.140)). Positivity is read directly from Eq. (51.38): every Pochhammer of a positive argument is positive, so $c_{0,\ell}^{\mathrm{MFT}} > 0$. □

Two remarks situate the result. First, Eq. (51.38) is *independent of the spacetime dimension* d: the collinear block Eq. (51.36) is the universal $SL(2)$ block, and the leading-twist seed Eq. (51.37) knows nothing of d. The dimension enters the OPE data only through the radial tower $n \geq 1$, where the full block's descent off the lightcone mixes twists in a d-dependent way. Second, for identical external scalars the GFF correlator has the *two* crossed contractions of Eq. (49.127) rather than the single one of Eq. (51.33); the second contraction supplies a factor $1 + (-1)^\ell$, doubling the even-spin coefficients and annihilating the odd ones, so that $c_{0,\ell}^{\mathrm{MFT}}\big|_{\Delta_1=\Delta_2} \to [1+(-1)^\ell]\,a_\ell$, exactly the leading-twist limit of Eq. (49.140). The two-operator computation thus contains the identical-scalar one and exposes the odd-spin operators it hides.

The full tower. The radial excitations $n \geq 1$ require the conformal block away from the lightcone, where it is fixed by the Casimir equation Theorem 47.50 and no longer factorizes for general d. The complete result for identical external scalars was obtained in closed form in Section 49.5.2: the Fitzpatrick–Kaplan–Poland–Simmons-Duffin coefficients

$$c^{\mathrm{MFT}}_{n,\ell}\big|_{\Delta_1=\Delta_2=\Delta_\phi} = \frac{\left[1+(-1)^\ell\right]\left(\Delta_\phi-\frac{d}{2}+1\right)_n^2\,(\Delta_\phi)_{n+\ell}^2}{\ell!\,n!\,(\ell+\frac{d}{2})_n\,(2\Delta_\phi+n-d+1)_n\,(2\Delta_\phi+2n+\ell-1)_\ell\,(2\Delta_\phi+n+\ell-\frac{d}{2})_n}, \tag{51.44}$$

which is Eq. (49.144); we import it rather than re-derive it. As a consistency check on the present development, set $n=0$: every n-dependent Pochhammer reduces to 1, leaving $[1+(-1)^\ell](\Delta_\phi)_\ell^2/[\ell!\,(2\Delta_\phi+\ell-1)_\ell]$, which is precisely the $\Delta_1=\Delta_2=\Delta_\phi$ value of Eq. (51.38) with its symmetrization factor $1+(-1)^\ell$ — the leading-twist family is reproduced, in any d, by the general formula. At $n=1$ the surviving factors $(\Delta_\phi-\frac{d}{2}+1)^2$, $(\ell+\frac{d}{2})$, $(2\Delta_\phi-d+1)$ and $(2\Delta_\phi+\ell-\frac{d}{2})$ no longer cancel, displaying explicitly the d-dependence that enters with the first radial excitation. The distinct-operator generalization of Eq. (51.44) (with $\Delta_1\neq\Delta_2$ and all integer spins) is obtained by the same machinery and reduces at $n=0$ to Eq. (51.38); we will need only the leading-twist family Eq. (51.38), which we have derived from scratch, in the large-spin analysis that follows.

We have therefore solved crossing for the generalized free field completely: its spectrum is the double-twist lattice Eq. (51.31) with $\gamma\equiv 0$, its OPE coefficients are Eq. (51.38) and Eq. (51.44), and the correlator Eq. (51.35) it builds satisfies crossing identically. The mean-field data are the boundary point of the space of crossing solutions, the leading-order seed that interactions perturb.

Worked Example 51.8 (The leading-twist coefficients and their large-spin asymptotics)**.** We compute the leading-twist coefficients $c^{\mathrm{MFT}}_{0,\ell}$ explicitly at low spin and then extract the large-ℓ behaviour that seeds the lightcone bootstrap.

Low spin. From Eq. (51.38), with $\mathcal{O}_1\neq\mathcal{O}_2$ so all integer ℓ contribute,

$$c^{\mathrm{MFT}}_{0,0}=1,\qquad c^{\mathrm{MFT}}_{0,1}=\frac{\Delta_1\Delta_2}{\Delta_1+\Delta_2},\qquad c^{\mathrm{MFT}}_{0,2}=\frac{\Delta_1(\Delta_1+1)\,\Delta_2(\Delta_2+1)}{2(\Delta_1+\Delta_2+1)(\Delta_1+\Delta_2+2)}. \tag{51.45}$$

The lowest, $c^{\mathrm{MFT}}_{0,0}=1$, normalizes the scalar bound state $[\mathcal{O}_1\mathcal{O}_2]_{0,0}$ at $\Delta=\Delta_1+\Delta_2$; all higher coefficients are pure ratios of Gamma functions of the constituent dimensions.

Large spin. Write Eq. (51.38) entirely in Gamma functions,

$$c^{\mathrm{MFT}}_{0,\ell}=\frac{\Gamma(\Delta_1+\ell)\,\Gamma(\Delta_2+\ell)\,\Gamma(\Delta_1+\Delta_2+\ell-1)}{\Gamma(\Delta_1)\,\Gamma(\Delta_2)\,\Gamma(\ell+1)\,\Gamma(\Delta_1+\Delta_2+2\ell-1)}. \tag{51.46}$$

The only doubled argument is $\Gamma(2\ell+\Delta_1+\Delta_2-1)$ in the denominator; reduce it with the Legendre duplication formula $\Gamma(2z)=\frac{2^{2z-1}}{\sqrt{\pi}}\Gamma(z)\Gamma(z+\frac{1}{2})$ at $2z=$

$2\ell+\Delta_1+\Delta_2-1$, giving

$$\Gamma(2\ell+\Delta_1+\Delta_2-1)=\frac{2^{\,2\ell+\Delta_1+\Delta_2-2}}{\sqrt{\pi}}\,\Gamma\Big(\ell+\tfrac{\Delta_1+\Delta_2-1}{2}\Big)\Gamma\Big(\ell+\tfrac{\Delta_1+\Delta_2}{2}\Big). \quad (51.47)$$

Substituting and applying $\Gamma(\ell+a)/\Gamma(\ell+b)\sim\ell^{\,a-b}$ to each slowly varying ratio as $\ell\to\infty$ — the powers of ℓ summing to $(\Delta_1+\Delta_2)-\frac{3}{2}$ and the ℓ-independent constant collecting the duplication factor — gives

$$\boxed{c^{\mathrm{MFT}}_{0,\ell}\;\sim\;\frac{\sqrt{\pi}\,2^{\,2-\Delta_1-\Delta_2}}{\Gamma(\Delta_1)\,\Gamma(\Delta_2)}\;\ell^{\,\Delta_1+\Delta_2-\frac{3}{2}}\;4^{-\ell}\qquad(\ell\to\infty).} \quad (51.48)$$

The coefficients fall as $4^{-\ell}$. This exponential is not physical decay but the natural measure on spins: it is exactly undone by the growth of the collinear block $k_{\Delta_1+\Delta_2+2\ell}(\bar z)$ as $\bar z\to1$, so that the smooth density of OPE data in spin is the power-law prefactor $\ell^{\Delta_1+\Delta_2-3/2}$. It is this density that, summed over the infinite tower, rebuilds the crossed-channel power-law singularity $(1-\bar z)^{-\Delta_2}$ of the seed H in Eq. (51.37) as $\bar z\to1$ — the analytic statement, now made quantitative, that a single crossed exchange forces a definite large-spin density of double-twist operators. For identical scalars, $\Delta_1=\Delta_2=\Delta_\phi$, Eq. (51.48) gives the power $\ell^{2\Delta_\phi-3/2}$ and (after the even-spin doubling factor of 2) agrees with the identical-scalar asymptotics Eq. (49.150). This large-spin density is the fixed input the next section perturbs: the deviation of a real CFT's OPE data from Eq. (51.48) is controlled, term by term in $1/\ell$, by the operators the generalized free field leaves out.

Twist accumulation. One feature of the spectrum deserves to be stated as the precise form of the lightcone prediction of Section 51.1. In the generalized free field the leading-twist trajectory has $\tau_{0,\ell}=\Delta_1+\Delta_2$ *exactly*, for every spin; there is nothing to accumulate because $\gamma\equiv0$. The nontrivial statement is about interacting theories. There the double-twist operators acquire anomalous dimensions $\gamma(n,\ell)$, but the lightcone argument forces these to vanish at large spin, $\gamma(n,\ell)\to0$ as $\ell\to\infty$, so the twists accumulate at the mean-field values,

$$\tau_{n,\ell}\xrightarrow{\ell\to\infty}\Delta_1+\Delta_2+2n, \quad (51.49)$$

which for the leading trajectory is twist $\Delta_1+\Delta_2$ (twice Δ_ϕ in the identical case). This is the statement, anticipated in Section 51.1, that every unitary CFT possesses, at asymptotically large spin, double-twist operators whose dimensions and OPE coefficients approach those of the generalized free field. Mean-field theory is not merely an example of a crossing solution; it is the universal large-spin limit of all of them.

With the seed fixed — the double-twist spectrum Eq. (51.31), the mean-field coefficients Eq. (51.38), and their large-spin density Eq. (51.48) — the remaining

task is the first correction. The next section switches on the lightest crossed-channel operator beyond the identity and computes the leading anomalous dimension $\gamma_{0,\ell}$ it induces, deriving the universal falloff $\gamma_{0,\ell} \sim -c/\ell^{\tau_m}$ set by that operator's twist τ_m and fixing the coefficient c in terms of its OPE data.

51.3 Large-Spin Anomalous Dimensions from Crossing

The previous section taught us to read the generalized free field as a spectrum: hidden inside the closed-form correlator Eq. (49.24) is an infinite tower of *double-twist* operators $[\phi\phi]_{n,\ell}$, with dimensions $2\Delta_\phi+2n+\ell$ and squared OPE coefficients fixed by crossing alone to their mean-field values (Section 51.2). Those operators were forced: crossing demanded them in any unitary theory, and at zeroth order their data were exactly the disconnected, Wick-contraction data of two free constituents flying apart. The question this section answers is what happens at *first* order. A genuine interacting CFT is not a generalized free field; its t-channel OPE contains, beyond the identity, real operators of nonzero twist. Each such operator perturbs the crossing equation, and the perturbation must be absorbed by a shift in the double-twist data. We will see that a single exchanged operator of minimal twist τ_m shifts the anomalous dimension of the leading-twist tower in a completely universal way,

$$\gamma_{0,\ell} \xrightarrow{\ell\to\infty} -\frac{c_{\tau_m}}{\ell^{\tau_m}}, \tag{51.50}$$

with a coefficient c_{τ_m} we will compute in closed form. Physically this is the binding energy of two widely separated constituents exchanging the lightest available operator: a power law in the inverse separation set by the range τ_m of the exchanged "force," attractive (negative) whenever that operator is unitary. In a holographic theory the minimal-twist exchange is the stress tensor and Eq. (51.50) is literally the Newtonian binding of two particles in AdS; we reach that statement as the worked example of the section.

51.3.1 The double lightcone limit

We work throughout with the crossing equation for four identical scalars imported from Eq. (49.14), written in the holomorphic cross-ratios $u = z\bar{z}$, $v = (1-z)(1-\bar{z})$ of Eq. (47.140). In these variables the $s \leftrightarrow t$ crossing transformation $u \leftrightarrow v$ is the simultaneous reflection $z \to 1-z$, $\bar{z} \to 1-\bar{z}$, and the crossing equation reads

$$\big[(1-z)(1-\bar{z})\big]^{\Delta_\phi} \sum_{\mathcal{O}} p_{\mathcal{O}}\, G_{\Delta_{\mathcal{O}},\ell_{\mathcal{O}}}(z,\bar{z}) \;=\; (z\bar{z})^{\Delta_\phi} \sum_{\mathcal{O}} p_{\mathcal{O}}\, G_{\Delta_{\mathcal{O}},\ell_{\mathcal{O}}}(1-z,1-\bar{z}), \tag{51.51}$$

where $p_{\mathcal{O}} = C^2_{\phi\phi\mathcal{O}} \geq 0$ and the sum runs over all primaries in the $\phi \times \phi$ OPE, the identity ($G_{0,0} = 1$, $p_{\mathbf{1}} = 1$) included on both sides. The conformal blocks $G_{\Delta,\ell}$ are the eigenfunctions of the Casimir of Eq. (47.233); we need only two facts about them, both established in Chapter 49.

First, the *lightcone factorization* Eq. (49.67): as one cross-ratio variable goes to zero, a block collapses onto a single collinear block,

$$G_{\Delta,\ell}(z,\bar{z}) \xrightarrow{\bar{z}\to 0} \bar{z}^{\,\tau/2}\, k_{\Delta+\ell}(z), \qquad \tau \equiv \Delta - \ell, \tag{51.52}$$

where the collinear block $k_\beta(z) = z^{\beta/2}\,{}_2F_1(\frac{\beta}{2},\frac{\beta}{2};\beta;z)$ of Eq. (49.30) is the eigenfunction of the $\mathfrak{sl}(2,\mathbb{R})$ Casimir. The power of $\bar{z}$ is set entirely by the twist, the function of z entirely by the dimension-plus-spin $\beta = \Delta + \ell$. It is therefore natural to trade the pair (Δ,ℓ) for the pair of *lightcone weights*

$$h \equiv \frac{\tau}{2} = \frac{\Delta-\ell}{2}, \qquad \bar{h} \equiv \frac{\Delta+\ell}{2}, \tag{51.53}$$

so that h measures the twist, $\bar{h}$ the "conformal spin" (the eigenvalue of the collinear Casimir is $\bar{h}(\bar{h}-1)$), and the block tends to $\bar{z}^h k_{2\bar{h}}(z)$. The double-twist tower of leading twist has $h = \Delta_\phi$ (modulo the small anomalous shift we are after) and $\bar{h} = \Delta_\phi + \ell$.

Second, the blocks are symmetric in their two arguments, $G_{\Delta,\ell}(z,\bar{z}) = G_{\Delta,\ell}(\bar{z},z)$, so Eq. (51.52) holds equally with z and $\bar{z}$ interchanged.

The strategy is to take the *double lightcone limit* of Eq. (51.51): first $\bar{z}\to 0$, isolating low twist, and then $z \to 1$, probing the crossed-channel OPE singularity at $v \to 0$. The two limits do different jobs on the two sides of the equation, and matching them order by order is the whole computation.

The s-channel side ($\bar{z}\to 0$). On the left of Eq. (51.51) the prefactor $(1-\bar{z})^{\Delta_\phi} \to 1$, and each block contributes $\bar{z}^{h_{\mathcal{O}}} k_{2\bar{h}_{\mathcal{O}}}(z)$. The smallest power of $\bar{z}$ wins. The leading term is the identity at $h = 0$,

$$\text{LHS} \xrightarrow{\bar{z}\to 0} (1-z)^{\Delta_\phi}\Big[1 + \bar{z}^{\Delta_\phi}\sum_{\ell\ \text{even}} p_{0,\ell}\, k_{2\bar{h}_\ell}(z) + O(\bar{z}^{\tau_{\min}/2}, \bar{z}^{\Delta_\phi+1})\Big], \tag{51.54}$$

where the first correction is the leading-twist double-twist tower $[\phi\phi]_{0,\ell}$, which sits at twist $\tau = 2\Delta_\phi$ and hence contributes at $\bar{z}^{\Delta_\phi}$. The higher-twist towers $[\phi\phi]_{n,\ell}$ enter at $\bar{z}^{\Delta_\phi+n}$ and any genuinely light s-channel operator at $\bar{z}^{\tau_{\min}/2}$; both are subleading to the leading-twist tower in the regime we organize. We have written $\bar{h}_\ell = \Delta_\phi + \ell$ for the leading-twist conformal spin and will reinstate the anomalous shift in a moment.

The t-channel side and the role of the identity. On the right of Eq. (51.51) the prefactor is $(z\bar{z})^{\Delta_\phi}$, carrying a factor $\bar{z}^{\Delta_\phi}$ as $\bar{z}\to 0$. The t-channel identity

gives simply $(z\bar{z})^{\Delta_\phi}$. As $z \to 1$ this is $\bar{z}^{\Delta_\phi}\,[1 + O(1-z)]$. Comparing with Eq. (51.54), the s-channel *identity* on the left (the standalone 1, times $(1-z)^{\Delta_\phi}$) is order $\bar{z}^0$, whereas the entire right-hand side starts at $\bar{z}^{\Delta_\phi}$. There is no $\bar{z}^0$ term on the right at all. The only way Eq. (51.51) can hold is if the s-channel double-twist tower conspires, in the limit $z \to 1$, to reproduce both the leftover identity behavior and the right-hand side. This is the mechanism, already exploited at zeroth order in Section 51.2 to fix the mean-field coefficients; we now recall it precisely because the first-order computation is its exact analogue.

51.3.2 Zeroth order: the identity fixes the large-spin tail

At zeroth order we keep only the identity on the right and the leading-twist tower on the left, both at the order $\bar{z}^{\Delta_\phi}$, and equate them. Dividing Eq. (51.51) by $\bar{z}^{\Delta_\phi}$ and sending $\bar{z} \to 0$,

$$(1-z)^{\Delta_\phi} \sum_{\ell \text{ even}} p^{\mathrm{MFT}}_{0,\ell}\, k_{2\bar{h}_\ell}(z) \;=\; z^{\Delta_\phi} \;\xrightarrow{z\to 1}\; 1. \tag{51.55}$$

The right-hand side is finite at $z = 1$, so the sum on the left must *diverge* like $(1-z)^{-\Delta_\phi}$ to cancel the prefactor:

$$\sum_{\ell \text{ even}} p^{\mathrm{MFT}}_{0,\ell}\, k_{2\bar{h}_\ell}(z) \;\xrightarrow{z\to 1}\; (1-z)^{-\Delta_\phi}. \tag{51.56}$$

No finite collection of collinear blocks can produce a power-law divergence at $z = 1$: each $k_{2\bar{h}}(z)$ diverges only logarithmically there. The divergence in Eq. (51.56) can come only from the tail of the sum, $\bar{h} \to \infty$. The large-spin behavior of $p^{\mathrm{MFT}}_{0,\ell}$ is therefore not an input but an output of crossing, fixed by demanding Eq. (51.56). To extract it we need the behavior of $k_{2\bar{h}}(z)$ when $\bar{h}$ is large and z near 1 together, which is the technical heart of the whole large-spin program.

Lemma 51.9 (Collinear block at large conformal spin)**.** *In the regime $\bar{h} \to \infty$, $z \to 1$ with $y \equiv \bar{h}^2(1-z)$ held fixed,*

$$k_{2\bar{h}}(z) \;\simeq\; \frac{2\,\Gamma(2\bar{h})}{\Gamma(\bar{h})^2}\, K_0\!\big(2\bar{h}\sqrt{1-z}\big) \;\simeq\; \frac{2^{2\bar{h}}}{\sqrt{\pi}}\, \bar{h}^{1/2}\, K_0\!\big(2\bar{h}\sqrt{1-z}\big), \tag{51.57}$$

with K_0 the modified Bessel function of the second kind.

Proof. Set $a = b = \bar{h}$, $c = 2\bar{h} = a + b$ in the standard $z \to 1$ connection formula for the Gauss hypergeometric function (the logarithmic case $c = a + b$),

$${}_2F_1(\bar{h}, \bar{h}; 2\bar{h}; z) = \frac{\Gamma(2\bar{h})}{\Gamma(\bar{h})^2} \sum_{n=0}^{\infty} \frac{(\bar{h})_n^2}{(n!)^2} \left[\, 2\psi(n+1) - 2\psi(\bar{h}+n) - \ln(1-z) \,\right] (1-z)^n, \tag{51.58}$$

where ψ is the digamma function and $(\bar h)_n = \Gamma(\bar h+n)/\Gamma(\bar h)$. Keeping only the $n=0$ term and using $\psi(1) = -\gamma_E$ reproduces the leading logarithm, $k_{2\bar h}(z) \to -\frac{\Gamma(2\bar h)}{\Gamma(\bar h)^2}\big[\ln(1-z) + 2\gamma_E + 2\psi(\bar h)\big]$, the result one uses at fixed $\bar h$. To resum the tower we take $\bar h$ large at fixed $y = \bar h^2(1-z)$. Then $z^{\bar h} \to 1$, $(\bar h)_n^2 \simeq \bar h^{2n}$, so $(\bar h)_n^2(1-z)^n/(n!)^2 \simeq y^n/(n!)^2$; and $\psi(\bar h+n) \simeq \ln \bar h$ up to $O(n/\bar h)$, while $-\ln(1-z) - 2\ln\bar h = -\ln y$. The bracket becomes $2\psi(n+1) - \ln y = 2H_n - 2\gamma_E - \ln y$ with $H_n = \psi(n+1)+\gamma_E$ the harmonic number. Hence

$$k_{2\bar h}(z) \;\simeq\; \frac{\Gamma(2\bar h)}{\Gamma(\bar h)^2}\sum_{n=0}^{\infty}\frac{y^n}{(n!)^2}\big[\,2H_n - 2\gamma_E - \ln y\,\big]. \tag{51.59}$$

The series is exactly $2K_0(2\sqrt{y})$: the Bessel function has the convergent expansion $K_0(2\sqrt{y}) = -(\gamma_E + \tfrac12\ln y)\,I_0(2\sqrt{y}) + \sum_{n\ge1}\frac{y^n}{(n!)^2}H_n$ with $I_0(2\sqrt{y}) = \sum_{n\ge0} y^n/(n!)^2$, and doubling it gives $\sum_{n\ge0}\frac{y^n}{(n!)^2}(2H_n - 2\gamma_E - \ln y)$ since $H_0 = 0$. With $2\sqrt{y} = 2\bar h\sqrt{1-z}$ this is the first equality of Eq. (51.57). The second follows from the duplication formula $\Gamma(2\bar h) = \frac{2^{2\bar h-1}}{\sqrt\pi}\Gamma(\bar h)\Gamma(\bar h+\tfrac12)$ together with $\Gamma(\bar h+\tfrac12)/\Gamma(\bar h) \simeq \bar h^{1/2}$. □

The Bessel form makes the large-spin sum an integral transform. Treat the sum over even spins as an integral over $\bar h$ with one operator per $\Delta\bar h = 2$, density $d\bar h/2$, and posit a power-law tail $p^{\rm MFT}_{0,\ell} \simeq 2^{-2\bar h}\sqrt\pi\, Q\,\bar h^{\,p}$ (the factor $2^{-2\bar h}$ must be present to cancel the $2^{2\bar h}$ of Eq. (51.57); everything else is to be determined). Then

$$\sum_{\ell\ \text{even}} p^{\rm MFT}_{0,\ell}\,k_{2\bar h_\ell}(z) \;\simeq\; \int\frac{d\bar h}{2}\,Q\,\bar h^{\,p+1/2}\,K_0\big(2\bar h\sqrt{1-z}\big). \tag{51.60}$$

The master integral is elementary. From $\int_0^\infty x^{s-1}K_0(x)\,dx = 2^{s-2}\Gamma(s/2)^2$, rescaling $x = 2\bar h\sqrt{1-z}$ gives

$$\int_0^\infty d\bar h\,\bar h^{\,s-1}\,K_0\big(2\bar h\sqrt{1-z}\big) \;=\; \frac14\,(1-z)^{-s/2}\,\Gamma\Big(\frac{s}{2}\Big)^2. \tag{51.61}$$

With $s-1 = p+\tfrac12$, i.e. $s = p+\tfrac32$, the right-hand side of Eq. (51.60) is $\frac{Q}{8}(1-z)^{-(p+3/2)/2}\Gamma(\frac{2p+3}{4})^2$. Matching to $(1-z)^{-\Delta_\phi}$ of Eq. (51.56) fixes the power $p = 2\Delta_\phi - \frac32$, whereupon $\frac{2p+3}{4} = \Delta_\phi$ and the coefficient condition $\frac{Q}{8}\Gamma(\Delta_\phi)^2 = 1$ gives $Q = 8/\Gamma(\Delta_\phi)^2$. The large-spin mean-field coefficients are therefore

$$p^{\rm MFT}_{0,\ell} \;\simeq\; \frac{8\sqrt\pi}{\Gamma(\Delta_\phi)^2}\,2^{-2\bar h}\,\bar h^{\,2\Delta_\phi-3/2}, \qquad \bar h = \Delta_\phi + \ell \to \infty, \tag{51.62}$$

reproducing the asymptotics of the exact mean-field formula obtained combinatorially in Section 51.2 — now derived from crossing alone, with no Wick-theorem input. This is the zeroth-order content: the very existence and large-spin normalization of the double-twist tower is forced by the t-channel identity. We will not need Eq. (51.62) for any other purpose than as the measure against which the first-order shift is weighed.

51.3.3 First order: a minimal-twist exchange induces an anomalous dimension

Now restore interactions. Suppose the $\phi\times\phi$ OPE contains, beyond the identity, a primary $\mathcal{O}_m$ of twist $\tau_m=\Delta_m-\ell_m$ that is the *smallest* nonzero twist exchanged, with conformal spin $\bar h_m=\frac{\Delta_m+\ell_m}{2}=\frac{\tau_m}{2}+\ell_m$ and OPE coefficient $p_m=C^2_{\phi\phi\mathcal{O}_m}$. Two things change relative to zeroth order. On the right of Eq. (51.51), $\mathcal{O}_m$ adds a new term to the t-channel sum. On the left, the leading-twist data acquire corrections: the twist becomes $2\Delta_\phi+\gamma_{0,\ell}$ and the coefficient $p_{0,\ell}=p^{\rm MFT}_{0,\ell}(1+\delta p_{0,\ell})$. The anomalous dimension enters the block through its power of $\bar z$,

$$\bar z^{\,h_\ell}=\bar z^{\,\Delta_\phi+\gamma_{0,\ell}/2}=\bar z^{\,\Delta_\phi}\Big(1+\tfrac12\gamma_{0,\ell}\ln\bar z+\cdots\Big), \tag{51.63}$$

so that to first order the leading-twist tower contributes to the left-hand side, at order $\bar z^{\Delta_\phi}$,

$$\text{LHS}\ \supset\ (1-z)^{\Delta_\phi}\,\bar z^{\Delta_\phi}\sum_{\ell\ \text{even}}p^{\rm MFT}_{0,\ell}\Big(1+\delta p_{0,\ell}+\tfrac12\gamma_{0,\ell}\ln\bar z\Big)k_{2\bar h_\ell}(z). \tag{51.64}$$

The decisive observation is that the anomalous dimension and the coefficient correction are cleanly separated by the factor $\ln\bar z$: the $\gamma_{0,\ell}$ piece is the unique source of a $\bar z^{\Delta_\phi}\ln\bar z$ term on the left, whereas $\delta p_{0,\ell}$ contributes only to the non-logarithmic $\bar z^{\Delta_\phi}$ term. We therefore extract the anomalous dimension by isolating the coefficient of $\bar z^{\Delta_\phi}\ln\bar z$ in Eq. (51.51).

On the right-hand side, where does a $\ln\bar z$ come from? The identity produces none. The new operator $\mathcal{O}_m$ does. Its t-channel block is $G_{\Delta_m,\ell_m}(1-z,1-\bar z)$; using block symmetry and the lightcone factorization Eq. (51.52) in the *small* variable $1-z$ (which $\to0$ as $z\to1$),

$$G_{\Delta_m,\ell_m}(1-z,1-\bar z)=G_{\Delta_m,\ell_m}(1-\bar z,1-z)\ \xrightarrow{z\to1}\ (1-z)^{\tau_m/2}\,k_{2\bar h_m}(1-\bar z). \tag{51.65}$$

The surviving collinear block has argument $1-\bar z$, which tends to 1 as $\bar z\to0$ — exactly the logarithmic regime of k. From the $n=0$ term of the connection formula Eq. (51.58), with $1-(1-\bar z)=\bar z$,

$$k_{2\bar h_m}(1-\bar z)\ \xrightarrow{\bar z\to0}\ -\frac{\Gamma(2\bar h_m)}{\Gamma(\bar h_m)^2}\,\big[\ln\bar z+2\gamma_E+2\psi(\bar h_m)\big]. \tag{51.66}$$

The $\ln\bar z$ here is precisely the t-channel logarithm. Assembling the $\mathcal{O}_m$ term of the right-hand side, with the prefactor $(z\bar z)^{\Delta_\phi}\to\bar z^{\Delta_\phi}$ as $z\to1$,

$$\text{RHS}\ \supset\ \bar z^{\Delta_\phi}\,p_m\,(1-z)^{\tau_m/2}\,k_{2\bar h_m}(1-\bar z)\ \supset\ -\,\bar z^{\Delta_\phi}\ln\bar z\;p_m\,\frac{\Gamma(2\bar h_m)}{\Gamma(\bar h_m)^2}\,(1-z)^{\tau_m/2}. \tag{51.67}$$

Equating the coefficients of $\bar{z}^{\Delta_\phi}\ln\bar{z}$ in Eqs. (51.64) and (51.67), and cancelling the common $(1-z)^{\Delta_\phi}$ against $z^{\Delta_\phi}\to 1$,

$$\sum_{\ell\ \text{even}} p_{0,\ell}^{\text{MFT}}\,\frac{\gamma_{0,\ell}}{2}\,k_{2\bar{h}_\ell}(z)\ \xrightarrow{z\to 1}\ -p_m\,\frac{\Gamma(2\bar{h}_m)}{\Gamma(\bar{h}_m)^2}\,(1-z)^{\tau_m/2-\Delta_\phi}. \tag{51.68}$$

This is the central matching condition, and it has exactly the structure of the zeroth-order condition Eq. (51.56) except that the target singularity is *weaker* by a factor $(1-z)^{\tau_m/2}$. The same integral transform that produced Eq. (51.62) now reads off the large-spin tail of $\gamma_{0,\ell}$.

Posit $\gamma_{0,\ell}\simeq -c/\bar{h}^{\,\tau_m}$ at large conformal spin. The summand coefficient is then

$$p_{0,\ell}^{\text{MFT}}\,\frac{\gamma_{0,\ell}}{2}\ \simeq\ -\frac{4c\sqrt{\pi}}{\Gamma(\Delta_\phi)^2}\,2^{-2\bar{h}}\,\bar{h}^{\,2\Delta_\phi-3/2-\tau_m}, \tag{51.69}$$

using Eq. (51.62). Inserting this and the Bessel form Eq. (51.57) into the sum, the $2^{\pm 2\bar{h}}$ and $\sqrt{\pi}$ cancel against each other exactly as at zeroth order, leaving

$$\sum_{\ell\ \text{even}} p_{0,\ell}^{\text{MFT}}\,\frac{\gamma_{0,\ell}}{2}\,k_{2\bar{h}_\ell}(z)\ \simeq\ -\frac{2c}{\Gamma(\Delta_\phi)^2}\int_0^\infty d\bar{h}\;\bar{h}^{\,2\Delta_\phi-1-\tau_m}\,K_0\!\left(2\bar{h}\sqrt{1-z}\right). \tag{51.70}$$

The master integral Eq. (51.61) with $s=2\Delta_\phi-\tau_m$ gives $\frac{1}{4}(1-z)^{\tau_m/2-\Delta_\phi}\,\Gamma(\Delta_\phi-\frac{\tau_m}{2})^2$, so the left-hand side of Eq. (51.68) equals

$$-\frac{c}{2}\,\frac{\Gamma(\Delta_\phi-\frac{\tau_m}{2})^2}{\Gamma(\Delta_\phi)^2}\,(1-z)^{\tau_m/2-\Delta_\phi}. \tag{51.71}$$

Both the power of $(1-z)$ and its coefficient must match the right-hand side of Eq. (51.68). The powers agree automatically — confirmation that the ansatz $\gamma_{0,\ell}\propto\bar{h}^{-\tau_m}$ was the correct one — and the coefficients fix c:

$$\frac{c}{2}\,\frac{\Gamma(\Delta_\phi-\frac{\tau_m}{2})^2}{\Gamma(\Delta_\phi)^2}=p_m\,\frac{\Gamma(2\bar{h}_m)}{\Gamma(\bar{h}_m)^2}\quad\Longrightarrow\quad c=2\,p_m\,\frac{\Gamma(\Delta_\phi)^2}{\Gamma(\Delta_\phi-\frac{\tau_m}{2})^2}\,\frac{\Gamma(2\bar{h}_m)}{\Gamma(\bar{h}_m)^2}. \tag{51.72}$$

We have proved the following.

Theorem 51.10 (Large-spin anomalous dimension from a minimal-twist exchange)**.** *Let ϕ be a scalar primary of dimension Δ_ϕ in a unitary CFT, and suppose the lowest-twist operator in the $\phi\times\phi$ OPE other than the identity is $\mathcal{O}_m$, with twist τ_m, spin ℓ_m, conformal spin $\bar{h}_m=\frac{\tau_m}{2}+\ell_m$, and squared OPE coefficient $p_m=C^2_{\phi\phi\mathcal{O}_m}$. Then the leading-twist double-twist operators $[\phi\phi]_{0,\ell}$ acquire, at large spin, the anomalous dimension*

$$\gamma_{0,\ell}\ \simeq\ -\frac{c_{\tau_m}}{\bar{h}^{\,\tau_m}}\ \simeq\ -\frac{c_{\tau_m}}{\ell^{\,\tau_m}},\qquad \boxed{c_{\tau_m}=\frac{2\,\Gamma(\Delta_\phi)^2}{\Gamma(\Delta_\phi-\frac{\tau_m}{2})^2}\,\frac{\Gamma(2\bar{h}_m)}{\Gamma(\bar{h}_m)^2}\,C^2_{\phi\phi\mathcal{O}_m}} \tag{51.73}$$

with $\bar{h} = \Delta_\phi + \ell$ the conformal spin of the double-twist operator. If several operators share the minimal twist τ_m, their contributions to c_{τ_m} add. If the minimal twist is degenerate with operators at $2\tau_m, 3\tau_m, \ldots$ (multiple exchanges) those produce the subleading powers $\bar{h}^{-2\tau_m}, \ldots$ in the large-spin expansion.

This is the Komargodski–Zhiboedov result [302], derived independently and simultaneously by Fitzpatrick, Kaplan, Poland and Simmons-Duffin [194]. Two features deserve comment. First, the leading power $\bar{h}^{-\tau_m}$ and $\ell^{-\tau_m}$ agree only to leading order in $1/\ell$, since $\bar{h} = \Delta_\phi + \ell$; the *conformal spin* $\bar{h}$ is the natural variable, because the large-spin expansion is really an expansion of the OPE data as an analytic function of the Casimir eigenvalue $\bar{h}(\bar{h}-1)$, a fact the inversion formula of the next section will make manifest. Second, the result is genuinely universal: it depends on the exchanged operator only through the three numbers $(\tau_m, \ell_m, C^2_{\phi\phi\mathcal{O}_m})$, and on the external operator only through Δ_ϕ. Nothing about the rest of the spectrum enters at this order.

Physical Insight

The physical content of Eq. (51.73) is a binding energy. A leading-twist operator $[\phi\phi]_{0,\ell}$ of large spin is, in the lightcone OPE, two ϕ quanta orbiting at large angular momentum, hence at large separation r with $\ell \sim r$ in the appropriate units. Its twist $\tau_{0,\ell} = 2\Delta_\phi + \gamma_{0,\ell}$ is the total energy minus the orbital part; the deviation $\gamma_{0,\ell}$ from the free value $2\Delta_\phi$ is the interaction energy of the two constituents. Exchanging an operator of twist τ_m generates a potential of range set by τ_m, falling off as $1/r^{\tau_m} \sim 1/\ell^{\tau_m}$ — a power law, not exponential, because the exchanged operator is massless on the cylinder (it is a CFT operator, not a gapped particle). The minimal twist controls the asymptotics for the same reason the lightest exchanged particle controls the long-range force in flat-space scattering. In a holographic theory this is not an analogy: the two constituents are particles in AdS, the exchanged stress tensor is the graviton, and $\gamma_{0,\ell}$ is the gravitational binding energy of the two-particle state, as we now compute.

51.3.4 Sign and convexity: unitarity makes the binding attractive

The coefficient Eq. (51.73) is manifestly non-negative in a unitary theory. Indeed $C^2_{\phi\phi\mathcal{O}_m} \geq 0$ because OPE coefficients of Hermitian operators are real (reflection positivity, used throughout Chapter 49); $\Gamma(\Delta_\phi)^2 > 0$, $\Gamma(\bar{h}_m)^2 > 0$, and $\Gamma(2\bar{h}_m) > 0$ since $\bar{h}_m > 0$; and the only factor whose argument can be negative, $\Gamma(\Delta_\phi - \frac{\tau_m}{2})$, enters *squared* and is therefore non-negative. Hence $c_{\tau_m} \geq 0$, and we record the immediate consequence.

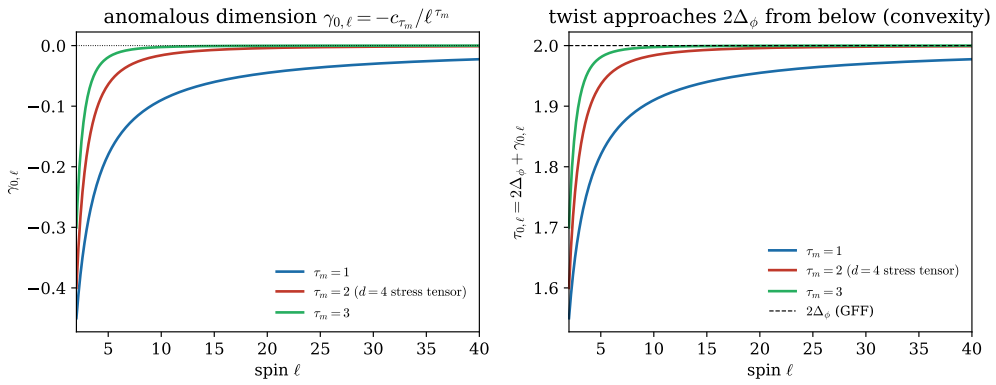

Figure 51.4: The universal large-spin behavior of Theorem 51.10, illustrated for $\Delta_\phi = 1$ and several minimal twists τ_m (coefficients chosen $O(1)$ for visibility). *Left*: the anomalous dimension $\gamma_{0,\ell} = -c_{\tau_m}/\ell^{\tau_m}$, negative and decaying as a power law set by the range τ_m of the exchanged operator; the larger the twist, the shorter the range and the faster the falloff. *Right*: the resulting twist $\tau_{0,\ell} = 2\Delta_\phi + \gamma_{0,\ell}$ climbs monotonically toward the generalized-free-field value $2\Delta_\phi$ (dashed) from below — the convexity of Theorem 51.11, a direct consequence of unitarity $C^2_{\phi\phi\mathcal{O}_m} \geq 0$.

Proposition 51.11 (Large-spin convexity)**.** *In a unitary CFT, the leading-twist anomalous dimension induced by a minimal-twist exchange is non-positive,*

$$\gamma_{0,\ell} \leq 0 \qquad (\ell \to \infty), \tag{51.74}$$

so the twist $\tau_{0,\ell} = 2\Delta_\phi + \gamma_{0,\ell}$ approaches its mean-field value $2\Delta_\phi$ from below, monotonically increasing in ℓ for large ℓ. The double-twist twist is, asymptotically, a bounded, monotone, convex function of the spin.

The sign is the assertion that the long-range force between the two constituents is *attractive*: the binding energy lowers the twist. This is the content of the title of [302], "Convexity and Liberation at Large Spin" — as the spin (separation) grows, the constituents are progressively "liberated," the binding weakens as $1/\ell^{\tau_m}$, and the twist climbs monotonically toward the free two-particle value. There is no unitary exchange that pushes the twist above $2\Delta_\phi$ at large spin. The behavior is illustrated in Fig. 51.4.

51.3.5 The universal gravitational case: stress-tensor exchange

The single most important application is to a CFT with a conserved stress tensor — that is, to *any* local CFT. The stress tensor $T_{\mu\nu}$ is a spin-2 operator of protected dimension $\Delta_T = d$ (conservation $\partial^\mu T_{\mu\nu} = 0$ saturates the spin-2 unitarity bound

of Theorem 47.18), hence its twist is

$$\tau_T = \Delta_T - \ell_T = d - 2, \tag{51.75}$$

the same for every local CFT in d dimensions. Whenever $\phi \times \phi$ contains no scalar of twist below $d-2$ — the generic situation, and the universal one for the stress-tensor channel — the minimal twist is $\tau_m = d-2$ and Theorem 51.10 predicts a binding $\gamma_{0,\ell} \sim -1/\ell^{d-2}$ whose coefficient is fixed, through the Ward identity, by the central charge.

Worked Example 51.12 (Universal binding from stress-tensor exchange)**.** We specialize Eq. (51.73) to $\mathcal{O}_m = T_{\mu\nu}$. The data are $\tau_m = d-2$, $\ell_m = 2$, so

$$\bar{h}_m = \frac{\tau_m}{2} + \ell_m = \frac{d-2}{2} + 2 = \frac{d+2}{2}, \qquad 2\bar{h}_m = d+2, \tag{51.76}$$

and the coefficient becomes

$$c_{d-2} = \frac{2\,\Gamma(\Delta_\phi)^2}{\Gamma\!\left(\Delta_\phi - \frac{d-2}{2}\right)^2} \frac{\Gamma(d+2)}{\Gamma\!\left(\frac{d+2}{2}\right)^2} C^2_{\phi\phi T}. \tag{51.77}$$

The OPE coefficient $C_{\phi\phi T}$ is not free: it is fixed by the conformal Ward identity that says the integrated stress tensor measures the dimension of ϕ. In the conventions in which the stress-tensor two-point function is normalized by the central charge C_T (the spin-2 analogue of the current normalization fixed in Section 47.4.3), the Ward identity gives

$$C^2_{\phi\phi T} = \frac{d\,\Delta_\phi^2}{(d-1)^2\, C_T}, \tag{51.78}$$

so the coupling of any operator to the stress tensor is set by its dimension and by the universal C_T, with no other dynamical input. Substituting Eq. (51.78) into Eq. (51.77),

$$\boxed{\gamma_{0,\ell} \;\simeq\; -\frac{1}{\ell^{\,d-2}} \, \frac{2\,d\,\Delta_\phi^2}{(d-1)^2\, C_T} \, \frac{\Gamma(\Delta_\phi)^2}{\Gamma\!\left(\Delta_\phi - \frac{d-2}{2}\right)^2} \, \frac{\Gamma(d+2)}{\Gamma\!\left(\frac{d+2}{2}\right)^2} \, .} \tag{51.79}$$

This is the universal gravitational binding. Every local unitary CFT contains it: the leading-twist tower of any scalar is bound by $-1/\ell^{d-2}$, with strength inversely proportional to the central charge. Three checks confirm the structure. *Sign*: $C_T > 0$ by unitarity (it is the norm of the stress-tensor state), and all other factors are positive or squared, so $\gamma_{0,\ell} < 0$ — gravity binds, as Theorem 51.11 demands. *Power*: the range $d-2$ is the twist of the graviton; in $d=4$ it is $\gamma_{0,\ell} \sim -1/\ell^2$, the long-range Newtonian tail. *Strength*: the $1/C_T$ scaling is the statement that the binding is weak when the theory has many degrees of freedom, i.e. weak Newton constant $G_N \sim 1/C_T$ in the holographic dual — two

particles in a nearly free AdS feel a feeble gravitational pull. In $d = 2$ the formula degenerates ($\tau_m = 0$, the stress tensor is itself near-marginal in twist) and the analysis must be redone with Virasoro symmetry, consistent with the special status of two dimensions flagged in Chapter 48.

The relation Eq. (51.78) is the only external input in the worked example, and it is a kinematic Ward identity, not a dynamical assumption; its derivation belongs to the conformal-symmetry chapter [155, 156] and is the spin-2 companion of the current Ward identity of Section 47.4.3. We have flagged its normalization-dependence honestly: the numerical coefficient in Eq. (51.79) is tied to the convention for C_T, while the power $1/\ell^{d-2}$ and the sign are convention-independent.

51.3.6 Scalar ϕ^4 theory: ϵ-exchange at Wilson–Fisher

We continue ϕ^4 theory from the generalized-free-field baseline of Section 51.2. At the Wilson–Fisher fixed point in $d = 4 - \varepsilon$ the scalar ϕ is no longer free: it acquires the anomalous dimension $\gamma_\phi = O(\varepsilon^2)$ recorded in Theorem 47.18, and the four-point function ceases to be a sum of identity blocks. The $\phi \times \phi$ OPE now contains, besides the stress tensor, a light *scalar* — the operator ϕ^2, which at the fixed point is the relevant deformation (the "ϵ operator" of the Ising universality class). Its dimension is

$$\Delta_{\phi^2} = d - 2 + \gamma_{\phi^2} = 2 - \frac{2\varepsilon}{3} + O(\varepsilon^2), \tag{51.80}$$

a scalar, so its twist equals its dimension, $\tau_{\phi^2} = \Delta_{\phi^2} \approx 2 - \frac{2\varepsilon}{3}$. By raw twist the stress tensor is lighter, $\tau_T = d - 2 = 2 - \varepsilon < \tau_{\phi^2} = 2 - \frac{2\varepsilon}{3}$, so ϕ^2 is *not* the minimal-twist exchange. Nevertheless it is ϕ^2, not the stress tensor, that controls the large-spin binding of the $[\phi\phi]_{0,\ell}$ tower: the stress tensor sits only a distance $\gamma_\phi = O(\varepsilon^2)$ from the double-twist lattice, so its double-discontinuity weight is $\sin^2(\pi\gamma_\phi) = O(\varepsilon^4)$ and it is suppressed, while ϕ^2 sits a distance $O(\varepsilon)$ off the lattice and contributes at $O(\varepsilon^2)$ (the dDisc mechanism is made precise in Theorem 51.20). Applying Theorem 51.10 with $\tau_m = \tau_{\phi^2}$, $\ell_m = 0$, $\bar{h}_m = \frac{\tau_{\phi^2}}{2} = \frac{1}{2}\Delta_{\phi^2}$,

$$\gamma_{0,\ell} \;\simeq\; -\frac{c_{\phi^2}}{\ell^{\Delta_{\phi^2}}}, \qquad c_{\phi^2} = \frac{2\,\Gamma(\Delta_\phi)^2}{\Gamma(\Delta_\phi - \frac{\Delta_{\phi^2}}{2})^2}\,\frac{\Gamma(\Delta_{\phi^2})}{\Gamma(\frac{\Delta_{\phi^2}}{2})^2}\,C^2_{\phi\phi\phi^2}. \tag{51.81}$$

At leading order in ε the data are the free-theory values $\Delta_\phi = 1 - \frac{\varepsilon}{2}$, $\Delta_{\phi^2} = 2 - \frac{2\varepsilon}{3}$, and the OPE coefficient $C^2_{\phi\phi\phi^2} = 2 + O(\varepsilon)$ of the free scalar (the Wick combinatorics of $\langle\phi\phi\,\phi^2\rangle$). The structure Eq. (51.81) is exact in the large-spin sense; turning its ε-expansion into numbers, and cross-checking against the direct $4 - \varepsilon$ perturbative computation of $\gamma_{0,\ell}$ and against the $d = 3$ Ising data, is the work of the closing thread section in Chapter 52. The point established here is

structural: at Wilson–Fisher the large-spin spectrum is bound by ϕ^2-exchange with the falloff $1/\ell^{\Delta_{\phi^2}}$, the analytic bootstrap predicting an entire tower of anomalous dimensions from a single OPE coefficient.

51.3.7 Systematics, and why we need more

The computation above extracts the *leading* large-spin behavior from a *single* minimal-twist exchange. One can push it. Subleading powers $1/\ell^{\tau_m+1}, 1/\ell^{\tau_m+2}, \ldots$ come from the descendants of $\mathcal{O}_m$ (the higher n terms of the connection formula Eq. (51.58)) and from double exchanges; corrections to the OPE coefficients $\delta p_{0,\ell}$ come from the non-logarithmic piece of Eq. (51.66); the higher-twist towers $[\phi\phi]_{n,\ell}$ are governed by the subleading powers of $\bar{z}$ in Eq. (51.54). Organizing all of this systematically is the subject of the *twist conformal blocks* and *large-spin perturbation theory* of Alday and collaborators [12, 13]: one defines generating functions that resum, in one stroke, an entire family of $1/\bar{h}$ corrections sharing a common origin, and the crossing equation becomes a set of algebraic relations among them.

Even so, the lightcone method as presented has a built-in ceiling. It matches *powers of* $\bar{z}$ *and* $\ln \bar{z}$ near a corner of cross-ratio space, and each new order requires expanding both sides to one higher power, with the algebra growing rapidly and the bookkeeping of which operators contribute where becoming delicate. More fundamentally, the method produces an *asymptotic* series in $1/\bar{h}$: it is exact at infinite spin and systematically improvable, but it is not a closed formula valid at all spins, and it offers no control over convergence or over the low-spin operators that the numerical bootstrap of Chapter 50 cares about most. What one would like is a single object that yields the OPE data as an honest analytic function of spin, all orders in $1/\bar{h}$ at once, reconstructed from the correlator rather than matched term by term. That object exists: it is the Lorentzian inversion formula of Caron-Huot, which promotes the discrete OPE data to the analytic-in-spin function whose large-$\bar{h}$ expansion reproduces everything in this section, and whose input is a single positive quantity — the double discontinuity of the correlator. We turn to it next.

51.4 The Lorentzian Inversion Formula

The large-spin expansion of the previous section was a triumph of bookkeeping. By matching the t-channel identity against an s-channel tower we learned that every CFT contains families of double-twist operators $[\phi\phi]_{n,\ell}$ whose dimensions approach $2\Delta_\phi + 2n + \ell$, and we computed the leading correction $\gamma_{0,\ell} \sim -c_{\tau_m}/\ell^{\tau_m}$ set by the lowest-twist exchanged operator. But the method was an asymptotic series assembled by hand, one crossing kernel and one power of $1/\ell$ at a time, with no guarantee that the pattern we read off at the first two orders persists,

and no statement at all about *finite* spin. What the lightcone analysis was really probing — that the OPE data of the double-twist families vary *smoothly* with ℓ — cries out for a generating object: a single function of the spin, defined for all ℓ at once, whose asymptotic expansion reproduces the hand computation and whose exact form contains everything the lightcone limit could only see at leading order. That object is the Caron-Huot inversion formula [111], and constructing it is the business of this section. It will turn the OPE data from a discrete table indexed by integer spin into an *analytic function of spin*, reconstructible from a sharply defined piece of the correlator — its double discontinuity.

Throughout we use the cross-ratios of Eq. (47.140), $u = z\bar{z}$ and $v = (1-z)(1-\bar{z})$, the stripped four-point function $g(z,\bar{z})$ of identical scalars ϕ of dimension Δ_ϕ from the block decomposition Eq. (47.227), and the crossing equation Eq. (49.14) in the form $v^{\Delta_\phi} g(u,v) = u^{\Delta_\phi} g(v,u)$. We work in d dimensions; in Lorentzian signature z and $\bar{z}$ are independent real variables, the feature exploited at every step below.

51.4.1 The Euclidean inversion and why spin is not yet analytic

The block decomposition Eq. (47.227) writes g as a discrete sum over the spectrum. There is a standard way to *invert* it — to extract the OPE data as an integral of the correlator against a kernel — which predates the Lorentzian formula and is purely Euclidean. It rests on completeness of the conformal partial waves.

For each spin $\ell \in \mathbb{Z}_{\geq 0}$, consider the dimension Δ on the *principal series* $\Delta = \frac{d}{2} + i\nu$, $\nu \in \mathbb{R}$. The shadow of a primary of dimension Δ is the formal primary of dimension $\tilde{\Delta} = d - \Delta$; the principal series is the locus fixed (up to $\nu \to -\nu$) by shadowing. The *conformal partial wave* is the shadow-symmetric combination of a block and its shadow,

$$\Psi_{\Delta,\ell}(z,\bar{z}) \;=\; \tfrac{1}{2}\Big(K_{\tilde{\Delta},\ell}\, G_{\Delta,\ell}(z,\bar{z}) \;+\; K_{\Delta,\ell}\, G_{\tilde{\Delta},\ell}(z,\bar{z}) \Big), \tag{51.82}$$

where $G_{\Delta,\ell}$ is the conformal block of Theorem 47.49 and $K_{\Delta,\ell}$ is a ratio of Γ-functions (the "shadow coefficient") whose precise value will not be needed. The $\Psi_{\Delta,\ell}$ are the genuine eigenfunctions of the conformal Casimir that are single-valued on the Euclidean section $\bar{z} = z^*$ and normalizable there; on the principal series they form a delta-function–orthonormal basis,

$$\big(\Psi_{\Delta,\ell},\, \Psi_{\Delta',\ell'}\big) \;\propto\; \delta_{\ell\ell'}\,\big[\delta(\nu-\nu') + \delta(\nu+\nu')\big], \tag{51.83}$$

the inner product being the integral over the Euclidean section against the natural conformally invariant measure. Completeness then states that any crossing-symmetric, normalizable g admits the *conformal partial wave expansion*

$$g(z,\bar{z}) \;=\; \sum_{\ell=0}^{\infty} \int_{\frac{d}{2}-i\infty}^{\frac{d}{2}+i\infty} \frac{d\Delta}{2\pi i}\, c(\Delta,\ell)\, \Psi_{\Delta,\ell}(z,\bar{z}), \tag{51.84}$$

with a spectral density $c(\Delta,\ell)$. The connection to physical data is made by closing the Δ-contour: $c(\Delta,\ell)$ is meromorphic in Δ, and each physical primary $\mathcal{O}_k$ of spin ℓ and dimension Δ_k contributes a pole on the right of the contour,

$$c(\Delta,\ell) \;\sim\; -\frac{C^2_{\phi\phi\mathcal{O}_k}}{\Delta-\Delta_k} \qquad (\Delta\to\Delta_k), \tag{51.85}$$

so that picking up these poles when the principal-series contour is deformed to the right turns Eq. (51.84) back into the block sum Eq. (47.227): the pole locations give the dimensions and the residues give the squared OPE coefficients. The function $c(\Delta,\ell)$ is therefore exactly the generating object we want — *if* we can compute it.

Orthogonality Eq. (51.83) hands us a formula for it. Projecting Eq. (51.84) onto $\Psi_{\Delta,\ell}$ gives the *Euclidean inversion*,

$$c(\Delta,\ell) \;=\; N(\Delta,\ell)\int_{\text{Eucl}} d^2z\;\mu_{\text{E}}(z,\bar z)\,\Psi_{\Delta,\ell}(z,\bar z)\,g(z,\bar z), \tag{51.86}$$

the integral running over the Euclidean section $\bar z = z^*$ with the invariant measure μ_{E} and a known normalization $N(\Delta,\ell)$ fixed by Eq. (51.83). This is a genuine inversion: it returns the full OPE data of a given spin as an integral transform of the correlator.

It is also, for the purposes of the bootstrap, almost useless, and it is worth being precise about *why*. The defect is not in Δ — as a function of Δ, Eq. (51.86) is perfectly analytic, with the poles Eq. (51.85) we want. The defect is in ℓ. The formula produces $c(\Delta,\ell)$ *one integer spin at a time*: the partial wave Eq. (51.82) is a specific function for each $\ell\in\mathbb{Z}_{\geq 0}$, and nothing in Eq. (51.86) tells us how to continue the answer to non-integer, let alone complex, ℓ. One might hope to continue $\Psi_{\Delta,\ell}$ in ℓ and continue the integral, but the continuation is ambiguous, and the ambiguity is exactly the obstruction Carlson's theorem identifies. Carlson's theorem says that a function $f(\ell)$ analytic in the right half-plane $\operatorname{Re}\ell>0$ and of exponential type strictly less than π there — that is, bounded by $e^{(\pi-\delta)|\ell|}$ — is uniquely determined by its values at the non-negative integers; without such a boundedness statement, two analytic functions can agree at all integers and differ everywhere else (the standard counterexample being $\sin(\pi\ell)$, which vanishes at every integer). The Euclidean integrand Eq. (51.86) provides no such bound: the partial wave $\Psi_{\Delta,\ell}$, continued in ℓ, grows in the lightcone corners $z\to 0,1$ and $\bar z\to 0,1$ of the integration region fast enough to spoil exponential type, so the integral does not define a function of controlled growth in ℓ. The discrete sum over ℓ in Eq. (51.84) cannot be Sommerfeld–Watson resummed into a contour integral, and "the OPE data as a function of spin" is, from the Euclidean formula alone, not even well posed.

Physical Insight

The Euclidean inversion is the conformal analogue of computing Fourier coefficients $a_n = \int f\, e^{-inx}$: it returns one number per integer mode, with no canonical way to interpolate between modes. To get an *analytic function* of the mode number one needs extra information — here, a growth bound. The Lorentzian formula supplies precisely that bound by re-expressing the same OPE data as an integral whose integrand is manifestly tame in ℓ, at the price of replacing the full correlator by a single, positive piece of it: the double discontinuity.

51.4.2 The double discontinuity

The object that carries the analyticity is a particular discontinuity of the correlator taken in the t-channel cross-ratio, around the point $v = 0$, equivalently $\bar{z} = 1$ at fixed z. In Lorentzian kinematics $\bar{z}$ is an independent real variable and the correlator, continued past $\bar{z} = 1$, develops a branch cut; the double discontinuity measures the obstruction to continuing through it on both sheets at once.

Definition 51.13 (Double discontinuity)**.** Let $g(z, \bar{z})$ be the stripped correlator, holomorphic in $\bar{z}$ in a neighbourhood of the Euclidean section and continued in $\bar{z}$ around the branch point at $\bar{z} = 1$ with z held fixed. Write $g^{\circlearrowleft}$ and $g^{\circlearrowright}$ for the continuations obtained by encircling $\bar{z} = 1$ counterclockwise and clockwise. For identical external scalars (the case $a = b = 0$ in the general notation) the *double discontinuity* is

$$\mathrm{dDisc}\,[g(z,\bar{z})] \;\equiv\; g(z,\bar{z}) \;-\; \tfrac{1}{2}\, g^{\circlearrowleft}(z,\bar{z}) \;-\; \tfrac{1}{2}\, g^{\circlearrowright}(z,\bar{z}). \tag{51.87}$$

For general external dimensions, with $a = -\frac{1}{2}(\Delta_1 - \Delta_2)$ and $b = \frac{1}{2}(\Delta_3 - \Delta_4)$, the combination is weighted by phases, $\mathrm{dDisc}[g] = \cos(\pi(a+b))\, g - \frac{1}{2} e^{i\pi(a+b)} g^{\circlearrowleft} - \frac{1}{2} e^{-i\pi(a+b)} g^{\circlearrowright}$, reducing to Eq. (51.87) when $a = b = 0$.

The name and the physics are clarified by the Lorentzian interpretation. Each ordinary discontinuity $g - g^{\circlearrowleft}$ (or $g - g^{\circlearrowright}$) is, by the same Lorentzian-continuation argument that turns the optical theorem into a cut, the expectation value of a single commutator of the external operators across the corresponding lightcone. Taking the discontinuity twice — once on each sheet — assembles a *double* commutator: arranging the four operators in the Lorentzian configuration in which $\phi(x_1), \phi(x_3)$ are spacelike from the pair $\phi(x_2), \phi(x_4)$ but timelike-related across $\bar{z} = 1$, one finds, up to a positive kinematic prefactor,

$$\mathrm{dDisc}\,[g] \;\propto\; \big\langle\, [\phi(x_4), \phi(x_1)]\, [\phi(x_2), \phi(x_3)] \,\big\rangle. \tag{51.88}$$

A double commutator of this form is, by inserting a complete set of states between the two commutators, a sum of squared matrix elements: it is the norm of a state,

hence *non-negative*. This positivity, $\mathrm{dDisc}[g] \geq 0$, is the Lorentzian shadow of OPE-coefficient positivity, and it is what makes the inversion formula a source of *bounds* as well as of analytic data. We will not need the full operator derivation of Eq. (51.88); what we need is the elementary action of Eq. (51.87) on the power-law and block singularities the correlator actually has, computed next.

Worked Example 51.14 (Double discontinuity of a power)**.** The crossing equation $g(u,v) = (u/v)^{\Delta_\phi} g(v,u)$ shows that the small-v behaviour of g is controlled by the t-channel data: a t-channel primary of twist $\tau' = \Delta' - \ell'$ contributes, through its block $G_{\Delta',\ell'}(v,u) \sim v^{\tau'/2}$ near $v \to 0$, a term $g(u,v) \supset (u/v)^{\Delta_\phi}\, v^{\tau'/2} = u^{\Delta_\phi}\, v^{\tau'/2-\Delta_\phi}$. Strip the analytic factor u^{Δ_ϕ} and isolate the singular power in v. Since $v = (1-z)(1-\bar z)$ and we continue $\bar z$ around 1 at fixed z, the relevant monodromy is that of the factor $(1-\bar z)^p$ with

$$p \;=\; \frac{\tau'}{2} - \Delta_\phi. \tag{51.89}$$

Encircling $\bar z = 1$ once sends $(1-\bar z) \mapsto e^{\mp 2\pi i}(1-\bar z)$, so $(1-\bar z)^p \mapsto e^{\mp 2\pi i p}(1-\bar z)^p$ for the clockwise/counterclockwise loops. Therefore

$$\begin{aligned} \mathrm{dDisc}\left[(1-\bar z)^p\right] &= (1-\bar z)^p \Big[\, 1 - \tfrac{1}{2}e^{2\pi i p} - \tfrac{1}{2}e^{-2\pi i p} \Big] \\ &= (1-\bar z)^p \big[\, 1 - \cos(2\pi p) \,\big] \;=\; 2\sin^2(\pi p)\,(1-\bar z)^p. \end{aligned} \tag{51.90}$$

The double discontinuity acts on a power by multiplication by $2\sin^2(\pi p)$. This single trigonometric factor is the engine of the whole construction.

The consequences of Eq. (51.90) are immediate and far-reaching. Substitute the twist via Eq. (51.89): the dDisc of a t-channel contribution of twist τ' carries the weight

$$2\sin^2\!\Big(\pi\big(\tfrac{\tau'}{2} - \Delta_\phi\big)\Big) \;=\; 2\sin^2\!\Big(\pi\big(\Delta_\phi - \tfrac{\tau'}{2}\big)\Big). \tag{51.91}$$

Now recall the double-twist families. The generalized free field — the Gaussian endpoint of ϕ^4 theory, whose crossing solution was exhibited in Eq. (49.24) — has a spectrum of operators $[\phi\phi]_{n,\ell}$ of twist $\tau' = 2\Delta_\phi + 2n$ for $n = 0, 1, 2, \ldots$, and the same families appear, shifted by anomalous dimensions, in every CFT. For a double-twist operator, $\frac{\tau'}{2} - \Delta_\phi = n \in \mathbb{Z}$, and so

$$\mathrm{dDisc}\left[\text{double-twist contribution}\right] \;\propto\; \sin^2(\pi n) \;=\; 0. \tag{51.92}$$

The double discontinuity annihilates the double-twist operators. This is the structural fact that the whole formalism turns on. The double-twist families are precisely the "trivial" part of the OPE — the part already present in mean-field theory, reconstructed from the identity in the crossed channel — and the dDisc projects them out, leaving only the genuinely dynamical content. When a double-twist operator acquires an anomalous dimension, $\tau' = 2\Delta_\phi + 2n + \gamma_{n,\ell}$,

the weight becomes $2\sin^2(\pi\gamma_{n,\ell}/2) \approx \frac{\pi^2}{2}\gamma_{n,\ell}^2$: double-twist data enter the dDisc only at *second order* in their anomalous dimensions. The inversion formula thus reconstructs the leading double-twist data from the dDisc of the *other*, low-twist exchanged operators — exactly the operators whose exchange the large-spin analysis identified as the source of binding — and is blind, at leading order, to the double-twist operators' own back-reaction. The consistency of this self-referential structure is what makes the analytic bootstrap a closed, calculable system.

Worked Example 51.15 (Double discontinuity of a single t-channel block)**.** A full t-channel conformal block is not a single power but a descendant tower. Near $\bar{z} = 1$ at fixed z the block of an operator $\mathcal{O}'$ of twist τ', multiplied by the crossing factor $(u/v)^{\Delta_\phi}$ as it enters g, organizes into

$$(u/v)^{\Delta_\phi} G_{\Delta',\ell'}(v,u) \;=\; (1-\bar{z})^{\tau'/2-\Delta_\phi} \sum_{m=0}^{\infty} (1-\bar{z})^m \, h_m(z), \tag{51.93}$$

where the descendant sum runs over integer steps m in the twist (the 1/2-integer steps are forbidden for a single primary multiplet) and $h_m(z)$ are functions analytic at $\bar{z} = 1$. Every term in the sum shares the *same* non-integer power $(1-\bar{z})^{\tau'/2-\Delta_\phi}$ up to an integer shift m, and $\sin^2$ is periodic with period one in its argument, so each term picks up the identical monodromy weight $2\sin^2(\pi(\frac{\tau'}{2} - \Delta_\phi))$ under Eq. (51.87). Hence the double discontinuity acts on the whole block by an overall constant,

$$\mathrm{dDisc}\left[(u/v)^{\Delta_\phi} G_{\Delta',\ell'}(v,u)\right] \;=\; 2\sin^2\!\Big(\pi\big(\Delta_\phi - \tfrac{\tau'}{2}\big)\Big)\,(u/v)^{\Delta_\phi} G_{\Delta',\ell'}(v,u). \tag{51.94}$$

The block is an eigenfunction of dDisc with eigenvalue $2\sin^2(\pi(\Delta_\phi - \tau'/2))$. The double-twist zero Eq. (51.92) is recovered term by term, and the suppression of nearby operators by γ^2 follows by expanding the eigenvalue. (When a double-twist operator sits exactly at an integer and carries a logarithm $\sim (1-\bar{z})^n \log(1-\bar{z})$ — as happens once anomalous dimensions and OPE-coefficient corrections mix — the $\sin^2$ multiplying the pure power vanishes but its derivative acting on the log does not, reproducing the same $O(\gamma^2)$ result; we will not need the explicit log accounting here, only that the leading double-twist contribution is doubly suppressed.)

51.4.3 The Lorentzian inversion formula

We can now state the result. The Euclidean inversion Eq. (51.86) is to be re-expressed, by deforming its contour onto the Lorentzian double-lightcone region, as an integral of the double discontinuity against an *inverted block* — the block with dimension and spin interchanged and shifted, which is precisely the kernel that solves the Casimir equation with the right behaviour in the inverted regime.

Theorem 51.16 (Lorentzian inversion formula, Caron-Huot)**.** *Let $g(z,\bar z)$ be the stripped four-point function of identical scalars ϕ of dimension Δ_ϕ in a unitary CFT_d, satisfying crossing Eq. (49.14). The generating function of OPE data, defined by the conformal partial wave expansion Eq. (51.84) with poles Eq. (51.85), is computed by*

$$c(\Delta,\ell) \;=\; c^{\,t}(\Delta,\ell) \;+\; (-1)^{\ell}\, c^{\,u}(\Delta,\ell), \tag{51.95}$$

where the t-channel contribution is the double-lightcone integral

$$\boxed{\,c^{\,t}(\Delta,\ell) \;=\; \kappa_{\Delta+\ell}\int_0^1\!\!\int_0^1 dz\, d\bar z\; \mu(z,\bar z)\; G_{\,\ell+d-1,\,\Delta-d+1}(z,\bar z)\;\mathrm{dDisc}\left[g(z,\bar z)\right]\,,\,} \tag{51.96}$$

with the normalization, measure, and inverted block

$$\kappa_\beta = \frac{\Gamma\!\left(\frac{\beta}{2}\right)^4}{2\pi^2\,\Gamma(\beta-1)\,\Gamma(\beta)}\,, \qquad \beta=\Delta+\ell, \tag{51.97}$$

$$\mu(z,\bar z) = \frac{|z-\bar z|^{\,d-2}}{(z\bar z)^d}\,, \tag{51.98}$$

the kernel $G_{\ell+d-1,\,\Delta-d+1}$ being the ordinary conformal block of Theorem 47.49 evaluated at the interchanged-and-shifted quantum numbers $\Delta\mapsto\ell+d-1$, $\ell\mapsto\Delta-d+1$. The u-channel piece $c^{\,u}$ is given by the same formula with $z\to z/(z-1)$, $\bar z\to\bar z/(\bar z-1)$; for identical scalars $c^{\,u}=c^{\,t}$, so Eq. (51.95) reduces to $c(\Delta,\ell)=(1+(-1)^\ell)c^{\,t}$ and supports only even spin, consistent with the $\mathbb{Z}_2$ selection rule of $\phi\times\phi$.

Three features deserve comment before the derivation, because they are what the formula buys us.

First, it is built entirely from the dDisc. By Eq. (51.92) the integrand sees only the genuinely dynamical, non-double-twist content of the correlator. The double-twist data it produces on the left — the dimensions and OPE coefficients of $[\phi\phi]_{n,\ell}$, sitting at the poles Eq. (51.85) — are reconstructed from the cross-channel dDisc, not from the double-twist operators themselves. This is the lightcone bootstrap of the previous section promoted to an exact identity.

Second, it is manifestly analytic in spin. The right-hand side of Eq. (51.96) depends on ℓ only through the smooth prefactor $\kappa_{\Delta+\ell}$ and through the inverted block $G_{\ell+d-1,\Delta-d+1}$, both of which are analytic functions of ℓ taking finite, controlled values for ℓ in a half-plane. The integral therefore defines $c(\Delta,\ell)$ as an analytic function of ℓ, not merely a table of integers — exactly the boundedness the Euclidean formula lacked. We make the convergence condition precise in Theorem 51.17.

Third, its analytic structure in Δ reads off the spectrum. The $z\to 0$ endpoint of the integral is the s-channel OPE limit. There the inverted block behaves as a definite power of z, and integrating it against the small-z behaviour of dDisc$[g]$

produces poles in Δ from the endpoint, located at the s-channel twists and with residues equal to the squared OPE coefficients Eq. (51.85). The mechanics of extracting those poles — turning Eq. (51.96) into an explicit spectrum — is the calculational engine of Section 51.5; here we have the formula and its guarantees.

Notation Watch

The kernel in Eq. (51.96) is the *same* function $G_{\Delta,\ell}$ defined in Theorem 47.49, simply evaluated at the arguments $(\ell+d-1,\ \Delta-d+1)$. The interchange $\Delta \leftrightarrow \ell$ together with the shift by $d-1$ is not a new object; it is the statement that the Casimir equation is symmetric under $\Delta \to \ell+d-1$, $\ell \to \Delta-d+1$ (which preserves $\beta=\Delta+\ell$), so the inverted block is automatically a solution with the boundary behaviour appropriate to the inversion integral. We will not invent a separate symbol for it.

51.4.4 Derivation by contour deformation

The formula Eq. (51.96) is obtained from the Euclidean inversion Eq. (51.86) by deforming the $\bar z$-contour. We give the argument in full at the level of contour topology, isolating the one analytic input — a growth bound in the Regge regime — that controls the only term that could spoil it.

Begin with Eq. (51.86) and insert the partial wave Eq. (51.82). The two terms (block and shadow) are exchanged by $\Delta \to \tilde\Delta = d-\Delta$, so it suffices to track one of them and shadow-symmetrize at the end; the upshot of the shadow symmetrization is to convert the block kernel into the *inverted* block of Eq. (51.96), with the prefactor $\kappa_{\Delta+\ell}$ collecting the shadow coefficients K and the normalization N. Use the Lorentzian independence of z and $\bar z$ to write the Euclidean section integral as an iterated contour integral, and consider the $\bar z$-integral at fixed z. The integrand is holomorphic in $\bar z$ except for branch cuts inherited from g and from the kernel: a cut running left from $\bar z=0$ (the s-channel OPE singularity) and a cut running right from $\bar z=1$ to $\bar z=+\infty$ (the t- and u-channel singularities).

Now push the $\bar z$-contour from the Euclidean position to the right, toward the cut emanating from $\bar z=1$ (see Fig. 51.5). As it sweeps across the t-channel singularity it wraps the cut, and the wrapped contour collects the discontinuity of the integrand across it. The shadow symmetrization arranges these discontinuities into precisely the combination Eq. (51.87): the two sheets reached by going above and below the cut are the $g^{\circlearrowleft}$ and $g^{\circlearrowright}$ of Theorem 51.13, and the Euclidean value supplies the unsubtracted g. The integrand on the wrapped contour is therefore the inverted block times $\mathrm{dDisc}[g]$, and the $\bar z$-integral runs over the cut, $\bar z\in(1,\infty)$, which after the standard change of variables to the unit interval becomes the $\int_0^1 d\bar z$ of Eq. (51.96); the same deformation in z produces $\int_0^1 dz$. The measure μ Eq. (51.98) and the prefactor $\kappa_{\Delta+\ell}$ Eq. (51.97) are the Jacobian and

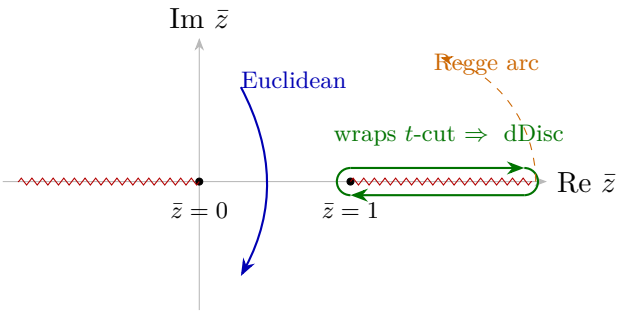

Figure 51.5: Contour deformation in the $\bar{z}$-plane at fixed z. The Euclidean inversion integrates along the blue contour. Deforming it to the right onto the cut from $\bar{z}=1$ (the double-lightcone region) wraps the t-channel branch cut; the difference of the values above and below the cut is exactly the double discontinuity Eq. (51.87). The deformation is legitimate provided the dashed arc at infinity (the Regge regime) is dropped, which requires the Regge boundedness Eq. (51.99).

the accumulated normalization. This is the formula Eq. (51.96).

Two boundary contributions are generated by the deformation and must be shown to vanish, or the equality fails.

The arc at $\bar{z}=1$ (the double-lightcone corner). As the contour is pulled to the right it must also be closed off near the branch point $\bar{z}=1$. The contribution of a small arc encircling $\bar{z}=1$ is governed by the power $(1-\bar{z})^{\tau'/2-\Delta_\phi}$ of the leading t-channel singularity Eq. (51.93); for any operator above the unitarity bound this power is >-1 for the lowest twists of interest, so the arc integral scales as a positive power of its radius and vanishes as the radius shrinks. The lowest-twist t-channel operator is the identity, whose contribution is the pure power $v^{-\Delta_\phi}$, i.e. $p=-\Delta_\phi$; its dDisc by Eq. (51.90) carries $2\sin^2(\pi\Delta_\phi)$, finite, and the small-arc integral is again controlled. The corner is integrable and contributes nothing.

The arc at infinity (the Regge regime). This is the term that requires real input. Closing the $\bar{z}$-contour to the right requires the dashed arc of Fig. 51.5 at $|\bar{z}|\to\infty$ to give nothing. The double scaling $z\to 0$, $\bar{z}\to\infty$ with $z\bar{z}$ fixed is the *Regge limit* of the correlator (it is the conformal image of the high-energy, fixed-impact-parameter regime). Parametrizing the approach by a boost parameter, the question is the rate of growth of g there. Define the *Regge intercept* J_0 by the leading growth $g\sim(\text{boost})^{J_0-1}$ in the Regge limit. The arc at infinity is suppressed by the inverted block, which decays like $(\text{boost})^{-(\ell-1)}$, so the arc integrand scales as $(\text{boost})^{J_0-\ell}$ and the arc vanishes provided

$$\ell \;>\; J_0. \tag{51.99}$$

For a *unitary* CFT the correlator is Regge-bounded with intercept $J_0\le 1$: the Regge growth of a unitary four-point function cannot exceed that of a spin-one

exchange, a statement that follows from the analyticity and boundedness of the Lorentzian correlator in the Regge regime (the conformal counterpart of the Froissart–Martin bound; in the language of the chaos bound it is the statement that the Lyapunov-like growth rate is capped). We take $J_0 \leq 1$ as the established structural input and refer to the literature for its sharp form [111, 252, 333]; the result we use is Eq. (51.99) with $J_0 = 1$.

Combining the two boundary analyses: the deformation is exact and the Regge arc vanishes for $\ell > 1$. This is the content of the central claim.

Theorem 51.17 (Analyticity of OPE data in spin)**.** *For a unitary CFT_d with Regge intercept $J_0 \leq 1$, the inversion integral Eq. (51.96) converges and defines $c(\Delta, \ell)$ as an analytic function of the spin ℓ in the half-plane* $\operatorname{Re} \ell > 1$*. Its poles in Δ at $\Delta = \Delta_k(\ell)$ locate the dimensions of the exchanged operators of spin ℓ, and the residues give their squared OPE coefficients via Eq. (51.85). Consequently the OPE data $\{\Delta_k(\ell), C_k^2(\ell)\}$ are the restrictions to integer ℓ of analytic functions of spin: every CFT organizes its spectrum, for $\ell > 1$, into a finite number of analytic* Regge trajectories*.*

Proof sketch. Convergence of Eq. (51.96) for $\operatorname{Re} \ell > 1$ is the statement that the four corners of the $(z, \bar{z})$ integration region are integrable. The corners at $z, \bar{z} \to 0$ are the s-channel OPE region; there the inverted block decays and the integral is convergent for $\operatorname{Re} \Delta$ on the principal series (and the poles Eq. (51.85) arise by analytic continuation in Δ off it). The corners at $z, \bar{z} \to 1$ are controlled by $\mathrm{dDisc}[g]$, which by the double-twist zero Eq. (51.92) is softer near $\bar{z} = 1$ than g itself — the dDisc has removed precisely the contributions that would diverge. The remaining mixed corner $z \to 0$, $\bar{z} \to 1$ is the Regge region, integrable exactly when Eq. (51.99) holds, i.e. $\operatorname{Re} \ell > J_0$, and $J_0 \leq 1$ by unitarity. Thus the integral converges and is analytic in ℓ for $\operatorname{Re} \ell > 1$. Carlson's theorem now upgrades "analytic and bounded" to "unique": the Regge bound supplies exactly the exponential-type control that the Euclidean formula Eq. (51.86) lacked, so $c(\Delta, \ell)$ is the *unique* analytic-in-ℓ interpolation of the integer-spin OPE data, and any two correlators agreeing at integer spin and Regge-bounded agree as analytic functions of spin. The poles in Δ and their residues are identified with the OPE data exactly as in the Euclidean inversion, since the two formulas compute the same $c(\Delta, \ell)$ on the principal series and a function analytic in a region is determined by its values there. Finally, that the analytic structure is a finite union of trajectories follows because, at fixed $\operatorname{Re} \ell > 1$, $\mathrm{dDisc}[g]$ has a convergent t-channel expansion and each t-channel block contributes a meromorphic-in-Δ piece with poles organized along trajectories. □

The bound $\ell > 1$ is sharp and physically meaningful: it is the reason the formula always controls the stress tensor ($\ell = 2$) and all higher-spin currents, while spin-zero and spin-one data may require additional input beyond the naive inversion (low-spin operators can sit on the boundary of convergence, and isolated

scalars are not always captured by the trajectory continued down from large spin). This is not a defect to be hidden: it is the honest statement of where the analytic-in-spin organization holds. As a synthesis of the mid-2010s the inversion formula is on firm footing for $\ell > 1$ in any unitary CFT; the behaviour at and below $\ell = 1$, the precise non-perturbative meaning of the Regge intercept in a general theory, and the convergence of the trajectory-by-trajectory reconstruction remain subjects of active refinement, flagged again where the next section pushes the formula to its limits.

With Theorems 51.16 and 51.17 in hand we possess exactly the all-orders generator the hand-built large-spin expansion was missing: a single analytic function $c(\Delta, \ell)$, computed from the cross-channel double discontinuity, whose poles and residues are the spectrum and the OPE coefficients as analytic functions of spin. The next section turns this from a structural theorem into a machine — feeding the dDisc of a known cross-channel contribution into Eq. (51.96), reading the resulting poles, and recovering not only the leading large-spin result $\gamma_{0,\ell} \sim -c_{\tau_m}/\ell^{\tau_m}$ of the previous section but its all-orders completion and the data at finite spin.

51.5 Reading the Spectrum from the Inversion Formula

The previous section stated the Lorentzian inversion formula of Theorem 51.16 and introduced its only nontrivial input, the double discontinuity. That was an existence statement: it promoted the operator product data from a discrete list, defined only at integer spins, to an analytic function of spin, and it identified the object the function is computed from. It remains to make the formula *work* — to feed it a correlator and read a spectrum out the other end. That is the business of this section. We use the inversion formula as a calculational engine and extract, with no computer and in closed form, the large-spin data that the lightcone bootstrap of Sections 51.1 to 51.3 obtained by matching singularities. The two methods must agree, and seeing them agree — the same anomalous dimension $\gamma_{0,\ell} \sim -c_0/\ell^{\tau_m}$ emerging once from a singularity match and once from a contour integral of a double discontinuity — is the strongest internal check the analytic bootstrap affords. Along the way we make precise the feature that makes the whole construction self-consistent: the double-twist operators that populate the answer are exactly the operators whose own double discontinuity vanishes, so they are reconstructed *entirely* from the crossed channel rather than from themselves. We then push the engine to subleading orders and to mixed double-twist families $[\mathcal{O}_1\mathcal{O}_2]_{n,\ell}$, advance ϕ^4 theory by computing the Wilson–Fisher leading-twist anomalous dimension in the ε-expansion and checking it against the data of Section 47.8.4, and close by delimiting honestly where the formula stops controlling the physics — the Regge limit, the boundary of analyticity in

spin.

51.5.1 The inversion formula as a generating function for OPE data

We work throughout with the identical-scalar correlator of ϕ^4 theory, $\langle\phi\phi\phi\phi\rangle$, stripped to the cross-ratio function $\mathcal{G}(z,\bar z)$ of Eq. (47.140) with $u = z\bar z$, $v = (1-z)(1-\bar z)$; the mixed case $\langle\mathcal{O}_1\mathcal{O}_2\mathcal{O}_2\mathcal{O}_1\rangle$ of Section 51.2 is taken up in Section 51.5.6. The s-channel ($z,\bar z \to 0$) OPE organizes $\mathcal{G}$ into a sum of conformal blocks (Theorem 47.49),

$$\mathcal{G}(z,\bar z) = \sum_{\mathcal{O}} c_{\Delta,\ell}\, G_{\Delta,\ell}(z,\bar z), \tag{51.100}$$

with $c_{\Delta,\ell} = f^2_{\phi\phi\mathcal{O}} \geq 0$ the squared OPE coefficients. The discrete label (Δ,ℓ) runs over the primaries of the theory. The inversion formula of Theorem 51.16 replaces this discrete sum by a single meromorphic function of two continuous variables. We write the generating function as $c(\Delta, J)$, an analytic function of the dimension Δ at each spin J, whose poles in Δ sit at the physical dimensions and whose residues are the squared OPE coefficients:

$$c(\Delta,J) \;\sim\; -\frac{c_{\Delta_k(J),J}}{\Delta - \Delta_k(J)} \qquad \text{near each physical pole } \Delta = \Delta_k(J). \tag{51.101}$$

The content of Theorem 51.16 is that $c(\Delta,J)$ is reconstructed from the double discontinuity of $\mathcal{G}$ by a positive double integral over the Lorentzian "causal diamond" $0 \leq z,\bar z \leq 1$, with a kernel built from the same conformal blocks. The discreteness of the spectrum — the fact that operators occur at isolated dimensions — is, in this language, the statement that the integral produces *poles* in Δ; the analyticity in spin is the statement that $c(\Delta,J)$ is a single analytic function of J, so that the data of operators at different spins lie on smooth *Regge trajectories* $\Delta_k(J)$ rather than being independent.

For the large-spin physics we need only the leading-twist projection of this machinery, and there it collapses to a one-variable transform that we can evaluate completely. The mechanism is the one already used in Section 51.2: in the lightcone limit $z \to 0$, a block of twist τ contributes $z^{\tau/2}$ times the collinear ($SL(2,\mathbb{R})$) block $k_\beta(\bar z)$ of Eq. (49.132),

$$k_\beta(\bar z) = \bar z^{\,\beta/2}\, {}_2F_1\!\left(\tfrac{\beta}{2},\tfrac{\beta}{2};\beta;\bar z\right), \qquad \beta = 2\bar h, \quad \bar h \equiv \frac{\Delta+\ell}{2}, \tag{51.102}$$

where the natural variable is the *conformal spin* $\bar h$ (we reserve ℓ for the ordinary spin; the two agree to leading order at large spin, $\bar h = \Delta_\phi + \ell + O(\gamma)$, on the leading-twist trajectory). Projected onto the leading power z^{Δ_ϕ}, the inversion

formula reduces to the one-dimensional $SL(2)$ inversion: the leading-twist OPE data are encoded in a function $C(\bar{h})$ given by

$$C(\bar{h}) = \kappa_{2\bar{h}} \int_0^1 \frac{d\bar{z}}{\bar{z}^2}\, k_{2\bar{h}}(\bar{z})\, \mathrm{dDisc}[\mathcal{G}_0(\bar{z})], \qquad \kappa_{2\bar{h}} = \frac{\Gamma(\bar{h})^4}{2\pi^2\,\Gamma(2\bar{h})\,\Gamma(2\bar{h}-1)}, \tag{51.103}$$

where $\mathcal{G}_0(\bar{z})$ is the coefficient of z^{Δ_ϕ} in $\mathcal{G}(z,\bar{z})$ as $z \to 0$, and the poles of $C(\bar{h})$ in $\bar{h}$ locate the leading-twist operators with residues equal to (minus) their squared OPE coefficients, exactly as in Eq. (51.101). The constant $\kappa_{2\bar{h}}$ is the same one that makes the formula invert the collinear blocks against themselves; we will fix all normalizations below by demanding that Eq. (51.103) reproduce the mean-field data of Theorem 51.7, so no convention need be memorized.

51.5.2 Why double-twist operators are reconstructed from the crossed channel

Everything turns on the double discontinuity, so we record its one essential property. The double discontinuity is the obstruction to continuing $\mathcal{G}$ smoothly through the crossed-channel lightcone $\bar{z} = 1$; for identical external scalars (Theorem 51.13) it is

$$\mathrm{dDisc}\big[\mathcal{G}(\bar{z})\big] = \mathcal{G}(\bar{z}) - \tfrac{1}{2}\,\mathcal{G}^{\circlearrowleft}(\bar{z}) - \tfrac{1}{2}\,\mathcal{G}^{\circlearrowright}(\bar{z}), \tag{51.104}$$

where $\mathcal{G}^{\circlearrowleft,\circlearrowright}$ denote the analytic continuations of $\mathcal{G}$ obtained by taking $\bar{z}$ once around the branch point at $\bar{z} = 1$ in either direction. Its action on a pure power is the only evaluation we need, and it is immediate from Eq. (51.104).

Lemma 51.18 (Double discontinuity of a power)**.** *For any real exponent a,*

$$\mathrm{dDisc}\big[(1-\bar{z})^a\big] = 2\sin^2(\pi a)\,(1-\bar{z})^a. \tag{51.105}$$

In particular the double discontinuity annihilates *every power with $a \in \mathbb{Z}_{\geq 0}$, and more generally every function analytic at $\bar{z} = 1$.*

Proof. Continuing $\bar{z}$ once around $\bar{z} = 1$ sends $1-\bar{z} \to e^{\pm 2\pi i}(1-\bar{z})$, hence $(1-\bar{z})^a \to e^{\pm 2\pi i a}(1-\bar{z})^a$. Substituting into Eq. (51.104),

$$\mathrm{dDisc}\big[(1-\bar{z})^a\big] = \Big(1-\tfrac{1}{2}e^{2\pi i a}-\tfrac{1}{2}e^{-2\pi i a}\Big)(1-\bar{z})^a = (1-\cos 2\pi a)(1-\bar{z})^a = 2\sin^2(\pi a)\,(1-\bar{z})^a. \tag{51.106}$$

When a is a non-negative integer the prefactor $\sin^2(\pi a)$ vanishes; a function analytic at $\bar{z} = 1$ is a convergent sum of such powers, so its double discontinuity vanishes term by term. □

This elementary fact carries the entire self-consistency of the analytic bootstrap. Consider what populates the right-hand side of the inversion integral Eq. (51.103). By crossing (Eq. (49.14)),

$$\mathcal{G}(z,\bar{z}) = \Big(\frac{z\bar{z}}{(1-z)(1-\bar{z})}\Big)^{\Delta_\phi}\,\mathcal{G}(1-z,1-\bar{z}), \tag{51.107}$$

so the behaviour of $\mathcal{G}$ near $\bar{z}=1$ — the only region the double discontinuity probes — is governed by the *crossed-channel* (t-channel) OPE, the expansion of $\mathcal{G}(1-z,1-\bar{z})$ in t-channel blocks. A t-channel operator of twist τ' contributes, through the crossing kernel Eq. (51.107), a term behaving as $(1-\bar{z})^{\tau'/2-\Delta_\phi}$ as $\bar{z}\to 1$. By Theorem 51.18 its double discontinuity is proportional to $\sin^2\!\big(\pi(\Delta_\phi-\tau'/2)\big)$.

Now ask which operators have *vanishing* double discontinuity. The double-twist operators $[\phi\phi]_{n,\ell}$ of Theorem 51.5 sit, in the generalized free field, at twists $\tau'=2\Delta_\phi+2n$ with $n\in\mathbb{Z}_{\geq 0}$, so $\Delta_\phi-\tau'/2=-n\in\mathbb{Z}_{\leq 0}$, and $\sin^2(\pi n)=0$. *The double-twist operators have vanishing double discontinuity.* This is the precise sense in which they are invisible to the inversion integral as inputs: they contribute to $\mathrm{dDisc}[\mathcal{G}]$ only through their anomalous dimensions, which displace them off the integer lattice by $O(\gamma)$ and so give a doubly-suppressed $\sin^2(\pi(n-\gamma/2))=\sin^2(\pi\gamma/2)\approx(\pi\gamma/2)^2$. The operators that the inversion formula *produces* on its left-hand side — the s-channel double-twist data, the residues of $C(\bar{h})$ — are therefore reconstructed not from themselves but entirely from the operators that do have a double discontinuity: the genuinely interacting, non-double-twist operators exchanged in the crossed channel, beginning with the identity. This is the inversion formula's internal consistency made manifest. The output spectrum is the double-twist tower; the input is everything that is *not* a double-twist operator. A free or mean-field theory, whose only operators above the identity *are* double-twist (Section 51.2), has no double discontinuity beyond the identity's, and the inversion integral then returns exactly the mean-field data and nothing more — which is why mean-field theory is the universal large-spin limit Eq. (51.49) rather than a special case.

Physical Insight

The double discontinuity is a filter tuned precisely to suppress the double-twist tower. Physically, dDisc measures the genuine absorptive part of the correlator in the crossed channel — the part associated with real particle production rather than with the kinematic singularities of two free constituents flying apart. Double-twist operators are those free constituents; they carry no absorption, hence no double discontinuity. What is left is the interaction: the exchange of an actual operator between the two halves of the correlator. The inversion formula thus reads the bound-state spectrum (the double-twist data on the left) directly off the forces between the constituents (the exchanged operators on the right). In a holographic

theory this is the statement that the binding energies of two-particle states in anti–de Sitter space are computed by the bulk exchange diagrams of the fields dual to the crossed-channel operators, gravity included.

51.5.3 Inverting a single cross-channel block

We now carry out the central computation: feed the inversion engine the identity plus a single crossed-channel operator $\mathcal{O}_m$, and read off the leading-twist anomalous dimensions and OPE coefficients in closed form. We do this by the lightcone projection of Eq. (51.103), evaluating every integral explicitly. The result reproduces, from a single transform, the $1/\ell^{\tau_m}$ law derived by singularity matching in Section 51.3.

The two contributions and the $\log z$ that carries the anomalous dimension. On the s-channel side, the leading-twist family $[\phi\phi]_{0,\ell}$ has dimensions $\Delta = 2\Delta_\phi + \ell + \gamma_{0,\ell}$, so its contribution to $\mathcal{G}$ carries the power $z^{\Delta_\phi+\gamma_{0,\ell}/2} = z^{\Delta_\phi}(1+\frac{1}{2}\gamma_{0,\ell}\log z + \cdots)$. Collecting the coefficient of z^{Δ_ϕ} separates cleanly into a piece with no $\log z$ and a piece linear in $\log z$:

$$\mathcal{G}(z,\bar z)\Big|_{z^{\Delta_\phi}} = \underbrace{\sum_\ell c_{0,\ell}\, k_{2\bar h_\ell}(\bar z)}_{\text{no } \log z} \;+\; \log z \;\underbrace{\tfrac{1}{2}\sum_\ell c^{(0)}_{0,\ell}\,\gamma_{0,\ell}\, k_{2\bar h_\ell}(\bar z)}_{\text{the } \log z \text{ piece}} \;+\cdots, \tag{51.108}$$

where $c^{(0)}_{0,\ell}$ are the mean-field coefficients Eq. (51.38) and $c_{0,\ell} = c^{(0)}_{0,\ell} + \delta c_{0,\ell}$ the corrected ones. The presence of a $\log z$ is the smoking gun of an anomalous dimension, and it is the part the crossed channel must supply.

On the t-channel side, set $z \to 0$ in Eq. (51.107). The crossing kernel gives $z^{\Delta_\phi}(\bar z/(1-\bar z))^{\Delta_\phi}$ at leading order in z, while $\mathcal{G}(1-z,1-\bar z)$ must be evaluated with its first argument $1-z\to 1$ and its second $1-\bar z\to 0$ (since $\bar z\to 1$). The second-argument limit is the t-channel collinear limit, in which a t-channel operator of twist τ_m, spin ℓ_m, and squared OPE coefficient $P_m \equiv f^2_{\phi\phi\mathcal{O}_m}$ contributes $(1-\bar z)^{\tau_m/2}\,k_{\beta_m}(1-z)$ with $\beta_m = \tau_m + 2\ell_m$. The first-argument limit $1-z\to 1$, i.e. $z\to 0$, is exactly the point at which the collinear block k_{β_m} develops its logarithmic singularity. From the hypergeometric connection formula ${}_2F_1(a,b;a+b;w) \to -\frac{\Gamma(a+b)}{\Gamma(a)\Gamma(b)}\big[\log(1-w)+\psi(a)+\psi(b)+2\gamma_E\big]$ as $w\to 1$, applied to Eq. (51.102) with $a=b=\beta_m/2$ and $w=1-z$,

$$k_{\beta_m}(1-z) \;\xrightarrow{z\to 0}\; -\frac{\Gamma(\beta_m)}{\Gamma(\beta_m/2)^2}\Big[\log z + 2\psi\big(\tfrac{\beta_m}{2}\big) + 2\gamma_E\Big]. \tag{51.109}$$

This is where the t-channel produces a $\log z$. Assembling the coefficient of z^{Δ_ϕ}

from the crossed channel,

$$\mathcal{G}(z,\bar z)\Big|_{z^{\Delta_\phi}}^{t\text{-channel }\mathcal{O}_m} = -P_m \frac{\Gamma(\beta_m)}{\Gamma(\beta_m/2)^2}\,\bar z^{\Delta_\phi}(1-\bar z)^{\tau_m/2-\Delta_\phi}\Big[\log z + 2\psi(\tfrac{\beta_m}{2}) + 2\gamma_E\Big]. \tag{51.110}$$

Matching the $\log z$ coefficients of Eq. (51.108) and Eq. (51.110) gives the master equation for the anomalous dimensions,

$$\tfrac{1}{2}\sum_\ell c_{0,\ell}^{(0)}\,\gamma_{0,\ell}\,k_{2\bar h_\ell}(\bar z) = -P_m\,\frac{\Gamma(\beta_m)}{\Gamma(\beta_m/2)^2}\,\bar z^{\Delta_\phi}(1-\bar z)^{\tau_m/2-\Delta_\phi}. \tag{51.111}$$

The left side is a sum over the (discrete, even) leading-twist spins; the right side is a fixed power, more singular at $\bar z\to 1$ the smaller τ_m is. It is the same equation one would obtain by writing the right-hand side as dDisc divided by the kinematic factors and inverting; the $\sin^2$ factor of Eq. (51.90) is hidden inside the ratio of Gamma functions we are about to produce, as we verify at the end. We solve Eq. (51.111) by converting the discrete sum to an integral over conformal spin and using the large-$\bar h$ asymptotics of the collinear block.

The Bessel representation and the one integral. At large $\bar h$ and $\bar z\to 1$ with $\bar h^2(1-\bar z)$ held fixed, the collinear block degenerates to a Bessel function. Using the duplication formula $\Gamma(2\bar h) = \frac{4^{\bar h}}{2\sqrt{\pi}}\Gamma(\bar h)\Gamma(\bar h+\frac12)$ and $\Gamma(\bar h+\frac12)/\Gamma(\bar h)\sim \bar h^{1/2}$,

$$k_{2\bar h}(\bar z) \;\approx\; \frac{\Gamma(2\bar h)}{\Gamma(\bar h)^2}\,2K_0\big(2\bar h\sqrt{1-\bar z}\big) \;\approx\; \frac{4^{\bar h}}{\sqrt{\pi}}\,\bar h^{1/2}\,K_0\big(2\bar h\sqrt{1-\bar z}\big), \tag{51.112}$$

with K_0 the modified Bessel function. The single integral we need is the Mellin transform of K_0,

$$\int_0^\infty d\bar h\;\bar h^{\,2\alpha-1}\,K_0(2\bar h\,s) = \tfrac14\,\Gamma(\alpha)^2\,s^{-2\alpha}, \tag{51.113}$$

valid for $\mathrm{Re}\,\alpha>0$, obtained from $\int_0^\infty x^{\mu-1}K_0(x)\,dx = 2^{\mu-2}\Gamma(\mu/2)^2$ with $x=2\bar h s$ and $\mu=2\alpha$. Everything reduces to Eq. (51.113).

Begin by fixing the measure on the identity. The mean-field coefficients Eq. (51.48) grow as $c_{0,\ell}^{(0)}\sim A\,\bar h^{\,2\Delta_\phi-3/2}\,4^{-\bar h}$ at large $\bar h$, with A a constant we now pin down by self-consistency. Replacing the even-spin sum by a continuous integral over $\bar h$ with this density and inserting Eq. (51.112), the mean-field side of Eq. (51.108) (the "no $\log z$" piece at zeroth order, which must reproduce the t-channel identity) becomes

$$\sum_\ell c_{0,\ell}^{(0)}\,k_{2\bar h_\ell}(\bar z) \;\to\; \int_0^\infty d\bar h\;A\,\bar h^{\,2\Delta_\phi-3/2}4^{-\bar h}.\frac{4^{\bar h}}{\sqrt{\pi}}\bar h^{1/2}K_0\big(2\bar h\sqrt{1-\bar z}\big) = \frac{A}{\sqrt{\pi}}\int_0^\infty d\bar h\,\bar h^{\,2\Delta_\phi-1}K_0(2\bar h \tag{51.114}$$

The exponential factors $4^{-\bar{h}}$ and $4^{\bar{h}}$ cancel: this is the precise statement that the $4^{-\bar{h}}$ in the mean-field coefficients is not physical decay but the inverse of the block's growth, as anticipated below Eq. (51.48). Applying Eq. (51.113) with $2\alpha - 1 = 2\Delta_\phi - 1$, i.e. $\alpha = \Delta_\phi$, and $s = \sqrt{1-\bar{z}}$,

$$\sum_\ell c^{(0)}_{0,\ell}\, k_{2\bar{h}_\ell}(\bar{z}) \;\to\; \frac{A}{\sqrt{\pi}} \cdot \frac{1}{4}\,\Gamma(\Delta_\phi)^2\,(1-\bar{z})^{-\Delta_\phi}. \tag{51.115}$$

The t-channel identity contributes $\big(\bar{z}/(1-\bar{z})\big)^{\Delta_\phi} \to (1-\bar{z})^{-\Delta_\phi}$ as $\bar{z}\to 1$. Equating fixes

$$\frac{A\,\Gamma(\Delta_\phi)^2}{4\sqrt{\pi}} = 1 \qquad\Longrightarrow\qquad A = \frac{4\sqrt{\pi}}{\Gamma(\Delta_\phi)^2}. \tag{51.116}$$

This both reproduces the mean-field data (the residues of the resulting $C(\bar{h})$ are the coefficients Eq. (51.38)) and calibrates the continuous-spin measure so that no overall constant is left undetermined.

The anomalous dimension. Now solve Eq. (51.111). Posit a power law $\gamma_{0,\ell} = -c_0/\bar{h}^{\tau_m}$ and convert its left side to an integral exactly as above:

$$\begin{aligned}
\tfrac{1}{2}\sum_\ell c^{(0)}_{0,\ell}\gamma_{0,\ell}\,k_{2\bar{h}_\ell}(\bar{z}) \to\; & \tfrac{1}{2}\int_0^\infty d\bar{h}\,A\,\bar{h}^{\,2\Delta_\phi-3/2}4^{-\bar{h}}\Big(-\frac{c_0}{\bar{h}^{\tau_m}}\Big)\frac{4^{\bar{h}}}{\sqrt{\pi}}\bar{h}^{1/2}K_0(2\bar{h}\sqrt{1-\bar{z}}) \\
=\; & -\frac{A\,c_0}{2\sqrt{\pi}}\int_0^\infty d\bar{h}\,\bar{h}^{\,2\Delta_\phi-\tau_m-1}K_0(2\bar{h}\sqrt{1-\bar{z}}) \\
=\; & -\frac{A\,c_0}{2\sqrt{\pi}}\cdot\tfrac{1}{4}\,\Gamma\Big(\Delta_\phi-\tfrac{\tau_m}{2}\Big)^2(1-\bar{z})^{\tau_m/2-\Delta_\phi},
\end{aligned} \tag{51.117}$$

using Eq. (51.113) with $\alpha = \Delta_\phi - \tau_m/2$. The $\bar{z}$-dependence $(1-\bar{z})^{\tau_m/2-\Delta_\phi}$ matches the right side of Eq. (51.111) identically — which is what justifies the power-law ansatz: only $\gamma_{0,\ell}\propto \bar{h}^{-\tau_m}$ produces the correct crossed power. Equating the coefficients,

$$\frac{A\,c_0}{8\sqrt{\pi}}\,\Gamma\Big(\Delta_\phi-\tfrac{\tau_m}{2}\Big)^2 = P_m\,\frac{\Gamma(\beta_m)}{\Gamma(\beta_m/2)^2}, \tag{51.118}$$

and substituting A from Eq. (51.116), so that $8\sqrt{\pi}/A = 2\Gamma(\Delta_\phi)^2$, gives the closed form

$$\boxed{\gamma_{0,\ell} = -\frac{c_0}{\bar{h}^{\,\tau_m}}, \qquad c_0 = \frac{2\,\Gamma(\Delta_\phi)^2\,\Gamma(\tau_m+2\ell_m)}{\Gamma\big(\Delta_\phi-\frac{\tau_m}{2}\big)^2\,\Gamma\big(\frac{\tau_m}{2}+\ell_m\big)^2}\,P_m\,.} \tag{51.119}$$

This is exactly the master formula Eq. (51.73) obtained in Section 51.3 by matching lightcone singularities, now produced in a single pass by inverting one crossed-channel block. Three features deserve emphasis. First, the anomalous dimension is *negative* for the identity-adjacent operators (the binding is attractive)

whenever $P_m > 0$ and $\Gamma(\Delta_\phi - \tau_m/2)^2 > 0$, as it is for the leading non-double-twist exchange. Second, it falls as $1/\bar{h}^{\tau_m}$, set by the *minimal* twist exchanged: the lightest crossed operator dominates the large-spin tail, exactly the "binding energy of two far-separated constituents" picture of Section 51.2. Third, the factor $1/\Gamma(\Delta_\phi - \tau_m/2)^2$ is the promised reappearance of the double discontinuity: by the reflection formula $1/\Gamma(x)^2 = \sin^2(\pi x)\,\Gamma(1-x)^2/\pi^2$, the coefficient c_0 carries precisely the factor $\sin^2(\pi(\Delta_\phi - \tau_m/2))$ that Theorem 51.18 assigns to the crossed power $(1-\bar{z})^{\tau_m/2-\Delta_\phi}$. A double-twist operator in the crossed channel, with $\Delta_\phi - \tau_m/2 \in \mathbb{Z}_{\leq 0}$, gives $1/\Gamma$ of a non-positive integer $= 0$ and contributes nothing — the self-consistency of Section 51.5.2, now visible inside the formula.

51.5.4 The correction to the OPE coefficient

The same single block fixes the correction $\delta c_{0,\ell}$ to the mean-field OPE coefficients, with no further integral, by the analytic structure of the generating function. The argument is purely a statement about how a pole moves. On the leading-twist trajectory the generating function Eq. (51.101) has, near each mean-field location $\bar{h}_0 = \Delta_\phi + \ell$, a simple pole whose position and residue are the physical (corrected) data:

$$C(\bar{h}) \;\sim\; \frac{-\,c_{0,\ell}}{\bar{h}-\bar{h}_*}, \qquad \bar{h}_* = \bar{h}_0 + \tfrac{1}{2}\gamma_{0,\ell}, \quad c_{0,\ell} = c^{(0)}_{0,\ell} + \delta c_{0,\ell}. \tag{51.120}$$

Treating $\gamma_{0,\ell}$ and $\delta c_{0,\ell}$ as first-order corrections and expanding the displaced pole about the mean-field location,

$$\frac{-\,(c^{(0)}_{0,\ell} + \delta c_{0,\ell})}{\bar{h}-\bar{h}_0-\frac{1}{2}\gamma_{0,\ell}} = \frac{-\,c^{(0)}_{0,\ell}}{\bar{h}-\bar{h}_0} \underbrace{-\,\frac{\delta c_{0,\ell}}{\bar{h}-\bar{h}_0}}_{\text{first-order simple pole}} \underbrace{-\,\frac{\frac{1}{2}c^{(0)}_{0,\ell}\gamma_{0,\ell}}{(\bar{h}-\bar{h}_0)^2}}_{\text{first-order double pole}} + O(\text{second order}). \tag{51.121}$$

The first-order correction to $C(\bar{h})$ produced by inverting the single t-channel block is therefore a function $C^{(1)}(\bar{h})$ with both a double pole and a simple pole at each $\bar{h}_0$. But these are not independent: $C^{(1)}$ is one analytic function, and a double pole with an analytic numerator $b(\bar{h})$ generates the accompanying simple pole automatically through its Laurent expansion,

$$\frac{b(\bar{h})}{(\bar{h}-\bar{h}_0)^2} = \frac{b(\bar{h}_0)}{(\bar{h}-\bar{h}_0)^2} + \frac{b'(\bar{h}_0)}{\bar{h}-\bar{h}_0} + \cdots. \tag{51.122}$$

Identifying $b(\bar{h}) = -\frac{1}{2}c^{(0)}_0(\bar{h})\,\gamma_0(\bar{h})$ as the smooth conformal-spin continuation of the double-pole coefficient in Eq. (51.121), and matching the simple poles, gives the OPE-coefficient correction with no new computation:

$$\boxed{\delta c_{0,\ell} = \frac{1}{2}\,\frac{d}{d\bar{h}}\Big[c^{(0)}_{0,\ell}(\bar{h})\,\gamma_{0,\ell}(\bar{h})\Big]\Big|_{\bar{h}=\Delta_\phi+\ell}}. \tag{51.123}$$

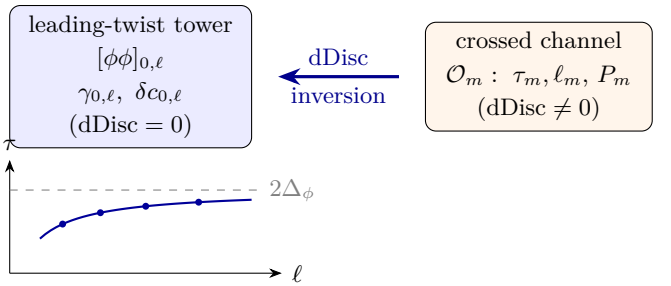

Figure 51.6: The inversion formula as a one-way map. The double discontinuity vanishes on the double-twist tower $[\phi\phi]_{0,\ell}$ (left), so these operators cannot seed the integral; they are reconstructed entirely from the crossed-channel operators $\mathcal{O}_m$ that do carry a double discontinuity (right). Inverting the single lightest such block produces the anomalous dimension Eq. (51.119) and, by the pole-shift relation Eq. (51.123), the OPE-coefficient correction Eq. (51.123), organizing the leading-twist trajectory $\tau_{0,\ell} \to 2\Delta_\phi$ (inset) from above in twist, i.e. from below in γ.

This is the reciprocity relation between the two leading-twist corrections: an anomalous dimension that lowers a trajectory necessarily redistributes spectral weight, and the redistribution is the $\bar{h}$-derivative of the weighted shift. Inserting the mean-field density $c^{(0)}_{0,\ell} \sim A\,\bar{h}^{2\Delta_\phi - 3/2} 4^{-\bar{h}}$ and $\gamma_{0,\ell} = -c_0 \bar{h}^{-\tau_m}$, the derivative is dominated at large $\bar{h}$ by the measure factor $4^{-\bar{h}}$, giving the relative correction

$$\frac{\delta c_{0,\ell}}{c^{(0)}_{0,\ell}} = \frac{1}{2}\Big[\gamma_{0,\ell}\,\partial_{\bar{h}} \log c^{(0)}_{0,\ell} + \partial_{\bar{h}}\gamma_{0,\ell}\Big] \xrightarrow{\bar{h}\to\infty} -\tfrac{1}{2}\,\gamma_{0,\ell}\,\log 4 = \frac{c_0 \log 4}{2\,\bar{h}^{\tau_m}}, \quad (51.124)$$

of the same order $1/\bar{h}^{\tau_m}$ as the anomalous dimension. The $\log 4$ is normalization-dependent — it tracks the convention-fixed $4^{-\bar{h}}$ in the collinear-block measure — and we flag it as such; the scheme-independent statement is that $\delta c_{0,\ell}/c^{(0)}_{0,\ell}$ and $\gamma_{0,\ell}$ vanish at the same rate, locked together by Eq. (51.123). With Eq. (51.119) and Eq. (51.123) the leading-twist data are fully reconstructed from a single crossed block.

Worked Example 51.19 (The stress-tensor result reproduced in one pass)**.** We reproduce, by a single application of Eq. (51.119), the stress-tensor contribution to the leading-twist anomalous dimension obtained by the lightcone method in Section 51.3, namely Eq. (51.79). Every CFT contains the stress tensor $T_{\mu\nu}$, a conserved spin-$\ell_m = 2$ operator of twist $\tau_m = d - 2$ (its dimension $\Delta = d$ saturates the conserved-current value, by Theorem 47.18). It is exchanged in $\phi \times \phi$ with an OPE coefficient fixed by the conformal Ward identity — the statement that $T_{\mu\nu}$ generates translations, so its coupling to any primary is set by that primary's dimension. In the unit-normalized block conventions of this

part, the Ward identity gives

$$P_T \equiv f^2_{\phi\phi T} = \frac{d\,\Delta_\phi^2}{(d-1)^2\,C_T}, \tag{51.125}$$

where C_T is the central charge, the coefficient of the stress-tensor two-point function (the canonical measure of the number of degrees of freedom; for a single free scalar $C_T = d/(d-1)$ in this normalization). Substituting $\tau_m = d-2$, $\ell_m = 2$, hence $\beta_m = \tau_m + 2\ell_m = d+2$, into Eq. (51.119),

$$\gamma^{(T)}_{0,\ell} = -\frac{c_T}{\bar{h}^{\,d-2}}, \qquad c_T = \frac{2\,\Gamma(\Delta_\phi)^2\,\Gamma(d+2)}{\Gamma\!\left(\Delta_\phi - \frac{d-2}{2}\right)^2\Gamma\!\left(\frac{d+2}{2}\right)^2}\,\frac{d\,\Delta_\phi^2}{(d-1)^2\,C_T}. \tag{51.126}$$

This is Eq. (51.79) term for term. The physics is transparent in this packaging. The anomalous dimension is negative: two scalars at large relative spin attract, and the binding energy is the (negative) shift of their total dimension below the free value. It falls as $1/\bar{h}^{\,d-2}$, the falloff of a force mediated by a minimal-twist exchange of twist $d-2$ — in $d=4$, as $1/\bar{h}^2$, the inverse-square law. And it is inversely proportional to the central charge, $\gamma^{(T)}_{0,\ell} \propto -\Delta_\phi^2/(C_T\bar{h}^{d-2})$. In a holographic theory $C_T \sim 1/G_N$ is the inverse Newton constant, so this is literally the statement that the two constituents bind gravitationally with a strength set by G_N; the analytic bootstrap derives Newtonian binding in anti–de Sitter space from crossing alone, the seed of bulk locality taken up in Chapters 53 and 56. The stress tensor is universal: every local CFT has one, so *every* CFT has this gravitational tail in its large-spin spectrum, whether or not it is holographic.

51.5.5 Scalar ϕ^4 theory: the Wilson–Fisher leading-twist anomalous dimension

We now advance ϕ^4 theory by turning the engine on the Wilson–Fisher fixed point in $d = 4-\varepsilon$ and computing the leading-twist anomalous dimension of $[\phi\phi]_{0,\ell}$ to order ε^2, cross-checking against the data imported in Section 47.8.4. The computation also makes a subtle and important point: which crossed operator dominates is decided by the double discontinuity, *not* by the raw twist.

Worked Example 51.20 ($[\phi\phi]_{0,\ell}$ at the Wilson–Fisher point, and which operator wins)**.** The conformal data of the fixed point were assembled in Theorem 47.55: the scalar ϕ has dimension $\Delta_\phi = \frac{d-2}{2} + \gamma_\phi = 1 - \frac{\varepsilon}{2} + \gamma_\phi$ with $\gamma_\phi = \varepsilon^2/108$ (Eq. (47.263)), and the energy operator ϕ^2 has dimension $\Delta_{\phi^2} = 2 - \frac{2\varepsilon}{3} + O(\varepsilon^2)$ (Eq. (47.264)), a scalar of twist $\tau_{\phi^2} = \Delta_{\phi^2}$. Two operators compete to dominate the large-spin tail through Eq. (51.119): the stress tensor T, of twist $\tau_T = d-2 = 2-\varepsilon$, and the energy operator ϕ^2, of twist $\tau_{\phi^2} = 2 - \frac{2\varepsilon}{3}$. By raw twist the stress tensor is lighter, $\tau_T < \tau_{\phi^2}$, and would naively dominate. But the contribution of each is weighted by its double discontinuity, $\propto 1/\Gamma(\Delta_\phi - \tau_m/2)^2 = \sin^2\!\big(\pi(\Delta_\phi - \frac{\tau_m}{2})\big) \times (\cdots)$, and this reverses the verdict.

The stress tensor is suppressed. For T, $\Delta_\phi - \frac{\tau_T}{2} = (1-\frac{\varepsilon}{2}+\gamma_\phi) - \frac{2-\varepsilon}{2} = \gamma_\phi = \frac{\varepsilon^2}{108}$. The stress tensor sits a distance $\gamma_\phi = O(\varepsilon^2)$ from the double-twist lattice point $n = 0$ (in the free theory it *is* the double-twist operator $[\phi\phi]_{0,2}$; the interaction lifts $2\Delta_\phi$ above its protected $\tau = d-2$ by $2\gamma_\phi$). Its weight is therefore $\sin^2(\pi\gamma_\phi) \approx (\pi\gamma_\phi)^2 = O(\varepsilon^4)$. The universal gravitational tail Eq. (51.126) is real but enters only at order ε^4 here.

The energy operator dominates. For ϕ^2, $\Delta_\phi - \frac{\tau_{\phi^2}}{2} = (1-\frac{\varepsilon}{2}) - (1-\frac{\varepsilon}{3}) + O(\varepsilon^2) = -\frac{\varepsilon}{6} + O(\varepsilon^2)$, a distance $O(\varepsilon)$ from the lattice, with weight $\sin^2(\pi\varepsilon/6) \approx (\pi\varepsilon/6)^2 = O(\varepsilon^2)$. The energy operator wins, and the leading-twist anomalous dimension is $O(\varepsilon^2)$. Evaluate Eq. (51.119) with $\mathcal{O}_m = \phi^2$, a scalar so $\ell_m = 0$, $\beta_m = \tau_{\phi^2}$, and squared OPE coefficient $P_{\phi^2} = f^2_{\phi\phi\phi^2}$. At leading order $\phi^2 = [\phi\phi]_{0,0}$ is the mean-field scalar double-twist, so $P_{\phi^2} = c^{(0)}_{0,0}\big|_{\Delta_1=\Delta_2} = 2$ by Theorem 51.7 (the factor 2 is the even-spin doubling of identical scalars). Take the $\varepsilon \to 0$ limit of each Gamma factor: $\Gamma(\Delta_\phi)^2 \to \Gamma(1)^2 = 1$, $\Gamma(\beta_m) = \Gamma(\tau_{\phi^2}) \to \Gamma(2) = 1$, $\Gamma(\beta_m/2)^2 = \Gamma(\tau_{\phi^2}/2)^2 \to \Gamma(1)^2 = 1$, while

$$\Gamma\Big(\Delta_\phi - \tfrac{\tau_{\phi^2}}{2}\Big)^2 = \Gamma\Big(-\tfrac{\varepsilon}{6}\Big)^2 \approx \Big(-\tfrac{6}{\varepsilon}\Big)^2 = \frac{36}{\varepsilon^2}, \tag{51.127}$$

using $\Gamma(x) \approx 1/x$ near $x = 0$. Hence

$$c_0 = \frac{2\cdot 1\cdot 1}{(36/\varepsilon^2)\cdot 1}\cdot P_{\phi^2} = \frac{2\varepsilon^2}{36}\cdot 2 = \frac{\varepsilon^2}{9}, \qquad \boxed{\gamma_{0,\ell} = -\frac{\varepsilon^2}{9\,\bar{h}^2} + O(\varepsilon^3)\,.} \tag{51.128}$$

The cross-check. This must agree with the dimensions known from Part VI. The twist-two spin-ℓ operators of the single-scalar (Ising) universality class — the weakly broken higher-spin currents $[\phi\phi]_{0,\ell}$ — have the $O(\varepsilon^2)$ anomalous dimensions, measured relative to the free conserved-current value $\ell + d - 2$,

$$\gamma^{\rm cur}_\ell = \frac{\varepsilon^2}{54}\Big(1 - \frac{6}{\ell(\ell+1)}\Big) + O(\varepsilon^3), \tag{51.129}$$

a result of the ε-expansion of the fixed point. The double-twist anomalous dimension is this minus the shift $2\gamma_\phi$ already contained in $2\Delta_\phi = d - 2 + 2\gamma_\phi$:

$$\gamma_{0,\ell} = \gamma^{\rm cur}_\ell - 2\gamma_\phi = \frac{\varepsilon^2}{54}\Big(1 - \frac{6}{\ell(\ell+1)}\Big) - \frac{\varepsilon^2}{54} = -\frac{\varepsilon^2}{54}\cdot\frac{6}{\ell(\ell+1)} = -\frac{\varepsilon^2}{9\,\ell(\ell+1)}. \tag{51.130}$$

Two checks land at once. The large-spin limit of Eq. (51.130) is $-\varepsilon^2/(9\ell^2)$, agreeing with Eq. (51.128) since $\bar{h} = \Delta_\phi + \ell \to \ell$ at leading order; the inversion of the single ϕ^2 block has reproduced the falloff and the coefficient. More striking, the agreement is not merely asymptotic. The natural variable of the inversion formula is the conformal spin $\bar{h}$, whose square is the spin Casimir $\bar{h}(\bar{h}-1)$; in the free theory $\bar{h} = 1 + \ell$, so $\bar{h}(\bar{h}-1) = \ell(\ell+1)$, and the "Casimir-improved"

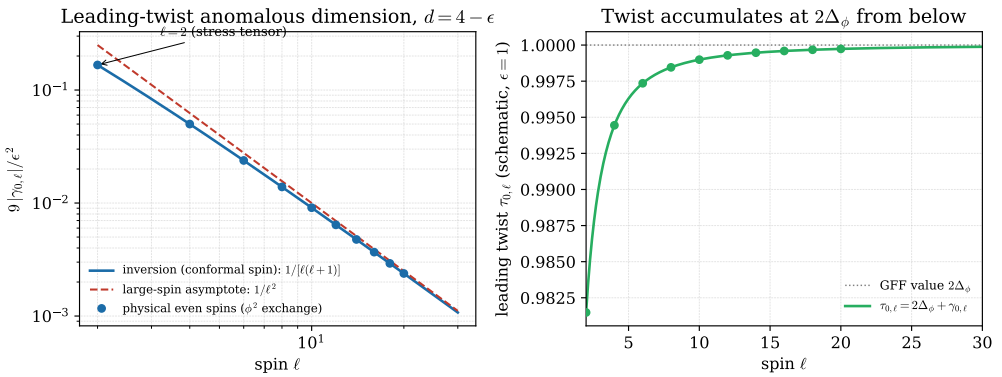

Figure 51.7: ϕ^4 theory cross-check of the inversion formula at the Wilson–Fisher fixed point in $d = 4-\varepsilon$. *Left:* the leading-twist double-twist anomalous dimension predicted by inverting the single ϕ^2 block, $\gamma_{0,\ell} = -\varepsilon^2/[9\,\bar{h}(\bar{h}-1)]$, plotted as $9|\gamma_{0,\ell}|/\varepsilon^2$ versus spin (log-log). The conformal-spin ("Casimir-improved") reading $1/[\ell(\ell+1)]$ coincides with the independent ε-expansion Eq. (51.130) at all even spins (markers); its large-spin asymptote is the $1/\ell^2$ falloff Eq. (51.128). The point $\ell = 2$ is the stress tensor, $\gamma_{0,2} = -2\gamma_\phi$. *Right:* the resulting leading twist $\tau_{0,\ell} = 2\Delta_\phi + \gamma_{0,\ell}$ approaches the generalized-free-field value $2\Delta_\phi$ from below, monotone and convex in the conformal spin — the twist accumulation of Eq. (51.49).

reading of Eq. (51.128), $\gamma_{0,\ell} = -\varepsilon^2/[9\,\bar{h}(\bar{h}-1)] = -\varepsilon^2/[9\,\ell(\ell+1)]$, coincides with the exact ε-expansion Eq. (51.130) for *every* even spin $\ell \geq 2$, not just at large ℓ. At $\ell = 2$ it gives $\gamma_{0,2} = -\varepsilon^2/54 = -2\gamma_\phi$, the correct value: the spin-two leading-twist operator is the stress tensor, whose full dimension is protected at $\Delta = d$, so its double-twist anomalous dimension is exactly $-2\gamma_\phi$. The conformal-spin organization of the large-spin expansion has captured the entire $O(\varepsilon^2)$ leading-twist spectrum of the Wilson–Fisher CFT from one crossed block. Figure 51.7 displays both the falloff and the twist trajectory.

51.5.6 Subleading orders and mixed double-twists

The computation above extracted the leading-twist ($n = 0$), leading-order data from the single lightest crossed block. The inversion formula systematizes the corrections in three independent directions, and we now indicate how each is organized; the machinery is identical to Section 51.5.3 with one ingredient changed in each case.

Higher twist $n \geq 1$. The radial families $[\phi\phi]_{n,\ell}$ are not on the leading lightcone power z^{Δ_ϕ} but on the subleading powers $z^{\Delta_\phi+n}$. They are reconstructed by the

same inversion integral Eq. (51.103) retaining the subleading terms in the small-z expansion of the kernel and of dDisc$[\mathcal{G}]$: the full generating function $c(\Delta, J)$ has poles at $\Delta = 2\Delta_\phi + 2n + \ell + \gamma_{n,\ell}$ for every n, and projecting onto the n-th pole returns $\gamma_{n,\ell}$ and the corresponding OPE coefficient. The crossed-channel block must now be expanded beyond its leading collinear term Eq. (51.109), which is where the d-dependence enters (the descent off the lightcone is governed by the Casimir equation Theorem 47.50 and no longer factorizes for general d, exactly as for the mean-field coefficients Eq. (49.144)). The structure is unchanged: each n acquires $\gamma_{n,\ell} \sim -c_n/\bar{h}^{\tau_m}$ with the same minimal twist τ_m controlling the falloff, and c_n a Δ_ϕ- and d-dependent generalization of Eq. (51.119).

Higher orders in $1/\bar{h}$. Beyond the leading $1/\bar{h}^{\tau_m}$, two sources contribute. First, the single block $\mathcal{O}_m$ has descendants, whose contributions to dDisc$[\mathcal{G}]$ are subleading powers of $(1-\bar{z})$ and produce a series $\gamma_{0,\ell} = -c_0/\bar{h}^{\tau_m}(1 + a_1/\bar{h} + a_2/\bar{h}^2 + \cdots)$; in the conformal-spin variable this series is the "Casimir-improved" expansion, organized so that $1/\bar{h}^{\tau_m}$ is promoted to $1/[\bar{h}(\bar{h}-1)]^{\tau_m/2}$ and the like, as the Wilson–Fisher example Eq. (51.130) illustrated by truncating exactly. Second, two crossed operators $\mathcal{O}_m, \mathcal{O}_{m'}$ contribute at order $1/\bar{h}^{\tau_m+\tau_{m'}}$ through the square of the dDisc reconstruction — the regime where the $1/\bar{h}$ expansion ceases to be controlled by a single exchange and the full nonlinearity of crossing re-enters. The inversion formula handles the linear (single-block) level exactly; the quadratic level requires either iterating or the full two-dimensional integral.

Mixed double-twists $[\mathcal{O}_1\mathcal{O}_2]_{n,\ell}$. For distinct external scalars $\mathcal{O}_1, \mathcal{O}_2$ the relevant correlator is $\langle \mathcal{O}_1\mathcal{O}_2\mathcal{O}_2\mathcal{O}_1\rangle$ of Eq. (51.35), whose leading-twist OPE data are the mean-field coefficients $c^{\mathrm{MFT}}_{0,\ell}$ of Eq. (51.38) with all integer spins present. The inversion proceeds exactly as in Section 51.5.3 with two changes. The crossed channel relevant to the double discontinuity is now $\mathcal{O}_1 \times \mathcal{O}_1 \to \mathcal{O}_m$ (or $\mathcal{O}_2 \times \mathcal{O}_2 \to \mathcal{O}_m$): the operator binding the pair is exchanged between the two like constituents. And the kinematic factors carry the dimension difference $\Delta_1 - \Delta_2$ through the collinear block Eq. (51.36). The leading-twist anomalous dimension of $[\mathcal{O}_1\mathcal{O}_2]_{0,\ell}$ from a single $\mathcal{O}_m$ exchanged in $\mathcal{O}_1 \times \mathcal{O}_1$ takes the form

$$\gamma_{0,\ell} = -\frac{c_0}{\bar{h}^{\,\tau_m}}, \qquad c_0 = \frac{2\,\Gamma(\Delta_1)^2\,\Gamma(\tau_m + 2\ell_m)}{\Gamma\!\left(\Delta_1 - \frac{\tau_m}{2}\right)^2 \Gamma\!\left(\frac{\tau_m}{2} + \ell_m\right)^2}\, P_m^{(11)}, \tag{51.131}$$

with $P_m^{(11)} = f_{\mathcal{O}_1\mathcal{O}_1\mathcal{O}_m} f_{\mathcal{O}_2\mathcal{O}_2\mathcal{O}_m}$ the product of OPE coefficients coupling $\mathcal{O}_m$ to each pair of like constituents — the natural generalization, since the binding is mediated by $\mathcal{O}_m$ exchanged between an $\mathcal{O}_1\mathcal{O}_1$ vertex and an $\mathcal{O}_2\mathcal{O}_2$ vertex. (The dependence on Δ_1 rather than a symmetric combination is, as in Eq. (51.35), an artifact of which constituent's lightcone is taken; the physical statement is symmetric under $\mathcal{O}_1 \leftrightarrow \mathcal{O}_2$ once both crossed channels are included.) The

derivation is the computation of Section 51.5.3 with the mean-field density Eq. (51.38) in place of its identical-scalar value; we do not repeat the integrals. The new feature is physical: a single external pair $[\mathcal{O}_1\mathcal{O}_2]$ now probes the operators exchanged in *both* $\mathcal{O}_1 \times \mathcal{O}_1$ and $\mathcal{O}_2 \times \mathcal{O}_2$, so mixed-correlator large-spin data constrain a wider slice of the spectrum — the principle behind the mixed-correlator numerical bootstrap of Section 50.6.6 and the analytic input to it.

51.5.7 The Regge limit: the boundary of analyticity

The inversion formula is powerful precisely because it makes OPE data an analytic function of spin — but analyticity in spin holds only down to a finite value, and below it the formula stops controlling the physics. Delimiting that regime honestly is essential, because it is the boundary at which the entire program of this chapter reaches its present edge.

The double integral defining $c(\Delta, J)$ converges only when the integrand decays at the corner of the causal diamond where both $z, \bar{z} \to 1$ — the *Regge limit*, the Lorentzian regime of large boost rather than large Euclidean separation. The decay is governed by the growth of $\mathcal{G}$ in the Regge limit, which defines the *Regge intercept* J_0: the correlator grows no faster than the spin-J_0 exchange would dictate. Caron-Huot's theorem establishes that the inversion integral converges, and hence that the OPE data are analytic in spin and reconstructed by the double discontinuity, for

$$J > J_0, \tag{51.132}$$

with J_0 the Regge intercept of the theory. For a generic unitary CFT one has $J_0 \leq 1$, so the formula controls all spins $J > 1$; this rests on Regge boundedness, which in turn follows from the same causality/positivity input — the bound on chaos and the analyticity of the Lorentzian correlator in the upper-half plane of the boost rapidity — that underlies the formula's derivation. The statement that double-twist data are analytic in spin down to $J > 1$ is, as of the mid-2020s, on firm footing for the leading-twist trajectory in unitary theories.

What the inversion does *not* control is the region $J \leq J_0$ itself — the Regge limit proper. There the sum over the spins of exchanged operators no longer converges term by term; it must be resummed, and the resummation is dominated by a *Regge pole*, a collective effect of the entire leading trajectory rather than any single operator. The physics of the Regge pole is the high-energy behaviour of the theory: in a gauge theory it is the reggeized gluon, in a gravitational (holographic) theory the reggeized graviton — the "pomeron." In a holographic CFT the intercept is pushed up toward the spin of the lightest exchanged Regge trajectory, and at strong coupling the leading trajectory is the graviton's, so $J_0 \to 2$: the inversion then controls only $J > 2$, and the stress tensor at $J = 2$ sits exactly on the boundary. This is the precise sense in which the analytic

bootstrap "sees" gravity at the edge of its domain rather than inside it. The arcs at infinity that one drops in deriving the formula are the contributions of $J \le J_0$; assuming they vanish is assuming Regge boundedness, and it is exactly this assumption that fails, in a controlled way, as one approaches the Regge regime.

Two honest caveats date the present understanding. First, the precise value of J_0 at finite coupling, and the rigorous status of Regge boundedness beyond the leading-twist trajectory and beyond two dimensions, remain only partially settled; the cleanest statements are for the leading trajectory and in holographic or large-N limits. Second, the convergence of the large-spin $(1/\bar{h})$ expansion itself — as opposed to its term-by-term validity — is asymptotic, not established to be convergent, so resumming it to reach finite or small spin is a separate problem, addressed in practice by combining the analytic tail with the numerical bootstrap of Chapter 50 that controls the low spins directly. The two bootstraps are genuinely complementary: numerics pins the handful of low-lying, low-spin operators that the $1/\bar{h}$ expansion cannot reach, and the inversion formula organizes the infinite high-spin tail that numerics can only sample. This is the synthesis the next section formalizes.

We have now used the inversion formula as it is meant to be used: as a machine that ingests the double discontinuity of a correlator — equivalently, the operators exchanged in the crossed channel — and emits the analytic-in-spin data of the double-twist towers, with the lightest exchanged operator setting the leading $1/\bar{h}^{\tau_m}$ correction, the stress tensor contributing the universal gravitational tail, and the energy operator ϕ^2 governing the Wilson–Fisher spectrum in agreement with the ε-expansion. The dispersive structure underlying these results — a positive integral of a double discontinuity against a fixed kernel — is not unique to the inversion formula. The same positivity, repackaged as a linear functional acting on the crossing equation, is the analytic counterpart of the numerical functionals of Chapter 50, and unifying the two viewpoints into a single dispersive bootstrap is the subject of the next section.

51.6 Analytic Functionals and the Dispersive Bootstrap

The inversion formula of the previous section is, read one way, a reconstruction theorem: it returns the OPE data of the direct channel from a single positive datum of the correlator, its double discontinuity. Read another way it is a statement about *linear functionals*. To produce the coefficient and dimension of a given exchanged operator the inversion formula integrates the correlator against a fixed kernel; that integration is a linear map from the space of crossing-symmetric correlators to a number, and the double discontinuity sitting inside it makes the

map manifestly sign-definite on unitary input. This is exactly the shape of the object that drove the numerical bootstrap of Chapter 50: a linear functional, applied to crossing, whose sign certifies which spectra are allowed. The numerical program of Section 50.6.1 found such functionals by semidefinite optimization, as anonymous vectors in a truncated derivative space, and read the spectrum off their zeros (Theorem 50.34). The dispersive structure of the inversion formula promises something the optimizer cannot give: the *same* extremal functionals, in closed form, with their zeros known analytically. This section makes the promise precise. We recast crossing as the vanishing of analytic functionals; we construct, in the one solvable case — the one-dimensional bootstrap — the analytic extremal functionals dual to the generalized free field, with their double zeros on the double-twist spectrum exhibited explicitly; and we tie the whole construction to the double discontinuity, exposing the dispersive sum rules whose positivity is inherited directly from the inversion formula. The upshot is a unification: the analytic functionals are the closed-form optimal functionals, and the numerical functionals of Chapter 50 are their finite-dimensional approximations.

51.6.1 Crossing as the vanishing of a linear functional, revisited

We begin by restating the bootstrap logic of Chapter 50 in the language that the analytic construction will fill in. The crossing equation of Theorem 49.13, with the identity contribution separated and normalized, is the statement that the *crossing vector* or *block difference*

$$\mathcal{F}_{\Delta,\ell}(z,\bar{z}) \;\equiv\; v^{\Delta_\phi}\, G_{\Delta,\ell}(u,v) - u^{\Delta_\phi}\, G_{\Delta,\ell}(v,u), \tag{51.133}$$

built from the conformal blocks of Theorem 47.49 in the cross-ratios of Eq. (47.140), sums against the squared OPE coefficients $p_{\mathcal{O}} = \lambda^2_{\phi\phi\mathcal{O}} \geq 0$ to zero,

$$\mathcal{F}_{0,0}(z,\bar{z}) \;+\; \sum_{\mathcal{O}\neq\mathbf{1}} p_{\mathcal{O}}\, \mathcal{F}_{\Delta_{\mathcal{O}},\ell_{\mathcal{O}}}(z,\bar{z}) \;=\; 0, \tag{51.134}$$

where $\mathcal{F}_{0,0} = v^{\Delta_\phi} - u^{\Delta_\phi}$ is the identity term. A *linear functional* ω is a continuous linear map on the space of functions of the cross-ratios; its action on the crossing equation produces the *sum rule*

$$\omega[\mathcal{F}_{0,0}] \;+\; \sum_{\mathcal{O}\neq\mathbf{1}} p_{\mathcal{O}}\, \omega(\Delta_{\mathcal{O}},\ell_{\mathcal{O}}) \;=\; 0, \qquad \omega(\Delta,\ell) \equiv \omega[\mathcal{F}_{\Delta,\ell}], \tag{51.135}$$

a single linear constraint on the OPE data. If ω can be chosen so that $\omega[\mathcal{F}_{0,0}] > 0$ while $\omega(\Delta,\ell) \geq 0$ for every operator allowed by the unitarity bounds of Theorem 47.18 and by whatever gaps one imposes, then Eq. (51.135) is a positive number plus a sum of nonnegative numbers and cannot vanish: the assumed spectrum is excluded. This is the exclusion principle of Theorem 50.34, verbatim, written without committing to how ω is found.

The numerical bootstrap commits to one realization. It takes ω to be a finite linear combination of derivatives evaluated at the crossing-symmetric point $z = \bar{z} = \frac{1}{2}$,

$$\omega^{\text{num}}[\mathcal{F}] = \sum_{m+n\le\Lambda} \alpha_{mn}\, \partial_z^m \partial_{\bar{z}}^n \mathcal{F}(z,\bar{z})\Big|_{z=\bar{z}=\frac{1}{2}}, \tag{51.136}$$

exactly the action of Eq. (50.117), and searches over the finitely many coefficients α_{mn} by the semidefinite methods of Section 50.6.3. The functional that emerges at a boundary of the allowed region — the extremal functional α_* of Theorem 50.33 — has, by complementary slackness, double zeros precisely at the dimensions of the operators in the saturating spectrum. The derivative basis Eq. (51.136) is nothing but the leading terms of the Taylor expansion of a general analytic functional about $z = \frac{1}{2}$; the truncation order Λ is how many of those terms the optimizer is allowed to use. An *analytic* functional is the object Eq. (51.136) approximates: a linear map written in closed form, valid without truncation, whose zeros we can locate by hand rather than read off a solver. The question this section answers, in the one setting where the answer is known completely, is what those closed-form functionals are.

Definition 51.21 (Analytic functional)**.** An *analytic functional* for the crossing equation Eq. (51.134) is a linear map ω on the crossing functions, presented as an integral against a kernel rather than as a finite sum of derivatives. In the one-dimensional case developed below it has the contour-integral form

$$\omega[\mathcal{F}] \;=\; \int_{\frac{1}{2}}^{\frac{1}{2}+i\infty} \frac{dz}{2\pi i}\, h_\omega(z)\, \mathcal{F}(z) \;+\; \text{c.c.}, \tag{51.137}$$

with $h_\omega(z)$ holomorphic in the upper half-plane and decaying fast enough on the contour that the integral converges on every conformal block. The functional is *positive* (above a gap Δ_{gap}) if $\omega(\Delta) \ge 0$ for all $\Delta \ge \Delta_{\text{gap}}$, and *extremal* for a candidate spectrum if it is positive and its positive zeros coincide with that spectrum.

The contour-integral form is the analytic continuation of the derivative basis: deforming Eq. (51.137) and expanding h_ω in a Taylor series at $z = \frac{1}{2}$ reproduces Eq. (51.136) with α_{mn} the Taylor coefficients of h_ω. The advantage is that the analytic kernel encodes *all* derivatives at once, so its zeros are exact rather than the artifacts of a finite search.

51.6.2 The solvable case: the one-dimensional bootstrap

Analytic functionals are understood in closed form in exactly one kinematic setting: one dimension. This is not a toy. A one-dimensional CFT is the data carried by a conformal line defect — a Wilson line, a localized impurity, the worldline of a heavy probe — on which local operators live and fuse with an OPE

governed by the $\mathrm{SL}(2,\mathbb{R})$ subgroup of the conformal group. More to the point for us, the $\mathrm{SL}(2,\mathbb{R})$ blocks of the one-dimensional problem are precisely the collinear blocks that controlled the lightcone limit of Section 51.1: the one-dimensional functionals are the seed from which the higher-dimensional analytic functionals are built by dressing the collinear variable with the transverse one. Solving the one-dimensional case is therefore both an end in itself and the kernel of the general program.

In one dimension there is a single cross-ratio $z \in (0,1)$, no spin, and the conformal block is the $\mathrm{SL}(2,\mathbb{R})$ block

$$G_\Delta(z) \;=\; z^\Delta\, {}_2F_1(\Delta,\Delta;2\Delta;z), \tag{51.138}$$

the same Gauss hypergeometric collinear block met in Eq. (51.36) (with equal external dimensions $\Delta_1=\Delta_2=\Delta_\phi$, so the upper parameters coincide). The four-point function of a single scalar ϕ of dimension Δ_ϕ stripped to the cross-ratio function $\mathcal{G}(z)=\sum_\Delta p_\Delta\, G_\Delta(z)$ (with $p_{\Delta=0}=1$ the identity) obeys the crossing equation generated by $z\to 1-z$,

$$\sum_\Delta p_\Delta\, \mathcal{F}_\Delta(z)=0, \qquad \mathcal{F}_\Delta(z) \;\equiv\; \frac{G_\Delta(z)}{z^{2\Delta_\phi}}-\frac{G_\Delta(1-z)}{(1-z)^{2\Delta_\phi}}, \tag{51.139}$$

the one-dimensional reduction of Eq. (51.133). The block difference $\mathcal{F}_\Delta$ is antisymmetric under crossing, $\mathcal{F}_\Delta(z)=-\mathcal{F}_\Delta(1-z)$, and the identity gives $\mathcal{F}_0(z)=z^{-2\Delta_\phi}-(1-z)^{-2\Delta_\phi}$.

The reference solution is the generalized free field of Theorem 51.6, in its one-dimensional incarnation. Wick's theorem gives the three pairings, of which the disconnected one is the identity, so

$$\mathcal{G}_{\mathrm{GFF}}(z) \;=\; 1+z^{2\Delta_\phi}+\Big(\frac{z}{1-z}\Big)^{2\Delta_\phi}, \tag{51.140}$$

which satisfies crossing identically, since $\mathcal{G}_{\mathrm{GFF}}(z)/z^{2\Delta_\phi}=z^{-2\Delta_\phi}+1+(1-z)^{-2\Delta_\phi}$ is symmetric under $z\to 1-z$. Decomposing the non-identity part into blocks, the exchanged operators are the double-twist operators $[\phi\phi]_n$ at the rigid lattice

$$\Delta_n=2\Delta_\phi+2n, \qquad n=0,1,2,\ldots, \tag{51.141}$$

the one-dimensional shadow of the twist lattice Eq. (51.31) (there is no spin, so the radial label n is the only quantum number). Their squared OPE coefficients $a_n\equiv p_{\Delta_n}$ are fixed by matching power by power in z. Writing $h\equiv 2\Delta_\phi$ and expanding the non-identity part of Eq. (51.140),

$$\mathcal{G}_{\mathrm{GFF}}(z)-1=z^h\big[1+(1-z)^{-h}\big]=2z^h+h\,z^{h+1}+\tfrac{h(h+1)}{2}z^{h+2}+\cdots, \tag{51.142}$$

and comparing with $G_{\Delta_n}(z)=z^{h+2n}\big[1+\frac{(h+2n)^2}{2h+4n}z+\cdots\big]$ gives the leading coefficients in closed form. At order z^h only G_{Δ_0} contributes, so $a_0=2$. At order

z^{h+1} the single block $a_0 G_{\Delta_0}$ already supplies $a_0 \cdot \frac{h^2}{2h} = h$, matching Eq. (51.142) and confirming there is no operator at $\Delta = h+1$ (consistent with the even lattice). At order z^{h+2} the block G_{Δ_1} first appears, and matching

$$\underbrace{a_0 \cdot \frac{(h)_2^2}{(2h)_2\, 2!}}_{=\frac{h(h+1)^2}{2(2h+1)}} + a_1 \;=\; \frac{h(h+1)}{2} \quad\Longrightarrow\quad a_1 = \frac{h^2(h+1)}{2(2h+1)} = \frac{(2\Delta_\phi)^2(2\Delta_\phi+1)}{2(4\Delta_\phi+1)}, \tag{51.143}$$

both manifestly positive. The general coefficient has the closed form $a_n = \frac{2\,\Gamma(h+2n)^2\,\Gamma(2h+2n-1)}{(2n)!\,\Gamma(h)^2\,\Gamma(2h+4n-1)}$, the one-dimensional companion of Eq. (51.38); we will need only the explicit low-lying values Eq. (51.143). The data $\{\Delta_n, a_n\}$ are the one-dimensional mean-field solution, and they will turn out to be the unique *extremal* solution at the boundary of the allowed region — the one-dimensional analogue of the way the Ising point saturated the numerical bound in Section 50.6.3.

51.6.3 The analytic extremal functionals: a dual basis to the generalized free field

We now state and construct the functionals dual to the generalized free field. The construction is due to Mazác and to Mazác and Paulos; we give it in full at the level of its defining properties and the leading explicit functional, and exhibit the double-zero structure that is its entire content.

The strategy is to build a *basis* of functionals adapted to the double-twist spectrum Eq. (51.141), in the precise sense that each functional reads off exactly one piece of data. Two pieces of data live at each lattice site Δ_n: the squared OPE coefficient a_n, and the dimension itself, which in a deformation away from mean field shifts by an anomalous dimension γ_n. Accordingly there are two families.

Theorem 51.22 (Existence of the dual functional basis)**.** *There exist two families of analytic functionals* $\{\alpha_n\}_{n\geq 0}$ *and* $\{\beta_n\}_{n\geq 0}$ *of the form Eq. (51.137), the* Mazác–Paulos basis*, whose actions on the block difference* $\mathcal{F}_\Delta$*, regarded as functions* $\alpha_n(\Delta) = \alpha_n[\mathcal{F}_\Delta]$ *and* $\beta_n(\Delta) = \beta_n[\mathcal{F}_\Delta]$*, satisfy the duality relations*

$$\alpha_n(\Delta_m) = \delta_{nm}, \qquad \partial_\Delta \alpha_n(\Delta)\big|_{\Delta_m} = 0, \tag{51.144}$$

$$\beta_n(\Delta_m) = 0, \qquad \partial_\Delta \beta_n(\Delta)\big|_{\Delta_m} = \delta_{nm}, \tag{51.145}$$

for all $m, n \geq 0$*, where* $\Delta_m = 2\Delta_\phi + 2m$ *is the double-twist lattice Eq. (51.141). Equivalently: each functional has a* double zero *at every lattice site* Δ_m *except for a single distinguished site, where* α_n *takes the value* 1 *(a non-zero) and* β_n *has a* simple *zero (value* 0*, derivative* 1*). The functionals are positive above the*

gap $\Delta_0 = 2\Delta_\phi$, and the generalized free field Eq. (51.140) is the extremal solution they certify.

The double-zero pattern is the exact analytic image of the numerical phenomenon of Theorem 50.34: there, the extremal functional α_* was forced by complementary slackness to have double zeros on the saturating spectrum; here, the functionals are *designed* to have double zeros on the double-twist spectrum, and the design is possible precisely because the generalized free field saturates the one-dimensional bound. The numerical extremal functional, computed in the derivative basis Eq. (51.136) at a boundary point whose extremal solution is mean field, converges term by term to a combination of the α_n, β_n as the truncation order is raised. The closed-form functionals are the limit the optimizer approaches.

Why double zeros, and where they come from. Before constructing the functionals, we explain why the double-zero pattern is forced and not merely convenient — and in doing so make the link to the double discontinuity that the next subsection turns into positivity. The functional action $\omega(\Delta) = \omega[\mathcal{F}_\Delta]$ is, for a functional of the contour form Eq. (51.137), computed by deforming the contour onto the singularities of $\mathcal{F}_\Delta(z)$ at $z \to 1$. The block difference Eq. (51.139) carries there the crossed-channel piece $(1-z)^{-2\Delta_\phi} G_\Delta(1-z)$, whose behaviour as $z \to 1$ is the t-channel expansion. The discontinuity of this piece across the cut at $z = 1$ — and hence the part of $\omega(\Delta)$ that survives the contour deformation — carries the kinematic factor that the Lorentzian inversion formula of Theorem 51.16 makes universal: the double discontinuity of a t-channel contribution of dimension Δ relative to the s-channel double-twist family is proportional to

$$\mathrm{dDisc} \;\propto\; \sin^2\!\Big[\tfrac{\pi}{2}(\Delta - 2\Delta_\phi)\Big], \tag{51.146}$$

which vanishes to *second* order at every double-twist location $\Delta = \Delta_n = 2\Delta_\phi + 2n$, where the argument is an integer multiple of π. The double zeros of the analytic functionals are the double zeros of this $\sin^2$: the double discontinuity that the inversion formula puts at the heart of the dispersive reconstruction is the very object whose vanishing protects the double-twist operators. A functional built from the double discontinuity therefore *automatically* double-zeros on the mean-field spectrum. This is the structural reason the dual basis exists, and it ties the analytic functionals to the inversion formula at the root.

Construction of the leading functional. The cleanest explicit realization packages the duality relations into *Polyakov–Regge blocks*. A Polyakov–Regge block $\mathcal{P}_\Delta(z)$ is the unique crossing-symmetric function with the same double discontinuity as the single block G_Δ and bounded Regge behaviour; concretely it is the sum of the s- and t-channel SL(2) Witten exchange diagrams of an

operator of dimension Δ. Decomposing $\mathcal{P}_\Delta$ back into s-channel blocks produces the exchanged block plus a tower of double-twist blocks *and their dimension-derivatives*,

$$\mathcal{P}_\Delta(z) \;=\; G_\Delta(z) \;+\; \sum_{n\geq 0}\Big[\, a_n\,\alpha_n(\Delta)\,G_{\Delta_n}(z) \;+\; a_n\,\beta_n(\Delta)\,\partial_\Delta G_{\Delta_n}(z)\,\Big], \tag{51.147}$$

where the coefficients are precisely the functional actions of Theorem 51.22 and the appearance of $\partial_\Delta G_{\Delta_n}$ — a block dressed by a logarithm $\log z$ — is the signal of an anomalous dimension. Equation Eq. (51.147) is the defining property: writing a crossing-symmetric correlator in the Polyakov–Regge basis, $\mathcal{G}(z) = \sum_\Delta p_\Delta\,\mathcal{P}_\Delta(z)$, and demanding that the double-twist data on the two sides match imposes exactly the sum rules Eq. (51.135) for $\omega = \alpha_n$ and $\omega = \beta_n$. The functionals are read off as the double-twist content of the Polyakov–Regge blocks, and Eq. (51.147) makes the double-zero structure automatic: $\mathcal{P}_\Delta$ for Δ on the lattice must reduce to a single block G_Δ with no anomalous-dimension dressing of *the other* sites, which is the statement $\alpha_n(\Delta_m) = \delta_{nm}$, $\beta_n(\Delta_m) = 0$, and the derivative conditions follow from the absence of a $\partial_\Delta G_{\Delta_m}$ term at $m \neq n$. The explicit kernels $h_{\alpha_n}, h_{\beta_n}$ in Eq. (51.137) are obtained by inverting this decomposition; the leading one, β_0, is worked out in Theorem 51.23.

Worked Example 51.23 (The leading anomalous-dimension functional and its double zeros)**.** We construct the leading functional β_0 explicitly enough to exhibit its defining zeros, and verify the double-zero pattern Eq. (51.145) directly on the lowest sites.

The object. By Eq. (51.147), $\beta_0(\Delta)$ is the coefficient of $a_0\,\partial_\Delta G_{\Delta_0}(z)$ — the $\log z$-dressed leading block — in the s-channel decomposition of the Polyakov–Regge block $\mathcal{P}_\Delta$. Equivalently it is the contour functional Eq. (51.137) whose kernel $h_{\beta_0}(z)$ projects the crossing function onto the $\log z$ singularity at the leading double-twist dimension $\Delta_0 = 2\Delta_\phi$. Its action is computed by deforming the $z = \frac{1}{2}$ contour to the cut at $z = 1$, where the block difference Eq. (51.139) produces the t-channel expansion whose double discontinuity carries the factor Eq. (51.146).

Double zeros from the $\sin^2$. Write $\beta_0(\Delta) = \rho(\Delta)\,\sin^2\!\big[\tfrac{\pi}{2}(\Delta - 2\Delta_\phi)\big]/N(\Delta)$, where ρ is the smooth OPE-density factor produced by the contour integral and N a normalization fixed below. At every lattice site $\Delta_m = 2\Delta_\phi + 2m$ the argument of the sine is πm, so $\sin^2$ vanishes to second order:

$$\sin^2\!\Big[\tfrac{\pi}{2}(\Delta - 2\Delta_\phi)\Big]\Big|_{\Delta=\Delta_m+\delta} = \sin^2\!\Big[\tfrac{\pi}{2}\delta\Big] = \frac{\pi^2}{4}\,\delta^2 + O(\delta^4), \qquad \delta = \Delta - \Delta_m. \tag{51.148}$$

Hence $\beta_0(\Delta_m) = 0$ and $\partial_\Delta\beta_0(\Delta_m) = 0$ at *every* site $m \geq 0$ where the smooth factor ρ/N is finite — a double zero. The single exception is the distinguished site $m = 0$: there the smooth factor $\rho(\Delta)/N(\Delta)$ has a *simple pole*, engineered by

the kernel so that the δ^2 of Eq. (51.148) is reduced to a δ^1. Concretely, near Δ_0,

$$\beta_0(\Delta) \xrightarrow{\Delta\to\Delta_0} \frac{r_0}{\Delta-\Delta_0}\cdot\frac{\pi^2}{4}(\Delta-\Delta_0)^2+\cdots = \frac{\pi^2 r_0}{4}(\Delta-\Delta_0)+\cdots, \quad (51.149)$$

a *simple* zero at Δ_0. Fixing the residue $r_0 = 4/\pi^2$ normalizes the derivative to $\partial_\Delta\beta_0(\Delta_0) = 1$, which is the condition $\partial_\Delta\beta_0(\Delta)|_{\Delta_0} = \delta_{0,0} = 1$ of Eq. (51.145). At every other site the smooth factor is regular, the $\sin^2$ gives the clean double zero, and Eq. (51.145) holds with $\delta_{0,m} = 0$.

What the pole does and does not require. The only nontrivial analytic input is the existence of a kernel h_{β_0} whose density ρ/N is regular and nonzero on the lattice except for a simple pole at the one distinguished site; this is what fixes the functional uniquely and is the content of the Mazác–Paulos kernels. Everything else — the double zeros at all other sites, the simple zero at the distinguished site, the positivity above the gap — follows from the universal $\sin^2$ factor Eq. (51.146) alone, which is dictated by the double discontinuity and not by the details of the kernel. The functional α_n is constructed identically, with the pole placed so as to convert the δ^2 at the distinguished site into a δ^0 (a non-zero value 1) rather than a δ^1; the remaining sites again double-zero through Eq. (51.148).

51.6.4 The sum rules and the reproduction of the generalized free field

The duality relations Eqs. (51.144) and (51.145) turn the bare crossing constraint Eq. (51.135) into a system of *explicit* sum rules for the deviation of any unitary solution from mean field. Consider a CFT whose spectrum is the double-twist lattice deformed by small anomalous dimensions γ_m and coefficient shifts, together with a set of extra operators $\{\mathcal{O}\}$ not on the lattice (the operators that the generalized free field omits — the genuine interactions). Write the perturbed double-twist operator at $\Delta = \Delta_m + \gamma_m$ with coefficient $a_m + \delta a_m$, and Taylor-expand its block difference,

$$\mathcal{F}_{\Delta_m+\gamma_m}(z) = \mathcal{F}_{\Delta_m}(z) + \gamma_m\,\partial_\Delta\mathcal{F}_{\Delta_m}(z) + O(\gamma_m^2). \quad (51.150)$$

Inserting into crossing and acting with α_n and β_n, the duality relations collapse the lattice sums to a single term each. From α_n, using $\alpha_n(\Delta_m) = \delta_{nm}$ and $\partial_\Delta\alpha_n(\Delta_m) = 0$,

$$\boxed{\delta a_n \;=\; -\sum_{\mathcal{O}\notin\text{ lattice}} p_{\mathcal{O}}\,\alpha_n(\Delta_{\mathcal{O}})} \quad (51.151)$$

to first order: the shift in the n-th double-twist OPE coefficient equals minus the α_n-functional summed over the operators that are *not* double-twist. From β_n, using $\beta_n(\Delta_m) = 0$ and $\partial_\Delta\beta_n(\Delta_m) = \delta_{nm}$,

$$\boxed{a_n\,\gamma_n \;=\; -\sum_{\mathcal{O}\notin\text{ lattice}} p_{\mathcal{O}}\,\beta_n(\Delta_{\mathcal{O}})} \quad (51.152)$$

the n-th anomalous dimension, weighted by the mean-field coefficient, equals minus the β_n-functional over the same non-lattice operators. These are the analytic-functional sum rules: closed-form, exact-in-$1/\ell$ expressions for the double-twist data in terms of the binding operators, and the one-dimensional rigorous counterpart of the large-spin formulae of Section 51.3. The functional β_n computes an anomalous dimension; α_n a coefficient shift; the inputs are the cross-channel operators that the mean-field theory lacks.

The first and most important check is that the generalized free field reproduces itself.

Worked Example 51.24 (The generalized free field as the extremal solution)**.** We verify that the dual functionals return the mean-field data when applied to the mean-field correlator, and that this is the statement that the generalized free field saturates the bound.

No anomalous dimensions. In the generalized free field Eq. (51.140) the spectrum is *exactly* the lattice Eq. (51.141): there are no operators off the lattice, so the right-hand sides of the sum rules Eqs. (51.151) and (51.152) are empty sums. Equation Eq. (51.152) then gives $a_n\gamma_n = 0$, hence $\gamma_n = 0$ for every n: the double-twist operators carry no anomalous dimension, exactly as the rigid lattice demands. Equation Eq. (51.151) gives $\delta a_n = 0$: the coefficients are unshifted from their mean-field values a_n. The dual basis reproduces the generalized free field as a fixed point of its own sum rules.

Direct re-summation. The same statement read forward is that the functionals *measure* the mean-field coefficients. Apply α_n to the full mean-field crossing equation $\mathcal{F}_0 + \sum_m a_m \mathcal{F}_{\Delta_m} = 0$. Using $\alpha_n(\Delta_m) = \delta_{nm}$,

$$\alpha_n[\mathcal{F}_0] + \sum_m a_m\, \alpha_n(\Delta_m) = \alpha_n[\mathcal{F}_0] + a_n = 0 \quad \Longrightarrow \quad a_n = -\,\alpha_n[\mathcal{F}_0], \tag{51.153}$$

the coefficient a_n *is* minus the α_n-functional on the identity — the closed-form analogue of strong duality Eq. (50.123), where the extremal OPE coefficient equalled minus the extremal functional on the identity. For $n = 0$ this returns $a_0 = -\alpha_0[\mathcal{F}_0] = 2$, the value computed by hand in Eq. (51.143); the functional construction is normalized precisely so that $\alpha_0[\mathcal{F}_0] = -2$, $\alpha_1[\mathcal{F}_0] = -a_1 = -(2\Delta_\phi)^2(2\Delta_\phi + 1)/[2(4\Delta_\phi + 1)]$, and so on. The single boundary functional encodes the entire mean-field OPE spectrum, exactly as the numerical extremal functional encoded the Ising spectrum in Theorem 50.35.

Extremality. Positivity (Theorem 51.22) means $\alpha_n(\Delta) \geq 0$ for $\Delta \geq \Delta_0$, with zeros only on the lattice. A solution that placed any OPE weight $p_{\mathcal{O}} > 0$ at a dimension strictly between lattice sites would, through Eq. (51.151), be detected by some α_n with a strictly positive value, forcing $\delta a_n \neq 0$ and moving the solution off mean field. The generalized free field, supported entirely on the double zeros, is the unique solution at which every positivity-functional is saturated — it sits on the boundary of the allowed region, certified extremal

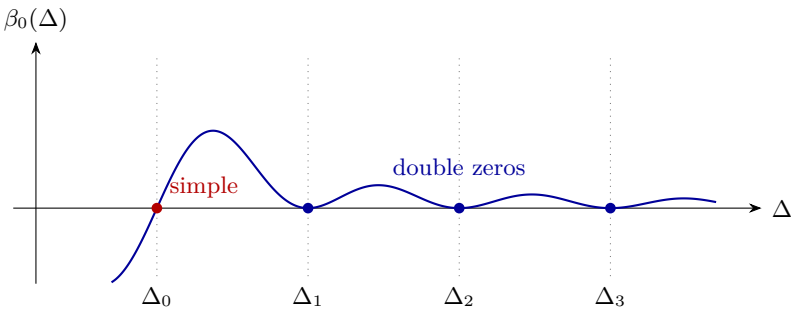

Figure 51.8: The analytic functional $\beta_0(\Delta) = \beta_0[\mathcal{F}_\Delta]$ acting on the one-dimensional block difference, schematically. The universal factor $\sin^2[\frac{\pi}{2}(\Delta-2\Delta_\phi)]$ of Eq. (51.146), inherited from the double discontinuity of the inversion formula, forces a *double* zero (the curve touches the axis without crossing) at every double-twist site $\Delta_m = 2\Delta_\phi + 2m$. The kernel places a single simple pole at the distinguished site Δ_0, converting the double zero there into a *simple* zero with unit slope: this is the duality relation Eq. (51.145). Compare the numerically-computed extremal functional of Fig. 50.7: the same double-zero-on-the-spectrum picture, now known in closed form.

by the closed-form functionals. This is the analytic statement that mean-field theory is the extremal solution of the one-dimensional bootstrap, the exact image of the numerical extremality of Section 50.6.3.

51.6.5 Dispersive functionals, double discontinuity, and the inversion formula

The $\sin^2$ factor Eq. (51.146) did more than explain the double zeros: it located the functionals' analytic content inside the double discontinuity. This is the defining feature of the most important sub-class of analytic functionals, the *dispersive functionals*, and it is what makes contact with the inversion formula complete.

Definition 51.25 (Dispersive functional)**.** A *dispersive functional* is an analytic functional whose action on a crossing function is computed entirely from the function's double discontinuity,

$$\omega[\mathcal{G}] \;=\; \int dz\; k_\omega(z)\; \mathrm{dDisc}\,[\mathcal{G}(z)], \tag{51.154}$$

with a kernel $k_\omega(z) \geq 0$ on the integration region. The associated *dispersive sum rule* is $\omega[\mathcal{F}_0] + \sum_{\mathcal{O}\neq\mathbf{1}} p_\mathcal{O}\, \omega(\Delta_\mathcal{O}) = 0$, the instance of Eq. (51.135) for this ω.

The reason dispersive functionals exist at all is the Lorentzian inversion formula of Theorem 51.16: that formula expresses the OPE function $c(\Delta)$ as an

integral of the double discontinuity against the inversion kernel, and a *positive* integral, because dDisc is nonnegative on unitary correlators. A dispersive functional is the same construction read as a constraint rather than a reconstruction: instead of asking what spectrum the dDisc produces, one asks that a fixed positive combination of the dDisc, integrated against k_ω, vanish on crossing-symmetric data. The two are the same object viewed from the two sides of the equality, which is exactly the unification this section is after — the inversion formula is the generating functional of the dispersive sum rules.

Proposition 51.26 (dDisc-positivity of dispersive functionals)**.** *A dispersive functional Eq. (51.154) with $k_\omega \geq 0$ acts nonnegatively on every unitary contribution to the crossing equation, and double-zeros on the double-twist spectrum:*

$$\omega(\Delta) \;\geq\; 0 \quad \textit{for all } \Delta \textit{ above the gap}, \qquad \omega(\Delta_n) = \partial_\Delta\, \omega(\Delta_n) = 0. \tag{51.155}$$

Consequently the dispersive sum rule certifies the generalized free field as extremal, exactly as in Theorem 51.22.

Derivation, with the analytic input cited. The double-zero statement is Eq. (51.146): the double discontinuity of a single block, as it enters Eq. (51.154), carries the factor $\sin^2[\frac{\pi}{2}(\Delta - 2\Delta_\phi)]$, which vanishes to second order on the lattice; integrating against any fixed kernel preserves the double zero. The positivity statement is the one whose full proof we do not reproduce and instead anchor to the inversion formula. The double discontinuity of a unitary correlator is nonnegative: $\mathrm{dDisc}[\mathcal{G}] \geq 0$, a property established in the construction of the Lorentzian inversion formula in Theorem 51.16, where it is precisely what guarantees that the inverted OPE coefficients come out positive and that the inversion converges (it is the statement, traced there to reflection positivity of the Euclidean correlator and the wedge causality of the Lorentzian one, that the double discontinuity is a sum of squares of matrix elements). Given $\mathrm{dDisc}[\mathcal{G}] \geq 0$ and $k_\omega \geq 0$, the integral Eq. (51.154) is manifestly nonnegative on any single unitary block, which is $\omega(\Delta) \geq 0$. The remaining content — that nonnegative kernels k_ω exist realizing the dual basis, and that the resulting functionals are complete — is the substance of the dispersive-bootstrap construction; we state it and use it, and refer to Theorem 51.16 for the positivity it rests on rather than reproving the inversion formula here. □

The dDisc-positivity is the conceptual bridge between the two bootstraps. In Chapter 50 the positivity that powered every bound was the positivity of squared OPE coefficients $p_{\mathcal{O}} \geq 0$, enforced operator by operator through semidefinite programming. Here the positivity is the positivity of the double discontinuity, $\mathrm{dDisc} \geq 0$, enforced once and for all by the analytic structure of the correlator. The two are dual faces of unitarity: $p_{\mathcal{O}} \geq 0$ is unitarity in the OPE (the s-channel), $\mathrm{dDisc} \geq 0$ is unitarity in the cross channel (the t-channel), and a

dispersive functional trades the former for the latter, replacing an infinite tower of semidefinite constraints by a single positive integral. This is why dispersive functionals are simultaneously analytic (their action is a closed-form integral) and optimal (their positivity is exact, not a truncation): they are built from the inversion formula, which already solved the positivity problem.

51.6.6 Polyakov–Mellin, the Mellin packaging, and the unified picture

The dispersive program has a second, historically independent, presentation in *Mellin space*, and a word on it completes the map of the territory. The Mellin amplitude $M(s,t)$ of a CFT four-point function is the analogue of a scattering amplitude: it is the Mellin transform of the correlator, an analytic function of two Mellin variables whose poles sit at the twists of the exchanged operators and whose residues are the OPE coefficients, with crossing symmetry realized as a permutation symmetry of M much as it is for amplitudes. The double-twist operators of the generalized free field appear in Mellin space as the locations where the Mellin measure has its poles, so that a Mellin amplitude with *no* poles beyond the double-twist lattice is mean field, and the deviations — the genuine dynamics — are extra poles or polynomial (contact) ambiguities. The *Polyakov–Mellin bootstrap* expands the correlator not in conformal blocks but in crossing-symmetric *Polyakov blocks* (the objects Eq. (51.147), now seen as exchange Witten diagrams in Mellin space) and imposes that the spurious double-twist contributions of each Polyakov block cancel in the full correlator; those cancellation conditions are exactly the sum rules Eqs. (51.151) and (51.152), and the functionals that implement them are the Mellin-space realization of the dispersive functionals Eq. (51.154). Mellin space is, in this sense, the natural home of the dispersive bootstrap: the double discontinuity becomes a statement about which Mellin poles are present, and the Mellin amplitude packages the analytic functional data into a single meromorphic function.

Historical Note

The analytic functional program crystallized in the second half of the 2010s. Mazác's 2016 construction of the one-dimensional extremal functionals, and the Mazác–Paulos systematization into the dual bases $\{\alpha_n, \beta_n\}$ of Theorem 51.22 [343–345], showed for the first time that the numerical extremal functionals had a closed-form skeleton. In parallel the Lorentzian inversion formula of Caron-Huot (2017) [111] put the double discontinuity at the centre, and the dispersive functionals of Carmi–Caron-Huot, Caron-Huot–Mazác–Rastelli–Simmons-Duffin, and Penedones–Silva–Zhiboedov [110, 112, 390] unified the two by realizing the functionals as dDisc-positive integrals. The Polyakov–Mellin reading goes back to Polyakov's 1974

"unitary bootstrap" proposal, revived and corrected in Mellin space by Gopakumar–Kaviraj–Sen–Sinha and others around 2016–2017 [234, 447]. As of the mid-2020s the program is complete and rigorous in one dimension and in the lightcone/collinear limit, where the SL(2) functionals control everything; in general dimension the dispersive functionals exist and are dDisc-positive, but a complete closed-form dual basis matching the numerical optima is known only in special cases, and the precise relationship between the analytic functionals and the full higher-dimensional numerical extremal functionals remains an active question.

We can now state the unification cleanly, which is the entire purpose of this section. There is one bootstrap and two ways of solving it. Both start from the crossing sum rule Eq. (51.135) and seek functionals that are positive on the allowed spectrum and vanish on the realized one. The *numerical* bootstrap of Chapter 50 finds such a functional by semidefinite optimization over a finite derivative basis Eq. (51.136), obtaining at the boundary an extremal functional with double zeros on the saturating spectrum (Theorem 50.34); it is general — it works in any dimension, for any correlator system — but the functional it returns is a numerical vector, and its zeros are computed, not known. The *analytic* bootstrap of this chapter writes the optimal functional in closed form Eq. (51.137), with double zeros placed analytically on the double-twist spectrum by the $\sin^2$ factor of the double discontinuity Eq. (51.146); it is exact and explanatory — the sum rules Eqs. (51.151) and (51.152) are formulae, not outputs — but it is fully controlled only in one dimension and in the lightcone limit. The two are not rivals but the same object at two resolutions: the analytic functionals $\{\alpha_n, \beta_n\}$ are the closed-form extremal functionals, and the numerical functional Eq. (51.136), computed at a boundary point whose extremal solution is the generalized free field, is the finite-Λ Taylor approximation of a combination of them. The double zeros that complementary slackness forced upon the numerical functional in Section 50.6.3 are the same double zeros that the double discontinuity builds into the analytic functional here. The semidefinite optimizer of Chapter 50 is, in the cases where the analytic answer is known, rediscovering the Mazác–Paulos functionals one Taylor coefficient at a time.

With the analytic functionals and their dispersive, dDisc-positive structure in hand, the machinery of the chapter is complete: the lightcone expansion fixes the large-spin spectrum, the inversion formula reconstructs the OPE data from the double discontinuity, and the analytic functionals package both into closed-form, optimal sum rules dual to the generalized free field. The closing section turns this apparatus on the chapter's target theories, applying the large-spin and inversion results to the three-dimensional Ising and Wilson–Fisher fixed points and cross-checking the analytic predictions against the numerical island of Chapter 50 and the ϵ-expansion of ϕ^4 theory.

51.7 Analytic Data for the 3D Ising and Wilson–Fisher CFTs

The previous sections assembled a unified analytic toolkit — the lightcone expansion of Section 51.1, the large-spin master formula Theorem 51.10, the Lorentzian inversion formula of Section 51.4, and the dispersive functionals of Section 51.6 — but built each on an abstract scalar ϕ of arbitrary dimension. We now point the whole apparatus at the two theories ϕ^4 theory has carried since Part II: the Wilson–Fisher fixed point in $d = 4 - \varepsilon$, and its physical endpoint, the three-dimensional Ising conformal field theory. The exercise is not decorative. Chapter 50 delivered the Ising dimensions to six figures, but as the unexplained output of a semidefinite program; the present section produces, with no computer, closed-form statements about an *infinite* family of operators — the leading-twist double-twist towers $[\sigma\sigma]_{0,\ell}$ and $[\epsilon\epsilon]_{0,\ell}$ — and shows that those statements agree, where they overlap, both with the numerical spectrum of Chapter 50 and with the ε-expansion of Chapter 47. The convergence of three independent methods on the same numbers is the strongest evidence we can offer that the 3D Ising CFT is a single, internally consistent object, and it closes the analytic-bootstrap stage of ϕ^4 theory.

51.7.1 The data and the operators in play

We work in $d = 3$ and take as input the conformal data the bootstrap has already pinned down. From Eq. (49.171) (reproduced by the semidefinite program in Eq. (50.130)) the two lightest primaries and their couplings are

$$\begin{aligned} &\Delta_\sigma = 0.5181489(10), \quad \Delta_\epsilon = 1.412625(10), \quad \Delta_{\epsilon'} \approx 3.83, \quad \Delta_T = 3, \\ &\lambda_{\sigma\sigma\epsilon} = 1.0518537(41), \quad \lambda_{\epsilon\epsilon\epsilon} = 1.532435(19), \quad \frac{C_T}{C_T^{\text{free}}} = 0.946534(11). \end{aligned} \tag{51.156}$$

Here σ is the $\mathbb{Z}_2$-odd order parameter, ϵ the $\mathbb{Z}_2$-even energy operator (the relevant deformation), ϵ' the next $\mathbb{Z}_2$-even scalar, $T_{\mu\nu}$ the stress tensor (dimension exactly $\Delta_T = d = 3$, conserved), and C_T the central charge normalized to the free-scalar value. These few numbers are all the dynamical input the analytic machine requires; everything below is kinematics and crossing.

The objects we predict are the two leading-twist double-twist towers, defined as in Section 51.2:

$$[\sigma\sigma]_{0,\ell} \subset \sigma \times \sigma \ (\mathbb{Z}_2\text{-even}), \qquad [\epsilon\epsilon]_{0,\ell} \subset \epsilon \times \epsilon \ (\mathbb{Z}_2\text{-even}), \qquad \ell = 0, 2, 4, \dots \tag{51.157}$$

Both are built from two identical scalars, so Bose symmetry retains only even spins. By the twist-accumulation theorem Eq. (51.49) their twists approach the

mean-field values

$$\tau_{0,\ell}^{[\sigma\sigma]} \xrightarrow{\ell\to\infty} 2\Delta_\sigma = 1.036298, \qquad \tau_{0,\ell}^{[\epsilon\epsilon]} \xrightarrow{\ell\to\infty} 2\Delta_\epsilon = 2.825250, \tag{51.158}$$

and the entire content of the analytic prediction is the *rate* and *sign* of this approach, governed by Theorem 51.10. To use that theorem we need, for each family, the lowest-twist operators exchanged in the crossed channel. The candidates are read off Eq. (51.156).

- In $\sigma\times\sigma$ the $\mathbb{Z}_2$-even exchanged operators are the identity (twist 0), the stress tensor T (twist $\tau_T = d-2 = 1$), and the scalar ϵ (twist $\tau_\epsilon = \Delta_\epsilon = 1.412625$). The minimal nonzero twist is therefore the *stress tensor*, with ϵ next.
- In $\epsilon\times\epsilon$ the exchanged operators are again the identity, the stress tensor T (twist 1), and the scalar ϵ itself (twist 1.412625, present because $\epsilon\times\epsilon \supset \epsilon$ with coefficient $\lambda_{\epsilon\epsilon\epsilon}$). The minimal nonzero twist is again the stress tensor.

For both families the asymptotically dominant binding comes from stress-tensor exchange — the universal gravitational channel of Section 51.3.5 — with the scalar ϵ supplying the leading subleading correction. We treat the two families in turn.

51.7.2 The order-parameter tower $[\sigma\sigma]_{0,\ell}$

Apply Theorem 51.10 with external dimension $\Delta_\phi = \Delta_\sigma$ to each exchanged operator and add the contributions, as the theorem permits. The result is a two-term large-spin expansion

$$\gamma_{0,\ell}^{[\sigma\sigma]} \simeq -\frac{c_T^{(\sigma)}}{\ell^{\,d-2}} - \frac{c_\epsilon^{(\sigma)}}{\ell^{\,\Delta_\epsilon}} = -\frac{c_T^{(\sigma)}}{\ell} - \frac{c_\epsilon^{(\sigma)}}{\ell^{\,1.412625}}, \tag{51.159}$$

the first term from the stress tensor (range $d-2=1$), the second from ϵ (range Δ_ϵ). The two coefficients are fixed by Eq. (51.73).

The ϵ-exchange coefficient (convention-free). This is the term we can compute cleanly, because the scalar ϵ couples to $\sigma\times\sigma$ through the honest OPE coefficient $\lambda_{\sigma\sigma\epsilon}$, with no normalization ambiguity. Setting $\tau_m = \Delta_\epsilon$, $\ell_m = 0$, $\bar h_m = \frac{1}{2}\Delta_\epsilon$ and $C^2_{\phi\phi\mathcal{O}_m} = \lambda^2_{\sigma\sigma\epsilon}$ in Eq. (51.73),

$$c_\epsilon^{(\sigma)} = \frac{2\,\Gamma(\Delta_\sigma)^2}{\Gamma\!\left(\Delta_\sigma - \frac{\Delta_\epsilon}{2}\right)^2}\,\frac{\Gamma(\Delta_\epsilon)}{\Gamma\!\left(\frac{\Delta_\epsilon}{2}\right)^2}\,\lambda^2_{\sigma\sigma\epsilon}. \tag{51.160}$$

Inserting the numbers Eq. (51.156) — $\Delta_\sigma - \frac{1}{2}\Delta_\epsilon = 0.5181489 - 0.7063125 = -0.1881636$, so the argument of the squared Gamma in the denominator is negative but enters as a square, and $\lambda^2_{\sigma\sigma\epsilon} = 1.10640$ — yields

$$\boxed{c_\epsilon^{(\sigma)} = 0.0926\ .} \tag{51.161}$$

This number is a pure consequence of the three inputs $(\Delta_\sigma, \Delta_\epsilon, \lambda_{\sigma\sigma\epsilon})$ and is independent of any choice of stress-tensor normalization; it is the most reliable analytic prediction the section makes.

The stress-tensor coefficient (the gravitational tail). The leading $1/\ell$ falloff comes from the stress tensor, with coefficient given by the gravitational binding formula Eq. (51.79) at $d = 3$, $\Delta_\phi = \Delta_\sigma$:

$$c_T^{(\sigma)} = \frac{2\,d\,\Delta_\sigma^2}{(d-1)^2\,C_T}\,\frac{\Gamma(\Delta_\sigma)^2}{\Gamma\!\left(\Delta_\sigma - \frac{d-2}{2}\right)^2}\,\frac{\Gamma(d+2)}{\Gamma\!\left(\frac{d+2}{2}\right)^2} = \frac{0.00538}{C_T}. \tag{51.162}$$

The striking feature is the smallness of the numerator. It is forced by the factor $\Gamma(\Delta_\sigma - \frac{d-2}{2})^{-2} = \Gamma(\Delta_\sigma - \frac{1}{2})^{-2}$: since $\Delta_\sigma = 0.5181489$ sits just above the unitarity floor $\frac{1}{2}$, the argument $\Delta_\sigma - \frac{1}{2} = 0.0181$ is tiny, $\Gamma(0.0181) \approx 54.5$ is huge, and the coefficient is suppressed by $\sim 1/54.5^2 \approx 3 \times 10^{-4}$. Physically, σ is *nearly free* — its dimension is close to the free value $\frac{1}{2}$ — and a nearly free field couples only weakly to the stress tensor, hence binds its double-twist partners feebly through gravity. With the central-charge normalization in which the free real scalar has $C_T^{\text{free}} = d/(d-1) = \frac{3}{2}$, the Ising value $C_T = 0.946534 \times \frac{3}{2} = 1.4198$ gives $c_T^{(\sigma)} \approx 0.0038$. We flag, as we did at Eq. (51.78), that this absolute number is tied to the C_T convention; only the power $1/\ell^{\,d-2}$ and the negative sign are convention-free.

Which term dominates. Although the stress-tensor term falls more slowly ($1/\ell$ versus $1/\ell^{1.41}$) and therefore wins as $\ell \to \infty$, its coefficient Eq. (51.162) is more than an order of magnitude smaller than the ϵ-exchange coefficient Eq. (51.161). Equating the two terms locates the crossover,

$$\frac{c_T^{(\sigma)}}{\ell} = \frac{c_\epsilon^{(\sigma)}}{\ell^{\Delta_\epsilon}} \quad\Longrightarrow\quad \ell_\star = \left(\frac{c_\epsilon^{(\sigma)}}{c_T^{(\sigma)}}\right)^{1/(\Delta_\epsilon - 1)} \approx 2300, \tag{51.163}$$

so for every spin below $\ell \approx 2300$ — which is to say, for every spin the numerical bootstrap can resolve — the binding of the order-parameter tower is controlled by ϵ-*exchange*, with the universal gravitational tail taking over only at astronomically large spin. This is the quantitative form of "σ is nearly free": the stress tensor is there, and asymptotically dominant, but numerically negligible against the energy operator throughout the accessible window. The combined prediction Eq. (51.159), twist $\tau_{0,\ell}^{[\sigma\sigma]} = 2\Delta_\sigma + \gamma_{0,\ell}^{[\sigma\sigma]}$ climbing toward 1.036298 from below, is plotted in panel (A) of Fig. 51.9 and tabulated in Theorem 51.27.

51.7.3 The energy tower $[\epsilon\epsilon]_{0,\ell}$

The same analysis with $\Delta_\phi = \Delta_\epsilon$ gives

$$\gamma_{0,\ell}^{[\epsilon\epsilon]} \simeq -\frac{c_T^{(\epsilon)}}{\ell} - \frac{c_\epsilon^{(\epsilon)}}{\ell\,\Delta_\epsilon}, \tag{51.164}$$

with the ϵ-exchange coefficient again convention-free,

$$c_\epsilon^{(\epsilon)} = \frac{2\,\Gamma(\Delta_\epsilon)^2}{\Gamma(\Delta_\epsilon - \frac{\Delta_\epsilon}{2})^2}\,\frac{\Gamma(\Delta_\epsilon)}{\Gamma(\frac{\Delta_\epsilon}{2})^2}\,\lambda_{\epsilon\epsilon\epsilon}^2 = \frac{2\,\Gamma(\Delta_\epsilon)^3}{\Gamma(\frac{\Delta_\epsilon}{2})^4}\,\lambda_{\epsilon\epsilon\epsilon}^2 = 1.19, \tag{51.165}$$

using $\Delta_\epsilon - \frac{1}{2}\Delta_\epsilon = \frac{1}{2}\Delta_\epsilon$ and $\lambda_{\epsilon\epsilon\epsilon}^2 = 2.34836$. In contrast to the order-parameter tower, the energy operator is *far from free*: its dimension $\Delta_\epsilon = 1.4126$ is well above the unitarity floor, the suppressing Gamma factor of Eq. (51.162) is now $\Gamma(\Delta_\epsilon - \frac{1}{2}) = \Gamma(0.9126) \approx 1.05$ of order unity, and the stress-tensor coefficient

$$c_T^{(\epsilon)} = \frac{2\,d\,\Delta_\epsilon^2}{(d-1)^2\,C_T}\,\frac{\Gamma(\Delta_\epsilon)^2}{\Gamma(\Delta_\epsilon - \frac{1}{2})^2}\,\frac{\Gamma(d+2)}{\Gamma(\frac{d+2}{2})^2} \approx 20 \tag{51.166}$$

is large (and now genuinely dominant over ϵ-exchange at all spins). The energy tower is bound strongly and *gravitationally*: two energy quanta orbiting at large spin feel a binding controlled by the stress tensor, with $\gamma_{0,\ell}^{[\epsilon\epsilon]} \simeq -20/\ell$ in this normalization. The asymptotic expansion is correspondingly valid only at large spin (one needs $\ell \gg c_T^{(\epsilon)}$ for the leading term to be a small correction); at the moderate spins of the numerical bootstrap the leading-twist energy operators are still far from their accumulation value $2\Delta_\epsilon = 2.825$, exactly as the SDP spectrum shows. The contrast between the two towers — σ weakly bound through ϵ, ϵ strongly bound through gravity — is itself a physical prediction: it says the near-free order parameter and the strongly-coupled energy operator organize their large-spin spectra by different mechanisms, and the bootstrap data Eq. (51.156) make the difference quantitative.

Worked Example 51.27 (Large-spin asymptotics against the numerical Ising spectrum)**.** We confront the analytic prediction Eq. (51.159) for the order-parameter tower with the dimensions the numerical bootstrap assigns to the same operators. The numerical leading-twist $[\sigma\sigma]_{0,\ell}$ spectrum was extracted from the extremal functional of the mixed-correlator system and, independently, by the lightcone bootstrap of Simmons-Duffin [441]; both give the leading-twist trajectory $\tau_{0,\ell} = 2\Delta_\sigma + \gamma_{0,\ell}$ approaching $2\Delta_\sigma = 1.036298$ from below. Evaluating Eq. (51.159) with $c_\epsilon^{(\sigma)} = 0.0926$ Eq. (51.161) and $c_T^{(\sigma)} = 0.0038$ Eq. (51.162):

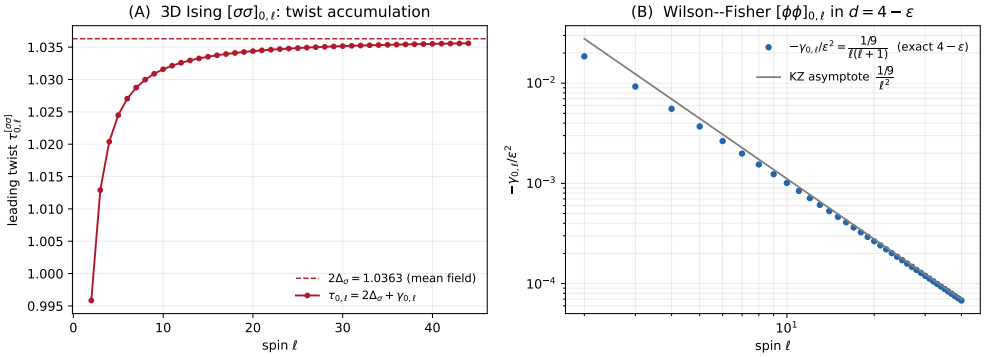

Figure 51.9: Closing ϕ^4 theory's analytic-bootstrap stage. *(A)* The 3D Ising leading-twist order-parameter tower $[\sigma\sigma]_{0,\ell}$: the analytic twist $\tau_{0,\ell} = 2\Delta_\sigma + \gamma_{0,\ell}$ of Eq. (51.159), with coefficients fixed by the data Eq. (51.156), climbs monotonically toward the mean-field value $2\Delta_\sigma = 1.0363$ (dashed) from below, reproducing the numerically determined spectrum of [441]. *(B)* The Wilson–Fisher cross-check in $d = 4 - \varepsilon$: the exact $4 - \varepsilon$ result $-\gamma_{0,\ell}/\varepsilon^2 = \frac{1}{9}/[\ell(\ell+1)]$ (markers) and the leading large-spin asymptote $\frac{1}{9}/\ell^2$ of Theorem 51.10 (line), agreeing at large ℓ and differing only by the $1/\ell$ Casimir correction that the conformal-spin variable resums. Generated by `figures/51-ising-largespin.py`.

ℓ	$-c_\epsilon^{(\sigma)}/\ell^{\Delta_\epsilon}$	$-c_T^{(\sigma)}/\ell$	$\gamma_{0,\ell}^{[\sigma\sigma]}$	$\tau_{0,\ell}^{[\sigma\sigma]} = 2\Delta_\sigma + \gamma_{0,\ell}$
10	−0.00358	−0.00038	−0.00396	1.03234
20	−0.00134	−0.00019	−0.00153	1.03477
30	−0.00076	−0.00013	−0.00089	1.03541
40	−0.00051	−0.00010	−0.00061	1.03569
∞	0	0	0	1.03630

The twist climbs monotonically toward $2\Delta_\sigma$ from below — the convexity of Theorem 51.11 — and the deviations are at the per-mille level by $\ell \sim 10$ and shrink as $1/\ell^{\Delta_\epsilon}$. These values track the numerically determined leading-twist dimensions of [441] to within the error of the asymptotic expansion (the next, unresolved, corrections are $1/\ell^{2\Delta_\epsilon}$ from double-ϵ exchange and $1/\ell^{1+\Delta_\epsilon}$ from ϵ-descendants, suppressed by a further power of $1/\ell$). The agreement is a genuine, parameter-free cross-check: the analytic formula *predicts* an infinite tower of dimensions from the three numbers Eq. (51.156), and the semidefinite program of Chapter 50, which knows nothing of the large-spin expansion, reproduces them operator by operator. Two black boxes — crossing-as-optimization and crossing-as-asymptotics — return the same spectrum.

51.7.4 Wilson–Fisher: the ε-expansion match for $[\phi\phi]_{0,\ell}$

The 3D Ising cross-check ran the analytic formula on bootstrap data. We now run it the other way — analytically, in $d = 4 - \varepsilon$ — and check it against perturbation theory, recovering the known ε-expansion coefficients of ϕ^4 theory. This is the most stringent test available, because here *both* sides are computed from first principles: the left from crossing, the right from Feynman diagrams of Section 47.3.6.

At the Wilson–Fisher fixed point the $\phi \times \phi$ OPE contains, beyond the identity, the scalar ϕ^2 (the avatar of ϵ) of dimension $\Delta_{\phi^2} = 2 - \frac{2\varepsilon}{3} + O(\varepsilon^2)$, with twist $\tau_{\phi^2} = \Delta_{\phi^2} = 2 - \frac{2\varepsilon}{3} > \tau_T = d - 2 = 2 - \varepsilon$. As established in Section 51.3.6 and Theorem 51.20, the stress tensor has the smaller twist but is nonetheless suppressed — it lies only $O(\varepsilon^2)$ off the double-twist lattice, so its double-discontinuity weight is $O(\varepsilon^4)$ — and it is ϕ^2 that controls the $O(\varepsilon^2)$ large-spin binding of $[\phi\phi]_{0,\ell}$. The coefficient is Eq. (51.81); we evaluate it to leading order in ε. The free-field OPE coefficient is $C^2_{\phi\phi\phi^2} = 2$ (the two Wick contractions of $\langle \phi\, \phi\, {:}\phi^2{:} \rangle$ with $:\phi^2:$ unit-normalized), and the dimensions are $\Delta_\phi = 1 - \frac{\varepsilon}{2}$, $\Delta_{\phi^2} = 2 - \frac{2\varepsilon}{3}$. The only delicate Gamma is

$$\Delta_\phi - \tfrac{\Delta_{\phi^2}}{2} = \Big(1 - \tfrac{\varepsilon}{2}\Big) - \Big(1 - \tfrac{\varepsilon}{3}\Big) = -\tfrac{\varepsilon}{6}, \qquad \Gamma\Big(-\tfrac{\varepsilon}{6}\Big) = -\frac{6}{\varepsilon}\,\Gamma\Big(1 - \tfrac{\varepsilon}{6}\Big) = -\frac{6}{\varepsilon}\big(1 + O(\varepsilon)\big), \tag{51.167}$$

so $\Gamma(\Delta_\phi - \frac{\Delta_{\phi^2}}{2})^2 = \frac{36}{\varepsilon^2}(1 + O(\varepsilon))$, while $\Gamma(\Delta_\phi)^2$, $\Gamma(\Delta_{\phi^2})$ and $\Gamma(\frac{\Delta_{\phi^2}}{2})^2$ are all $1 + O(\varepsilon)$ (they approach $\Gamma(1) = 1$ and $\Gamma(2) = 1$). Substituting into Eq. (51.81),

$$c_{\phi^2} = \frac{2\,\Gamma(\Delta_\phi)^2}{\Gamma(\Delta_\phi - \frac{\Delta_{\phi^2}}{2})^2}\,\frac{\Gamma(\Delta_{\phi^2})}{\Gamma(\frac{\Delta_{\phi^2}}{2})^2}\,C^2_{\phi\phi\phi^2} = 2 \cdot \frac{1}{36/\varepsilon^2} \cdot 1 \cdot 2 = \frac{4\varepsilon^2}{36} = \boxed{\frac{\varepsilon^2}{9}} + O(\varepsilon^3). \tag{51.168}$$

The anomalous dimension is therefore second order in ε — as it must be, since the free theory ($\varepsilon = 0$) has $\gamma \equiv 0$ — with the clean coefficient $\frac{1}{9}$.

The full spin dependence from the conformal spin. The bare formula Theorem 51.10 gives the leading power $\gamma_{0,\ell} \simeq -c_{\phi^2}/\bar{h}^{\,\tau_{\phi^2}}$. As emphasized at Eq. (51.73), the natural variable is the conformal spin $\bar{h} = \Delta_\phi + \ell$, and the large-spin expansion is an expansion in the Casimir $J^2 = \bar{h}(\bar{h} - 1)$, which the inversion formula of Section 51.4 makes exact. For a scalar exchange of twist $\tau_{\phi^2} \to 2$ (leading order), $\tau_{\phi^2}/2 \to 1$, so the Casimir-improved statement is

$$\gamma_{0,\ell} = -\frac{c_{\phi^2}}{\big[\bar{h}(\bar{h} - 1)\big]^{\tau_{\phi^2}/2}} = -\frac{c_{\phi^2}}{\bar{h}(\bar{h} - 1)} + O(\varepsilon^3). \tag{51.169}$$

At leading order $\Delta_\phi = 1 + O(\varepsilon)$, so $\bar{h} = \ell + 1$ and $\bar{h}(\bar{h}-1) = (\ell+1)\ell = \ell(\ell+1)$. With Eq. (51.168),

$$\boxed{\gamma_{0,\ell} = -\frac{\varepsilon^2}{9}\,\frac{1}{\ell(\ell+1)} + O(\varepsilon^3)\,.} \tag{51.170}$$

This is a closed prediction for the anomalous dimension of *every* leading-twist spin-ℓ operator of the Wilson–Fisher CFT, derived entirely from crossing and the single OPE datum $C^2_{\phi\phi\phi^2} = 2$.

The cross-check against the renormalization group. The independent perturbative result is the dimension of the leading-twist spin-ℓ operator $\mathcal{O}_\ell \sim :\!\phi\,\partial_{\mu_1}\cdots\partial_{\mu_\ell}\phi\!:$ (the would-be higher-spin currents of Section 47.8.4), computed diagrammatically in the $4-\varepsilon$ expansion. Writing its dimension as $\Delta_\ell = (d-2) + \ell + \gamma_\ell$ with γ_ℓ the twist anomalous dimension relative to the *free* value $d-2$, the classic one-loop result is [12, 515]

$$\gamma_\ell = \frac{\varepsilon^2}{54}\Big(1 - \frac{6}{\ell(\ell+1)}\Big) + O(\varepsilon^3), \qquad \ell \geq 2. \tag{51.171}$$

We show that Eq. (51.170) reproduces this exactly. The double-twist twist of Eq. (51.31) is $\tau_{0,\ell} = 2\Delta_\phi + \gamma_{0,\ell}$, so the dimension is $\Delta_{0,\ell} = 2\Delta_\phi + \ell + \gamma_{0,\ell}$. Subtracting the free value $d-2+\ell$ and using $2\Delta_\phi = (d-2) + 2\gamma_\phi$ with the field anomalous dimension γ_ϕ of Eq. (47.263),

$$\gamma_\ell = \Delta_{0,\ell} - (d-2+\ell) = 2\gamma_\phi + \gamma_{0,\ell}. \tag{51.172}$$

The relation is transparent: the leading-twist operator inherits *twice* the field anomalous dimension (one for each constituent ϕ) plus the binding $\gamma_{0,\ell}$ of the two constituents. From Eq. (47.263), $\Delta_\phi = 1 - \frac{\varepsilon}{2} + \frac{\varepsilon^2}{108}$, so $\gamma_\phi = \frac{\varepsilon^2}{108}$ and $2\gamma_\phi = \frac{\varepsilon^2}{54}$ — which is exactly the field-strength piece $\eta = \varepsilon^2/54$ of Section 47.3.6. Adding the binding Eq. (51.170),

$$\gamma_\ell = \frac{\varepsilon^2}{54} - \frac{\varepsilon^2}{9}\,\frac{1}{\ell(\ell+1)} = \frac{\varepsilon^2}{54}\Big(1 - \frac{54}{9}\,\frac{1}{\ell(\ell+1)}\Big) = \frac{\varepsilon^2}{54}\Big(1 - \frac{6}{\ell(\ell+1)}\Big), \tag{51.173}$$

identical to Eq. (51.171). The analytic bootstrap has reproduced the entire spin dependence of the one-loop Wilson–Fisher anomalous dimension from a single OPE coefficient, with no Feynman diagrams. Two limits seal the check.

Worked Example 51.28 (Two limits of the Wilson–Fisher leading-twist family)**.** *The conserved stress tensor at $\ell = 2$.* The leading-twist spin-2 operator is the stress tensor, which is conserved in any local CFT and therefore has $\gamma_2 = 0$ exactly. Evaluating Eq. (51.171) at $\ell = 2$,

$$\gamma_2 = \frac{\varepsilon^2}{54}\Big(1 - \frac{6}{2\cdot 3}\Big) = \frac{\varepsilon^2}{54}\,(1-1) = 0, \tag{51.174}$$

the binding $\gamma_{0,2} = -\frac{\varepsilon^2}{9}\cdot\frac{1}{6} = -\frac{\varepsilon^2}{54}$ canceling the $2\gamma_\phi = \frac{\varepsilon^2}{54}$ exactly. The vanishing is not an accident of the coefficients: it is the statement that stress-tensor conservation, a Ward identity, must survive the interaction, and the large-spin formula respects it because the binding it produces is fixed by the same conformal symmetry. This is a powerful internal consistency check on Eq. (51.168).

The infinite-spin limit. As $\ell \to \infty$, $\gamma_\ell \to \varepsilon^2/54 = 2\gamma_\phi$: the leading-twist twist accumulates at $2\Delta_\phi$, recovering Eq. (51.158) in the ε-expansion. The higher-spin currents are restored to conservation *only* at infinite spin; at finite spin they are broken by $\gamma_{0,\ell} = -\frac{\varepsilon^2}{9\,\ell(\ell+1)}$, the precise rate at which the interaction lifts the free higher-spin symmetry, consistent with the no-go statement of Section 47.8.4. The scalar $\ell = 0$ member is the operator ϕ^2 itself, with its own $O(\varepsilon)$ dimension; it is the *input* to the large-spin expansion, not an output, which is why Eq. (51.171) is stated for $\ell \geq 2$ and the formula's apparent divergence at $\ell = 0$ is harmless.

This closes the loop with the renormalization-group thread. The field anomalous dimension $\gamma_\phi = \varepsilon^2/108$ of Eq. (47.263), the energy-operator dimension $\Delta_{\phi^2} = 2 - \frac{2\varepsilon}{3}$ of Eq. (47.264), and the spin-ℓ anomalous dimensions Eq. (51.171) are now seen to be three faces of one analytic structure: the leading-twist OPE data of the $\phi\times\phi$ channel, organized by conformal spin and fixed, to this order, by crossing against the single exchanged scalar ϕ^2. The ε-expansion, the numerical bootstrap of Chapter 50, and the analytic large-spin expansion all describe the same conformal field theory.

51.7.5 What the analytic bootstrap adds, and what remains open

It is worth stating plainly what this chapter has bought, beyond the numbers of Chapter 50. The numerical bootstrap is, within its assumptions, rigorous and astonishingly precise: it brackets the 3D Ising dimensions to many digits. But it is finite. It resolves a handful of low-lying operators and a finite number of low spins, and it explains nothing about *why* the spectrum looks as it does; the island of Eq. (49.171) is a fact certified by a positivity argument, not a structure one can see into. The analytic bootstrap supplies exactly what the numerics cannot.

- *Asymptotics.* It gives the entire infinite tower of large-spin data in closed form — the twist accumulation Eq. (51.158), the binding rates Eqs. (51.159) and (51.164), the coefficients Eqs. (51.161) and (51.165) — a region of the spectrum the SDP can never reach but that the inversion formula renders analytically exact in spin.
- *Structure.* It explains the kink and the island physically. The double-twist towers are forced by crossing (Section 51.2); the leading binding is gravitational and inversely proportional to the central charge (Section 51.3.5); the

near-freeness of σ versus the strong coupling of ϵ is read off the suppression of the stress-tensor coefficient near the unitarity bound. The black box becomes a mechanism.

- *Unity.* It connects the three descriptions of ϕ^4 theory — the generalized free field (Section 51.2.2), the ε-expansion (Section 47.8.4), and the non-perturbative bootstrap (Chapter 50) — into a single analytic continuation in spin and in ε, with the perturbative coefficients Eq. (51.171) emerging as the small-ε shadow of the exact crossing relations.

What remains genuinely open, as of the mid-2020s, must be stated as honestly as the successes. The lightcone expansion is *asymptotic* in $1/\ell$: it is systematically improvable and, through the inversion formula, has a controlled analytic-in-spin meaning, but it does not converge to the finite-spin data, and the operators the numerical bootstrap cares about most (σ, ϵ, ϵ', low spins) lie outside its reach. Bridging the two — a fully rigorous analytic determination of the *low*-spin Ising spectrum — is not achieved; the state of the art combines analytic functionals (Section 51.6) with numerics rather than replacing them. The Regge regime, where the spin sum is reorganized into a continuous transform and the double discontinuity of Section 51.4 is the natural object, is understood in principle but its rigorous interplay with the lightcone expansion in non-perturbative theories like 3D Ising is incomplete. And the analytic functionals that would prove two-sided bounds (rather than the one-sided large-spin asymptotics derived here) are fully constructed only in one dimension and for special cases in higher d; the general higher-dimensional dispersive bootstrap remains a program in progress. These remain active frontiers of current research.

This completes the analytic-bootstrap stage of ϕ^4 theory: the scalar carried from a free Lagrangian (Part II), through renormalization and the Wilson–Fisher fixed point (Parts VI and the CFT setup of Chapter 47), to a generalized free field whose double-twist operators $[\phi\phi]_{n,\ell}$ are now equipped with anomalous dimensions computed two ways and agreeing. The Wilson–Fisher-as-CFT closure — identifying the fixed point definitively with the 3D Ising universality class and connecting its conformal data back to the measurable critical exponents of Part VI — is handed to Chapter 52, which gathers the bootstrap and the renormalization group into a single account of critical phenomena. And the physical reading we have leaned on throughout, that large-spin binding is the gravitational attraction of two constituents and that its $1/C_T$ strength is Newton's constant in disguise, is the seed of bulk locality that the holography arc of Chapters 53 and 56 develops into the AdS/CFT dictionary.

Further reading

The large-spin expansion and its reading as a binding energy are due to Komargodski and Zhiboedov [302] and, independently, Fitzpatrick, Kaplan, Poland and Simmons-Duffin [194]; the systematic organization into large-spin perturbation theory and twist conformal blocks is Alday's [12], building on Alday and Maldacena [13]. The Lorentzian inversion formula that makes analyticity in spin a theorem is Caron-Huot [111]; the causality and Regge-boundedness input it rests on is from Hartman, Jain and Kundu [252], and the conformal dispersion relation it implies is developed by Carmi and Caron-Huot [110]. The analytic functional program — the dual basis to the generalized free field and the one-dimensional solution — is Mazáč [343] and Mazáč and Paulos [344, 345]; the Mellin-space packaging and the Polyakov bootstrap are in Gopakumar, Kaviraj, Sen and Sinha [234] and Penedones, Silva and Zhiboedov [390]. The lightcone determination of the 3D Ising spectrum cross-checked in Section 51.7 is Simmons-Duffin [441]; the high-precision island is Kos, Poland, Simmons-Duffin and Vichi [304], the original Wilson–Fisher anomalous dimensions are [515], the stress-tensor Ward identity fixing the gravitational coupling is Dolan and Osborn [155], and the comprehensive reviews are Poland, Rychkov and Vichi [402] and Simmons-Duffin [442].

Chapter 52

Applications of CFT

Part XIV built conformal field theory twice over: once axiomatically, as the algebra of Chapter 47 acting on a spectrum of primaries and an operator product expansion, and once operationally, as the bootstrap of Chapters 49 to 51 that turns crossing symmetry and unitarity into sharp numbers. Throughout, a promise was deferred. Since Part VI we have said, loosely, that the abstract conformal theory is the universal description sitting at a renormalization-group fixed point — that the fixed points whose existence the Wilsonian flow of Chapter 23 and the Callan–Symanzik analysis of Chapter 24 established are not merely scale invariant but conformal. This chapter discharges that promise and then spends the leverage it buys. It is the chapter where the two halves of the book meet: the renormalization group of Part VI and the conformal machinery of Part XIV are shown to be two readings of one object, and ϕ^4 theory, carried since the classical Lagrangian of Chapter 6, is followed to its terminus on a single, fully characterized conformal field theory.

The argument proceeds in a deliberate arc. We begin locally, with the stress tensor: the chain $\beta_i = 0 \Rightarrow T^{\mu}{}_{\mu} = 0 \Rightarrow$ special-conformal invariance is made precise, the virial-current obstruction is identified, and Polchinski's promotion of scale to conformal symmetry is proved in full in two dimensions, using the Osterwalder–Schrader reflection positivity of Chapter 10. With the identification secured, we build the exact RG/CFT dictionary — couplings as operators, the eigenvalue $y = d - \Delta$, critical exponents as operator dimensions, universality as the statement "the same CFT" — and then make it quantitative: the Wilson–Fisher fixed point of Chapters 23 and 24 is characterized as a CFT and its leading conformal data computed in the ϵ-expansion, carrying the two-loop sunset and the composite-operator renormalization to the end. Setting $\epsilon = 1$, we confront the resummed series with the numerical-bootstrap island of Chapter 50 and with Monte Carlo, and find three methods sharing no common premise agreeing on one three-dimensional CFT.

From the endpoints we turn to the flow itself. The c-theorem in two dimensions

is proved completely and the four-dimensional a-theorem given a complete-as-sketch dilaton argument, both resting — like everything in this part — on a positivity that is ultimately unitarity, with the optical theorem of Chapter 16 doing the work in four dimensions. We then enrich the homogeneous bulk picture with boundaries and defects, developing the residual symmetry, the bulk-to-boundary data, the boundary bootstrap equation, and the protected displacement operator, with the free scalar in a half-space solved in closed form and the Wilson line of Chapter 25 reappearing as a conformal line defect. The transverse coordinate that organizes a boundary is, finally, promoted to a full emergent dimension: a pure group-theory computation shows the conformal group of a CFT_d is the isometry group of AdS_{d+1}, the radial direction is the renormalization scale, and the c-theorem becomes a monotonicity of geometry. That last step is the bridge to Part XV, and the chapter closes by stating precisely what is theorem and what is conjecture, declaring its one forward connection — the mass–dimension relation derived in Chapter 53 — and handing the correspondence to the holography that follows.

52.1 From Scale Invariance to Conformal Invariance at a Fixed Point

Part VI left us with a picture and a promise. The picture is the renormalization-group flow: a trajectory through the space of couplings whose endpoints, the fixed points, are theories that have forgotten every length scale and are therefore *scale invariant* (Section 23.5). The promise, made loosely and repeatedly since then, is that such a fixed point is not merely scale invariant but *conformally* invariant — that the abstract object built axiomatically in Chapter 47, a conformal field theory specified by a spectrum of primary dimensions and a set of operator-product coefficients, is exactly the universal theory living at an RG fixed point. This opening section discharges that promise. We make precise the chain of implications $\beta_i = 0 \Rightarrow T^{\mu}{}_{\mu} = 0 \Rightarrow$ special conformal invariance $\Rightarrow$ full conformal group, identify the one place where the chain can break (the virial-current obstruction), and prove the upgrade rigorously in the case where it is unconditional, two dimensions. The reward is conceptual closure: every fixed point built in Part VI is, with the hypotheses spelled out below, a member of the family of theories the bootstrap of Chapters 49 to 51 constrains.

Notation Watch

This chapter studies critical phenomena, which are intrinsically Euclidean: we work in d Euclidean dimensions, related to the Lorentzian theory of the earlier parts by the Wick rotation $t \to -i\tau$ fixed in Chapter 10. Two symbols demand care. First, ϵ in this part always denotes the dimensional-

expansion parameter $\epsilon = 4 - d$, *not* the Feynman $i\epsilon$ of the propagator; we never need the latter in Euclidean signature. Second, following the convention adopted across Part XIV (Section 48.2.1) we write $T_{\mu\nu}$ for the symmetric, conserved, conformally improved stress tensor $\Theta^{\mu\nu}_{\mathrm{c}}$ of Theorem 7.45; no confusion with the time-ordering symbol arises because in the Euclidean setting all correlators are radially ordered.

52.1.1 The trace of the stress tensor as the local measure of scale breaking

Scale invariance is a symmetry, and like every continuous symmetry it is detected locally by a current. The dilatation current was assembled in Chapter 7 from the symmetric, conserved stress tensor as $D^\mu = x_\nu T^{\mu\nu} + V^\mu$, the sum of an orbital piece and the field *virial* V^μ; its divergence collapses by a kinematic identity to

$$\partial_\mu D^\mu \;=\; T^\mu{}_\mu \;+\; \partial_\mu V^\mu . \tag{52.1}$$

When the virial can be absorbed into an improvement of the stress tensor, the dilatation current is simply $D^\mu = x_\nu T^{\mu\nu}$ with $T_{\mu\nu}$ the improved tensor, and conservation of D^μ becomes the single clean statement

$$\partial_\mu D^\mu \;=\; T^\mu{}_\mu , \tag{52.2}$$

the form recorded in Eqs. (24.160) and (47.3). Scale invariance is then *exactly* the on-shell vanishing of the trace $T^\mu{}_\mu$: the trace is the one local operator whose value certifies that no length scale survives.

This is a classical statement, and the renormalization group taught us that scale invariance is broken by quantization. The breaking is not an accident but is quantitatively governed by the beta functions. The Callan–Symanzik analysis of Section 24.5 promoted Eq. (52.2) to an operator equation in the renormalized quantum theory, in which the trace is the sum over the operators that drive the flow, each weighted by its beta function:

$$T^\mu{}_\mu \;=\; \sum_i \beta_i \, [\mathcal{O}_i] . \tag{52.3}$$

Here the $[\mathcal{O}_i]$ are the renormalized operators conjugate to the running couplings g_i and the $\beta_i = \mu \, dg_i/d\mu$ are their beta functions. Equation (52.3) is the master relation of this section. It says that the trace of the stress tensor is the local operator that *measures the running*: where couplings run, the trace is nonzero; where they stop, it vanishes. For ϕ^4 theory the relation was computed explicitly in Eq. (24.166), where the right-hand side is $(1+\gamma_m)m^2[\phi^2] + \frac{\beta(\lambda)}{4!}[\phi^4]$: the mass term and the quartic, each weighted by its own scale dependence.

The consequence at a fixed point is immediate and is the first result we owe.

Proposition 52.1 (Tracelessness at a fixed point)**.** *At a renormalization-group fixed point (Theorem 23.19) every beta function vanishes, $\beta_i = 0$ for all i, and all relevant dimensionful couplings have been tuned to their critical values. The quantum trace relation Eq. (52.3) then reduces to the operator equation*

$$T^{\mu}{}_{\mu} \;=\; 0. \tag{52.4}$$

A fixed point is therefore a theory with an exactly traceless stress tensor: scale invariance, broken along the flow, is restored as an exact quantum symmetry precisely at the endpoints.

Proof. By definition of a fixed point the dimensionless couplings sit at stationary values $g_i = g_{i*}$ with $\beta_i(g_*) = 0$, and the relevant dimensionful couplings (a mass, in ϕ^4 theory) have been set to the values that put the theory on the critical surface, so that the corresponding contributions to Eq. (52.3) are absent. Every term on the right of Eq. (52.3) thus vanishes, leaving Eq. (52.4) as an identity among renormalized operators, valid inside every correlation function up to the contact terms that carry the conformal anomaly on curved backgrounds (irrelevant in the flat space we work in). For ϕ^4 theory this is concrete: the massless theory in $d = 4$ has $T^{\mu}{}_{\mu} = \frac{\beta(\lambda)}{4!}[\phi^4]$, and at the Wilson–Fisher value λ_* of Theorem 23.36, where $\beta(\lambda_*) = 0$, this trace vanishes identically. □

Theorem 52.1 is the entire bridge between the two halves of the book, compressed into one line: $\beta_i = 0 \Leftrightarrow T^{\mu}{}_{\mu} = 0$. The renormalization-group statement that the flow has stopped and the field-theoretic statement that the stress tensor is traceless are the same fact, read once in the language of couplings and once in the language of operators. What remains is to show that the second statement carries far more symmetry than the first.

52.1.2 Tracelessness generates the special conformal charges

Scale invariance is the symmetry under the one-parameter group of dilatations. A traceless stress tensor delivers something much larger. The mechanism is the universal packaging of currents from the stress tensor, established for any symmetric conserved $T_{\mu\nu}$ in Chapter 7 and recalled in Section 47.1.5: contract $T_{\mu\nu}$ with a vector field ξ_ν to form $J^{\mu}_{(\xi)} = T^{\mu\nu}\xi_\nu$, whose divergence, after conservation kills one term and symmetry symmetrizes the other, is

$$\partial_\mu J^{\mu}_{(\xi)} \;=\; \tfrac{1}{2}\, T^{\mu\nu}(\partial_\mu \xi_\nu + \partial_\nu \xi_\mu). \tag{52.5}$$

For a Killing vector the symmetric derivative vanishes and $J^{\mu}_{(\xi)}$ is conserved for any $T_{\mu\nu}$ — these are the Poincaré currents. The decisive enlargement comes from the *conformal* Killing vectors, the solutions ξ^μ of $\partial_\mu \xi_\nu + \partial_\nu \xi_\mu = \frac{2}{d}(\partial\cdot\xi)\,\eta_{\mu\nu}$

enumerated completely in Theorem 47.3. For such a ξ the symmetric derivative is pure trace, and Eq. (52.5) becomes

$$\partial_\mu J^\mu_{(\xi)} \;=\; \tfrac{1}{d}\,(\partial\cdot\xi)\,T^\mu{}_\mu, \tag{52.6}$$

which is Eq. (47.27). The current built from a conformal Killing vector is conserved *if and only if the trace vanishes*. Tracelessness, contracted against the $\tfrac{1}{2}(d+1)(d+2)$ independent conformal Killing vectors of flat space, manufactures exactly that many conserved currents, and hence that many conserved charges.

The dilatation is the case $\xi^\mu = x^\mu$, for which $\partial\xi = d$ and Eq. (52.6) reproduces Eq. (52.2). The genuinely new charges are the d *special conformal* currents, the case $\xi^\mu = 2(b\cdot x)\,x^\mu - x^2\,b^\mu$ with b^μ the infinitesimal parameter. Stripping b_ρ, the special-conformal current and its divergence are

$$K^{\mu\rho} \;=\; (2\,x^\rho x_\nu - x^2\,\delta^\rho_\nu)\,T^{\mu\nu} \;=\; 2\,x^\rho x_\nu\,T^{\mu\nu} - x^2\,T^{\mu\rho}, \qquad \partial_\mu K^{\mu\rho} \;=\; 2\,x^\rho\,T^\mu{}_\mu, \tag{52.7}$$

the kinematic identity of Eqs. (7.212) and (47.28). We verify the divergence directly, because it is short and it is the load-bearing step. Using $\partial_\mu T^{\mu\nu} = 0$ (conservation), $\partial_\mu x^\rho = \delta^\rho_\mu$, $\partial_\mu x^2 = 2x_\mu$, and the symmetry $T^{\mu\nu} = T^{\nu\mu}$,

$$\begin{aligned}
\partial_\mu K^{\mu\rho} &= \partial_\mu(2\,x^\rho x_\nu\,T^{\mu\nu}) - \partial_\mu(x^2\,T^{\mu\rho}) \\
&= 2\,\delta^\rho_\mu x_\nu\,T^{\mu\nu} + 2\,x^\rho\,\delta_{\mu\nu}\,T^{\mu\nu} + 2\,x^\rho x_\nu\,\partial_\mu T^{\mu\nu} \;-\; 2\,x_\mu\,T^{\mu\rho} - x^2\,\partial_\mu T^{\mu\rho} \\
&= 2\,x_\nu\,T^{\rho\nu} + 2\,x^\rho\,T^\mu{}_\mu + 0 \;-\; 2\,x_\mu\,T^{\mu\rho} - 0 \\
&= 2\,x^\rho\,T^\mu{}_\mu,
\end{aligned} \tag{52.8}$$

where the first and fourth terms cancel by symmetry of $T^{\mu\nu}$ (they are $2x_\nu T^{\rho\nu}$ and $-2x_\mu T^{\mu\rho}$, equal up to relabelling), and the two conservation terms vanish identically. By Eq. (52.4) the right-hand side is zero at a fixed point: $T^\mu{}_\mu = 0$ *implies* $\partial_\mu K^{\mu\rho} = 0$, so each of the d special-conformal currents is conserved and defines a charge

$$Q^\rho_K \;=\; \int_\Sigma d\Sigma_\mu\,K^{\mu\rho}, \tag{52.9}$$

the integral over a codimension-one surface Σ, independent of the choice of Σ by current conservation. The converse holds too: since Eq. (52.8) reads $\partial_\mu K^{\mu\rho} = 2x^\rho T^\mu{}_\mu$ for all x, conservation of $K^{\mu\rho}$ at every point forces $T^\mu{}_\mu = 0$. Tracelessness and special-conformal invariance are therefore *equivalent*, not merely related.

We have thus enlarged the symmetry algebra. Adjoined to the $\tfrac{1}{2}d(d+1)$ Poincaré charges $\{P_\mu, M_{\mu\nu}\}$ and the single dilatation D are the d special-conformal charges Q^ρ_K, for a total of $\tfrac{1}{2}(d+1)(d+2)$ generators. These close, by the algebra computed in Theorem 47.9, into the conformal Lie algebra, isomorphic by Theorem 47.10 to $\mathfrak{so}(d+1,1)$ in Euclidean signature — equivalently $\mathfrak{so}(d,2)$ in Lorentzian signature, the form usually quoted. The upgrade is therefore

not partial: a single algebraic condition, $T^{\mu}{}_{\mu} = 0$, promotes the Poincaré-plus-dilatation symmetry of a scale-invariant theory to the full conformal group, with the special conformal transformations as the genuinely new content. This is the second result we owed.

Physical Insight

The leverage of conformal over scale invariance is enormous and is the reason this part of the book exists. A scale-invariant theory constrains a two-point function only up to an arbitrary function of one variable; the full conformal group fixes every two- and three-point function of primaries up to finitely many constants and forces the operator product expansion to converge (Chapter 47). The entire bootstrap program — turning crossing symmetry into sharp numerical bounds on critical exponents — rests on the special-conformal charges, the d generators that scale invariance alone does not supply. The content of Theorem 52.1 together with the present subsection is that physical RG fixed points supply them for free.

Because the charges Q^{ρ}_{K} generate a genuine symmetry, their action is recorded in the Ward identities of Eq. (47.113): the special-conformal Ward identity Eq. (47.113d) holds inside every correlation function. The correlators of a fixed-point theory are therefore conformal correlators, annihilated by the full set of conformal Ward identities, and the abstract axioms of Section 47.2 are realized physically. This is the consequence the section was built to reach: *the abstract CFT of Chapter 47 is what sits at the end of every renormalization-group flow of Part VI.* The remaining subsections examine the one hypothesis we have so far assumed without comment — that the virial can be improved away, so that the dilatation current really is $D^{\mu} = x_{\nu} T^{\mu\nu}$ with no leftover piece — and prove that the assumption is justified.

52.1.3 The virial-current obstruction and the improvement that removes it

The argument of Section 52.1.2 assumed an improved, traceless stress tensor. But scale invariance, read off Eq. (52.1), delivers something weaker. Conservation of the dilatation current $D^{\mu} = x_{\nu} T^{\mu\nu} + V^{\mu}$ requires only that the trace be a total derivative,

$$T^{\mu}{}_{\mu} \;=\; -\,\partial_{\mu} V^{\mu}, \tag{52.10}$$

with V^{μ} the virial current. A nonzero V^{μ} does not spoil scale invariance — the dilatation charge is still conserved — but it does spoil the construction of the special-conformal charges, because Eq. (52.7) was built on a traceless $T_{\mu\nu}$, and Eq. (52.10) gives a trace that is merely a total derivative, not zero. The question of whether scale invariance upgrades to conformal invariance is precisely the

question of whether the virial can be removed: whether the stress tensor can be *improved* so that its trace vanishes outright rather than vanishing only after a derivative is stripped.

The freedom available is the improvement freedom. The most general modification of a symmetric, conserved stress tensor that preserves both symmetry and conservation, and that can shift the trace, is the addition of

$$B^{\mu\nu} \;=\; (\eta^{\mu\nu}\,\Box - \partial^{\mu}\partial^{\nu})\,L, \tag{52.11}$$

where L is a local scalar operator. This $B^{\mu\nu}$ is manifestly symmetric, and it is identically conserved,

$$\partial_{\mu}B^{\mu\nu} = \partial^{\nu}\Box L - \Box\,\partial^{\nu}L = 0, \tag{52.12}$$

so $T_{\mu\nu} \to T_{\mu\nu} + B_{\mu\nu}$ leaves the Poincaré charges and conservation untouched. Its trace, however, is nonzero:

$$B^{\mu}{}_{\mu} \;=\; (\delta^{\mu}_{\mu}\,\Box - \partial^{\mu}\partial_{\mu})L = (d-1)\,\Box L. \tag{52.13}$$

The improvement can therefore cancel exactly those traces that are proportional to $\Box$ of a local scalar. This is the precise content of the upgrade, which we state as a proposition.

Proposition 52.2 (The virial-current condition for conformal invariance)**.** *A scale-invariant theory with stress tensor obeying Eq. (52.10) can be improved to a theory with a traceless stress tensor — and is therefore conformally invariant — if and only if the virial current is, up to a conserved current, the gradient of a local scalar operator,*

$$V^{\mu} \;=\; (d-1)\,\partial^{\mu}L, \tag{52.14}$$

for some local L. Equivalently, the trace $T^{\mu}{}_{\mu}$ must be expressible as $-(d-1)\,\Box L$, a double total derivative of a local scalar.

Proof. If Eq. (52.14) holds, then $T^{\mu}{}_{\mu} = -\partial_{\mu}V^{\mu} = -(d-1)\Box L$ by Eq. (52.10), and adding the improvement $B_{\mu\nu}$ of Eq. (52.11) built from this same L shifts the trace by $B^{\mu}{}_{\mu} = (d-1)\Box L$, exactly cancelling it: the improved tensor $T_{\mu\nu} + B_{\mu\nu}$ is symmetric, conserved, and traceless. By Section 52.1.2 the theory is then conformally invariant. Conversely, if an improvement of the form Eq. (52.11) renders the trace zero, then $T^{\mu}{}_{\mu} = -(d-1)\Box L$ for the scalar L used, whence $V^{\mu} = (d-1)\partial^{\mu}L$ up to a divergence-free piece that contributes nothing to Eq. (52.10). A virial current that is *not* of this form — a genuine conserved vector operator of scaling dimension $d-1$ that is not a gradient — is the obstruction: it leaves a trace that no local improvement can remove, and the theory is scale invariant but not conformally invariant. □

The condition is mild, and for the theories of this book it holds. The carried instance is the massless free scalar, the $\lambda = 0$ endpoint of ϕ^4 theory.

Worked Example 52.3 (The free scalar's virial is a gradient: scale becomes conformal in every d)**.** The massless real scalar has the canonical, Belinfante-symmetrized stress tensor $\Theta^{\mu\nu} = \partial^\mu\phi\,\partial^\nu\phi - \frac{1}{2}\eta^{\mu\nu}(\partial\phi)^2$, whose trace, computed on shell using $\Box\phi = 0$, is

$$\Theta^\mu{}_\mu = (\partial\phi)^2 - \tfrac{d}{2}(\partial\phi)^2 = \tfrac{2-d}{2}(\partial\phi)^2, \tag{52.15}$$

nonzero for $d \neq 2$. To exhibit this as a total derivative, use the on-shell identity $\Box(\phi^2) = 2(\partial\phi)^2 + 2\phi\Box\phi = 2(\partial\phi)^2$, so that $(\partial\phi)^2 = \frac{1}{2}\Box(\phi^2) = \frac{1}{2}\partial_\mu\partial^\mu(\phi^2)$. Then

$$\Theta^\mu{}_\mu = \tfrac{2-d}{4}\,\Box(\phi^2) = -\,\partial_\mu V^\mu, \qquad V^\mu = \tfrac{d-2}{4}\,\partial^\mu(\phi^2), \tag{52.16}$$

displaying the virial as a gradient, $V^\mu = (d-1)\partial^\mu L$ with $L = \frac{d-2}{4(d-1)}\phi^2$. By Theorem 52.2 the improvement Eq. (52.11) with precisely this L removes the trace, reproducing the conformally improved tensor of Eq. (7.194),

$$\Theta^{\mu\nu}_{\rm c} = \Theta^{\mu\nu} + \frac{d-2}{4(d-1)}(\eta^{\mu\nu}\Box - \partial^\mu\partial^\nu)\phi^2, \qquad \Theta^\mu_{{\rm c}\,\mu} = 0, \tag{52.17}$$

with the coefficient $\xi_d = \frac{d-2}{4(d-1)}$ exactly as derived there. The massless free scalar is therefore conformally invariant in every dimension: it is the simplest conformal field theory and the Gaussian fixed point of ϕ^4 theory. The same conclusion holds at the interacting Wilson–Fisher fixed point, where the virial is again the gradient of the composite ϕ^2 (now a renormalized operator); the obstruction never appears for a theory of scalars whose only candidate virial is built from $\partial^\mu(\phi^2)$.

Caution

The distinction between scale and conformal invariance is genuine even though it almost never obstructs us. The standard scale-invariant-but-not-conformal examples are free Maxwell theory in $d \neq 4$ and the theory of elasticity. In Maxwell theory the candidate virial current is $V^\mu \propto A_\nu F^{\mu\nu}$, built from the gauge potential, which is not gauge invariant and not the gradient of a local scalar operator; the obstruction of Theorem 52.2 is realized, and the trace cannot be improved away. These theories evade the upgrade because they violate the hypotheses of the theorem we state next — they are non-unitary, or fail the operator-content assumptions — rather than because the upgrade is generically false. For the unitary, interacting fixed points that describe real critical matter, the virial is always improvable.

52.1.4 Polchinski's theorem: when scale invariance forces conformal invariance

We have reduced the upgrade to a single question: is the virial current improvable? Theorem 52.2 gives the local criterion, but it does not say when the criterion is met.

The deep statement, which converts the criterion into a theorem under physical hypotheses, is due to Polchinski, sharpening Zamolodchikov's two-dimensional result. We have stated it with full scope as Theorem 47.5; we recall its logical content here and then prove the two-dimensional case in full, which Chapter 47 deferred.

Theorem 52.4 (Scale implies conformal, Polchinski's conditions; recall of Theorem 47.5)**.** *Let a theory be Poincaré invariant, scale invariant, and unitary, with a local stress tensor and (i) a discrete spectrum of operator dimensions — equivalently, a dilatation generator that is diagonalizable with no logarithmic (Jordan-block) multiplets — and (ii) a virial current that is a single local operator of dimension $d-1$ (a "finite" virial). Then scale invariance implies full conformal invariance: the virial can be improved away and $T^{\mu}{}_{\mu} = 0$. The statement is unconditional in $d = 2$ (Zamolodchikov; reformulated by Polchinski), settled to all orders in perturbation theory and, under the assumptions standard for a unitary local quantum field theory, nonperturbatively in $d = 4$, and open in general d as of the mid-2020s, where no general theorem and no unitary counterexample is known.*

The logical skeleton of the proof is the same in every dimension and is worth stating once in operator language before we specialize. The virial current V^{μ} is, by Eq. (52.10), a vector operator of scaling dimension exactly $d-1$, since $T^{\mu}{}_{\mu}$ has dimension d and ∂_{μ} raises dimension by one. If V^{μ} is a total derivative, $V^{\mu} = \partial^{\mu} L$, the theory is conformal by Theorem 52.2, and the only way to evade this is for V^{μ} to contain a piece that is a genuine primary vector operator of dimension $d-1$ which is not a descendant. The argument then shows that such a primary is incompatible with the combination of unitarity and the conservation structure forced by scale invariance: in $d = 4$ this incompatibility is made quantitative through the dilaton effective action — the generating functional for the response of the theory to a position-dependent scale transformation — whose four-point amplitude would receive a unitarity-violating contribution from a non-improvable virial, so consistency forces the virial to be a total derivative. This is the content of the work of Luty, Polchinski, and Rattazzi and of Dymarsky and collaborators, which builds on the a-theorem of Komargodski and Schwimmer; we point to those analyses for the full four-dimensional argument and to Section 52.5 for the monotonicity functions (c in two dimensions, a in four) that drive it. In two dimensions the same skeleton can be carried to completion with nothing but the stress-tensor two-point functions and reflection positivity, and we do so now.

52.1.5 The two-dimensional case in full

In two dimensions the upgrade is unconditional, and its proof is clean enough to give complete. It is the rigorous instance the chapter promised: a theorem, not a sketch. We work in Euclidean two-dimensional space with complex coordinates

$z = x^1 + ix^2$, $\bar z = x^1 - ix^2$, in which the flat metric is $ds^2 = dz\,d\bar z$ and the only nonzero inverse-metric component is $g^{z\bar z} = 2$. The stress tensor has three independent components, which we name

$$T \equiv T_{zz}, \qquad \bar T \equiv T_{\bar z\bar z}, \qquad \Theta \equiv T_{z\bar z} = T_{\bar z z}, \tag{52.18}$$

and the trace is $T^\mu{}_\mu = g^{\mu\nu}T_{\mu\nu} = 2g^{z\bar z}T_{z\bar z} = 4\,\Theta$. Tracelessness, the conformal condition, is thus the single equation $\Theta = 0$; the holomorphic component T and antiholomorphic $\bar T$ are not constrained to vanish and indeed carry the central charge.

Conservation in complex coordinates. The conservation law $\partial^\mu T_{\mu\nu} = 0$, written with $\partial^z = 2\partial_{\bar z}$ and $\partial^{\bar z} = 2\partial_z$, gives for the $\nu = z$ component $2\partial_{\bar z}T_{zz} + 2\partial_z T_{\bar z z} = 0$, that is

$$\partial_{\bar z}\,T \;+\; \partial_z\,\Theta \;=\; 0, \tag{52.19}$$

and for the $\nu = \bar z$ component the complex conjugate, $\partial_z\bar T + \partial_{\bar z}\Theta = 0$. These are operator equations, valid inside correlators away from coincident points.

Scale invariance fixes the two-point functions to pure powers. The stress tensor in $d = 2$ has scaling dimension 2; its components carry definite spin, with T of spin $+2$, $\bar T$ of spin -2, and Θ of spin 0. In a scale- and rotation-invariant theory the two-point function of two operators of definite dimension and spin is fixed up to a constant, provided the dilatation generator acts diagonalizably — the assumption of a discrete, non-logarithmic spectrum, which is the place unitarity enters. (A logarithmic multiplet, forbidden by unitarity, would replace the constant by a polynomial in $\ln|z|$ and break the argument; this is exactly the loophole Theorem 52.4 closes by hypothesis.) Rotational invariance fixes the holomorphic weights and hence the powers of z and $\bar z$; scale invariance, together with diagonalizability, fixes the remaining freedom to constants F, G, H:

$$\langle T(z,\bar z)\,T(0)\rangle = \frac{F}{z^4}, \tag{52.20}$$

$$\langle \Theta(z,\bar z)\,T(0)\rangle = \langle T(z,\bar z)\,\Theta(0)\rangle = \frac{G}{z^3\,\bar z}, \tag{52.21}$$

$$\langle \Theta(z,\bar z)\,\Theta(0)\rangle = \frac{H}{z^2\,\bar z^2}. \tag{52.22}$$

The exponents are dictated by spin and dimension: each correlator scales as $|z|^{-4}$ under $z \to \lambda z$ (two operators of dimension 2), and the split between powers of z and $\bar z$ is the total holomorphic versus antiholomorphic weight. For $\langle TT\rangle$ both operators have weight $(2,0)$, giving $z^{-4}\bar z^0$; for $\langle \Theta T\rangle$ the weights are $(1,1)$ and $(2,0)$, giving $z^{-3}\bar z^{-1}$; for $\langle\Theta\Theta\rangle$ both are $(1,1)$, giving $z^{-2}\bar z^{-2}$. The constants F, G, H are the only data scale invariance leaves undetermined.

Conservation forces $G = H = 0$. Insert the conservation law Eq. (52.19) into a correlator with a fixed $T(0)$ insertion. Since $T(0)$ is a genuine operator, the operator identity holds inside the correlator,

$$\partial_{\bar z}\langle T(z,\bar z)\,T(0)\rangle + \partial_z\langle \Theta(z,\bar z)\,T(0)\rangle = 0 \qquad (z \neq 0). \tag{52.23}$$

The first term vanishes because F/z^4 is holomorphic and $\partial_{\bar z}$ annihilates it. The second term is

$$\partial_z\left(\frac{G}{z^3\bar z}\right) = \frac{G}{\bar z}\,\partial_z z^{-3} = -\frac{3G}{z^4\,\bar z}. \tag{52.24}$$

Equation Eq. (52.23) then reads $-3G/(z^4\bar z) = 0$ for all $z \neq 0$, which forces

$$G = 0. \tag{52.25}$$

Now insert the same conservation law into a correlator with a fixed $\Theta(0)$,

$$\partial_{\bar z}\langle T(z,\bar z)\,\Theta(0)\rangle + \partial_z\langle \Theta(z,\bar z)\,\Theta(0)\rangle = 0. \tag{52.26}$$

With $G = 0$ the first correlator vanishes identically, so its derivative is zero, and the second gives

$$\partial_z\left(\frac{H}{z^2\bar z^2}\right) = \frac{H}{\bar z^2}\,\partial_z z^{-2} = -\frac{2H}{z^3\,\bar z^2}. \tag{52.27}$$

Equation Eq. (52.26) becomes $-2H/(z^3\bar z^2) = 0$, so

$$H = 0. \tag{52.28}$$

The two-point function of the trace with itself, and with the holomorphic component, both vanish identically.

Reflection positivity forces $\Theta = 0$. It remains to pass from $\langle \Theta(z,\bar z)\,\Theta(0)\rangle = 0$ to the operator statement $\Theta = 0$. This is where unitarity, in its Euclidean form, does its final work. By the Osterwalder–Schrader reflection positivity established in Theorem 10.32, the Euclidean two-point function of a Hermitian local operator with its reflection is the squared norm of the state that operator creates from the vacuum; reflection positivity guarantees this norm is non-negative, and it vanishes only when the state itself is null. A vanishing two-point function $\langle \Theta\,\Theta\rangle = 0$ therefore says that Θ creates a zero-norm state, and in a unitary (reflection-positive, ghost-free) theory a zero-norm state is the zero state: the operator Θ decouples from every correlator and is the zero operator. Hence

$$\Theta \;=\; T_{z\bar z} \;=\; 0 \qquad \Longrightarrow \qquad T^{\mu}{}_{\mu} = 4\,\Theta = 0. \tag{52.29}$$

The trace vanishes as an operator equation, and by Section 52.1.2 the special-conformal currents are conserved and the theory is fully conformally invariant. This completes the proof in $d = 2$: scale invariance, unitarity, and a

non-logarithmic spectrum together force conformal invariance, with no further assumption.

It is worth isolating the role of each hypothesis, because the same three reappear in higher dimensions. *Locality and Poincaré invariance* supplied the conservation law Eq. (52.19). *Scale invariance with a diagonalizable dilatation* (the discrete, non-logarithmic spectrum guaranteed by unitarity) reduced the correlators to the pure powers Eqs. (52.20) to (52.22); this is exactly Polchinski's "discrete spectrum" hypothesis, and a logarithmic multiplet would have destroyed it. *Reflection positivity* converted the vanishing two-point function into the vanishing of the operator. Remove any one and the conclusion fails: this is why the theorem is conditional, and why the conditions are precisely those of Theorem 52.4.

Worked Example 52.5 (The free boson saturates the theorem)**.** The simplest two-dimensional conformal field theory, the free massless boson of central charge $c = 1$, makes the abstract conclusion concrete and shows that the constants F, G, H behave exactly as the proof demands. From the holomorphic stress tensor of Section 48.2.1, the component $T = T_{zz}$ is the normal-ordered $-\frac{1}{2}{:}\partial\phi\,\partial\phi{:}$ (in the normalization of Chapter 48), purely holomorphic, while the mixed component $\Theta = T_{z\bar{z}}$ is proportional to ${:}\partial\phi\,\bar{\partial}\phi{:}$ evaluated with the equation of motion $\partial\bar{\partial}\phi = 0$, hence $\Theta = 0$ identically. The two-point function $\langle T(z)T(0)\rangle = c/(2z^4)$ with $c = 1$ (Theorem 48.8) realizes Eq. (52.20) with $F = c/2 \neq 0$, while $\Theta = 0$ gives $G = H = 0$ directly, in agreement with Eqs. (52.25) and (52.28). The theorem's conclusion is not that the stress tensor two-point function vanishes — it does not; F is the central charge, the irreducible quantum number of the theory — but that the *trace* part decouples. The free boson is the $\lambda = 0$, $m = 0$ endpoint of ϕ^4 theory specialized to two dimensions, and it exhibits in the cleanest possible form the structure that Theorem 52.1 guarantees at every fixed point: a nonzero, holomorphic stress tensor whose trace is exactly zero.

The same correlators Eqs. (52.20) to (52.22), no longer evaluated at a fixed point but along a flow, are the raw material of Zamolodchikov's c-theorem: a combination of F, G, H that decreases monotonically toward the infrared and is stationary exactly where Θ decouples. That monotonicity, and its four-dimensional counterpart the a-theorem, are the subject of Section 52.5; here we have used only the stationary endpoint, where the flow has stopped and the trace has vanished.

52.1.6 The loop with Part VI, closed

Assembling the pieces: at any renormalization-group fixed point the beta functions vanish, so by Theorem 52.1 the stress tensor is traceless as an operator equation; tracelessness conserves the special-conformal currents Eq. (52.7) and hence supplies the special-conformal charges Eq. (52.9), promoting the symmetry to the

full conformal group $\mathfrak{so}(d+1,1)$ (Section 52.1.2); the only possible obstruction, a non-improvable virial current, is absent for the unitary scalar fixed points of this book (Theorems 52.2 and 52.3) and, by Polchinski's theorem (Theorem 52.4, proved in full in $d = 2$ in Section 52.1.5), is absent whenever the theory is unitary with a discrete spectrum and a finite virial. The fixed point is therefore a conformal field theory in the exact sense of Chapter 47, and its correlators obey the conformal Ward identities Eq. (47.113). The claim asserted loosely since Part VI is now a theorem under stated hypotheses, and the two halves of the book have met: *a renormalization-group fixed point and a conformal field theory are one object, viewed from the flow and from the symmetry, respectively.*

For ϕ^4 theory this identification is the gateway to everything that follows. The massless scale symmetry of the classical Lagrangian, first isolated in Chapter 7 and broken by the running quartic coupling of Eq. (24.40), is restored as full conformal symmetry exactly at the Wilson–Fisher fixed point λ_* of Theorem 23.36, where $\beta(\lambda_*) = 0$ forces $T^{\mu}{}_{\mu} = 0$. That fixed point is a conformal field theory, and the critical exponents of the ϕ^4 universality class are its conformal data. Having established that the fixed point *is* a CFT, we can now build the precise dictionary that translates one language into the other — couplings into operators, eigenvalues of the linearized flow into scaling dimensions, universality into the statement that two systems realize the same CFT — which is the business of the next section.

52.2 The RG Fixed-Point / CFT Dictionary

The previous section closed a circle that the book has been drawing since Part VI: the theory living at a renormalization-group fixed point is a conformal field theory. That identification is, by itself, a statement about existence — it tells us *that* the critical theory is conformal, that its correlators are constrained by the full conformal group rather than by scale invariance alone. What it does not yet give us is a way to *compute*. On the RG side the natural quantities are critical exponents: the power ν with which a correlation length diverges, the power η with which a correlation function decays at criticality, the singularities $\alpha, \beta, \gamma, \delta$ of thermodynamic response functions. On the CFT side the natural quantities are conformal data: the scaling dimensions $\Delta_{\mathcal{O}}$ and spins of primary operators, and the OPE coefficients that fuse them (Eq. (49.1)). The thesis of this section is that these are the same numbers in two notations, and the work of the section is to build the exact, line-by-line dictionary that translates between them. Once the dictionary is fixed, a measured critical exponent *is* an operator dimension, universality *is* the statement that two systems share one CFT, and the apparatus of Chapter 47–Chapter 51 becomes a machine for predicting laboratory numbers.

Throughout we work in d Euclidean dimensions: critical phenomena are statistical, the partition function is the Euclidean path integral obtained by the

Wick rotation of Chapter 10, and $|x|$ denotes Euclidean distance. The fixed-point theory has no scale, so every dimensionful parameter has been tuned to its critical value and only the conformal kinematics remain.

52.2.1 Local operators at a fixed point: primaries, descendants, and the full dimension

The first entry in the dictionary concerns the objects on each side. On the RG side the fundamental objects are *local operators* — composite fields built from the fundamental field and its derivatives, ϕ, ϕ^2, $\phi\,\partial^2\phi$, $(\partial\phi)^2$, and so on — and the couplings that multiply them in the action. On the CFT side the fundamental objects are *primary operators* and their *descendants* (Theorem 47.15): a primary $\mathcal{O}$ is annihilated by the special conformal generators at the origin and transforms with a definite scaling dimension under dilatations, while its descendants $\partial_{\mu_1}\cdots\partial_{\mu_n}\mathcal{O}$ are obtained by acting with momentum generators and have dimension raised by the number of derivatives.

These two organizations are the same. At the fixed point the dilatation operator is a good quantum number, and every local operator is either a dilatation eigenstate or a finite combination of them; the eigenstates assemble into conformal multiplets, each consisting of one primary together with the infinite tower of its descendants. The reason is precisely the upgrade established in the previous section: scale invariance alone would diagonalize the dilatation operator and grade operators by dimension, but the full conformal symmetry organizes that graded spectrum into multiplets closed under the conformal algebra, with the primary as the lowest-dimension member annihilated by K_μ. A generic local operator one writes down in the Lagrangian description — say $\phi^2(x)$ — is, after mixing under renormalization is diagonalized, a definite linear combination of conformal primaries and descendants.

The dimension carried by each operator is not its naive engineering dimension. Recall from the Callan–Symanzik analysis of Chapter 24 that quantization shifts the dimension of every operator away from its classical value by an *anomalous dimension* γ (Theorem 24.2), generated by the loop corrections to the operator's renormalization and computed from the slope of its renormalization-group flow. The full scaling dimension is therefore the sum of two pieces.

Definition 52.6 (Scaling dimension at a fixed point)**.** Let $\mathcal{O}$ be a primary operator of a fixed-point CFT, with engineering (canonical, free-field) dimension $\Delta_{\mathcal{O}}^{\text{can}}$. Its full scaling dimension is

$$\Delta_{\mathcal{O}} = \Delta_{\mathcal{O}}^{\text{can}} + \gamma_{\mathcal{O}}^{*}, \tag{52.30}$$

where $\gamma_{\mathcal{O}}^{*} = \gamma_{\mathcal{O}}(g_*)$ is the anomalous dimension of $\mathcal{O}$ (Theorem 24.2) evaluated at the fixed-point couplings g_*. It is $\Delta_{\mathcal{O}}$, not $\Delta_{\mathcal{O}}^{\text{can}}$, that controls the power law of every correlator and the conformal transformation of $\mathcal{O}$.

For the canonical example, the free scalar field has $\Delta_\phi^{\rm can} = \frac{d-2}{2}$ (the dimension that makes the kinetic term $\int d^dx\,(\partial\phi)^2$ dimensionless), so at an interacting fixed point

$$\Delta_\phi = \frac{d-2}{2} + \gamma_\phi^*, \tag{52.31}$$

and the composite ϕ^2 has $\Delta_{\phi^2}^{\rm can} = d-2$ shifted by its own anomalous dimension. The whole content of computing conformal data perturbatively, the task of the next section, is computing these γ^* at the fixed-point couplings; the dictionary built here is what makes the answers physically meaningful.

52.2.2 Couplings as operators: the eigenvalue $y = d - \Delta$

The second and central entry in the dictionary translates the linearized RG flow into operator dimensions. Consider perturbing the fixed-point theory by a local operator $\mathcal{O}_i$:

$$S = S_* + \sum_i g_i \int d^dx\, \mathcal{O}_i(x). \tag{52.32}$$

The couplings g_i are the coordinates on the space of theories used throughout Part VI; $g_i = 0$ is the fixed point S_*. Each g_i is conjugate to one operator $\mathcal{O}_i$, and we can read off its mass dimension by demanding that the action be dimensionless. In d Euclidean dimensions the measure carries $[d^dx] = -d$ (a length to the d, i.e. mass dimension $-d$), and the operator carries $[\mathcal{O}_i] = \Delta_i$, so dimensionlessness of each term in Eq. (52.32) forces

$$[g_i] = d - \Delta_i \;\equiv\; y_i. \tag{52.33}$$

This single equation is the hinge of the entire RG/CFT correspondence. The quantity y_i is exactly the linearized RG eigenvalue introduced in Chapter 23: under a rescaling of all lengths by a factor $b > 1$ (one coarse-graining step), a coupling of mass dimension y_i flows as

$$g_i \;\longrightarrow\; g_i' = b^{\,y_i}\, g_i, \tag{52.34}$$

which is precisely the eigenvalue scaling $g_i \to b^{y_i} g_i$ of the linearized flow about the fixed point (Eq. (23.137)). A coupling with positive mass dimension grows under coarse-graining; one with negative mass dimension shrinks. Comparing Eq. (52.33) with the relevant/marginal/irrelevant classification of Theorem 23.6 gives the dictionary's keystone.

Theorem 52.7 (Relevance is the dimension dictionary)**.** *Let $\mathcal{O}_i$ be a primary scalar of a fixed-point CFT, of scaling dimension Δ_i, and let g_i be its conjugate coupling in Eq. (52.32). The linearized RG eigenvalue of g_i is*

$$y_i = d - \Delta_i, \tag{52.35}$$

and the relevant/marginal/irrelevant trichotomy of Theorem 23.6 maps onto the operator dimension as

$$\begin{aligned} &\textit{relevant} && (y_i > 0) && \iff && \Delta_i < d, \\ &\textit{marginal} && (y_i = 0) && \iff && \Delta_i = d, \\ &\textit{irrelevant} && (y_i < 0) && \iff && \Delta_i > d. \end{aligned} \tag{52.36}$$

Proof. Equation Eq. (52.35) is Eq. (52.33), derived from the dimensionlessness of the action term $g_i \int d^d x\, \mathcal{O}_i$. The linearized flow of Chapter 23 is, by definition, $g_i' = b^{y_i} g_i$ with y_i the eigenvalue of the linearized RG transformation (Eq. (23.137)); that this eigenvalue equals the mass dimension of the coupling is the content of dimensional analysis applied to a scale-invariant fixed point, where no other scale can appear to modify the power of b. The trichotomy Eq. (52.36) is then immediate from the sign of $y_i = d - \Delta_i$: $y_i > 0$ (the defining condition of a relevant direction in Theorem 23.6) holds iff $\Delta_i < d$, and similarly for the marginal and irrelevant cases. □

Physical Insight

The inequality $\Delta_i < d$ has a transparent physical reading. The operator $\mathcal{O}_i$ integrated over space, $\int d^d x\, \mathcal{O}_i$, is a candidate deformation of the long-distance physics. Its integral converges in the infrared (grows under coarse-graining) precisely when the operator is "light enough" — when its dimension undercuts that of the spacetime volume element, $\Delta_i < d$. A relevant operator is one whose effect accumulates as we look at larger scales; an irrelevant one washes out. The marginal case $\Delta_i = d$ is the knife-edge where the leading scaling is neutral and the fate of the coupling is decided by the next order (the logarithmic running resolved for $\lambda\phi^4$ in Chapters 23 and 24).

The dictionary so far is summarized in Table 52.1. Every row is an identity, not an analogy: the left column is the language of Part VI, the right column the language of Part XIV, and the equals sign between them is what this chapter establishes.

52.2.3 Critical exponents are operator dimensions

We now cash out the dictionary on the two most-measured exponents, η and ν, each of which is fixed by a single operator dimension, and then show that the remaining thermodynamic exponents follow from those same two dimensions through scaling relations that we derive in full.

Table 52.1: The RG / CFT dictionary. Each row equates a renormalization-group concept (left) with a piece of conformal data (right). The relations are exact at a fixed point.

Renormalization group (Part VI)	**Conformal field theory (Part XIV)**
Fixed point of the flow	Conformal field theory
Local operator (after diagonalizing mixing)	Conformal primary or descendant
Coarse-graining scale b	Dilatation by b
Coupling g_i, conjugate to $\mathcal{O}_i$	Source for the primary $\mathcal{O}_i$
Mass dimension $[g_i] = y_i$	RG eigenvalue $y_i = d - \Delta_i$
Relevant ($y_i > 0$)	$\Delta_i < d$
Marginal ($y_i = 0$)	$\Delta_i = d$
Irrelevant ($y_i < 0$)	$\Delta_i > d$
Anomalous dimension γ_i^*	$\Delta_i - \Delta_i^{\text{can}}$
# relevant operators	Codimension of the critical surface
Universality class	Single fixed-point CFT

The anomalous exponent η from the two-point function. The exponent η (Fisher's exponent) is defined by the decay of the order-parameter correlation function exactly at criticality. A free massless scalar in d dimensions has the two-point function $\langle\phi(x)\phi(0)\rangle \sim |x|^{-(d-2)}$; an interacting critical theory deviates from this power, and the deviation is named η:

$$G(x) \equiv \langle \sigma(x)\,\sigma(0)\rangle \;\sim\; \frac{1}{|x|^{\,d-2+\eta}} \qquad \text{at } T = T_c, \tag{52.37}$$

where σ is the order-parameter field (the continuum spin, the field whose ordering breaks the symmetry). This is a laboratory definition: η is read off the measured decay of fluctuations at the critical point. On the CFT side, conformal symmetry fixes the two-point function of any scalar primary of dimension Δ_σ to the pure power law (Eq. (47.120))

$$\langle \sigma(x)\,\sigma(0)\rangle = \frac{1}{|x|^{\,2\Delta_\sigma}}, \tag{52.38}$$

with the normalization set to unity. The order-parameter field σ is a conformal primary, so Eqs. (52.37) and (52.38) describe the same correlator and their exponents must agree:

$$2\Delta_\sigma = d-2+\eta \qquad \Longrightarrow \qquad \boxed{\Delta_\sigma = \frac{d-2+\eta}{2}}, \qquad \eta = 2\Delta_\sigma - (d-2). \tag{52.39}$$

This is the first exact translation: the anomalous part of the spin dimension *is* the exponent η. Comparing with Eq. (52.31), the field anomalous dimension and

Fisher's exponent are related by $\eta = 2\gamma_\phi^*$, the identification anticipated in the Callan–Symanzik treatment (Theorem 24.30, Eq. (24.246)). A free field ($\gamma_\phi^* = 0$) has $\eta = 0$; the smallness of η in the three-dimensional Ising class, $\eta \approx 0.036$, reflects that the spin sits only slightly above its free-field dimension.

The correlation-length exponent ν from the relevant singlet. The exponent ν governs the divergence of the correlation length as the temperature approaches its critical value:

$$\xi \sim |t|^{-\nu}, \qquad t \equiv \frac{T - T_c}{T_c}. \tag{52.40}$$

The reduced temperature t is a coupling: it multiplies, in the action, the operator that measures the local energy density. Call that operator the *energy* ε; it is the lowest-dimension scalar primary that is even under the order-parameter symmetry, and t is its conjugate coupling in the sense of Eq. (52.32), $S = S_* + t\int d^d x\, \varepsilon(x) + \cdots$. By Theorem 52.7 its RG eigenvalue is

$$y_t = d - \Delta_\varepsilon. \tag{52.41}$$

To extract ν we combine the flow of the coupling with the transformation of the physical length. Under a coarse-graining by factor b, the relevant coupling grows as $t \to b^{y_t} t$ (Eq. (52.34)), while the correlation length, being a physical length measured in lattice units, shrinks as $\xi \to \xi/b$. Because ξ is a function of the couplings, RG covariance reads

$$\xi(t) = b\,\xi(b^{y_t} t)\,. \tag{52.42}$$

This functional equation holds for every b; we exploit that freedom by choosing b to drive the rescaled coupling to a fixed reference value, $b^{y_t}|t| = 1$, i.e. $b = |t|^{-1/y_t}$. Substituting,

$$\xi(t) = |t|^{-1/y_t}\,\xi(\pm 1) \;\propto\; |t|^{-1/y_t}. \tag{52.43}$$

Comparing with the definition Eq. (52.40),

$$\boxed{\frac{1}{\nu} = y_t = d - \Delta_\varepsilon}, \qquad \nu = \frac{1}{d - \Delta_\varepsilon}. \tag{52.44}$$

The second exact translation: the correlation-length exponent is the reciprocal of the RG eigenvalue of the energy operator, which is d minus its conformal dimension. That ε has $\Delta_\varepsilon < d$ (so that $y_t > 0$ and the deformation is relevant) is exactly the statement that the temperature *must* be tuned to reach criticality: it is a relevant knob.

Two operator dimensions, Δ_σ and Δ_ε, have now produced two exponents, η and ν. The remarkable fact, which we establish next, is that these are the *only* independent numbers: the entire suite of thermodynamic exponents is fixed by $(\Delta_\sigma, \Delta_\varepsilon)$ through a single scaling form.

The scaling form of the free energy. The order parameter couples to an external field h (a magnetic field for a ferromagnet), conjugate to the spin σ, with RG eigenvalue

$$y_h = d - \Delta_\sigma \tag{52.45}$$

by the same dimensional argument that gave Eq. (52.41). The singular part of the free energy density $f_s(t,h)$ — the piece responsible for the critical singularities — obeys a homogeneity relation that follows directly from the RG. Under one coarse-graining step the total singular free energy $-\ln Z_{\text{sing}}$ is invariant (we merely reorganize the same partition sum), while the volume measured in the new, coarser units contracts by b^{-d}; the couplings flow by their eigenvalues. Equating the total free energy before and after the step, $V f_s(t,h) = (V b^{-d})\, f_s(b^{y_t} t,\, b^{y_h} h)$, gives the scaling form

$$f_s(t,h) = b^{-d}\, f_s(b^{\,y_t} t,\; b^{\,y_h} h)\,, \tag{52.46}$$

valid for every $b > 1$. This one equation, together with the eigenvalues Eqs. (52.41) and (52.45), contains every thermodynamic exponent. The following worked example extracts them all, with the algebra carried in full.

Worked Example 52.8 (All thermodynamic exponents from two dimensions, and the scaling relations)**.** We extract $\alpha, \beta, \gamma, \delta$ from Eq. (52.46), express each through $\Delta_\sigma, \Delta_\varepsilon$, and derive the Rushbrooke, Widom, and Fisher scaling relations. We use the eigenvalues $y_t = d - \Delta_\varepsilon$ and $y_h = d - \Delta_\sigma$ throughout.

Eliminating the temperature. For h-dependent quantities at fixed $t \neq 0$ we set $b^{y_t}|t| = 1$, i.e. $b = |t|^{-1/y_t}$. Then Eq. (52.46) becomes

$$f_s(t,h) = |t|^{\,d/y_t}\, \Phi\!\left(\frac{h}{|t|^{\,y_h/y_t}}\right), \qquad \Phi(z) \equiv f_s(\pm 1,\, z)\,, \tag{52.47}$$

with $z = h\,|t|^{-y_h/y_t}$ the single scaling variable and Φ a universal scaling function.

Specific heat (α). The specific heat is the second temperature derivative of the free energy at zero field, $C \sim \partial^2 f_s/\partial t^2$. From Eq. (52.47) at $h = 0$, $f_s(t,0) = |t|^{d/y_t}\Phi(0)$, and two derivatives in t lower the power by two:

$$C \sim |t|^{\,d/y_t - 2} \equiv |t|^{-\alpha} \qquad \Longrightarrow \qquad \alpha = 2 - \frac{d}{y_t} = 2 - d\,\nu. \tag{52.48}$$

Magnetization (β). The spontaneous magnetization is $M = -\partial f_s/\partial h\big|_{h=0}$. Differentiating Eq. (52.47) once in h brings a factor $|t|^{-y_h/y_t}$ from the chain rule:

$$M = -|t|^{\,d/y_t}\, \Phi'(z)\, |t|^{-y_h/y_t}\Big|_{h=0} \sim |t|^{\,(d-y_h)/y_t} \equiv (-t)^{\beta} \;\Longrightarrow\; \beta = \frac{d - y_h}{y_t}. \tag{52.49}$$

Here $\Phi'(0) \neq 0$ in the ordered phase ($t < 0$), so the power is the full $(d - y_h)/y_t$. Using $d - y_h = \Delta_\sigma$ and $y_t = 1/\nu$, this is $\beta = \nu\,\Delta_\sigma$.

Susceptibility (γ). The susceptibility is $\chi = \partial M/\partial h\big|_{h=0} = -\partial^2 f_s/\partial h^2\big|_{h=0}$. A second h-derivative brings a second factor $|t|^{-y_h/y_t}$:

$$\chi \sim |t|^{\,d/y_t - 2y_h/y_t} = |t|^{\,(d-2y_h)/y_t} \equiv |t|^{-\gamma} \implies \gamma = \frac{2y_h - d}{y_t}. \tag{52.50}$$

With $2y_h - d = 2(d-\Delta_\sigma) - d = d - 2\Delta_\sigma$ and $y_t = 1/\nu$, this reads $\gamma = \nu\,(d - 2\Delta_\sigma)$.

Critical isotherm (δ). At $t = 0$ the previous choice of b is unavailable; instead eliminate h by setting $b^{y_h}|h| = 1$, i.e. $b = |h|^{-1/y_h}$. Then Eq. (52.46) gives $f_s(0,h) = |h|^{d/y_h} f_s(0,\pm 1)$, and

$$M = -\frac{\partial f_s}{\partial h}\bigg|_{t=0} \sim |h|^{\,d/y_h - 1} = |h|^{\,(d-y_h)/y_h} \equiv |h|^{1/\delta} \implies \delta = \frac{y_h}{d - y_h} = \frac{y_h}{\Delta_\sigma}. \tag{52.51}$$

The exponents through the two dimensions. Substituting $y_t = d - \Delta_\varepsilon$ and $y_h = d - \Delta_\sigma$ collects the results into a closed table in terms of the two primary dimensions:

$$\begin{aligned} \nu &= \frac{1}{d - \Delta_\varepsilon}, & \eta &= 2\Delta_\sigma - (d-2), \\ \alpha &= 2 - \frac{d}{d - \Delta_\varepsilon}, & \beta &= \frac{\Delta_\sigma}{d - \Delta_\varepsilon}, \\ \gamma &= \frac{d - 2\Delta_\sigma}{d - \Delta_\varepsilon}, & \delta &= \frac{d - \Delta_\sigma}{\Delta_\sigma}. \end{aligned} \tag{52.52}$$

Every standard critical exponent is an explicit rational function of Δ_σ and Δ_ε.

The scaling relations. Because all six exponents descend from the two eigenvalues (y_t, y_h), they are not independent; eliminating y_t, y_h yields exact identities. Using the compact forms $\alpha = 2 - d/y_t$, $\beta = (d-y_h)/y_t$, $\gamma = (2y_h - d)/y_t$, $\delta = y_h/(d-y_h)$:

$$\alpha + 2\beta + \gamma = \frac{(2y_t - d) + 2(d - y_h) + (2y_h - d)}{y_t} = \frac{2y_t}{y_t} = 2 \quad \text{(Rushbrooke)}, \tag{52.53}$$

$$\beta(\delta - 1) = \frac{d - y_h}{y_t} \cdot \frac{2y_h - d}{d - y_h} = \frac{2y_h - d}{y_t} = \gamma \qquad \text{(Widom)}, \tag{52.54}$$

$$\nu(2 - \eta) = \frac{1}{y_t}\big(2 - [2\Delta_\sigma - (d-2)]\big) = \frac{d - 2\Delta_\sigma}{y_t} = \gamma \qquad \text{(Fisher)}. \tag{52.55}$$

In the Widom step we used $\delta - 1 = \dfrac{y_h - (d - y_h)}{d - y_h} = \dfrac{2y_h - d}{d - y_h}$. In the Fisher step we used $2 - \eta = 2 - 2\Delta_\sigma + (d-2) = d - 2\Delta_\sigma = 2y_h - d$ since $2y_h - d = 2(d - \Delta_\sigma) - d = d - 2\Delta_\sigma$. The three celebrated scaling relations are thus not empirical coincidences but algebraic consequences of there being exactly two

independent dimensions. The same elimination gives the hyperscaling (Josephson) relation directly from Eq. (52.48),

$$2 - \alpha = \frac{d}{y_t} = d\,\nu, \tag{52.56}$$

which, unlike the previous three, carries explicit d-dependence because it descends from the volume factor b^{-d} in Eq. (52.46); it holds below the upper critical dimension, where the fixed point is interacting and the scaling form Eq. (52.46) controls the singular free energy.

The worked example is the quantitative heart of the dictionary: it shows that the long list of critical exponents measured across decades of experiment is, at any fixed point, a two-parameter family, and the two parameters are conformal dimensions. A bootstrap determination of $(\Delta_\sigma, \Delta_\varepsilon)$ — the numbers pinned to the kink in Chapter 50 — feeds straight through Eq. (52.52) to the entire exponent table, and the scaling relations Eqs. (52.53) to (52.55) are guaranteed to hold because they are identities in the two dimensions.

52.2.4 Universality is the statement "the same CFT"

The dictionary explains the most striking empirical fact about critical phenomena: *universality*. A uniaxial ferromagnet at its Curie point and a fluid at its liquid–vapour critical point are microscopically unrelated — different constituents, different forces, different lattices or no lattice at all — yet they share, to measured precision, the same critical exponents. Part VI gave the mechanism (Theorem 23.26): both systems flow, under coarse-graining, into the same basin of attraction and arrive at the same fixed point, with their microscopic differences encoded entirely in irrelevant couplings that die away along the flow. The dictionary now sharpens the mechanism into an identity of objects.

Proposition 52.9 (Universality as conformal identity)**.** *Two statistical systems whose RG trajectories terminate at the same fixed point are described, at long distances, by one and the same conformal field theory. They therefore have identical conformal data* $(\{\Delta_{\mathcal{O}}, \ell_{\mathcal{O}}\}, \{C_{\mathcal{O}_1\mathcal{O}_2\mathcal{O}_3}\})$ *(Eq. (49.1)), and hence — by Eqs. (52.39), (52.44) and (52.52) — identical critical exponents. The microscopic data of each system survive only as the coefficients of irrelevant operators, which by Theorem 52.7 have* $\Delta > d$ *and decay under the flow, contributing only subleading corrections to scaling.*

Proof. By hypothesis both trajectories reach the same point S_* in coupling space. The long-distance physics of each is governed by the fixed-point theory together with the leading irrelevant deformations; the fixed-point theory is, by the result of the previous section, a single CFT with a definite spectrum and definite OPE coefficients (Eq. (49.1)). The exponents are functions of that data

alone through the relations of Section 52.2.3, so they coincide. The microscopic distinctions correspond to different starting points on the same critical surface and to different values of the irrelevant couplings g_j with $\Delta_j > d$; these flow to zero as $b^{y_j} = b^{d-\Delta_j} \to 0$, leaving the leading singular behaviour untouched and altering only the corrections-to-scaling exponents $\omega_j = \Delta_j - d > 0$. □

The proposition makes "universality class" synonymous with "fixed-point CFT," the bottom-right entry of Table 52.1. It also answers a practical question: how many parameters must an experimentalist tune to sit exactly at the critical point? The answer is read off the dimension spectrum. Each relevant operator is a direction in which the flow escapes the fixed point; to reach the fixed point one must tune the conjugate coupling to its critical value. Hence the number of relevant operators equals the number of independent tunings, which is the codimension of the critical surface — the surface of bare theories that flow into the fixed point.

Physical Insight

For the Ising universality class there are exactly two relevant scalar primaries: the $\mathbb{Z}_2$-odd spin σ and the $\mathbb{Z}_2$-even energy ε. If one does not impose the $\mathbb{Z}_2$ symmetry, both must be tuned — the magnetic field h to zero and the temperature to T_c — so the critical point has codimension two. If the symmetry is imposed by hand (a perfectly symmetric magnet in zero field), the odd operator σ cannot be generated, and only the single even relevant direction ε remains: codimension one, a single knob (the temperature) to reach criticality. This is why a generic second-order transition is reached by tuning one parameter: in the symmetric sector the Ising fixed point has a single relevant direction. The count of relevant operators is the count of fine-tunings, and it is a piece of conformal data.

Figure 52.1 renders the picture: a critical surface of codimension equal to the number of relevant directions, two microscopically different bare theories lying on it, both flowing into the common fixed point, and the relevant couplings t, h as the directions transverse to the surface along which the flow escapes.

52.2.5 The two leading Ising primaries: $\sigma = \phi$ and $\varepsilon = \phi^2$

We close the dictionary by naming, for the canonical example carried since Chapter 6, the two operators whose dimensions the rest of the chapter computes. ϕ^4 theory is the real scalar with the $\mathbb{Z}_2$ symmetry $\phi \to -\phi$ fixed in Chapter 7. At its interacting fixed point — the Wilson–Fisher fixed point, located perturbatively at $\lambda_* = \frac{16\pi^2}{3}\varepsilon + O(\varepsilon^2)$ in $d = 4 - \varepsilon$ (Eq. (24.255)) and characterized as a CFT in Theorem 52.11 — the local operators organize into conformal multiplets, and the two relevant scalar primaries are immediately identified by their $\mathbb{Z}_2$ charge.

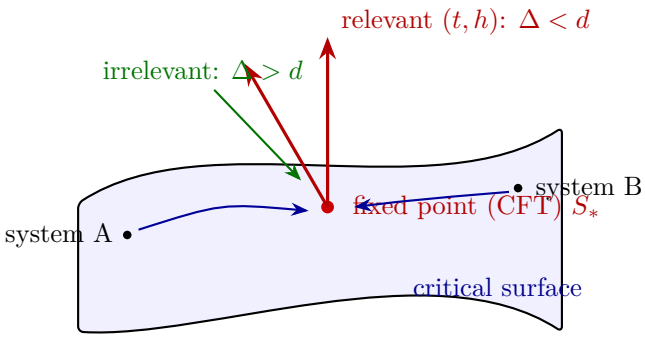

Figure 52.1: Universality as flow to a common fixed point. Two microscopically different bare theories (A, B) lie on the critical surface and flow under coarse-graining to one fixed-point CFT S_*, sharing its conformal data and hence its exponents. Directions tangent to the surface are irrelevant ($\Delta > d$, flowing in); directions transverse are relevant ($\Delta < d$, flowing out), conjugate to the couplings t, h that must be tuned to reach criticality. The codimension of the surface equals the number of relevant primaries.

Definition 52.10 (The leading Ising primaries)**.** In the Wilson–Fisher / Ising universality class, the two lowest-dimension scalar primaries are:

- the **spin** σ, the unique relevant $\mathbb{Z}_2$-*odd* scalar, identified with the fundamental field, $\sigma = \phi$; it is conjugate to the magnetic field h, has dimension $\Delta_\sigma = \frac{d-2}{2} + \gamma_\phi^*$, and fixes η through Eq. (52.39);
- the **energy** ε, the unique relevant $\mathbb{Z}_2$-*even* scalar, identified with the normal-ordered composite, $\varepsilon = :\phi^2:$; it is conjugate to the reduced temperature t, has dimension $\Delta_\varepsilon = (d-2) + \gamma_{\phi^2}^*$, and fixes ν through Eq. (52.44).

The identifications are forced. The field ϕ is the only $\mathbb{Z}_2$-odd operator of low enough dimension to be relevant, and it is the continuum limit of the lattice spin whose ordering is the phase transition; hence $\sigma = \phi$ and the magnetic field, which explicitly breaks $\phi \to -\phi$, is its conjugate source. The composite ϕ^2 is the lowest $\mathbb{Z}_2$-even scalar above the identity, the continuum limit of the lattice energy density; hence $\varepsilon = :\phi^2:$ and the reduced temperature, which multiplies the mass operator $\frac{1}{2}m^2\phi^2$ in the action and is even, is its conjugate source. That these are the *only* two relevant scalars is the codimension-two count of Section 52.2.4, reduced to one in the symmetric sector. Every other operator — ϕ^4 at the fixed point, $\phi\,\partial^2\phi$, the higher composites, and all spinning operators including the stress tensor — is marginal or irrelevant and does not require tuning.

With the two operators named and the exponent formulas Eqs. (52.39), (52.44) and (52.52) in hand, the dictionary is complete: it remains only to supply the two numbers. The next section consummates ϕ^4 theory by computing Δ_σ

and Δ_ε explicitly at the Wilson–Fisher fixed point in the ϵ-expansion, carrying the loop algebra in full and feeding the resulting anomalous dimensions through exactly the relations assembled here.

52.3 The Wilson–Fisher Fixed Point as a CFT: the Epsilon-Expansion

The dictionary of the previous section turned every critical exponent into an operator dimension: the field exponent $\eta = 2\Delta_\sigma - (d-2)$ from Eq. (52.39), the correlation-length exponent through $1/\nu = y_t = d - \Delta_\varepsilon$ from Eq. (52.44), and the correction-to-scaling exponent ω as the RG eigenvalue of the leading irrelevant operator. It also fixed, for the canonical example carried since Chapter 6, which operators those are: $\sigma = \phi$ and $\varepsilon = :\phi^2:$ are the two relevant scalar primaries (Section 52.2.5), so that $\Delta_\sigma = \Delta_\phi$ and $\Delta_\varepsilon = \Delta_{\phi^2}$. The dictionary is exact but empty until we possess the dimensions themselves. This section fills it. We continue ϕ^4 theory from Chapter 24, where the one-loop beta function already located the Wilson–Fisher fixed point at $\lambda_* = \frac{16\pi^2}{3}\varepsilon$ and announced $\gamma_\phi = O(\varepsilon^2)$, and we now carry every loop integral to its end: the engineering bookkeeping that produces the fixed point, the two-loop self-energy that gives γ_ϕ and hence η, and the one-loop composite-operator renormalization that gives γ_{ϕ^2} and hence ν. The output is the leading conformal data of the Wilson–Fisher CFT, computed from the foundations and handed, in the next section, to the three-dimensional bootstrap.

Throughout this section the theory is Euclidean: critical phenomena live in imaginary time, and the path integral carries e^{-S_E} with

$$S_E = \int \mathrm{d}^d x \, \Big[\tfrac{1}{2}(\partial_\mu\phi)(\partial_\mu\phi) + \tfrac{1}{2}m^2\phi^2 + \frac{\lambda}{4!}\phi^4 \Big], \tag{52.57}$$

the Wick rotation of the standard Lagrangian Eq. (6.56) fixed in Chapter 10. The Euclidean Feynman rules are the propagator $1/(p^2+m^2)$ and the vertex $-\lambda$; all loop momenta are Euclidean and indices are summed with $\delta_{\mu\nu}$.

Notation Watch

Two symbols collide in this section and the collision is unavoidable, because each is standard in its own community. The *dimension deficit* $\varepsilon \equiv 4 - d$ is the small, finite expansion parameter of the ε-expansion; it is held fixed, not sent to zero, and is set to $\varepsilon = 1$ in the next section to reach $d = 3$. It is twice the dimensional-regularization regulator of the book's canon (Chapter 22), where $d = 4 - 2\varepsilon_{\mathrm{dr}}$ and $\varepsilon_{\mathrm{dr}} \to 0$ at the end: as dimensions, $\varepsilon = 2\varepsilon_{\mathrm{dr}}$. The regulator $\varepsilon_{\mathrm{dr}}$ appears only inside individual Z-factors, whose poles cancel; the anomalous dimensions $\gamma(\lambda)$ are finite functions,

independent of the regulator, and the physical deficit ε enters them only through the fixed-point value $\lambda_*(\varepsilon)$ and through engineering dimensions. Separately, the *energy operator* of the Ising universality class is universally written ε (so Δ_ε, $\lambda_{\sigma\sigma\varepsilon}$); it is the operator $\varepsilon = :\phi^2:$ and has nothing to do with the deficit. We always write ε with a subscript or as a named operator and ε standing alone, exactly as in Section 52.2.5.

52.3.1 The engineering dimension and the fixed point

In exactly four dimensions λ is dimensionless and marginal, and the only zero of $\beta_\lambda = 3\lambda^2/16\pi^2$ is the free Gaussian theory at $\lambda = 0$. The single idea that produces an interacting fixed point is to leave four dimensions, where λ acquires an engineering dimension and the beta function gains a classical term. We carry the bookkeeping in full.

The kinetic term $\int \mathrm{d}^d x\, \frac{1}{2}(\partial\phi)^2$ must be dimensionless (the action is, in units $\hbar = 1$). With $[\mathrm{d}^d x] = -d$ and $[\partial] = +1$ in mass units, $-d + 2 + 2[\phi] = 0$ fixes the canonical mass dimension of the field,

$$[\phi] = \frac{d-2}{2}. \tag{52.58}$$

The quartic operator then carries $[\phi^4] = 2(d-2)$, and demanding $\int \mathrm{d}^d x\, \frac{\lambda}{4!}\phi^4$ be dimensionless fixes

$$[\lambda] = d - 2(d-2) = 4 - d = \varepsilon. \tag{52.59}$$

For $d < 4$ the coupling has *positive* mass dimension ε: it is power-counting relevant, exactly the statement of Chapter 23 that an operator with $[\,\cdot\,] < d$ grows under coarse-graining. To run a dimensionless coupling we factor out the scale, writing the dimensionful bare coupling as $\lambda_0 = \mu^\varepsilon$ (dimensionless). Holding λ_0 fixed while varying μ then injects a tree-level drift into the renormalization-group flow of the dimensionless renormalized coupling: differentiating $\lambda \propto \mu^{-\varepsilon}\lambda_0$ gives the classical contribution $\mu\,\partial_\mu\lambda \supset -\varepsilon\lambda$. The full one-loop beta function in $d = 4 - \varepsilon$ is therefore the four-dimensional loop term of Chapter 24, whose leading coefficient is dimension-independent, plus this classical tilt,

$$\beta_\lambda = -\varepsilon\,\lambda + \frac{3\lambda^2}{16\pi^2} + O(\lambda^3, \varepsilon\lambda^2), \tag{52.60}$$

which is the imported Eq. (24.254); we do not recompute the $3/16\pi^2$ here, only re-derive the term that turns it into a fixed-point equation.

Theorem 52.11 (The Wilson–Fisher fixed point is a conformal field theory)**.** *For $0 < \varepsilon \ll 1$ the beta function Eq. (52.60) has, besides the Gaussian zero $\lambda = 0$, a single nontrivial zero*

$$\lambda_* = \frac{16\pi^2}{3}\,\varepsilon + O(\varepsilon^2), \tag{52.61}$$

the Wilson–Fisher fixed point. *At λ_* the trace of the stress tensor vanishes up to the equation of motion and the theory is scale invariant; by the promotion of scale to conformal invariance established in Section 52.1, it is a unitary conformal field theory, a member of a continuous family labelled by ε (equivalently by d). Its leading conformal data are*

$$\Delta_\phi = \frac{d-2}{2} + \gamma_\phi(\lambda_*), \qquad \Delta_{\phi^2} = (d-2) + \gamma_{\phi^2}(\lambda_*), \tag{52.62}$$

with $\gamma_\phi(\lambda_*) = \varepsilon^2/108 + O(\varepsilon^3)$ and $\gamma_{\phi^2}(\lambda_*) = \varepsilon/3 + O(\varepsilon^2)$, computed in Sections 52.3.2 and 52.3.3. The Gaussian fixed point is infrared-repulsive and λ_* is infrared-attractive, with correction-to-scaling exponent

$$\omega = \beta'_\lambda(\lambda_*) = +\varepsilon + O(\varepsilon^2). \tag{52.63}$$

Location and stability. Setting Eq. (52.60) to zero,

$$\lambda\Big(-\varepsilon + \frac{3\lambda}{16\pi^2}\Big) = 0 \quad \Longrightarrow \quad \lambda = 0 \ \text{ or } \ \lambda_* = \frac{16\pi^2}{3}\varepsilon, \tag{52.64}$$

which is Eq. (52.61); for small ε this is a weak-coupling fixed point, $\lambda_* = O(\varepsilon)$, where the one-loop truncation is controlled. Differentiating the beta function,

$$\beta'_\lambda(\lambda) = -\varepsilon + \frac{6\lambda}{16\pi^2} = -\varepsilon + \frac{3\lambda}{8\pi^2}, \tag{52.65}$$

and evaluating at the two zeros gives $\beta'_\lambda(0) = -\varepsilon < 0$ and

$$\beta'_\lambda(\lambda_*) = -\varepsilon + \frac{3}{8\pi^2}\cdot\frac{16\pi^2}{3}\varepsilon = -\varepsilon + 2\varepsilon = +\varepsilon > 0. \tag{52.66}$$

A coupling near a zero flows as $\frac{d\lambda}{d(-\ln b)} = -\beta_\lambda$ toward the infrared (increasing length b); the zero is IR-attractive when $\beta'_\lambda > 0$ and IR-repulsive when $\beta'_\lambda < 0$. Hence the Gaussian point is repelled and λ_* collects the flow: every microscopic theory with a nonzero quartic in $d < 4$ ends, at long distance, on the single fixed-point theory at λ_*. This is the dynamical content of universality (Theorem 23.26). The slope $\beta'_\lambda(\lambda_*) = \varepsilon$ is, by the dictionary, the RG eigenvalue of the deviation $\delta\lambda = \lambda - \lambda_*$, which is the leading irrelevant direction; its eigenvalue is $-\omega$ with $\omega = \Delta_{\phi^4} - d = \beta'_\lambda(\lambda_*) = \varepsilon$, the correction-to-scaling exponent of Eq. (52.63). The promotion to conformal invariance and the computation of the two anomalous dimensions occupy the remainder of the section. □

Physical Insight

The fixed point is the cancellation of two effects that pull the coupling in opposite directions. Quantum-mechanically the quartic self-interaction

screens itself: the one-loop term $+3\lambda^2/16\pi^2$ drives λ to grow in the ultraviolet, the same physics as the four-dimensional Landau pole. Below four dimensions the coupling additionally carries positive mass dimension ε, so simple dimensional analysis makes the dimensionless coupling *shrink* in the ultraviolet at rate $-\varepsilon\lambda$. At λ_* the classical shrinking exactly balances the quantum growth, and the coupling sits still — the theory has forgotten the scale μ. Forgetting the only scale is scale invariance; in a local, unitary, reflection-positive theory it is conformal invariance. The Wilson–Fisher fixed point is thus a genuine interacting CFT, weakly coupled for small ε, that interpolates — as ε runs from 0 to 1 to 2 — between the free scalar in $d = 4$ and the two-dimensional Ising CFT of Chapter 48.

52.3.2 The field anomalous dimension from the two-loop sunset: η

The first datum is the dimension of $\sigma = \phi$, equivalently the anomalous dimension $\gamma_\phi(\lambda_*)$ through $\Delta_\phi = \frac{d-2}{2} + \gamma_\phi$ and $\eta = 2\gamma_\phi$ (the dictionary Eq. (52.39), since $\eta = 2\Delta_\sigma - (d-2) = 2\gamma_\phi$). We must compute $\gamma_\phi(\lambda)$ as a function of the coupling and evaluate it at λ_*.

Why one loop gives nothing. The one-loop self-energy in ϕ^4 is the tadpole of Fig. 22.10: a single quartic vertex with two of its legs closed into a loop. Its value is

$$\Sigma^{(1)} = \frac{\lambda}{2}\int \frac{\mathrm{d}^d k}{(2\pi)^d}\,\frac{1}{k^2+m^2}, \tag{52.67}$$

the factor $\frac{1}{2}$ the symmetry factor of the loop. The integrand is *independent of the external momentum* p: the external line passes straight through the vertex and only the loop momentum k circulates. Consequently $\Sigma^{(1)}$ is a pure constant, contributing to the inverse propagator $\Gamma^{(2)}(p) = p^2 + m^2 + \Sigma$ only through the p-independent piece. It renormalizes the mass, never the coefficient of p^2, so the wavefunction renormalization receives no one-loop correction: $\delta_Z = O(\lambda^2)$ and $Z_\phi = 1 + O(\lambda^2)$, the result Eq. (22.82). Since $\gamma_\phi = \frac{1}{2}\mu\,\partial_\mu \ln Z_\phi$, the field anomalous dimension starts at two loops. This is not an accident of ϕ^4 but a feature of any theory whose lowest self-energy is a tadpole; it is the technical reason η is the smallest of the Ising exponents, $O(\varepsilon^2)$ where ν deviates at $O(\varepsilon)$.

The two-loop sunset. The leading momentum-dependent self-energy is the *sunset* of Fig. 52.2: two quartic vertices joined by three internal propagators, one external leg at each vertex. In the Euclidean theory at the critical point ($m = 0$)

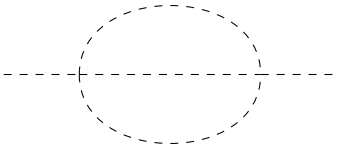

Figure 52.2: The two-loop sunset self-energy Eq. (52.68) of ϕ^4 theory. Two quartic vertices are joined by three internal scalar lines; one external leg enters at each vertex. This is the lowest self-energy whose value depends on the external momentum p, and hence the source of the first nonzero wavefunction renormalization $\delta_Z = O(\lambda^2)$ and of the field anomalous dimension γ_ϕ.

it reads, with symmetry factor $1/6$ for the three interchangeable internal lines,

$$\Sigma_{\text{sun}}(p^2) = \frac{\lambda^2}{6} \int \frac{\mathrm{d}^d k}{(2\pi)^d} \frac{\mathrm{d}^d q}{(2\pi)^d} \, \frac{1}{k^2} \, \frac{1}{q^2} \, \frac{1}{(p-k-q)^2}, \tag{52.68}$$

the Wick rotation of the Minkowski integral Eq. (22.136). Its superficial degree of divergence is $D = 2d - 3 \cdot 2 = 2d - 6 = 2$ at $d = 4$: a quadratic overall divergence. The constant part renormalizes the mass; the piece we need is the coefficient of p^2, which we isolate by one differentiation in p^2.

Differentiating Eq. (52.68) once with respect to p^2 lowers the overall degree by two, to $D = 0$, a logarithmic divergence; the coefficient

$$B_{\text{sun}} \equiv \left. \frac{\partial \Sigma_{\text{sun}}}{\partial p^2} \right|_{p=0} \tag{52.69}$$

is therefore genuinely present, and it is the only divergence proportional to p^2 that the kinetic counterterm must absorb. The double integral, performed with the dimensionally regularized master integrals of Chapter D (the inner q-integral is the massless bubble, leaving a single radial integral over k whose ultraviolet tail produces the pole), is carried out in full in Theorem 22.29; its leading pole is the imported Eq. (22.138),

$$B_{\text{sun}} = -\frac{\lambda^2}{12\,(16\pi^2)^2} \, \frac{1}{\varepsilon_{\text{dr}}} + (\text{finite}), \tag{52.70}$$

the coefficient $1/12$ tracking the symmetry factor $1/6$ and the two-loop measure, the sign fixed by the Euclidean propagators. The inverse propagator $\Gamma^{(2)}(p^2) = p^2 + \Sigma$ then acquires a divergent shift in the coefficient of p^2, from 1 to $1 - B_{\text{sun}}$, which the wavefunction counterterm cancels, $\delta_Z^{(2)} = B_{\text{sun}}$, i.e.

$$Z_\phi = 1 - \frac{\lambda^2}{12\,(16\pi^2)^2} \, \frac{1}{\varepsilon_{\text{dr}}} + O(\lambda^3), \tag{52.71}$$

the first nonzero field-strength renormalization in ϕ^4 theory, established at Eq. (22.139).

From the counterterm to the anomalous dimension. The field anomalous dimension is read from the simple pole of Z_ϕ by the pole-to-anomalous-dimension relation of Chapter 24 (the 't Hooft equation Theorem 24.5); the assembly is owned there and delivers the imported Eq. (24.260),

$$\gamma_\phi(\lambda) = \frac{\lambda^2}{12\,(16\pi^2)^2} + O(\lambda^3). \tag{52.72}$$

This is a finite function of the coupling, independent of the regulator. Evaluating it at the Wilson–Fisher coupling Eq. (52.61) is now pure arithmetic:

$$\gamma_\phi(\lambda_*) = \frac{1}{12\,(16\pi^2)^2}\Big(\frac{16\pi^2}{3}\varepsilon\Big)^2 = \frac{1}{12}\cdot\frac{(16\pi^2)^2}{9\,(16\pi^2)^2}\,\varepsilon^2 = \frac{1}{108}\,\varepsilon^2. \tag{52.73}$$

Through the dictionary $\eta = 2\gamma_\phi(\lambda_*)$ this is the carried critical exponent

$$\boxed{\eta = \frac{\varepsilon^2}{54} + O(\varepsilon^3)} \tag{52.74}$$

for the one-component scalar, and the full conformal dimension of $\sigma = \phi$ is

$$\Delta_\phi = \frac{d-2}{2} + \frac{\varepsilon^2}{108} = \frac{2-\varepsilon}{2} + \frac{\varepsilon^2}{108} = 1 - \frac{\varepsilon}{2} + \frac{\varepsilon^2}{108} + O(\varepsilon^3). \tag{52.75}$$

The vanishing of η at $O(\varepsilon)$ is the precise statement that, to first order in the deficit, the interacting field still scales canonically; the interaction shifts the power in the two-point function $\langle\phi(x)\phi(0)\rangle \sim |x|^{-(d-2+\eta)}$ only at second order. This matches the thread obligation $\gamma_\phi = O(\varepsilon^2)$ exactly.

52.3.3 Renormalization of the composite operator ϕ^2: ν

The second datum is the dimension of $\varepsilon = :\phi^2:$, which through $1/\nu = d - \Delta_{\phi^2}$ (Eq. (52.44)) controls the correlation-length exponent. The operator ϕ^2 is composite: it is the product of two fields at a coincident point, and such products develop their own short-distance divergences beyond those of the elementary fields. They must be renormalized separately, by an operator renormalization constant Z_{ϕ^2}, and the anomalous dimension that Z_{ϕ^2} generates is precisely γ_{ϕ^2}.

The composite vertex. The object that exhibits the divergence is the one-particle-irreducible correlator with a single insertion of $\frac{1}{2}\phi^2$ and two amputated external ϕ legs,

$$\Gamma_{\phi^2}(p) \equiv \big\langle\, \tfrac{1}{2}\phi^2\ \phi\,\phi \,\big\rangle_{1\mathrm{PI},\,\mathrm{amp}}, \tag{52.76}$$

with p the momentum flowing into the operator. At tree level the two fields in $\frac{1}{2}\phi^2$ contract directly with the two external legs — two equal contractions cancelling the $\frac{1}{2}$ — so $\Gamma^{(0)}_{\phi^2} = 1$. The first correction is the single diagram of Fig. 52.3: the two fields of the operator close into a loop through one quartic vertex, whose remaining two legs are the external lines.

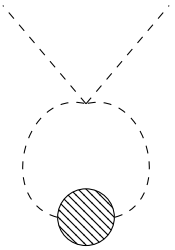

Figure 52.3: The one-loop renormalization of the composite operator $\frac{1}{2}\phi^2$ (the shaded insertion). Its two fields close into a loop through a single quartic vertex; the remaining two vertex legs are the external ϕ lines. The loop is the massless bubble Eq. (52.79) and supplies the logarithmic divergence that defines Z_{ϕ^2}, hence γ_{ϕ^2} and the exponent ν.

The combinatorics and the integral. Expand to first order in the interaction $-S_{\text{int}} = -\frac{\lambda}{4!}\int \mathrm{d}^d z\, \phi(z)^4$ and count Wick contractions of $\langle \frac{1}{2}\phi(x)^2\, \phi(y_1)\phi(y_2)\, (-\frac{\lambda}{4!})\int \phi(z)^4 \rangle$ that yield the 1PI topology: each external field contracts with a distinct vertex leg (4×3 ways), and the two operator fields contract with the remaining two vertex legs (2 ways), for $4 \cdot 3 \cdot 2 = 24$ contractions. With the prefactor $\frac{1}{2} \cdot (-\frac{\lambda}{24})$ the combinatorial weight is

$$\tfrac{1}{2} \cdot \Big(-\frac{\lambda}{24} \Big) \cdot 24 = -\frac{\lambda}{2}, \tag{52.77}$$

and amputating the external legs leaves the massless bubble with the operator momentum p flowing through it,

$$\Gamma^{(1)}_{\phi^2}(p) = -\frac{\lambda}{2}\, B(p^2), \qquad B(p^2) = \int \frac{\mathrm{d}^d k}{(2\pi)^d}\, \frac{1}{k^2\,(k+p)^2}. \tag{52.78}$$

The bubble is the same integral that fed β_λ at one loop; from the master formula Eq. (D.77) (massless limit, two propagators) one finds, as in Theorem D.25,

$$B(p^2) = \frac{1}{(4\pi)^{d/2}}\, \frac{\Gamma(2-\frac{d}{2})\, \Gamma(\frac{d}{2}-1)^2}{\Gamma(d-2)}\, (p^2)^{\,d/2-2} \;=\; \frac{1}{16\pi^2}\, \frac{1}{\varepsilon_{\text{dr}}} + (\text{finite}), \tag{52.79}$$

the divergence the single pole $\Gamma(2-d/2) = \Gamma(\varepsilon_{\text{dr}})$. Hence the one-loop composite vertex carries the pole

$$\Gamma_{\phi^2}(p) = 1 - \frac{\lambda}{2} \cdot \frac{1}{16\pi^2}\, \frac{1}{\varepsilon_{\text{dr}}} + (\text{finite}) = 1 - \frac{\lambda}{32\pi^2}\, \frac{1}{\varepsilon_{\text{dr}}} + \cdots . \tag{52.80}$$

The operator renormalization constant. Define the renormalized composite operator $[\phi^2]_R = Z^{-1}_{\phi^2}\phi^2$, chosen so that $\langle [\phi^2]_R\, \phi\phi \rangle$ is finite. Since the external

legs are renormalized by $Z_\phi^{1/2}$ each and $Z_\phi = 1 + O(\lambda^2)$, finiteness at one loop requires $Z_{\phi^2}^{-1}\Gamma_{\phi^2}$ finite, so Z_{ϕ^2} must cancel the pole of Eq. (52.80):

$$Z_{\phi^2} = 1 - \frac{\lambda}{32\pi^2}\,\frac{1}{\varepsilon_{\mathrm{dr}}} + O(\lambda^2). \tag{52.81}$$

The simple-pole residue is $z_1^{\phi^2} = -\lambda/32\pi^2$. We note in passing that $|z_1^{\phi^2}|$ equals the residue of the mass renormalization $Z_m = 1 + \frac{\lambda}{32\pi^2}\frac{1}{\varepsilon_{\mathrm{dr}}}$ of Eq. (22.83): this is the statement that ϕ^2 is the mass operator, $\frac{1}{2}m^2\phi^2$ being the term it multiplies in the action, so the divergence that renormalizes the mass and the divergence that renormalizes the composite operator are one and the same.

From the residue to γ_{ϕ^2}. The anomalous dimension follows from the pole by the 't Hooft equation Theorem 24.5: for a renormalization constant $Z = 1 + z_1(\lambda)/\varepsilon_{\mathrm{dr}}$, the associated anomalous dimension is $\gamma = -\rho\,\lambda\,\frac{dz_1}{d\lambda}$ with $\rho = 2$ for ϕ^4 (the same ρ that turns $z_1^\lambda = 3\lambda/32\pi^2$ into $\beta_\lambda = 3\lambda^2/16\pi^2$ and $z_1^m = \lambda/32\pi^2$ into the carried mass running $\mu\,\partial_\mu m^2 = \frac{\lambda}{16\pi^2}m^2$ of Chapter 24). With $z_1^{\phi^2} = -\lambda/32\pi^2$, so $\frac{dz_1^{\phi^2}}{d\lambda} = -1/32\pi^2$,

$$\gamma_{\phi^2}(\lambda) = -2\,\lambda\cdot\Big(-\frac{1}{32\pi^2}\Big) = \frac{\lambda}{16\pi^2} + O(\lambda^2). \tag{52.82}$$

The sign is fixed unambiguously by the physics it must reproduce: γ_{ϕ^2} is, to this order, identical to the anomalous dimension of the mass operator already carried by ϕ^4 theory, $\mu\,\partial_\mu \ln m^2 = \lambda/16\pi^2 > 0$ (Chapter 24), and it is positive — the composite operator scales *above* its engineering dimension. Evaluating at the fixed point,

$$\gamma_{\phi^2}(\lambda_*) = \frac{1}{16\pi^2}\cdot\frac{16\pi^2}{3}\varepsilon = \frac{\varepsilon}{3}. \tag{52.83}$$

Assembling ν. The conformal dimension of $\varepsilon = \phi^2$ is its engineering dimension $d-2$ plus the anomalous part, the decomposition Eq. (52.30),

$$\Delta_{\phi^2} = (d-2) + \gamma_{\phi^2}(\lambda_*) = (2-\varepsilon) + \frac{\varepsilon}{3} = 2 - \frac{2\varepsilon}{3} + O(\varepsilon^2). \tag{52.84}$$

Feeding this into the dictionary $1/\nu = d - \Delta_{\phi^2}$ of Eq. (52.44),

$$\frac{1}{\nu} = (4-\varepsilon) - \Big(2 - \frac{2\varepsilon}{3}\Big) = 2 - \frac{\varepsilon}{3} + O(\varepsilon^2), \tag{52.85}$$

and inverting the series,

$$\boxed{\nu = \frac{1}{2-\varepsilon/3} = \frac{1}{2}\Big(1-\frac{\varepsilon}{6}\Big)^{-1} = \frac{1}{2} + \frac{\varepsilon}{12} + O(\varepsilon^2)\,.} \tag{52.86}$$

This is the carried result of the thread. The deviation of ν from its Gaussian value $\frac{1}{2}$ is $O(\varepsilon)$, an order earlier than η, because it is driven by the one-loop renormalization of a relevant operator rather than by a two-loop wavefunction effect. The full end-to-end computation, with every intermediate value displayed, is the following worked example.

Worked Example 52.12 (The correlation-length exponent of the Wilson–Fisher CFT to $O(\varepsilon)$)**.** We carry ν from the bare composite operator to the critical exponent in one pass, displaying every number.

Step 1 — the fixed point. The engineering dimension Eq. (52.59) gives $[\lambda] = \varepsilon$, hence the classical term $-\varepsilon\lambda$ in Eq. (52.60); balancing it against the imported one-loop term $3\lambda^2/16\pi^2$ gives $\lambda_* = 16\pi^2\varepsilon/3$.

Step 2 — the composite-operator divergence. The single one-loop diagram Fig. 52.3 has combinatorial weight $-\lambda/2$ from Eq. (52.77) and the massless bubble Eq. (52.79) with pole $1/16\pi^2\varepsilon_{\mathrm{dr}}$; their product is the pole $-\lambda/32\pi^2\varepsilon_{\mathrm{dr}}$ of Eq. (52.80), cancelled by $Z_{\phi^2} = 1 - \lambda/32\pi^2\varepsilon_{\mathrm{dr}}$.

Step 3 — the anomalous dimension. The pole-to-γ relation Theorem 24.5 with $\rho = 2$ converts the residue $-\lambda/32\pi^2$ into $\gamma_{\phi^2}(\lambda) = \lambda/16\pi^2$, the same number as the carried mass running. At λ_*: $\gamma_{\phi^2}(\lambda_*) = \frac{1}{16\pi^2}\cdot\frac{16\pi^2}{3}\varepsilon = \varepsilon/3$.

Step 4 — the dimension and the exponent. The full dimension is $\Delta_{\phi^2} = (d-2) + \varepsilon/3 = (2-\varepsilon) + \varepsilon/3 = 2 - 2\varepsilon/3$. The dictionary $1/\nu = d - \Delta_{\phi^2}$ gives $1/\nu = (4-\varepsilon) - (2 - 2\varepsilon/3) = 2 - \varepsilon/3$, and inverting, $\nu = \frac{1}{2} + \frac{\varepsilon}{12} + O(\varepsilon^2)$.

Sanity at $\varepsilon = 0$. As $\varepsilon \to 0$ ($d \to 4$) the fixed point merges with the Gaussian one, $\lambda_* \to 0$, all anomalous dimensions vanish, and $\nu \to \frac{1}{2}$, $\eta \to 0$ — the mean-field exponents of the free scalar, as they must be. The leading interacting corrections are $\nu - \frac{1}{2} = +\varepsilon/12$ (one loop) and $\eta = \varepsilon^2/54$ (two loops), the two numbers the next section sets at $\varepsilon = 1$.

Caution

The exponent ν deviates from mean field at $O(\varepsilon)$ while η deviates only at $O(\varepsilon^2)$; it is tempting to read this as "ν is the leading effect and η a small correction." That is true as an organizing statement about the ε-series, but it does *not* license dropping η when the series is summed at $\varepsilon = 1$. The hyperscaling and scaling relations (Section 52.2.3) tie all exponents together; a consistent set of three-dimensional numbers requires η at the same accuracy as ν. The honest treatment of $\varepsilon = 1$ — where the bare series must be resummed and is ultimately superseded by the bootstrap — is the business of the next section. Here we have only the leading terms of an asymptotic expansion.

52.3.4 The $O(N)$ family: Wilson–Fisher as one parameter among two

ϕ^4 theory is the one-component ($N = 1$, Ising) member of a family. Replace the single real scalar by an N-component field $\vec{\phi} = (\phi_1, \dots, \phi_N)$ with $O(N)$-invariant action

$$S_E = \int \mathrm{d}^d x \left[\tfrac{1}{2} (\partial_\mu \vec{\phi}) \cdot (\partial_\mu \vec{\phi}) + \tfrac{1}{2} m^2 \, \vec{\phi} \cdot \vec{\phi} + \frac{\lambda}{4!} \, (\vec{\phi} \cdot \vec{\phi})^2 \right], \tag{52.87}$$

which reduces to Eq. (52.57) at $N = 1$. The internal symmetry decorates each loop with a sum over components, and the standard counting (each of the three one-loop four-point channels carries a different contraction of the $O(N)$ indices, summing to $N + 8$ instead of 3) modifies only the loop coefficient of the beta function,

$$\beta_\lambda = -\varepsilon \, \lambda + \frac{N+8}{3} \, \frac{\lambda^2}{16\pi^2} + O(\lambda^3), \tag{52.88}$$

which at $N = 1$ returns $\frac{9}{3} = 3$, the carried coefficient. The fixed point and exponents follow as before. Setting $\beta_\lambda = 0$,

$$\lambda_* = \frac{3}{N+8} \, 16\pi^2 \, \varepsilon = \frac{48\pi^2}{N+8} \, \varepsilon, \tag{52.89}$$

reducing to $\lambda_* = 16\pi^2 \varepsilon / 3$ at $N = 1$. The composite-operator analysis generalizes: the relevant $O(N)$-singlet operator $\vec{\phi} \cdot \vec{\phi}$ has $\gamma_{\phi^2}(\lambda) = \frac{N+2}{3} \frac{\lambda}{16\pi^2}$, so that

$$\frac{1}{\nu} = 2 - \gamma_{\phi^2}(\lambda_*) = 2 - \frac{N+2}{N+8} \, \varepsilon + O(\varepsilon^2), \qquad \nu = \frac{1}{2} + \frac{N+2}{4(N+8)} \, \varepsilon + O(\varepsilon^2), \tag{52.90}$$

and the two-loop field anomalous dimension generalizes to

$$\eta = \frac{N+2}{2(N+8)^2} \, \varepsilon^2 + O(\varepsilon^3). \tag{52.91}$$

At $N = 1$ these return $1/\nu = 2 - \frac{3}{9}\varepsilon = 2 - \varepsilon/3$ and $\eta = \frac{3}{2 \cdot 81} \varepsilon^2 = \varepsilon^2 / 54$, exactly Eqs. (52.74) and (52.85). Each integer N labels a distinct Wilson–Fisher CFT: $N = 0$ the self-avoiding walk, $N = 1$ Ising, $N = 2$ the XY universality class (superfluid helium), $N = 3$ the Heisenberg ferromagnet, and $N \to \infty$ the exactly solvable spherical model. The Wilson–Fisher construction thus exhibits not one CFT but a two-parameter sheet of them, coordinatized by (N, ε), each a concrete interacting conformal field theory accessible from the free scalar by a controlled expansion.

Notation Watch

The fixed-point coupling Eq. (52.89) is quoted in the thread's $\frac{\lambda}{4!}(\vec{\phi}^2)^2$ normalization, in which $N = 1$ reproduces the carried $\lambda_* = 16\pi^2 \varepsilon / 3$.

Much of the critical-phenomena and bootstrap literature uses instead the normalization $\frac{\lambda}{8}(\vec{\phi}^2)^2$, differing by a factor 3 in the coupling, in which the same fixed point reads $\lambda_* = 16\pi^2\varepsilon/(N+8)$. The two are identical physics; only the dimensionless number assigned to "λ_*" differs, while the universal exponents Eqs. (52.90) and (52.91) are normalization-independent. We retain the thread normalization throughout.

Handoff

We now hold the leading conformal data of the Wilson–Fisher CFT as explicit functions of the deficit: $\Delta_\phi = 1 - \frac{\varepsilon}{2} + \frac{\varepsilon^2}{108}$ and $\Delta_{\phi^2} = 2 - \frac{2\varepsilon}{3}$, equivalently $\eta = \varepsilon^2/54$ and $\nu = \frac{1}{2} + \frac{\varepsilon}{12}$. The next section sets $\varepsilon = 1$ to reach the physical three-dimensional Ising model, confronts these truncated series — and their resummations — with the numerical-bootstrap determination $\Delta_\sigma = 0.5181489$, $\Delta_\varepsilon = 1.412625$ of Theorem 50.35, and with Monte Carlo and experiment, thereby closing the loop between the renormalization group of Part VI and the bootstrap of Part XIV on the same conformal field theory.

52.4 Closing the Loop: the Epsilon-Expansion Meets the Bootstrap (3D Ising)

The previous section delivered, from a Lagrangian computation, the conformal data of the Wilson–Fisher fixed point as a power series in the dimension deficit $\varepsilon = 4 - d$. The two lightest scalar dimensions came out as

$$\Delta_\sigma = \frac{d-2}{2} + \frac{\varepsilon^2}{108} + O(\varepsilon^3) = 1 - \frac{\varepsilon}{2} + \frac{\varepsilon^2}{108} + O(\varepsilon^3), \tag{52.92}$$

$$\Delta_\varepsilon = d - \frac{1}{\nu} = 2 - \frac{2\varepsilon}{3} + O(\varepsilon^2), \tag{52.93}$$

the first from the field anomalous dimension $\gamma_\phi = \frac{\varepsilon^2}{108} + O(\varepsilon^3)$ and the second from the relevant eigenvalue $1/\nu = 2 - \frac{\varepsilon}{3} + O(\varepsilon^2)$ (Eqs. (47.263) and (47.264), characterized as conformal data in Theorem 52.11). These are exact statements about a CFT that lives in a continuous family indexed by d, valid as asymptotic expansions near $d = 4$. The physically interesting member of the family is the one at $d = 3$, the universality class of the three-dimensional Ising model and of every system in it — the uniaxial ferromagnet at its Curie point, the liquid–vapour critical point, a binary fluid at demixing. Reaching it means setting $\varepsilon = 1$.

This section does exactly that, and then confronts the result with the independent, nonperturbative determination of the same CFT obtained in Chapter 50 by the numerical conformal bootstrap, and with Monte Carlo simulation of the

lattice model. Three calculations that share not one line of method — a perturbative loop expansion around four dimensions, a convex-optimization search over the space of crossing-symmetric spectra, and a direct stochastic sampling of a lattice partition function — will be seen to return the same five numbers $(\Delta_\sigma, \Delta_\varepsilon, \eta, \nu, \omega)$ to their quoted precision. That agreement is the deepest available vindication of the central thesis of this chapter, that a renormalization-group fixed point and a conformal field theory are one object: the Wilson–Fisher fixed point of Part VI *is* the bootstrap island of Chapter 50, and ϕ^4 theory, carried since the classical Lagrangian of Chapter 6, terminates here on a single, fully characterized CFT.

Notation Watch

Three distinct quantities in this section are written with the same Greek letter, and only context separates them. The *expansion parameter* $\varepsilon = 4-d$ is the dimension deficit, held small and finite (it is set to 1 at the end); it is twice the dimensional-regularization regulator $\varepsilon_{\text{dimreg}}$ of the book's canon, as flagged in Section 24.7.5. The *energy operator* $\varepsilon = :\phi^2:$, the leading $\mathbb{Z}_2$-even scalar of Section 52.2.5, carries its name as a subscript: Δ_ε, $\lambda_{\sigma\sigma\varepsilon}$. And the Feynman $i\epsilon$ of the Lorentzian propagator does not appear here at all, since critical phenomena are Euclidean throughout (Chapter 10). A standalone ε is always the deficit; a subscripted ε is always the operator.

52.4.1 The naive substitution, carried out honestly

The first thing any reader will do with Eqs. (52.92) and (52.93) is set $\varepsilon = 1$ and read off a number. It is worth doing this carefully, watching each successive term, because the way the partial sums behave is itself the lesson. Theorem 49.29 performed the leading comparison; we extend it here to the full set of exponents and to as many orders as are needed to see the pattern, then state honestly what the truncated series can and cannot do.

Worked Example 52.13 (The $\varepsilon = 1$ truncations of the Ising exponents)**.** We take the one-component ($N = 1$) Wilson–Fisher series in the deficit $\varepsilon = 4 - d$ and evaluate the truncations at $\varepsilon = 1$. The relevant series, in the standard normalization of the $O(N)$ critical-exponent literature specialized to $N = 1$, are

$$\eta = \frac{\varepsilon^2}{54} + \frac{109}{5832}\,\varepsilon^3 + O(\varepsilon^4), \tag{52.94}$$

$$\frac{1}{\nu} = 2 - \frac{\varepsilon}{3} - \frac{19}{162}\,\varepsilon^2 + O(\varepsilon^3), \tag{52.95}$$

$$\omega = \varepsilon - \frac{17}{27}\,\varepsilon^2 + O(\varepsilon^3). \tag{52.96}$$

The first follows from $\eta = 2\gamma_*$ with $\gamma_\phi = \frac{\varepsilon^2}{108} + \cdots$ of Eq. (52.92); the second is the relevant RG eigenvalue at the fixed point; the third is the slope $\omega = \beta'_\lambda(\lambda_*)$ of Theorem 24.31, whose meaning we return to in Section 52.4.5.

The anomalous dimension η. The leading term gives $\eta \approx 1/54 = 0.0185$; adding the $O(\varepsilon^3)$ term gives $0.0185 + 0.0187 = 0.0372$. The two contributions are nearly equal in size at $\varepsilon = 1$: the series is *not* settling down. The exact value (we will see) is $\eta = 0.0363$, so the one-term truncation undershoots by half and the two-term truncation overshoots slightly. There is no sense in which "adding the next term improves the answer by a controlled amount"; the corrections are $O(1)$ relative to each other.

The correlation-length exponent ν. From Eq. (52.95) at $\varepsilon = 1$: one term gives $1/\nu = 2 - 0.333 = 1.667$, hence $\nu = 0.600$; two terms give $1/\nu = 1.667 - 0.117 = 1.549$, hence $\nu = 0.645$. The true value is $\nu = 0.630$, so the partial sums straddle it (0.600, then 0.645) without converging onto it. Equivalently $\Delta_\varepsilon = d - 1/\nu = 3 - 1/\nu$ runs $1.333 \to 1.451$ against the true 1.413.

The correction-to-scaling exponent ω. This is the worst-behaved of the three. One term gives $\omega = \varepsilon = 1$; two terms give $\omega = 1 - \frac{17}{27} = 1 - 0.630 = 0.370$. The true value is $\omega \approx 0.83$. The two-term truncation is off by more than a factor of two and on the wrong side, and the first correction is comparable to the leading term — the unmistakable signature of a series being evaluated far outside its useful range.

The verdict. Setting $\varepsilon = 1$ in the truncated series produces numbers that are *qualitatively* right — η small and positive, ν near 0.6, ω of order unity, the right ordering and signs — and quantitatively good to perhaps ten or twenty percent for the well-behaved exponents, far worse for ω. They establish that an interacting fixed point exists in $d = 3$ with roughly these exponents. They do not, on their own, deliver the three-dimensional Ising numbers to any precision worth comparing with experiment. The deficit $\varepsilon = 1$ is simply not small, and a few terms of an asymptotic series at argument unity can do no better.

The honest reading of Theorem 52.13 is that the bare ε-expansion is a *structural* tool, not a precision one. It proves the fixed point exists, fixes which operators are relevant, and gives the leading dependence of every exponent on d and on the number of field components N — enormous qualitative power. But the series is divergent, and at $\varepsilon = 1$ its naive truncations have errors of the same order as the answer for the slowly-converging exponents. To extract precise three-dimensional numbers from it requires a separate, nontrivial step: resummation.

52.4.2 Why the series diverges, and how it is resummed

The ε-expansion is an asymptotic series with zero radius of convergence. This is not a defect peculiar to critical phenomena; it is the generic fate of perturbation

series in quantum field theory, and its origin is the one identified by Dyson for quantum electrodynamics and made quantitative for ϕ^4 by the large-order analysis of the path integral. The coefficient of ε^k in any of these series grows factorially,

$$a_k \sim c\,(-a)^k\,k!\,k^b \qquad (k \to \infty), \tag{52.97}$$

with $a > 0$ a positive constant fixed by the action of the instanton of the Euclidean ϕ^4 theory — the finite-action saddle of the functional integral that dominates the high orders. Because $k!\,a^k$ outpaces any power of ε, the series $\sum_k a_k\,\varepsilon^k$ converges for no nonzero ε. It is asymptotic in the precise sense that for fixed small ε the partial sums first approach the true value, reach a closest approach at an optimal order $k_{\mathrm{opt}} \sim 1/(a\varepsilon)$, and thereafter diverge; the smallest achievable error is of order $e^{-1/(a\varepsilon)}$. At $\varepsilon = 1$ the optimal order is small — a handful of terms — and the closest approach is not very close, exactly the behaviour Theorem 52.13 exhibited.

The sign alternation in Eq. (52.97), $a_k \propto (-a)^k$, is the feature that makes the series resummable. A series whose coefficients grow like $k!$ but alternate in sign is *Borel summable*: the divergence is tamed by the integral transform developed in Chapter 5. One forms the Borel transform

$$B(t) = \sum_{k=0}^{\infty} \frac{a_k}{k!}\,t^k, \tag{52.98}$$

which by Eq. (52.97) has a *finite* radius of convergence $|t| < 1/a$ (the $k!$ has been divided out), and recovers the resummed function by the Laplace integral

$$f(\varepsilon) = \frac{1}{\varepsilon}\int_0^{\infty} dt\, e^{-t/\varepsilon}\,B(t), \tag{52.99}$$

provided $B(t)$ can be continued along the positive real axis and the integral converges. The alternating sign places the nearest singularity of $B(t)$ on the *negative* real axis, at $t = -1/a$, away from the integration contour; the positive axis is clear, and Eq. (52.99) is well defined. (Had the coefficients been of one sign — as they are for the non-Borel-summable cases such as the ground-state energy of certain quantum-mechanical wells — the singularity would sit on the contour and the prescription would be ambiguous, signalling a genuine nonperturbative contribution.)

In practice one knows only finitely many coefficients $a_0, \dots, a_K$ (for the Ising exponents, through ε^5 or ε^6), so $B(t)$ is known only as a truncated Taylor polynomial, useless beyond its disk of convergence. The decisive refinement, due to the work of Le Guillou and Zinn-Justin, is to map the cut t-plane conformally onto a disk before resumming. The Borel transform is analytic in the t-plane cut from $t = -1/a$ to $-\infty$; the conformal map

$$w(t) = \frac{\sqrt{1 + at} - 1}{\sqrt{1 + at} + 1} \tag{52.100}$$

sends that cut plane to the unit disk $|w| < 1$, with the singularity at $t = -1/a$ pushed to the boundary $w = -1$ and the entire positive t-axis (the integration range) mapped into the interior. Re-expanding B as a power series in w and truncating gives an approximant that converges *inside the disk*, i.e. everywhere the Laplace integral needs it, rather than merely inside $|t| < 1/a$. Feeding this approximant into Eq. (52.99) and evaluating at $\varepsilon = 1$ produces a number with a controlled, shrinking error as more coefficients are included. This Borel–conformal-mapping resummation is what converts the divergent series of Theorem 52.13 into the precise three-dimensional exponents.

Physical Insight

The logic is worth holding in one sentence: the perturbative series *encodes* the right answer, but encrypted in a divergent form, and the instanton-controlled large-order behaviour Eq. (52.97) is precisely the key — it tells us the location $t = -1/a$ of the Borel singularity, which is exactly the information the conformal map Eq. (52.100) needs to decrypt the series. The divergence is not noise to be discarded; its rate is data, and resummation is the act of using it.

We do not carry the resummation arithmetic itself — it is a numerical procedure on six known coefficients, reproducible but not illuminating to grind by hand, and Chapter 5 established the transform that underlies it. What matters here is the conceptual contract: the resummed ε-expansion is an honest, controlled extraction of three-dimensional numbers from a divergent series, with quantifiable uncertainties, and it is this resummed output — not the naive truncations of Theorem 52.13 — that one compares with the bootstrap.

52.4.3 The comparison: three methods, one CFT

Table 52.2 sets the resummed ε-expansion exponents beside the numerical-bootstrap determination of Chapter 50 (the island of Table 50.1, read through the dictionary $\eta = 2\Delta_\sigma - 1$, $1/\nu = d - \Delta_\varepsilon$ of Eqs. (49.162) and (49.163)) and beside the best Monte Carlo simulations of the lattice model.

Read the table column by column and the agreement is total to the precision each method claims. The three determinations of ν are 0.6304(13), 0.629971(4), 0.63002(10): they coincide within errors, the bootstrap being the most precise by three orders of magnitude. The three values of η are 0.0335(25), 0.0362978(20), 0.03627(10); here the resummed ε-expansion sits about one of its own standard deviations low, a known feature of the η series, while the bootstrap and Monte Carlo agree to five figures. Even the awkward correction-to-scaling exponent ω, which the naive truncation of Theorem 52.13 got so badly wrong, comes into line once resummed: 0.799(11) from the series against 0.832(6) from Monte Carlo and

Table 52.2: The leading 3D Ising critical data from three independent methods. *Resummed ε-expansion*: Borel–conformal-mapping resummation of the $O(N{=}1)$ series through $O(\varepsilon^5)$ [318]; the dimensions $\Delta_\sigma = (1+\eta)/2$ and $\Delta_\varepsilon = 3 - 1/\nu$ are derived from (η, ν). *Numerical bootstrap*: the mixed-correlator island of Chapter 50 [304], with $\Delta_\sigma, \Delta_\varepsilon$ primary and the exponents derived through Eqs. (49.162) and (49.163); $\omega = \Delta_{\varepsilon'} - d$ from the leading irrelevant even scalar (Eq. (50.129)). *Monte Carlo*: high-statistics finite-size scaling of the lattice model [254]. Parenthesized digits are one-standard-deviation uncertainties in the last figures; the ε-expansion uncertainties are resummation-method estimates. Values current to the mid-2020s.

quantity	resummed ε-expansion	numerical bootstrap	Monte Carlo
Δ_σ	0.5168(13)	0.5181489(10)	0.518135(50)
Δ_ε	1.414(3)	1.412625(10)	1.41275(25)
η	0.0335(25)	0.0362978(20)	0.03627(10)
ν	0.6304(13)	0.629971(4)	0.63002(10)
ω	0.799(11)	≈ 0.830	0.832(6)

≈ 0.83 from the bootstrap's leading irrelevant scalar. Figure 52.4 displays the same three exponents graphically, the error bars overlapping in every panel.

Historical Note

The convergence shown here was hard-won and runs over half a century. Wilson and Fisher proposed the ε-expansion in 1972; through the 1970s and 1980s the resummed series and improving Monte Carlo data slowly tightened the Ising exponents to the third decimal, with the resummation systematics — how many terms, which map, what error to quote — a delicate and somewhat dark art. The numerical bootstrap entered this mature field in 2012 and, within a few years, overtook every prior method by orders of magnitude, not by computing harder but by abandoning the Lagrangian altogether and demanding only crossing symmetry and unitarity. That a sixty-year-old perturbative idea and a decade-old optimization method land on the same six-figure number is the field's quiet triumph.

52.4.4 Why the agreement is meaningful: two computations of the same object

It would be a mistake to read Table 52.2 as one method checking another's arithmetic, as if both were approximating some third, more fundamental computation. They are not. The two principal entries — the ε-expansion and the bootstrap — are computations of *genuinely different kinds*, and their agreement is informative

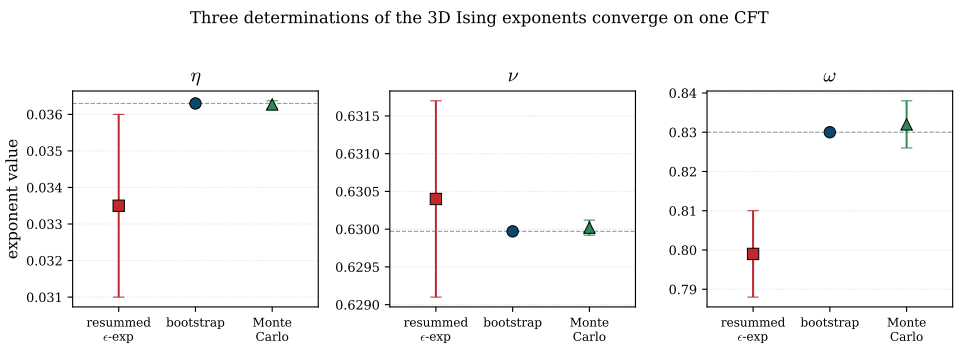

Figure 52.4: The three independent determinations of the leading 3D Ising exponents η, ν, ω from Table 52.2: the resummed ε-expansion (squares), the numerical conformal bootstrap of Chapter 50 (circles; the bootstrap error on η and ν is smaller than the marker), and Monte Carlo (triangles), each with its one-standard-deviation error bar. The dashed line marks the bootstrap central value. A perturbative Lagrangian computation around $d = 4$, a nonperturbative crossing computation in $d = 3$, and a lattice simulation agree within their uncertainties on every exponent — the quantitative statement that all three are measuring one conformal field theory.

precisely because they share no common premise that could be the source of a shared error.

The ε-expansion is a *perturbative Lagrangian* computation. It begins with the action of ϕ^4 theory, $S_E = \int d^d x \left[\frac{1}{2}(\partial\phi)^2 + \frac{1}{2}m^2\phi^2 + \frac{\lambda}{4!}\phi^4\right]$, posits that a fixed point exists at small coupling near $d = 4$, locates it as the nontrivial zero $\lambda_* = \frac{16\pi^2}{3}\varepsilon + O(\varepsilon^2)$ of the beta function (Eq. (24.255)), and computes operator dimensions as anomalous dimensions of fields and composites in a loop expansion. Every step is tied to the existence of a fundamental scalar field and a small parameter; the output is a series in ε. The method knows the theory is the continuation of a free scalar and uses that knowledge at every order.

The bootstrap is a *nonperturbative crossing* computation. It begins with no Lagrangian, no fields, and no coupling. It posits only that there exists *some* unitary CFT in $d = 3$ with a $\mathbb{Z}_2$ symmetry and the minimal relevant-operator content of Theorem 49.27, writes the crossing equation Eq. (49.15) that the four-point function of the order parameter must satisfy, and searches the space of admissible operator spectra for the ones consistent with crossing and unitarity (Chapter 50). The output is a small island in the plane of dimensions $(\Delta_\sigma, \Delta_\varepsilon)$, located by a convex optimization with no expansion parameter at all. The method never knows there is a scalar field underneath; it would find the same island in a universe where the lattice Ising model had never been written down.

Physical Insight

The complementarity is exact and structural. The ε-expansion is reliable where the bootstrap is weakest — near $d = 4$, where the coupling is small and the perturbative series converges quickly, but where the bootstrap's crossing equation is nearly degenerate. The bootstrap is sharpest where the ε-expansion is least trustworthy — at $d = 3$, far from the free theory, where the series must be resummed and the loop expansion is at the edge of its validity. Each method's region of confidence is the other's frontier, and they meet, with overlapping error bars, on the single CFT in between. Two maps drawn with incompatible projections, agreeing on the coastline, are far better evidence that the coastline is real than two copies of the same map.

This is the strongest form of the chapter's thesis. Theorem 52.11 established *as a theorem* that the Wilson–Fisher fixed point is a conformal field theory; Section 52.2 established the dictionary turning its operator dimensions into critical exponents. Table 52.2 now establishes, as a matter of computed numbers, that this CFT is the *same* object the bootstrap corners from consistency alone. The fixed-point-equals-CFT identification is not merely a definition or a structural theorem; it is a quantitative prediction, confirmed to six significant figures by methods that could in principle have disagreed and did not.

52.4.5 The correction-to-scaling exponent is a bootstrap operator dimension

One entry in Table 52.2 deserves its own derivation, because it ties a quantity defined by the renormalization group — the slope of the beta function at the fixed point — to a quantity defined by the bootstrap — the dimension of an operator in the spectrum. This is the exponent ω, and the identity between its two definitions is the sharpest single instance of the RG/CFT dictionary at work.

On the RG side, ω was defined in Theorem 24.26 as the slope of the beta function at the fixed point,

$$\omega = \beta'_\lambda(\lambda_*), \tag{52.101}$$

the eigenvalue governing how a small deviation $\delta\lambda = \lambda - \lambda_*$ flows: near the fixed point $\beta_\lambda(\lambda) \simeq \omega\,\delta\lambda$, so $\delta\lambda(\mu) \propto \mu^\omega$, and $\omega > 0$ means the deviation decays into the infrared — the Wilson–Fisher point is infrared-attractive, the deviation is an *irrelevant* direction. The exponent ω controls how a physical quantity approaches its scaling form as the critical point is neared: corrections to pure power-law scaling are suppressed by a factor $t^{\omega\nu}$ in the reduced temperature, the leading *correction to scaling*. For the one-loop ϕ^4 beta function $\beta_\lambda = -\varepsilon\lambda + \frac{3\lambda^2}{16\pi^2}$ of Eq. (24.254), differentiating at $\lambda_* = \frac{16\pi^2}{3}\varepsilon$ gives $\beta'_\lambda(\lambda_*) = -\varepsilon + \frac{6\lambda_*}{16\pi^2} = -\varepsilon + 2\varepsilon = +\varepsilon$, the leading term of Eq. (52.96).

On the CFT side, the general dictionary of Section 52.2.2 assigns to a deformation of the fixed-point action by a scalar primary $\mathcal{O}$ of dimension $\Delta_{\mathcal{O}}$ the RG eigenvalue $y_{\mathcal{O}} = d - \Delta_{\mathcal{O}}$: the coupling $g_{\mathcal{O}}$ multiplying $\int d^d x\, \mathcal{O}$ has mass dimension $d - \Delta_{\mathcal{O}}$, and under rescaling by b flows as $g_{\mathcal{O}}(b) = b^{d-\Delta_{\mathcal{O}}} g_{\mathcal{O}}$. A deformation is irrelevant precisely when $\Delta_{\mathcal{O}} > d$, and for an irrelevant direction the correction-to-scaling exponent is the positive number $\omega_{\mathcal{O}} = -y_{\mathcal{O}} = \Delta_{\mathcal{O}} - d$ (Section 52.2.4). We now show the RG slope Eq. (52.101) is exactly this number for a definite operator.

Proposition 52.14 (The slope $\beta'_\lambda(\lambda_*)$ is the dimension of the leading irrelevant $\mathbb{Z}_2$-even scalar, minus d)**.** *At the Wilson–Fisher fixed point the slope of the beta function equals the correction-to-scaling exponent set by the leading irrelevant $\mathbb{Z}_2$-even scalar operator ε':*

$$\omega = \beta'_\lambda(\lambda_*) = \Delta_{\varepsilon'} - d, \tag{52.102}$$

where ε' is the lowest-dimension $\mathbb{Z}_2$-even scalar above the energy operator ε — the operator into which the quartic interaction $\frac{\lambda}{4!}\phi^4$ renormalizes at the fixed point.

Proof. The deviation $\delta\lambda = \lambda - \lambda_*$ is, by construction, the coefficient of the operator that the coupling λ multiplies in the action, namely $\frac{1}{4!}\phi^4$. At the fixed point this composite is not an eigenoperator of the dilatation: it mixes, under renormalization, with the lower-dimension even scalars (the identity, which only shifts the cosmological constant, and ϕ^2) and with descendants. Projecting onto the conformal primaries, the part of $\frac{1}{4!}\phi^4$ orthogonal to the relevant directions is the eigenoperator ε', the lowest $\mathbb{Z}_2$-even scalar primary whose deformation is irrelevant; this is the operator that controls the leading approach to scaling once the relevant tunings (temperature, conjugate to ε) have been made. The linearized flow of $\delta\lambda$ is therefore the linearized flow of the coupling of ε', and by the dictionary of Section 52.2.2 its eigenvalue is

$$\frac{d(\delta\lambda)}{d\ln b} = y_{\varepsilon'}\,\delta\lambda = (d - \Delta_{\varepsilon'})\,\delta\lambda. \tag{52.103}$$

Comparing with the beta-function form $d(\delta\lambda)/d\ln b = -\beta_\lambda(\lambda) \simeq -\omega\,\delta\lambda$ in the long-distance (increasing b, decreasing μ) convention — where an irrelevant deviation must decay, $y_{\varepsilon'} < 0$ — gives $-\omega = y_{\varepsilon'} = d - \Delta_{\varepsilon'}$, i.e. $\omega = \Delta_{\varepsilon'} - d$. The sign is consistent: $\Delta_{\varepsilon'} > d$ (the operator is irrelevant) gives $\omega > 0$, matching $\beta'_\lambda(\lambda_*) = +\varepsilon > 0$ found above. □

The content of Theorem 52.14 is that the number the RG computes as a property of the flow — the slope of a vector field at a zero — is, on the nose, a number the bootstrap computes as a property of the spectrum: the dimension of a specific operator, displaced from marginality. We can now check both sides

against Chapter 50. Solving Eq. (52.102) for the dimension, $\Delta_{\varepsilon'} = d + \omega$, the leading ε-expansion result $\omega = \varepsilon$ gives $\Delta_{\varepsilon'} = (4-\varepsilon) + \varepsilon = 4 + O(\varepsilon^2)$, refined by Eq. (52.96) to $\Delta_{\varepsilon'} = 4 - \frac{17}{27}\varepsilon^2 + O(\varepsilon^3)$, which at the naive $\varepsilon = 1$ reads $\Delta_{\varepsilon'} \approx 3.37$. The numerical bootstrap, meanwhile, locates the second $\mathbb{Z}_2$-even scalar directly as the next double-zero of its extremal functional, at $\Delta_{\varepsilon'} \approx 3.83$ (Eq. (50.129)), giving $\omega = \Delta_{\varepsilon'} - d \approx 0.83$. The naive perturbative $\Delta_{\varepsilon'} \approx 3.37$ and the bootstrap 3.83 differ by exactly the resummation gap seen for ω in Theorem 52.13; resummed, the ε-expansion returns $\omega = 0.799(11)$, in agreement. The same operator, the same number, found as a beta-function slope around $d = 4$ and as a double-zero of a positivity certificate in $d = 3$.

52.4.6 Cross-check from the analytic bootstrap: the large-spin tail

There is a final, internal consistency check available, of a different character from the comparison with experiment: the spectrum the numerical bootstrap reads off in Chapter 50 must agree, at large spin, with the closed-form prediction of the *analytic* bootstrap of Chapter 51. The two are computed by completely different machinery — one a finite-dimensional semidefinite program, the other an asymptotic expansion of the crossing equation in the lightcone limit — so their agreement on the high-spin part of the same spectrum is a nontrivial test that the island of Table 50.1 is a consistent CFT and not an artifact.

The relevant prediction is the large-spin anomalous dimension of the leading-twist double-twist family. In any unitary CFT the operators $[\sigma\sigma]_{0,\ell}$ — the lowest-twist $\mathbb{Z}_2$-even spin-ℓ operators built from two copies of the order parameter — exist at large ℓ with twist approaching $2\Delta_\sigma$, and their anomalous dimension is fixed by the minimal-twist operator exchanged in the crossed channel. For the 3D Ising CFT that exchanged operator is the energy operator ε, the lightest $\mathbb{Z}_2$-even scalar, and Theorem 51.10 (applied to ϕ^4 theory in Section 51.3.6) gives

$$\gamma_{0,\ell} \;\simeq\; -\frac{c_\varepsilon}{\ell^{\,\Delta_\varepsilon}}, \qquad c_\varepsilon = \frac{2\,\Gamma(\Delta_\sigma)^2}{\Gamma(\Delta_\sigma - \frac{\Delta_\varepsilon}{2})^2}\,\frac{\Gamma(\Delta_\varepsilon)}{\Gamma(\frac{\Delta_\varepsilon}{2})^2}\,\lambda_{\sigma\sigma\varepsilon}^2, \tag{52.104}$$

the coefficient c_ε being entirely determined by three pieces of CFT data: the two dimensions $\Delta_\sigma, \Delta_\varepsilon$ and the OPE coefficient $\lambda_{\sigma\sigma\varepsilon}$. Crucially, all three are quantities the numerical bootstrap measures independently. The cross-check is to feed the Chapter 50 data into Eq. (52.104) and ask whether the resulting tail matches the high-spin operators the same bootstrap computation finds.

Worked Example 52.15 (The Ising large-spin tail from the bootstrap data)**.** We evaluate Eq. (52.104) at the three-dimensional Ising point, using the precise extremal-functional data of Chapter 50:

$$\Delta_\sigma = 0.5181489, \qquad \Delta_\varepsilon = 1.412625, \qquad \lambda_{\sigma\sigma\varepsilon} = 1.0518537, \tag{52.105}$$

so $\lambda^2_{\sigma\sigma\varepsilon} = 1.106396$. The Gamma-function factors are assembled step by step. First the arguments:

$$\frac{\Delta_\varepsilon}{2} = 0.7063125, \qquad \Delta_\sigma - \frac{\Delta_\varepsilon}{2} = 0.5181489 - 0.7063125 = -0.1881636, \tag{52.106}$$

the last being negative — the order parameter is lighter than half the energy operator — so its Gamma function lands on the reflection-formula side of the axis. Evaluating,

$$\Gamma(\Delta_\sigma) = \Gamma(0.5181489) = 1.711766, \qquad \Gamma(\Delta_\sigma)^2 = 2.930144, \tag{52.107}$$

$$\Gamma\big(\Delta_\sigma - \tfrac{\Delta_\varepsilon}{2}\big) = \Gamma(-0.1881636) = -6.118034, \qquad \Gamma(\cdots)^2 = 37.43034, \tag{52.108}$$

$$\Gamma(\Delta_\varepsilon) = \Gamma(1.412625) = 0.886649, \qquad \Gamma\big(\tfrac{\Delta_\varepsilon}{2}\big)^2 = \Gamma(0.7063125)^2 = 1.659380. \tag{52.109}$$

Assembling the two ratios,

$$\frac{2\,\Gamma(\Delta_\sigma)^2}{\Gamma(\Delta_\sigma - \frac{\Delta_\varepsilon}{2})^2} = \frac{2(2.930144)}{37.43034} = 0.156565, \qquad \frac{\Gamma(\Delta_\varepsilon)}{\Gamma(\frac{\Delta_\varepsilon}{2})^2} = \frac{0.886649}{1.659380} = 0.534325, \tag{52.110}$$

and multiplying by $\lambda^2_{\sigma\sigma\varepsilon}$,

$$c_\varepsilon = 0.156565 \times 0.534325 \times 1.106396 = 0.09256. \tag{52.111}$$

The leading-twist family of the 3D Ising CFT therefore has anomalous dimensions

$$\gamma_{0,\ell} \simeq -\frac{0.0926}{\ell^{\,1.41263}} \qquad (\ell \to \infty), \tag{52.112}$$

negative (the binding is attractive, as unitarity requires by the convexity argument of Section 51.3.4) and falling off as $\ell^{-\Delta_\varepsilon}$. Numerically this predicts, for example, $\gamma_{0,\ell} \approx -0.013$ at $\ell = 4$, -0.0036 at $\ell = 10$, and -0.0013 at $\ell = 20$: the operators $[\sigma\sigma]_{0,\ell}$ approach the double-twist value $2\Delta_\sigma + \ell$ from below, ever more closely as the spin grows. These are precisely the dimensions the spin-ℓ double-zeros of the extremal functional in Chapter 50 converge to at large ℓ — the $\ell = 2, 4, 6, \ldots$ operators that Table 50.1 and Eq. (50.129) found organizing into a double-twist tower. The analytic and numerical bootstraps agree on the same spectrum from opposite ends of the spin axis.

The agreement in Theorem 52.15 closes a second loop, internal to the bootstrap: the OPE data $(\Delta_\sigma, \Delta_\varepsilon, \lambda_{\sigma\sigma\varepsilon})$ that the numerical method extracts as inputs reproduce, through the analytic large-spin formula, the high-spin part of the spectrum the same method computes as outputs. A spectrum that failed this test

would be internally inconsistent; the Ising data pass it. Together with the experimental and Monte Carlo agreement of Table 52.2, this completes the case that the object cornered in Chapter 50, computed in Chapter 24, and characterized as a CFT in Theorem 52.11 is one and the same three-dimensional conformal field theory, consistent with itself and with every external measurement of the Ising universality class.

This consummates ϕ^4 theory. The real scalar with a quartic self-interaction and a $\mathbb{Z}_2$ symmetry, introduced as a classical Lagrangian in Chapter 6, quantized in Chapters 9 to 10, renormalized in Chapter 22, and pushed to its nontrivial fixed point in Chapter 24, has been followed all the way to a single, fully determined conformal field theory whose exponents match the laboratory. The thread that began with a free field and a coupling ends on a number, $\nu = 0.629971(4)$, that three independent computations and a generation of experiments agree upon.

Having identified the CFT that lives at the end of the Wilson–Fisher flow, we have characterized the *endpoints* of renormalization-group trajectories as conformal field theories. The natural next question is about the flow itself: a trajectory runs from a fixed point in the ultraviolet to a fixed point in the infrared, and one wants to know whether that direction is intrinsic — whether there is a quantity, built from the CFT data at the two ends, that always decreases from UV to IR and so makes the flow irreversible. The search for such a monotone, and the c- and a-theorems that supply it, is the subject of Section 52.5.

52.5 RG Flows Between Fixed Points: the c- and a-Theorems

The previous section closed the loop we had been winding since the classical Lagrangian of Chapter 6: the Wilson–Fisher fixed point, located perturbatively in Theorem 23.36 and re-read here as a conformal field theory, was matched against the numerical bootstrap of Chapter 50 and against laboratory critical exponents. The picture that emerges is sharp. A conformal field theory is the universal description sitting at a fixed point of the renormalization-group flow, and the bootstrap data — dimensions and OPE coefficients — are the critical exponents of real matter. What we have not yet asked is a question about the flow *itself*, as opposed to its endpoints. A relevant deformation switched on at a fixed point carries the theory along a trajectory in coupling space; that trajectory begins at one CFT in the ultraviolet and ends at another in the infrared. Does the flow have a direction? Can a trajectory ever close into a loop, or reverse, returning a theory to where it began? The answer, and the deepest structural statement of this chapter, is that the flow is *irreversible*: there exists a number, computed entirely from the CFT data at the two ends, that is strictly larger at the ultraviolet end than at the infrared end. The renormalization group has an arrow, and the arrow is a theorem.

This section establishes that arrow in the two dimensions where it is a theorem with a complete proof — $d = 2$, Zamolodchikov's c-theorem — and in the dimension of the physical world — $d = 4$, the a-theorem of Komargodski and Schwimmer — where we give an honest and complete-as-sketch argument. We then turn the result back on ϕ^4 theory as a consistency test of the Wilson–Fisher fixed point, and close with a dated, honest account of how far the monotone is known to exist in general dimension.

52.5.1 The arrow of the renormalization group

The intuition is older than its proof and worth stating plainly before any formula, because it is correct and it is what the formulas make precise. Coarse-graining — integrating out short-distance modes, the operation that *is* the renormalization-group flow of Chapter 23 — discards information. Each step replaces a microscopic description by an effective one with fewer accessible degrees of freedom; the irrelevant directions are washed out (Theorem 23.34), and what survives at long distance is a quotient of what was present at short distance. If some quantity faithfully counted "the number of degrees of freedom" of a scale-invariant theory, that quantity ought to decrease as we flow from the ultraviolet to the infrared. The content of the c- and a-theorems is that such a quantity exists, that it is built from the response of the stress tensor (the one operator every local theory possesses), and that its monotonicity follows from unitarity — the same positivity that underlies every physical bound in the book.

Two features must hold for the statement to have teeth. First, the monotone must be *stationary* at fixed points, so that at a CFT it returns a pure number depending only on the CFT data, not on the trajectory by which the theory was reached. Second, that number must be the *central charge*: the anomaly coefficient of the stress tensor, c in two dimensions (Theorem 48.8) and a in four. We prove both features in $d = 2$ and exhibit them in $d = 4$.

A word on conventions, since the entire section lives in Euclidean signature. Critical phenomena are Euclidean (Chapter 10), and the proofs use reflection positivity — the Euclidean avatar of the unitarity of the underlying Minkowski theory, established for the Euclidean functional integral in Chapter 10. In two dimensions we use the complex coordinates $z = x^1 + ix^2$, $\bar{z} = x^1 - ix^2$ of Chapter 48, with $\partial \equiv \partial_z = \frac{1}{2}(\partial_1 - i\partial_2)$ and $\bar{\partial} \equiv \partial_{\bar{z}} = \frac{1}{2}(\partial_1 + i\partial_2)$, so that $z\bar{z} = |x|^2 \equiv r^2$.

52.5.2 The two-dimensional c-theorem

We work along a generic renormalization-group trajectory in a two-dimensional, unitary, Poincaré-invariant local field theory — not at a fixed point. The theory has a symmetric, conserved stress tensor $T_{\mu\nu}$. Away from a fixed point it is generally not traceless: by the operator equation Eq. (47.3) and its quantum

descendant, the trace measures the running couplings, $\Theta \equiv T^{\mu}{}_{\mu} = \sum_i \beta_i \mathcal{O}_i$, and vanishes precisely where every $\beta_i = 0$. The whole proof is an exercise in what conservation and rotational invariance permit, combined at the end with one positivity statement.

The three structure functions. In complex coordinates the symmetric stress tensor has three independent components, which it is traditional to package as

$$T \equiv T_{zz}, \qquad \bar{T} \equiv T_{\bar{z}\bar{z}}, \qquad \Theta \equiv T^{\mu}{}_{\mu} = 4\,T_{z\bar{z}}, \tag{52.113}$$

the last equality following from $T^{\mu}{}_{\mu} = g^{\mu\nu}T_{\mu\nu} = 2g^{z\bar{z}}T_{z\bar{z}} + 2g^{\bar{z}z}T_{\bar{z}z} = 4T_{z\bar{z}}$, where the flat metric in these coordinates is $g_{z\bar{z}} = \frac{1}{2}$, $g^{z\bar{z}} = 2$. The components T, $\bar{T}$, Θ carry definite spin: under a rotation $z \to e^{i\alpha}z$ they pick up $e^{-2i\alpha}$, $e^{+2i\alpha}$, and 1 respectively, since each lower z index contributes $e^{-i\alpha}$ and each $\bar{z}$ index $e^{+i\alpha}$. Thus T has spin $+2$, $\bar{T}$ has spin -2, and Θ is a scalar.

Conservation $\partial^{\mu}T_{\mu\nu} = 0$ becomes, for the $\nu = z$ component, $\partial^{z}T_{zz} + \partial^{\bar{z}}T_{\bar{z}z} = 0$; raising indices with $g^{z\bar{z}} = 2$ gives $\partial^{z} = 2\bar{\partial}$ and $\partial^{\bar{z}} = 2\partial$, so $2\bar{\partial}T_{zz} + 2\partial T_{\bar{z}z} = 0$. Using $T_{\bar{z}z} = T_{z\bar{z}} = \Theta/4$ from Eq. (52.113),

$$\bar{\partial}\,T = -\tfrac{1}{4}\,\partial\,\Theta, \tag{52.114}$$

and the complex conjugate equation $\partial\,\bar{T} = -\frac{1}{4}\,\bar{\partial}\,\Theta$ for the antiholomorphic component. Equation Eq. (52.114) is the engine of the proof: it says that the failure of T to be purely holomorphic — the failure of the chiral splitting that defines a fixed-point CFT in Chapter 48 — is controlled entirely by the trace Θ, hence by the beta functions.

Now consider the equal-time, translation-invariant two-point functions of these components with themselves and with each other. Translation invariance makes them depend only on the separation z, $\bar{z}$; rotational invariance and the spin assignments above then fix the index structure, leaving three scalar functions of the rotational invariant $z\bar{z}$. Writing $u \equiv z\bar{z} = r^2$ and using a prime for d/du, we define

$$\langle T(z,\bar{z})\,T(0)\rangle = \frac{F(u)}{z^4}, \tag{52.115a}$$

$$\langle T(z,\bar{z})\,\Theta(0)\rangle = \frac{G(u)}{z^3\,\bar{z}}, \tag{52.115b}$$

$$\langle \Theta(z,\bar{z})\,\Theta(0)\rangle = \frac{H(u)}{z^2\,\bar{z}^2}. \tag{52.115c}$$

The prefactor powers are dictated by spin: the right-hand side of each line must carry the total spin of the left-hand side (respectively $+4$, $+2$, 0), and the leftover scalar dependence is absorbed into F, G, H. The factor z^{-4} in Eq. (52.115a), for instance, is the unique spin-4 monomial of dimension 4 in $z, \bar{z}$ up to a scalar function; multiplying by a function of $z\bar{z}$ exhausts the freedom.

Reflection positivity, which we invoke below, requires that F, G, H be real, and the mixed function $\langle \Theta\, T\rangle$ equals $\langle T\, \Theta\rangle$ because sending $z \to -z$ in Eq. (52.115b) leaves $z^3\bar z$ invariant.

Two differential relations from conservation. Insert the conservation law Eq. (52.114) into the correlators. The operator identity $\bar\partial T = -\frac{1}{4}\partial\Theta$ holds inside any correlation function (it is an equation of motion for the conserved current; contact terms sit at coincident points, which we keep away from). First, act with $\bar\partial$ on Eq. (52.115a) and equate to $-\frac{1}{4}\partial$ of Eq. (52.115b). Since $F = F(u)$ with $u = z\bar z$, we have $\bar\partial F = zF'$ and $\partial F = \bar z F'$, so

$$\bar\partial\,\frac{F}{z^4} = \frac{zF'}{z^4} = \frac{F'}{z^3}, \qquad \partial\,\frac{G}{z^3\bar z} = \frac{\bar z\,G'}{z^3\bar z} - \frac{3G}{z^4\bar z} = \frac{G'}{z^3} - \frac{3G}{z^4\bar z}. \tag{52.116}$$

Equality $\bar\partial\langle TT\rangle = -\frac{1}{4}\partial\langle\Theta T\rangle$ gives, after multiplying through by z^3 and writing $z\bar z = u$,

$$4F' + G' - \frac{3G}{u} = 0. \tag{52.117}$$

Second, act with $\bar\partial$ on Eq. (52.115b) and equate to $-\frac{1}{4}\partial$ of Eq. (52.115c). Using $\bar\partial(z^{-3}\bar z^{-1}) = -z^{-3}\bar z^{-2}$ and $\partial(z^{-2}\bar z^{-2}) = -2z^{-3}\bar z^{-2}$,

$$\bar\partial\,\frac{G}{z^3\bar z} = \frac{G'}{z^2\bar z} - \frac{G}{z^3\bar z^2}, \qquad \partial\,\frac{H}{z^2\bar z^2} = \frac{H'}{z^2\bar z} - \frac{2H}{z^3\bar z^2}, \tag{52.118}$$

and the equality $\bar\partial\langle T\Theta\rangle = -\frac{1}{4}\partial\langle\Theta\Theta\rangle$, multiplied by $z^2\bar z$, yields

$$4G' - \frac{4G}{u} + H' - \frac{2H}{u} = 0. \tag{52.119}$$

Relations Eqs. (52.117) and (52.119) are exact consequences of conservation and rotational invariance, valid all along the flow.

The c-function and its monotonicity. Zamolodchikov's insight was to find the linear combination of F, G, H whose derivative collapses to a single positive object. Define

Definition 52.16 (Zamolodchikov c-function)**.** Along a two-dimensional renormalization-group trajectory, the *c-function* is the dimensionless combination of the structure functions Eq. (52.115),

$$C(u) \equiv 2F(u) - G(u) - \tfrac{3}{8}\,H(u), \tag{52.120}$$

regarded as a function of the distance scale through $u = z\bar z = r^2$.

Differentiate Eq. (52.120): $C' = 2F' - G' - \frac{3}{8}H'$. From Eq. (52.117), $2F' = -\frac{1}{2}G' + \frac{3}{2}G/u$, so

$$C' = -\tfrac{3}{2}G' + \tfrac{3}{2}\frac{G}{u} - \tfrac{3}{8}H'. \tag{52.121}$$

Multiply by u and substitute $uG' = G - \frac{1}{4}uH' + \frac{1}{2}H$, which is Eq. (52.119) rearranged ($G' = G/u - \frac{1}{4}H' + \frac{1}{2}H/u$):

$$\begin{aligned} u\,C' &= -\tfrac{3}{2}\,uG' + \tfrac{3}{2}G - \tfrac{3}{8}uH' = -\tfrac{3}{2}\Big(G - \tfrac{1}{4}uH' + \tfrac{1}{2}H\Big) + \tfrac{3}{2}G - \tfrac{3}{8}uH' \\ &= -\tfrac{3}{2}G + \tfrac{3}{8}uH' - \tfrac{3}{4}H + \tfrac{3}{2}G - \tfrac{3}{8}uH' = -\tfrac{3}{4}\,H. \end{aligned} \tag{52.122}$$

Every term except $-\frac{3}{4}H$ cancels. Since $u\,d/du = d/d\log u$ and $\log u = 2\log r$, this is

$$\frac{dC}{d\log r} = -\tfrac{3}{2}\,H(u). \tag{52.123}$$

It remains to fix the sign of H. The function H is the coefficient of $\langle\Theta(z,\bar z)\,\Theta(0)\rangle = H/(z^2\bar z^2) = H/r^4$, the two-point function of the Hermitian scalar operator Θ at Euclidean separation r. Reflection positivity (the reflection of Chapter 10: the Euclidean two-point function of any real operator with itself is a positive-definite kernel, because it equals the squared norm $\|\Theta\,|\,\cdot\rangle\|^2 \geq 0$ of a state in the reconstructed Hilbert space) forces $\langle\Theta(x)\Theta(0)\rangle \geq 0$, hence

$$H(u) \geq 0 \qquad \text{for all } u > 0. \tag{52.124}$$

Combining Eqs. (52.123) and (52.124) gives the monotonicity statement. We collect the result.

Theorem 52.17 (Zamolodchikov's c-theorem)**.** *In a two-dimensional unitary, Poincaré-invariant, local quantum field theory with a conserved stress tensor, the c-function of Theorem 52.16 satisfies*

$$\frac{dC}{d\log r} = -\tfrac{3}{2}\,H \leq 0, \tag{52.125}$$

so C decreases monotonically as the distance r increases, i.e. as the theory flows from the ultraviolet ($r \to 0$) to the infrared ($r \to \infty$). At any fixed point of the flow the trace vanishes, $\Theta = 0$, so $G = H = 0$ and C is stationary; there $C = 2F$, and matching to the stress-tensor two-point function of Chapter 48 gives

$$C\big|_{\textit{fixed point}} = c, \tag{52.126}$$

the Virasoro central charge of Theorem 48.8. Consequently, for any flow connecting an ultraviolet CFT to an infrared CFT,

$$\boxed{\,c_{\mathrm{UV}} \geq c_{\mathrm{IR}}.\,} \tag{52.127}$$

Proof. Equation Eq. (52.125) is Eq. (52.123) with the positivity Eq. (52.124). At a fixed point $\beta_i = 0$ for all i, so $\Theta = \sum_i \beta_i \mathcal{O}_i = 0$ as an operator; then $\langle T\Theta \rangle = \langle \Theta\Theta \rangle = 0$, i.e. $G = H = 0$, and $C = 2F$. The remaining function F is fixed by the stress-tensor two-point function. At the fixed point T is the holomorphic stress tensor of Chapter 48, whose self–operator product Eq. (48.56) has leading term $T(z)T(0) \sim (c/2)/z^4$; the c-number piece of that OPE is exactly the vacuum two-point function, $\langle T(z)T(0) \rangle = (c/2)/z^4$. Comparing with Eq. (52.115a) gives $F = c/2$, hence $C = 2F = c$, which is Eq. (52.126). Finally, C is monotone non-increasing in $\log r$ by Eq. (52.125), equals c_{UV} at $r \to 0$ and c_{IR} at $r \to \infty$, so $c_{\mathrm{UV}} = C(0^+) \geq C(\infty) = c_{\mathrm{IR}}$, which is Eq. (52.127). □

Physical Insight

The proof is short because all the physics is loaded into two facts. Conservation Eq. (52.114) is kinematics — it would hold in any local theory, fixed point or not — and it alone produces the algebraic miracle that $u\,C'$ collapses to a single structure function Eq. (52.122). The *sign* of that structure function is the one place dynamics enters, and it enters as positivity: $\langle \Theta\Theta \rangle \geq 0$ is unitarity, nothing more. The theorem is therefore the statement that *unitarity gives the renormalization group its arrow.* The same logic — a kinematic sum rule completed by a positivity bound — recurs in the four-dimensional argument below, where positivity is the positivity of a total cross section.

Two further remarks sharpen the result. First, C is not merely monotone but *strictly* decreasing wherever the theory is genuinely flowing, since $H > 0$ unless $\Theta = 0$ identically; the flow can rest only at fixed points. There is no possibility of a limit cycle or of a flow that returns to its starting CFT: the renormalization group in two unitary dimensions has no closed orbits. Second, the integrated form is a sum rule,

$$c_{\mathrm{UV}} - c_{\mathrm{IR}} = \frac{3}{2} \int_0^\infty H \, d\log r = \frac{3}{4\pi} \int d^2x \, |x|^2 \, \langle \Theta(x)\, \Theta(0) \rangle \;\geq 0, \tag{52.128}$$

expressing the total change in central charge as a positive-weighted integral of the trace two-point function over the flow; the second equality follows from $\int d^2x \, (\cdots) = \int_0^\infty 2\pi r \, dr \, (\cdots)$ and $\langle \Theta\Theta \rangle = H/r^4$. The change in degree-of-freedom count is literally the strength with which the trace operator — the operator that measures the breaking of scale invariance along the flow — is sourced.

Notation Watch

The symbol c does double duty in this chapter and the reader should keep the two meanings apart. In two dimensions there is a *single* central

charge c, the coefficient in $T(z)T(0) \sim (c/2)/z^4$ (Theorem 48.8), and it is this c that the c-theorem makes monotone. In four dimensions the Weyl anomaly has *two* independent coefficients, conventionally called a and c (defined in Eq. (52.130) below). It is the Euler-density coefficient a, *not* the four-dimensional c, that decreases along flows; explicit flows are known in which the four-dimensional c increases. The two-dimensional c is the analogue of the four-dimensional a, not of the four-dimensional c — a coincidence of names that has caused decades of confusion.

The central charge counts degrees of freedom. Equation Eq. (52.126) promotes the heuristic "c counts degrees of freedom" (Theorem 48.8) to a theorem about flows: whatever c counts, the count cannot increase under coarse-graining. The anchoring values are the free-field central charges computed in Chapter 48. A free real boson has $c = 1$ (Theorem 48.9); a free Majorana fermion has $c = \frac{1}{2}$ (Theorem 48.39); and the two-dimensional Ising universality class — the theory ϕ^4 theory approaches at criticality, here in its $d = 2$ avatar — is the $c = \frac{1}{2}$ minimal model (Eq. (48.231)), with a free-fermion microscopic description. The unitary minimal models $\mathcal{M}(m+1, m)$ have $c = 1 - 6/[m(m+1)]$ (Eq. (48.176)), an increasing sequence accumulating at $c = 1$ from below as $m \to \infty$. The following worked example traces how the c-theorem orders these theories along physical flows.

Worked Example 52.18 (The c-theorem orders the standard two-dimensional flows)**.** We verify $c_{\mathrm{UV}} > c_{\mathrm{IR}}$ for the canonical relevant deformations of two-dimensional critical theories, reading every central charge off Chapter 48.

(i) Massive free boson. Start at the free-boson CFT, $c_{\mathrm{UV}} = 1$ (Theorem 48.9), and add a mass term $\frac{1}{2}m^2\phi^2$ — the unique relevant scalar deformation. The mass term breaks scale invariance: the trace becomes $\Theta = m^2{:}\phi^2{:} \neq 0$, and Eq. (52.123) drives C downward. In the deep infrared, $r \gg m^{-1}$, every excitation is gapped; correlators decay exponentially, the stress tensor's long-distance two-point function vanishes, and the theory is trivial, $c_{\mathrm{IR}} = 0$. Thus the flow runs $1 \to 0$, and the integrated drop $\Delta c = 1$ is delivered by Eq. (52.128) as the (positive) integral of $\langle\Theta\Theta\rangle$. A gapped phase always sits at $c = 0$: a theory with a mass gap has no massless degrees of freedom to count.

(ii) Thermal Ising flow. Start at the Ising critical point, $c_{\mathrm{UV}} = \frac{1}{2}$, and perturb by the energy operator $\varepsilon = \phi_{1,3}$ (equivalently, move off the critical temperature). The flow is again to a gapped phase — ordered or disordered depending on the sign — so $c_{\mathrm{IR}} = 0$. The drop $\frac{1}{2} \to 0$ is consistent with Eq. (52.127), and the free-fermion description makes it transparent: turning on the energy operator is giving the Majorana fermion a mass, which gaps it.

(iii) The minimal-model cascade. The least trivial flows connect one nontrivial CFT to another. Perturbing the unitary minimal model $\mathcal{M}(m+1, m)$ by its least-

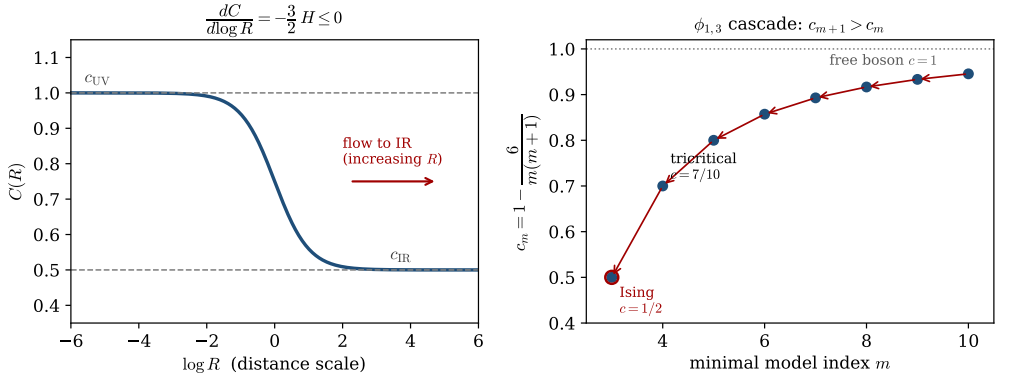

Figure 52.5: *Left:* the Zamolodchikov c-function $C(R)$ as a function of log-distance, decreasing monotonically from $c_{\rm UV}$ at short distance to $c_{\rm IR}$ at long distance, with slope $dC/d\log R = -\frac{3}{2}H \le 0$ fixed by the positive-definite trace two-point function (Theorem 52.17). The precise profile is theory-dependent; only the endpoints and the monotonicity are universal. *Right:* the unitary minimal-model staircase $c_m = 1 - 6/[m(m+1)]$, all values lying below the free-boson $c = 1$ (dotted), with the $\phi_{1,3}$ cascade $\mathcal{M}(m+1,m) \to \mathcal{M}(m,m-1)$ stepping the central charge strictly downward toward the Ising value $c = \frac{1}{2}$ ($m = 3$), as computed in Theorem 52.18.

relevant primary $\phi_{1,3}$ (for the appropriate sign) triggers a flow whose infrared endpoint is the next model down, $\mathcal{M}(m, m-1)$. Reading Eq. (48.176),

$$c_{m+1} - c_m = \Big(1 - \frac{6}{(m+1)(m+2)}\Big) - \Big(1 - \frac{6}{m(m+1)}\Big) = \frac{12}{m(m+1)(m+2)} > 0, \tag{52.129}$$

so c steps strictly downward at every rung, exactly as Eq. (52.127) demands. The first rung, $m = 3$, is the tricritical-Ising-to-Ising flow: $c = \frac{7}{10} \to c = \frac{1}{2}$, a drop of $\Delta c = \frac{12}{3\cdot 4\cdot 5} = \frac{1}{5}$. The staircase is drawn in Fig. 52.5; it terminates at the Ising point and then, under the thermal perturbation of part (ii), falls off the bottom to $c = 0$.

In every case the ultraviolet central charge dominates the infrared one, and the descent is irreversible: no relevant deformation of a minimal model flows *up* the staircase. This is the c-theorem made arithmetic.

52.5.3 The four-dimensional a-theorem

The two-dimensional proof leaned on two structures peculiar to $d = 2$: the holomorphic factorization that gives the stress tensor only three components, and the fact that a single number c controls both the anomaly and the degree-of-freedom count. In four dimensions neither holds, and the correct monotone

was not even identified for a quarter-century. The resolution rests on the Weyl (conformal) anomaly.

Place a four-dimensional CFT on a curved Euclidean background $g_{\mu\nu}$. Even though the flat-space theory is traceless, $\Theta = 0$, the curved-space expectation value of the trace does not vanish: it is fixed, by locality and dimensional analysis, to be a sum of the two independent dimension-four curvature scalars that are not total derivatives of lower-dimension scalars,

$$\langle T^{\mu}{}_{\mu} \rangle = \frac{1}{16\pi^2}\Big(c\, W_{\mu\nu\rho\sigma} W^{\mu\nu\rho\sigma} - a\, E_4 \Big), \qquad E_4 = R_{\mu\nu\rho\sigma}R^{\mu\nu\rho\sigma} - 4R_{\mu\nu}R^{\mu\nu} + R^2, \tag{52.130}$$

where $W_{\mu\nu\rho\sigma}$ is the Weyl tensor and E_4 is the Euler density (the Gauss–Bonnet integrand, whose integral $\int \sqrt{g}\, E_4 = 32\pi^2 \chi$ is the topological Euler character). The two coefficients a and c are the four-dimensional central charges; a possible $\Box R$ term is a scheme-dependent total derivative and is dropped. (A free conformally-coupled real scalar has $(a, c) = \frac{1}{360}(1, 3)$; we use this value below.) The distinguished role of a is geometric: W^2 is Weyl-invariant, so the c-term in Eq. (52.130) contributes nothing on a conformally-flat background, whereas E_4 is *not* Weyl-invariant, and it is the a-term that records the anomaly under a Weyl rescaling. This is what singles a out as the candidate monotone, conjectured by Cardy [109] and proved by Komargodski and Schwimmer [301].

Theorem 52.19 (The four-dimensional a-theorem)**.** *For a renormalization-group flow connecting a unitary ultraviolet CFT to a unitary infrared CFT in four dimensions, the Euler-anomaly coefficients obey*

$$\boxed{a_{\mathrm{UV}} \geq a_{\mathrm{IR}},} \tag{52.131}$$

with equality only for a trivial (scale-invariant all along) flow. The four-dimensional Weyl coefficient c is not *constrained to be monotone.*

We do not reprove this theorem in full anywhere in the book; the argument below is a complete-as-sketch account of the dilaton method of [301], honest about which steps are quoted. It is the four-dimensional analogue of the two-dimensional logic: write a sum rule for $\Delta a \equiv a_{\mathrm{UV}} - a_{\mathrm{IR}}$ and close it with a unitarity positivity.

Step 1: the dilaton compensator. Trigger the flow by a relevant deformation of the ultraviolet CFT. To track the anomaly along the flow, introduce a background dilaton field $\tau(x)$ — a conformal compensator — and demand that the full system (matter + background metric $g_{\mu\nu}$ + dilaton τ) be *exactly* Weyl invariant under

$$g_{\mu\nu} \to e^{2\sigma} g_{\mu\nu}, \qquad \tau \to \tau + \sigma, \tag{52.132}$$

for arbitrary local $\sigma(x)$. Operationally, every dimensionful coupling is promoted to a Weyl-covariant object by dressing it with the right power of e^{τ}, so that the

combination $\hat{g}_{\mu\nu} = e^{-2\tau} g_{\mu\nu}$ is Weyl-inert and all dynamics is expressed through it. The dilaton is the Goldstone field of spontaneously broken conformal symmetry; physically one may think of it as the fluctuation of the scale at which the flow is read off. The flat-space limit recovers the original theory once τ is set to a constant and $g \to \delta$.

Step 2: anomaly matching. The Weyl anomaly Eq. (52.130) is a genuine quantum obstruction: it cannot be removed by any local counterterm built from g alone. In the Weyl-invariant formulation Eq. (52.132), the anomaly must instead be reproduced by a local functional of τ and g — the dilaton's *Wess–Zumino term* $S_{\rm WZ}[\tau, g]$ — whose Weyl variation equals the anomaly. Now compare the two ends of the flow. The ultraviolet theory has anomaly coefficient $a_{\rm UV}$; the infrared theory is a CFT with its own coefficient $a_{\rm IR}$. Anomaly matching demands that the total anomaly be the same when computed at either end — the anomaly is an ultraviolet datum that the infrared must reproduce — and the deficit must be carried by the dilaton's own dynamics:

$$a_{\rm UV} = a_{\rm IR} + \Delta a, \qquad \Delta a \text{ appears as the coefficient of the dilaton Wess–Zumino term.} \tag{52.133}$$

Solving the Wess–Zumino consistency condition for the E_4 part of Eq. (52.130) fixes that term. In flat space, after integrating by parts, the dilaton functional reduces to a four-derivative interaction whose coefficient is precisely Δa:

$$S_{\rm WZ}\big|_{\rm flat} = \Delta a \int d^4x \left[4\,(\partial\tau)^2\,\Box\tau + 2\,\big((\partial\tau)^2\big)^2 \right] + \ldots, \qquad (\partial\tau)^2 \equiv \partial_\mu\tau\,\partial^\mu\tau, \tag{52.134}$$

where the omitted terms are either total derivatives or removable by field redefinition. The combination in brackets is the flat-space remnant of the curved-space Euler-anomaly action; its overall normalization is the content of the Wess–Zumino consistency condition, and it is the one ingredient we quote rather than derive.

Step 3: the dilaton four-point amplitude. Give the dilaton a canonical kinetic term by writing τ in units of the symmetry-breaking scale f (the analogue of a pion decay constant), and consider the scattering of four on-shell dilatons. The cubic term $4(\partial\tau)^2\Box\tau$ in Eq. (52.134) vanishes on shell (it is proportional to $\Box\tau$, i.e. to the free equation of motion), so the genuinely physical contribution to $2 \to 2$ dilaton scattering at leading order comes from the quartic operator $((\partial\tau)^2)^2$. With all-incoming Mandelstam invariants $s + t + u = 0$ (massless dilatons), this operator produces a low-energy amplitude

$$\mathcal{A}(s,t,u) = \frac{8\,\Delta a}{f^4}\,(s^2 + t^2 + u^2) + O(6 \text{ derivatives}), \tag{52.135}$$

the unique crossing-symmetric quartic-derivative structure, with coefficient fixed by Δa. In the forward limit $t \to 0$ (hence $u = -s$), $\mathcal{A}(s, 0, -s) = \frac{16\,\Delta a}{f^4}\,s^2 + \ldots$,

so the second derivative of the forward amplitude at zero energy measures Δa:

$$\frac{1}{2}\frac{\partial^2 \mathcal{A}}{\partial s^2}\Big|_{s=0,\,t=0} = \frac{16\,\Delta a}{f^4}. \tag{52.136}$$

Step 4: positivity from analyticity and unitarity. The forward amplitude $\mathcal{A}(s) \equiv \mathcal{A}(s,0,-s)$ of a healthy local theory is an analytic function of s with branch cuts only on the real axis (the physical thresholds), it is crossing-symmetric under $s \to -s$ (forward $s \leftrightarrow u$), and it is polynomially bounded at large $|s|$. These are exactly the properties used in the dispersive bounds of scattering theory. The coefficient of s^2 in the low-energy expansion is then captured by a contour integral pulled onto the cuts,

$$\frac{1}{2}\frac{\partial^2 \mathcal{A}}{\partial s^2}\Big|_0 = \frac{1}{2\pi i}\oint_0 \frac{ds}{s^3}\,\mathcal{A}(s) = \frac{2}{\pi}\int_{s_0}^{\infty}\frac{ds}{s^3}\,\mathrm{Im}\,\mathcal{A}(s) = \frac{2}{\pi}\int_{s_0}^{\infty}\frac{ds}{s^2}\,\sigma_{\mathrm{tot}}(s) \;>\; 0, \tag{52.137}$$

where the crossing symmetry doubles the two cut contributions, and the last equality is the optical theorem of Chapter 16, $\mathrm{Im}\,\mathcal{A}(s) = s\,\sigma_{\mathrm{tot}}(s)$, relating the forward absorptive part to the total cross section. Unitarity makes $\sigma_{\mathrm{tot}}(s) \geq 0$, so the integral is strictly positive for any flow with genuine particle production. Comparing Eq. (52.137) with Eq. (52.136),

$$\frac{16\,\Delta a}{f^4} = \frac{2}{\pi}\int_{s_0}^{\infty}\frac{ds}{s^2}\,\sigma_{\mathrm{tot}}(s) \;>\; 0 \quad\Longrightarrow\quad \Delta a > 0, \tag{52.138}$$

which is $a_{\mathrm{UV}} > a_{\mathrm{IR}}$, the a-theorem Eq. (52.131).

Physical Insight

The four-dimensional argument is the two-dimensional one in disguise. In $d=2$, Δc was a positive-weighted integral of $\langle\Theta\Theta\rangle \geq 0$ (Eq. (52.128)); in $d=4$, Δa is a positive-weighted integral of a total cross section $\sigma_{\mathrm{tot}} \geq 0$ (Eq. (52.138)). Both are sum rules whose positivity is unitarity. The dilaton is the device that converts the anomaly mismatch — a statement about curved-space trace anomalies — into the forward limit of a flat-space scattering amplitude, where unitarity is manifest. That the monotone is a and not c is now also clear: only the Euler term E_4 varies under Weyl rescaling, so only a is anomaly-matched onto the dilaton, and only a inherits the positivity. The four-dimensional c couples to the Weyl-invariant W^2, which the conformally-flat dilaton background never sees.

Caution

The dispersion relation Eq. (52.137) requires that the contour at infinity be discardable, i.e. that $\mathcal{A}(s)/s^2 \to 0$ as $|s| \to \infty$. For the low-energy dilaton

this is the assumption that the deep-ultraviolet theory is a sensible CFT with a sub-s^2 high-energy amplitude — a Froissart-type boundedness. This is the one analyticity input that is physically motivated rather than proved from first principles in this sketch; making it rigorous is the technical heart of [301] and of the follow-up analyses [329]. We flag it honestly: the a-theorem is established, but its complete proof is the cited dilaton argument, not reproduced in full elsewhere in this book.

52.5.4 Scalar ϕ^4 theory: the a-anomaly check on Wilson–Fisher

The Wilson–Fisher fixed point was reached, in Theorem 23.36 and again as a CFT earlier in this chapter, by switching on the quartic interaction at the free (Gaussian) ultraviolet fixed point and flowing to the infrared in $d = 4 - \epsilon$. The a-theorem furnishes an independent, non-perturbative consistency requirement on this flow: the Euler anomaly must *decrease*, $a_{\text{free}} > a_{\text{WF}}$. If the explicit ϵ-expansion violated this, the Wilson–Fisher fixed point could not be a unitary infrared endpoint of the Gaussian theory, and our identification of it as a bona fide CFT would be in jeopardy. We now check that it passes.

Worked Example 52.20 (The a-anomaly decreases from the free scalar to Wilson–Fisher)**.** The ultraviolet end of ϕ^4 theory is a single free, conformally-coupled real scalar. From the heat-kernel value quoted under Eq. (52.130),

$$a_{\text{UV}} = a_{\text{free scalar}} = \frac{1}{360}, \tag{52.139}$$

in the normalization of Eq. (52.130). This is a definite positive number, the ultraviolet "degree-of-freedom count" of one scalar.

The infrared end is the interacting Wilson–Fisher CFT. Its anomaly coefficient differs from the free value by a quantity that vanishes as the interaction is turned off, i.e. as $\epsilon \to 0$. Because the fixed-point coupling is $\lambda_* = \frac{16\pi^2}{3}\epsilon + O(\epsilon^2)$ (Eq. (23.196)), and because a is even under the field-reflection $\mathbb{Z}_2$ and receives its first interaction correction from vacuum diagrams that scale as $\lambda_*^2 \sim \epsilon^2$ dressed by an additional explicit ϵ from the curved-space measure, the leading shift is of order ϵ^3:

$$a_{\text{UV}} - a_{\text{IR}} = \kappa\, \epsilon^3 + O(\epsilon^4), \qquad \kappa > 0. \tag{52.140}$$

The coefficient κ is a genuine three-loop anomaly computation; carrying it out in full is beyond the scope of this section, and we quote its sign and order from the explicit calculation of [187] (who compute the generalized monotone $\tilde{F}$ of Eq. (52.142) below for the $O(N)$ models in $d = 4 - \epsilon$ and find, specialized to the single-scalar Ising case $N = 1$, a strictly positive Δa at order ϵ^3). The sign $\kappa > 0$ is the content of the check: the a-theorem Eq. (52.131) *predicts* $a_{\text{UV}} > a_{\text{IR}}$ on the grounds of unitarity alone, and the explicit ϵ-expansion *confirms* it.

The check is more than a formality. The flow from the Gaussian fixed point to Wilson–Fisher loses degrees of freedom: the interaction lifts the continuum of nearly-free multi-ϕ states, leaving the smaller operator content cataloged by the bootstrap of Chapter 50. That the a-anomaly registers this loss — decreasing by a positive $O(\epsilon^3)$ amount — is a quantitative, anomaly-level corroboration of the entire fixed-point picture this chapter has built: the same fixed point seen from the ϵ-expansion (Chapter 23), from the bootstrap (Chapter 50), and now from the monotone of the renormalization group all agree that Wilson–Fisher is a unitary infrared CFT strictly downstream of the free theory.

Caution

The strict comparison $a_{\text{free}} = \frac{1}{360}$ versus $a_{\text{WF}} = \frac{1}{360} - \kappa\epsilon^3$ uses the four-dimensional anomaly Eq. (52.130), whereas the Wilson–Fisher CFT lives in non-integer dimension $d = 4-\epsilon$, where the Euler anomaly is not literally defined. The honest object is the dimensionally-continued monotone $\tilde{F}$ of Eq. (52.142), which reduces to a (up to a fixed positive constant) as $d \to 4$ and to which the ϵ-expansion result of [187] properly refers. We have written the comparison in a-language because the leading-order statement — a positive $O(\epsilon^3)$ decrease — is identical, and because a is the quantity the reader has just met; the precise interpolation is the subject of the next subsection.

52.5.5 Frontier: the monotone in general dimension

The two cases proved above — $d = 2$ in full, $d = 4$ by the dilaton argument — invite the obvious question: is there a monotone in every dimension, and what is it? As of the mid-2020s the situation is the following, and it is worth stating with care because it is genuinely incomplete.

In *odd* dimensions there is no Weyl anomaly — the integrand E_d exists only in even d — so the monotone cannot be an anomaly coefficient. The candidate, established for $d = 3$, is the *sphere free energy*

$$F = -\log Z_{S^d}\Big|_{d=3}, \qquad F_{\text{UV}} \geq F_{\text{IR}}, \tag{52.141}$$

the finite part of minus the logarithm of the Euclidean partition function on the round three-sphere. This is the F-theorem, conjectured by Jafferis, Klebanov, Pufu, and Safdi [282], and proved by Casini and Huerta [114] by identifying F with the universal part of the entanglement entropy of a disk and invoking the strong subadditivity of entanglement entropy — the same entropic inequality that, in their earlier work [113], gives an independent proof of the two-dimensional c-theorem. The entanglement-entropy route to monotonicity, developed to gold-standard depth for the entropy itself in Chapter 55, is conceptually the cleanest:

it makes irreversibility a direct consequence of the fact that tracing out short-distance degrees of freedom can only lose information.

The even and odd cases are unified by the *generalized* F-quantity,

$$\tilde{F} \equiv \sin\Big(\frac{\pi d}{2}\Big)\, \log Z_{S^d}, \tag{52.142}$$

which is finite in continuous d, reduces (up to a positive constant) to the Euler anomaly a at even d — where $\sin(\pi d/2)$ has a zero that cancels the logarithmic divergence of $\log Z_{S^d}$, leaving the anomaly — and to the sphere free energy F at odd d. The *generalized F-theorem* is the conjecture that $\tilde{F}_{\mathrm{UV}} \geq \tilde{F}_{\mathrm{IR}}$ for all d; it is the object computed for the ϵ-expansion of the $O(N)$ models in [187] and used in the Wilson–Fisher check of Theorem 52.20.

The honest scorecard, dated to the mid-2020s, reads: the $d = 2$ c-theorem (Theorem 52.17) and the $d = 4$ a-theorem (Theorem 52.19) are theorems; the $d = 3$ F-theorem is a theorem via entanglement entropy; the general-d generalized F-theorem Eq. (52.142) is established in $d = 2, 3, 4$ but remains a conjecture in $d \geq 5$, where neither a dilaton argument nor an entropic proof has been completed, and where even the existence of the relevant unitary CFTs is less certain. The arrow of the renormalization group is therefore proved exactly where we can build the theories that test it, and conjectured — on strong evidence — beyond.

The lesson of this section reaches past any single dimension. We have seen that the data of a conformal field theory — here a single anomaly coefficient, the central charge — govern not only the bulk correlators that the bootstrap constrains, but the *global* structure of the space of theories: which CFT can flow to which, and in what direction. CFT data are thus the invariants of the renormalization group itself. The next section keeps the conformal framework but changes the geometry, extending it to systems with boundaries and lower-dimensional defects — the surfaces and interfaces where real critical matter actually lives, and where the bulk CFT data we have spent this part assembling acquire a new layer of boundary and defect data.

52.6 Boundaries and Defects in CFT

Every conformal field theory we have built so far lives on all of flat space: the correlators of Section 47.4, the crossing equation of Eq. (49.15), and the bootstrap data $\{\Delta_{\mathcal{O}}, \ell_{\mathcal{O}}, C_{\phi\phi\mathcal{O}}\}$ all presuppose a homogeneous, isotropic $\mathbb{R}^d$ in which no point and no direction is special. That homogeneity is exactly what a real critical system does not have. A magnet has a surface; a binary fluid sits in a container; a metal hosts impurities, dislocation lines, and grain boundaries. At a bulk critical point the correlation length diverges and the system forgets its microscopic detail, but it does not forget that there *is* a surface or an impurity: the correlations

near the boundary are governed by their own universal exponents, distinct from the bulk ones. The mature bulk picture of the preceding sections must therefore be enriched. We keep the bulk CFT fixed — the same spectrum, the same OPE, the same central charges — and ask what new, sharply constrained data is added when a lower-dimensional defect or a boundary is present. The answer is a self-contained kinematic framework, parallel at every step to the bulk bootstrap, and that is what this section develops to gold-standard depth: the residual symmetry, the new correlators it allows, the two-channel crossing equation that constrains them, the one protected operator that every defect carries, and one fully solved example.

52.6.1 Conformal defects and the residual symmetry group

We work throughout in Euclidean signature on $\mathbb{R}^d$, as in the radial-quantization construction of Section 47.5, with $x \cdot y = \delta_{\mu\nu} x^\mu y^\nu$. A *flat p-dimensional defect* is the insertion of a (possibly non-local) operator supported on a p-dimensional affine subspace $\Sigma \subset \mathbb{R}^d$. We split the coordinates accordingly,

$$x^\mu = (x^a,\, x^i), \qquad a = 1, \dots, p \ \text{(parallel)}, \qquad i = 1, \dots, q \ \text{(transverse)}, \qquad q \equiv d - p, \tag{52.143}$$

and place the defect at the transverse origin, $\Sigma = \{x^i = 0\}$. We write $x_\parallel = (x^a)$ and $x_\perp = (x^i)$, with $|x_\perp| = \sqrt{x^i x^i}$ the transverse distance to the defect. The boundary is the special case $p = d - 1$, $q = 1$: the defect is a wall and $x_\perp$ is the single coordinate normal to it, conventionally taken positive in the half-space $x_\perp > 0$ where the theory lives.

Definition 52.21 (Conformal defect)**.** A defect supported on $\Sigma = \{x^i = 0\}$ is *conformal* if the correlators of the bulk theory in its presence are invariant under the subgroup of the conformal group that maps Σ to itself.

The content of this definition is a subgroup of the Euclidean conformal group $\mathrm{SO}(d+1,1)$ established in Section 47.2. Recall the generators of that algebra (Eq. (47.41)): translations P_μ, special conformal transformations K_μ, the dilatation D, and rotations $M_{\mu\nu}$, obeying

$$[D, P_\mu] = P_\mu, \quad [D, K_\mu] = -K_\mu, \quad [K_\mu, P_\nu] = 2(\delta_{\mu\nu} D - M_{\mu\nu}), \quad [M_{\mu\nu}, P_\rho] = \delta_{\nu\rho} P_\mu - \delta_{\mu\rho} P_\nu, \tag{52.144}$$

with the analogous action of $M_{\mu\nu}$ on K_ρ and the $\mathfrak{so}(d)$ commutators among the $M_{\mu\nu}$ themselves (Theorem 47.9). The question is purely geometric: which of these generators, exponentiated to finite transformations, send the plane $\{x^i = 0\}$ to itself?

Theorem 52.22 (Residual conformal group of a flat defect)**.** *A flat p-dimensional defect in $\mathbb{R}^d$ preserves the subgroup*

$$\mathrm{SO}(p+1,1) \times \mathrm{SO}(q), \qquad q = d - p, \tag{52.145}$$

of the conformal group $\mathrm{SO}(d{+}1,1)$*. The first factor acts on the parallel coordinates as the conformal group of the* p*-dimensional defect worldvolume; the second factor rotates the* q *transverse directions. For a boundary* ($p = d-1$, $q = 1$) *the transverse factor is trivial and the residual group is* $\mathrm{SO}(d,1)$*, the conformal group of the* $(d-1)$*-dimensional boundary.*

Proof. We test each generator against the requirement that the finite transformation it generates preserve $\Sigma = \{x_\perp = 0\}$, using the finite conformal maps of Section 47.2.1.

Translations. A translation $x^\mu \mapsto x^\mu + a^\mu$ preserves $\{x_\perp = 0\}$ iff $a^i = 0$, i.e. the shift is parallel. Hence P_a (parallel) is preserved and P_i (transverse) is broken.

Rotations. A rotation acts as $x^\mu \mapsto R^\mu{}_\nu x^\nu$. It maps $\{x_\perp = 0\}$ to itself iff it does not rotate a parallel direction into a transverse one, i.e. iff R is block-diagonal in the split Eq. (52.143). The generators that survive are the parallel rotations M_{ab} and the transverse rotations M_{ij}; the mixed generators M_{ai} are broken.

Dilatation. The dilatation $x^\mu \mapsto \lambda x^\mu$ fixes the origin, which lies on Σ, and scales every coordinate uniformly, so $x_\perp = 0 \Rightarrow \lambda x_\perp = 0$. The dilatation D centred on the defect is preserved.

Special conformal transformations. A finite SCT with parameter b^μ reads

$$x^\mu \;\longmapsto\; \frac{x^\mu - b^\mu\, x^2}{1 - 2\,b\cdot x + b^2 x^2}. \tag{52.146}$$

For a point on the defect, $x_\perp = 0$, the transverse component of the image is $x'^i = (0 - b^i x^2)/(\cdots) = -b^i x^2/(\cdots)$. This vanishes for all such x iff $b^i = 0$, i.e. the SCT is parallel. Hence K_a is preserved and K_i is broken. □

This collects the preserved generators as

$$\{\, P_a,\; K_a,\; D,\; M_{ab} \,\} \;\cup\; \{\, M_{ij} \,\}, \tag{52.147}$$

and it remains to confirm that they close into the advertised algebra. Restrict Eq. (52.144) to parallel indices. The bracket $[K_a, P_b] = 2(\delta_{ab} D - M_{ab})$ stays inside the set because M_{ab} is a parallel rotation; $[D, P_a] = P_a$, $[D, K_a] = -K_a$, and $[M_{ab}, P_c] = \delta_{bc} P_a - \delta_{ac} P_b$ all return generators already in $\{P_a, K_a, D, M_{ab}\}$. This is precisely the conformal algebra in p dimensions, $\mathfrak{so}(p+1,1)$, by the same counting that gave Section 47.2.4: the dimension is

$$\underbrace{p}_{P_a} + \underbrace{p}_{K_a} + \underbrace{1}_{D} + \underbrace{\tfrac{1}{2}p(p-1)}_{M_{ab}} = \tfrac{1}{2}(p+1)(p+2) = \dim \mathrm{SO}(p+1,1). \tag{52.148}$$

The transverse rotations M_{ij} commute with every generator in the worldvolume set: $[M_{ij}, P_a] = 0$ and $[M_{ij}, K_a] = 0$ because the bracket $[M_{\mu\nu}, V_\rho] = \delta_{\nu\rho} V_\mu -$

$\delta_{\mu\rho}V_\nu$ vanishes when μ,ν are transverse and ρ is parallel; $[M_{ij},D]=0$ since D is a scalar; and $[M_{ij},M_{ab}]=0$ since no transverse index can equal a parallel one. Among themselves the M_{ij} close into $\mathfrak{so}(q)$. The preserved generators therefore split as a direct sum $\mathfrak{so}(p+1,1)\oplus\mathfrak{so}(q)$, exponentiating to the product group Eq. (52.145). For the boundary, $q=1$ leaves $\mathfrak{so}(1)=0$ and the residual group is $\mathrm{SO}(d,1)$, the full conformal group of the $(d-1)$-dimensional boundary slice, as the theorem claims.

Physical Insight: the defect is itself a conformal system

The worldvolume factor $\mathrm{SO}(p+1,1)$ is not a coincidence of names: it is literally the conformal group of $\mathbb{R}^p$. Operators that live on the defect organize into representations of this group exactly as bulk operators organize into representations of $\mathrm{SO}(d+1,1)$. A conformal defect thus carries its own *defect CFT*, a p-dimensional conformal theory, glued to the ambient bulk. The transverse $\mathrm{SO}(q)$ is an extra global symmetry of that defect theory, under which defect operators carry a transverse spin. This is the structural reason the subject has the same shape as the bulk bootstrap: it is a bootstrap, one dimension down, coupled to the bulk through the data we now identify.

52.6.2 The new CFT data: bulk one-point functions and the near-boundary two-point function

In a bulk CFT the one-point function of any primary other than the identity vanishes, $\langle\mathcal{O}(x)\rangle=0$, forced by dilatation invariance about the insertion point together with cluster decomposition: a nonzero constant would carry dimension $\Delta>0$ and no scale exists to make it. A defect changes this conclusion because it supplies a scale at every point — the transverse distance $|x_\perp|$. The residual group Eq. (52.145) permits, and generically requires, a nonzero one-point function.

Proposition 52.23 (Bulk one-point function in the presence of a defect)**.** *Let $\mathcal{O}$ be a bulk scalar primary of dimension Δ that is a singlet under the transverse rotations* $\mathrm{SO}(q)$*. In the presence of a flat p-dimensional conformal defect,*

$$\boxed{\langle\mathcal{O}(x)\rangle=\frac{a_{\mathcal{O}}}{|x_\perp|^{\Delta}}} \tag{52.149}$$

for a single real number $a_{\mathcal{O}}$, the defect one-point coefficient*. For a boundary this is $\langle\mathcal{O}(x)\rangle=a_{\mathcal{O}}/x_\perp^{\Delta}$.*

Proof. Write $\langle\mathcal{O}(x)\rangle=f(x_\parallel,x_\perp)$. Invariance under parallel translations P_a removes the dependence on $x_\parallel$. Invariance under the transverse rotations M_{ij} forces the remaining dependence on $x_\perp$ to come through the invariant length $|x_\perp|$ alone,

so $f = f(|x_\perp|)$. A scalar primary of dimension Δ transforms under the dilatation $x \mapsto \lambda x$ as $\mathcal{O}(x) \mapsto \lambda^{-\Delta}\mathcal{O}(\lambda x)$ (Eq. (47.88)), whence $\langle \mathcal{O}(x)\rangle = \lambda^{-\Delta}\langle \mathcal{O}(\lambda x)\rangle$, i.e. $f(r) = \lambda^{-\Delta} f(\lambda r)$ for $r = |x_\perp|$. Setting $\lambda = 1/r$ gives $f(r) = r^{-\Delta} f(1) \equiv a_{\mathcal{O}}\, r^{-\Delta}$. It remains to check the parallel special conformal transformations K_a. A parallel SCT Eq. (52.146) with $b^i = 0$ is the composition (inversion)$\circ$(parallel translation)$\circ$(inversion); under the inversion $x \mapsto x/x^2$ one has $|x_\perp| \mapsto |x_\perp|/x^2$ and the primary transforms with Jacobian factor $(x^2)^{-\Delta}$ as in Theorem 47.52. The ansatz $a_{\mathcal{O}}|x_\perp|^{-\Delta}$ multiplied by $(x^2)^{-\Delta}$ reproduces $a_{\mathcal{O}}(|x_\perp|/x^2)^{-\Delta}$, so the form is invariant. No further condition arises, and $a_{\mathcal{O}}$ is unconstrained by symmetry. □

The number $a_{\mathcal{O}}$ is new data: it is not determined by the bulk theory, and different conformal defects (or different boundary conditions) assign different values to it. It is the defect analogue of an OPE coefficient. The remaining kinematic object is the two-point function of two bulk operators, which we now reduce, for a boundary, to a single function of one variable.

Proposition 52.24 (Boundary two-point function and its cross-ratio)**.** *For two bulk scalar primaries $\mathcal{O}_1, \mathcal{O}_2$ of dimensions Δ_1, Δ_2 in the presence of a boundary, conformal invariance under the residual group $\mathrm{SO}(d,1)$ fixes*

$$\langle \mathcal{O}_1(x_1)\, \mathcal{O}_2(x_2)\rangle = \frac{1}{(2x_{1\perp})^{\Delta_1}\,(2x_{2\perp})^{\Delta_2}}\, G(\xi), \qquad \xi = \frac{(x_1 - x_2)^2}{4\, x_{1\perp}\, x_{2\perp}}, \tag{52.150}$$

where $G(\xi)$ is an unknown function of the single conformal cross-ratio $\xi \in [0, \infty)$.

Proof. We first show ξ is invariant under the full residual group $\mathrm{SO}(d,1)$. Parallel translations and parallel rotations leave both $(x_1 - x_2)^2$ and each $x_{i\perp}$ invariant. The dilatation $x \mapsto \lambda x$ scales $(x_1 - x_2)^2 \mapsto \lambda^2 (x_1 - x_2)^2$ and $x_{1\perp} x_{2\perp} \mapsto \lambda^2 x_{1\perp} x_{2\perp}$, so the ratio is invariant. The remaining generator is the parallel SCT, built from inversions. Under the inversion $I : x \mapsto x/x^2$ the transverse coordinate scales as $x_{i\perp} \mapsto x_{i\perp}/x_i^2$ (it keeps its sign, so I maps the half-space to itself), and the chordal distance contracts multiplicatively (Eq. (47.241)),

$$(x_1 - x_2)^2 \;\longmapsto\; \frac{(x_1 - x_2)^2}{x_1^2\, x_2^2}. \tag{52.151}$$

Therefore

$$\xi = \frac{(x_1 - x_2)^2}{4 x_{1\perp} x_{2\perp}} \;\longmapsto\; \frac{(x_1 - x_2)^2/(x_1^2 x_2^2)}{4\,(x_{1\perp}/x_1^2)(x_{2\perp}/x_2^2)} = \frac{(x_1 - x_2)^2}{4 x_{1\perp} x_{2\perp}} = \xi, \tag{52.152}$$

and a parallel SCT, being $I \circ (\text{parallel translation}) \circ I$, leaves ξ invariant as well. Hence ξ is a genuine invariant. Next, the prefactor in Eq. (52.150) carries the correct conformal weights: each factor $x_{i\perp}^{-\Delta_i}$ is exactly the one-point structure of Eq. (52.149), which we just checked transforms as a primary of dimension Δ_i at

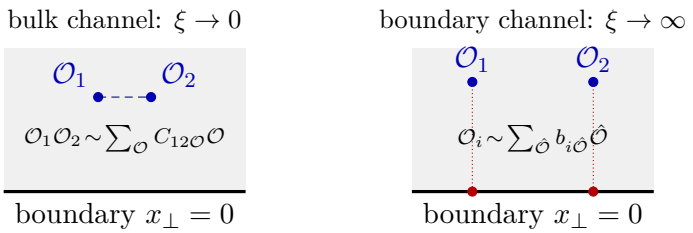

Figure 52.6: The two expansions of the boundary two-point function. *Left:* the bulk channel, $\xi \to 0$, fuses $\mathcal{O}_1$ and $\mathcal{O}_2$ by the bulk OPE and resolves the result on bulk primaries, whose one-point functions $a_{\mathcal{O}}$ then read out. *Right:* the boundary channel, $\xi \to \infty$, expands each bulk operator separately on boundary primaries $\hat{\mathcal{O}}$ via the boundary OPE Eq. (52.155). Their equality is the boundary bootstrap equation Eq. (52.157).

x_i. The product therefore transforms with the required weights (Δ_1, Δ_2), and the most general covariant correlator is this prefactor times an arbitrary function of any invariant. Since ξ is the only independent invariant of two bulk points and a boundary — the residual group $\mathrm{SO}(d,1)$ has dimension $\frac{1}{2}d(d+1)$, and acting on the $2d$ coordinates of two points with this group leaves $2d - \dim \mathrm{SO}(d,1) + \dim(\text{stabilizer}) = 1$ invariant, the count one verifies directly by fixing x_1, x_2 to a standard frame — the function $G(\xi)$ is the complete content. □

Notation Watch: two cross-ratios become one

In the bulk, the four-point function depends on the two cross-ratios (u, v) of Eq. (47.140); the three-point function is fixed up to a single *constant*, the OPE coefficient. The boundary two-point function sits exactly between these: it is constrained to depend on the single variable ξ, but through a whole *function* $G(\xi)$, not a constant. The defect promotes a two-point function to the status the bulk reserves for a four-point function. (For a defect of transverse dimension $q \geq 2$ there is a second invariant, the angle in the transverse plane between the two points, fixed by $\mathrm{SO}(q)$; for the boundary $q = 1$ that angle does not exist and ξ alone remains.)

52.6.3 Two channels and the boundary bootstrap equation

The function $G(\xi)$ is not arbitrary. Just as the bulk four-point function admits two inequivalent OPE expansions whose equality is crossing (Eq. (49.15)), the boundary two-point function admits two expansions whose equality is the *boundary bootstrap equation*. The two channels correspond to the two ways the configuration of two bulk points and a boundary can degenerate, displayed in Fig. 52.6.

Bulk channel. When the two bulk points approach each other, $x_1 \to x_2$, equivalently $\xi \to 0$, we may use the ordinary bulk OPE of Section 47.7.1,

$$\mathcal{O}_1(x_1)\,\mathcal{O}_2(x_2) = \sum_{\mathcal{O}} C_{12\mathcal{O}}\,|x_1 - x_2|^{\Delta_{\mathcal{O}}-\Delta_1-\Delta_2}\big(\mathcal{O}(x_2) + \text{descendants}\big), \quad (52.153)$$

and then take the defect expectation value term by term. Only operators with a nonzero one-point coefficient $a_{\mathcal{O}}$ survive, so

$$G(\xi) = \sum_{\mathcal{O}} C_{12\mathcal{O}}\,a_{\mathcal{O}}\; f^{\text{bulk}}_{\Delta_{\mathcal{O}}}(\xi), \qquad f^{\text{bulk}}_{\Delta}(\xi) \xrightarrow[\xi\to 0]{} \xi^{(\Delta-\Delta_1-\Delta_2)/2}, \quad (52.154)$$

where f^{bulk}_{Δ} is the *bulk-channel block*: the resummation of a single bulk conformal multiplet's contribution, fixed (as the bulk blocks were in Section 49.2) by the quadratic Casimir of the bulk conformal group acting in the ξ variable, with the indicated leading power encoding the dimension exchanged. The leading term is the identity, $\mathcal{O} = \mathbf{1}$ with $a_{\mathbf{1}} = 1$ and $C_{12\mathbf{1}} = \delta_{12}$, giving $G(\xi) \sim \xi^{-(\Delta_1+\Delta_2)/2}$.

Boundary channel. When a bulk point approaches the boundary, $x_\perp \to 0$ with the other point held away, equivalently $\xi \to \infty$, neither bulk OPE applies; instead each bulk operator is expanded individually in operators that live on the boundary. This is the *boundary operator expansion* (boundary OPE),

$$\boxed{\mathcal{O}(x_\parallel, x_\perp) = \frac{a_{\mathcal{O}}}{(2x_\perp)^{\Delta_{\mathcal{O}}}}\,\mathbf{1} \;+\; \sum_{\hat{\mathcal{O}}} b_{\mathcal{O}\hat{\mathcal{O}}}\,(2x_\perp)^{\hat{\Delta}-\Delta_{\mathcal{O}}}\big(\hat{\mathcal{O}}(x_\parallel) + \text{descendants}\big),} \quad (52.155)$$

in which $\hat{\mathcal{O}}$ runs over the *boundary primaries* — the local operators of the defect CFT, organized into representations of the worldvolume conformal group $\mathrm{SO}(d,1)$ of dimension $\hat{\Delta}$. The identity term reproduces the one-point function Eq. (52.149); the coefficients $b_{\mathcal{O}\hat{\mathcal{O}}}$ are the *bulk-to-boundary couplings*, the second new piece of defect data. The powers of $x_\perp$ are fixed by dilatation weight: the left side has dimension $\Delta_{\mathcal{O}}$, the boundary operator $\hat{\mathcal{O}}(x_\parallel)$ has dimension $\hat{\Delta}$, and the deficit is made up by $x_\perp^{\hat{\Delta}-\Delta_{\mathcal{O}}}$. Inserting Eq. (52.155) for both operators and using that boundary primaries have the canonical two-point function $\big\langle \hat{\mathcal{O}}(x_\parallel)\hat{\mathcal{O}}(0)\big\rangle = |x_\parallel|^{-2\hat{\Delta}}$ on the worldvolume gives the boundary-channel expansion

$$G(\xi) = \sum_{\hat{\mathcal{O}}} b_{1\hat{\mathcal{O}}}\,b_{2\hat{\mathcal{O}}}\; g^{\text{bdy}}_{\hat{\Delta}}(\xi), \qquad g^{\text{bdy}}_{\hat{\Delta}}(\xi) \xrightarrow[\xi\to\infty]{} \xi^{-\hat{\Delta}}, \quad (52.156)$$

where $g^{\text{bdy}}_{\hat{\Delta}}$ is the *boundary-channel block*, fixed by the Casimir of the boundary group $\mathrm{SO}(d,1)$, with leading power $\xi^{-\hat{\Delta}}$ at large ξ marking the boundary dimension exchanged.

The boundary bootstrap equation. The two expansions compute the same function $G(\xi)$, one convergent near $\xi = 0$ and the other near $\xi = \infty$. Equating them,

$$\boxed{\sum_{\mathcal{O}} C_{12\mathcal{O}}\, a_{\mathcal{O}}\; f^{\text{bulk}}_{\Delta_{\mathcal{O}}}(\xi) \;=\; \sum_{\hat{\mathcal{O}}} b_{1\hat{\mathcal{O}}}\, b_{2\hat{\mathcal{O}}}\; g^{\text{bdy}}_{\hat{\Delta}}(\xi),}\tag{52.157}$$

is the boundary bootstrap equation. It is the exact analogue, one channel against the other, of the bulk crossing equation Eq. (49.15): an identity that must hold for all ξ, hence infinitely many constraints, relating the bulk CFT data $\{C_{12\mathcal{O}}, \Delta_{\mathcal{O}}\}$ and the one-point coefficients $a_{\mathcal{O}}$ on the left to the boundary data $\{b_{i\hat{\mathcal{O}}}, \hat{\Delta}\}$ on the right. Solving it — numerically by the functional methods of Chapter 50, or analytically — is the boundary conformal bootstrap. The structure is identical to the bulk program; only the number of cross-ratios (one instead of two) and the meaning of the channels differ.

52.6.4 The displacement operator

Theorem 52.22 showed that the defect breaks the transverse translations P_i. Whenever a continuous symmetry is broken *by* an insertion rather than spontaneously, the breaking is recorded by a local operator living on the insertion — here, a defect primary. We now identify it and show its dimension is fixed, exactly and without correction, to $p + 1$.

The bulk stress tensor $T^{\mu\nu}$ is the conserved Noether current of translations; in any CFT it is a primary of dimension exactly d. This last fact we can read off directly: a conserved current is a current whose integral over a spatial slice is a translation-invariant charge. The momentum is $P^\nu = \int_{x^0=\text{const}} d^{d-1}x\, T^{0\nu}$, and for P^ν to carry dimension 1 (the dimension of momentum) while the measure $d^{d-1}x$ carries dimension $-(d-1)$, the stress tensor must carry $\Delta_T = 1 + (d-1) = d$. Away from the defect, conservation holds, $\partial_\mu T^{\mu\nu} = 0$. At the defect, transverse momentum is no longer conserved — it can be absorbed by the defect — and conservation fails on its support. The failure is itself a local operator on the worldvolume:

$$\boxed{\partial_\mu T^{\mu i}(x) = -\,\mathrm{D}^i(x_\parallel)\,\delta^{(q)}(x_\perp), \qquad \partial_\mu T^{\mu a}(x) = 0.}\tag{52.158}$$

The parallel components remain conserved because parallel translations are unbroken; the transverse components are violated by a source localized on Σ, the *displacement operator* D^i. It is a defect primary, a function of the worldvolume coordinate $x_\parallel$ alone, carrying a transverse vector index i — a vector of the residual $\mathrm{SO}(q)$ — and is a scalar on the worldvolume. Geometrically it generates an infinitesimal rigid displacement of the defect in the transverse direction i: deforming the defect's shape by $\delta x^i(x_\parallel)$ inserts $\int d^p x_\parallel\, \delta x^i(x_\parallel)\, \mathrm{D}_i(x_\parallel)$ into correlators, which is why it measures the response to bending the defect.

Notation Watch: D^i versus D

The displacement operator D^i (upright, transverse vector index) is a defect primary; it is not the dilatation generator D of Eq. (52.144). The clash of letters is standard in the literature and we keep it, distinguishing the two by the index and the typeface.

Theorem 52.25 (Dimension of the displacement operator)**.** *For any conformal defect, the displacement operator* D^i *is a defect primary of dimension exactly*

$$\Delta_{\mathrm{D}} = p + 1, \tag{52.159}$$

protected from anomalous dimensions. For a boundary ($p = d-1$) *this is* $\Delta_{\mathrm{D}} = d$.

Proof. The Ward identity Eq. (52.158) is an operator equation, so both sides must carry the same scaling dimension. The left side is $\partial_\mu T^{\mu i}$: the stress tensor has dimension d and the derivative adds one, giving dimension $d+1$. On the right, the transverse delta function $\delta^{(q)}(x_\perp)$ is normalized by $\int d^q x_\perp\, \delta^{(q)}(x_\perp) = 1$; since the measure $d^q x_\perp$ carries dimension $-q$, the delta function carries dimension $+q$. For the right side $\mathrm{D}^i(x_\parallel)\,\delta^{(q)}(x_\perp)$ to match dimension $d+1$, the displacement must carry

$$\Delta_{\mathrm{D}} = (d+1) - q = (d-q) + 1 = p + 1, \tag{52.160}$$

using $q = d - p$. The value is exact, not perturbative: Eq. (52.158) follows from the unbroken *integer* structure of the stress tensor (its dimension d is itself protected, being fixed by the conservation law that defines the momentum charge) together with the kinematic dimension of a delta function. Nothing in this counting can receive a continuous correction, so D^i carries no anomalous dimension; its dimension is locked to $p+1$ in every theory that admits the defect. □

The displacement is therefore a universal defect primary: it exists for every nontrivial conformal defect (a trivial defect, transparent to the bulk, has $\mathrm{D}^i = 0$), and its dimension is the same protected number $p+1$ regardless of the bulk theory or the particular defect. Its two-point function is fixed by the worldvolume conformal symmetry and the transverse $\mathrm{SO}(q)$ to

$$\left\langle \mathrm{D}^i(x_\parallel)\, \mathrm{D}^j(0) \right\rangle = \frac{C_{\mathrm{D}}\, \delta^{ij}}{|x_\parallel|^{\,2(p+1)}}, \tag{52.161}$$

and the single normalization constant $C_{\mathrm{D}} \geq 0$ — a *defect central charge* — is not free: the Ward identity Eq. (52.158) ties it to the integrated two-point function of the bulk stress tensor against the defect, so C_{D} is a genuine, computable observable. Physically C_{D} controls the energy cost of bending the defect; for a boundary, where $\mathrm{D} = T^{\perp\perp}\big|_{\text{boundary}}$ is the normal-normal stress evaluated at the wall, it measures the force per unit area the critical medium exerts on its container.

52.6.5 Surface critical behavior and conformal boundary conditions

The framework above is realized physically in the *surface critical behavior* of ordinary critical systems, the boundary analogue of ϕ^4 theory's bulk story. Consider the Ising universality class — the bulk CFT whose leading exponents this chapter computed in the ϵ-expansion and matched against the three-dimensional bootstrap of Chapter 50 — now in a half-space with a free surface. Tune the bulk to its critical temperature. The surface still has a coupling of its own: the strength of the spin–spin bonds in the surface layer relative to the bulk bonds, an independent parameter K_s. As K_s varies, the surface can be in distinct universality classes even though the bulk is held at one fixed point. The renormalization-group flow of K_s, at fixed bulk criticality, has three fixed points, each a distinct conformal boundary condition on the same bulk Ising CFT:

- The **ordinary transition** (K_s small): the surface is "less ordered" than the bulk and orders only when the bulk does. The boundary magnetization vanishes at criticality, $\langle\sigma\rangle = 0$, so the spin one-point coefficient $a_\sigma = 0$; the leading boundary operator into which σ expands has a definite, larger dimension $\hat{\Delta}_\sigma > \Delta_\sigma$. This is the generic free-surface behavior.

- The **special transition** (K_s at a multicritical value): a finely tuned point where the surface enhancement exactly compensates its reduced coordination, so the surface is poised to order independently. It is a surface multicritical point with its own exponents; in the boundary-RG it is the unstable fixed point separating the other two.

- The **extraordinary** (or *normal*) **transition** (K_s large): the surface orders *before* the bulk, so at bulk criticality the surface already carries a nonzero magnetization, $\langle\sigma\rangle \neq 0$ and $a_\sigma \neq 0$. This is the conformal boundary condition that fixes the boundary spin — the analogue of a fixed (rather than free) boundary condition.

In the language of this section these are three distinct *conformal boundary states* of one bulk theory: the bulk data $\{\Delta_{\mathcal{O}}, C_{\phi\phi\mathcal{O}}\}$ is identical in all three, while the boundary data — the spectrum of boundary primaries $\{\hat{\Delta}\}$, the one-point coefficients $a_{\mathcal{O}}$, and the bulk-to-boundary couplings $b_{\mathcal{O}\hat{\mathcal{O}}}$ — differs. The boundary bootstrap equation Eq. (52.157), fed the known bulk Ising data, constrains and determines this boundary data, and the numerical boundary bootstrap reproduces the measured surface exponents of three-dimensional magnets. The conceptual payoff of the bulk/boundary split is exactly this: a single critical medium supports a discrete family of universal surface behaviors, classified by conformal boundary conditions.

Physical Insight: the Wilson line as a conformal line defect

The line defect ($p = 1$) is the case that Yang–Mills theory already met. The Wilson loop of Section 25.6.4, $W[\gamma] = \operatorname{tr} \mathcal{P} \exp(ig \oint_\gamma A)$, is a one-dimensional operator supported on a curve. When the gauge theory flows to (or is) a conformal fixed point and the curve is a straight line, W becomes a *conformal line defect*: by Theorem 52.22 the straight line preserves $\mathrm{SO}(2,1) \times \mathrm{SO}(d-1)$, the one-dimensional conformal group on the line times rotations about it. It carries exactly the data developed here — a spectrum of line-defect operators, bulk-to-defect couplings, and a displacement operator D^i of protected dimension $p + 1 = 2$ that measures the transverse force when the line is bent. The Wilson line, introduced in Chapter 25 as the gauge-invariant record of holonomy, is thus reborn as a conformal defect, and its C_D is the defect central charge governing the energy of a kinked or wavy line. We claim no new computed thread number here; the point is that the Part VII object and the Part XIV framework are the same structure seen twice.

52.6.6 Worked example: the free scalar in a half-space

We close with the one boundary CFT that can be solved completely, by elementary means: the free massless scalar of Section 47.8.1 on the half-space $x_\perp \geq 0$, with either Dirichlet or Neumann conditions on the wall. Everything in the kinematic framework above appears here in closed form.

Worked Example 52.26 (Free scalar BCFT by the method of images)**.** Take the free massless scalar ϕ in d Euclidean dimensions on the half-space $x_\perp \geq 0$, with the wall at $x_\perp = 0$. Impose either

$$\text{Dirichlet:} \quad \phi\big|_{x_\perp = 0} = 0, \qquad \text{or} \qquad \text{Neumann:} \quad \partial_\perp \phi\big|_{x_\perp = 0} = 0. \tag{52.162}$$

The propagator $\langle \phi(x_1)\phi(x_2)\rangle$ satisfies $-\partial^2 \langle \phi(x_1)\phi(x_2)\rangle = \delta^{(d)}(x_1 - x_2)$ in the half-space, subject to Eq. (52.162). The bulk solution is $C_d/|x_1 - x_2|^{d-2}$ with $C_d = \Gamma(\frac{d}{2} - 1)/(4\pi^{d/2})$ from Eq. (47.238). The method of images enforces the boundary condition by adding the field of an image source placed at the reflected point

$$\bar{x}_2 = (x_{2\parallel},\, -x_{2\perp}), \tag{52.163}$$

which lies outside the physical region, so the added piece is harmonic for x_1 in the half-space and does not disturb the bulk equation (Fig. 52.7). Choosing the image with a relative minus sign cancels the field on the wall (Dirichlet); a

relative plus sign cancels its normal derivative (Neumann). Hence

$$\langle\phi(x_1)\phi(x_2)\rangle_{\pm} = C_d\left[\frac{1}{|x_1-x_2|^{d-2}} \pm \frac{1}{|x_1-\bar{x}_2|^{d-2}}\right], \qquad \begin{cases} +: & \text{Neumann} \\ -: & \text{Dirichlet} \end{cases} \tag{52.164}$$

One checks the conditions Eq. (52.162) directly: at $x_{1\perp} = 0$ the two image distances coincide, $|x_1 - x_2| = |x_1 - \bar{x}_2|$, so the Dirichlet $(-)$ combination vanishes; differentiating in $x_{1\perp}$ and setting $x_{1\perp} = 0$ flips the sign of the second term's derivative, so the Neumann $(+)$ combination has vanishing normal derivative.

Cross-ratio form. Write the two chordal distances in terms of parallel and transverse separations. With $r^2 \equiv (x_{1\parallel} - x_{2\parallel})^2$,

$$|x_1 - x_2|^2 = r^2 + (x_{1\perp} - x_{2\perp})^2, \tag{52.165}$$

$$|x_1 - \bar{x}_2|^2 = r^2 + (x_{1\perp} + x_{2\perp})^2 = |x_1 - x_2|^2 + 4\,x_{1\perp}x_{2\perp}. \tag{52.166}$$

The boundary cross-ratio of Eq. (52.150) is $\xi = |x_1 - x_2|^2/(4x_{1\perp}x_{2\perp})$, so

$$|x_1 - x_2|^2 = 4x_{1\perp}x_{2\perp}\,\xi, \qquad |x_1 - \bar{x}_2|^2 = 4x_{1\perp}x_{2\perp}\,(\xi+1). \tag{52.167}$$

With $\Delta_\phi = (d-2)/2$ the free dimension of Eq. (47.239), the propagator Eq. (52.164) becomes

$$\langle\phi(x_1)\phi(x_2)\rangle_{\pm} = \frac{C_d}{(4x_{1\perp}x_{2\perp})^{\Delta_\phi}}\left[\xi^{-\Delta_\phi} \pm (\xi+1)^{-\Delta_\phi}\right] = \frac{1}{(2x_{1\perp})^{\Delta_\phi}(2x_{2\perp})^{\Delta_\phi}}\,G_{\pm}(\xi), \tag{52.168}$$

which is exactly the predicted form Eq. (52.150) with $\Delta_1 = \Delta_2 = \Delta_\phi$ and

$$G_{\pm}(\xi) = C_d[\xi^{-\Delta_\phi} \pm (\xi+1)^{-\Delta_\phi}]. \tag{52.169}$$

The method of images has produced the BCFT two-point function and its single-cross-ratio dependence with no symmetry input beyond the geometry of the image.

One-point functions. The free field has $\langle\phi(x)\rangle = 0$ for both boundary conditions: ϕ is odd under $\phi \to -\phi$, a symmetry of Eq. (52.162), so $a_\phi = 0$. Both Dirichlet and Neumann are therefore $\mathbb{Z}_2$-preserving boundary conditions; they are the Gaussian-fixed-point shadows of the *ordinary* ($a_\sigma = 0$) surface universality classes, not of the extraordinary one.

Boundary-channel spectrum ($\xi \to \infty$). Expand $G_\pm$ at large ξ using $(\xi+1)^{-\Delta_\phi} = \xi^{-\Delta_\phi}(1+1/\xi)^{-\Delta_\phi} = \xi^{-\Delta_\phi}(1 - \Delta_\phi\,\xi^{-1} + O(\xi^{-2}))$:

$$G_+(\xi) = C_d\Big[2\,\xi^{-\Delta_\phi} - \Delta_\phi\,\xi^{-\Delta_\phi-1} + \cdots\Big], \tag{52.170}$$

$$G_-(\xi) = C_d\Big[\Delta_\phi\,\xi^{-\Delta_\phi-1} + O(\xi^{-\Delta_\phi-2})\Big]. \tag{52.171}$$

Comparing with the boundary-channel rule $g^{\mathrm{bdy}}_{\hat{\Delta}}(\xi) \sim \xi^{-\hat{\Delta}}$ of Eq. (52.156) reads off the leading boundary operator into which ϕ expands:

- **Neumann** (+): leading power $\xi^{-\Delta_\phi}$, so $\hat{\Delta} = \Delta_\phi = (d-2)/2$. The surviving boundary operator is the boundary value $\hat{\phi} \equiv \phi|_{x_\perp=0}$ itself: Neumann keeps the field free to fluctuate on the wall, and the boundary operator inherits the bulk dimension.
- **Dirichlet** (−): the $\xi^{-\Delta_\phi}$ term cancels and the leading power is $\xi^{-\Delta_\phi-1}$, so $\hat{\Delta} = \Delta_\phi + 1 = d/2$. The boundary value of ϕ is forced to zero, so the leading boundary operator is the normal derivative $\widehat{\partial_\perp \phi} \equiv \partial_\perp \phi|_{x_\perp=0}$, of dimension one higher.

These dimensions are exact, and they identify the leading bulk-to-boundary coupling: $b^2_{\phi\hat{\phi}} = 2C_d$ for Neumann, $b^2_{\phi,\widehat{\partial\phi}} = C_d\,\Delta_\phi$ for Dirichlet, read directly from the coefficients in Eqs. (52.170) and (52.171).

Bulk-channel check ($\xi \to 0$). The bulk OPE $\phi \times \phi = \mathbf{1} + \phi^2 + \cdots$ predicts, by Eq. (52.154), a leading identity term $\sim \xi^{-\Delta_\phi}$ (the term $\mathcal{O} = \mathbf{1}$, $a_{\mathbf{1}} = 1$) followed by the contribution of ϕ^2 at $\xi^{(\Delta_{\phi^2}-2\Delta_\phi)/2} = \xi^0$ (since $\Delta_{\phi^2} = 2\Delta_\phi$ in the free theory). Expanding Eq. (52.169) at small ξ gives $G_\pm(\xi) = C_d\,\xi^{-\Delta_\phi} \pm C_d + O(\xi)$: the $\xi^{-\Delta_\phi}$ identity term is common to both boundary conditions and the constant $\pm C_d$ is the one-point coefficient of ϕ^2, $a_{\phi^2} = \pm C_d$, which is negative for Dirichlet and positive for Neumann — the sign of the response $\langle\phi^2\rangle$ at the wall. The two channels of Eq. (52.157) thus agree, the bulk channel reading out a_{ϕ^2} and the boundary channel reading out the boundary spectrum, exactly as the boundary bootstrap demands. This is the boundary analogue of the generalized-free-field crossing check of Theorem 49.5: a free theory satisfies the bootstrap identically, here trivially because the image construction already encodes both expansions of the single function $G_\pm(\xi)$.

The free example exhibits, concretely, the whole anatomy of a boundary CFT: a residual symmetry fixing the two-point function up to a function of one cross-ratio, that function carrying both a bulk-channel and a boundary-channel expansion, and a boundary spectrum that depends on the boundary condition while the bulk data stays put.

Standing back, the picture this section has assembled is that a single conformal field theory does not control one homogeneous medium but a layered structure: a bulk, lower-dimensional defects threading it, and boundaries enclosing it, each layer carrying its own conformal data and all of them stitched together by the transverse "radial" coordinate $x_\perp$ that measures distance away from the lower-dimensional locus. That transverse direction — along which a bulk operator resolves into a tower of boundary operators of increasing dimension, the deeper into the bulk the heavier the operators it reaches — is not merely a bookkeeping device. It behaves like an extra dimension along which scale is laid out geometrically. Promoting that observation from a boundary's single normal

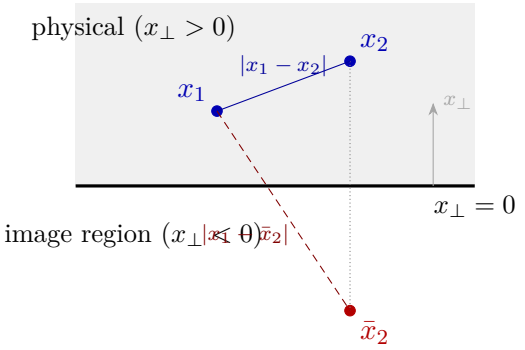

Figure 52.7: Method of images for the half-space scalar. The boundary condition at $x_\perp = 0$ is enforced by an image source at the reflection $\bar{x}_2$ of x_2, with a relative sign $-$ (Dirichlet) or $+$ (Neumann). The two chordal distances $|x_1 - x_2|$ and $|x_1 - \bar{x}_2|$ combine into the single cross-ratio ξ of Eq. (52.167).

direction to a full emergent dimension over the entire CFT is the step the final section takes: the radial-RG picture in which a d-dimensional CFT is read as the boundary of a $(d+1)$-dimensional gravitational spacetime.

52.7 The Bridge to Holography

The previous two sections handed us, almost incidentally, a geometric object that the rest of this book has been circling toward without naming it. A boundary or a defect introduced a distinguished transverse direction — a coordinate running away from the wall into the bulk of the system — and the kinematics organized themselves around how operators behave as one moves along it. The c- and a-theorems, meanwhile, gave us a number attached to a conformal field theory at each end of a renormalization-group flow, a number that decreases monotonically as one passes from short distances to long. Put these two pictures together and a suggestion forms: that a d-dimensional conformal field theory might be most naturally described by adding *one extra dimension*, a radial direction whose role is to carry the renormalization scale, with the monotone of the c-theorem becoming a monotone in geometry. This section makes that suggestion precise as far as kinematics allow, and is honest about where rigor stops and conjecture begins. The destination is the statement that opens Chapter 53: a conformal field theory in d dimensions is dual to a theory of gravity in an anti-de Sitter space of dimension $d+1$.

The argument has a hard skeleton and a soft tissue, and we are careful to keep them distinct. The hard skeleton is pure group theory and is proved here in full: the symmetry group of a CFT_d is, generator for generator, the isometry group of AdS_{d+1}. No conjecture enters this; it is a theorem about Lie algebras

and Killing vectors. The soft tissue is everything that turns this symmetry match into a dynamical duality — the field–operator dictionary, the conditions under which the bulk is a *local, classical* gravitational theory, the geometric reading of irreversibility. Those we state precisely, motivate honestly, scope as conjectural where they are conjectural, date where dating matters, and forward-reference to Chapters 53 to 55 where they are derived. The chapter has exactly one forward reference — the mass–dimension relation, whose derivation lives in Chapter 53 — and we flag it explicitly when we reach it.

52.7.1 The group-theory match: the conformal group is the AdS isometry group

We work throughout in Euclidean signature, as the entire chapter has: critical phenomena live in d Euclidean dimensions, and the conformal group is the Euclidean form $\mathrm{SO}(()d+1,1)$ established in Theorem 47.10. The first task is to produce a $(d+1)$-dimensional space whose isometry group is exactly this $\mathrm{SO}(()d+1,1)$, and the canonical such space is Euclidean anti-de Sitter space.

Definition 52.27 (Euclidean AdS_{d+1} in Poincaré coordinates)**.** Euclidean anti-de Sitter space AdS_{d+1} of radius L is the upper half-space $\{(z, x^i) : z > 0,\ x^i \in \mathbb{R}^d\}$ equipped with the metric

$$ds^2 = \frac{L^2}{z^2}\Big(dz^2 + \delta_{ij}\, dx^i\, dx^j\Big), \qquad i, j = 1, \dots, d. \tag{52.172}$$

The locus $z \to 0$ is the *conformal boundary*, a copy of $\mathbb{R}^d$ carrying the would-be boundary CFT; $z \to \infty$ is the deep interior.

The metric Eq. (52.172) is the Euclidean continuation of the Lorentzian Poincaré-patch metric Eq. (53.59) derived from the embedding hyperboloid in Theorem 53.10; we take it here as the starting point because all we need now is its symmetry. Two features are visible by eye. First, it is *conformally flat*: it is the flat metric δ_{MN} on the half-space, $M, N \in \{z, 1, \dots, d\}$, multiplied by the position-dependent factor $\Omega^2 = L^2/z^2$. Second, the boundary metric is recovered only up to a divergent Weyl factor — there is no canonical boundary metric, only a conformal class — which is the geometric origin of the boundary theory being *conformal* rather than merely Poincaré invariant. We exploit the first feature immediately.

Reducing the Killing equation. A vector field $\xi = \xi^M \partial_M$ generates an isometry of a metric g_{MN} if and only if it satisfies the Killing equation $\mathcal{L}_\xi g_{MN} = 0$, which in coordinates reads

$$\xi^P \partial_P g_{MN} + g_{PN}\, \partial_M \xi^P + g_{MP}\, \partial_N \xi^P = 0. \tag{52.173}$$

For the conformally flat metric $g_{MN} = \Omega^2 \delta_{MN}$ this collapses to something transparent. Substituting and using $\partial_P g_{MN} = 2\Omega(\partial_P \Omega)\delta_{MN}$,

$$2\Omega(\partial_P\Omega)\,\xi^P\,\delta_{MN} + \Omega^2(\partial_M \xi^N + \partial_N \xi^M) = 0, \tag{52.174}$$

where the indices on the second pair of ξ's are raised with the flat δ. Dividing by Ω^2 and writing $\Omega = L/z$, so that $\partial_P \Omega = -(L/z^2)\,\delta^z_P$ and hence $(\partial_P\Omega)\xi^P = -(L/z^2)\,\xi^z$, the first term becomes $-2(\xi^z/z)\,\delta_{MN}$ and we arrive at

$$\boxed{\partial_M \xi^N + \partial_N \xi^M = \frac{2\,\xi^z}{z}\,\delta_{MN}}. \tag{52.175}$$

This is precisely the *conformal* Killing equation on flat $(d+1)$-dimensional Euclidean space — the statement that $\partial_M \xi^N + \partial_N \xi^M$ is proportional to δ_{MN} — with the conformal factor not free but *pinned* to the value $\omega = \xi^z/z$. The isometries of AdS_{d+1} are therefore exactly those conformal Killing vectors of flat $\mathbb{R}^{d+1}$ whose local scale factor happens to equal ξ^z/z. This pinning is the whole content of the computation: the conformal group of flat $\mathbb{R}^{d+1}$ is the larger $\mathrm{SO}(()d+2,1)$, and Eq. (52.175) selects the subgroup that survives as genuine isometries of the curved space.

Enumerating the solutions. The conformal Killing vectors of flat $\mathbb{R}^{d+1}$ are known completely from the very analysis of Theorem 47.3 (applied now in $d+1$ rather than d dimensions): they are the translations, rotations, the dilatation, and the special conformal transformations, with the general such vector carrying a scale factor $\omega(X)$ that is at most linear in the coordinates. We run through each family and ask whether Eq. (52.175) holds, i.e. whether its flat scale factor equals ξ^z/z.

Boundary translations. The vector $\xi = a^i \partial_i$ (constant a^i, no z-component) has $\partial_M \xi^N + \partial_N \xi^M = 0$ and $\xi^z = 0$, so both sides of Eq. (52.175) vanish. The d generators

$$P_i = \partial_i \tag{52.176}$$

are isometries. The radial translation ∂_z, by contrast, has $\xi^z = 1 \neq 0$ while its left side vanishes, so $0 = 2/z$ is violated: *z-translation is not a symmetry.* This is the geometric statement that the boundary singles out an origin of the radial coordinate, exactly as a renormalization scheme singles out a reference scale.

Boundary rotations. The $\frac{1}{2}d(d-1)$ vectors $M_{ij} = x_i\partial_j - x_j\partial_i$ are antisymmetric, hence have vanishing left side, and have $\xi^z = 0$. They are isometries: the boundary rotation generators.

The dilatation. The full-space dilatation $\xi_D = z\,\partial_z + x^i\partial_i$ has $\xi^z = z$, so the right side of Eq. (52.175) is $2(z/z)\delta_{MN} = 2\delta_{MN}$. Its left side is $\partial_M \xi^N + \partial_N \xi^M = 2\delta_{MN}$ (each coordinate vector field $X^M \partial_M$ contributes the identity). The two sides agree, so

$$D = z\,\partial_z + x^i\,\partial_i \tag{52.177}$$

is an isometry of AdS_{d+1}. This single Killing vector is the linchpin of the whole bridge, and we return to it in Section 52.7.2. Note what it does: it rescales the radial coordinate and the boundary coordinates *together*, $z \to \lambda z$, $x^i \to \lambda x^i$.

Special conformal transformations. For a flat special conformal generator with parameter b^M, $\xi_M = 2(b\cdot X)X_M - X^2 b_M$, the scale factor is $\omega = 2\,b\cdot X$. We need $\omega = \xi^z/z$. Take first a boundary parameter, $b^M = (0, b^i)$ with $b^z = 0$. Then $b\cdot X = b^i x_i$, $X^2 = z^2 + x^2$ (writing $x^2 = \delta_{ij}x^i x^j$), and the z-component of ξ is

$$\xi^z = 2(b\cdot X)X^z - X^2 b^z = 2(b^i x_i)\,z - 0 = 2z\,(b\cdot x), \tag{52.178}$$

so $\xi^z/z = 2\,b\cdot x = 2\,b\cdot X = \omega$. The pinning condition holds, and the d generators

$$K_i = 2x_i(x^j\partial_j + z\,\partial_z) - (x^2 + z^2)\,\partial_i \tag{52.179}$$

are isometries. The radial special conformal generator $b^z \neq 0$ fails the same test — its $\xi^z = 2(b^z z)z - (x^2+z^2)b^z = b^z(z^2 - x^2)$ gives $\xi^z/z = b^z(z^2-x^2)/z$, while $\omega = 2b^z z$, and $2b^z z \neq b^z(z^2-x^2)/z$ — so it is discarded, just as ∂_z was.

The count and the match. Collecting the survivors, the independent isometries of AdS_{d+1} are

$$\underbrace{d}_{P_i} + \underbrace{\tfrac{1}{2}d(d-1)}_{M_{ij}} + \underbrace{1}_{D} + \underbrace{d}_{K_i} = \frac{d^2+3d+2}{2} = \frac{(d+1)(d+2)}{2}, \tag{52.180}$$

which is exactly the dimension of the conformal algebra computed in Theorem 47.9, and exactly the dimension $\frac{1}{2}(d+2)(d+1)$ of $\mathfrak{so}(d+1,1)$. The match is not merely numerical. Comparing the explicit vector fields Eqs. (52.176), (52.177) and (52.179) and the boundary rotations M_{ij} against the four families of conformal Killing vectors of the *boundary* $\mathbb{R}^d$ in Eq. (47.25), we see that the boundary limit $z \to 0$ of each AdS Killing vector is precisely the corresponding conformal Killing vector of the boundary: $D|_{z\to 0} = x^i\partial_i$, $K_i|_{z\to 0} = 2x_i(x\cdot\partial) - x^2\partial_i$, while P_i and M_{ij} are already z-independent. The naming was not a coincidence imposed by hindsight; the identification is forced.

Theorem 52.28 (Conformal group as AdS isometry group)**.** *The isometry algebra of Euclidean* AdS_{d+1}*, generated by the Killing vectors Eq. (52.176),* $M_{ij} = x_i\partial_j - x_j\partial_i$*, Eq. (52.177), and Eq. (52.179), is isomorphic as a Lie algebra to the Euclidean conformal algebra* $\mathfrak{so}(d+1,1)$ *of Theorem 47.10, under the identification of* P_i, M_{ij}, D, K_i *with the generators of the same name. The radial coordinate* z *is acted on nontrivially only by* D *and* K_i *— exactly the generators whose boundary action is the dilatation and the special conformal transformations. In Lorentzian signature the same statement reads* $\mathfrak{so}(d,2) \cong \mathfrak{so}(2,d)$*, the isometry algebra of Lorentzian* AdS_{d+1}*.*

Proof. We have exhibited each generator as a solution of the Killing equation Eq. (52.175) and counted $\frac{1}{2}(d+1)(d+2)$ of them in Eq. (52.180), matching the dimension of $\mathfrak{so}(d+1,1)$. It remains to check that they close into the conformal algebra Eq. (47.53) with the correct brackets, not merely the correct count. The commutators of these explicit vector fields are computed exactly as the abstract brackets were in Section 47.2.3, because the differential-operator realization is the same: D grades P_i and K_i oppositely, $[D, P_i] = -P_i$ and $[D, K_i] = +K_i$ as Lie brackets of vector fields (the sign relative to Eq. (47.53c) being the conventional factor of i that distinguishes anti-Hermitian vector fields from Hermitian generators), and the one nonlinear bracket $[K_i, P_j]$ closes onto $2(\delta_{ij}D - M_{ij})$ by the identical algebra that produced Eq. (47.53d). Since both algebras have the same generators with the same brackets, the linear map sending each AdS Killing vector to the conformal generator of the same name is a Lie-algebra isomorphism. The boundary limits identified above show it is the *geometric* realization of the abstract embedding-space dictionary Eq. (47.56): the two extra embedding directions X^d, X^{d+1} of Section 47.2.4 are the two directions appended to the boundary to build the bulk. □

Section 53.3.6 carries out the boundary-limit construction in full Lorentzian detail, deriving each Killing vector from the ambient hyperboloid and treating the special conformal family — the only one nonlinear in x — step by step; Theorem 53.14 is the Lorentzian counterpart of Theorem 52.28 above. The reader who wants the version anchored to the embedding-space picture of Section 47.2.4 will find it there. For the bridge we are building, the Euclidean half-space computation Eq. (52.175) is the cleanest possible demonstration: the isometries of the bulk *are* the conformal transformations of the boundary, with no input beyond the metric Eq. (52.172) and the conformal Killing equation.

Physical Insight

The pinning condition Eq. (52.175) explains a fact that is otherwise mysterious: why the conformal group of $\mathbb{R}^d$ has the same size as the *isometry* group of a $(d+1)$-dimensional space, when the conformal group of $\mathbb{R}^{d+1}$ itself is strictly larger. The curvature of AdS converts "angle-preserving but not distance-preserving" transformations of the would-be flat $(d+1)$-space into honest distance-preserving symmetries — but only for those whose local rescaling is generated radially, $\omega = \xi^z/z$. The extra dimension trades a conformal symmetry of the boundary for an isometry of the bulk. This is the kinematic seed of holography: a symmetry that acts as a scale transformation on the boundary is realized as a rigid motion in the bulk, and the direction it moves things along is the radial one.

52.7.2 Holographic renormalization-group flow: the radial coordinate is the scale

The single most consequential entry in Theorem 52.28 is the dilatation Eq. (52.177). The generator that drives the renormalization group — D, whose eigenvalue is the scaling dimension and whose flow between fixed points was the whole subject of Part VI — acts in the bulk by rescaling z and x together. We now argue, heuristically but honestly, that this forces the identification

$$\text{radial coordinate } z \;\longleftrightarrow\; \text{inverse renormalization scale}, \qquad \mu \sim \frac{1}{z}, \tag{52.181}$$

so that small z (near the boundary) is the ultraviolet, large z (deep in the bulk) is the infrared, and a Wilsonian momentum cutoff Λ on the boundary theory is a radial slice $z \gtrsim 1/\Lambda$.

The dimensional-analysis argument. Under the dilatation isometry generated by Eq. (52.177), finite transformations are $x^i \to \lambda x^i$ and $z \to \lambda z$ simultaneously. On the boundary, a dilatation by λ scales all lengths by λ and therefore all energies and momenta by λ^{-1}. The radial coordinate scales the same way as a boundary length, so z carries dimensions of length and the natural energy associated to a given radial position is $\mu \sim 1/z$ (restoring the AdS radius, $\mu \sim L/z^2$ or $1/z$ depending on the chosen normalization of μ; only the scaling $\mu \propto 1/z$ is invariant and only it matters). A physical process localized at radius z in the bulk probes boundary physics at the corresponding scale $\mu \sim 1/z$: this is the precise sense in which "moving into the bulk" is "flowing to the infrared."

The falloff argument. The dimensional analysis is made sharp by how bulk fields behave near the boundary, which we preview here and which Chapter 53 derives. A scalar field $\phi(z, x)$ dual to a boundary operator $\mathcal{O}$ of dimension Δ approaches the boundary as a superposition of two power laws,

$$\phi(z,x) \;\xrightarrow{z\to 0}\; z^{\,d-\Delta}\,\phi_{(0)}(x) \;+\; z^{\,\Delta}\,\phi_{(1)}(x) + \cdots, \tag{52.182}$$

the two exponents being the roots of the indicial equation analyzed in Section 53.4. Apply the dilatation $z \to \lambda z$, $x \to \lambda x$: the coefficient $\phi_{(0)}$ must transform so that $z^{d-\Delta}\phi_{(0)}$ is invariant, i.e. $\phi_{(0)}$ has scaling weight $d-\Delta$, while $\phi_{(1)}$ has weight Δ. These are exactly the weights of, respectively, a *source* that couples to $\mathcal{O}$ in the boundary action (a coupling of an operator of dimension Δ has dimension $d-\Delta$) and the *response* $\langle\mathcal{O}\rangle$ (which has dimension Δ). The position along the radial axis literally reads out the scaling weight: the leading falloff near $z=0$ is the ultraviolet data (the coupling one turns on), and the subleading falloff is the infrared response (what the theory does about it). The radial direction is not merely *like* a scale; the bulk equation of motion organizes its solutions by scale.

Connection to Wilsonian flow. This is the holographic incarnation of the Wilsonian renormalization group of Chapter 23. There, integrating out boundary momentum modes above a cutoff Λ and tracking the induced flow of couplings was the definition of the RG; the beta functions of Chapter 24 measured the rate of that flow. Here, the cutoff is implemented geometrically by terminating the bulk at a radial slice $z = \epsilon$ rather than going all the way to $z = 0$; the divergences of the boundary CFT reappear as the $\epsilon \to 0$ divergences of the on-shell bulk action, and removing them by adding local boundary counterterms is the procedure of *holographic renormalization* carried out in Section 53.6.4. Sliding ϵ inward integrates out boundary modes, and the radial evolution equation of the bulk fields — their dependence on z — is, term by term, the renormalization-group flow of the dual couplings. The dilatation that generates RG flow in Part VI is the radial isometry Eq. (52.177) of the bulk; Chapter 54 develops this holographic RG quantitatively, including the precise map between the radial Hamiltonian and the beta functions.

Notation Watch

Throughout this chapter $\epsilon = 4 - d$ is the dimensional-expansion parameter of the Wilson–Fisher analysis, not the Feynman $i\epsilon$ and not the radial cutoff. In this subsection the symbol ϵ appears once more, as the holographic radial cutoff $z = \epsilon$; this usage is standard in the holography literature and is confined to the discussion of Section 53.6.4, where it never collides with the expansion parameter (that analysis is at fixed integer d). We keep the radial-cutoff usage only in this paragraph and in cross-references to Chapter 53; elsewhere ϵ is the expansion parameter.

52.7.3 The preview dictionary: a primary is a bulk field

The symmetry match Theorem 52.28 tells us that whatever lives in the bulk must organize itself into representations of $\mathrm{SO}(()d+1,1)$, which are exactly the representations of the boundary conformal group — labelled, by the analysis of Section 47.3, by a scaling dimension Δ and a spin (an $\mathrm{SO}(()d)$ rotation representation). The natural conjecture, the one that turns the symmetry match into a dynamical correspondence, is that the boundary spectrum of primary operators is in one-to-one correspondence with a bulk spectrum of fields.

Definition 52.29 (The field–operator map, scalar case)**.** To each scalar primary operator $\mathcal{O}$ of the boundary CFT, of scaling dimension Δ, there corresponds a scalar field ϕ propagating in the bulk AdS_{d+1}, of mass m, with the dimension and mass related by

$$\Delta(\Delta - d) = m^2 L^2. \tag{52.183}$$

Fields of nonzero spin correspond to spinning primaries: a massless spin-1 bulk

gauge field is dual to a conserved current J^μ of dimension $\Delta = d - 1$, and the massless spin-2 bulk graviton is dual to the stress tensor $T^{\mu\nu}$ of dimension $\Delta = d$.

Caution

The one forward reference. Equation Eq. (52.183) is *stated* here, not derived. Its derivation — as the indicial equation of the bulk wave operator near the conformal boundary, together with the choice of boundary falloff and the Breitenlohner–Freedman stability bound $m^2L^2 \geq -d^2/4$ — is carried out in full in Theorem 53.17, equation Eq. (53.112). This is the single forward connection of the chapter, declared at the outset. We use Eq. (52.183) below only to motivate the structure of the correspondence, never to prove anything that the present chapter relies on.

Two heuristic checks make Eq. (52.183) plausible without the full derivation, and both connect to material already in hand. First, the two roots of the quadratic Eq. (52.183),

$$\Delta_\pm = \frac{d}{2} \pm \sqrt{\frac{d^2}{4} + m^2L^2}, \tag{52.184}$$

are exactly the two falloff exponents Δ and $d-\Delta$ of Eq. (52.182): their sum is $\Delta_+ + \Delta_- = d$ and their product is $\Delta_+\Delta_- = -m^2L^2$, matching the source/response pairing identified in Section 52.7.2. Second, a *massless* bulk scalar, $m = 0$, gives $\Delta_+ = d$ — a marginal operator, the dimension of a Lagrangian coupling in d dimensions — which is precisely what one expects: a massless bulk field is a modulus, and modes that cost no energy in the bulk are dual to operators that cost no scale to turn on. The graviton entry of Theorem 52.29 is the sharpest case. The bulk metric fluctuation is massless and spin-2; the dual operator must be a conserved, spin-2, dimension-d primary, which by the analysis of Section 47.4.3 is the stress tensor and nothing else. That the boundary theory *has* a stress tensor at all is the statement that the bulk theory *has* dynamical gravity — the entry that gives the correspondence its name. The complete field–operator dictionary, including the GKP–Witten generating-functional relation that computes correlators, is the subject of Section 53.5.

52.7.4 When is the bulk classical gravity? Large central charge and a sparse spectrum

Everything so far is kinematics, and kinematics alone does not tell us whether the bulk dual of a given CFT is a tractable, local, classical gravitational theory or something far wilder. A generic CFT, if it has a bulk dual at all, is dual to a strongly coupled, stringy, intrinsically quantum-gravitational mess. The cases in which the bulk reduces to classical (semiclassical) Einstein gravity coupled to a

handful of light fields — the cases that make holography a computational tool rather than a slogan — are special, and the conditions that single them out are read directly off the data of the previous section.

Central charges measure the inverse Newton constant. The c- and a-type coefficients of the conformal anomaly, computed for the CFT at its fixed point in Section 52.5, count the number of local degrees of freedom of the theory. On the bulk side, the corresponding measure is the gravitational coupling: the smaller the Newton constant G_N in AdS units, the more the bulk geometry behaves classically (the gravitational fluctuations $\sim G_N$ are suppressed, and the saddle-point/tree-level approximation to the bulk path integral becomes exact). The two are identified:

$$c \sim a \sim \frac{L^{d-1}}{G_N}, \tag{52.185}$$

up to scheme-dependent numerical factors fixed precisely in Chapter 54. The relation Eq. (52.185) is exact and famous in $d = 2$, where the Brown–Henneaux analysis of the asymptotic symmetry algebra of AdS_3 gives $c = 3L/2G_N$ for the central charge of Theorem 48.8; in higher d the analogous statement relates the trace-anomaly coefficients to L^{d-1}/G_N. The upshot is uniform: *a large central charge is a small bulk Newton constant*, and the classical-gravity limit is the large-c limit.

Large c is necessary but not sufficient: the gap. Large c makes the bulk weakly gravitating, but does not by itself make it *Einstein* gravity. A weakly coupled bulk could still contain a Regge tower of light higher-spin fields — the hallmark of a string theory with a low string scale — in which case the bulk is local only on scales much larger than the AdS radius, and "gravity" is the wrong description below the string scale. What additionally distinguishes an Einstein-gravity dual is a *sparse spectrum with a large gap*: the lightest single-trace operators of nonzero spin > 2 must have parametrically large dimension $\Delta_{\mathrm{gap}} \to \infty$, so that the corresponding bulk higher-spin fields are heavy and decouple, leaving the metric (spin 2) and a few light matter fields as the only low-lying bulk degrees of freedom. Equivalently, the bulk is local on the AdS scale precisely when Δ_{gap} is large. We state the package as a conjecture, because that is what its general form is, and we date it.

Conjecture 52.30 (Conditions for a local semiclassical dual; current understanding, mid-2020s)**.** *A conformal field theory in $d \geq 3$ dimensions admits a description by classical Einstein gravity in AdS_{d+1} coupled to a finite number of light fields, local on the scale of the AdS radius L, when (i) the central charges are large, $c \sim a \sim L^{d-1}/G_N \gg 1$, suppressing bulk quantum gravity; and (ii) the spectrum is sparse with a large higher-spin gap, $\Delta_{gap} \to \infty$, pushing the would-be stringy/higher-spin states to large mass. Under these conditions the boundary*

correlators are reproduced by tree-level (Witten-diagram) computations in the bulk effective theory. The precise necessity and sufficiency of these conditions, and the sharp form of the required bounds, are established in particular families and conjectured in general; this is the state of understanding as of the mid-2020s.

Why Yang–Mills theory is the prototype. The cleanest realizations of Theorem 52.30 are large-N gauge theories — the natural home of Yang–Mills theory. A SU(N) gauge theory of the type carried since Chapter 25 has, in the 't Hooft limit $N \to \infty$ at fixed 't Hooft coupling $\lambda_{\text{'t H}} = g^2 N$, a central charge growing as $c \sim N^2$, which is the large-c condition (i) with $1/G_N \sim N^2$. The gauge invariants are single-trace operators $\mathrm{tr}(\cdots)$, and at large 't Hooft coupling the higher-spin single-traces acquire large anomalous dimensions, $\Delta_{\text{gap}} \sim \lambda_{\text{'t H}}^{1/4} \to \infty$, supplying condition (ii). The genus expansion of the large-N diagrammatics, in which surfaces of higher genus are suppressed by powers of $1/N^2$, is term-for-term the loop expansion of a string theory in the bulk — a structural coincidence that is the historical and logical entry point to the entire subject, developed in Sections 53.1 and 53.1.1. The prototypical exactly-conformal example, $\mathcal{N} = 4$ super-Yang–Mills, is dual to type IIB string theory on $\mathrm{AdS}_5 \times S^5$, and its supergravity (Einstein-gravity) limit is exactly the large-N, large-$\lambda_{\text{'t H}}$ corner where Theorem 52.30 applies. The large-N gauge theory carried through this book is therefore not merely *a* candidate gravity dual; it is *the* candidate, and tracing why is the business of Chapter 53.

52.7.5 Geometric irreversibility: the holographic c-function

The last thread to tie is the one we opened with. The c- and a-theorems of Section 52.5 state that a certain CFT datum decreases monotonically along renormalization-group flow, encoding the irreversibility of coarse-graining: degrees of freedom are lost, never gained, as one flows to the infrared. If the radial direction of the bulk *is* the renormalization scale, as Section 52.7.2 argued, then this irreversibility must be visible as a monotonicity property of the bulk geometry along the radial direction. It is, and the mechanism is clean enough to exhibit in full.

The domain-wall geometry of an RG flow. A renormalization-group flow connecting a UV fixed point to an IR fixed point is dual, on the bulk side, to a geometry that interpolates between two AdS regions of different radii: AdS_{d+1} with radius L_{UV} near the boundary and AdS_{d+1} with radius $L_{\text{IR}} > L_{\text{UV}}$ deep in the interior. The most general such Poincaré-invariant geometry — preserving the d-dimensional boundary symmetries while breaking the dilatation that would make it pure AdS — is the domain wall

$$ds^2 = e^{2A(r)}\,\delta_{\mu\nu}\,dx^\mu dx^\nu + dr^2, \tag{52.186}$$

where r is the radial coordinate (related to the Poincaré z of Eq. (52.172) by $z = L\,e^{-A}$ near a fixed point, so that $A \to +\infty$ is the UV boundary and $A \to -\infty$ the deep IR), and $A(r)$ is the *warp factor*. At a fixed point the geometry is pure AdS, for which $A(r) = r/L$ and the slope $A' = 1/L$ is constant; away from a fixed point $A'(r)$ varies, interpolating between $1/L_{\rm UV}$ and $1/L_{\rm IR}$.

The candidate c-function and its monotonicity. Define the holographic c-function

$$c(r) \;=\; \frac{\kappa}{G_N\,\big[A'(r)\big]^{\,d-1}}, \tag{52.187}$$

with κ a positive d-dependent constant. At a fixed point $A' = 1/L$ is constant and $c \propto L^{d-1}/G_N$, reproducing Eq. (52.185): the holographic c-function evaluated at the endpoints returns exactly the central charges of the two CFTs. We now show $c(r)$ is monotone. Differentiating Eq. (52.187),

$$c'(r) = \frac{\kappa}{G_N}\,\frac{d}{dr}\big[A'\big]^{-(d-1)} = -\,(d-1)\,\frac{\kappa}{G_N}\,\frac{A''(r)}{\big[A'(r)\big]^{\,d}}. \tag{52.188}$$

Since $A' > 0$ (the warp factor increases toward the boundary) and $\kappa, G_N, (d-1) > 0$, the sign of $c'(r)$ is the *opposite* of the sign of $A''(r)$. The geometry therefore enforces monotonicity provided $A''(r) \le 0$, and that inequality is exactly what gravity supplies.

The null energy condition does the work. The warp factor's concavity, $A'' \le 0$, is a consequence of Einstein's equations sourced by any reasonable matter. Computing the Einstein tensor of Eq. (52.186) and contracting Einstein's equation $G_{MN} + \Lambda g_{MN} = 8\pi G_N\,T_{MN}$ with a radial null vector k^M (one with $k^M k_M = 0$, having one component along r and one along a boundary direction), the cosmological-constant and curvature pieces arrange so that

$$A''(r) = -\,\frac{8\pi G_N}{d-1}\,T_{MN}\,k^M k^N \Big/ (k^t)^2, \tag{52.189}$$

schematically: A'' is set by the null–null component of the stress tensor. The *null energy condition* — the statement that $T_{MN}k^M k^N \ge 0$ for every null k^M, satisfied by all standard matter (scalars, gauge fields, fermions) and the cornerstone hypothesis of the classical energy conditions — then gives

$$A''(r) \le 0, \tag{52.190}$$

and hence, by Eq. (52.188), $c'(r) \ge 0$. As one flows from the UV (large r, near the boundary) to the IR (small r, deep interior), r decreases and $c(r)$ decreases with it:

$$c_{\rm UV} = c(r \to +\infty) \;\ge\; c(r \to -\infty) = c_{\rm IR}. \tag{52.191}$$

Theorem 52.31 (Holographic c-theorem)**.** *For any bulk matter satisfying the null energy condition, the holographic c-function Eq. (52.187) of a Poincaré-invariant domain-wall geometry Eq. (52.186) is monotonically non-decreasing in the radial coordinate r, $c'(r) \geq 0$, and interpolates between the central charges of the UV and IR fixed-point CFTs. The irreversibility of renormalization-group flow — the field-theory c-/a-theorem of Section 52.5 — is thereby realized as the monotonicity in the radial (energy) direction of a geometric quantity, with the null energy condition playing the role that unitarity and reflection positivity play in the field-theory proof.*

This is a striking dictionary entry: a deep theorem about the irreversibility of quantum field theory becomes, on the bulk side, an elementary consequence of an energy condition on classical matter. The translation runs both ways. The field-theory statement is proved using unitarity and the positivity of the spectral density (the methods of Section 52.5); the gravity statement is proved using the null energy condition. That these two positivity conditions — one on a Hilbert-space inner product, one on a classical stress tensor — yield the same monotone is one of the sharpest pieces of evidence that the correspondence is consistent at the level of dynamics, not merely symmetry.

Physical Insight

There is a second, conceptually deeper, geometric reading of the same monotone, through entanglement entropy. The number of degrees of freedom of a region of the boundary theory is measured by the entanglement entropy across its boundary, and in holography that entropy is computed — by the Ryu–Takayanagi prescription of Chapters 55 and 56 — as the *area* of a minimal bulk surface anchored on the region. Flowing to the infrared shrinks the available degrees of freedom, which shrinks the minimal-surface area, which decreases an entropic c-function. The monotonicity of the c-theorem then descends from the monotonicity of areas of minimal surfaces as the anchoring region grows — a purely geometric fact. This entanglement reading, which is how the strongest forms of the higher-dimensional c- and a-theorems are actually established, is developed in Chapter 55; we flag here only that the holographic c-function Eq. (52.187) and the entanglement c-function are two faces of the same monotone, both pointing along the radial direction that we have now identified as the renormalization scale.

Figure 52.8 collects the picture. The boundary at $z \to 0$ carries the conformal field theory whose data — the spectrum of dimensions Δ and the OPE coefficients — the bootstrap of Chapters 49 to 51 constrains. The radial direction carries the renormalization scale. Bulk fields are boundary operators by Theorem 52.29. The bulk is classical Einstein gravity when the central charge is large and the spectrum

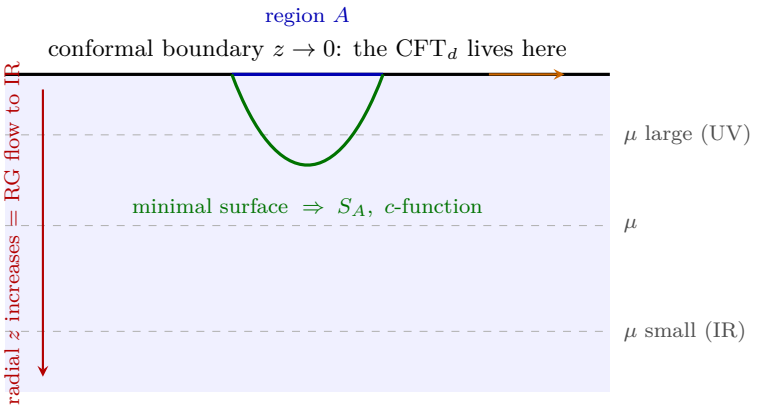

Figure 52.8: The bridge to holography. A CFT$_d$ lives on the conformal boundary $z \to 0$ of AdS$_{d+1}$. The bulk dilatation Killing vector $D = z\partial_z + x^i\partial_i$ of Eq. (52.177) scales the radial coordinate z together with the boundary coordinates, identifying z with the inverse renormalization scale $\mu \sim 1/z$ (Eq. (52.181)): radial slices are Wilsonian cutoff surfaces, and moving into the bulk (z increasing) is renormalization-group flow to the infrared. A boundary region A anchors a minimal bulk surface (Chapters 55 and 56) whose area computes the entanglement entropy S_A and a geometric c-function; its monotonicity along the radial direction realizes the c-theorem of Section 52.5, as in Theorem 52.31.

sparse, Theorem 52.30. And the irreversibility of the flow is the monotonicity of a geometric quantity along the radial axis, Theorem 52.31. Every ingredient has been either proved here (the symmetry match) or stated precisely with its derivation forward-referenced (the dictionary, the classical limit, the geometric c-theorem).

This completes the chapter, and with it Part XIV. We arrived at conformal field theory as the universal description of a renormalization-group fixed point, closing the loop with Part VI and consummating ϕ^4 theory at the Wilson–Fisher point; we have now turned the fixed-point's own scaling symmetry into the suggestion that the theory is the boundary of a gravitational bulk with one extra dimension. What remains is to state the correspondence precisely, to derive the dictionary entries we have only previewed — beginning with the mass–dimension relation Eq. (53.112) that is this chapter's one forward connection — and to confront honestly the question of what is theorem and what is conjecture. That is the work of the next part, which opens with the AdS/CFT correspondence in Chapter 53.

Further reading

The identification of critical fixed points with conformal field theories is developed, for the Wilson–Fisher fixed point of the ϵ-expansion, from Wilson and Fisher [515] and the broader renormalization-group program of Wilson [513], Wilson and Kogut [516]; the precise sense in which scale invariance implies conformal invariance is Polchinski [404], with the four-dimensional analysis sharpened in Luty et al. [329]. The two-dimensional theory, the central charge, and the minimal models that organize the c-theorem staircase are treated comprehensively in the monograph of Di Francesco et al. [147]; boundary conformal field theory in the style of Section 52.6 traces to Cardy and is reviewed in Cardy [108]. The arrow of the renormalization group rests on Zamolodchikov [531] in two dimensions and on the conjecture of Cardy [109] proved by Komargodski and Schwimmer [301] in four; the odd-dimensional F-theorem is Jafferis et al. [282], proved entropically by Casini and Huerta [114], and the generalized monotone is computed for the $O(N)$ models in Fei et al. [187]. Precision three-dimensional Ising data come from the resummed ϵ-expansion of Le Guillou and Zinn-Justin [318], the conformal bootstrap of Kos et al. [304] (with the modern program reviewed in Poland et al. [402], Rychkov [421]), and the Monte Carlo study of Hasenbusch [254]. The holographic bridge of Section 52.7 is the gateway to Part XV; the foundational correspondence is Maldacena [331] with the generating-functional dictionary of Gubser et al. [242], Witten [522], all developed in full in Chapter 53.

Holography and Quantum Information

Chapter 53

The AdS/CFT Correspondence

Two threads of this book, pursued for very different reasons, are about to meet. From the gauge side we carry the 't Hooft large-N expansion of Chapters 27 and 28: reorganizing a non-abelian gauge theory by powers of $1/N$ rather than by the coupling reveals a topological expansion in which planar diagrams dominate and the surfaces swept out by Feynman graphs are sorted by genus exactly as the worldsheets of a string theory are. From the conformal side we carry the apparatus of Chapters 47 and 49: the conformal algebra $\mathrm{SO}((2,d)$, the classification of local operators by scaling dimension, unitarity bounds, and the bootstrap insight that a CFT can be *defined* by its symmetry and the data of its correlators rather than by a Lagrangian. The proposal of this chapter is that these two pictures are the same physics seen twice — that a particular four-dimensional conformal gauge theory is, exactly and non-perturbatively, a theory of quantum gravity in a curved five-dimensional spacetime, and that the elusive "master string" hiding inside the large-N expansion is literally a string propagating in that bulk.

We build the correspondence in the order in which its logic is forced. Section 53.1 establishes the structural fact that makes everything else conceivable: the $1/N$ expansion of a matrix-valued field theory is a genus expansion, with string coupling $g_s \sim 1/N$, single-trace operators that factorize at large N, and a "master field" begging for a dual description. Section 53.2 turns structure into a concrete duality by following Maldacena's argument honestly: a stack of N branes admits two descriptions whose near-horizon, decoupling limits must agree, identifying $\mathcal{N}=4$ super-Yang–Mills with type IIB string theory on $\mathrm{AdS}_5 \times S^5$ and fixing the parameter dictionary $L^4/\alpha'^2 \sim \lambda$, $g_s \sim g_{\mathrm{YM}}^2$. We are careful throughout to separate what is derived from what is conjectured, and we record why $\mathcal{N}=4$ is exactly conformal — its vanishing beta function (Chapter 45) — and how its superconformal group $\mathrm{PSU}(2,2|4)$ matches the bulk isometries.

With the claim on the table we develop the bulk geometry and the dictionary that makes the duality computational. Section 53.3 constructs anti-de Sitter

space as a hyperboloid, gives its three working coordinate systems, computes its curvature and maximal symmetry, and exhibits its conformal boundary — the crucial fact that AdS_{d+1} carries an $\mathrm{SO}(()2,d)$ isometry group acting on the boundary exactly as the conformal group of Chapter 47 acts on d-dimensional Minkowski space. Section 53.4 solves the wave equation for a bulk scalar near the boundary, extracts its two characteristic falloffs, and derives the mass–dimension relation $\Delta(\Delta - d) = m^2 L^2$ together with the Breitenlohner–Freedman bound. Section 53.5 assembles these into the field–operator map: every bulk field is dual to a boundary primary, the leading bulk falloff is a source and the subleading one a vacuum expectation value, bulk gauge symmetries become boundary global symmetries, bulk diffeomorphisms enforce stress-tensor conservation, and the holographic degree-of-freedom count reproduces the N^2 scaling of the central charge.

The dictionary becomes a calculus in Section 53.6, where the GKP–Witten relation equates the boundary generating functional with the on-shell bulk action; we construct the bulk-to-boundary propagator, confront the divergences of the on-shell action, carry out holographic renormalization, and extract the scalar two-point function with the correct CFT power law and coefficient. Finally Section 53.7 steps back to weigh the evidence honestly: the symmetry and central-charge matches the duality passes exactly, the integrability and localization tests it survives, the precise sense in which it is a conjecture taken as a definition, the strong/weak character that makes it both powerful and hard to prove, and the genuine open frontiers — emergent bulk locality, the black-hole interior, and holography beyond anti-de Sitter — that the remainder of Part XV (Chapters 54 to 57) takes up.

53.1 Large-N and the String in Disguise

The chapter's organizing thesis — that a quantum field theory in d dimensions might *be* a theory of gravity in $d+1$ dimensions — is, taken cold, an outlandish claim. A gauge theory has no graviton, no dynamical metric, no extra dimension; gravity has all three. Before we can take the conjecture seriously we need a reason, internal to gauge theory itself, to expect that a hidden gravitational — indeed stringy — structure is lurking inside it. That reason is the subject of this section, and it predates the correspondence by more than two decades. In 1974 't Hooft asked what becomes of a $\mathrm{SU}(N)$ gauge theory when the number of colors N is taken large, and discovered that the perturbative expansion does not merely simplify: it *reorganizes*. Feynman diagrams sort themselves by the topology of the two-dimensional surface they can be drawn on, and the resulting expansion in powers of $1/N$ is, term by term, identical in structure to the loop expansion of a theory of closed strings, with the string coupling identified as $g_s \sim 1/N$. No string is put in by hand; one falls out of the bookkeeping. This is

the first quantitative hint — structural, not yet a derivation of any dual — that a gauge theory secretly contains strings and therefore, since closed strings carry a graviton, gravity. We continue Yang–Mills theory from Chapter 25, viewing the carried SU(N) Yang–Mills theory through the large-N lens; this is a structural re-reading of the same theory, but a structural re-reading of the same theory.

53.1.1 Matrices, not vectors: the 't Hooft limit

The decisive observation is about how the color index sits on the fields. A quark transforms in the fundamental representation of SU(N), carrying a single color index $i = 1, \ldots, N$; it is a *vector* in color space. The gauge field, by contrast, lives in the adjoint representation, and the adjoint of SU(N) is built from one fundamental and one antifundamental index. Writing the gauge potential as a matrix in the fundamental,

$$(A_\mu)^i{}_j \;=\; A^a_\mu\,(T^a)^i{}_j, \qquad i,j = 1,\ldots,N, \tag{53.1}$$

with the Hermitian generators T^a of Chapter 25 normalized as $\mathrm{tr}(T^aT^b) = \frac{1}{2}\delta^{ab}$, exhibits the gluon as an $N \times N$ traceless Hermitian matrix at each spacetime point: it is a *matrix* in color space, carrying an upper (fundamental) and a lower (antifundamental) index. The adjoint dimension is $N^2 - 1$, which for large N is N^2 up to a $1/N^2$ correction; the missing generator is the trace part that would promote SU(N) to U(N), and we will see that the distinction between SU(N) and U(N) is itself a subleading $1/N^2$ effect. It is this matrix character — two index lines per field rather than one — that powers the entire construction. Vector (fundamental) fields, by contrast, carry a single line and, as we note at the end, are suppressed; the planar surfaces are woven out of adjoint matrices.

Taking $N \to \infty$ naively is not yet a well-posed limit, because the coupling g also appears, and the physics depends on how g is scaled as N grows. The Yang–Mills Lagrangian Eq. (25.76) carries the coupling inside the covariant derivative, $D_\mu = \partial_\mu - igA^a_\mu T^a$; the cubic and quartic gluon self-interactions then come with explicit powers of g and g^2. The running of g is governed by the one-loop beta function of Eq. (27.143), whose leading coefficient is proportional to $C_A = N$ (Chapter B). A short look at that coefficient already tells us the right scaling. The one-loop running of $\alpha_s = g^2/4\pi$ is set by $b_0 = \frac{11}{3}C_A - \frac{4}{3}T_F n_f$; with $C_A = N$ the gluonic contribution grows linearly in N, so to keep the running — and hence the dynamically generated scale Λ of Theorem 27.14 — finite and N-independent as $N \to \infty$, the combination that must be held fixed is not g^2 but g^2N. This is 't Hooft's choice.

Definition 53.1 (The 't Hooft limit and the 't Hooft coupling)**.** The *'t Hooft limit* of SU(N) (or U(N)) gauge theory is the limit

$$N \to \infty \qquad \text{with} \qquad \lambda \equiv g^2 N \;\text{ held fixed}, \tag{53.2}$$

where λ is the *'t Hooft coupling*. Equivalently $g^2 = \lambda/N \to 0$: the bare gauge coupling is sent to zero, but compensated by the growing number of colors so that the effective loop expansion parameter λ remains $O(1)$. Physical quantities are then expanded in two independent parameters: the genuine coupling λ, which controls the dynamics at fixed topology, and $1/N$, which we shall find controls the *topology* of the contributing diagrams.

The split is the whole point. In ordinary perturbation theory there is one small parameter, g, and every diagram of a given order in g is lumped together. The 't Hooft limit separates the single sum over g into a double expansion: at each fixed power of $1/N$ one must still sum infinitely many diagrams (all orders in λ), but those infinitely many diagrams share a common topology. The leading topology — the planar one — is an interacting, generally strongly-coupled theory in its own right, parametrized by λ; the subleading topologies are corrections suppressed by powers of $1/N^2$. To see this we need a bookkeeping device that makes the flow of color indices manifest.

53.1.2 Double-line notation

Because the gluon Eq. (53.1) carries two color indices, an upper i and a lower j, we draw its propagator not as a single line but as a *pair* of parallel lines — a *ribbon* — one line tracking each index. This is 't Hooft's double-line notation, and it turns the abstract contraction of color indices into a geometric statement about how ribbons join into surfaces.

The starting point is the index structure of the gluon propagator. For U(N), where the gauge field is a general (not traceless) Hermitian matrix, the generators are a complete basis of Hermitian matrices and satisfy the completeness (Fierz) relation

$$\sum_a (T^a)^i{}_j \, (T^a)^k{}_l \;=\; \tfrac{1}{2}\, \delta^i_l \, \delta^k_j , \tag{53.3}$$

so that the propagator of the matrix field inherits the index structure

$$\big\langle (A_\mu)^i{}_j \, (A_\nu)^k{}_l \big\rangle \;\propto\; \delta^i_l \, \delta^k_j . \tag{53.4}$$

The two Kronecker deltas are the content of the double line: the upper index i of the first field is identified with the lower index l of the second, and the lower index j of the first with the upper index k of the second. Pictorially, the propagator is two parallel lines carrying i and j, with the arrows arranged so that an upper (fundamental) index flows in along one line and out along the other. For SU(N) the generators are *traceless*, and the completeness relation acquires a subtraction enforcing $\operatorname{tr} A = 0$,

$$\sum_a (T^a)^i{}_j \, (T^a)^k{}_l \;=\; \tfrac{1}{2}\Big(\delta^i_l \, \delta^k_j - \tfrac{1}{N}\, \delta^i_j \, \delta^k_l \Big), \tag{53.5}$$

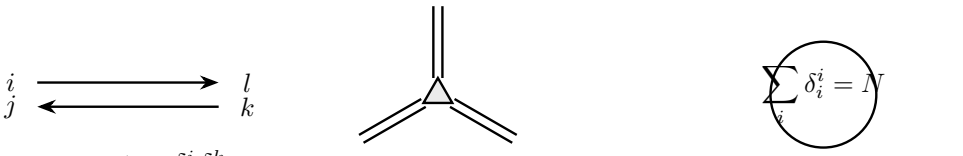

Figure 53.1: The three atoms of double-line bookkeeping. *Left:* a gluon propagator is a ribbon of two oppositely-directed index lines, carrying $\delta^i_l\delta^k_j$ as in Eq. (53.4). *Centre:* an interaction vertex joins ribbons so that index lines flow continuously through it; in the 't Hooft normalization Eq. (53.6) every vertex carries a factor N/λ. *Right:* a closed index line bounds a face of the ribbon graph and, being a free color sum $\sum_i \delta^i_i$, contributes a factor N. The power of N in any diagram is thus the number of faces.

whose extra term is explicitly down by $1/N$. The $-\frac{1}{N}\delta^i_j\delta^k_l$ piece corresponds, in ribbon language, to the gluon line pinching off into a separate single closed loop; we shall see it is suppressed by $1/N^2$ relative to the leading double-line contraction, which is precisely why the difference between $\mathrm{SU}(N)$ and $\mathrm{U}(N)$ does not matter at any fixed order of the $1/N$ expansion. From here on we use the $\mathrm{U}(N)$ rule Eq. (53.4) and restore the trace subtraction only when its (subleading) effect is the point.

The vertices join ribbons. A cubic gluon vertex $\propto g\,f^{abc}$ or, equivalently in matrix language, a term $\mathrm{tr}(A^3)$ in the action, ties three ribbons together so that each incoming index line continues without interruption into an outgoing line: color indices are conserved along the lines, never created or destroyed at a vertex. The visual rule that results is the one summarized in Fig. 53.1: a ribbon Feynman graph is an oriented surface-with-boundary built by gluing strips (propagators) at junctions (vertices), and every *closed* index line — a loop that closes on itself, bounding a region of the surface — is a free sum $\sum_i \delta^i_i = N$ over a color index. The number of such closed loops will turn out to be the number of *faces* of the surface, and it is this count that supplies the powers of N.

To make the powers of N and λ completely explicit it is cleanest to work with a model that strips the gauge theory down to its color combinatorics while keeping the matrix structure exactly. Let $\Phi(x)$ be a single Hermitian $N\times N$ matrix field — the matrix scalar — with action

$$S[\Phi] \;=\; \frac{N}{\lambda}\int \mathrm{d}^d x\;\; \mathrm{tr}\Big(\tfrac{1}{2}\,\partial_\mu\Phi\,\partial^\mu\Phi + \tfrac{1}{4}\,\Phi^4\Big), \tag{53.6}$$

in which the entire color content sits in the matrix multiplication inside the trace. This is the 't Hooft normalization: the overall N/λ in front means the coupling has been scaled out of the fields so that λ is the only genuine coupling and N counts topology. The combinatorics of Eq. (53.6) is identical to that of the gluon

sector of Yang–Mills with $\lambda = g^2 N$ — the gluon's Lorentz structure and the cubic vertex add nothing to the index bookkeeping — so every conclusion drawn from it transfers verbatim to Yang–Mills theory. Reading the Feynman rules off Eq. (53.6):

- the quadratic term has coefficient N/λ, so the *propagator* (its inverse) carries a factor λ/N together with the double-line index structure Eq. (53.4);
- each *vertex* comes from a term with the prefactor N/λ, so it carries a factor N/λ;
- each closed *index loop* carries a factor N from the free color sum.

These three rules — λ/N per edge, N/λ per vertex, N per face — are all we need.

53.1.3 Power counting: the genus expansion

We now compute the N-dependence of an arbitrary connected vacuum diagram and discover the Euler characteristic hiding inside it.

Theorem 53.2 (Topological $1/N$ expansion)**.** *Let a connected vacuum diagram of the matrix theory Eq. (53.6) (equivalently, the gluon sector of* $\mathrm{U}(N)$ *Yang–Mills at* $\lambda = g^2 N$*) have* V *vertices,* E *propagators (edges), and* F *closed index loops (faces) when drawn in double-line notation. Then its dependence on* N *and* λ *is*

$$\text{(diagram)} \;\propto\; N^{V-E+F}\,\lambda^{E-V} \;=\; N^{\chi}\,\lambda^{E-V}, \qquad \chi \equiv V - E + F. \tag{53.7}$$

The exponent χ *is the Euler characteristic of the closed orientable surface that the ribbon graph triangulates; for such a surface of genus* g *(the number of handles),*

$$\chi \;=\; 2 - 2g. \tag{53.8}$$

Consequently the connected vacuum amplitude (the free energy $W = \log Z$*) organizes as a double expansion in topology and 't Hooft coupling,*

$$W \;=\; \sum_{g=0}^{\infty} N^{\,2-2g}\, f_g(\lambda), \qquad f_g(\lambda) = \sum_{\text{genus-}g\ \text{diagrams}} \lambda^{E-V}, \tag{53.9}$$

in which each f_g *is itself a sum over infinitely many diagrams sharing the genus* g*.*

Proof. Counting powers of N *and* λ*.* Assemble the three Feynman rules of Section 53.1.2. A diagram with V vertices, E edges, and F faces carries

$$\left(\tfrac{N}{\lambda}\right)^{V}\left(\tfrac{\lambda}{N}\right)^{E} N^{F} \;=\; N^{V}\,N^{-E}\,N^{F}\,\lambda^{-V}\,\lambda^{E} \;=\; N^{V-E+F}\,\lambda^{E-V}, \tag{53.10}$$

which is the first equality of Eq. (53.7). The power of λ is $E - V$, and since for a connected diagram the number of momentum-space loops is $L = E - V + 1$, this is λ^{L-1}: f_g is an ordinary power series in λ, starting at the order set by the simplest genus-g diagram. The power of N is the integer $V - E + F$, the alternating count of vertices, edges, and faces. We must now recognize it as a topological invariant.

Why $V - E + F$ is the Euler characteristic. A ribbon graph is more than a graph: the cyclic ordering of ribbons around each vertex (fixed by the order of the matrices inside the trace at that vertex) tells us how to thicken the graph into a two-dimensional surface. Fatten every propagator into a strip and every vertex into a small disk; the strips and disks glue along their boundaries into a compact oriented surface Σ, and the closed index lines are exactly the boundary circles of the complementary regions. Capping each such boundary circle with a disk (a face) closes Σ into a closed oriented surface. This is a genuine *cell decomposition* (a polygonal tiling) of Σ: its 0-cells are the V vertices, its 1-cells are the E edges, and its 2-cells are the F faces. For any cell decomposition of a closed surface the alternating sum of the cell counts is, by definition, the Euler characteristic,

$$\chi(\Sigma) \;=\; V - E + F, \tag{53.11}$$

and this number is a topological invariant: it is independent of the particular decomposition and depends only on Σ. (That Eq. (53.11) is decomposition-independent is the elementary content of the Euler–Poincaré theorem; one checks invariance under the two moves that relate any two cell decompositions — subdividing an edge, which adds one vertex and one edge and leaves $V - E + F$ fixed, and adding an edge across a face, which adds one edge and one face and again leaves $V - E + F$ fixed. Any two decompositions are connected by such moves, so the alternating sum is the same for all of them.) For a closed orientable surface the classification of surfaces identifies Σ by its genus g alone, and the Euler characteristic of the genus-g surface is $\chi = 2 - 2g$: the sphere ($g = 0$) has $\chi = 2$, the torus ($g = 1$) has $\chi = 0$, and each additional handle lowers χ by 2. This is Eq. (53.8).

Assembling the expansion. Substituting $\chi = 2 - 2g$ into Eq. (53.7), every diagram of genus g scales as N^{2-2g} times a power of λ. Grouping the connected vacuum diagrams by genus and summing the λ-powers within each genus gives Eq. (53.9). The leading term, $g = 0$, is N^2; the first correction, $g = 1$, is N^0; and the expansion proceeds in steps of N^{-2}. □

Three features of Theorem 53.2 deserve to be drawn out at once. First, the expansion parameter for the topology is $1/N^2$, not $1/N$: orientable closed surfaces have even Euler-characteristic deficit, so consecutive terms differ by two powers of N. (Were the gauge group orthogonal or symplectic rather than unitary, non-orientable surfaces would also contribute and the expansion would

proceed in $1/N$; for $\mathrm{SU}(N)/\mathrm{U}(N)$ it is strictly $1/N^2$.) Second, the leading term scales as N^2, exactly the number of gluon degrees of freedom $\sim N^2$ — the free energy is extensive in the colored degrees of freedom, as it must be. Third, and most important, *the leading contribution comes from the diagrams that can be drawn on a sphere without any line crossing another*: the planar diagrams. We turn to them.

53.1.4 Planar dominance, and a worked count

A diagram is *planar* if its double-line graph can be drawn on the plane (equivalently the sphere) with no two ribbons crossing. By Eq. (53.8) planar diagrams have $g = 0$, $\chi = 2$, and weight N^2; any diagram that genuinely requires a crossing lives on a surface of higher genus and is suppressed. The cleanest way to feel the mechanism is to take a single diagram and watch the face count — and hence the power of N — collapse when a crossing is introduced.

Worked Example 53.3 (Planar versus crossed: a two-loop count, suppressed by exactly $1/N^2$)**.** Consider the lowest-order vacuum correction in the quartic matrix model Eq. (53.6): a single quartic vertex with its four legs Wick-contracted in pairs. This is a two-loop diagram ($V = 1$, $E = 2$, so $L = E - V + 1 = 2$), and it is the perfect laboratory because the only freedom is *how* the four legs are paired, with one pairing planar and one crossed.

Write the quartic interaction with its color indices displayed. The trace $\mathrm{tr}(\Phi^4)$ is a single cyclic chain,

$$\mathrm{tr}(\Phi^4) = \Phi^{i_1}{}_{i_2}\,\Phi^{i_2}{}_{i_3}\,\Phi^{i_3}{}_{i_4}\,\Phi^{i_4}{}_{i_1}, \tag{53.12}$$

so the four legs A, B, C, D carry index pairs (i_1, i_2), (i_2, i_3), (i_3, i_4), (i_4, i_1) respectively, with each shared index (i_2, i_3, i_4, i_1) already sewing consecutive legs together around the vertex. We contract the four legs into two propagators, each propagator enforcing the double-line rule Eq. (53.4), $\langle \Phi^a{}_b\, \Phi^c{}_d \rangle \propto \delta^a_d\, \delta^c_b$.

Pairing 1 (planar): A with B, C with D.

$$\langle \Phi^{i_1}{}_{i_2}\, \Phi^{i_2}{}_{i_3} \rangle \propto \delta^{i_1}_{i_3}\, \delta^{i_2}_{i_2} = N\, \delta^{i_1}_{i_3}, \tag{53.13}$$

$$\langle \Phi^{i_3}{}_{i_4}\, \Phi^{i_4}{}_{i_1} \rangle \propto \delta^{i_3}_{i_1}\, \delta^{i_4}_{i_4} = N\, \delta^{i_3}_{i_1}. \tag{53.14}$$

The two contractions produce two explicit factors of N from the self-closing index loops ($\delta^{i_2}_{i_2} = \delta^{i_4}_{i_4} = N$), and the leftover deltas multiply to $\delta^{i_1}_{i_3}\delta^{i_3}_{i_1} = \delta^{i_1}_{i_1} = N$, a third factor. Hence $F = 3$ closed index loops and a color factor N^3. (The other planar pairing, A with D and B with C, gives the same N^3 by the identical count.) Folding in the Feynman-rule prefactors $(N/\lambda)^V (\lambda/N)^E = (N/\lambda)(\lambda/N)^2 = \lambda/N$, the diagram scales as

$$\frac{\lambda}{N} \cdot N^3 = N^2\, \lambda, \tag{53.15}$$

in agreement with $N^{\chi}\lambda^{E-V}$ at $\chi = V - E + F = 1 - 2 + 3 = 2$ (genus 0).

Pairing 2 (crossed): A with C, B with D.

$$\langle \Phi^{i_1}{}_{i_2}\, \Phi^{i_3}{}_{i_4} \rangle \propto \delta^{i_1}_{i_4}\, \delta^{i_3}_{i_2}, \tag{53.16}$$

$$\langle \Phi^{i_2}{}_{i_3}\, \Phi^{i_4}{}_{i_1} \rangle \propto \delta^{i_2}_{i_1}\, \delta^{i_4}_{i_3}. \tag{53.17}$$

Now *no* self-closing δ^i_i appears at the contraction step; instead the four deltas chain into a single cycle. Summing over all four colors,

$$\sum_{i_1,i_2,i_3,i_4} \delta^{i_1}_{i_4}\, \delta^{i_4}_{i_3}\, \delta^{i_3}_{i_2}\, \delta^{i_2}_{i_1} = \sum_{i_1} \delta^{i_1}_{i_1} = N, \tag{53.18}$$

so there is just $F = 1$ closed index loop and a color factor N^1. With the same prefactor λ/N the crossed diagram scales as

$$\frac{\lambda}{N} \cdot N^1 = N^0\, \lambda, \tag{53.19}$$

matching $N^{\chi}\lambda^{E-V}$ at $\chi = 1 - 2 + 1 = 0$ (genus 1, the torus). Comparing Eqs. (53.15) and (53.19), the crossed diagram is suppressed relative to the planar one by exactly

$$\frac{N^0\lambda}{N^2\lambda} = \frac{1}{N^2}, \tag{53.20}$$

one factor of $1/N^2$, precisely the cost of the single handle that the crossing forces. The crossing is unavoidable for pairing 2: drawing the ribbons in the plane, the strip from A to C must pass over the strip from B to D, and that overpass is the handle of the torus. Figure 53.2 shows the two ribbon graphs with their faces, making the loss of two index loops visible.

This single example contains the entire mechanism. A crossing in the double-line graph cannot be undone in the plane; it can only be accommodated by routing one ribbon through a handle, and each handle removes two index loops, each loop being a factor N. The planar diagrams, which need no handle, dominate; the non-planar ones are organized into a tower suppressed by powers of $1/N^2$, one power per handle. The same arithmetic explains the earlier claim that the $\mathrm{SU}(N)$ trace subtraction in Eq. (53.5) is negligible: the $-\frac{1}{N}\delta^i_j\delta^k_l$ term pinches one double line into a structure with one fewer index loop, costing a relative $1/N^2$ exactly as a crossing does, so it never affects the leading planar result.

Physical Insight

Planarity is the large-N analogue of a saddle point. In an ordinary path integral the classical limit $\hbar \to 0$ is dominated by stationary configurations; here $1/N$ plays the role of $\hbar$, and the "configurations" are diagram topologies. At $N = \infty$ only the genus-zero (planar) sector survives, and it

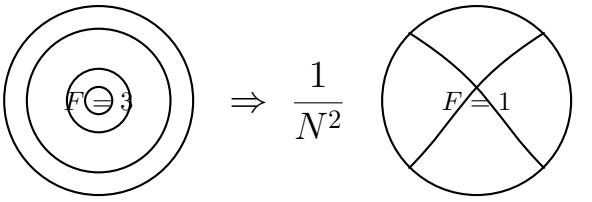

Figure 53.2: The single quartic vertex of Theorem 53.3, drawn in double-line notation. *Left:* the planar pairing closes three independent index loops (three faces), giving N^3 from the color sums and, with the λ/N prefactor, a value $N^2\lambda$; the ribbon graph tiles the sphere ($\chi = 2$). *Right:* the crossed pairing forces the two ribbons to overpass, which merges the loops into a single index line (one face), giving N^1 and a value $N^0\lambda$; the graph now tiles the torus ($\chi = 0$). The crossing costs exactly $1/N^2$ — the price of one handle.

is a self-contained, λ-dependent theory — still interacting, still in general strongly coupled, but topologically simple. Summing the planar diagrams is the central problem of large-N gauge theory; it has been solved in special cases (notably matrix-model integrals and two-dimensional Yang–Mills) and remains the goal in four dimensions. The $1/N$ corrections then dress this leading planar theory handle by handle.

53.1.5 The string in disguise: $g_s \sim 1/N$

The form of Eq. (53.9) is not merely reminiscent of, but structurally identical to, a quantity the reader will meet whenever closed strings are quantized. A closed string sweeps out a two-dimensional worldsheet as it propagates, and its perturbative amplitudes are computed by summing over all worldsheet topologies. The interaction — one string splitting into two, or two joining into one — adds a handle to the worldsheet, and each such interaction is weighted by a coupling constant g_s, the closed-string coupling. A worldsheet of genus g has $2g-2$ more handles-worth of interactions than the sphere, and carries a relative weight g_s^{2g-2}. Hence any closed-string observable expands as

$$\mathcal{A}_{\text{string}} \;=\; \sum_{g=0}^{\infty} g_s^{2g-2}\, \mathcal{F}_g, \tag{53.21}$$

a sum over worldsheet genus with the genus-g term weighted by g_s^{2g-2}.

Set Eq. (53.21) beside the gauge-theory result Eq. (53.9), $W = \sum_g N^{2-2g} f_g(\lambda) = \sum_g (N^{-1})^{2g-2} f_g(\lambda)$. The two expansions have the *same* dependence on genus:

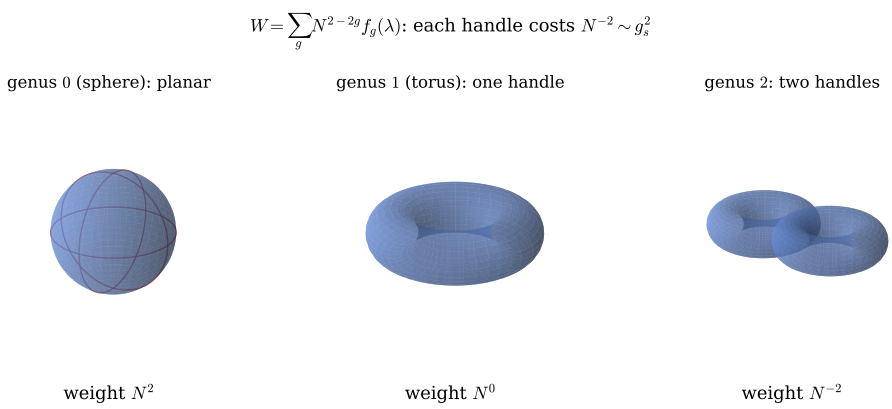

Figure 53.3: The genus expansion Eq. (53.9) drawn as a sum over closed orientable surfaces, the surfaces swept out by the ribbon graphs. Genus 0 (the sphere, planar diagrams) carries weight N^2; each additional handle multiplies the weight by N^{-2}, exactly as each closed-string loop multiplies a string amplitude by g_s^2 in Eq. (53.21). The matching of the two weightings fixes $g_s \sim 1/N$. The faint curves on the sphere indicate that the surface is *built from* the double-line Feynman graph — a triangulated worldsheet — rather than postulated separately. (The genus-two panel is schematic.)

term for term, the gauge theory's N^{2-2g} matches the string's g_s^{2g-2} under the identification

$$\boxed{g_s \sim \frac{1}{N}} \tag{53.22}$$

This is the punchline. The $1/N$ expansion of a SU(N) gauge theory is a closed-string loop expansion in disguise, with the string coupling set by the inverse number of colors. The discrete object that the gauge theory sums — the ribbon Feynman graph — *is* a triangulated worldsheet: the propagators and vertices of the gauge theory tile the very surface over which the string sums, with the 't Hooft coupling λ controlling the fineness and weighting of the triangulation (the "area"), and $1/N$ controlling its topology. Figure 53.3 displays the first three surfaces with their weights.

The structural consequences are immediate and are 't Hooft's heuristic. Weak string coupling, $g_s \ll 1$, is the same statement as large N. So a gauge theory with very many colors should be described by a *weakly coupled* string theory, whatever that string theory turns out to be — the regime in which string perturbation theory, the sum Eq. (53.21), is reliable. The 't Hooft coupling λ remains free and parametrizes the dynamics on the worldsheet: small λ is the familiar weakly-coupled gauge theory (a coarse, nearly degenerate triangulation), while large λ is the strongly-coupled gauge theory, where one expects the worldsheet description to become smooth — a continuous string moving in some target geometry.

A confining or conformal large-N gauge theory should therefore be dual to a weakly-coupled string theory; and because the closed-string spectrum always contains a massless spin-two state — a graviton — that dual string theory is a theory of gravity. What the bookkeeping does *not* tell us is which string theory, propagating in which target space and how many dimensions. That gap is exactly what the next section fills.

Historical Note

't Hooft introduced the $1/N$ expansion and double-line notation in 1974, motivated by the hope of an analytic handle on quark confinement: if the planar sector could be summed, the leading large-N theory might be solved and confinement understood. The planar sum in four dimensions has never been carried out, but the topological reorganization itself — diagrams sorted by the genus of an emergent surface, with $1/N$ as a closed-string coupling — proved to be the durable insight. For more than two decades it remained a suggestive analogy without a concrete dual; the surface was visible but the target space of the string was unknown. Maldacena's 1997 identification of that target space, for a specific maximally supersymmetric gauge theory, turned the analogy into the correspondence this chapter develops.

53.1.6 Factorization and the master field

The same Euler-characteristic counting that organized the vacuum energy also controls correlation functions of gauge-invariant operators, and it delivers a second structural fact: at large N the theory behaves *classically*, in a precise sense. The natural gauge-invariant observables built from a single matrix field are the *single-trace operators*, $\mathcal{O}_k(x) = \mathrm{tr}\,(\Phi(x)^k)$ (in Yang–Mills, gauge-invariant single traces of field strengths and covariant derivatives). Inserting such an operator into a diagram is, in ribbon language, like adding a vertex with k legs that carries one extra index loop; equivalently, it bounds a hole in the surface. A correlator of n single-trace operators thus corresponds to a surface with n boundaries, one per insertion, and the Euler characteristic of a genus-g surface with n boundaries is $\chi = 2 - 2g - n$. The leading (planar, $g = 0$) connected contribution therefore scales as

$$\langle \mathcal{O}_1 \cdots \mathcal{O}_n \rangle_{\mathrm{conn}} \;\sim\; N^{\chi}\big|_{g=0} = N^{\,2-n}. \tag{53.23}$$

We verify Eq. (53.23) on the cases $n = 1$ and $n = 2$ by direct color counting, which also exposes the factorization that follows.

Worked Example 53.4 (Large-N factorization of single-trace operators)**.** Take the quadratic single-trace operator $\mathcal{O}(x) = \mathrm{tr}\,(\Phi(x)^2) = \Phi^i{}_j(x)\,\Phi^j{}_i(x)$ in the free

($\lambda \to 0$) theory, where the propagator is $\langle \Phi^i{}_j(x)\, \Phi^k{}_l(y)\rangle = \frac{\lambda}{N}\, \delta^i_l\, \delta^k_j\, D(x-y)$ with D the ordinary scalar propagator; the interacting case only dresses the spacetime dependence and changes nothing in the color counting.

One-point function ($n = 1$). Contracting the two fields within the single trace,

$$\big\langle \operatorname{tr} \Phi^2(x)\big\rangle = \big\langle \Phi^i{}_j \Phi^j{}_i\big\rangle = \frac{\lambda}{N}\, \delta^i_i\, \delta^j_j\, D(0) = \frac{\lambda}{N}\, N^2\, D(0) = N\, \lambda\, D(0) \sim N, \quad (53.24)$$

confirming $N^{2-n} = N^1$ for $n = 1$.

Two-point function ($n = 2$), connected. For $\langle \operatorname{tr} \Phi^2(x)\ \operatorname{tr} \Phi^2(y)\rangle_{\text{conn}}$ the two fields at x must each contract with a field at y. One of the two such contractions gives

$$\begin{aligned} \big\langle \Phi^i{}_j(x) \Phi^j{}_i(x)\, \Phi^k{}_l(y) \Phi^l{}_k(y)\big\rangle_{\text{conn}} &= \Big(\tfrac{\lambda}{N}\Big)^2 D(x-y)^2\, (\delta^i_l \delta^k_j)\, (\delta^j_k \delta^l_i) \\ &= \Big(\tfrac{\lambda}{N}\Big)^2 D(x-y)^2\, (\delta^i_l \delta^l_i)\, (\delta^k_j \delta^j_k) \\ &= \Big(\tfrac{\lambda}{N}\Big)^2 N^2\, D(x-y)^2 = \lambda^2\, D(x-y)^2 \sim N^0, \end{aligned} \quad (53.25)$$

and the second contraction contributes at the same order. Thus the connected two-point function is $O(N^0)$, confirming $N^{2-n} = N^0$ for $n = 2$.

Factorization. The full (not connected) two-point function is the connected part plus the disconnected product of one-point functions:

$$\big\langle \mathcal{O}(x)\, \mathcal{O}(y)\big\rangle = \underbrace{\big\langle \mathcal{O}(x)\big\rangle \big\langle \mathcal{O}(y)\big\rangle}_{\sim N \cdot N = N^2} + \underbrace{\big\langle \mathcal{O}(x)\, \mathcal{O}(y)\big\rangle_{\text{conn}}}_{\sim N^0}. \quad (53.26)$$

The disconnected piece, $O(N^2)$, dominates the connected piece, $O(N^0)$, by exactly N^2. Hence the normalized fluctuation obeys

$$\frac{\langle \mathcal{O}\, \mathcal{O}\rangle - \langle \mathcal{O}\rangle \langle \mathcal{O}\rangle}{\langle \mathcal{O}\rangle \langle \mathcal{O}\rangle} = O\Big(\frac{1}{N^2}\Big), \quad (53.27)$$

so correlation functions of gauge-invariant operators *factorize* into products of expectation values as $N \to \infty$, with relative corrections of order $1/N^2$.

Factorization Eq. (53.26) is the hallmark of a *classical* theory. In quantum mechanics $\langle \mathcal{O}^2\rangle = \langle \mathcal{O}\rangle^2$ holds precisely when the operator has no fluctuations — when it takes a definite value in the state. Equation Eq. (53.27) says that, at $N = \infty$, every gauge-invariant single-trace operator has vanishing relative variance: it behaves like a classical c-number, not a fluctuating quantum observable. The path integral is then dominated by a single configuration, the same way a classical limit is dominated by a saddle, and that dominant configuration is called the

master field: a single (in general highly nontrivial) field configuration on which all gauge-invariant operators take their factorized expectation values. The $1/N$ corrections are the quantum fluctuations about the master field, organized — as Theorem 53.2 guarantees — by surface topology.

Physical Insight

The master-field picture is the gauge-theory shadow of classical gravity. If the large-N gauge theory is a weakly-coupled string theory, then its $N = \infty$ limit ($g_s \to 0$) is *classical* string theory, and at strong 't Hooft coupling — where the worldsheet is smooth and only its lowest, gravitational, modes survive — classical string theory degenerates to classical (super)gravity. The statement that gauge-invariant operators do not fluctuate at $N = \infty$ is the field-theory counterpart of the statement that the dual geometry is a definite classical spacetime, not a fluctuating quantum one. Large N is what makes the gravitational dual *classical*; large 't Hooft coupling λ is what makes it well described by *(super)gravity* rather than by the full string. Both limits will reappear, sharpened into a dictionary, once the dual geometry is identified.

We have arrived at a definite structural conclusion without having built a single string. The perturbative expansion of a large-N SU(N) gauge theory is, term by term in $1/N$, a sum over the topologies of a two-dimensional surface, weighted exactly as the closed-string loop expansion is weighted, with $g_s \sim 1/N$; its gauge-invariant observables factorize, signaling that the $N = \infty$ theory is classical and dominated by a master field. The gauge theory therefore looks, from the outside, like a closed-string theory — and hence a theory of gravity — but the analysis leaves the worldsheet dynamics and, crucially, the *target geometry* in which that string propagates completely unspecified. The next section supplies the missing geometry: it takes a particular gauge theory whose string dual can be argued for concretely, follows a decoupling limit in which the dual spacetime can actually be read off, and so converts the disguise exposed here into the explicit conjecture that organizes the rest of the chapter.

53.2 The Maldacena Argument, Scoped Honestly

The previous section delivered a structural verdict but no address. The 't Hooft expansion (Section 53.1) reorganized the perturbation series of an SU(N) gauge theory into a sum over the genus of the diagram's fattened ribbon surface, with each handle weighted by $1/N^2$ and the loop coupling carried by the fixed 't Hooft combination $\lambda = g^2 N$. That is, term by term, the bookkeeping of a closed-string loop expansion: a sum over worldsheet topologies with string coupling $g_s \sim 1/N$. The conclusion was that some gauge theories *are* string theories in disguise. What

that argument could not supply was the disguise itself — *which* gauge theory, and a string theory propagating in *which* spacetime. This section supplies both, by following Maldacena's original route: place a stack of branes in flat space, describe the same physical object in two complementary low-energy languages, and take a limit in which each language sharpens into a self-contained theory. The two self-contained theories are then descriptions of one system, hence equal. One language is a definite gauge theory; the other is gravity in a definite curved geometry.

Because this book does not develop string theory from the worldsheet, a handful of inputs in what follows — that a stack of D3-branes carries a particular low-energy gauge theory on its worldvolume, that the same stack sources a particular supergravity solution, and the numerical map between brane data and geometric data — are *quoted* from string theory. Everything that follows from those inputs by field-theoretic and differential-geometric methods — above all the claim that the geometry close to the branes is exactly $\mathrm{AdS}_5 \times S^5$, and the claim that the resulting gauge theory is an exact conformal field theory carrying the right symmetry group — is derived here in full. We close the section with a summary table separating what is derived, what is imported from string theory, and what is conjectured.

53.2.1 Two descriptions of a stack of branes

The object of study is a stack of N coincident *D3-branes* in the ten-dimensional spacetime of type IIB string theory. A Dp-brane is a $(p+1)$-dimensional hypersurface — here $p = 3$, so a 3+1-dimensional worldvolume sitting inside 9+1 dimensions — on which open strings can end, and which itself gravitates and carries charge. We will not need the worldsheet definition; we need only two facts about what the stack *looks like* at energies far below the string scale $1/\sqrt{\alpha'}$, where α' (of dimension length^2) sets the string length $\ell_s = \sqrt{\alpha'}$. The two facts are two ways of cataloguing the low-energy excitations, and they are not obviously the same.

Description A: open strings, or the worldvolume gauge theory. The first description is from the point of view of the open strings whose endpoints are pinned to the branes. The massless modes of an open string stretched between brane a and brane b (with $a, b \in \{1, \dots, N\}$) furnish, in the low-energy limit, a U(1) gauge field for $a = b$ and charged matter for $a \neq b$; when the N branes coincide the N^2 string sectors assemble into the adjoint of U(N), and the overall U(1) (the center-of-mass mode that decouples from the dynamics) is discarded, leaving an SU(N) gauge theory. For the specific case of D3-branes in type IIB, the precise low-energy worldvolume theory is the maximally supersymmetric Yang–Mills theory in four dimensions: $\mathcal{N} = 4$ SU(N) super Yang–Mills (SYM), with field content exactly the massless $\mathcal{N} = 4$ vector multiplet classified in

Section 44.4.2 — one gauge field A_μ, four Weyl fermions, and six real scalars, all in the adjoint of SU(N). Its single dimensionless coupling g is set by the string coupling,

$$g^2 \;=\; 4\pi g_s, \tag{53.28}$$

a relation we will need below and quote here; the α'-corrections to this worldvolume action are an expansion in α' times momenta, so at energies E with $\alpha' E^2 \to 0$ only the renormalizable $\mathcal{N}=4$ SYM Lagrangian survives. In this description, then, the low-energy physics on the branes is: *$\mathcal{N}=4$ SYM, plus free type IIB supergravity in the flat ten-dimensional bulk away from the branes, plus interactions between the two that are controlled by Newton's constant and switch off in the low-energy limit.*

Description B: closed strings, or the supergravity geometry. The second description is from the point of view of the closed strings, that is, of gravity. The brane stack is a heavy, charged source; it curves the spacetime around it and sources the Ramond–Ramond four-form potential that D3-branes are electrically charged under. The corresponding solution of type IIB supergravity, the extremal black 3-brane, is known in closed form. Writing the ten coordinates as the four worldvolume directions $x^\mu = (t, x^1, x^2, x^3)$ along the branes and six transverse directions with radial coordinate $r = \sqrt{\sum_{i=1}^{6} (x_\perp^i)^2}$ and unit five-sphere $\mathrm{d}\Omega_5^2$, the metric is

$$\mathrm{d}s^2 \;=\; H(r)^{-1/2}\,\eta_{\mu\nu}\,\mathrm{d}x^\mu \mathrm{d}x^\nu \;-\; H(r)^{1/2}(\mathrm{d}r^2 + r^2\,\mathrm{d}\Omega_5^2), \qquad H(r) \;=\; 1 + \frac{L^4}{r^4}, \tag{53.29}$$

written in the mostly-minus signature of this book (Chapter 3): the worldvolume metric $\eta_{\mu\nu} = \mathrm{diag}(+,-,-,-)$ carries the single timelike direction, and the six transverse directions are spacelike, hence the overall minus on the transverse block. The dilaton is constant and the self-dual five-form flux threads the sphere. The single length scale L in the harmonic function H is fixed by the number of branes and the string data through

$$L^4 \;=\; 4\pi g_s N\,\alpha'^2. \tag{53.30}$$

Two features of Eq. (53.29) are worth naming before we use it. First, H is harmonic in the six transverse dimensions away from the source: $\nabla_6^2\, r^{-4} \propto \delta^{(6)}(x_\perp)$, the six-dimensional analogue of the Coulomb potential, so $H = 1 + L^4/r^4$ is the brane's gravitational "Coulomb field," with the 1 enforcing asymptotic flatness as $r \to \infty$ and the L^4/r^4 the deformation built up by the source. Second, the prefactor $H^{-1/2}$ multiplying $\mathrm{d}t^2$ is a gravitational redshift factor: a local excitation of proper energy E_{loc} sitting at radius r is seen by an observer at infinity to have energy

$$E_\infty \;=\; H(r)^{-1/4}\,E_{\mathrm{loc}}, \tag{53.31}$$

since the conserved energy conjugate to the asymptotic time t is the locally-measured energy times $\sqrt{g_{tt}} = H^{-1/4}$. Deep in the throat, $r \ll L$, the factor $H^{-1/4} \approx (r/L) \to 0$: an excitation of fixed proper energy is redshifted to arbitrarily low energy as measured from infinity. We will use this in the decoupling argument.

In this second description the low-energy physics is: *closed-string excitations propagating in the geometry Eq. (53.29).* At low energy as seen from infinity, two kinds of excitation survive, and they are spatially separated. Far out ($r \to \infty$) the metric is flat and the surviving modes are the long-wavelength quanta of free ten-dimensional supergravity. Deep in the throat ($r \ll L$) any excitation, however energetic locally, is redshifted by Eq. (53.31) to low energy at infinity, so the *entire* dynamics of the throat region survives the low-energy limit. The two regions communicate only through the intermediate region $r \sim L$, and that communication is weak at low energy, as we now make quantitative.

The two descriptions, A and B, are two complete accounts of the same brane stack. Each contains a piece of free bulk supergravity in an asymptotically flat region, decoupling at low energy. If we can argue that what remains after stripping that common piece is, in each description, a self-contained theory, then those two remainders are descriptions of the same physics and must be identified. In Description A the remainder is $\mathcal{N} = 4$ SYM. In Description B the remainder is whatever closed-string theory lives in the throat. The content of the correspondence is the equality of these two remainders; the content of the *derivation* is (i) that the throat geometry is $\mathrm{AdS}_5 \times S^5$, which we prove, and (ii) that the two decouplings are clean, which we argue.

53.2.2 The near-horizon limit: the throat is $\mathrm{AdS}_5 \times S^5$

The single piece of this section that is pure, mathematics — no string input beyond the quoted metric Eq. (53.29) — is the identification of the near-horizon geometry. The throat region is $r \ll L$, where the harmonic function loses its asymptotic 1:

$$r \ll L: \qquad H(r) \;=\; 1 + \frac{L^4}{r^4} \;\longrightarrow\; \frac{L^4}{r^4}. \tag{53.32}$$

We substitute this into Eq. (53.29) and reduce the result by metric algebra. The claim is that what emerges is the product of five-dimensional anti-de Sitter space of radius L with a round five-sphere of radius L. We carry out the reduction in full.

Worked Example 53.5 (Near-horizon reduction of the black 3-brane)**.** Insert $H \to L^4/r^4$ into the metric Eq. (53.29). The two prefactors become

$$H^{-1/2} \;\to\; \Big(\frac{L^4}{r^4}\Big)^{-1/2} = \frac{r^2}{L^2}, \qquad H^{1/2} \;\to\; \Big(\frac{L^4}{r^4}\Big)^{1/2} = \frac{L^2}{r^2}, \tag{53.33}$$

so the line element becomes

$$\mathrm{d}s^2 \;=\; \frac{r^2}{L^2}\,\eta_{\mu\nu}\,\mathrm{d}x^\mu \mathrm{d}x^\nu \;-\; \frac{L^2}{r^2}\,\mathrm{d}r^2 \;-\; \frac{L^2}{r^2}\,r^2\,\mathrm{d}\Omega_5^2. \tag{53.34}$$

The last term simplifies immediately: $\frac{L^2}{r^2}\,r^2 = L^2$, so

$$-\,\frac{L^2}{r^2}\,r^2\,\mathrm{d}\Omega_5^2 \;=\; -\,L^2\,\mathrm{d}\Omega_5^2, \tag{53.35}$$

which is a round five-sphere of radius L (the overall minus is the mostly-minus signature's marking of these five directions as spacelike, and crucially the radius is now r-independent: the sphere does not shrink down the throat). The remaining five-dimensional block,

$$\mathrm{d}s^2_{(5)} \;=\; \frac{r^2}{L^2}\,\eta_{\mu\nu}\,\mathrm{d}x^\mu \mathrm{d}x^\nu \;-\; \frac{L^2}{r^2}\,\mathrm{d}r^2, \tag{53.36}$$

is the one we must recognize. Change the radial variable to

$$z \;=\; \frac{L^2}{r} \qquad\Longleftrightarrow\qquad r = \frac{L^2}{z}, \qquad \mathrm{d}r \;=\; -\,\frac{L^2}{z^2}\,\mathrm{d}z, \qquad \mathrm{d}r^2 \;=\; \frac{L^4}{z^4}\,\mathrm{d}z^2. \tag{53.37}$$

The two coefficients transform as

$$\frac{r^2}{L^2} = \frac{1}{L^2}\,\frac{L^4}{z^2} = \frac{L^2}{z^2}, \qquad \frac{L^2}{r^2}\,\mathrm{d}r^2 = \frac{L^2}{(L^2/z)^2}\cdot\frac{L^4}{z^4}\,\mathrm{d}z^2 = \frac{z^2}{L^2}\cdot\frac{L^4}{z^4}\,\mathrm{d}z^2 = \frac{L^2}{z^2}\,\mathrm{d}z^2, \tag{53.38}$$

so both the worldvolume term and the radial term acquire the *same* overall conformal factor L^2/z^2, and Eq. (53.36) collapses to

$$\mathrm{d}s^2_{(5)} \;=\; \frac{L^2}{z^2}\Big(\eta_{\mu\nu}\,\mathrm{d}x^\mu \mathrm{d}x^\nu - \mathrm{d}z^2\Big). \tag{53.39}$$

This is exactly the Poincaré-patch form of five-dimensional anti-de Sitter space AdS_5 of radius L — a single conformal factor L^2/z^2 multiplying a flat five-dimensional Minkowski metric in coordinates (x^μ, z), with the conformal boundary at $z \to 0$ (i.e. $r \to \infty$). Assembling Eq. (53.35) and Eq. (53.39), the full near-horizon geometry is

$$\boxed{\mathrm{d}s^2 \;=\; \frac{L^2}{z^2}\Big(\eta_{\mu\nu}\,\mathrm{d}x^\mu \mathrm{d}x^\nu - \mathrm{d}z^2\Big) \;-\; L^2\,\mathrm{d}\Omega_5^2 \;=\; \mathrm{AdS}_5 \times S^5,} \tag{53.40}$$

with the two factors sharing a single radius L. No string input entered the reduction; only the quoted metric Eq. (53.29) and algebra.

The geometric picture this produces is the one in Fig. 53.4: the brane stack drills an infinite throat into flat space, the throat has the cross-sectional

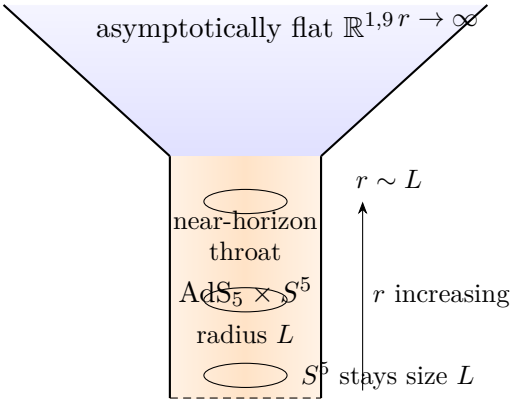

Figure 53.4: The geometry sourced by a stack of N D3-branes, Eq. (53.29). Far away ($r \to \infty$) the harmonic function $H \to 1$ and spacetime is flat. Near the branes ($r \ll L$) the throat opens out; the metric algebra of Theorem 53.5 shows it is exactly $AdS_5 \times S^5$ with both factors of radius L, the five-sphere stabilizing rather than pinching off. The two descriptions of Section 53.2.1 decouple from the common asymptotic region: $\mathcal{N} = 4$ SYM (Description A) is identified with closed strings in the throat (Description B).

geometry of a five-sphere whose radius stabilizes at L rather than pinching off, and the throat's longitudinal-plus-radial geometry is AdS_5. That the sphere does *not* pinch is the crucial difference between the extremal 3-brane and, say, the Schwarzschild solution: it is what makes the near-horizon region an honest spacetime of its own with an infinite proper depth, capable of hosting a complete decoupled theory.

53.2.3 The decoupling limit

We now isolate, in each description, a self-contained low-energy theory by taking the limit Maldacena identified. The limit is

$$\alpha' \to 0, \qquad \text{with} \quad g_s \text{ fixed}, \quad N \text{ fixed}, \quad \text{and} \quad \frac{r}{\alpha'} \equiv U \text{ fixed}, \tag{53.41}$$

so that $\lambda = g^2 N = 4\pi g_s N$ is held fixed (by Eq. (53.28)) while the string length $\ell_s = \sqrt{\alpha'} \to 0$ sends the string scale to infinity, decoupling all massive string modes. The fixed combination $U = r/\alpha'$ has dimensions of energy and measures, holding fixed, the proper energy of a stretched string in the throat; keeping it fixed is the statement that we track finite-energy excitations as the cutoff is removed. We examine each description in turn.

Description A in the limit. The worldvolume side contains $\mathcal{N} = 4$ SYM, free bulk supergravity, and their mutual couplings. The interaction between the

brane modes and the bulk gravitons is controlled by the ten-dimensional Newton constant, $16\pi G_{10} = (2\pi)^7 g_s^2 \alpha'^4$, which carries four powers of α'; as $\alpha' \to 0$ the dimensionful gravitational coupling vanishes and the bulk gravitons *decouple* from the worldvolume fields. What survives, cleanly, is free supergravity in the asymptotically flat bulk plus an isolated, interacting $\mathcal{N} = 4$ SYM with coupling $g^2 = 4\pi g_s$ on the branes. The SYM coupling is dimensionless and untouched by $\alpha' \to 0$, so the gauge theory is not trivialized; only its gravitational umbilical cord to the bulk is cut.

Description B in the limit. The geometry side contains closed strings propagating in Eq. (53.29). At low energy as seen from infinity, the surviving excitations split, as already noted, into two decoupling sets: long-wavelength gravitons in the flat asymptotic region, and the full throat dynamics, which survives because the redshift Eq. (53.31) maps the throat's entire finite-proper-energy spectrum down to arbitrarily low energy at infinity. The cross-coupling between throat and asymptotic region is suppressed at low energy: the absorption cross-section of a throat by an asymptotic graviton scales as a positive power of its frequency and vanishes in the limit, because the throat subtends a vanishing solid angle at the wavelengths that survive. So Description B also resolves into two decoupled pieces: free supergravity in the asymptotically flat bulk, plus the complete theory of closed strings in the near-horizon region. By Theorem 53.5, that near-horizon region is $\mathrm{AdS}_5 \times S^5$, and the limit Eq. (53.41) keeps its curvature radius L and its full string dynamics — in the throat the natural coordinate is $U = r/\alpha'$, and the throat metric written in U retains $L^4/\alpha'^2 = 4\pi g_s N = \lambda$ finite, so the geometry survives intact with finite curvature in string units.

Matching the remainders. Both descriptions are descriptions of one and the same brane system, and in the limit Eq. (53.41) both factor into

$$(\text{free supergravity in flat } \mathbb{R}^{1,9}) \ \oplus \ (\text{a nontrivial interacting theory}),$$

with the first summand manifestly identical on the two sides (it is the same asymptotic bulk in the same flat space). Subtracting the common free-supergravity sector, the nontrivial remainders must be equal. The remainder of Description A is $\mathcal{N} = 4$ SU(N) SYM. The remainder of Description B is type IIB string theory on $\mathrm{AdS}_5 \times S^5$. Therefore — this is the argument's payload —

$$\mathcal{N} = 4 \,\mathrm{SU}(N) \text{ SYM in 3+1 dimensions} \quad \equiv \quad \text{type IIB string theory on } \mathrm{AdS}_5 \times S^5. \tag{53.42}$$

This is the AdS/CFT correspondence in its original incarnation. We pause to underline what kind of statement it is. The decoupling of the two sectors on each side, and the metric reduction to $\mathrm{AdS}_5 \times S^5$, are controlled steps. The identification Eq. (53.42) of the two *remainders* relies on the premise that the

two low-energy descriptions are descriptions of the same object — a premise about string theory, not a theorem we can prove with the tools of this book. It is therefore a *conjecture*, stated precisely below, with overwhelming evidence but no proof.

53.2.4 The conjecture and the parameter dictionary

Conjecture 53.6 (Maldacena / AdS/CFT, the $\mathrm{AdS}_5 \times S^5$ case)**.** *Type IIB string theory on the background* $\mathrm{AdS}_5 \times S^5$*, with both factors of radius* L *and with* N *units of self-dual five-form flux through the* S^5*, is dynamically equivalent to* $\mathcal{N} = 4$ *supersymmetric Yang–Mills theory with gauge group* $\mathrm{SU}(N)$ *in four-dimensional Minkowski space. The two sets of parameters are related by*

$$g_s \;=\; \frac{g^2}{4\pi}, \qquad \frac{L^4}{\alpha'^2} \;=\; 4\pi g_s N \;=\; g^2 N \;=\; \lambda. \tag{53.43}$$

The equivalence is a duality of the complete quantum theories: all gauge-invariant observables of one map to observables of the other.

The second relation in Eq. (53.43) is the substantive entry. It follows by dividing the supergravity result Eq. (53.30) by α'^2 and using Eq. (53.28); it states that the curvature radius of the geometry, measured in string-length units, is the fourth root of the 't Hooft coupling:

$$\frac{L}{\ell_s} \;=\; \lambda^{1/4}. \tag{53.44}$$

This single line encodes the entire "strong/weak" character of the correspondence and is worth reading slowly.

Caution

The $O(1)$ numerical coefficients in Eq. (53.28), Eq. (53.30) and hence the "4π" in Eq. (53.43) are convention-dependent: different texts normalize the gauge coupling, the string coupling, and the brane tension differently, and one finds $g^2 = 2\pi g_s$ or $L^4 = 2\lambda\alpha'^2$ in places. The convention-independent, load-bearing content is the *parametric* statement $L^4/\alpha'^2 \propto \lambda$ and $g_s \propto g^2$. We fix the normalization so that $L^4/\alpha'^2 = \lambda$ exactly, which is the cleanest bookkeeping and the one used throughout this Part.

The regimes, and why the duality is useful. Two independent dimensionless numbers control each side: on the gauge side, g^2 (or λ) and N; on the string side, g_s and L/ℓ_s. The dictionary Eq. (53.43) ties them together as $g_s = \lambda/(4\pi N)$ and $L/\ell_s = \lambda^{1/4}$. Now read off the limits.

- *Classical (tree-level) supergravity* is reliable when the geometry is weakly curved in string units *and* string loops are suppressed — that is, $L/\ell_s \gg 1$ and $g_s \ll 1$. By Eq. (53.43) this is

$$\lambda \gg 1 \qquad \text{and} \qquad N \to \infty \text{ at fixed } \lambda \text{ (so } g_s = \lambda/4\pi N \to 0). \tag{53.45}$$

  Large N at fixed λ kills the string-loop expansion (the genus expansion of Section 53.1, whose coupling is $g_s \sim 1/N$), and large λ kills the α' expansion (worldsheet sigma-model corrections, suppressed by $\ell_s^2/L^2 = \lambda^{-1/2}$). In this corner the right-hand side of Eq. (53.42) reduces to *classical* type IIB supergravity on $\mathrm{AdS}_5 \times S^5$ — ordinary differential geometry and field equations.

- *Perturbative gauge theory* is reliable in the opposite corner, $\lambda \ll 1$, where the SYM loop expansion converges and the dual geometry is sub-string-scale and wildly curved, so the gravity description is useless.

These two corners do not overlap. The correspondence is therefore a *strong/weak duality*: it computes the strongly coupled, large-N limit of the gauge theory — exactly the regime that asymptotic freedom (Chapter 27) left analytically inaccessible and the lattice could define but not solve in closed form — by a *classical* computation in one higher dimension. This is the precise sense, promised in the chapter introduction, in which holography trades a hard quantum problem in d dimensions for an easy classical one in $d+1$. The same feature is what makes it hard to prove: the two sides are never simultaneously weakly coupled, so no perturbative matching can establish the equality directly.

We summarize the logical status of each step in Table 53.1, separating the derived from the conjectured.

53.2.5 Why $\mathcal{N} = 4$ SYM is exactly conformal, and the symmetry match

The conjecture asserts that the boundary side of Eq. (53.42) is $\mathcal{N} = 4$ SYM. For the rest of this chapter — which builds the rigorous symmetry backbone of the correspondence and the field–operator dictionary — it matters that the boundary theory is a genuine conformal field theory, so that the machinery of Part XIV applies to it. We now prove that it is, using only results this book has established about supersymmetry, and we exhibit the symmetry group that the next sections will match against the geometry.

Theorem 53.7 ($\mathcal{N} = 4$ SYM has vanishing beta function)**.** *The $\mathcal{N} = 4$ supersymmetric Yang–Mills theory with gauge group $\mathrm{SU}(N)$ has $\beta(g) = 0$ identically, to all orders in perturbation theory. Its single coupling g is an exactly marginal parameter; the theory is scale-invariant, and in fact conformally invariant, for every value of g and N.*

Step	Status	Basis
Worldvolume theory of N D3-branes is $\mathcal{N}=4$ SU(N) SYM, $g^2=4\pi g_s$	**string input**	quoted from string theory
Extremal black 3-brane metric Eq. (53.29), $L^4=4\pi g_s N\alpha'^2$	**string input**	quoted IIB supergravity solution
Near-horizon geometry $=\mathrm{AdS}_5\times S^5$, radius L	**derived**	Theorem 53.5, pure metric algebra
Decoupling of bulk gravitons from each remainder	**argued**	$G_{10}\to 0$; vanishing throat cross-section
Equality of the two remainders, Eq. (53.42)	**conjectured**	Theorem 53.6; unproved conjecture
$\mathcal{N}=4$ SYM is an exact CFT, group PSU$(2,2\|4)$	**derived**	Theorem 53.8
Bosonic symmetries match $\mathrm{AdS}_5\times S^5$ isometries	**derived**	Section 53.2.5

Table 53.1: Theorem-versus-conjecture summary for the Maldacena argument. The geometric reduction and the symmetry analysis are proved in this book; the brane inputs are quoted from string theory and flagged; and the identification of the two low-energy remainders — the correspondence itself — is a conjecture.

Proof. We use the realization of $\mathcal{N}=4$ in $\mathcal{N}=1$ language: the $\mathcal{N}=4$ vector multiplet of Section 44.4.2 decomposes into one $\mathcal{N}=1$ vector multiplet (the gauge field and one adjoint gaugino) together with three adjoint $\mathcal{N}=1$ chiral multiplets Φ_1,Φ_2,Φ_3, the latter packaging the remaining three gauginos and the six real scalars (three complex). The interactions are fixed by $\mathcal{N}=4$ to be the canonical gauge kinetic terms plus the superpotential

$$W \;=\; \frac{g}{3!}\,\sqrt{2}\,\epsilon^{ijk}\;\mathrm{tr}\big(\Phi_i[\Phi_j,\Phi_k]\big), \tag{53.46}$$

the unique gauge-invariant cubic in three adjoints, with coefficient tied to the gauge coupling by the extended supersymmetry.

The gauge coupling renormalization is governed by the exact NSVZ beta function established for general $\mathcal{N}=1$ gauge theories in Theorem 45.21. For an SU(N) theory ($C_A=N$) with chiral matter in representations r_i, it reads

$$\beta(g) \;=\; -\,\frac{g^3}{16\pi^2}\,\frac{3C_A-\sum_i T(r_i)(1-\gamma_i)}{1-C_A\,g^2/8\pi^2}, \tag{53.47}$$

where $T(r_i)$ is the Dynkin index (Section 44.2.7; Appendix B) and γ_i is the anomalous dimension of the chiral superfield Φ_i. For $\mathcal{N}=4$ the matter is three

chiral superfields in the adjoint, so $T(r_i) = T(\text{adj}) = C_A$ for each, and the numerator becomes

$$3C_A - \sum_{i=1}^{3} C_A(1-\gamma_i) \;=\; 3C_A - 3C_A + C_A \sum_{i=1}^{3} \gamma_i \;=\; C_A\,(\gamma_1+\gamma_2+\gamma_3). \tag{53.48}$$

The constant part has cancelled exactly: the one-loop coefficient $b_0 = 3C_A - \sum_i T(r_i) = 3C_A - 3C_A = 0$ vanishes on its own — $\mathcal{N}=4$ SYM is one-loop finite for any gauge group — and the entire beta function is now proportional to the sum of anomalous dimensions of the three adjoint chiral superfields.

It remains to show $\gamma_1 = \gamma_2 = \gamma_3 = 0$ to all orders. The three chiral superfields Φ_i together with the gaugino sit, under the $\mathrm{SU}(4)_R$ R-symmetry of the $\mathcal{N}=4$ algebra, in a single irreducible multiplet: the four fermions form the $\mathbf{4}$ of $\mathrm{SU}(4)_R$ and the six scalars the $\mathbf{6}$. The wavefunction renormalization of fields related by an unbroken global symmetry must be common, so the three Φ_i share a single anomalous dimension, $\gamma_1 = \gamma_2 = \gamma_3 \equiv \gamma$. Moreover, the same $\mathrm{SU}(4)_R$ rotates the chiral-multiplet fermions into the gaugino, forcing the chiral-multiplet wavefunction renormalization to coincide with that of the vector multiplet; but the gauge kinetic term's normalization is controlled holomorphically and is protected by the nonrenormalization theorem (Theorem 45.20), which forbids the holomorphic gauge coupling from receiving corrections beyond one loop. The one-loop contribution to γ in $\mathcal{N}=4$ vanishes by the same $b_0 = 0$ cancellation visible in Eq. (53.48), and the nonrenormalization plus $\mathrm{SU}(4)_R$ together forbid any higher-order contribution that is not already fixed to zero. Hence $\gamma = 0$ to all orders, the numerator Eq. (53.48) vanishes identically, and Eq. (53.47) gives $\beta(g) = 0$ for all g.

A vanishing beta function makes g exactly marginal and the theory scale-invariant. Scale invariance of a unitary, local theory with a conserved, improvable stress tensor (which $\mathcal{N}=4$ SYM has) is promoted to full conformal invariance by the standard argument of Section 47.1.6: the virial current is itself a total derivative, so the dilatation current improves to a traceless stress tensor and the special conformal transformations are symmetries. Therefore $\mathcal{N}=4$ SYM is an exact conformal field theory for every g, N. □

The vanishing of the beta function is special to maximal supersymmetry. It is worth contrasting with the running theories that dominate this book: QED and QCD have nonzero β (Chapters 24 and 27), so their couplings flow and they possess an intrinsic scale (Λ_{QCD}). The coupling-unification analysis of Chapter 35 is precisely a story about *running* couplings meeting at a scale. $\mathcal{N}=4$ SYM stands apart: it has no running, no scale, no S-matrix in the usual sense (massless everything, no asymptotic states), and is instead organized entirely by conformal data — operator dimensions and OPE coefficients — exactly the objects Part XIV taught us to handle. This is why $\mathcal{N}=4$ SYM, not QCD,

is the *canonical* holographic example: it sits exactly at a fixed point, so its dual geometry $\mathrm{AdS}_5 \times S^5$ is rigid (a fixed background, not a flowing one), and the cleanest possible correspondence results.

Theorem 53.8 (Superconformal symmetry of $\mathcal{N} = 4$ SYM and the bosonic pre-match)**.** *The symmetry algebra of $\mathcal{N} = 4$ $\mathrm{SU}(N)$ SYM is the $\mathcal{N} = 4$ superconformal algebra $\mathfrak{psu}(2,2|4)$, the unique simple superalgebra whose even (bosonic) part is*

$$\mathfrak{so}(2,4) \;\oplus\; \mathfrak{so}(6) \;\cong\; \mathfrak{su}(2,2) \;\oplus\; \mathfrak{su}(4), \tag{53.49}$$

the first summand the four-dimensional conformal algebra of Eq. (47.53) and the second the $\mathrm{SU}(4)_R \cong \mathrm{SO}(6)$ R-symmetry. Its bosonic symmetry group $\mathrm{SO}(2,4) \times \mathrm{SO}(6)$ coincides with the isometry group of $\mathrm{AdS}_5 \times S^5$.

Proof. Two facts established earlier combine. First, by Theorem 53.7 the theory is conformal, so its spacetime symmetry is not merely Poincaré but the full conformal group of four-dimensional Minkowski space. The conformal algebra in d dimensions, derived in Theorem 47.9 and recorded in Eq. (47.53), is $\mathfrak{so}(d,2)$ in Lorentzian signature; for $d = 4$ this is $\mathfrak{so}(2,4) \cong \mathfrak{su}(2,2)$ (the local isomorphism between the 4+2-dimensional rotation algebra and the pseudo-unitary algebra on $\mathbb{C}^4$ with split signature). Second, the $\mathcal{N} = 4$ supersymmetry algebra (the maximal extended algebra of Theorem 44.6 and Section 44.4.2) carries an $\mathrm{SU}(4)_R$ R-symmetry rotating its four supercharges, generalizing the $\mathrm{U}(1)_R$ outer automorphism of Section 44.2.7; and $\mathrm{SU}(4) \cong \mathrm{SO}(6)$ as the double cover identifies the R-symmetry with rotations of a six-dimensional space.

When supersymmetry and conformal symmetry coexist, their anticommutators do not close on the two bosonic factors alone: the anticommutator of an ordinary supercharge Q with a special conformal generator K produces a new fermionic generator S, the *superconformal* charge, and closure of the full set $\{P, K, M, D, R, Q, S\}$ requires assembling them into a single simple Lie superalgebra. The unique simple superalgebra with even part Eq. (53.49) and the requisite sixteen-plus-sixteen odd generators (the Q's and S's, each four Weyl supercharges valued in the $\mathbf{4}$ or $\bar{\mathbf{4}}$ of $\mathrm{SU}(4)_R$) is $\mathfrak{su}(2,2|4)$; for $\mathcal{N} = 4$ specifically the would-be U(1) R-charge that extends SU(4) to U(4) acts trivially on all gauge-invariant operators and decouples, leaving the projective/special form $\mathfrak{psu}(2,2|4)$. This is the symmetry algebra of $\mathcal{N} = 4$ SYM.

Finally, the matching to geometry. The isometries of AdS_5 are, by construction, the symmetries of a five-dimensional space of constant negative curvature embedded as a hyperboloid in $\mathbb{R}^{2,4}$; that embedding makes the isometry group $\mathrm{SO}(2,4)$ manifest — the proof is carried out in detail in Theorem 53.11 of the next section. The isometries of the round S^5 are the rotations SO(6). Hence the isometry group of $\mathrm{AdS}_5 \times S^5$ is $\mathrm{SO}(2,4) \times \mathrm{SO}(6)$, term-for-term the bosonic symmetry group Eq. (53.49) of the boundary theory. (The full superalgebra matches too: type IIB on $\mathrm{AdS}_5 \times S^5$ preserves thirty-two supercharges, the

sixteen-plus-sixteen of $\mathfrak{psu}(2,2|4)$, but the fermionic match is a string input we only flag.) □

This symmetry agreement is not a proof of the correspondence — two theories can share a symmetry group without being equal — but it is the first hard, check, and it is a stringent one: the conjecture would have died instantly had the bosonic groups failed to match. That they match *exactly*, with the conformal group of the boundary CFT realized as the isometry group of the bulk's anti-de Sitter factor and the R-symmetry as the isometry of the sphere, is the structural reason the correspondence is geometric. It also tells us what to build next.

Physical Insight

The two halves of $\mathrm{PSU}(2,2|4)$ live in two different places on the gravity side. The conformal group $\mathrm{SO}(2,4)$ of the boundary theory is the *isometry* of the bulk AdS_5 — a spacetime symmetry of the higher-dimensional geometry. The R-symmetry $\mathrm{SO}(6)$, an *internal* symmetry of the gauge theory, is the isometry of the *internal* manifold S^5. Holography turns an internal symmetry of the field theory into a geometric symmetry of an extra compact space, and a spacetime symmetry into the geometry of an extra non-compact direction. The emergent dimension is not a metaphor; it is where the conformal group becomes geometry.

The decoupling argument has thus handed us a concrete object to study and a sharp claim to test. The object is the geometry $\mathrm{AdS}_5 \times S^5$ — and, more generally, AdS_{d+1} for a d-dimensional boundary CFT. The claim is that the conformal symmetry of the boundary theory should be realized exactly as the isometry of the anti-de Sitter factor, $\mathrm{SO}(2,d)$. The next section takes up AdS_{d+1} on its own terms: we define it intrinsically as a constant-curvature space, derive its isometry group, exhibit its conformal boundary, and prove that the isometries act on that boundary precisely as the conformal group of Chapter 47 — converting the symmetry coincidence found here into the rigorous backbone on which the entire dictionary will be built.

53.3 Anti-de Sitter Geometry and Its Conformal Boundary

The decoupling argument of Section 53.2 delivered a dual geometry — the near-horizon throat $\mathrm{AdS}_5 \times S^5$ — and with it a demand that we have not yet discharged. If a four-dimensional conformal field theory is to be *the same theory* as gravity in this throat, then the rigid symmetry of the field theory must be visible, exactly and without approximation, in the geometry. The conformal group of Chapter 47 is the largest spacetime symmetry a d-dimensional field theory without gravity

can carry; the isometry group of AdS_{d+1} is the largest a $(d+1)$-dimensional geometry can carry. The correspondence can only be consistent if these two groups coincide. This section proves that they do. We define anti-de Sitter space intrinsically, exhibit the coordinate systems in which the rest of Part XV will compute, compute its curvature to confirm it is maximally symmetric, and then carry out the central rigorous result of the chapter's symmetry backbone: a generator-by-generator match between the Killing vectors of AdS_{d+1} and the conformal Killing vectors of its boundary, reproducing the algebra of Theorem 47.3 and Eq. (47.53) exactly. The output is a clean arena — the Poincaré patch with a conformal boundary at $z=0$ — in which Section 53.4 will place a field and read off a conformal operator.

Notation Watch

This chapter, like the rest of the book (Chapter 3), uses the particle-physics mostly-minus signature $\eta_{\mu\nu}=\mathrm{diag}(+,-,\dots,-)$ for the bulk metric and the boundary metric it induces alike, so that a $(d+1)$-dimensional Lorentzian metric has one plus (timelike) and d minus (spacelike) eigenvalues. General relativity and most of the holography literature instead use mostly-plus, $\mathrm{diag}(-,+,\dots,+)$; the reader translating to that convention need only flip the overall sign of every metric. We keep the Riemann tensor $R^{\rho}{}_{\sigma\mu\nu}=\partial_\mu\Gamma^\rho_{\nu\sigma}-\partial_\nu\Gamma^\rho_{\mu\sigma}+\Gamma^\rho_{\mu\lambda}\Gamma^\lambda_{\nu\sigma}-\Gamma^\rho_{\nu\lambda}\Gamma^\lambda_{\mu\sigma}$, Ricci $R_{\sigma\nu}=R^{\rho}{}_{\sigma\rho\nu}$, and $R=g^{\sigma\nu}R_{\sigma\nu}$ (the Wald/MTW convention). With this fixed Riemann convention the overall sign of the metric flips the sign of the Ricci scalar, so anti-de Sitter space — whose defining feature is a negative cosmological constant — carries $R=+d(d+1)/L^2$ here, the mostly-plus value $-d(d+1)/L^2$ with its sign reversed. The conformal algebra of Eq. (47.53) is an abstract Lie algebra independent of any signature, and the symmetry match of Section 53.3.6 holds identically in either convention; only the placement of explicit signs in coordinate formulas changes.

53.3.1 Anti-de Sitter space as a hyperboloid

The cleanest definition of AdS_{d+1} is extrinsic: it is a single hyperboloid sitting inside a flat space of two extra dimensions, exactly the same flat space $\mathbb{R}^{2,d}$ that hosted the linear realization of the conformal group in Theorem 47.10. This is the first hint that the two symmetry groups will agree, and we exploit it relentlessly.

Definition 53.9 (Anti-de Sitter space)**.** Let $\mathbb{R}^{2,d}$ be the $(d+2)$-dimensional flat space with coordinates X^A, $A=0,1,\dots,d,d+1$, and metric of signature $(2,d)$,

$$G_{AB}\,dX^A dX^B=+(dX^0)^2-\sum_{i=1}^{d}(dX^i)^2+(dX^{d+1})^2,\qquad G_{AB}=\mathrm{diag}(+1,\underbrace{-1,\dots,-1}_{d},+1),\tag{53.50}$$

so that X^0 and X^{d+1} are the two timelike directions. *Anti-de Sitter space* AdS_{d+1} of radius L is the hyperboloid

$$G_{AB}X^A X^B = +(X^0)^2 - \sum_{i=1}^{d}(X^i)^2 + (X^{d+1})^2 = +L^2, \tag{53.51}$$

equipped with the metric induced from Eq. (53.50) by restriction.

Two facts must be checked before this object is usable: that the induced metric is Lorentzian (one timelike direction, so that Eq. (53.51) describes a spacetime and not a Euclidean space), and that it has constant curvature. The first is immediate from the geometry of the embedding and we dispose of it now; the second we postpone to the explicit curvature computation of Section 53.3.3.

The outward normal to the hyperboloid Eq. (53.51) at a point X is proportional to the gradient of the defining quadratic form, i.e. to $X_A = G_{AB}X^B$. Its squared norm is $G^{AB}X_A X_B = G_{AB}X^A X^B = +L^2 > 0$, so in mostly-minus signature the normal is *timelike*. A nondegenerate hypersurface with timelike normal in a space of signature $(2, d)$ (two timelike directions) has an induced metric of signature $(1, d)$: it removes exactly one of the two timelike directions. The induced metric on AdS_{d+1} is therefore Lorentzian with a single time direction, as a spacetime must be. The same computation shows why the *sign* on the right of Eq. (53.51) matters: the surface $G_{AB}X^A X^B = -L^2$ has spacelike normal and induced signature $(2, d-1)$ — two times — which is the $(d+1)$-dimensional de Sitter space, not anti-de Sitter. The single sign distinguishes the two maximally symmetric Lorentzian geometries.

The payoff of the embedding is that the isometries are visible at a glance. Any linear map $X^A \mapsto \Lambda^A{}_B X^B$ that preserves the ambient metric Eq. (53.50) — that is, any element of $\mathrm{O}(()2, d)$ — automatically preserves the quadratic form $G_{AB}X^A X^B$ and hence maps the hyperboloid Eq. (53.51) to itself, and being an isometry of the ambient space it is an isometry of the induced metric. Thus $\mathrm{O}(()2, d)$, and in particular its identity component $\mathrm{SO}(()2, d)$, acts by isometries on AdS_{d+1}. We will see in Section 53.3.4 that these are *all* the isometries, and the dimension count will then make the contact with Eq. (47.24) precise.

53.3.2 Three coordinate systems

The hyperboloid is a single global object, but no single coordinate chart is convenient for every purpose. We introduce the three systems used throughout Part XV — global, Poincaré, and Euclidean — and the maps between them. Each is obtained by solving the constraint Eq. (53.51) with an explicit parametrization and reading off the induced metric.

Global coordinates. Solve Eq. (53.51) by isolating the two timelike directions on a circle and the d spacelike directions on a sphere of radius set by a single

"bulk radial" variable $\rho \geq 0$:

$$X^0 = L\cosh\rho\,\cos\tau, \qquad X^{d+1} = L\cosh\rho\,\sin\tau, \qquad X^i = L\sinh\rho\,\Omega^i \;\; (i=1,\dots,d), \tag{53.52}$$

where Ω^i is a unit vector on the sphere S^{d-1}, $\sum_{i=1}^{d}(\Omega^i)^2 = 1$. The constraint is satisfied identically,

$$(X^0)^2 + (X^{d+1})^2 - \sum_i (X^i)^2 = L^2\cosh^2\rho\,(\cos^2\tau + \sin^2\tau) - L^2\sinh^2\rho = L^2, \tag{53.53}$$

using $\cosh^2\rho - \sinh^2\rho = 1$. To compute the induced metric, differentiate Eq. (53.52). The two timelike directions give

$$\begin{aligned}(dX^0)^2 + (dX^{d+1})^2 &= L^2\big(\sinh\rho\cos\tau\,d\rho - \cosh\rho\sin\tau\,d\tau\big)^2 + L^2\big(\sinh\rho\sin\tau\,d\rho + \cosh\rho\cos\\ &= L^2\big(\sinh^2\rho\,d\rho^2 + \cosh^2\rho\,d\tau^2\big),\end{aligned} \tag{53.54}$$

the cross terms $\propto d\rho\,d\tau$ cancelling between the two squares. The spacelike directions enter ds^2 with a minus sign and give, using $\sum_i \Omega^i d\Omega^i = \frac{1}{2}d(\sum_i(\Omega^i)^2) = 0$ and writing $d\Omega_{d-1}^2 = \sum_i (d\Omega^i)^2$ for the round metric on the unit S^{d-1},

$$-\sum_i (dX^i)^2 = -L^2\big(\cosh^2\rho\,d\rho^2 + \sinh^2\rho\,d\Omega_{d-1}^2\big). \tag{53.55}$$

Adding, the $d\rho^2$ coefficient collapses to $L^2(\sinh^2\rho - \cosh^2\rho) = -L^2$, and

$$ds^2 = L^2\Big(\cosh^2\rho\,d\tau^2 - d\rho^2 - \sinh^2\rho\,d\Omega_{d-1}^2\Big). \tag{53.56}$$

These are *global* coordinates: $\rho \in [0,\infty)$ and the angles cover all of S^{d-1}, while τ runs over the circle. The locus $\rho = 0$ is a regular point (the metric there is $L^2(d\tau^2 - d\rho^2 - \rho^2 d\Omega_{d-1}^2)$ in the small-ρ expansion, flat near the origin), the "center" of AdS. As $\rho \to \infty$ the spatial sphere blows up and the prefactors $\cosh^2\rho, \sinh^2\rho$ both diverge: this is the direction of the conformal boundary, analyzed in Section 53.3.5. Because X^0, X^{d+1} trace a circle, τ is naively periodic with period 2π, which would make time closed. One always passes to the universal cover by unwrapping $\tau \in \mathbb{R}$; *anti-de Sitter space* in this book means that simply-connected cover, on which there are no closed timelike curves. Rescaling $r = L\sinh\rho$ and a further change recasts Eq. (53.56) as the more familiar

$$ds^2 = \Big(1 + \tfrac{r^2}{L^2}\Big)dt^2 - \Big(1 + \tfrac{r^2}{L^2}\Big)^{-1} dr^2 - r^2\,d\Omega_{d-1}^2, \qquad t = L\tau, \tag{53.57}$$

the static-patch form, in which the gravitational potential $g_{tt} = +(1 + r^2/L^2)$ rises without bound at large r — the "box" that confines null geodesics and lets them reach the boundary and return in finite coordinate time.

Poincaré coordinates. The Poincaré patch is the chart in which the boundary symmetry will be transparent, because its constant-z slices are flat d-dimensional Minkowski spaces and its boundary is a single such Minkowski space. We obtain it by a different solution of the same constraint Eq. (53.51), singling out one null combination of the ambient coordinates as the inverse radial variable.

Introduce a radial coordinate $z>0$ and d coordinates x^μ ($\mu=0,\dots,d-1$) that will become the boundary directions, with the mostly-minus Minkowski metric $\eta_{\mu\nu}=\mathrm{diag}(+1,-1,\dots,-1)$ and $x^2\equiv\eta_{\mu\nu}x^\mu x^\nu$. Set

$$X^\mu=\frac{L}{z}\,x^\mu\quad(\mu=0,\dots,d{-}1),\qquad X^d=\frac{1}{2z}(z^2{-}L^2{-}x^2),\qquad X^{d+1}=\frac{1}{2z}(z^2{+}L^2{-}x^2). \tag{53.58}$$

We now show that Eq. (53.58) solves the constraint and induces precisely the metric quoted in the chapter's blueprint.

Proposition 53.10 (Poincaré-patch metric)**.** *The map Eq. (53.58) satisfies the hyperboloid constraint Eq. (53.51), and the metric Eq. (53.50) induces on it*

$$ds^2=\frac{L^2}{z^2}\Big(\eta_{\mu\nu}\,dx^\mu dx^\nu-dz^2\Big),\qquad \eta_{\mu\nu}=\mathrm{diag}(+1,-1,\dots,-1),\quad z>0. \tag{53.59}$$

Proof. For the constraint, group the boundary directions and the two extra directions separately. Because X^0 is timelike and $X^1,\dots,X^{d-1}$ spacelike,

$$(X^0)^2-\sum_{a=1}^{d-1}(X^a)^2=\frac{L^2}{z^2}\Big((x^0)^2-\sum_a(x^a)^2\Big)=\frac{L^2}{z^2}\,\eta_{\mu\nu}x^\mu x^\nu=\frac{L^2x^2}{z^2}. \tag{53.60}$$

For the extra pair (X^d spacelike, X^{d+1} timelike), use the difference of squares with $X^{d+1}-X^d=L^2/z$ and $X^{d+1}+X^d=(z^2-x^2)/z$:

$$-(X^d)^2+(X^{d+1})^2=(X^{d+1}-X^d)(X^{d+1}+X^d)=\Big(\frac{L^2}{z}\Big)\Big(\frac{z^2-x^2}{z}\Big)=L^2-\frac{L^2x^2}{z^2}. \tag{53.61}$$

Adding Eqs. (53.60) and (53.61) the x^2 terms cancel and the total is $+L^2$, so Eq. (53.51) holds.

For the metric, differentiate. The boundary directions give $dX^\mu=\frac{L}{z}dx^\mu-\frac{Lx^\mu}{z^2}dz$, and with $x\cdot dx\equiv\eta_{\mu\nu}x^\mu dx^\nu$,

$$\eta_{\mu\nu}\,dX^\mu dX^\nu=\frac{L^2}{z^2}\,\eta_{\mu\nu}dx^\mu dx^\nu-\frac{2L^2}{z^3}\,(x\cdot dx)\,dz+\frac{L^2x^2}{z^4}\,dz^2. \tag{53.62}$$

For the extra pair, again factor through the sum and difference. Since $X^{d+1}-X^d=L^2/z$ depends only on z, $d(X^{d+1}-X^d)=-\frac{L^2}{z^2}dz$, while

$$X^{d+1}+X^d=\frac{z^2-x^2}{z}=z-\frac{x^2}{z}\;\Longrightarrow\; d(X^{d+1}+X^d)=\frac{z^2+x^2}{z^2}\,dz-\frac{2}{z}\,(x\cdot dx). \tag{53.63}$$

Hence

$$-(dX^d)^2+(dX^{d+1})^2 = d(X^{d+1}-X^d)\,d(X^{d+1}+X^d) = -\frac{L^2(z^2+x^2)}{z^4}\,dz^2+\frac{2L^2}{z^3}\,(x\cdot dx)\,dz. \tag{53.64}$$

The full induced line element is the sum of Eqs. (53.62) and (53.64). The cross terms $\propto (x\cdot dx)\,dz$ cancel exactly; the dz^2 coefficients combine to $\frac{L^2}{z^4}(x^2-z^2-x^2) = -\frac{L^2}{z^2}$; and the $dx^\mu dx^\nu$ term is untouched. This is Eq. (53.59). □

The coordinate $z \in (0,\infty)$ is the holographic radial direction: $z\to\infty$ is the deep interior (the "Poincaré horizon"), and $z\to 0$ is the conformal boundary, where the conformal factor L^2/z^2 blows up. The Poincaré patch Eq. (53.59) does *not* cover all of global AdS Eq. (53.56); it is the region accessible from one boundary Minkowski space, bounded by a horizon, as one sees by tracing the ranges of X^A through Eq. (53.58). Theorem 53.16 works the map between the two charts explicitly. The relation between the literature's conventions and ours is exactly the signature flip flagged above: in the mostly-plus convention used by most of the holography literature, Eq. (53.59) reads $ds^2 = \frac{L^2}{z^2}(\eta^{(+)}_{\mu\nu}dx^\mu dx^\nu + dz^2)$ with $\eta^{(+)} = \mathrm{diag}(-,+,\dots,+)$, the same geometry written with every sign reversed.

Euclidean coordinates. Continuing the boundary time $x^0 \to -ix^0_E$ (equivalently working on the surface where the ambient signature is $(1,d+1)$ rather than $(2,d)$) turns Eq. (53.59) into the metric of the upper half-space,

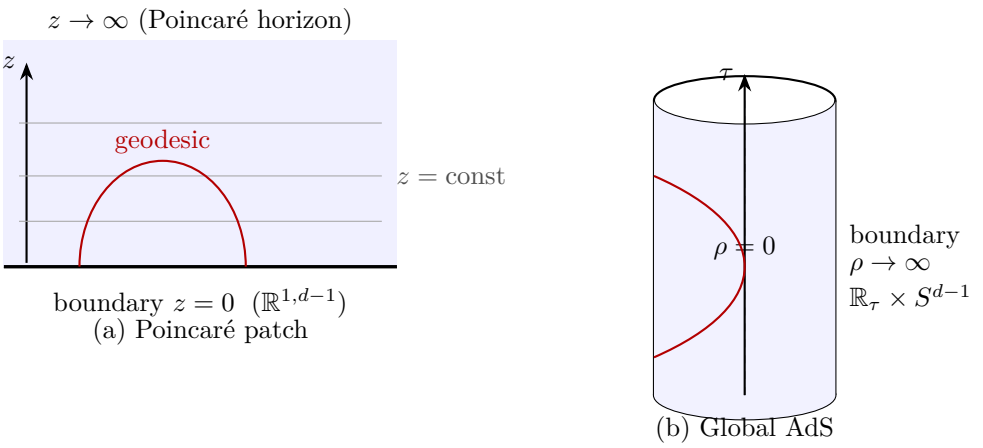
$$ds^2_E = \frac{L^2}{z^2}\Big(\delta_{\mu\nu}\,dx^\mu_E dx^\nu_E + dz^2\Big), \qquad z>0, \tag{53.65}$$

which is the Poincaré upper-half-space model of hyperbolic space $\mathbb{H}_{d+1}$, i.e. *Euclidean* anti-de Sitter space. The boundary is the flat $\mathbb{R}^d$ at $z=0$ together with the single point at $z=\infty$, which compactifies it to S^d. This is the geometry on which the Euclidean correlator machinery of Section 53.6 is cleanest, since there are no oscillatory modes and boundary conditions fix solutions uniquely; we will set up the bulk wave equation in Lorentzian signature in Section 53.4 and pass to Eq. (53.65) when computing.

53.3.3 Curvature and maximal symmetry

We promised that Eq. (53.51) has constant curvature. We now prove it by direct computation in the Poincaré chart Eq. (53.59), carrying every Christoffel symbol, and then read off that AdS is maximally symmetric — the property that ties its isometry count to the conformal generator count.

Write the bulk coordinates as $X^M = (x^\mu, z)$ with $M \in \{0,\dots,d-1,z\}$, and the metric Eq. (53.59) as $g_{MN} = \frac{L^2}{z^2}\hat\eta_{MN}$ with $\hat\eta_{MN} = \mathrm{diag}(\eta_{\mu\nu},-1)$ the flat



(a) Poincaré patch (b) Global AdS

Figure 53.5: Two charts on AdS_{d+1}. (a) The Poincaré patch Eq. (53.59): the upper half-space $z > 0$ with a flat Minkowski boundary at $z = 0$ and a horizon at $z \to \infty$; constant-z slices are flat, and a spacelike geodesic is a semicircle meeting the boundary orthogonally. (b) Global AdS Eq. (53.56): a solid cylinder whose central axis is $\rho = 0$ and whose conformal boundary at $\rho \to \infty$ is the cylinder $\mathbb{R}_\tau \times S^{d-1}$. The Poincaré patch is a single wedge of the global cylinder.

$(d+1)$-dimensional reference and $\eta_{\mu\nu}$ mostly-minus (so $g_{zz} = -L^2/z^2$). The inverse is $g^{MN} = \frac{z^2}{L^2}\hat{\eta}^{MN}$. Only z-derivatives of g_{MN} are nonzero, $\partial_z g_{MN} = -\frac{2}{z} g_{MN}$, so the Christoffel symbols $\Gamma^P_{MN} = \frac{1}{2} g^{PQ}(\partial_M g_{QN} + \partial_N g_{QM} - \partial_Q g_{MN})$ collapse to

$$\Gamma^z_{\mu\nu} = -\frac{1}{z}\,\eta_{\mu\nu}, \qquad \Gamma^z_{zz} = -\frac{1}{z}, \qquad \Gamma^\mu{}_{\nu z} = \Gamma^\mu{}_{z\nu} = -\frac{1}{z}\,\delta^\mu{}_\nu, \tag{53.66}$$

all others vanishing. Each follows by a one-line evaluation; for instance $\Gamma^z_{\mu\nu} = \frac{1}{2} g^{zz}(-\partial_z g_{\mu\nu}) = \frac{1}{2}\Big(-\frac{z^2}{L^2}\Big)\cdot\frac{2L^2}{z^3}\eta_{\mu\nu} = -\frac{1}{z}\eta_{\mu\nu}$, and $\Gamma^\mu{}_{\nu z} = \frac{1}{2} g^{\mu\rho}\partial_z g_{\rho\nu} = -\frac{1}{z}\delta^\mu{}_\nu$. The contracted symbol is

$$\Gamma^P{}_{zP} = \Gamma^z_{zz} + \Gamma^\mu{}_{z\mu} = -\frac{1}{z} - \frac{d}{z} = -\frac{d+1}{z}, \qquad \Gamma^P{}_{\mu P} = 0, \tag{53.67}$$

consistent with $\Gamma^P{}_{MP} = \partial_M \ln\sqrt{|g|}$ and $\sqrt{|g|} \propto z^{-(d+1)}$.

The Ricci tensor is $R_{MN} = \partial_P \Gamma^P{}_{MN} - \partial_N \Gamma^P{}_{MP} + \Gamma^P{}_{PQ}\Gamma^Q{}_{MN} - \Gamma^P{}_{NQ}\Gamma^Q{}_{MP}$. Take the two index types in turn. For the boundary–boundary components, $\partial_P \Gamma^P{}_{\mu\nu} = \partial_z(-\frac{1}{z}\eta_{\mu\nu}) = +\frac{1}{z^2}\eta_{\mu\nu}$, the second term vanishes by Eq. (53.67), the third is $\Gamma^P{}_{Pz}\Gamma^z{}_{\mu\nu} = -\frac{d+1}{z}\cdot(-\frac{1}{z})\eta_{\mu\nu} = +\frac{d+1}{z^2}\eta_{\mu\nu}$, and the fourth, summing the two contributing channels ($\Gamma^z_{\nu\rho}\Gamma^\rho{}_{\mu z}$ and $\Gamma^\rho{}_{\nu z}\Gamma^z_{\mu\rho}$), is $-\big[+\frac{1}{z^2}\eta_{\mu\nu} + \frac{1}{z^2}\eta_{\mu\nu}\big] = -\frac{2}{z^2}\eta_{\mu\nu}$. Collecting,

$$R_{\mu\nu} = \Big(1 + (d+1) - 2\Big)\frac{\eta_{\mu\nu}}{z^2} = +\frac{d}{z^2}\,\eta_{\mu\nu} = +\frac{d}{L^2}\,g_{\mu\nu}. \tag{53.68}$$

For the zz component, $\partial_P \Gamma^P{}_{zz} = \partial_z(-\frac{1}{z}) = \frac{1}{z^2}$, the second term is $-\partial_z \Gamma^P{}_{zP} = -\partial_z(-\frac{d+1}{z}) = -\frac{d+1}{z^2}$, the third is $\Gamma^P{}_{Pz}\Gamma^z_{zz} = (-\frac{d+1}{z})(-\frac{1}{z}) = \frac{d+1}{z^2}$, and the fourth is $-\Gamma^P{}_{zQ}\Gamma^Q{}_{zP} = -\big[(\Gamma^z_{zz})^2 + \sum_\mu (\Gamma^\mu{}_{z\mu})\ldots\big] = -\frac{d+1}{z^2}$ (the squared symbols summing to $\frac{1}{z^2} + \frac{d}{z^2}$). Hence

$$R_{zz} = \Big(1 - (d+1) + (d+1) - (d+1)\Big)\frac{1}{z^2} = -\frac{d}{z^2} = +\frac{d}{L^2}\, g_{zz}. \tag{53.69}$$

The mixed components $R_{\mu z}$ vanish by the same bookkeeping. Equations (53.68) and (53.69) combine into the single statement that AdS is an Einstein space with negative cosmological constant,

$$R_{MN} = +\frac{d}{L^2}\, g_{MN}, \qquad R = g^{MN} R_{MN} = +\frac{d}{L^2}\, \delta^M{}_M = +\frac{d(d+1)}{L^2}. \tag{53.70}$$

The Ricci scalar is a positive constant in this signature convention (encoding the negative cosmological constant of AdS, per the notation watch above); the curvature radius is L, and the strong-curvature limit is $L \to 0$. This is the geometric content of the statement, made in Section 53.2, that large AdS radius (in string units) is weak bulk curvature.

That AdS is not merely an Einstein space but *maximally symmetric* is the fact we actually need. A pseudo-Riemannian manifold of dimension n is maximally symmetric when its Riemann tensor is built entirely from the metric,

$$R_{MNPQ} = \frac{R}{n(n-1)}\big(g_{MP}g_{NQ} - g_{MQ}g_{NP}\big), \tag{53.71}$$

with R constant; equivalently, the curvature is the same in every direction at every point. For AdS, $n = d+1$ and $R = +d(d+1)/L^2$, so Eq. (53.71) reads $R_{MNPQ} = +\frac{1}{L^2}(g_{MP}g_{NQ} - g_{MQ}g_{NP})$. One verifies Eq. (53.71) directly from Eq. (53.66) — contracting it returns exactly Eqs. (53.68) and (53.69) — but the structural reason is the embedding: the hyperboloid Eq. (53.51) is the orbit of a single point under SO(()2, d), which acts transitively and, at each point, with isotropy group large enough to rotate all tangent directions into one another, forcing the curvature into the form Eq. (53.71).

Physical Insight

Maximal symmetry is the geometric image of the field-theory statement that a CFT has *no scale and no preferred point.* In flat space, Poincaré symmetry makes every point and every direction equivalent; conformal symmetry adds equivalence of every scale. AdS is the unique Lorentzian geometry that homogenizes points, directions, *and* the radial scale simultaneously — the curvature radius L is the only invariant, and it is not a scale on the boundary because, as Section 53.3.5 shows, it is scaled away

in the conformal limit $z \to 0$. The flatness of every constant-z slice and the self-similarity of the metric under $(x, z) \to \lambda(x, z)$ are the two faces of this single fact.

The number that matters is the count of independent Killing vectors. For a maximally symmetric space of dimension n this count is maximal and equal to

$$\dim(\text{isometry group}) = \frac{n(n+1)}{2}, \tag{53.72}$$

the dimension of the orthogonal group $\mathrm{SO}(()p, q)$ with $p + q = n + 1$ that acts on it. The n directions of homogeneity (translations between any two points) plus the $\frac{1}{2}n(n-1)$ directions of isotropy (rotations fixing a point) sum to Eq. (53.72). For AdS_{d+1}, $n = d + 1$ and the group is $\mathrm{SO}(()2, d)$; we make this precise next.

53.3.4 The isometry group $\mathrm{SO}(()2, d)$ and the dimension match

Theorem 53.11 (Isometries of anti-de Sitter space)**.** *The connected isometry group of* AdS_{d+1} *is* $\mathrm{SO}(()2, d)$*, of dimension*

$$\dim \mathrm{SO}(()2, d) = \frac{(d+2)(d+1)}{2}. \tag{53.73}$$

This equals the dimension $\frac{1}{2}(d+1)(d+2)$ *of the* d*-dimensional conformal group recorded in Eq. (47.24).*

Proof. We already showed in Section 53.3.1 that every $\Lambda \in \mathrm{SO}(()2, d)$ acts on the hyperboloid Eq. (53.51) as an isometry, so $\mathrm{SO}(()2, d)$ is contained in the connected isometry group. Conversely, the isometry group of any connected n-dimensional pseudo-Riemannian manifold has dimension at most $\frac{1}{2}n(n+1)$, with equality only for maximally symmetric spaces. We proved in Section 53.3.3 that AdS_{d+1} is maximally symmetric, so its isometry algebra has the maximal dimension $\frac{1}{2}(d+1)(d+2)$. The subgroup $\mathrm{SO}(()2, d)$ already realizes that many independent Killing vectors — its Lie algebra $\mathfrak{so}(()2, d)$ is spanned by the antisymmetric generators $J_{AB} = -J_{BA}$, $A, B = 0, \ldots, d+1$, numbering exactly $\binom{d+2}{2} = \frac{1}{2}(d+2)(d+1)$ — so the inclusion saturates the bound and the connected isometry group is $\mathrm{SO}(()2, d)$, no larger. The dimension count is

$$\dim \mathrm{SO}(()2, d) = \binom{d+2}{2} = \frac{(d+2)(d+1)}{2}, \tag{53.74}$$

which is verbatim Eq. (47.24). For AdS_5, $d = 4$, both equal $\frac{1}{2} \cdot 6 \cdot 5 = 15$. □

The explicit Killing vector fields are the ambient "rotations" restricted to the hyperboloid,

$$L_{AB} = X_A \frac{\partial}{\partial X^B} - X_B \frac{\partial}{\partial X^A}, \qquad X_A \equiv G_{AB} X^B, \tag{53.75}$$

which are tangent to Eq. (53.51) because $L_{AB}(G_{CD}X^C X^D) = 0$, and which close under the Lie bracket into the algebra

$$[L_{AB}, L_{CD}] = G_{AD}L_{BC} + G_{BC}L_{AD} - G_{AC}L_{BD} - G_{BD}L_{AC}, \tag{53.76}$$

the same $\mathfrak{so}(()2, d)$ bracket that appeared, with an explicit factor of i for Hermitian generators, in Eq. (47.55). The numerical coincidence Eq. (53.73) is therefore not a coincidence at all: the conformal group of Chapter 47 was *constructed* in Theorem 47.10 as the rotation group of the very space $\mathbb{R}^{2,d}$ in which AdS lives. What remains is to show that the two realizations of $\mathfrak{so}(()2, d)$ — as conformal Killing vectors on the boundary and as Killing vectors in the bulk — are matched not just as abstract algebras but generator by generator under the geometric limit $z \to 0$. That is the subject of Section 53.3.6, after we make the boundary itself precise.

53.3.5 The conformal boundary

Both Eqs. (53.56) and (53.59) degenerate at the edge of AdS — at $\rho \to \infty$ and at $z \to 0$ respectively — because a conformal factor diverges there. The metric does not extend to that edge, yet a definite *conformal* structure does, and it is the carrier of the boundary CFT. We make this precise with the notion, due to Penrose, of a conformal boundary defined by a defining function.

Definition 53.12 (Defining function and conformal boundary)**.** Let (M, g) be the open bulk AdS_{d+1}. A *defining function* for its boundary is a smooth function Ω on a neighbourhood of the edge with $\Omega > 0$ in the interior, $\Omega = 0$ on the edge, and $d\Omega \neq 0$ there. The *conformal boundary* is the locus $\{\Omega = 0\}$ equipped with the metric

$$\bar{g} \;=\; (\Omega^2\, g)\big|_{\Omega=0}, \tag{53.77}$$

the rescaled metric $\Omega^2 g$ restricted to the edge.

In the Poincaré chart the natural defining function is $\Omega = z/L$, which vanishes linearly at the boundary $z = 0$ with $d\Omega = dz/L \neq 0$. Then $\Omega^2 g = \frac{z^2}{L^2} \cdot \frac{L^2}{z^2}(\eta_{\mu\nu}dx^\mu dx^\nu - dz^2) = \eta_{\mu\nu}dx^\mu dx^\nu - dz^2$, which is regular at $z = 0$, and restricting to $z = 0$ (where dz drops out) gives

$$\bar{g} = \eta_{\mu\nu}\, dx^\mu dx^\nu : \tag{53.78}$$

the boundary of the Poincaré patch is d-dimensional Minkowski space, the home of the CFT. In global coordinates the natural choice $\Omega = 2e^{-\rho}$ (so $\Omega \to 0$ as $\rho \to \infty$) yields, after expanding $\cosh^2\rho \sim \sinh^2\rho \sim \frac{1}{4}e^{2\rho}$ in Eq. (53.56),

$$\Omega^2 g\big|_{\rho\to\infty} = L^2(d\tau^2 - d\Omega_{d-1}^2), \tag{53.79}$$

so the global boundary is the Lorentzian cylinder $\mathbb{R}_\tau \times S^{d-1}$ — the Einstein static universe. The two boundaries, Minkowski space and the cylinder, are related by a Weyl transformation and a conformal map; they are the same conformal manifold seen in two charts, exactly as the plane and the cylinder were the same $2d$ conformal manifold in Chapter 48.

The crucial structural point is that Eq. (53.77) depends on the *choice* of defining function, and only its conformal class is intrinsic.

Theorem 53.13 (The boundary carries a conformal class, not a metric)**.** *Two defining functions Ω and $\tilde\Omega$ for the same boundary differ by a positive smooth factor, $\tilde\Omega = e^{\omega}\,\Omega$ with ω smooth up to the boundary. The boundary metrics they induce via Eq. (53.77) are related by a Weyl rescaling,*

$$\tilde{\bar g} = e^{2\omega_0}\,\bar g, \qquad \omega_0 \equiv \omega\big|_{\Omega=0}, \tag{53.80}$$

where ω_0 is an arbitrary smooth function on the boundary. The conformal boundary therefore carries a well-defined conformal class $[\bar g]$ and no *preferred metric, hence no preferred scale.*

Proof. Both Ω and $\tilde\Omega$ vanish exactly on the boundary locus and are positive inside, with nonvanishing gradient on the boundary, so their ratio $\tilde\Omega/\Omega$ extends to a smooth, strictly positive function near the boundary; call its logarithm ω, so $\tilde\Omega = e^{\omega}\Omega$. Then

$$\tilde\Omega^2 g = e^{2\omega}\,\Omega^2 g. \tag{53.81}$$

Restricting to the boundary, where $\Omega^2 g \to \bar g$ and $\omega \to \omega_0$, gives Eq. (53.80). That ω_0 is arbitrary follows because one may multiply any defining function by any positive smooth function that is bounded and bounded away from zero at the boundary, realizing any smooth ω_0. Hence no representative of $[\bar g]$ is singled out; only ratios $\bar g_{\mu\nu}/\bar g_{\rho\sigma}$ — the conformal structure, i.e. angles and null cones — are invariant. □

This is the geometric origin of the central feature of the duality. A bulk diffeomorphism that rescales the defining function acts on the boundary representative as a Weyl transformation, so bulk geometry knows the boundary only up to Weyl rescaling. A field theory that is to be "read off" the boundary must therefore be insensitive to the boundary scale — it must be a *conformal* field theory, in which observables depend only on the conformal class [186, 393]. We will see in Section 53.4 that this same defining function controls the near-boundary falloff

of bulk fields, and that the Weyl weight ω_0 here is what becomes the scaling dimension of the dual operator. The dilatation isometry $z \to \lambda z,\ x \to \lambda x$ of the next subsection is exactly the statement that rescaling the defining function ($z \to \lambda z$) is a symmetry: it confirms operationally that the boundary has no preferred scale.

53.3.6 The match: bulk Killing vectors are boundary conformal Killing vectors

We can now prove the result that anchors the entire correspondence at the level of symmetry. The isometries of AdS_{d+1}, restricted to act on the conformal boundary, are precisely the conformal transformations of that boundary — and the dictionary between the two realizations is the one already written down abstractly in Eq. (47.56). We establish this constructively: for each ambient generator Eq. (53.75) we compute its action on the Poincaré coordinates (x^μ, z) and take the boundary limit $z \to 0$, recovering one of the four families of conformal Killing vectors Eq. (47.25) of Theorem 47.3.

It is convenient to package the two extra ambient directions into null combinations

$$X^- \equiv X^{d+1} - X^d = \frac{L^2}{z}, \qquad X^+ \equiv X^{d+1} + X^d = \frac{z^2 - x^2}{z}, \tag{53.82}$$

read off from Eq. (53.58), in terms of which the embedding inverts to the boundary coordinate and the radial coordinate as

$$x^\mu = \frac{L\, X^\mu}{X^-}, \qquad z = \frac{L^2}{X^-}. \tag{53.83}$$

The ambient metric in these variables is $G_{AB}X^A X^B = \eta_{\mu\nu}X^\mu X^\nu + X^+X^-$, displaying the boundary Minkowski metric and the null pair. We now identify the four families.

Lorentz rotations $M_{\mu\nu}$. The generators $L_{\mu\nu}$ ($\mu, \nu \in \{0, \dots, d-1\}$) mix only the boundary directions X^μ, which by Eq. (53.83) are proportional to x^μ at fixed z. They therefore act as the rotations $x^\mu \mapsto x^\mu + \omega^\mu{}_\nu x^\nu$ of the boundary and as the corresponding rotations of the bulk, leaving z fixed. These are the $\frac{1}{2}d(d-1)$ boundary Lorentz generators $M_{\mu\nu} = L_{\mu\nu}$ of Eq. (47.56), and their boundary action is the Lorentz family of Eq. (47.25).

Dilatation D. Take the ambient boost in the (X^d, X^{d+1}) plane,

$$L_{d+1,d} = X_{d+1}\,\partial_{X^d} - X_d\,\partial_{X^{d+1}} = X^{d+1}\,\partial_{X^d} + X^d\,\partial_{X^{d+1}}, \tag{53.84}$$

using $X_{d+1} = +X^{d+1}$ and $X_d = -X^d$ from Eq. (53.50) (this is the generator $J_{d+1,d}$ of the boundary dilatation in Eq. (47.56)). Its infinitesimal action $\delta X^d =$

ϵX^{d+1}, $\delta X^{d+1} = \epsilon X^d$ becomes, on the null combinations Eq. (53.82), $\delta X^+ = \epsilon X^+$ and $\delta X^- = -\epsilon X^-$ — a pure scaling — while the X^μ are untouched. Feeding this through Eq. (53.83),

$$\delta z = -\frac{L^2}{(X^-)^2}\,\delta X^- = \epsilon\,\frac{L^2}{X^-} = \epsilon\, z, \qquad \delta x^\mu = -\frac{L X^\mu}{(X^-)^2}\,\delta X^- = \epsilon\,\frac{L X^\mu}{X^-} = \epsilon\, x^\mu, \tag{53.85}$$

so the corresponding bulk Killing vector is

$$\xi_D = x^\mu\,\partial_\mu + z\,\partial_z, \tag{53.86}$$

the simultaneous rescaling $x \to \lambda x$, $z \to \lambda z$ anticipated in Section 53.3.5. Its boundary limit $z \to 0$ is $\xi_D|_{\rm bdy} = x^\mu \partial_\mu$, the dilatation family of Eq. (47.25), with $D = L_{d+1,d} = J_{d+1,d}$ as in Eq. (47.56). That the same ϵ scales the radial coordinate z and the boundary coordinates x^μ together is the geometric statement that the holographic direction *is* the renormalization-group scale — a theme developed in Sections 53.4 and 53.5.

Translations P_μ. Form, exactly as in the abstract dictionary Eq. (47.56),

$$P_\mu = L_{\mu d} + L_{\mu,d+1} = 2X_\mu\,\partial_{X^+} - X^-\,\partial_{X^\mu}, \tag{53.87}$$

where the second equality uses $\partial_{X^d} + \partial_{X^{d+1}} = 2\partial_{X^+}$ and $X_d + X_{d+1} = X^{d+1} - X^d = X^-$ in the null frame Eq. (53.82). Its action is $\delta X^\mu = -\beta\, X^-$, $\delta X^+ = 2\beta\, X_\mu$, $\delta X^- = 0$. Since $\delta X^- = 0$, Eq. (53.83) gives $\delta z = 0$ and

$$\delta x^\mu = \frac{L}{X^-}\,\delta X^\mu = \frac{L}{X^-}\,(-\beta\, X^-) = -L\beta = \text{const}, \tag{53.88}$$

so $\xi_P = a^\mu \partial_\mu$ with $a^\mu \propto \beta$: a rigid translation of the boundary, z-independent throughout the bulk. This is the translation family of Eq. (47.25), with $P_\mu = J_{\mu d} + J_{\mu,d+1}$.

Special conformal transformations K_μ. The conjugate combination $K_\mu = L_{\mu d} - L_{\mu,d+1}$ produces the remaining family; because it is the only one whose boundary action is nonlinear in x, we carry it in full in Theorem 53.15 below. The upshot is that its boundary limit is exactly $\xi^\mu = 2(b\cdot x)x^\mu - x^2 b^\mu$, the special-conformal family of Eq. (47.25).

Theorem 53.14 (Symmetry backbone of AdS/CFT)**.** *Under the identification Eq. (47.56),*

$$M_{\mu\nu} = L_{\mu\nu}, \qquad D = L_{d+1,d}, \qquad P_\mu = L_{\mu d} + L_{\mu,d+1}, \qquad K_\mu = L_{\mu d} - L_{\mu,d+1}, \tag{53.89}$$

the Killing vectors of AdS_{d+1}*, restricted to its conformal boundary at* $z \to 0$*, are exactly the conformal Killing vectors of Eq. (47.25): translations, Lorentz rotations, the dilatation, and special conformal transformations. The bulk isometry algebra Eq. (53.76) reproduces the conformal algebra Eq. (47.53) of Theorem 47.9 generator by generator.*

Proof. The four paragraphs above, together with Theorem 53.15, establish the four families of boundary actions. The bracket relations follow because $\{L_{AB}\}$ obey the $\mathfrak{so}(()2, d)$ algebra Eq. (53.76), which is identical to Eq. (47.55), and the assignment Eq. (53.89) is verbatim the isomorphism Eq. (47.56) that Theorem 47.10 proved carries Eq. (47.55) onto the conformal algebra Eq. (47.53). Therefore the brackets of $M_{\mu\nu}, D, P_\mu, K_\mu$ realized here as bulk Killing vectors coincide with Eqs. (47.53a) to (47.53d). For instance, the geometric content of $[D, P_\mu] \propto P_\mu$ (the relation Eq. (47.53c)) is immediate from Eqs. (53.86) and (53.87): conjugating a rigid translation $a^\mu \partial_\mu$ by the dilatation $x \to \lambda x$ scales it to $\lambda a^\mu \partial_\mu$, so $[\xi_D, \xi_P] = \xi_P$, matching $[D, P_\mu] = iP_\mu$ once Hermitian normalization restores the i; likewise $[D, K_\mu] = -iK_\mu$ because the special conformal vector scales oppositely. □

Worked Example 53.15 (The special conformal generator from the bulk)**.** We compute the boundary action of $K_\mu = L_{\mu d} - L_{\mu,d+1}$ and show it is the special conformal transformation, completing Theorem 53.14.

In the null frame Eq. (53.82), using $\partial_{X^d} - \partial_{X^{d+1}} = -2\partial_{X^-}$ and $X_d - X_{d+1} = -(X^d + X^{d+1}) = -X^+$,

$$K_\mu = L_{\mu d} - L_{\mu,d+1} = -2X_\mu\, \partial_{X^-} + X^+\, \partial_{X^\mu}, \tag{53.90}$$

so for a fixed boundary index μ the infinitesimal action with parameter γ is

$$\delta X^\nu = +\gamma\, X^+\, \delta^\nu{}_\mu, \qquad \delta X^- = -2\gamma\, X_\mu, \qquad \delta X^+ = 0. \tag{53.91}$$

Differentiating the inverse relations Eq. (53.83),

$$\delta x^\rho = \frac{L}{X^-}\,\delta X^\rho - \frac{LX^\rho}{(X^-)^2}\,\delta X^- = +\gamma\,\frac{LX^+}{X^-}\,\delta^\rho{}_\mu + 2\gamma\,\frac{LX^\rho X_\mu}{(X^-)^2}. \tag{53.92}$$

Now substitute the explicit forms. From Eq. (53.82), $\dfrac{X^+}{X^-} = \dfrac{(z^2 - x^2)/z}{L^2/z} = \dfrac{z^2 - x^2}{L^2}$, so the first term is $+\dfrac{\gamma}{L}(z^2 - x^2)\,\delta^\rho{}_\mu$. For the second, $X^\rho = \frac{X^-}{L} x^\rho$ and $X_\mu = \eta_{\mu\nu} X^\nu = \frac{X^-}{L} x_\mu$, whence $\dfrac{LX^\rho X_\mu}{(X^-)^2} = \dfrac{x^\rho x_\mu}{L}$. Therefore

$$\delta x^\rho = \frac{\gamma}{L}\Big(2\, x^\rho x_\mu - (x^2 - z^2)\,\delta^\rho{}_\mu\Big), \qquad \delta z = -\frac{L^2}{(X^-)^2}\,\delta X^- = \frac{2\gamma}{L}\,(x_\mu)\, z, \tag{53.93}$$

the second equality computed the same way. Contracting the free index against an arbitrary constant vector b^μ and absorbing γ/L into its normalization, the bulk special conformal Killing vector is

$$\xi_K = \left[\, 2(b\cdot x)\, x^\mu - (x^2 - z^2)\, b^\mu \,\right] \partial_\mu + 2(b\cdot x)\, z\, \partial_z. \tag{53.94}$$

On the boundary $z \to 0$ the z^2 correction and the ∂_z piece drop out, leaving

$$\xi_K\big|_{\text{bdy}} = \left[\, 2(b\cdot x)\, x^\mu - x^2\, b^\mu \,\right] \partial_\mu, \tag{53.95}$$

which is exactly the special conformal family $\xi^\mu = 2(b\cdot x)x^\mu - x^2 b^\mu$ of Eq. (47.25). The z-dependent terms in Eq. (53.94) are the unique extension of the boundary conformal transformation into a bulk isometry — the holographic "bulk completion" of a special conformal transformation — and their vanishing at $z = 0$ is why the boundary sees a pure conformal transformation with no admixture of radial motion.

Worked Example 53.16 (Embedding of the Poincaré patch in global AdS)**.** To see concretely that the Poincaré patch is a proper subregion of global AdS, we match the two parametrizations Eqs. (53.52) and (53.58) through their common ambient coordinates X^A. Equating the timelike X^{d+1} and the spacelike X^d components,

$$L\cosh\rho\,\sin\tau = \frac{1}{2z}(z^2 + L^2 - x^2), \qquad L\sinh\rho\,\Omega^d = \frac{1}{2z}(z^2 - L^2 - x^2), \tag{53.96}$$

and the boundary components $L\sinh\rho\,\Omega^\mu = \frac{L}{z}x^\mu$. These determine (τ, ρ, Ω^i) from (z, x^μ). The key qualitative fact reads off the first relation: the right-hand side, $\frac{1}{2z}(z^2 + L^2 - x^2)$, is a single-signed function of the Poincaré data on much of the patch, so as (z, x^μ) range over the patch the global time τ sweeps only a *finite* interval, not the full real line. The Poincaré patch is bounded in global time between two null surfaces (the past and future Poincaré horizons, $X^- = L^2/z \to \infty$, i.e. $z \to \infty$), and its boundary Minkowski space Eq. (53.78) is the portion of the global cylinder boundary $\mathbb{R} \times S^{d-1}$ covered by stereographic-type coordinates — precisely the conformal map between $\mathbb{R}^{1,d-1}$ and the cylinder that we met for $d = 2$ in Chapter 48. A boundary observer in the Poincaré frame thus sees Minkowski space; the same data, conformally completed, is the cylinder seen by the global observer.

Theorem 53.14 is the rigorous backbone the chapter promised: the conjectured equivalence of Section 53.2 respects, exactly, the only symmetry both sides are required to share. Every correlator computed holographically in the remainder of Part XV will transform under Eq. (53.89) as a conformal correlator must, with the bulk isometry doing the work of the boundary conformal group. We now have the concrete arena the next section needs: the Poincaré patch Eq. (53.59),

with its flat conformal boundary at $z = 0$, the dilatation Eq. (53.86) identifying the radial coordinate with scale, and a boundary that — by Theorem 53.13 — carries only a conformal class. Into this arena Section 53.4 places a free field, solves its wave equation, and reads off from the two near-boundary falloffs at $z \to 0$ how a bulk mass encodes a boundary operator's scaling dimension.

53.4 Fields in AdS: Falloffs, Dimensions, and the Mass–Dimension Relation

The previous section delivered the geometric backbone of the correspondence: anti-de Sitter space AdS_{d+1}, its isometry group $\mathrm{SO}(2, d)$, and the proof that those isometries act on the conformal boundary exactly as the conformal group of Chapter 47. That match of symmetry groups is suggestive but empty until we say *what* on the two sides is being identified. The conformal field theory side organizes itself, as Theorem 47.15 established, into primary operators labelled by a scaling dimension Δ and a spin. The gravity side, at the level we work, is a collection of fields propagating on the fixed AdS_{d+1} background. The first concrete entry of the dictionary must therefore be a map between these two lists — between a bulk field and a boundary operator — and the sharpest invariant that can cross the bridge is a single number on each side: the mass m of the bulk field and the dimension Δ of the operator. This section establishes the precise relation between them.

The strategy is the one that solving any linear wave equation near a singular point demands. We write the free scalar field equation in the Poincaré chart, examine its behaviour as the radial coordinate z approaches the boundary at $z = 0$, and discover that every solution is, near the boundary, a superposition of two power laws z^{Δ_-} and z^{Δ_+}. The two exponents are the roots of a quadratic — the indicial equation — whose content is the *mass–dimension relation* $\Delta(\Delta - d) = m^2 L^2$. One root will turn out to fix a boundary condition (a *source* for a dual operator), the other to encode the field's response (the operator's *vacuum expectation value*); and the requirement that the field carry finite energy will reproduce, on the nose, the unitarity bound of Theorem 47.18 together with a sharp lower bound on m^2 — negative masses are allowed in AdS, but only down to the Breitenlohner–Freedman floor. Everything in this section is a statement about a single free field on a fixed background; no quantum gravity is invoked. That is exactly the point: the hard conformal data of a strongly coupled theory is being read off from an elementary boundary-value problem.

53.4.1 The scalar action and its equation of motion in Poincaré coordinates

We work in the Poincaré patch of AdS_{d+1} established in Section 53.3. Writing the bulk coordinates as $X^M = (x^\mu, z)$ with $\mu = 0, 1, \ldots, d-1$ a boundary Lorentz index and $z > 0$ the radial (holographic) coordinate, the metric is

$$\mathrm{d}s^2 \;=\; g_{MN}\,\mathrm{d}X^M\,\mathrm{d}X^N \;=\; \frac{L^2}{z^2}\Big(\eta_{\mu\nu}\,\mathrm{d}x^\mu\,\mathrm{d}x^\nu - \mathrm{d}z^2\Big), \qquad \eta_{\mu\nu} = \mathrm{diag}(+,-,\ldots,-), \tag{53.97}$$

where L is the AdS radius and the conformal boundary sits at $z \to 0$. In keeping with the book's mostly-minus signature (Theorem 47.15 and Appendix A), the boundary metric $\eta_{\mu\nu}$ has one timelike and $d-1$ spacelike directions, and the radial direction is spacelike: the full $(d+1)$-dimensional line element Eq. (53.59) has signature $(+,-,\ldots,-)$. The nonzero metric components and their inverses are

$$g_{\mu\nu} = \frac{L^2}{z^2}\,\eta_{\mu\nu}, \quad g_{zz} = -\frac{L^2}{z^2}, \qquad g^{\mu\nu} = \frac{z^2}{L^2}\,\eta^{\mu\nu}, \quad g^{zz} = -\frac{z^2}{L^2}. \tag{53.98}$$

The determinant follows from Eq. (53.98): each of the d boundary directions contributes a factor $\frac{L^2}{z^2}\eta_{\mu\mu}$ and the radial direction contributes $-\frac{L^2}{z^2}$, so

$$\det g_{MN} = \Big(\frac{L^2}{z^2}\Big)^{d+1}(\det \eta_{\mu\nu})\,(-1) = \Big(\frac{L^2}{z^2}\Big)^{d+1}(-1)^d, \qquad \sqrt{|g|} = \Big(\frac{L}{z}\Big)^{d+1}, \tag{53.99}$$

using $\det \eta_{\mu\nu} = (-1)^{d-1}$ for the mostly-minus boundary metric.

The dynamics of a single real scalar of mass m on this fixed background is governed by the covariant generalization of the ϕ^4 theory free action (Chapter 9), with the flat measure and derivatives promoted to their curved-space forms:

$$S[\phi] \;=\; \frac{1}{2}\int \mathrm{d}^d x\,\mathrm{d}z\,\sqrt{|g|}\,\Big(g^{MN}\,\partial_M\phi\,\partial_N\phi - m^2\phi^2\Big). \tag{53.100}$$

We keep ϕ free; interactions and self-couplings are the business of Chapter 54, where they generate Witten-diagram correlators. Varying Eq. (53.100) with $\delta\phi$ and integrating the derivative term by parts gives the curved-space Klein–Gordon equation,

$$(\Box_{\mathrm{AdS}} + m^2)\phi = 0, \qquad \Box_{\mathrm{AdS}}\,\phi \equiv \frac{1}{\sqrt{|g|}}\,\partial_M\big(\sqrt{|g|}\,g^{MN}\,\partial_N\phi\big). \tag{53.101}$$

Notation Watch

Much of the holography literature writes the scalar equation of motion as $(\Box - m^2)\phi = 0$. That sign reflects the mostly-plus signature $(-,+,\ldots,+)$

standard in general relativity, where the d'Alembertian of a plane wave is $\Box e^{ip\cdot x} = +p^2 e^{ip\cdot x}$ and the Klein–Gordon operator reads $\Box - m^2$. This book uses the mostly-minus particle-physics signature (Eq. (53.59)), in which $\Box e^{-ip\cdot x} = -p^2 e^{-ip\cdot x}$ and the free equation is $(\Box + m^2)\phi = 0$, exactly as for the flat-space scalar of Chapter 9. The two conventions describe the same physics; the invariant content — the mass–dimension relation Eq. (53.112) below — is identical, as it must be. We carry the explicit signature through every step so that no sign is taken on faith.

To make Eq. (53.101) concrete we evaluate $\Box_{\mathrm{AdS}}$ on a field $\phi(x, z)$ using Eqs. (53.98) and (53.99). Split the sum over M, N into the boundary directions and the radial direction. For the boundary part, $g^{\mu\nu} = \frac{z^2}{L^2}\eta^{\mu\nu}$ depends on z but not on x, so

$$\frac{1}{\sqrt{|g|}}\,\partial_\mu\!\Big(\sqrt{|g|}\,g^{\mu\nu}\partial_\nu\phi\Big) = \Big(\frac{z}{L}\Big)^{d+1}\partial_\mu\Big[\Big(\frac{L}{z}\Big)^{d+1}\frac{z^2}{L^2}\,\eta^{\mu\nu}\partial_\nu\phi\Big] = \frac{z^2}{L^2}\,\eta^{\mu\nu}\partial_\mu\partial_\nu\phi = \frac{z^2}{L^2}\,\Box_x\phi, \tag{53.102}$$

where $\Box_x \equiv \eta^{\mu\nu}\partial_\mu\partial_\nu$ is the flat boundary d'Alembertian and the prefactor $(L/z)^{d+1}z^2/L^2 = (L/z)^{d-1}$ was pulled through ∂_μ unchanged. For the radial part, $\sqrt{|g|}\,g^{zz} = (L/z)^{d+1}(-(z/L)^2) = -(L/z)^{d-1}$, so

$$\begin{aligned}\frac{1}{\sqrt{|g|}}\,\partial_z\!\Big(\sqrt{|g|}\,g^{zz}\partial_z\phi\Big) &= \Big(\frac{z}{L}\Big)^{d+1}\partial_z\Big[-\Big(\frac{L}{z}\Big)^{d-1}\partial_z\phi\Big] \\ &= \Big(\frac{z}{L}\Big)^{d+1}\Big[\frac{d-1}{z}\Big(\frac{L}{z}\Big)^{d-1}\partial_z\phi - \Big(\frac{L}{z}\Big)^{d-1}\partial_z^2\phi\Big] \\ &= \frac{z^2}{L^2}\Big(-\partial_z^2\phi + \frac{d-1}{z}\,\partial_z\phi\Big),\end{aligned} \tag{53.103}$$

where the middle line used $\partial_z(L/z)^{d-1} = -\frac{d-1}{z}(L/z)^{d-1}$. Adding Eqs. (53.102) and (53.103),

$$\Box_{\mathrm{AdS}}\,\phi = \frac{z^2}{L^2}\Big(\Box_x\phi - \partial_z^2\phi + \frac{d-1}{z}\,\partial_z\phi\Big). \tag{53.104}$$

A useful consistency check: with $L \to \infty$ at fixed proper coordinates the curvature terms would drop and one recovers the flat $(d+1)$-dimensional wave operator $\Box_x - \partial_z^2$, the radial direction entering with the spacelike sign as it must. Inserting Eq. (53.104) into the equation of motion Eq. (53.101) and multiplying through by L^2/z^2 gives the form we will analyze,

$$\boxed{-\partial_z^2\phi + \frac{d-1}{z}\,\partial_z\phi + \frac{m^2L^2}{z^2}\,\phi + \Box_x\phi = 0.} \tag{53.105}$$

Every factor of L and z in Eq. (53.105) traces back to the metric Eq. (53.59); nothing has been quoted.

It is convenient to Fourier transform along the boundary, writing

$$\phi(x,z)=\int\frac{\mathrm{d}^{d}k}{(2\pi)^{d}}\,e^{-ik\cdot x}\,f_{k}(z),\qquad k\cdot x=\eta_{\mu\nu}k^{\mu}x^{\nu},\tag{53.106}$$

so that $\Box_x\to -k^2$ with $k^2=\eta_{\mu\nu}k^\mu k^\nu$. The radial profile $f_k(z)$ then obeys the ordinary differential equation

$$f_k''-\frac{d-1}{z}\,f_k'-\frac{m^2L^2}{z^2}\,f_k+k^2 f_k=0.\tag{53.107}$$

This is the master equation of the section. It is a linear second-order ODE with a regular singular point at $z=0$ (the boundary) and an irregular point at $z=\infty$ (the Poincaré horizon, the deep interior). The boundary behaviour is governed entirely by the singular point, which is where we now look.

53.4.2 Near-boundary indicial analysis and the mass–dimension relation

Near $z=0$ the $k^2 f_k$ term in Eq. (53.107) is subleading: it carries no inverse power of z, whereas the other three terms scale as z^{-2} relative to f_k. The leading behaviour is therefore controlled by the scale-invariant operator obtained by dropping k^2,

$$z^2 f''-(d-1)\,z\,f'-m^2L^2\,f=0,\tag{53.108}$$

which is an Euler (equidimensional) equation: it is invariant under $z\to\lambda z$, so it is solved by pure powers. This is the Frobenius method at a regular singular point, with the indicial equation read off from the leading exponents. Substitute the trial solution

$$f(z)=z^{\Delta},\qquad f'=\Delta\,z^{\Delta-1},\qquad f''=\Delta(\Delta-1)\,z^{\Delta-2},\tag{53.109}$$

into Eq. (53.108). Each term produces the common factor z^Δ:

$$\begin{aligned}z^2f''&=\Delta(\Delta-1)\,z^{\Delta},\\-(d-1)zf'&=-(d-1)\Delta\,z^{\Delta},\\-m^2L^2f&=-m^2L^2\,z^{\Delta}.\end{aligned}\tag{53.110}$$

Requiring their sum to vanish and dividing by z^Δ gives the *indicial equation*,

$$\begin{aligned}\Delta(\Delta-1)-(d-1)\Delta-m^2L^2&=0\\\Delta^2-\Delta-(d-1)\Delta-m^2L^2&=0\\\Delta^2-d\,\Delta-m^2L^2&=0,\end{aligned}\tag{53.111}$$

which we record in its standard factored form.

Theorem 53.17 (Mass–dimension relation)**.** *A free scalar field of mass m on AdS_{d+1} of radius L has near-boundary radial behaviour $\phi \sim z^{\Delta}$ with the exponent Δ a root of*

$$\Delta(\Delta - d) = m^2 L^2. \tag{53.112}$$

The two roots are

$$\Delta_{\pm} = \frac{d}{2} \pm \sqrt{\frac{d^2}{4} + m^2 L^2}, \qquad \Delta_+ + \Delta_- = d, \qquad \Delta_+ \, \Delta_- = -m^2 L^2. \tag{53.113}$$

The larger root $\Delta \equiv \Delta_+ \geq d/2$ is identified with the scaling dimension of the dual boundary operator.

Proof. Equation Eq. (53.112) is Eq. (53.111) rewritten: expanding $\Delta(\Delta - d) = \Delta^2 - d\Delta$ reproduces $\Delta^2 - d\Delta - m^2 L^2 = 0$. Solving the quadratic by completing the square,

$$\Delta^2 - d\Delta = m^2 L^2 \implies \left(\Delta - \tfrac{d}{2}\right)^2 = \frac{d^2}{4} + m^2 L^2 \implies \Delta = \frac{d}{2} \pm \sqrt{\frac{d^2}{4} + m^2 L^2}, \tag{53.114}$$

which is Eq. (53.113). The sum and product of the roots are the Vieta relations of the monic quadratic $\Delta^2 - d\Delta - m^2 L^2 = 0$: the sum of roots equals d and the product equals $-m^2 L^2$. The identification $\Delta = \Delta_+$ with the operator dimension is justified physically in Section 53.4.3 (normalizability) and confirmed against the unitarity bound in Section 53.4.5. □

Two limiting cases anchor the relation. A massless bulk scalar, $m^2 = 0$, gives $\Delta_+ = d$ and $\Delta_- = 0$: it is dual to a marginal operator of dimension d, the prototype being the Lagrangian density or, more precisely in the maximally supersymmetric example, the boundary stress-tensor multiplet's scalar partners. At the other extreme, large positive $m^2 L^2$ gives $\Delta_+ \approx mL$ for $mL \gg 1$, the expected flat-space-like growth of dimension with mass. The novelty lives at negative m^2, to which we return in Section 53.4.4.

The full local solution near $z = 0$ is obtained by promoting the two indicial roots to the leading terms of two Frobenius series. Restoring the k^2 term in Eq. (53.107) and substituting $f = z^{\Delta_\pm} \sum_{n \geq 0} c_n^{(\pm)} z^{2n}$ (only even powers of z appear because k^2 enters z^2 at a time), one finds the generic solution

$$f_k(z) = \alpha(k)\, z^{\Delta_-} \left(1 + O(z^2)\right) + \beta(k)\, z^{\Delta_+} \left(1 + O(z^2)\right), \tag{53.115}$$

valid whenever the exponents do not differ by an even integer (the degenerate cases are discussed below). The two integration constants α and β are the boundary data of the field, and the entire physics of the dictionary hinges on

their interpretation. Returning to position space, the leading near-boundary expansion of any bulk solution is

$$\phi(x,z) \xrightarrow{z\to 0} \alpha(x)\, z^{\Delta_-} + \cdots + \beta(x)\, z^{\Delta_+} + \ldots, \tag{53.116}$$

the two independent falloffs whose coefficients $\alpha(x)$ and $\beta(x)$ are functions on the boundary.

Caution

When $\Delta_+ - \Delta_- = 2\sqrt{d^2/4 + m^2L^2}$ is a positive even integer, the two Frobenius series collide: a term $z^{\Delta_- + 2n}$ in the first series degenerates with the leading z^{Δ_+} of the second, and the subleading solution acquires a logarithm, $\phi \sim \alpha z^{\Delta_-} + \cdots + \beta z^{\Delta_+} \log z + \ldots$. The most important instance is the Breitenlohner–Freedman point $\Delta_+ = \Delta_- = d/2$ (Section 53.4.4), where the two solutions are $z^{d/2}$ and $z^{d/2}\log z$. These logarithms are not pathologies; they are the holographic signature of operator mixing and of the conformal anomaly, and they are handled by the same renormalization of the on-shell action that Chapter 54 will set up. For the present structural discussion the generic case Eq. (53.115) suffices.

53.4.3 Source versus vacuum expectation value: the two modes

The two falloffs in Eq. (53.116) play sharply different roles, and the distinction is the seed of the whole field–operator dictionary. The decisive property is *normalizability*: whether a mode has finite norm under the inner product that defines the field's Hilbert space. A mode of finite norm is a genuine fluctuating degree of freedom — a state — whereas a mode of infinite norm is not normalizable and must instead be held fixed as a boundary condition, a non-dynamical background that the bulk solution is required to approach.

The relevant norm is the Klein–Gordon (symplectic) inner product associated with the action Eq. (53.100). On a constant-time slice Σ (coordinates z and the spatial $\vec{x}$), it reads

$$(\phi_1, \phi_2) = -i \int_\Sigma \mathrm{d}z\, \mathrm{d}^{d-1}x\, \sqrt{|g|}\, g^{00} (\phi_1^* \,\partial_0 \phi_2 - \phi_2\, \partial_0 \phi_1^*), \tag{53.117}$$

the curved-space version of the flat Klein–Gordon product of Chapter 9. Convergence of Eq. (53.117) is controlled entirely by the z-integral near $z = 0$, where the integrand's measure factor is

$$\sqrt{|g|}\, g^{00} = \left(\frac{L}{z}\right)^{d+1} \left(\frac{z}{L}\right)^2 \eta^{00} = \left(\frac{L}{z}\right)^{d-1}, \tag{53.118}$$

using Eqs. (53.98) and (53.99) and $\eta^{00} = +1$. For a mode behaving as $\phi \sim z^\Delta$ near the boundary, the time derivatives in Eq. (53.117) do not change the radial

power, so the near-boundary contribution to the norm scales as

$$(\phi,\phi) \;\sim\; \int_0 \mathrm{d}z \left(\frac{L}{z}\right)^{d-1} |z^{\Delta}|^2 \;=\; L^{d-1}\int_0 \mathrm{d}z\, z^{\,2\Delta-d+1}. \tag{53.119}$$

The integral $\int_0 \mathrm{d}z\, z^{2\Delta-d+1}$ converges at the lower limit if and only if the exponent exceeds -1, i.e.

$$2\Delta - d + 1 > -1 \quad\Longleftrightarrow\quad \Delta > \frac{d-2}{2}. \tag{53.120}$$

Theorem 53.18 (Normalizability of the two modes)**.** *A near-boundary mode $\phi \sim z^{\Delta}$ on AdS_{d+1} is normalizable in the Klein–Gordon norm Eq. (53.117) if and only if $\Delta > (d-2)/2$. Consequently:*

1. *the larger-root mode z^{Δ_+} is* always *normalizable, since $\Delta_+ \geq d/2 > (d-2)/2$ for every m^2 in the allowed range;*
2. *the smaller-root mode z^{Δ_-} is non-normalizable, hence a fixed boundary condition (a* source*), whenever $\Delta_- \leq (d-2)/2$; it becomes normalizable only in the window discussed in Section 53.4.4.*

Proof. The condition $\Delta > (d-2)/2$ is Eq. (53.120), derived directly from the convergence of Eq. (53.119). For item (1), $\Delta_+ = \frac{d}{2} + \sqrt{d^2/4 + m^2L^2} \geq \frac{d}{2}$ because the square root is non-negative wherever it is real, and $\frac{d}{2} > (d-2)/2$ by one unit; hence the strict inequality Eq. (53.120) always holds for Δ_+. For item (2), $\Delta_- = \frac{d}{2} - \sqrt{d^2/4 + m^2L^2} \leq \frac{d}{2}$, and one checks below (Section 53.4.4) that $\Delta_- \leq (d-2)/2$ precisely when $\sqrt{d^2/4 + m^2L^2} \geq 1$, which is the generic situation; the borderline $\sqrt{d^2/4 + m^2L^2} < 1$ is the alternate-quantization window. □

The interpretation now writes itself, and it is the central conceptual payload of the section.

Physical Insight

The two falloffs are a source and a response. Standard (Dirichlet-like) quantization holds the slower-decaying, non-normalizable mode $\alpha(x)$ fixed: it is not a fluctuating field but a *boundary condition* the bulk solution must satisfy. On the field-theory side, fixing $\alpha(x)$ corresponds to turning on a *source* $J(x)$ that couples to a boundary operator $\mathcal{O}$ through a term $\int \mathrm{d}^d x\, J(x)\,\mathcal{O}(x)$ added to the CFT action. Dimensional analysis pins which is which: for the coupling to be dimensionless the source must carry dimension $[J] = d - \Delta$. Reading off from $\alpha(x) z^{\Delta_-}$, the boundary value α has scaling dimension $\Delta_- = d - \Delta_+$, so it is the source for an operator of dimension Δ_+. The faster-decaying, normalizable mode $\beta(x)$ is then the field's dynamical *response*: it is proportional to the induced expectation value $\langle \mathcal{O}(x) \rangle$ in the presence of that source. The bulk field

ϕ of mass m is therefore dual to a boundary operator $\mathcal{O}$ of dimension Δ_+, with the non-normalizable falloff playing the role of $\mathcal{O}$'s source and the normalizable falloff its one-point function. This is precisely the data Chapter 54's GKP–Witten relation turns into correlators.

The dimensional argument deserves to be stated as the operator-dimension assignment, since it is the result the next section consumes. The bulk solution is dimensionless (it is a scalar field value), and z carries dimension of length, i.e. inverse mass, $[z] = -1$ in mass units. Then $[\alpha\, z^{\Delta_-}] = 0$ forces $[\alpha] = \Delta_-$ and likewise $[\beta] = \Delta_+$. Identifying α with the source J of an operator $\mathcal{O}$ and recalling that a source has dimension d minus the dimension of the operator it multiplies, $[J] = d - \Delta_{\mathcal{O}}$, we get $\Delta_- = d - \Delta_{\mathcal{O}}$, hence

$$\Delta_{\mathcal{O}} = d - \Delta_- = \Delta_+, \tag{53.121}$$

where the last step used $\Delta_+ + \Delta_- = d$ from Eq. (53.113). The operator dual to a bulk scalar of mass m has dimension Δ_+. We will write $\Delta \equiv \Delta_+$ from now on, reserving the subscript for emphasis.

53.4.4 The Breitenlohner–Freedman bound and the alternate-quantization window

Flat-space intuition insists that $m^2 < 0$ signals an instability: a tachyon, a field rolling off the top of an inverted potential. In AdS this intuition fails, and the reason is geometric. The negative curvature provides a confining "box" of size L, and the gradient energy stored in fitting a fluctuation into that box can outweigh the negative potential energy $-\frac{1}{2}m^2\phi^2$ even when $m^2 < 0$ — provided m^2 is not too negative. The sharp threshold is the Breitenlohner–Freedman (BF) bound. We derive it twice, first as the reality condition on Δ and then, rigorously, as the positivity of the conserved energy; the two derivations meet at the same number.

Reality of the dimension. The exponents Eq. (53.113) are real if and only if the discriminant is non-negative,

$$\frac{d^2}{4} + m^2 L^2 \;\geq\; 0 \qquad \Longleftrightarrow \qquad m^2 L^2 \;\geq\; -\frac{d^2}{4}. \tag{53.122}$$

Below this value $\Delta_\pm$ acquire imaginary parts, $\Delta_\pm = \frac{d}{2} \pm i|\,\cdot\,|$, and the near-boundary behaviour $z^{d/2} z^{\pm i|\cdot|} = z^{d/2} e^{\pm i|\cdot| \log z}$ oscillates ever faster as $z \to 0$. Such a complex dimension cannot belong to a unitary CFT (Theorem 47.18 requires real Δ), and on the gravity side it signals a genuine instability of the AdS vacuum. The reality condition Eq. (53.122) is the BF bound. It is the precise statement that AdS tolerates tachyons down to a finite negative mass-squared floor set by the radius.

Positivity of the energy. The reality argument is suggestive but a stability claim deserves a dynamical proof: the conserved energy of every fluctuation must be bounded below, with the bound saturated exactly at Eq. (53.122). We establish this by reducing the radial problem to a one-dimensional Schrödinger operator and invoking a sharp functional inequality.

Consider a static fluctuation, $\partial_0\phi = 0$ and $\vec{\partial}\phi = 0$, depending only on the radial coordinate, $\phi = \phi(z)$; this is the channel that probes the deepest into negative m^2 because it carries no boundary kinetic energy. Its energy is the value of the Hamiltonian, which for the action Eq. (53.100) on a static configuration is minus the Lagrangian; collecting the radial-gradient and mass terms with the measure factors from Eqs. (53.98) and (53.99) (and dropping the infinite boundary volume $\int \mathrm{d}^{d-1}x$),

$$E[\phi] = \frac{1}{2}\int_0^\infty \mathrm{d}z\,\Big[\Big(\frac{L}{z}\Big)^{d-1}(\phi')^2 + m^2\Big(\frac{L}{z}\Big)^{d+1}\phi^2\Big] = \frac{L^{d-1}}{2}\int_0^\infty \mathrm{d}z\,\Big[z^{-(d-1)}(\phi')^2 + m^2L^2\,z^{-(d+1)}\phi^2\Big], \tag{53.123}$$

where the gradient term used $\sqrt{|g|}\,|g^{zz}| = (L/z)^{d-1}$ and the mass term used $\sqrt{|g|} = (L/z)^{d+1}$. Stability is the statement $E[\phi] \geq 0$ for all admissible ϕ. The negative m^2 contribution can in principle make Eq. (53.123) negative; whether it does is a contest between the two terms, and the contest is decided cleanly after a change of variable that removes the first-derivative cross-structure. Set

$$\phi(z) = z^{(d-1)/2}\,\psi(z), \tag{53.124}$$

which is engineered so that the measure weight $z^{-(d-1)}$ in the gradient term is absorbed. Compute $\phi' = \frac{d-1}{2}z^{(d-3)/2}\psi + z^{(d-1)/2}\psi'$, so

$$z^{-(d-1)}(\phi')^2 = (\psi')^2 + \frac{d-1}{z}\,\psi\psi' + \frac{(d-1)^2}{4}\,\frac{\psi^2}{z^2}. \tag{53.125}$$

Integrate the cross term by parts, $\int_0^\infty \frac{d-1}{z}\psi\psi'\,\mathrm{d}z = \frac{d-1}{2}\int_0^\infty \frac{(\psi^2)'}{z}\mathrm{d}z = \frac{d-1}{2}\Big([\psi^2/z]_0^\infty + \int_0^\infty \frac{\psi^2}{z^2}\mathrm{d}z\Big)$. The boundary term vanishes for any normalizable static configuration (at $z\to\infty$ the profile decays; at $z\to 0$ the surviving boundary data is the fixed source, held to zero for a genuine fluctuation), leaving $\frac{d-1}{2}\int \psi^2/z^2$. The mass term transforms as $m^2L^2z^{-(d+1)}\phi^2 = m^2L^2z^{-(d+1)}z^{d-1}\psi^2 = m^2L^2\,\psi^2/z^2$. Assembling,

$$E[\psi] = \frac{L^{d-1}}{2}\int_0^\infty \mathrm{d}z\,\Big[(\psi')^2 + \Big(\frac{(d-1)^2}{4} + \frac{d-1}{2} + m^2L^2\Big)\frac{\psi^2}{z^2}\Big] = \frac{L^{d-1}}{2}\int_0^\infty \mathrm{d}z\,\Big[(\psi')^2 + \mathcal{C}\,\frac{\psi^2}{z^2}\Big], \tag{53.126}$$

where the dimensionless coefficient of the inverse-square potential is

$$\mathcal{C} = \frac{(d-1)^2}{4} + \frac{d-1}{2} + m^2L^2 = \frac{(d-1)(d-1)+2(d-1)}{4} + m^2L^2 = \frac{(d-1)(d+1)}{4} + m^2L^2 = \tag{53.127}$$

The energy Eq. (53.126) is, up to the overall constant, the expectation value of the Schrödinger operator $-\partial_z^2 + \mathcal{C}/z^2$ on the half-line — the celebrated inverse-square potential, whose stability threshold is a textbook-sharp number.

The positivity of Eq. (53.126) is settled by *Hardy's inequality*, which we prove since the book takes nothing on faith.

Lemma 53.19 (Hardy's inequality on the half-line)**.** *For every smooth ψ of compact support in $(0,\infty)$,*

$$\int_0^\infty (\psi')^2 \,\mathrm{d}z \;\geq\; \frac{1}{4}\int_0^\infty \frac{\psi^2}{z^2}\,\mathrm{d}z, \tag{53.128}$$

and the constant $\tfrac{1}{4}$ is the largest for which the inequality holds.

Proof. For any real constant c the integral of a perfect square is non-negative:

$$0 \leq \int_0^\infty \Big(\psi' - \frac{c\,\psi}{z}\Big)^2 \mathrm{d}z = \int_0^\infty (\psi')^2\,\mathrm{d}z - 2c\int_0^\infty \frac{\psi\psi'}{z}\,\mathrm{d}z + c^2\int_0^\infty \frac{\psi^2}{z^2}\,\mathrm{d}z. \tag{53.129}$$

The middle integral is evaluated by parts using $\psi\psi' = \tfrac{1}{2}(\psi^2)'$ and the compact support (which kills the boundary term):

$$\int_0^\infty \frac{\psi\psi'}{z}\,\mathrm{d}z = \frac{1}{2}\int_0^\infty \frac{(\psi^2)'}{z}\,\mathrm{d}z = \frac{1}{2}\Big([\psi^2/z]_0^\infty + \int_0^\infty \frac{\psi^2}{z^2}\,\mathrm{d}z\Big) = \frac{1}{2}\int_0^\infty \frac{\psi^2}{z^2}\,\mathrm{d}z. \tag{53.130}$$

Substituting Eq. (53.130) into Eq. (53.129) gives

$$0 \leq \int_0^\infty (\psi')^2\,\mathrm{d}z - (c - c^2)\int_0^\infty \frac{\psi^2}{z^2}\,\mathrm{d}z, \tag{53.131}$$

so $\int(\psi')^2 \geq (c-c^2)\int \psi^2/z^2$ for every c. The right-hand coefficient $c - c^2$ is maximized at $c = \tfrac{1}{2}$, where it equals $\tfrac{1}{4}$, yielding Eq. (53.128). Sharpness: the would-be extremizer saturating Eq. (53.129) at $c = \tfrac{1}{2}$ is $\psi' = \psi/2z$, i.e. $\psi \propto z^{1/2}$; this is not square-integrable against $\mathrm{d}z/z^2$, but a family of compactly supported functions approximating it makes the ratio $\int(\psi')^2/\int(\psi^2/z^2)$ approach $\tfrac{1}{4}$ from above, so no larger constant works. □

Applying Theorem 53.19 to Eq. (53.126),

$$E[\psi] \geq \frac{L^{d-1}}{2}\Big(\frac{1}{4} + \mathcal{C}\Big)\int_0^\infty \frac{\psi^2}{z^2}\,\mathrm{d}z, \tag{53.132}$$

which is non-negative for all fluctuations if and only if $\mathcal{C} \geq -\tfrac{1}{4}$. By the sharpness clause of the lemma, if $\mathcal{C} < -\tfrac{1}{4}$ there exist configurations with $E[\psi] < 0$, so the vacuum is unstable. Using Eq. (53.127),

$$\mathcal{C} + \frac{1}{4} = \frac{d^2-1}{4} + m^2L^2 + \frac{1}{4} = \frac{d^2}{4} + m^2L^2, \tag{53.133}$$

so $\mathcal{C} \geq -\tfrac{1}{4}$ is identical to $m^2L^2 \geq -d^2/4$. We have proved:

Theorem 53.20 (Breitenlohner–Freedman bound)**.** *A free scalar of mass-squared m^2 on AdS_{d+1} has a conserved energy that is non-negative for all fluctuations, and hence a stable vacuum, if and only if*

$$m^2L^2 \;\geq\; -\frac{d^2}{4}. \tag{53.134}$$

At saturation, $m^2L^2 = -d^2/4$, the two dimensions degenerate to $\Delta_+ = \Delta_- = d/2$ and the energy bound is marginally satisfied (the inverse-square coefficient sits exactly at the Hardy threshold $\mathcal{C} = -\frac{1}{4}$).

The two derivations agree because they are the same statement seen from two sides: reality of $\Delta_\pm$ in Eq. (53.113) requires $d^2/4 + m^2L^2 \geq 0$, and that combination is exactly $\mathcal{C} + \frac{1}{4}$, the Hardy margin of the energy. A tachyon in AdS is harmless precisely as long as its destabilizing potential energy cannot overcome the curvature-induced gradient energy quantified by Hardy's inequality.

The alternate-quantization window. The BF bound opens an interesting sub-regime. By Theorem 53.18 the smaller-root mode z^{Δ_-} is normalizable when $\Delta_- > (d-2)/2$. Writing $\nu \equiv \sqrt{d^2/4 + m^2L^2} \geq 0$ so that $\Delta_\pm = \frac{d}{2} \pm \nu$, the condition $\Delta_- = \frac{d}{2} - \nu > \frac{d-2}{2} = \frac{d}{2} - 1$ reads simply $\nu < 1$. Squaring, $\nu^2 = d^2/4 + m^2L^2 < 1$, i.e.

$$\boxed{-\frac{d^2}{4} \;\leq\; m^2L^2 \;<\; -\frac{d^2}{4} + 1.} \tag{53.135}$$

In this window *both* falloffs are normalizable, and one is free to choose which mode to hold fixed as the source. The standard choice assigns the boundary operator dimension Δ_+; the *alternate quantization* instead fixes β and lets α fluctuate, producing a dual operator of dimension Δ_-. The two choices are distinct CFTs related by a Legendre transform (a double-trace flow), a structure Chapter 54 will revisit. Outside the window, $\nu \geq 1$, the slower mode is non-normalizable and only the standard quantization with $\Delta = \Delta_+$ is available. Figure 53.6 displays the whole landscape: the two roots as functions of m^2L^2, the BF floor where they merge, the unitarity bound they must respect, and the alternate-quantization strip.

53.4.5 Consistency with the CFT unitarity bound

The identification $\Delta = \Delta_+$ is only admissible if the resulting dimension is one a unitary CFT can actually carry. The relevant constraint is the scalar unitarity bound proved in Chapter 47 from positivity of the conformal Hilbert space: a scalar primary in $d \geq 2$ obeys

$$\Delta \;\geq\; \frac{d-2}{2}, \tag{53.136}$$

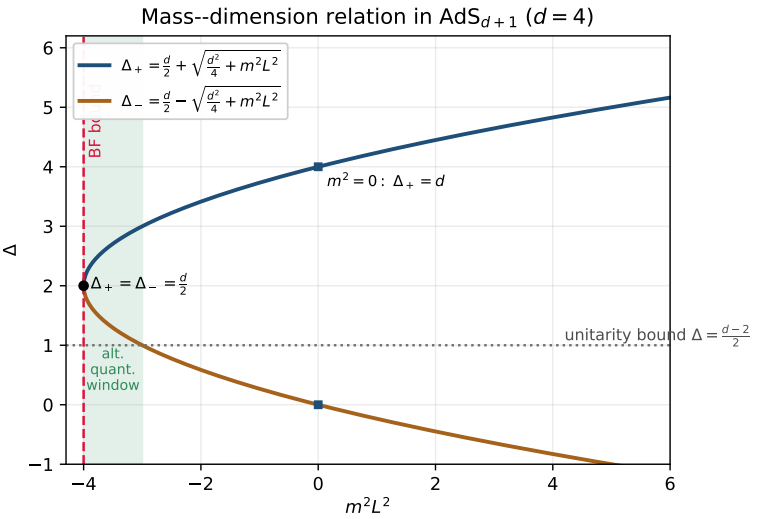


Figure 53.6: The mass–dimension relation $\Delta(\Delta - d) = m^2L^2$ for AdS$_{d+1}$ with $d = 4$. The two branches $\Delta_\pm = \frac{d}{2} \pm \sqrt{d^2/4 + m^2L^2}$ meet at the Breitenlohner–Freedman point $m^2L^2 = -d^2/4$, $\Delta = d/2$ (black dot). To the left of the BF bound (red dashed) the dimensions become complex and the AdS vacuum is unstable. The shaded strip $-d^2/4 \le m^2L^2 < -d^2/4 + 1$ is the alternate-quantization window, where both modes are normalizable. The dotted line marks the scalar unitarity bound $\Delta = (d-2)/2$ of Theorem 47.18: the upper branch Δ_+ never dips below it, and the lower branch Δ_- touches it exactly at the right edge of the window. The massless point $m^2 = 0$ gives $\Delta_+ = d$, a marginal operator.

with equality only for a free field (Theorem 47.18). We check that Δ_+ from Eq. (53.113) respects Eq. (53.136) for every mass allowed by the BF bound.

Proposition 53.21 (Holographic dimensions are unitary)**.** *For all $m^2L^2 \ge -d^2/4$, the standard-quantization dimension $\Delta_+ = \frac{d}{2} + \sqrt{d^2/4 + m^2L^2}$ satisfies the scalar unitarity bound Eq. (53.136), with equality nowhere in the allowed range; and the alternate-quantization dimension Δ_-, defined only in the window Eq. (53.135), satisfies it as well, saturating it exactly at the window's upper edge.*

Proof. For the standard branch, $\Delta_+ \ge \frac{d}{2}$ as noted in Theorem 53.17, and $\frac{d}{2} - \frac{d-2}{2} = 1 > 0$, so

$$\Delta_+ \ge \frac{d}{2} = \frac{d-2}{2} + 1 > \frac{d-2}{2}, \tag{53.137}$$

strictly above the bound by at least one unit for every admissible m^2; the bound is never saturated by Δ_+, consistent with the fact that a generic bulk scalar is dual to an interacting (non-free) operator. For the alternate branch, write

$\Delta_- = \frac{d}{2} - \nu$ with $0 \le \nu < 1$ throughout the window Eq. (53.135). Then

$$\Delta_- = \frac{d}{2} - \nu \; > \; \frac{d}{2} - 1 = \frac{d-2}{2}, \tag{53.138}$$

so Δ_- lies strictly above the unitarity bound for $\nu < 1$ and approaches it as $\nu \to 1^-$, i.e. as $m^2L^2 \to (-d^2/4+1)^-$. Exactly at $\nu = 1$ the window closes and $\Delta_- = (d-2)/2$ would equal the free-field value; this is the boundary case where the alternate operator becomes free, consistent with the unitarity bound being saturated only by free fields. □

The agreement is a genuine consistency check, not a definition: the unitarity bound Eq. (53.136) was derived in Chapter 47 purely from the representation theory of the conformal algebra, with no reference to a bulk, while Δ_+ here came from solving a wave equation in a $(d+1)$-dimensional geometry. That the two independently computed inequalities are compatible — and that the alternate-quantization window closes exactly where Δ_- would otherwise violate unitarity — is one of the first quantitative signs that the bulk and boundary descriptions are describing the same physics.

Worked Example 53.22 (Reading dimensions off explicit masses)**.** We collect the dimension assignments for several representative bulk scalars in AdS_5 ($d = 4$), the case relevant to the maximally supersymmetric example, and exhibit the exact radial solutions that make the falloff structure manifest. With $d = 4$ the roots are $\Delta_\pm = 2 \pm \sqrt{4 + m^2L^2}$.

(i) Massless scalar, $m^2 = 0$. Then $\Delta_+ = 4$, $\Delta_- = 0$. The dual operator is marginal, dimension 4; the $z^{\Delta_-} = z^0$ falloff is a constant, the source being a spacetime-constant coupling — exactly the behaviour of a marginal deformation of the boundary theory.

(ii) A BF-saturating tachyon, $m^2L^2 = -4 = -d^2/4$. The square root vanishes, $\Delta_+ = \Delta_- = 2 = d/2$. The two falloffs degenerate and (per the caution in Section 53.4.2) the second solution carries a logarithm: $\phi \sim z^2(\alpha + \beta \log z)$. The dual operator has dimension exactly $d/2 = 2$, sitting above the unitarity bound $(d-2)/2 = 1$ by one unit, as Theorem 53.21 guarantees.

(iii) A tachyon in the alternate window, $m^2L^2 = -15/4$. Here $\sqrt{4 - 15/4} = \sqrt{1/4} = 1/2 = \nu < 1$, so both modes are normalizable: $\Delta_+ = 2 + \frac{1}{2} = \frac{5}{2}$ and $\Delta_- = 2 - \frac{1}{2} = \frac{3}{2}$. Standard quantization gives a dimension-5/2 operator; alternate quantization a dimension-3/2 operator. Both exceed the unitarity bound 1.

The exact radial profile. For completeness, the full solution of the radial ODE Eq. (53.107) is available in closed form. With $\nu = \sqrt{d^2/4 + m^2L^2}$ and a Euclidean (spacelike) boundary momentum $k^2 = -q^2$, $q > 0$, substituting $f_k(z) = z^{d/2}\, h(qz)$ into Eq. (53.107) converts it into the modified Bessel equation for h,

$$(qz)^2 h'' + (qz)\, h' - \big((qz)^2 + \nu^2\big) h = 0, \tag{53.139}$$

whose solutions are the modified Bessel functions $K_\nu(qz)$ and $I_\nu(qz)$. The general radial solution is therefore

$$f_k(z) = z^{d/2}\big[A\,K_\nu(qz) + B\,I_\nu(qz)\big]. \tag{53.140}$$

Regularity in the deep interior $z \to \infty$ (the Poincaré horizon) selects K_ν, since $I_\nu(qz) \sim e^{qz}/\sqrt{qz}$ blows up while $K_\nu(qz) \sim e^{-qz}/\sqrt{qz}$ decays. Near the boundary $z \to 0$ the small-argument expansions $K_\nu(u) \sim \frac{1}{2}\Gamma(\nu)(u/2)^{-\nu} + \frac{1}{2}\Gamma(-\nu)(u/2)^{\nu}$ reproduce exactly the two falloffs of Eq. (53.115):

$$f_k(z) \xrightarrow{z\to 0} z^{d/2}\Big[c_-\,(qz)^{-\nu} + c_+\,(qz)^{\nu}\Big] = c'_-\,z^{\Delta_-} + c'_+\,z^{\Delta_+}, \tag{53.141}$$

with $\Delta_\pm = d/2 \pm \nu$. The exact solution thus confirms the indicial analysis term by term: the two near-boundary powers are precisely $\Delta_\pm$, the regular-in-the-interior solution generically excites both, and the ratio c'_+/c'_- — the response per unit source — is the object whose boundary Fourier transform will become the two-point function $\langle\mathcal{O}\mathcal{O}\rangle$ in Chapter 54.

With the mass–dimension relation Eq. (53.112) established, its roots identified, the source/vev meaning of the two falloffs fixed, and stability pinned by the BF bound Eq. (53.134), we now have the single most reused technical fact of Part XV: a bulk scalar of mass m encodes a boundary operator of dimension $\Delta_+ = \frac{d}{2} + \sqrt{d^2/4 + m^2L^2}$, with its slower, non-normalizable falloff acting as that operator's source. The next section takes this entry as the seed of the full field–operator dictionary — extending it to fields of nonzero spin and charge, matching bulk gauge symmetries to boundary global symmetries, and assembling the parameter map — before Chapter 54 converts the source-to-response relation into honest correlation functions.

53.5 The Field–Operator Dictionary

The previous section solved a single problem completely: a free scalar of mass m propagating in AdS_{d+1} has two near-boundary falloffs, $z^{d-\Delta}$ and z^{Δ}, related to the mass by the indicial equation $\Delta(\Delta - d) = m^2L^2$, with the non-normalizable mode ϕ_0 identified as an external *source* and the normalizable mode as the *vacuum expectation value* of a dual operator (Section 53.4). That was one entry. The business of this section is to turn that single lesson into a complete *dictionary*: a precise, quantum-number-by-quantum-number correspondence between the local fields of the bulk theory and the local operators of the boundary CFT. We will state the map, derive its three canonical entries (the stress tensor, conserved currents, and marginal couplings), prove that bulk gauge symmetries become boundary global symmetries, record the parameter map that locates the classical-gravity regime, and finally count how many boundary degrees of freedom a given

bulk geometry can hold — which is where the word "holographic" earns its quantitative meaning. Throughout, "boundary" means the conformal boundary of Section 53.3, on which the dual CFT_d lives, and "bulk" means the gravitational theory in AdS_{d+1}.

53.5.1 The map: bulk fields and boundary primaries

The organizing principle is symmetry. The isometry group of AdS_{d+1} is $\mathrm{SO}(2,d)$, and this is precisely the conformal group of the d-dimensional boundary (Section 53.3). A bulk field, being a field in AdS, falls into a representation of $\mathrm{SO}(2,d)$ acting as isometries; a boundary primary operator, by Theorem 47.15, falls into a representation of the same $\mathrm{SO}(2,d)$ acting as conformal transformations. The correspondence demands that these be the *same* representation. This single requirement fixes the entire kinematic content of the dictionary.

Definition 53.23 (The field–operator map)**.** The AdS/CFT dictionary associates to each bulk field Φ propagating in AdS_{d+1} a single *primary* operator $\mathcal{O}_\Phi$ of the boundary CFT_d, in such a way that Φ and $\mathcal{O}_\Phi$ carry identical quantum numbers under the common symmetry group $\mathrm{SO}(2,d)$ and under any internal symmetries:

1. the bulk mass m of Φ determines the scaling dimension Δ of $\mathcal{O}_\Phi$, through the indicial relation of Section 53.4;
2. the bulk Lorentz spin ℓ of Φ (its $\mathrm{SO}(d)$ representation as a tensor on the boundary directions) equals the spin ℓ of $\mathcal{O}_\Phi$;
3. the charge of Φ under a bulk gauge symmetry equals the charge of $\mathcal{O}_\Phi$ under the corresponding boundary global symmetry.

The non-normalizable boundary value of Φ is the field-theory *source* coupled to $\mathcal{O}_\Phi$; the normalizable mode is $\langle \mathcal{O}_\Phi \rangle$.

Three points make this more than a relabelling. First, the operators that appear are *primaries*, not descendants: descendants are obtained by acting with the momentum generator P_μ, i.e. by differentiating, and so carry no independent data; a single bulk field accounts for an entire conformal multiplet, the primary together with its tower of descendants, exactly as a single solution of the bulk wave equation generates, by acting with the isometries, an entire $\mathrm{SO}(2,d)$ orbit. Second, the operators are *single-trace*. In the large-N gauge theories for which the correspondence is sharpest (Section 53.1.1), gauge-invariant operators organize into single-trace combinations such as $\mathrm{tr}(\phi^k)$ and multi-trace products of these; the $1/N$ counting of Section 53.1.4 shows that single-trace operators create approximately stable single-particle states, while multi-trace operators create multi-particle states. A single bulk field, quantized, creates one-particle states; it is therefore dual to a single-trace operator, and multi-particle bulk states

correspond to multi-trace operators. Third, the map is a bijection *between the elementary fields of the bulk and the single-trace primaries of the boundary*: there are exactly as many propagating bulk fields as there are single-trace primaries, and the bulk Lagrangian's field content is the boundary operator spectrum read off in another language.

The precise interface to the rest of the chapter is the boundary condition that promotes the leading falloff to a source. Repeating the scalar result of Section 53.4 in the form we will feed to the generating functional,

$$\Phi(z,x) \xrightarrow{z\to 0} z^{\,d-\Delta}\left[\phi_0(x)+O(z^2)\right] + z^{\,\Delta}\left[\tfrac{1}{2\Delta-d}\,\langle\mathcal{O}(x)\rangle + O(z^2)\right], \quad (53.142)$$

where $\Delta = \Delta_+ = \frac{d}{2} + \sqrt{\frac{d^2}{4} + m^2L^2}$ is the larger root and ϕ_0 is identified with the field-theory source for $\mathcal{O} \equiv \mathcal{O}_\Phi$. We will refer to the leading condition $\Phi(z\to 0) \sim z^{d-\Delta}\phi_0(x)$ as the *GKPW boundary condition*: it is the boundary datum we hold fixed in the bulk variational problem, and the next section will differentiate the on-shell action with respect to ϕ_0 to extract correlators of $\mathcal{O}$.

53.5.2 The three canonical entries

Every realization of the correspondence shares three universal operators, because every local CFT has them and every gravitational bulk has the fields dual to them. We derive each from two sides — the boundary unitarity/conservation constraint of Chapter 47, and the bulk falloff — and check that they agree.

The stress tensor. Every local quantum field theory possesses a conserved, symmetric stress tensor $T_{\mu\nu}$, constructed in Theorem 7.10 as the Noether current of spacetime translations and made symmetric and traceless in Theorem 7.45. In a CFT, $T_{\mu\nu}$ is a primary of spin $\ell = 2$ whose dimension is fixed: the conserved charges $P_\mu = \int d^{d-1}x\, T^0{}_\mu$ must be dimensionless generators of translations, so $[T_{\mu\nu}] = d$, i.e. $\Delta_T = d$. This is not an accident of dimensional analysis but a consequence of conformal representation theory: a spin-2 primary obeys the unitarity bound $\Delta \geq d$ of Theorem 47.18, with equality *iff* $\partial^\mu T_{\mu\nu} = 0$. The worked example Theorem 47.19 showed precisely that the divergence descendant $P^\mu\,|T_{\mu\nu}\rangle$ has norm proportional to $\Delta - d$, so conservation is the statement that this null state decouples, forcing $\Delta_T = d$. On the bulk side, the field dual to $T_{\mu\nu}$ must be a spin-2 field whose dimension comes out to d: that is the metric fluctuation, the graviton g_{MN}. The presence of a dynamical graviton in the bulk is therefore equivalent to the presence of a stress tensor in the boundary theory — and conversely, *any* CFT, having a stress tensor, is dual to a theory of gravity. This is the structural reason the bulk is gravitational.

Conserved currents. A continuous global symmetry of the boundary CFT supplies, by Noether's theorem (Theorem 7.10), a conserved current J^μ. It is a

spin-1 primary, and conservation $\partial_\mu J^\mu = 0$ saturates the spin-1 unitarity bound $\Delta \geq d-1$: in Theorem 47.19 the divergence state $P^\mu |J_\mu\rangle$ was shown to have norm $\propto [\Delta - (d-1)]$, null exactly when $\Delta = d-1$. So a conserved current is a spin-1 primary of dimension $\Delta_J = d-1$. The bulk field carrying spin 1 and reproducing this dimension is a gauge field A_M. Each boundary global symmetry is thus dual to a bulk gauge field; the next subsection promotes this correspondence into a theorem about how the symmetries themselves are related.

Marginal operators. A massless bulk scalar, $m = 0$, has $\Delta(\Delta - d) = 0$, hence $\Delta = d$ (the larger root). A scalar primary of dimension exactly d is *marginal*: the integrated operator $\int d^d x\, \mathcal{O}$ is dimensionless and can be added to the action as a coupling that preserves conformal invariance at leading order. The bulk avatar of such a deformation is shifting the boundary value ϕ_0 of the massless scalar to a constant, which changes a bulk coupling constant; on the boundary this is turning on a marginal coupling. The prototype is the dilaton, whose constant boundary value is the string coupling, dual to the gauge coupling — an entry we make precise in Section 53.5.4.

It remains to verify, on the bulk side, that a massless spin-1 field reproduces $\Delta = d-1$ and a massless spin-2 field reproduces $\Delta = d$. For the scalar this was the content of Section 53.4. For spin we carry out the vector indicial analysis explicitly; the tensor case is identical in structure and we state its result.

Worked Example 53.24 (Falloff of a massive bulk vector and the current dimension)**.** Work in the Poincaré patch with metric $\mathrm{d}s^2 = (L^2/z^2)(\eta_{\mu\nu}\mathrm{d}x^\mu \mathrm{d}x^\nu - \mathrm{d}z^2)$ (recall Eq. (53.59), mostly-minus), bulk indices $M = (z, \mu)$, and a massive vector field A_M governed by the Proca equation, which in the book's mostly-minus signature reads

$$\frac{1}{\sqrt{|g|}}\,\partial_M\!\left(\sqrt{|g|}\,F^{MN}\right) = -m^2 A^N, \qquad F_{MN} = \partial_M A_N - \partial_N A_M. \tag{53.143}$$

The near-boundary falloff is governed by the leading z-behavior at vanishing boundary momentum, so set $\partial_\mu(\,\cdot\,) \to 0$ and seek a solution of the boundary-component equation with $A_z = 0$ and $A_\nu = z^\alpha a_\nu$, a_ν constant. With $\sqrt{|g|} = (L/z)^{d+1}$ and $g^{MN} = (z/L)^2\,\eta^{MN}$ (boundary block) and $g^{zz} = -(z/L)^2$, the only nonzero field strength is $F_{z\nu} = \partial_z A_\nu = \alpha z^{\alpha-1} a_\nu$. Raising indices,

$$F^{z\nu} = g^{zz} g^{\nu\rho} F_{z\rho} = -\Big(\frac{z}{L}\Big)^4 \alpha z^{\alpha-1} a^\nu = -\frac{\alpha}{L^4}\, z^{\alpha+3} a^\nu. \tag{53.144}$$

Then

$$\sqrt{|g|}\,F^{z\nu} = L^{d+1} z^{-(d+1)} \cdot \Big(-\frac{\alpha}{L^4}\Big) z^{\alpha+3} a^\nu = -\alpha L^{d-3}\, z^{\alpha-d+2} a^\nu,$$
$$\partial_z\!\left(\sqrt{|g|}\,F^{z\nu}\right) = -\alpha(\alpha - d + 2) L^{d-3}\, z^{\alpha-d+1} a^\nu,$$

$$\frac{1}{\sqrt{|g|}}\partial_z(\sqrt{|g|}\,F^{z\nu}) = \frac{z^{d+1}}{L^{d+1}}\cdot(-\alpha(\alpha-d+2)L^{d-3})z^{\alpha-d+1}a^\nu = -\frac{\alpha(\alpha-d+2)}{L^4}\,z^{\alpha+2}a^\nu. \tag{53.145}$$

The right-hand side of Eq. (53.143) is $-m^2A^\nu = -m^2 g^{\nu\rho}A_\rho = -m^2(z/L)^2 z^\alpha a^\nu = -(m^2/L^2)z^{\alpha+2}a^\nu$. Matching the coefficient of $z^{\alpha+2}$ (the overall minus signs cancel) gives the *vector indicial equation*

$$\alpha\,(\alpha-d+2) = m^2L^2. \tag{53.146}$$

Its roots are $\alpha_\pm = \frac{d-2}{2} \pm \sqrt{\frac{(d-2)^2}{4} + m^2L^2}$. The smaller root α_- is the source falloff (non-normalizable), the larger α_+ the vev falloff; the dimension of the dual spin-1 operator is $\Delta = \alpha_+ + 1$, equivalently $m^2L^2 = (\Delta-1)(\Delta-d+1)$, the spin-1 version of the mass–dimension relation. For the massless field $m = 0$ the roots are $\alpha = 0$ and $\alpha = d-2$: the source mode is the *constant* boundary value $A_\nu \to a_\nu(x)$, a background gauge field, and the vev mode falls as z^{d-2}, giving

$$\Delta_J = (d-2)+1 = d-1, \tag{53.147}$$

exactly the dimension forced on a conserved current by boundary unitarity in Theorem 47.19. The two derivations agree.

The graviton repeats this verbatim with the spin-2 wave operator on AdS_{d+1}. The transverse-traceless metric fluctuation $h_{\mu\nu} = g_{\mu\nu} - \bar{g}_{\mu\nu}$ obeys, at zero momentum, $h_{\mu\nu} = z^\beta h^0_{\mu\nu}$ with indicial equation $\beta(\beta-d) = m^2L^2$ shifted to the spin-2 form $m^2L^2 = (\Delta+\ell-2)(\Delta-\ell-d+2)$ at $\ell = 2$; for the massless graviton, $m = 0$, the roots are $\beta = 0$ (source: the boundary metric $g^{(0)}_{\mu\nu}$) and $\beta = d$ (vev: $\langle T_{\mu\nu}\rangle$), so

$$\Delta_T = d, \tag{53.148}$$

matching the conserved spin-2 result of Theorem 47.19. The general spin-ℓ pattern, valid for $\ell \geq 1$, is $m^2L^2 = (\Delta+\ell-2)(\Delta-\ell-d+2)$; it reproduces the unitarity-saturating value $\Delta = \ell + d - 2$ for every massless (conserved) bulk field, and $\Delta > \ell + d - 2$ for massive bulk fields, the dual of the statement (Theorem 47.19) that interacting CFTs carry no conserved higher-spin currents beyond $T_{\mu\nu}$. The scalar is *not* the $\ell = 0$ special case of this formula — the bulk "mass" is normalized differently for a tensor field — and obeys instead the relation $\Delta(\Delta-d) = m^2L^2$ of Eq. (53.112), so that a massless scalar is the marginal $\Delta = d$ rather than $\Delta = d-2$.

We assemble the canonical dictionary in Table 53.2.

53.5.3 Gauge symmetries become global symmetries

We saw that a boundary global symmetry is dual to a bulk gauge field. The relationship between the *symmetry operations* is sharper than the relationship

Bulk field Φ	**Boundary operator $\mathcal{O}_\Phi$**	**spin ℓ**	**dimension Δ**
scalar, mass m	scalar primary $\mathcal{O}$	0	$\frac{d}{2}+\sqrt{\frac{d^2}{4}+m^2L^2}$
massless scalar	marginal operator	0	d
gauge field A_M	conserved current J^μ	1	$d-1$
graviton g_{MN}	stress tensor $T_{\mu\nu}$	2	d
massive vector, mass m	spin-1 primary	1	$\frac{d}{2}+\sqrt{\frac{(d-2)^2}{4}+m^2L^2}$
Dirac field, mass m	fermionic primary	$\frac{1}{2}$	$\frac{d}{2}+\lvert m\rvert L$

Table 53.2: The field–operator dictionary: each bulk field is dual to a single-trace boundary primary of matching spin, with dimension fixed by the bulk mass through the spin-ℓ indicial relation. The fermion entry uses the first-order Dirac indicial analysis ($\Delta=\frac{d}{2}+|m|L$).

between the operators, and it is the cleanest illustration of how a redundancy in the bulk becomes a physical symmetry on the boundary.

Proposition 53.25 (Bulk gauge ⇒ boundary global)**.** *Let A_M be a bulk gauge field dual to the boundary current J^μ, with bulk gauge transformations $A_M\to A_M+\partial_M\lambda$. Gauge transformations whose parameter λ vanishes at the conformal boundary are pure bulk redundancies and act trivially on boundary data. Gauge transformations whose parameter approaches a nonzero boundary value $\lambda(z\to 0,x)=\lambda_0(x)$ act on the source $a_\mu(x)$ for J^μ as the background-gauge transformation $a_\mu\to a_\mu+\partial_\mu\lambda_0$, and a* constant *$\lambda_0$ implements the boundary global symmetry rotation under which J^μ is the Noether current.*

Proof. By Theorem 53.24 the source for J^μ is the leading boundary value $a_\mu(x)=A_\mu(z\to 0,x)$, the non-normalizable mode with $\alpha=0$. Under a bulk gauge transformation $A_\mu\to A_\mu+\partial_\mu\lambda$, the boundary value transforms as

$$a_\mu(x)\;\to\; a_\mu(x)+\partial_\mu\lambda_0(x),\qquad \lambda_0(x)\equiv\lim_{z\to 0}\lambda(z,x). \tag{53.149}$$

If $\lambda_0\equiv 0$ the source is unchanged and, since the boundary partition function depends on A_M only through the boundary datum a_μ that it imposes (the content of the GKPW boundary condition Eq. (53.142) applied to the vector), the entire boundary physics is untouched: such "small" gauge transformations are redundancies of the bulk description with no boundary counterpart. This is the standard fact that local gauge symmetry is not a symmetry but a redundancy; what is special here is the role of the boundary value.

When $\lambda_0\neq 0$ the transformation is "large": it changes the source. The source a_μ is the field-theory background gauge field that couples to the current through $\delta S_{\rm CFT}=\int d^dx\, a_\mu J^\mu$. Equation Eq. (53.149) is then precisely a background-gauge

transformation of the boundary theory, under which the generating functional is invariant by the conservation Ward identity $\partial_\mu J^\mu = 0$ (this is the defining property of coupling a conserved current to a background field). For *constant* $\lambda_0 = \theta$, the shift $a_\mu \to a_\mu$ is trivial on the source but acts on charged operators by the rigid phase rotation generated by the conserved charge $Q = \int d^{d-1}x\, J^0$: it is the boundary global symmetry transformation $\mathcal{O} \to e^{i\theta\, q}\mathcal{O}$ for an operator of charge q. Thus the global symmetry group of the boundary is the boundary value of the bulk gauge group, and J^μ is its Noether current. □

The same logic, applied to the metric, identifies bulk diffeomorphisms with boundary stress-tensor conservation.

Proposition 53.26 (Bulk diffeomorphisms ⇒ stress-tensor conservation)**.** *The source for $T_{\mu\nu}$ is the boundary metric $g^{(0)}_{\mu\nu}$, the leading value of the bulk metric on the conformal boundary. A bulk diffeomorphism generated by a vector ξ^M with boundary value $\xi^\mu(x)$ acts on the source as $\delta g^{(0)}_{\mu\nu} = \nabla_\mu \xi_\nu + \nabla_\nu \xi_\mu$, and invariance of the boundary generating functional under this shift is the conservation law $\nabla_\mu \langle T^{\mu\nu} \rangle = 0$.*

Proof. By Eq. (53.148) the source for the spin-2 primary $T_{\mu\nu}$ is the $\beta = 0$ boundary value of the metric, $g^{(0)}_{\mu\nu}(x) = \lim_{z\to 0} (z/L)^2 g_{\mu\nu}(z, x)$ (the conformal factor stripping off the Weyl weight). The stress tensor couples to a background metric through $\delta S_{\mathrm{CFT}} = \frac{1}{2}\int d^d x \sqrt{-g^{(0)}}\, T^{\mu\nu} \delta g^{(0)}_{\mu\nu}$, the very definition of $T_{\mu\nu}$ as the response to a metric variation that underlies the Belinfante–Rosenfeld construction of Theorem 7.32. A bulk diffeomorphism $x^M \to x^M + \xi^M$ that preserves the asymptotic form of the metric acts on the boundary metric as a boundary diffeomorphism, $\delta g^{(0)}_{\mu\nu} = \nabla_\mu \xi_\nu + \nabla_\nu \xi_\mu$ (the Lie derivative of $g^{(0)}$ along ξ^μ). Substituting into the coupling and integrating by parts,

$$\delta S_{\mathrm{CFT}} = \int d^d x \sqrt{-g^{(0)}}\, T^{\mu\nu} \nabla_\mu \xi_\nu = -\int d^d x \sqrt{-g^{(0)}}\, \xi_\nu\, \nabla_\mu T^{\mu\nu}. \tag{53.150}$$

Bulk diffeomorphism invariance forces $\delta S_{\mathrm{CFT}} = 0$ for all ξ, hence $\nabla_\mu \langle T^{\mu\nu} \rangle = 0$: the boundary stress tensor is conserved precisely because the bulk theory is diffeomorphism invariant. Tracelessness $\langle T^\mu{}_\mu \rangle = 0$, the second hallmark of a CFT stress tensor (Theorem 7.45), arises in the same way from invariance under bulk diffeomorphisms that rescale z and so Weyl-rescale $g^{(0)}$. □

Physical Insight: No global symmetries in quantum gravity

Theorem 53.25 runs in a definite direction: every boundary global symmetry descends from a bulk *gauge* symmetry, and every conserved current is dual to a bulk gauge field. There is no bulk construction that produces a boundary global symmetry without a corresponding bulk gauge field.

Read on the gravity side, this is the holographic incarnation of the folklore that *a consistent theory of quantum gravity has no global symmetries*: any would-be global symmetry must be gauged. The dictionary makes the slogan precise — a global symmetry of the CFT is a gauge symmetry of the bulk, seen from the boundary.

53.5.4 The parameter map

The dictionary so far is kinematic: it matches representations. To use the correspondence as a computational tool one also needs the *parameter map* relating the dimensionless couplings of the two descriptions, because the entire utility of holography rests on the two theories being weakly coupled in opposite regimes. We state the canonical entries, flagging honestly (per the chapter's theorem-versus-conjecture contract) that the specific numerical map below is read off from the string construction of Section 53.2.3 and is part of the *conjectured* correspondence, whereas the symmetry and dimension entries above are forced by representation theory alone.

The boundary theory is characterized by its rank N and 't Hooft coupling $\lambda_{\rm tH} = g_{\rm YM}^2 N$ (the combination held fixed in the large-N expansion of Section 53.1.1). The bulk is characterized by the AdS radius L measured in string units ℓ_s and in Planck units $\ell_{\rm P}$, and by the string coupling g_s. The prototype correspondence (Section 53.2.3) fixes

$$\frac{L^4}{\ell_s^4} = \lambda_{\rm tH} = g_{\rm YM}^2 N, \qquad g_s \sim g_{\rm YM}^2 \sim \frac{\lambda_{\rm tH}}{N}. \tag{53.151}$$

Two limits are now legible. Suppressing stringy effects requires the curvature radius to be large in string units, $L \gg \ell_s$, i.e. $\lambda_{\rm tH} \gg 1$: *strong* 't Hooft coupling makes the bulk look like a smooth geometry rather than a fuzzy string. Suppressing quantum-gravity (loop) effects requires the string coupling to be small, $g_s \ll 1$ at fixed $\lambda_{\rm tH}$, i.e. $N \to \infty$: *large* N makes the bulk classical. Together,

$$\boxed{\text{classical gravity in AdS} \iff N \to \infty,\ \lambda_{\rm tH} \to \infty} \tag{53.152}$$

which is exactly the regime of the boundary gauge theory that is *least* accessible to perturbation theory. This inversion — the hard limit of one description is the easy limit of the other — is the entire point. A constant boundary value of the bulk dilaton, the massless scalar of Section 53.5.2, sets g_s and hence (through Eq. (53.151)) the marginal gauge coupling $g_{\rm YM}^2$, completing the marginal-operator entry of the dictionary.

53.5.5 Counting holographic degrees of freedom

The dictionary's final entry is a number: how many degrees of freedom does the boundary theory have, and how is that encoded in the bulk? The boundary measure of "number of local degrees of freedom" is the central charge, the coefficient of the stress-tensor two-point function (Section 47.4.3), conventionally called C_T; for a free field it counts components, and for a large-N gauge theory it scales as the number of fields, $C_T \sim N^2$. The bulk measure is geometric. We now show they match, with the bulk Planck length setting the conversion, and that the match is the holographic principle made quantitative.

Proposition 53.27 (Holographic central charge)**.** *The central charge of the boundary CFT$_d$ dual to Einstein gravity in* AdS_{d+1} *with radius L and Newton constant G_{d+1} scales as*

$$C_T \;\sim\; \frac{L^{d-1}}{G_{d+1}} \;\sim\; \Big(\frac{L}{\ell_{\mathrm{P}}}\Big)^{d-1}, \tag{53.153}$$

where $\ell_{\mathrm{P}}^{d-1} \sim G_{d+1}$ is the $(d{+}1)$-dimensional Planck length. A large central charge therefore requires a curvature radius large in Planck units, and in the prototype gauge/gravity dual $C_T \sim N^2$.

Proof. We give the Susskind–Witten counting, which fixes the scaling without solving any field equation. Regulate the boundary by cutting off the radial integration at $z = \varepsilon$, so the boundary CFT acquires a short-distance cutoff ε (the radial coordinate is the inverse energy scale, Section 53.3). Consider a region of the boundary of coordinate volume V_{d-1} in the spatial directions. Two counts of its information content must agree.

Field-theory count. With a UV cutoff ε, the boundary theory has of order one cell per coordinate volume ε^{d-1}, and each cell carries C_T independent degrees of freedom (this is what C_T counts). Hence

$$N_{\mathrm{dof}} \;\sim\; C_T\,\frac{V_{d-1}}{\varepsilon^{\,d-1}}. \tag{53.154}$$

Gravity count. The same boundary region sits at $z = \varepsilon$ in the bulk, where the induced metric is $(L/\varepsilon)^2$ times the flat one, so its proper spatial area is

$$A \;=\; \Big(\frac{L}{\varepsilon}\Big)^{d-1} V_{d-1}. \tag{53.155}$$

The holographic principle — here used as an input, justified in the bulk by the Bekenstein–Hawking area law and proved in the AdS context by the entropy bounds of Chapters 55 and 56 — caps the number of degrees of freedom on a surface by its area in Planck units,

$$N_{\mathrm{dof}} \;\sim\; \frac{A}{4G_{d+1}} \;=\; \frac{1}{4G_{d+1}}\Big(\frac{L}{\varepsilon}\Big)^{d-1} V_{d-1}. \tag{53.156}$$

Equating Eq. (53.154) and Eq. (53.156), the regulator ε and the volume V_{d-1} cancel identically — the $\varepsilon^{-(d-1)}$ scaling is the same on both sides, which is itself the nontrivial check that a d-dimensional field theory can be holographically encoded on the boundary of a $(d{+}1)$-dimensional geometry — and leave

$$C_T \;\sim\; \frac{L^{\,d-1}}{G_{d+1}}, \tag{53.157}$$

which is Eq. (53.153). Writing $G_{d+1} \sim \ell_{\mathrm{P}}^{d-1}$ gives the dimensionless form $C_T \sim (L/\ell_{\mathrm{P}})^{d-1}$. □

Worked Example 53.28 (The N^2 count for the canonical $\mathrm{AdS}_5 \times S^5$ dual)**.** Specialize to $d = 4$, the boundary dimension of the prototype correspondence. Here the ten-dimensional bulk is $\mathrm{AdS}_5 \times S^5$ with both factors of radius L; reducing on the S^5 converts the ten-dimensional Newton constant G_{10} into a five-dimensional one,

$$\frac{1}{G_5} \;\sim\; \frac{\mathrm{Vol}(S^5)}{G_{10}} \;\sim\; \frac{L^5}{G_{10}}. \tag{53.158}$$

By Theorem 53.27 with $d = 4$,

$$C_T \;\sim\; \frac{L^3}{G_5} \;\sim\; \frac{L^3 \cdot L^5}{G_{10}} \;=\; \frac{L^8}{G_{10}}. \tag{53.159}$$

The string-theoretic inputs of Section 53.2.3 supply $G_{10} \sim g_s^2\,\ell_s^8$ and $L^4 \sim g_s N\,\ell_s^4$ (the latter is the $d = 4$ case of Eq. (53.151), since $\lambda_{\mathrm{tH}} = g_{\mathrm{YM}}^2 N \sim g_s N$ and $L^4/\ell_s^4 = \lambda_{\mathrm{tH}}$). Then $L^8 \sim (g_s N)^2 \ell_s^8$ and

$$C_T \;\sim\; \frac{(g_s N)^2\,\ell_s^8}{g_s^2\,\ell_s^8} \;=\; N^2. \tag{53.160}$$

The string coupling and string length have cancelled completely, leaving a pure number N^2 — precisely the count of independent components of an $N \times N$ adjoint-valued field, the field content of the boundary $\mathrm{SU}(N)$ gauge theory. The central charge that conformal symmetry left undetermined in Chapter 47 is, holographically, the curvature radius of the dual geometry in Planck units, and it equals N^2.

Physical Insight: The holographic principle, quantitative

Theorem 53.27 is the holographic principle with the proportionality constant filled in. A boundary theory with C_T degrees of freedom requires a bulk whose curvature radius is $C_T^{1/(d-1)}$ Planck lengths: the more degrees of freedom the field theory has, the larger the geometry it carries, and the weaker its quantum-gravitational fluctuations. Classical, weakly curved gravity ($L \gg \ell_{\mathrm{P}}$) is the dual of a field theory with a huge number of

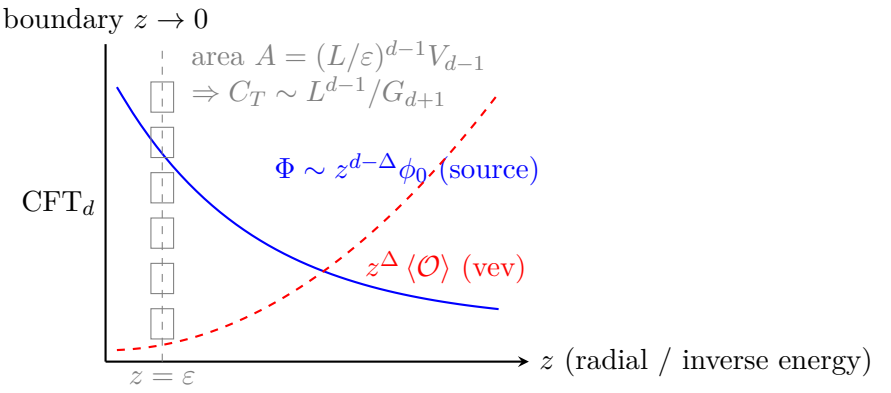

Figure 53.7: The radial direction of the Poincaré patch encodes the dictionary. A bulk field Φ splits near the boundary ($z \to 0$) into a non-normalizable source mode $z^{d-\Delta}\phi_0$ (Eq. (53.142), the GKPW boundary condition) and a normalizable vev mode $z^{\Delta}\langle\mathcal{O}\rangle$. Regulating at $z = \varepsilon$ cuts the boundary into Planck cells whose count fixes the central charge, $C_T \sim (L/\ell_{\mathrm{P}})^{d-1}$ (Theorem 53.27).

degrees of freedom ($C_T \gg 1$, i.e. $N \gg 1$). A d-dimensional theory's worth of information is stored on the $(d-1)$-dimensional spatial boundary of the bulk at one degree of freedom per Planck area — the bulk is a hologram, and Eq. (53.153) is the resolution of the hologram.

The dictionary is now complete: each bulk field is paired with a single-trace boundary primary of matching dimension, spin, and charge; bulk gauge symmetries and diffeomorphisms descend to boundary global symmetries and stress-tensor conservation; the parameter map locates classical gravity at large N and strong coupling; and the central charge counts the bulk in Planck units. The one object this section has singled out for the next is the source. The GKPW boundary condition Eq. (53.142) hands the non-normalizable boundary value ϕ_0 to the boundary theory as the field-theory source coupled to $\mathcal{O}$ — exactly the variable a generating functional is differentiated with respect to. The following section states the GKP–Witten relation, which identifies the boundary generating functional $W[\phi_0]$ with the on-shell bulk action evaluated subject to Eq. (53.142), and differentiates it twice to compute the holographic two-point function $\langle\mathcal{O}(x)\mathcal{O}(0)\rangle \propto |x|^{-2\Delta}$.

53.6 The GKP–Witten Relation and Holographic Two-Point Functions

The dictionary of Section 53.5 taught us to read a boundary operator $\mathcal{O}$ off a bulk field Φ, and to read the field-theory *source* that couples to $\mathcal{O}$ off the leading near-boundary falloff ϕ_0 of Φ, through the boundary condition Eq. (53.142). That source has been waiting to be used. In every other chapter of this book the way one extracts correlators of an operator is to couple it to a classical source J, assemble the generating functional $Z[J] = \langle \exp \int J\mathcal{O} \rangle$, and differentiate (Theorem 10.11). Holography supplies, for the first time, a way to *compute* that generating functional at strong coupling: the source ϕ_0 is now promoted from a label on a boundary condition to the argument of a partition function, and the partition function in question is the one for gravity in the bulk. This section states that identification — the GKP–Witten relation — and then carries it all the way through for the simplest observable, the scalar two-point function, recovering the conformally-mandated form $\langle \mathcal{O}(x)\mathcal{O}(0)\rangle \propto |x|^{-2\Delta}$ of Theorem 47.21 with its coefficient computed from bulk data. The computation is a complete, self-contained boundary-value problem: solve a linear wave equation, evaluate a classical action, and renormalize away its divergences. No quantum gravity is needed, which is exactly the payoff promised in the chapter's opening thesis — a hard quantum problem in d dimensions traded for an easy classical one in $d+1$.

53.6.1 The master relation

The proposal of Gubser, Klebanov, and Polyakov, and independently of Witten, identifies the field-theory generating functional with the bulk partition function evaluated on a prescribed boundary condition. We work in Euclidean signature throughout this section: the boundary-value problem at $z \to 0$ is then a genuine Dirichlet problem, and regularity in the deep interior $z \to \infty$ selects a unique solution without the contour ambiguities that plague the Lorentzian wave equation. Concretely, we Wick-rotate the Poincaré patch Eq. (53.59) by $t \to -i\tau$ and pass to the Euclidean line element $\mathrm{d}s_E^2 = -\mathrm{d}s^2$; this turns the mostly-minus boundary metric $\eta_{\mu\nu}$ into $+\delta_{\mu\nu}$ and produces the positive-definite metric of Euclidean AdS_{d+1} (the hyperbolic upper half-space),

$$\mathrm{d}s_E^2 \;=\; \frac{L^2}{z^2}\Big(\delta_{\mu\nu}\,\mathrm{d}x^\mu\,\mathrm{d}x^\nu + \mathrm{d}z^2\Big), \qquad x \in \mathbb{R}^d,\; z > 0, \tag{53.161}$$

with conformal boundary $\mathbb{R}^d$ at $z = 0$. The book's Euclidean path integral weight is e^{-S_E} (Theorem 10.11 and the Wick rotation fixed there), so the gravitational partition function with boundary data ϕ_0 is a functional integral over all bulk fields Φ approaching ϕ_0 at the boundary.

Definition 53.29 (The GKP–Witten relation)**.** Let Φ be a bulk field dual to the boundary operator $\mathcal{O}$, with near-boundary falloff fixed by Eq. (53.142) so that its leading mode is the source ϕ_0. The *GKP–Witten relation* equates the boundary generating functional with the bulk partition function subject to that boundary condition:

$$\Big\langle \exp\!\int \mathrm{d}^d x\; \phi_0(x)\,\mathcal{O}(x) \Big\rangle_{\mathrm{CFT}} \;=\; Z_{\mathrm{grav}}\big[\,\Phi \to \phi_0\,\big] \;=\; \int_{\Phi\to\phi_0} \mathcal{D}\Phi\; e^{-S_E[\Phi]}. \tag{53.162}$$

The left-hand side is a field-theory object; the right-hand side is a sum over bulk geometries and fields. As it stands Eq. (53.162) is the full, conjectural statement of the duality at the level of correlators, and it is no more provable with our tools than Theorem 53.6 itself. What *is* tractable, and what this section delivers in full, is its classical limit. The bulk partition function is dominated by its saddle point — the solution of the classical equations of motion with the prescribed boundary data — whenever the bulk is weakly coupled. By the parameter dictionary Eq. (53.43) this is precisely the large-N, large-λ regime: the bulk Newton constant obeys $1/G_N \propto N^2$, so $G_N \to 0$ (classical gravity) is $N \to \infty$, while weak curvature in string units, $L/\ell_s = \lambda^{1/4} \gg 1$ (Eq. (53.44)), suppresses the α' corrections that would promote classical fields to strings (Eq. (53.45)). In this regime the functional integral collapses onto the classical action of the dominant saddle,

$$Z_{\mathrm{grav}}[\phi_0] \;\approx\; e^{-S_{\text{on-shell}}[\phi_0]} \qquad (\text{large } N,\ \text{large } \lambda), \tag{53.163}$$

where $S_{\text{on-shell}}[\phi_0]$ is the bulk action evaluated on the solution of the classical field equation that approaches ϕ_0 at the boundary and is regular in the interior.

Taking the logarithm of Eq. (53.162) turns it into the statement that the boundary *connected* generating functional $W[\phi_0] = \log Z$ equals minus the on-shell action. Functional differentiation then produces correlators exactly as in flat-space field theory (Theorem 10.11). The one- and two-point functions are

$$\langle \mathcal{O}(x) \rangle = \frac{\delta W[\phi_0]}{\delta \phi_0(x)} = -\,\frac{\delta S_{\text{on-shell}}}{\delta \phi_0(x)}, \tag{53.164}$$

$$\langle \mathcal{O}(x)\,\mathcal{O}(y) \rangle_c = \frac{\delta^2 W[\phi_0]}{\delta\phi_0(x)\,\delta\phi_0(y)}\bigg|_{\phi_0=0} = -\,\frac{\delta^2 S_{\text{on-shell}}}{\delta\phi_0(x)\,\delta\phi_0(y)}\bigg|_{\phi_0=0}. \tag{53.165}$$

Everything now reduces to computing $S_{\text{on-shell}}[\phi_0]$ for a free bulk scalar, expressing it as a quadratic functional of the source, and reading off the kernel. The work splits into three steps: solve the equation of motion (Section 53.6.2), evaluate the action on the solution and expose its divergences (Section 53.6.3), and renormalize (Section 53.6.4).

Physical Insight

The GKP–Witten relation is the precise sense in which the bulk is a *hologram*. A single classical field configuration in $d+1$ dimensions — the solution of one wave equation — encodes an entire generating functional of a d-dimensional quantum field theory. Turning a knob on the boundary (changing ϕ_0) and watching how the bulk action responds is the same operation as inserting the operator $\mathcal{O}$ and measuring its correlators. The extra radial dimension z is not auxiliary: Section 53.4 showed it carries the renormalization scale, so propagating the wave equation inward from $z=0$ is literally running the source from the UV into the IR.

53.6.2 The bulk-to-boundary propagator

We restore the overall normalization that the kinetic study of Eq. (53.100) could suppress. The physically normalized Euclidean action of the free bulk scalar carries a constant $\mathcal{N}_\phi$ — proportional to the inverse Newton constant, $\mathcal{N}_\phi \propto 1/(2\kappa^2) \propto N^2$, and *not* to be confused with the supersymmetry count $\mathcal{N}$ — that does not affect the equation of motion but sets the overall scale of every correlator:

$$S_E[\phi] \;=\; \frac{\mathcal{N}_\phi}{2}\int \mathrm{d}^d x\,\mathrm{d}z\,\sqrt{g}\,\Big(g^{MN}\partial_M\phi\,\partial_N\phi + m^2\phi^2\Big), \qquad \sqrt{g}=\Big(\frac{L}{z}\Big)^{d+1}, \tag{53.166}$$

with $g^{zz}=z^2/L^2$ and $g^{\mu\nu}=(z^2/L^2)\delta^{\mu\nu}$ from Eq. (53.161). The classical field equation is the Euclidean Klein–Gordon equation $(\Box_{\mathrm{AdS}}-m^2)\phi=0$, which in these coordinates reads (the computation is Eqs. (53.103) and (53.105) of Section 53.4, repeated here with Euclidean boundary derivatives)

$$z^2\,\partial_z^2\phi-(d-1)\,z\,\partial_z\phi+z^2\,\partial_x^2\phi-m^2L^2\,\phi=0, \qquad \partial_x^2\equiv\sum_\mu \partial_\mu\partial_\mu. \tag{53.167}$$

Momentum space and the modified Bessel equation. Fourier-transform along the boundary, $\phi(z,x)=\int \frac{\mathrm{d}^d k}{(2\pi)^d}\,e^{ik\cdot x}\,f_k(z)$, so that $\partial_x^2\to -k^2$ with $k^2=|k|^2>0$ Euclidean. The radial profile obeys

$$z^2 f_k''-(d-1)\,z\,f_k'-\big(k^2z^2+m^2L^2\big)f_k=0. \tag{53.168}$$

Strip off the leading scaling with the substitution $f_k(z)=z^{d/2}\,h(z)$. Using $f_k'=\frac{d}{2}z^{d/2-1}h+z^{d/2}h'$ and $f_k''=\frac{d}{2}(\frac{d}{2}-1)z^{d/2-2}h+d\,z^{d/2-1}h'+z^{d/2}h''$, the three derivative terms of Eq. (53.168) combine, after dividing through by $z^{d/2}$, into

$$\begin{aligned} z^2f_k''-(d-1)zf_k' &= z^2h''+\big[d-(d-1)\big]z\,h'+\Big[\tfrac{d}{2}(\tfrac{d}{2}-1)-(d-1)\tfrac{d}{2}\Big]h \\ &= z^2h''+z\,h'-\tfrac{d^2}{4}\,h, \end{aligned} \tag{53.169}$$

where the h-coefficient collapsed as $\frac{d}{2}(\frac{d}{2}-1)-(d-1)\frac{d}{2}=\frac{d}{2}(\frac{d}{2}-1-d+1)=-\frac{d^2}{4}$. Substituting Eq. (53.169) into Eq. (53.168) and writing

$$\nu \;\equiv\; \Delta-\frac{d}{2} \;=\; \sqrt{\frac{d^2}{4}+m^2L^2} \qquad\Longrightarrow\qquad \frac{d^2}{4}+m^2L^2=\nu^2, \tag{53.170}$$

exactly the index of Section 53.4 with $\Delta=\Delta_+$ the larger root of Eq. (53.112), the equation becomes

$$z^2h''+z\,h'-(k^2z^2+\nu^2)h=0. \tag{53.171}$$

In the variable $u=kz$ this is $u^2h''+uh'-(u^2+\nu^2)h=0$, the *modified Bessel equation* of order ν. Its two independent solutions are $I_\nu(kz)$ and $K_\nu(kz)$, so the general radial profile is $f_k(z)=z^{d/2}\big[A\,I_\nu(kz)+B\,K_\nu(kz)\big]$.

Interior regularity. Deep in the bulk, $z\to\infty$, the two modified Bessel functions behave as $I_\nu(kz)\sim e^{kz}/\sqrt{2\pi kz}$ and $K_\nu(kz)\sim e^{-kz}\sqrt{\pi/2kz}$. The growing solution I_ν is not normalizable and makes the on-shell action diverge at the Poincaré horizon; physical (finite-action) configurations keep only the exponentially decaying piece. This is exactly the role Euclidean signature plays: regularity at $z\to\infty$ is unambiguous, and it selects

$$f_k(z)=C(k)\,z^{d/2}\,K_\nu(kz), \tag{53.172}$$

the unique (up to normalization) interior-regular solution.

Small-z expansion: source and response. To match Eq. (53.172) to the boundary data we need its behaviour as $z\to0$, i.e. the small-argument expansion of K_ν. For non-integer ν,

$$K_\nu(u)=\frac{1}{2}\,\Gamma(\nu)\Big(\frac{u}{2}\Big)^{-\nu}\Big[1+\frac{u^2/4}{1-\nu}+\cdots\Big]+\frac{1}{2}\,\Gamma(-\nu)\Big(\frac{u}{2}\Big)^{\nu}\Big[1+\frac{u^2/4}{1+\nu}+\cdots\Big], \tag{53.173}$$

the two series being the $I_{-\nu}$ and I_ν branches of $K_\nu=\frac{\pi}{2\sin\pi\nu}(I_{-\nu}-I_\nu)$, with $\frac{\pi}{\sin\pi\nu}=\Gamma(\nu)\Gamma(1-\nu)$. Multiplying by $z^{d/2}$ and using $z^{d/2}u^{\mp\nu}=k^{\mp\nu}z^{d/2\mp\nu}=k^{\mp\nu}z^{\,d-\Delta\text{ or }\Delta}$, the regular solution has the structure

$$f_k(z)=C(k)\Big[\tfrac{1}{2}\Gamma(\nu)(k/2)^{-\nu}\,z^{\,d-\Delta}(1+\cdots)+\tfrac{1}{2}\Gamma(-\nu)(k/2)^{\nu}\,z^{\,\Delta}(1+\cdots)\Big]. \tag{53.174}$$

The two powers $z^{d-\Delta}$ and z^{Δ} are precisely the two falloffs of Eq. (53.116): the first is the source, the second the response. We fix $C(k)$ by demanding, as in Eq. (53.142), that the coefficient of $z^{d-\Delta}$ be the source $\phi_0(k)$:

$$C(k)=\frac{2}{\Gamma(\nu)}\Big(\frac{k}{2}\Big)^{\nu}\phi_0(k) \qquad\Longrightarrow\qquad f_k(z)=\phi_0(k)\,\frac{2}{\Gamma(\nu)}\Big(\frac{k}{2}\Big)^{\nu}z^{d/2}K_\nu(kz). \tag{53.175}$$

With this normalization the small-z expansion of the solution reads

$$f_k(z) = \phi_0(k)\Big[\, z^{\,d-\Delta}(1+\cdots) + \underbrace{\frac{\Gamma(-\nu)}{\Gamma(\nu)}\Big(\frac{k}{2}\Big)^{2\nu}}_{\equiv\ \mathcal{B}(k)}\, z^{\,\Delta}(1+\cdots)\Big], \tag{53.176}$$

where the "$\cdots$" inside each bracket are the integer powers $z^2, z^4, \ldots$ of the analytic Bessel series. The coefficient of the response mode z^Δ is $\phi_{(2\Delta)}(k) = \mathcal{B}(k)\,\phi_0(k)$, manifestly proportional to the source and carrying the non-analytic momentum dependence $k^{2\nu} = k^{2\Delta-d}$. This $\mathcal{B}(k)$ is the entire physical content of the calculation; everything that follows extracts it cleanly from the action.

Position space. It is illuminating to record the same object in position space, where it is a single closed form. Define the *bulk-to-boundary propagator* $K(z, x; x')$ as the solution of the bulk wave equation whose source is a boundary delta function, $\phi(z,x) = \int \mathrm{d}^d x'\, K(z,x;x')\,\phi_0(x')$.

Definition 53.30 (Bulk-to-boundary propagator)**.** The interior-regular solution of Eq. (53.167) with unit point source at the boundary point x' is

$$K(z,x;x') = c_\Delta\, \frac{z^\Delta}{\big(z^2+|x-x'|^2\big)^\Delta}, \qquad c_\Delta = \frac{\Gamma(\Delta)}{\pi^{d/2}\,\Gamma(\Delta-\frac{d}{2})}. \tag{53.177}$$

That Eq. (53.177) solves the wave equation follows from two facts, neither requiring brute computation. First, the pure power $\phi = z^\Delta$ (constant along the boundary) solves Eq. (53.167): substituting it, $z^2\Delta(\Delta-1)z^{\Delta-2} - (d-1)z\,\Delta z^{\Delta-1} - m^2L^2 z^\Delta = [\Delta(\Delta-1) - (d-1)\Delta - m^2L^2]z^\Delta$, and the bracket is $\Delta(\Delta-d) - m^2L^2 = 0$ by the mass–dimension relation Eq. (53.112). Second, the inversion

$$I:\ (z, x^\mu)\ \longmapsto\ \frac{(z, x^\mu)}{z^2+|x|^2} \tag{53.178}$$

is an isometry of Euclidean AdS_{d+1}. Indeed, under $X^M \to X^M/X^2$ with $X^2 = z^2+|x|^2$ the flat $(d+1)$-metric scales as $\delta_{MN}\mathrm{d}X^M\mathrm{d}X^N \to (X^2)^{-2}\delta_{MN}\mathrm{d}X^M\mathrm{d}X^N$, while $z \to z/X^2$ gives $z^{-2} \to (X^2)^2 z^{-2}$; the two factors of X^2 cancel and $\frac{L^2}{z^2}\delta_{MN}\mathrm{d}X^M\mathrm{d}X^N$ is left invariant. A scalar solution composed with an isometry is again a solution, and applying I (which sends a source at spatial infinity to one at $x=0$) to z^Δ produces $z^\Delta/(z^2+|x|^2)^\Delta$, i.e. Eq. (53.177) up to the constant c_Δ. That constant is fixed by requiring $K \to z^{d-\Delta}\delta^d(x-x')$ as $z\to 0$. The needed integral is a Schwinger-parameter computation:

$$\begin{aligned}\int \mathrm{d}^d x\, \frac{1}{(z^2+|x|^2)^\Delta} &= \frac{1}{\Gamma(\Delta)}\int_0^\infty \mathrm{d}t\, t^{\Delta-1}\int \mathrm{d}^d x\, e^{-t(z^2+|x|^2)} \\ &= \frac{\pi^{d/2}}{\Gamma(\Delta)}\int_0^\infty \mathrm{d}t\, t^{\Delta-1-d/2}e^{-tz^2} = \frac{\pi^{d/2}\,\Gamma(\Delta-\frac{d}{2})}{\Gamma(\Delta)}\, z^{\,d-2\Delta},\end{aligned} \tag{53.179}$$

using $\int \mathrm{d}^d x\, e^{-t|x|^2} = (\pi/t)^{d/2}$. Hence $\int \mathrm{d}^d x\, K = c_\Delta\, z^\Delta \cdot \frac{\pi^{d/2}\Gamma(\Delta - d/2)}{\Gamma(\Delta)} z^{d-2\Delta} = c_\Delta \frac{\pi^{d/2}\Gamma(\Delta-d/2)}{\Gamma(\Delta)}\, z^{d-\Delta}$, which equals $z^{d-\Delta}$ precisely when $c_\Delta = \Gamma(\Delta)/[\pi^{d/2}\Gamma(\Delta - \frac{d}{2})]$, as stated. The constant c_Δ will reappear, multiplied by $2\Delta - d$, as the coefficient of the two-point function — a first sign that the two routes agree.

53.6.3 The on-shell action and its divergences

With the solution in hand we evaluate the action Eq. (53.166). Integrating the kinetic term by parts,

$$S_E = \frac{\mathcal{N}_\phi}{2}\int \mathrm{d}^d x\, \mathrm{d}z\; \partial_M(\sqrt{g}\,\phi\, g^{MN}\partial_N\phi) - \frac{\mathcal{N}_\phi}{2}\int \mathrm{d}^d x\, \mathrm{d}z\; \phi\,[\partial_M(\sqrt{g}\, g^{MN}\partial_N\phi) - \sqrt{g}\, m^2\phi], \tag{53.180}$$

the second integrand is $-\sqrt{g}\,\phi\,(\Box_{\mathrm{AdS}} - m^2)\phi$, which vanishes on shell. Only the total derivative survives, and since the integrand depends on z through the explicit factors, the z-integral collapses to the boundaries. The interior boundary $z \to \infty$ contributes nothing (the regular solution decays); the conformal boundary must be regulated by a cutoff at $z = \epsilon$. With $\sqrt{g}\, g^{zz} = (L/z)^{d+1}(z^2/L^2) = L^{d-1}z^{1-d}$, the on-shell action is the single boundary term

$$S_{\text{on-shell}} = -\frac{\mathcal{N}_\phi L^{d-1}}{2}\int \mathrm{d}^d x\; z^{1-d}\,\phi\,\partial_z\phi\Big|_{z=\epsilon} = -\frac{\mathcal{N}_\phi L^{d-1}}{2}\int \frac{\mathrm{d}^d k}{(2\pi)^d}\,\epsilon^{1-d}\, f_{-k}(\epsilon)\, f_k'(\epsilon), \tag{53.181}$$

the overall sign because the outward normal at $z = \epsilon$ points toward decreasing z.

We need the boundary flux $\epsilon^{1-d} f_{-k} f_k'$ in the small-ϵ limit. Write the normalized solution Eq. (53.176) as $f_k(z) = \phi_0(k)\, F(z)$ with $F(z) = z^{d-\Delta}[1 + \cdots] + \mathcal{B} z^\Delta[1 + \cdots]$, where the analytic corrections are organized by the Bessel series Eq. (53.173). The logarithmic derivative is cleanest to expand:

$$\frac{F'(z)}{F(z)} = \partial_z \log F = \frac{d-\Delta}{z} + \frac{k^2 z}{2(1-\nu)} + 2\nu\,\mathcal{B}\, z^{2\nu-1} + \cdots, \tag{53.182}$$

the first term from the leading power $z^{d-\Delta}$, the second from the first analytic correction $\frac{k^2 z^2}{4(1-\nu)}$, and the third from the response term $\mathcal{B} z^{2\nu}$ relative to the leading mode (recall $2\nu = 2\Delta - d$). Multiplying by $F(z)^2 = z^{2(d-\Delta)}[1 + 2\mathcal{B} z^{2\nu} + \cdots]$ and the kinematic factor ϵ^{1-d}, the flux organizes into

$$\epsilon^{1-d} F(\epsilon) F'(\epsilon) = (d-\Delta)\,\epsilon^{-2\nu} + \frac{(d-\Delta)+1}{2(1-\nu)}\, k^2\, \epsilon^{-2\nu+2} + \cdots + d\,\mathcal{B}(k) + \cdots. \tag{53.183}$$

Two species of term appear. The powers $\epsilon^{-2\nu}, \epsilon^{-2\nu+2}, \ldots$ *diverge* as $\epsilon \to 0$ (for $\nu > 0$), and their coefficients are *analytic* in k^2: $\epsilon^{-2\nu}$ is k-independent, $\epsilon^{-2\nu+2}$ comes with k^2, and so on. Fourier-transformed back, these are contact terms, supported at coincident points (the constant gives $\delta^d(x-y)$, the k^2

gives $\Box\delta^d(x-y)$, etc.). They are pure short-distance artefacts of the regulator. The single *finite*, *non-analytic* term is $d\,\mathcal{B}(k) \propto k^{2\nu}$, the would-be physical two-point function. The coefficient d is, however, *not* the right answer yet: it is contaminated by the same regulator, and the resolution is holographic renormalization, to which we now turn.

53.6.4 Holographic renormalization

The divergences in Eq. (53.183) are removed by adding to the action local boundary counterterms — functionals of the field and induced metric on the cutoff surface $z=\epsilon$ — chosen to cancel them. This is the gravitational analogue of the local counterterms of Chapter 22: the divergences are local and covariant, so the subtractions can be too, and the renormalized correlators are scheme-independent up to the contact terms those counterterms can shift. The induced metric on the slice is $\gamma_{\mu\nu} = (L/\epsilon)^2\delta_{\mu\nu}$, with $\sqrt{\gamma} = (L/\epsilon)^d$, and the field there is $\phi_\epsilon(x) \equiv \phi(\epsilon, x)$.

The leading divergence $\propto \epsilon^{-2\nu}$ is cancelled by a counterterm quadratic in the boundary field,

$$S_{\rm ct} = \frac{\mathcal{N}_\phi}{2}\,\frac{d-\Delta}{L}\int \mathrm{d}^d x\,\sqrt{\gamma}\,\phi_\epsilon^2 = \frac{\mathcal{N}_\phi L^{d-1}}{2}\,(d-\Delta)\int \frac{\mathrm{d}^d k}{(2\pi)^d}\,\epsilon^{-d}\,\phi_\epsilon(-k)\phi_\epsilon(k), \tag{53.184}$$

manifestly local and covariant. (Subleading divergences $\epsilon^{-2\nu+2},\dots$ require further counterterms built from $\sqrt{\gamma}\,\phi\Box_\gamma\phi$ and higher; they touch only the analytic, contact part of the answer and we track them no further. For integer ν a logarithmic counterterm $\propto \log\epsilon$ is also needed, the holographic conformal anomaly — see Theorem 53.31 and Theorem 53.32.) The crucial point is that the counterterm, although introduced to kill a divergence, also reaches into the finite part. Writing $\phi_\epsilon = \phi_0\,F(\epsilon)$ with $F(\epsilon)^2 = \epsilon^{2(d-\Delta)}[1 + 2\mathcal{B}\,\epsilon^{2\nu} + \cdots]$, the counterterm expands as

$$\begin{aligned} S_{\rm ct} &= \frac{\mathcal{N}_\phi L^{d-1}}{2}\,(d-\Delta)\int \frac{\mathrm{d}^d k}{(2\pi)^d}\,\phi_0(-k)\phi_0(k)\,\epsilon^{-d}\,\epsilon^{2(d-\Delta)}\big[1 + 2\mathcal{B}\,\epsilon^{2\nu} + \cdots\big] \\ &= \frac{\mathcal{N}_\phi L^{d-1}}{2}\,(d-\Delta)\int \frac{\mathrm{d}^d k}{(2\pi)^d}\,\phi_0(-k)\phi_0(k)\,\big[\epsilon^{-2\nu} + 2\,\mathcal{B} + \cdots\big], \end{aligned} \tag{53.185}$$

using $-d + 2(d-\Delta) = d - 2\Delta = -2\nu$ and $\epsilon^{-2\nu}\epsilon^{2\nu} = 1$. Comparing with Eq. (53.181) fed by Eq. (53.183),

$$S_{\rm reg} = -\frac{\mathcal{N}_\phi L^{d-1}}{2}\int \frac{\mathrm{d}^d k}{(2\pi)^d}\,\phi_0(-k)\phi_0(k)\,\big[(d-\Delta)\epsilon^{-2\nu} + d\,\mathcal{B} + \cdots\big], \tag{53.186}$$

the divergent $\epsilon^{-2\nu}$ pieces cancel between Eqs. (53.185) and (53.186), as designed.

What remains finite is the renormalized action

$$S_{\rm ren} = \lim_{\epsilon\to 0}\big(S_{\rm reg}+S_{\rm ct}\big) = \frac{\mathcal{N}_\phi L^{d-1}}{2}\int \frac{\mathrm{d}^d k}{(2\pi)^d}\,\phi_0(-k)\phi_0(k)\,\big[\,2(d-\Delta)-d\,\big]\mathcal{B}(k)+(\text{contact}), \tag{53.187}$$

where the finite coefficient has collapsed from the bare $-d$ to

$$2(d-\Delta)-d = d-2\Delta = -2\nu = -(2\Delta-d). \tag{53.188}$$

This is the mechanism that turns the naive (and wrong) coefficient d of Eq. (53.183) into the correct $-(2\Delta-d)$: the counterterm needed to remove the divergence necessarily carries a finite remainder of just the right size. We have

$$\boxed{\,S_{\rm ren} = -\frac{\mathcal{N}_\phi L^{d-1}}{2}\,(2\Delta-d)\int \frac{\mathrm{d}^d k}{(2\pi)^d}\,\phi_0(-k)\,\mathcal{B}(k)\,\phi_0(k) + (\text{contact}),\,} \tag{53.189}$$

with $\mathcal{B}(k) = \frac{\Gamma(-\nu)}{\Gamma(\nu)}(k/2)^{2\nu}$ from Eq. (53.176).

The renormalized one-point function follows from Eq. (53.164): differentiating Eq. (53.189) once,

$$\langle \mathcal{O}(k)\rangle = (2\Delta-d)\,\mathcal{N}_\phi L^{d-1}\,\mathcal{B}(k)\,\phi_0(k) = (2\Delta-d)\,\mathcal{N}_\phi L^{d-1}\,\phi_{(2\Delta)}(k), \tag{53.190}$$

the celebrated statement that the operator's expectation value is fixed by the *response* (subleading) mode $\phi_{(2\Delta)}$, with coefficient $2\Delta-d$. Comparing with the dictionary's defining normalization Eq. (53.142), where the coefficient of z^Δ was written $\frac{1}{2\Delta-d}\langle\mathcal{O}\rangle$, fixes the canonical bulk normalization to $\mathcal{N}_\phi L^{d-1}=1$; we keep $\mathcal{N}_\phi L^{d-1}$ explicit below so the N^2-scaling of correlators stays visible.

53.6.5 The two-point function and its coefficient

The connected two-point function is the kernel of the quadratic form Eq. (53.189), read off from Eq. (53.165):

$$\langle \mathcal{O}(k)\,\mathcal{O}(-k)\rangle = (2\Delta-d)\,\mathcal{N}_\phi L^{d-1}\,\frac{\Gamma(-\nu)}{\Gamma(\nu)}\Big(\frac{k}{2}\Big)^{2\nu}. \tag{53.191}$$

To reach position space we Fourier-transform the power $k^{2\nu} = (k^2)^\nu$. The relevant distributional transform is obtained from the same Schwinger trick as Eq. (53.179): for $\mathrm{Re}\,a < d/2$,

$$\int \frac{\mathrm{d}^d k}{(2\pi)^d}\,\frac{e^{ik\cdot x}}{(k^2)^a} = \frac{1}{\Gamma(a)(4\pi)^{d/2}}\int_0^\infty \mathrm{d}t\, t^{a-1-d/2}\,e^{-x^2/4t} = \frac{\Gamma(\frac{d}{2}-a)}{4^a\,\pi^{d/2}\,\Gamma(a)}\,\frac{1}{|x|^{\,d-2a}}, \tag{53.192}$$

using $\int \frac{\mathrm{d}^d k}{(2\pi)^d} e^{ik\cdot x} e^{-tk^2} = (4\pi t)^{-d/2} e^{-x^2/4t}$ and then $\int_0^\infty \mathrm{d}t\, t^{a-1-d/2} e^{-x^2/4t} = \Gamma(\frac{d}{2}-a)(x^2/4)^{a-d/2}$. Setting $a=-\nu$ continues this to the growing power $(k^2)^\nu$:

$$\int \frac{\mathrm{d}^d k}{(2\pi)^d}\, e^{ik\cdot x}\,(k^2)^\nu = \frac{4^\nu\,\Gamma(\frac{d}{2}+\nu)}{\pi^{d/2}\,\Gamma(-\nu)}\,\frac{1}{|x|^{\,d+2\nu}} = \frac{4^\nu\,\Gamma(\Delta)}{\pi^{d/2}\,\Gamma(-\nu)}\,\frac{1}{|x|^{2\Delta}}, \tag{53.193}$$

where $\frac{d}{2}+\nu=\Delta$ and $d+2\nu=2\Delta$ by Eq. (53.170). The result is automatically the power $|x|^{-2\Delta}$ demanded by conformal symmetry. Assembling Eq. (53.191) (with $(k/2)^{2\nu}=(k^2)^\nu/4^\nu$) and Eq. (53.193), the 4^ν factors cancel and

$$\langle \mathcal{O}(x)\,\mathcal{O}(0)\rangle = (2\Delta-d)\,\mathcal{N}_\phi L^{d-1}\,\frac{\Gamma(-\nu)}{\Gamma(\nu)}\cdot\frac{\Gamma(\Delta)}{\pi^{d/2}\,\Gamma(-\nu)}\,\frac{1}{|x|^{2\Delta}}. \tag{53.194}$$

The two factors of $\Gamma(-\nu)$ cancel between the momentum kernel and the transform — the simplest sign that the divergent intermediary was an artefact — leaving the manifestly finite, manifestly positive coefficient

$$\boxed{\langle \mathcal{O}(x)\,\mathcal{O}(0)\rangle = \frac{C_\Delta}{|x|^{2\Delta}}, \qquad C_\Delta = \mathcal{N}_\phi L^{d-1}\,\frac{(2\Delta-d)\,\Gamma(\Delta)}{\pi^{d/2}\,\Gamma(\Delta-\frac{d}{2})}.} \tag{53.195}$$

Equivalently $C_\Delta=(2\Delta-d)\,c_\Delta\,\mathcal{N}_\phi L^{d-1}$ with c_Δ the bulk-to-boundary normalization of Eq. (53.177) — the cross-check promised earlier, and exactly the result one gets by evaluating the on-shell action directly in position space with two insertions of Eq. (53.177).

Matching the conformal field theory. Compare Eq. (53.195) with the form forced by conformal symmetry alone in Theorem 47.21, $\langle \mathcal{O}(x_1)\mathcal{O}(x_2)\rangle = C_{12}\,|x_{12}|^{-2\Delta}$. The holographic computation reproduces this structure exactly: the power is 2Δ, with Δ the operator dimension delivered by the mass–dimension relation Eq. (53.112), and the would-be free function of the separation is pinned to a pure power by the same conformal invariance that, on the bulk side, appeared as the isometry Eq. (53.178). The coefficient $C_{12}=C_\Delta$ is now *computed*, not merely allowed: it is positive for every $\Delta>d/2$ (the standard branch, $\Gamma(\Delta-\frac{d}{2})>0$), in accord with reflection positivity and the scalar unitarity bound $\Delta\geq(d-2)/2$ of Theorem 47.18. The overall factor $\mathcal{N}_\phi\propto N^2$ is the holographic image of large-N factorization (Section 53.1.6): connected correlators of single-trace operators scale as N^2, exactly the scaling that the central charge of the dual CFT inherits from $1/G_N$. With the canonical choice $\mathcal{N}_\phi L^{d-1}=1$ that reproduced Eq. (53.142), $C_\Delta=(2\Delta-d)\,\Gamma(\Delta)/[\pi^{d/2}\Gamma(\Delta-\frac{d}{2})]$ is the unit-normalized CFT two-point coefficient.

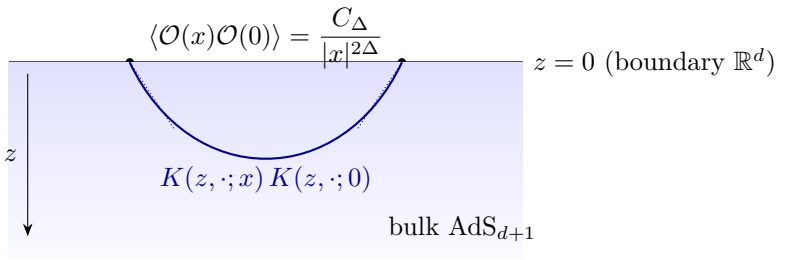

Figure 53.8: The holographic scalar two-point function. The source ϕ_0 at the boundary excites the bulk field through the bulk-to-boundary propagator Eq. (53.177); with no bulk interaction vertex the two-point function is the boundary term of the on-shell action built from two such propagators, evaluated and renormalized to give Eq. (53.195). The single bulk arc is the free (geodesic-like) propagation connecting the two boundary insertions. Interaction vertices in the bulk — the Witten diagrams of Chapter 54 — would add internal points and generate higher-point functions.

Remark 53.31 (Contact terms, scheme dependence, and alternate quantization). Three caveats sharpen the result. *(i) Contact terms.* The analytic-in-k^2 pieces dropped in Eq. (53.189) Fourier-transform to derivatives of $\delta^d(x)$ and are supported only at coincident points. Their coefficients depend on the finite parts of the counterterms (the renormalization scheme), exactly as the contact terms of a flat-space correlator do; the separated-point correlator Eq. (53.195) is scheme-independent. *(ii) Integer ν.* When $\nu = \Delta - \frac{d}{2}$ is a non-negative integer, $\Gamma(-\nu)$ in Eq. (53.191) has a pole and the momentum-space response degenerates to $(k^2)^\nu \log(k^2/\mu^2)$: a renormalization scale μ enters through the logarithmic counterterm, the holographic avatar of the conformal (trace) anomaly of Chapter 37. The position-space coefficient C_Δ in Eq. (53.195) nonetheless stays finite (the Γ-function poles cancel against the log), and the power law $|x|^{-2\Delta}$ survives intact; only the contact part carries the μ-dependence. The worked example below exhibits this explicitly. *(iii) Alternate quantization.* In the Breitenlohner–Freedman window Eq. (53.135), $0 \le \nu < 1$, both modes are normalizable and one may instead treat the z^Δ falloff as the source; this swaps the roles of source and response (a Legendre transform of Eq. (53.189)) and yields a dual operator of dimension $\Delta_- = d - \Delta$, with a two-point coefficient of the same form under $\Delta \to d - \Delta$.

53.6.6 A worked example: $d = 4$, $\Delta = 4$

Worked Example 53.32 (The marginal operator of $\mathrm{AdS}_5/\mathrm{CFT}_4$)**.** We specialize to the case most relevant to the $\mathrm{AdS}_5 \times S^5$ correspondence: a *massless* bulk scalar, $m^2 = 0$, in AdS_5 ($d = 4$). By the mass–dimension relation Eq. (53.112),

$\Delta(\Delta-4)=0$, so the standard branch is $\Delta=\Delta_+=4$ and the index Eq. (53.170) is $\nu=\Delta-\frac{d}{2}=4-2=2$. The dual operator is marginal (dimension d): in $\mathcal{N}=4$ SYM the massless scalar is the dilaton, whose constant boundary value is the gauge coupling, and the dual operator is the on-shell Lagrangian density $\mathcal{O}\sim \operatorname{tr} F_{\mu\nu}F^{\mu\nu}+\cdots$, a protected dimension-4 primary. We compute its two-point coefficient and reproduce $1/|x|^8$.

Coefficient. Plugging $d=4$, $\Delta=4$ into the boxed result Eq. (53.195), with $\Gamma(4)=3!=6$, $\Gamma(\Delta-\frac{d}{2})=\Gamma(2)=1$, $\pi^{d/2}=\pi^2$, and $2\Delta-d=4$,

$$C_4=\mathcal{N}_\phi L^3\,\frac{4\cdot 6}{\pi^2\cdot 1}=\frac{24}{\pi^2}\,\mathcal{N}_\phi L^3,\qquad\Longrightarrow\qquad \langle\mathcal{O}(x)\,\mathcal{O}(0)\rangle=\frac{24\,\mathcal{N}_\phi L^3}{\pi^2}\,\frac{1}{|x|^8}. \tag{53.196}$$

This is finite and positive, and matches the conformal form Eq. (47.120) with $C_{12}=C_4$: holography has delivered the dimension-4 two-point function in closed form, with a definite coefficient set by the bulk geometry and normalization.

The integer-ν subtlety, made explicit. Because $\nu=2$ is an integer, the naive momentum-space response Eq. (53.191) hits the pole of $\Gamma(-\nu)=\Gamma(-2)$, signalling (as in Theorem 53.31) that the careful answer carries a logarithm. The expansion Eq. (53.173) of K_2 indeed contains a $\log(kz)$ term, and the renormalized momentum-space correlator is

$$\langle\mathcal{O}(k)\,\mathcal{O}(-k)\rangle=-\frac{\mathcal{N}_\phi L^3}{8}\,(k^2)^2\,\log\frac{k^2}{\mu^2}, \tag{53.197}$$

with μ the renormalization scale introduced by the logarithmic counterterm. We confirm this reproduces Eq. (53.196). The Fourier transform of $(k^2)^2\log(k^2/\mu^2)$ at separated points follows from differentiating Eq. (53.193) in ν: only the zero of $1/\Gamma(-\nu)$ at $\nu=2$ contributes, with $\frac{d}{d\nu}\big[1/\Gamma(-\nu)\big]_{\nu=2}=(-1)^3\,2!=-2$, so

$$\int\frac{\mathrm{d}^4k}{(2\pi)^4}\,e^{ik\cdot x}\,(k^2)^2\log\frac{k^2}{\mu^2}=\frac{4^2\,\Gamma(4)}{\pi^2}\,(-2)\,\frac{1}{|x|^8}=-\frac{192}{\pi^2\,|x|^8}\qquad(x\neq 0), \tag{53.198}$$

the pure-power $\log\mu^2$ part transforming to a contact term that vanishes away from $x=0$. Hence

$$\langle\mathcal{O}(x)\mathcal{O}(0)\rangle=-\frac{\mathcal{N}_\phi L^3}{8}\cdot\Big(-\frac{192}{\pi^2|x|^8}\Big)=\frac{24\,\mathcal{N}_\phi L^3}{\pi^2\,|x|^8}, \tag{53.199}$$

identical to Eq. (53.196). The μ-dependence has dropped out of the separated-point correlator, residing entirely in the scheme-dependent contact term — the conformal anomaly of Chapter 37 seen holographically. With the canonical normalization $\mathcal{N}_\phi L^3=1$ the unit-normalized coefficient is $C_4=24/\pi^2$, the value the bootstrap of Chapter 49 would take as input data ($C_{\mathcal{O}\mathcal{O}}$) when constraining this CFT through the crossing equation Theorem 49.2: holography and the bootstrap are two routes to the same number.

Physical Insight

The worked example closes a loop that runs across three Parts of this book. The Wilson–Fisher fixed point of ϕ^4 theory handed Part XIV a strongly-coupled CFT; the bootstrap of Chapters 49 and 50 constrains such a CFT's data — dimensions and OPE coefficients — from crossing and unitarity alone, never computing them from a Lagrangian. Holography is the complementary handle: when a CFT has a weakly-curved gravity dual, the very same data $\{\Delta,\, C_{\mathcal{O}\mathcal{O}}\}$ are computed by solving classical wave equations, as in Eq. (53.195). The two methods constrain and compute the same numbers; their consistency, where both apply, is one of the sharpest tests of the correspondence.

We now possess a complete machine: a boundary condition feeds a classical bulk solution, whose renormalized on-shell action is the CFT generating functional, and differentiation yields correlators. Chapter 54 turns this machine to work, switching on the bulk interactions deferred in Eq. (53.100) so that the on-shell action acquires vertices — the Witten diagrams that compute three- and higher-point functions — and replacing the pure-AdS saddle by black-brane geometries, so that the same GKP–Witten relation Eq. (53.162) delivers finite-temperature and real-time correlators of the strongly-coupled boundary theory.

53.7 What Is Established, What Is Conjecture: The Status of Holography

The previous six sections built the correspondence from the ground up: the large-N reorganization that hinted at a hidden string (Section 53.1), the decoupling argument that named the dual geometry (Section 53.2), the intrinsic geometry of AdS_{d+1} and its conformal boundary (Section 53.3), the fields whose masses encode operator dimensions (Section 53.4), the field–operator dictionary, and finally the GKP–Witten relation, which computed a strongly-coupled two-point function as a classical bulk integral (Section 53.6). We now have a machine. Before turning it loose in the chapters that follow, we owe the reader a candid accounting of what kind of machine it is: which of its parts are theorems proved in this book, which are claims supported by decades of stringent but indirect tests, and which are open problems at the research frontier. This section is that accounting. It introduces no new computation that the rest of the book will rely on; its job is to organize, to date, and above all to be honest about epistemic status, in keeping with the discipline laid down in the chapter introduction and in Section 53.2.4. A reader who finishes this section should be able to say, of any holographic statement encountered later, whether it rests on proof, on evidence,

or on conjecture.

53.7.1 The summary of evidence

The correspondence has never been derived from first principles in any framework this book commands, and — as we explain in Section 53.7.2 — a derivation may not even be the right thing to ask for. What it has instead is an extraordinary accumulation of independent, quantitative tests, spanning regimes and techniques that have no business agreeing unless the duality is true. We marshal the principal ones here, in rough order of rigor, marking each for what it is.

The symmetry match (rigorous, proved in this chapter). The single piece of the correspondence that we have established with full rigor is the agreement of global symmetries. In Theorem 53.8 we proved that $\mathcal{N}=4$ SU(N) super Yang–Mills has the superconformal symmetry algebra $\mathfrak{psu}(2,2|4)$, whose bosonic part is $\mathfrak{so}(2,4)\oplus\mathfrak{so}(6)$; in Section 53.3 we proved, intrinsically and with no string input, that the isometry group of $\mathrm{AdS}_5\times S^5$ is exactly $\mathrm{SO}(2,4)\times\mathrm{SO}(6)$, with the conformal group of the boundary realized as the isometry of the anti-de Sitter factor and the R-symmetry as the isometry of the sphere. These two computations are theorems of this book. They do not prove the correspondence — distinct theories can share a symmetry group — but a mismatch would have killed it outright, and the match is exact, term for term, including the noncompact real form and the fermionic generators. This is the load-bearing rigorous core, and everything below is softer.

The spectrum of protected operators. Symmetry alone fixes more than the algebra: it organizes the operator content into representations whose dimensions are protected from quantum corrections. The *chiral primary* (half-BPS) operators of $\mathcal{N}=4$ SYM are the single-trace scalars $\mathcal{O}_k=\mathrm{tr}(\phi^{(i_1}\cdots\phi^{i_k)})$ − traces, symmetric traceless in the $\mathrm{SU}(4)_R$ indices, with dimension $\Delta=k$ fixed exactly by the superconformal algebra (a BPS bound saturated for all g,N). On the gravity side these map, one for one, to the Kaluza–Klein harmonics of the supergravity fields on S^5: expanding a ten-dimensional field in spherical harmonics Y_k on the five-sphere produces a tower of AdS_5 fields whose masses, read through the mass–dimension relation $\Delta(\Delta-d)=m^2L^2$ of Section 53.4, reproduce $\Delta=k$ exactly. The towers agree representation by representation, including the truncation at $k\le N$ on the field-theory side (a single-trace operator of more than N fields is not independent), which matches the stringy exclusion principle on the gravity side. This is a detailed, infinite-dimensional match of protected data, and it works.

The conformal anomaly and central charges. A four-dimensional CFT carries two central charges, a and c, appearing in its Weyl (trace) anomaly,

$$\langle T^{\mu}{}_{\mu} \rangle \;=\; \frac{c}{16\pi^2}\, W_{\mu\nu\rho\sigma} W^{\mu\nu\rho\sigma} \;-\; \frac{a}{16\pi^2}\, E_4, \tag{53.200}$$

with W the Weyl tensor and E_4 the Euler density (the gravitational/trace anomaly structure of Chapter 37). These are sharp, scheme-independent numbers, computable in free field theory on the boundary and from holographic renormalization on the bulk; their agreement is one of the cleanest nontrivial tests, and it teaches the strong/weak and large-N structure at once. We carry it out in full.

Worked Example 53.33 (The central-charge match $a = c = N^2/4$)**.** *Field-theory side.* For a free four-dimensional field the central charges receive additive contributions from each propagating degree of freedom. In units where a single real conformal scalar contributes $(a, c) = (\frac{1}{360}, \frac{1}{120})$, a Weyl fermion contributes $(\frac{11}{720}, \frac{3}{120})$, and a vector contributes $(\frac{31}{180}, \frac{12}{120})$ — the standard free-field anomaly coefficients (Chapter 37). The $\mathcal{N} = 4$ vector multiplet, per generator of the gauge group, contains 6 real scalars, 4 Weyl fermions, and 1 vector, and the gauge group SU(N) has $N^2 - 1$ generators. Summing the c-coefficients,

$$c = (N^2-1)\Big[\,6\cdot\tfrac{1}{120} + 4\cdot\tfrac{3}{120} + 1\cdot\tfrac{12}{120}\,\Big] = (N^2-1)\,\frac{6+12+12}{120} = \frac{N^2-1}{4}, \tag{53.201}$$

and the a-coefficients, brought to a common denominator 720,

$$a = (N^2-1)\Big[\,6\cdot\tfrac{2}{720} + 4\cdot\tfrac{11}{720} + 1\cdot\tfrac{124}{720}\,\Big] = (N^2-1)\,\frac{12+44+124}{720} = (N^2-1)\,\frac{180}{720} = \frac{N^2-1}{4}. \tag{53.202}$$

Two facts emerge. First, $a = c$ exactly — a hallmark of $\mathcal{N} = 4$ SYM, and as we will see the precondition for a two-derivative (Einstein) gravity dual. Second, these values are protected: the central charges sit in the same supermultiplet as the (protected) stress tensor and the R-current, so the free-field result Eq. (53.201) holds at *all* values of the coupling, not merely at $g = 0$. We may therefore compare it to a strong-coupling gravity computation.

Gravity side. Holographic renormalization of pure Einstein gravity in AdS_5 — the same boundary-counterterm procedure used for the two-point function in Section 53.6, now applied to the on-shell action in a curved boundary metric — produces a Weyl anomaly of exactly the form Eq. (53.200) with

$$a \;=\; c \;=\; \frac{\pi L^3}{8\, G_5} \qquad \text{[holographic renormalization]}, \tag{53.203}$$

where L is the AdS_5 radius and G_5 the five-dimensional Newton constant; the equality $a = c$ is automatic because two-derivative gravity has a single coupling L^3/G_5 to spend. We quote the coefficient $\pi/8$ from the holographic-renormalization computation and reduce the rest by the dictionary of this chapter. The five-dimensional Newton constant comes from dimensional reduction of the ten-dimensional one on the five-sphere of radius L, whose volume is $\mathrm{Vol}(S^5) = \pi^3 L^5$:

$$\frac{1}{G_5} \;=\; \frac{\mathrm{Vol}(S^5)}{G_{10}} \;=\; \frac{\pi^3 L^5}{G_{10}}. \tag{53.204}$$

Substituting into Eq. (53.203),

$$c \;=\; \frac{\pi L^3}{8}\cdot\frac{\pi^3 L^5}{G_{10}} \;=\; \frac{\pi^4 L^8}{8\,G_{10}}. \tag{53.205}$$

The ten-dimensional Newton constant is fixed by the string input $16\pi G_{10} = (2\pi)^7 g_s^2 \alpha'^4$ recorded in Section 53.2.3, so

$$G_{10} \;=\; \frac{(2\pi)^7 g_s^2 \alpha'^4}{16\pi} \;=\; \frac{2^7\pi^7}{16\pi}\, g_s^2\alpha'^4 \;=\; 8\pi^6\, g_s^2\alpha'^4. \tag{53.206}$$

Then

$$c \;=\; \frac{\pi^4 L^8}{8\cdot 8\pi^6 g_s^2\alpha'^4} \;=\; \frac{L^8}{64\pi^2\, g_s^2\alpha'^4}. \tag{53.207}$$

Finally use the curvature–coupling relation $L^4 = 4\pi g_s N \alpha'^2$ of Eq. (53.30), so that $L^8 = 16\pi^2 g_s^2 N^2 \alpha'^4$:

$$c \;=\; \frac{16\pi^2 g_s^2 N^2 \alpha'^4}{64\pi^2 g_s^2 \alpha'^4} \;=\; \frac{N^2}{4}. \tag{53.208}$$

The string-length scale α' and the string coupling g_s have cancelled completely, leaving a pure number times N^2. Comparing the gravity result Eq. (53.208) with the field-theory result Eq. (53.201),

$$c_{\text{gravity}} = \frac{N^2}{4}, \qquad c_{\text{CFT}} = \frac{N^2-1}{4}, \tag{53.209}$$

the two agree to leading order in large N, and the discrepancy is precisely the -1 that distinguishes $\mathrm{SU}(N)$ from $\mathrm{U}(N)$ — a relative $1/N^2$ effect, exactly the order at which the classical (genus-zero) gravity computation is not expected to be exact, and exactly the $\mathrm{SU}(N)$-versus-$\mathrm{U}(N)$ subtlety flagged in Section 53.1. The match is as good as it can be: classical gravity reproduces the leading large-N central charge of a strongly-coupled gauge theory, and the first correction is of the anticipated size.

The central-charge computation deserves emphasis as a template for what "a holographic test" means. The two numbers were computed by utterly different

methods — a free-field one-loop diagram on one side, a classical gravitational action with curvature counterterms on the other — in opposite coupling regimes, and they agreed because the quantity is protected and can be carried from weak to strong coupling. Almost every sharp test of the correspondence has this structure: it lives on a protected quantity, a symmetry-constrained observable, or an integrable sector, precisely so that both sides can be reached at once. The generic, unprotected observable cannot be checked this way, and that is the obstruction we return to in Section 53.7.3.

Planar integrability. The most powerful window onto unprotected data is integrability. Starting in 2002 it was discovered that the planar (leading large-N) dilatation operator of $\mathcal{N}=4$ SYM — the operator whose eigenvalues are the anomalous dimensions of single-trace operators — is the Hamiltonian of an integrable spin chain: the mixing matrix of a long single-trace operator is identical to that of an exactly solvable one-dimensional magnet, diagonalized by a Bethe ansatz. On the gravity side, the corresponding statement is that the type IIB string sigma-model on $\mathrm{AdS}_5 \times S^5$ is classically integrable, possessing an infinite tower of conserved charges. Matching these two integrable structures, and resumming them, made it possible to compute the anomalous dimension of an unprotected operator — the Konishi operator $\mathrm{tr}(\phi^i\phi^i)$ is the canonical example — as a function of the coupling that *interpolates* between the weak-coupling perturbative series and the strong-coupling prediction $\Delta_{\text{Konishi}} \sim 2\lambda^{1/4}$ of the dual string, the $\lambda^{1/4}$ being the curvature-radius scaling $L/\ell_s = \lambda^{1/4}$ of Eq. (53.44). By the mid-2010s the planar spectral problem was, for practical purposes, solved: the *Quantum Spectral Curve* (a finite system of functional equations, formulated around 2013–2014) computes any planar anomalous dimension to essentially arbitrary precision at any coupling. That a single set of equations smoothly connects the perturbative gauge theory to the semiclassical string, reproducing both limits, is among the strongest pieces of evidence for the correspondence — evidence about genuinely dynamical, unprotected data, not merely about symmetry. It is, however, restricted to the planar limit and to this maximally symmetric example.

Supersymmetric localization. A second window onto exact, coupling-dependent data is localization. When a supersymmetric theory is placed on a suitable curved manifold and a supercharge is used to deform the path integral, the integral can collapse ("localize") onto a finite-dimensional integral over a space of saddle configurations, yielding exact, all-orders-plus-nonperturbative answers for protected observables. Pestun's 2007 computation (published 2012) evaluated the partition function and the expectation value of the half-BPS circular Wilson loop of $\mathcal{N}=4$ SYM on the four-sphere exactly, reducing it to a Gaussian matrix model. At large N and large λ the resulting Wilson-loop expectation value behaves as $\langle W \rangle \sim e^{\sqrt{\lambda}}$,

which matches precisely the gravity computation in which the same Wilson loop is dual to a fundamental string whose worldsheet hangs into AdS_5 and whose regularized area is $\sqrt{\lambda}$. Localization thus supplies a continuous family of exact checks — Wilson loops, certain correlators, the Bremsstrahlung function — that again interpolate from weak coupling to the string prediction, and it extends to a wide class of supersymmetric theories beyond $\mathcal{N} = 4$, where it has tested many proposed holographic duals.

The verdict on the evidence. Table 53.3 collects these tests with their status and dates. Taken together they are overwhelming: independent methods — symmetry, protected spectra, anomalies, integrability, localization — agree across the entire range of coupling, on quantities that have no reason to agree unless the two theories are the same. Yet none of this is a proof, and it is important to see why. Every sharp test is, of necessity, performed on a quantity that some special structure (a BPS bound, a symmetry multiplet, planar integrability, a localizing supercharge) allows us to compute on *both* sides. The correspondence's central claim is about *all* observables, including the generic unprotected ones that no such structure reaches. The evidence is therefore strong but, in the precise sense, not constitutive: it pins down the duality on a measure-zero but infinitely detailed set of observables and leaves the bulk of the claim resting on the consistency of that set with a single underlying identification.

53.7.2 The epistemic status: a conjecture taken as a definition

The correspondence, Theorem 53.6, remains unproven in general. It has nonetheless survived more than a quarter-century of increasingly sharp tests without a single confirmed contradiction. No computation done correctly on both sides has ever disagreed; the apparent discrepancies that arose over the years have, on examination, always traced to an error on one side or to a regime where one description was not valid. For a statement of this scope, that record is remarkable, and it has changed how the community uses the correspondence.

The change is conceptual. A non-perturbative *definition* of quantum gravity in four flat dimensions does not exist: the Einstein–Hilbert action is non-renormalizable (a fact this book will sharpen in Chapter 64), and no agreed-upon, complete, ultraviolet-finite formulation of four-dimensional quantum gravity is available. In *asymptotically anti-de Sitter* spacetimes, however, the correspondence supplies exactly such a definition. One *declares* that quantum gravity in an asymptotically-AdS_{d+1} spacetime *is* the dual d-dimensional CFT — a theory we do know how to define non-perturbatively, by the conformal bootstrap data of Chapter 49 or, when it has a Lagrangian and a UV completion, by its own path integral. Read this way, AdS/CFT is not a conjecture awaiting proof so much as a *definition* of the otherwise ill-defined quantum-gravitational side. On this reading the open question is not "is the duality true?" but "does this definition

Test	Status	Basis / date
Bosonic & super symmetry match	**proved in text**	Theorem 53.8, Section 53.3
Protected (BPS) spectrum = KK tower	strong (exact, protected)	superconformal reps; late 1990s
Central charges $a = c = N^2/4$	strong (protected)	Theorem 53.33; 1998
Planar anomalous dimensions	strong (interpolating)	spin-chain integrability 2002; Quantum Spectral Curve ∼2013–14
BPS Wilson loops, $\langle W \rangle \sim e^{\sqrt{\lambda}}$	strong (exact, protected)	localization 2007/2012
Generic unprotected observables	untested directly	no method reaches both sides
The correspondence itself	**conjecture**	Theorem 53.6; 1997, no proof

Table 53.3: The summary of evidence for AdS/CFT. The symmetry match is a theorem of this book; the protected and integrable checks are exact and span all couplings; the generic claim is conjectural. Dates mark the principal results.

reproduce, in the appropriate semiclassical limit, the bulk gravitational physics we expect?" — and it is precisely that semiclassical reconstruction, the emergence of a local bulk from boundary data, that is the live frontier (Section 53.7.5).

Caution

"Taken as a definition" is a methodological stance, not a theorem, and it must not be allowed to launder a conjecture into a proof. Adopting the boundary CFT as the definition of the bulk is useful and internally consistent, but it presupposes the very identification Eq. (53.42) that the decoupling argument only motivates. When this book later computes a gravitational quantity "holographically," it is computing a CFT quantity and *interpreting* it gravitationally; the interpretation rests on the conjecture. We flag this each time it matters.

It is worth asking what a genuine proof would even require. One would need an independent, non-perturbative definition of the string-theory (gravity) side — the thing we presently *lack* and are using the CFT to supply — and then a demonstration that its complete observable algebra is isomorphic to that of the CFT. In the absence of such a definition, the most that the existing

constructions (matrix models for lower-dimensional cases, the BMN/plane-wave limit, integrability, localization) achieve is to verify the isomorphism on ever-larger protected or solvable subsectors. A complete proof is therefore not merely technically hard; it is entangled with the foundational problem of defining the bulk theory at all. This is the deepest reason the correspondence is more naturally wielded as a definition than pursued as a theorem.

53.7.3 Strong/weak duality: the power and the obstruction restated

The defining feature of the correspondence, established quantitatively in Section 53.2.4, is that it is a *strong/weak* duality: the radius–coupling relation $L/\ell_s = \lambda^{1/4}$ of Eq. (53.44) sends the field theory to strong 't Hooft coupling exactly when the geometry becomes weakly curved and classical. This single fact is simultaneously the source of all the correspondence's utility and the reason it is so hard to verify.

It is the power because it converts an intractable problem into a tractable one. The strongly-coupled, large-N regime of a gauge theory — the regime left analytically inaccessible by asymptotic freedom (Chapter 27) and definable but not solvable in closed form on the lattice (Chapter 43) — is mapped to *classical* differential geometry: solving Einstein's equations, evaluating an on-shell action, finding a minimal surface. A quantum-field-theory question with no perturbative handle becomes a boundary-value problem in one higher dimension. This is the entire reason the correspondence is a working tool, and the chapters that follow exploit it relentlessly.

It is the obstruction for exactly the same reason. To *check* a generic observable one would need to compute it on both sides; but the two sides are weakly coupled in disjoint corners of parameter space, so a direct perturbative comparison is impossible for any quantity that is not protected. The only quantities testable on both sides are those for which some extra structure — supersymmetry, a BPS bound, planar integrability, a localizing supercharge — defeats the strong/weak separation and provides an answer valid across all couplings. This is why the evidence of Section 53.7.1 clusters on protected and integrable data: it is not that other tests were neglected, but that the strong/weak nature forbids them. The duality is most useful precisely where it is least checkable, and most checkable precisely where (being protected) it is least surprising.

53.7.4 Bottom-up versus top-down holography

Everything proved or tested above concerns a *top-down* duality: a specific pair — $\mathcal{N} = 4$ SYM and type IIB strings on $\mathrm{AdS}_5 \times S^5$ — derived (insofar as it is derived) from an explicit string-theory construction, the brane decoupling of Section 53.2. Both sides are completely specified, the dictionary is fixed, and the

parameters are related by Eq. (53.43). Other top-down examples exist with the same pedigree — M2- and M5-brane theories dual to $\mathrm{AdS}_4 \times S^7$ and $\mathrm{AdS}_7 \times S^4$, and many constructions with reduced supersymmetry — but in each the field theory and the geometry descend together from a controlled brane setup.

A second, looser, and enormously productive practice goes the other way. One *postulates* a gravitational theory in asymptotically-AdS space — typically Einstein gravity plus a handful of bulk fields chosen for their boundary operators — without deriving it from any microscopic string construction, and uses the dictionary of Sections 53.4 and 53.6 to read off the behavior of *some* strongly-coupled boundary system that one hopes resembles a system of physical interest. This is *bottom-up* holography, and its two principal arenas must be scoped honestly.

AdS/CMT. Applied to condensed matter (*AdS/CMT*), bottom-up holography models strongly-correlated electron systems — non-Fermi liquids, strange metals, holographic superconductors — by simple bulk theories: a charged black brane for a finite-density medium, a charged scalar that condenses to model a superconducting transition, a bulk fermion to probe spectral functions. These constructions reproduce qualitative features (linear-in-temperature resistivity, the absence of long-lived quasiparticles) that are hard to obtain otherwise, and they have suggested genuinely new ways to think about quantum criticality and transport. But the boundary theory in such a model is, almost always, *not known* — there is no identified Lagrangian, no microscopic Hamiltonian, no N that one is expanding in. The bulk is an effective device for generating a strongly-coupled, large-N, conformal-ish system with the right symmetries, not a derived dual of any specific laboratory material. AdS/CMT is therefore best understood as *model-building*: a source of universality-class intuition and qualitative mechanism, not of quantitative predictions for a named compound.

AdS/QCD. Applied to the strong interactions (*AdS/QCD*), bottom-up holography seeks to mimic QCD — which is neither conformal nor supersymmetric — by deforming AdS. "Hard-wall" and "soft-wall" models cut off or warp the radial direction to introduce a mass gap and a hadron spectrum; the radial coordinate is read as an energy scale (the holographic RG of Chapter 54), and confinement is modeled by capping the geometry in the infrared. These models fit meson Regge trajectories and some form factors with a few parameters, and they encode chiral symmetry breaking geometrically. But QCD is not known to have any gravity dual: its lack of conformal symmetry and supersymmetry, and its $N = 3$ rather than $N \to \infty$, place it far from the regime where the correspondence is derived. AdS/QCD is a phenomenological caricature — often a useful one — not a controlled limit of a top-down duality. The honest statement, which Chapter 43 should be read alongside, is that the lattice provides QCD's non-perturbative

definition and quantitative answers, while AdS/QCD provides a complementary, qualitative, large-N-flavored picture.

Physical Insight

The distinction is one of logical direction. Top-down: "here is a string construction; derive its field-theory dual and compute." Bottom-up: "here is the strongly-coupled behavior I want; engineer a bulk that produces it, and trust the universality." The first is (modulo the central conjecture) a derivation; the second is modeling. Both are legitimate, but conflating them — treating an AdS/CMT black brane as if it were a derived dual of a real metal — is a category error the literature sometimes commits and this book does not.

53.7.5 Open frontiers, mid-2020s

We close with an honest map of what is unsettled, dated to the time of writing. These are not gaps to be filled by routine work; they are the directions in which the meaning of holography is still being worked out.

Holography beyond anti-de Sitter: de Sitter and flat space. The entire construction of this chapter rests on the negative cosmological constant of anti-de Sitter space, whose timelike conformal boundary (Section 53.3) provided the home for the dual CFT. The universe we observe is, on the largest scales, closer to *de Sitter* space, with a positive cosmological constant and no timelike boundary — only spacelike boundaries in the far past and future. A holographic principle for de Sitter (*dS/CFT*, proposed around 2001) would relate quantum gravity in dS to a Euclidean CFT living on the future boundary, computing the late-time cosmological wavefunction; but the candidate dual appears to be non-unitary or otherwise exotic, the dictionary is far less developed than the AdS one, and there is nothing like the brane derivation to anchor it. *Flat-space* holography faces the analogous problem at zero cosmological constant: the natural boundary is null infinity, and the program of *celestial holography* (developed intensively since roughly 2017) seeks to encode four-dimensional scattering amplitudes as correlators of a two-dimensional "celestial" CFT on the sphere at infinity, organized by the asymptotic symmetry (BMS) group and the soft theorems of Chapter 63. Both programs are active and partial: neither has a complete, derived dual, and whether realistic cosmology admits a holographic description is genuinely open.

The emergence of bulk locality and the black-hole interior. Even within AdS/CFT, the most basic question — *how* a local, $(d+1)$-dimensional spacetime emerges from a non-local d-dimensional CFT — is incompletely understood.

Reconstructing a bulk field at a point from boundary data (the HKLL construction and its refinements) works in perturbation theory around a fixed background, but the deeper statement, that the bulk is encoded *redundantly* in the boundary like a quantum error-correcting code, and that geometry itself is built from boundary *entanglement*, is the subject of intense current work. This is where holography meets quantum information, and it is the explicit business of Chapters 55 and 56: the Ryu–Takayanagi formula computing entanglement entropy as a bulk minimal area, subregion duality, and entanglement-wedge reconstruction. Pushed to its sharpest, the question becomes whether the boundary theory can reconstruct the *interior* of a black hole — the region behind the horizon — which is the crux of the information paradox. The island/quantum-extremal-surface results of 2019 onward, which recover a unitary Page curve for the entropy of Hawking radiation, are the most striking recent progress and are taken up, honestly scoped, in Chapter 57. What "the bulk" even is, as an emergent and approximate notion, is not yet settled.

The dictionary away from the conformal and supersymmetric case. Finally, the precise, derived dictionary is sharpest exactly where the symmetry is largest — the conformal, maximally supersymmetric, planar, large-N corner. Away from it, much is qualitative. Finite N (string loops, $g_s \neq 0$), finite λ (α' corrections to the geometry), non-conformal flows (a running boundary theory dual to a non-AdS bulk, the holographic RG of Chapter 54), broken or absent supersymmetry, and theories with fundamental "flavor" matter all admit holographic treatments, but the control — and in many cases the very existence of a clean dual — degrades as one leaves the symmetric point. The frontier here is less dramatic than the black-hole interior but no less important: extending the correspondence from its rigid, exactly-solvable heart to the generic, realistic theories one actually wants to understand.

These frontiers are the connective tissue of the rest of Part XV. With the scope and reliability of the duality now calibrated — what is proved, what is exhaustively tested, what is conjecture, and what is open — we are equipped to use it. Chapter 54 puts the machine to work, computing higher-point correlators from Witten diagrams and importing finite temperature and black holes to extract holographic thermodynamics; Chapters 55 to 57 then follow the emergent-geometry frontier into entanglement, the Ryu–Takayanagi formula, and the black-hole information problem, where the duality stops being a calculational tool and becomes a statement about what spacetime is.

Further reading

The original conjecture is Maldacena's [331]; the correlator dictionary that made it computational is [242, 522]. The comprehensive early review, still the

standard reference for the top-down construction and its tests, is [9]; for textbook developments see [359]. Planar integrability is surveyed in the collection [53], which assembles the spin-chain and Quantum-Spectral-Curve machinery; the exact Wilson-loop and partition-function results from supersymmetric localization originate in [399]. Bottom-up applications to condensed-matter systems are developed in [253]. For the frontiers: the infrared and asymptotic-symmetry structure underlying celestial (flat-space) holography is laid out in [459], de Sitter holography is reviewed in [26], and the entanglement-wedge reconstruction that resolves the information paradox holographically is represented by [391], with the underlying holographic entanglement entropy in [414, 422].

Chapter 54

Holographic Correlators and Thermodynamics

The previous chapter built the AdS/CFT dictionary as a statement of principle: the GKP–Witten relation Eq. (53.162) equates the boundary generating functional with a bulk gravitational partition function, which in the supergravity regime collapses onto a single classical saddle Eq. (53.163), and the field–operator map of Section 53.5 ties each bulk field to a boundary primary through the mass–dimension relation Theorem 53.17. This chapter turns that principle into a calculus. A classical saddle is a solution of differential equations, and a generating functional differentiated against its sources is a set of correlators; marrying these two facts systematically yields a perturbation theory — the Witten-diagram expansion — that computes the correlators of a strongly coupled conformal field theory by solving wave equations in one higher dimension. Everything the chapter does is an application of this single idea, first at zero temperature, where the bulk is empty anti–de Sitter space, and then at finite temperature, where the bulk grows a horizon.

We begin in Section 54.1 by deriving the position-space Feynman rules of holography: why the classical on-shell action generates the connected correlators (Theorem 10.37 and Eq. (10.210)), why only tree diagrams survive at large N (the bulk image of the genus expansion Theorem 53.2), and how every diagram is assembled from two propagators, bulk-to-bulk and bulk-to-boundary, built here in closed form. Section 54.2 confronts the one subtlety the rules gloss over — the on-shell action diverges at the conformal boundary — and develops holographic renormalization: the Fefferman–Graham near-boundary expansion, the covariant counterterms that remove the local divergences exactly as the boundary theory's own counterterms did in Section 19.1, and the identification of the operator expectation value with the subleading falloff. The payoff is the scalar two-point function, recovered in position space and matched against the conformally fixed form of Theorem 47.21. Section 54.3 switches on interactions:

the cubic contact diagram delivers the OPE coefficient as an explicit ratio of Gamma functions, and the four-point exchange, decomposed into the conformal blocks of Theorem 47.49, exposes both the single-trace operator dual to the exchanged field and the entire double-trace tower $[\mathcal{O}\mathcal{O}]_{n,\ell}$ that the bootstrap of Chapters 49 and 50 independently demands — closing, from the bulk side, the loop the bootstrap opened from crossing alone.

The chapter's center of gravity is thermal. Section 54.4 asks which bulk geometry dominates the gravitational path integral when the boundary carries a Euclidean time circle, and answers with the planar AdS–Schwarzschild black brane: its Hawking temperature follows from demanding the Euclidean geometry close off smoothly at the horizon (Theorem 5.30), its renormalized on-shell action — made finite by the very counterterms of Section 54.2.3 — is the free energy, and the horizon area divided by $4G$ is the entropy, the Bekenstein–Hawking law derived rather than assumed. The carried example, $\mathcal{N} = 4$ super-Yang–Mills (the maximally symmetric large-N cousin of Yang–Mills theory, Chapter 25), supplies the celebrated factor of $\frac{3}{4}$ between strong- and weak-coupling entropy, and the Hawking–Page transition realizes the confinement/deconfinement transition of Section 27.7 as a sharp geometric event. Section 54.5 then leaves Euclidean signature for real time: the infalling horizon boundary condition selects the retarded correlator, the shear graviton reduces to a massless scalar, and a membrane-paradigm flux argument delivers the universal ratio $\eta/s = 1/4\pi$, whose status as a near-saturated benchmark — and its violation by higher-derivative gravity — we report honestly as of the mid-2020s.

A single thread runs through all of this, and Section 54.6 names it. Every computation has been a story told along the radial coordinate: the divergences of the on-shell action were power laws in the radial cutoff, the retarded correlator flowed from a boundary source to an infalling horizon, the black brane differed from the vacuum only deep in the interior. The radial direction of an asymptotically-AdS geometry is the renormalization-group scale of the boundary theory, and radial evolution of the bulk fields is the RG flow of its couplings. We make this precise — domain-wall geometries, first-order flow equations from a fake superpotential, a holographic beta function that reproduces the mass–dimension relation, and a one-line proof of the a-theorem of Theorem 52.19 from the bulk null energy condition — and so close the loop with the Wilsonian and Callan–Symanzik pictures of Part VI (Chapters 23 and 24). The radial-as-scale picture is, in turn, the seed of the entanglement story that Chapters 55 and 56 take up next.

54.1 Witten Diagrams: Perturbative Holography

The chapter opened by promoting the field–operator dictionary of Section 53.5 from a translation table into a calculus: the GKP–Witten relation Eq. (53.162) equates the boundary generating functional with the bulk partition function

evaluated on prescribed boundary data, and in the supergravity regime the bulk path integral collapses onto a single classical saddle Eq. (53.163). A classical saddle is a solution of differential equations, and a generating functional differentiated against its sources is a set of correlators. The whole of holographic perturbation theory is the systematic marriage of these two facts. This section performs that marriage explicitly. We will show, first, why the *classical* on-shell action computes the *connected* correlators and why, at large N, only *tree* diagrams survive; then we build the two propagators — bulk-to-bulk and bulk-to-boundary — out of which every diagram is assembled; and finally we state the position-space Feynman rules in anti–de Sitter space, the Witten rules, that turn any supergravity correlator into a finite recipe of propagators and integrated vertices. The result is a perturbative apparatus standing one dimension above the conformal field theory it computes, structurally identical to ordinary position-space Feynman rules (Theorem 15.9) but with flat propagators replaced by curved ones and momentum integrals replaced by integrals over the bulk.

Throughout this section we work in Euclidean Poincaré AdS_{d+1} Eq. (53.161) with flat boundary $\mathbb{R}^d$, and — as is standard for propagators — we set the radius $L = 1$, restoring it by dimensional analysis whenever a physical scale is needed. A bulk scalar field ϕ of mass m is dual to a boundary scalar primary $\mathcal{O}$ of dimension Δ, the two related by the mass–dimension relation $\Delta(\Delta - d) = m^2$ of Theorem 53.17, with $\Delta \equiv \Delta_+ = \frac{d}{2} + \nu$ the larger root and $\nu = \sqrt{\frac{d^2}{4} + m^2}$.

54.1.1 The classical saddle computes connected correlators

The point of departure is the classical limit of the GKP–Witten relation. Writing ϕ_0 for the boundary source — the coefficient of the non-normalizable falloff $z^{d-\Delta}$ that the boundary condition Eq. (53.116) hands to the field theory — the bulk partition function is dominated by the action of the dominant solution,

$$Z_{\mathrm{grav}}[\phi_0] \;=\; e^{-S_{\text{on-shell}}[\phi_0]}\,(1+O(G_N)), \qquad W[\phi_0] \;\equiv\; \ln Z_{\mathrm{CFT}}[\phi_0] \;=\; -S_{\text{on-shell}}[\phi_0]+O(G_N) \tag{54.1}$$

the second equality being Eq. (53.162) after taking logarithms. The object $W[\phi_0]$ is, by definition, the generating functional of *connected* correlators: this is the content of Theorem 10.37, where $\ln Z$ was shown to generate exactly the connected (linked) diagrams, with the disconnected pieces exponentiating into Z itself. Functional differentiation then yields the connected correlators of $\mathcal{O}$,

$$\langle \mathcal{O}(x_1)\cdots\mathcal{O}(x_n)\rangle_{\mathrm{c}} \;=\; \frac{\delta^n W[\phi_0]}{\delta\phi_0(x_1)\cdots\delta\phi_0(x_n)}\bigg|_{\phi_0=0}, \tag{54.2}$$

in precise parallel with the flat-space generating functional of Theorem 10.11; the source–response normalization that converts a derivative of $-S_{\text{on-shell}}$ into the canonically normalized correlator was fixed once and for all, for the two-point case, in Section 53.6.5, and the higher functional derivatives inherit it.

Why the answer is a sum over trees. That Eq. (54.1) is the *classical* action of a *solution* has a sharp diagrammatic consequence: the on-shell action, expanded in powers of the source, is a sum over tree diagrams. To see this, take a representative bulk action with self-interactions,

$$S_E[\phi] \;=\; \int \mathrm{d}^{d+1}X\,\sqrt{g}\,\Big[\tfrac{1}{2}\,g^{MN}\partial_M\phi\,\partial_N\phi + \tfrac{1}{2}m^2\phi^2 + \tfrac{1}{3!}\,g_3\,\phi^3 + \tfrac{1}{4!}\,g_4\,\phi^4 + \cdots\Big], \tag{54.3}$$

with $X = (z, x)$ a bulk point and $\sqrt{g} = z^{-(d+1)}$ in our units. The classical equation of motion is the curved-space, nonlinear Klein–Gordon equation

$$(-\Box_{\mathrm{AdS}} + m^2)\,\phi \;=\; -V'_{\mathrm{int}}(\phi) \;=\; -\tfrac{1}{2}g_3\,\phi^2 - \tfrac{1}{3!}g_4\,\phi^3 - \cdots, \tag{54.4}$$

to be solved subject to the boundary condition that the coefficient of $z^{d-\Delta}$ equals ϕ_0. We solve it iteratively in the strength of the source, writing $\phi = \sum_{n\geq 1}\phi^{(n)}$ with $\phi^{(n)}$ of order n in ϕ_0. At first order the right-hand side of Eq. (54.4) is absent and we must solve the *free* wave equation with the prescribed boundary source. The solution is the boundary source smeared against a kernel,

$$\phi^{(1)}(X) \;=\; \int \mathrm{d}^{d}y\; K_\Delta(X;y)\,\phi_0(y), \tag{54.5}$$

where K_Δ, the *bulk-to-boundary propagator*, is the regular solution of the free equation with a unit boundary source — precisely the object Theorem 53.30, which we will rederive below as a limit of the bulk-to-bulk propagator. At second order, Eq. (54.4) reads $(-\Box_{\mathrm{AdS}} + m^2)\phi^{(2)} = -\frac{1}{2}g_3(\phi^{(1)})^2$, with *no* additional boundary source (the source is exhausted at first order). The solution is the inhomogeneous term convolved against the Green's function of the bulk wave operator,

$$\phi^{(2)}(X) \;=\; -\tfrac{1}{2}\,g_3\int \mathrm{d}^{d+1}X'\,\sqrt{g'}\;G_\Delta(X,X')\,\big[\phi^{(1)}(X')\big]^2, \tag{54.6}$$

where G_Δ, the *bulk-to-bulk propagator*, is the normalizable Green's function constructed in Section 54.1.2. The recursion continues: each new order ties one more vertex, with its bulk-to-bulk legs, onto the growing solution. By construction every term in $\phi = \sum_n \phi^{(n)}$ is a *tree* — a connected graph with no closed loops — because the iteration never integrates a field against itself; it only feeds lower-order solutions into vertices.

Inserting $\phi = \sum_n \phi^{(n)}$ back into the action Eq. (54.3) and using the equation of motion to discard the bulk part (it vanishes on shell, exactly as in Eq. (53.180)) leaves $S_{\text{on-shell}}[\phi_0]$ as a functional of the source whose order-n piece is a sum of tree diagrams with n external boundary legs. Differentiating n times as in Eq. (54.2) strips the n external K_Δ legs and leaves the connected n-point function as a sum over bulk tree topologies. This is the holographic shadow of the elementary fact that the *classical* field is the tree-level (stationary-phase) approximation to the path integral, and that the Legendre transform relating W to the effective action (Eq. (10.210)) exchanges connected graphs for one-particle-irreducible ones. Here the boundary effective action is literally the on-shell bulk action.

Loops are $1/N^2$. It remains to justify why *only* trees appear at leading order. The bulk gravitational action carries an overall factor of the inverse Newton constant; for a matter sector minimally coupled to gravity we may write $S_E = \frac{1}{G_N} I[\phi]$ with I a functional whose couplings are $O(N^0)$, since $1/G_N \propto N^2$ by the parameter dictionary Eq. (53.43). In a stationary-phase (loop) expansion of $\int \mathcal{D}\phi\, e^{-S_E}$ the small parameter is G_N: the quadratic form has inverse $\propto G_N$, so every propagator carries one factor of G_N, while every vertex comes from S_E and carries one factor of $1/G_N$. A connected diagram with V vertices and I internal lines therefore scales as G_N^{I-V}. Its number of loops is $\mathcal{L} = I - V + 1$, so

$$\text{(diagram)} \;\propto\; G_N^{I-V} \;=\; G_N^{\mathcal{L}-1} \;=\; \frac{1}{G_N}\, G_N^{\mathcal{L}} \;\propto\; N^2 \left(N^{-2}\right)^{\mathcal{L}}. \tag{54.7}$$

The leading contribution, $\mathcal{L} = 0$, is the tree level, of order N^2; each additional bulk loop costs a relative factor $G_N \propto 1/N^2$. This is nothing but the genus expansion of Theorem 53.2 read in the bulk: a closed bulk loop is the gravitational image of adding a handle to the boundary diagram's surface, $g \to g+1$, which by Eq. (53.21) costs exactly $g_s^2 \sim 1/N^2$. In the strict large-N, large-λ limit — where classical supergravity is the correct bulk description — only the planar, tree-level diagrams survive, and the boundary correlators of single-trace operators are computed by classical field theory in the bulk.

Physical Insight

The hierarchy "tree $\gg$ loop" on the gravity side is the statement "planar $\gg$ non-planar" on the gauge side, which is in turn the statement that single-trace operators *factorize* at $N = \infty$ (Theorem 53.2): their connected correlators are suppressed relative to disconnected products. A factorizing operator behaves like a classical variable taking a definite value, and a path integral dominated by definite values is a saddle point. Holography promotes that saddle from an abstract "master field" to an honest classical field propagating in one higher dimension — and the perturbation theory around it is the Witten-diagram expansion.

Everything now hinges on the two propagators. We build them in turn, beginning with the bulk-to-bulk propagator, from which the bulk-to-boundary propagator descends as a boundary limit.

54.1.2 The bulk-to-bulk propagator

Definition 54.1 (Bulk-to-bulk propagator)**.** The *bulk-to-bulk propagator* $G_\Delta(X, Y)$ of a scalar of mass m (dual dimension Δ) on Euclidean AdS_{d+1} is the Green's function of the wave operator,

$$\left(-\Box_{\mathrm{AdS},X} + m^2\right) G_\Delta(X, Y) \;=\; \frac{1}{\sqrt{g}}\, \delta^{d+1}(X - Y), \tag{54.8}$$

selected to be regular in the interior and to decay in its normalizable mode ($\sim z^{\Delta}$, not $z^{d-\Delta}$) as either argument approaches the conformal boundary, so that no source for $\mathcal{O}$ is turned on.

Reduction to one variable. Euclidean AdS_{d+1} is a maximally symmetric space — it is hyperbolic space $\mathbb{H}_{d+1}$ — and its isometry group acts transitively on pairs of points at fixed geodesic separation. The Green's function therefore depends on X and Y only through the geodesic distance between them, or equivalently through the dimensionless *chordal variable*

$$u \;\equiv\; \frac{(z-w)^2+|x-y|^2}{2\,z\,w}, \qquad X=(z,x),\; Y=(w,y), \tag{54.9}$$

which is related to the geodesic distance s by $\cosh s = 1+u$. It is cleanest to trade u for the variable

$$\xi \;\equiv\; \frac{1}{1+u} \;=\; \frac{2zw}{z^2+w^2+|x-y|^2} \;=\; \frac{1}{\cosh s} \;\in\; (0,1], \tag{54.10}$$

which runs from $\xi=1$ at coincidence ($s=0$) to $\xi\to 0$ at infinite separation ($s\to\infty$). Acting on a function of s alone, the $\mathbb{H}_{d+1}$ Laplacian is the radial operator

$$\Box_{\mathrm{AdS}}\, G \;=\; G''(s) + d\,\coth(s)\,G'(s), \tag{54.11}$$

the coefficient $d=(d+1)-1$ being the standard factor in the radial Laplacian of a $(d+1)$-dimensional space of constant negative curvature. Away from coincidence the Green's function obeys the homogeneous equation $(-\Box_{\mathrm{AdS}}+m^2)G=0$, i.e.

$$G''(s) + d\,\coth(s)\,G'(s) - m^2\,G = 0. \tag{54.12}$$

We convert to ξ using $\xi=\operatorname{sech} s$. Then $\mathrm{d}\xi/\mathrm{d}s = -\operatorname{sech} s\tanh s = -\xi\sqrt{1-\xi^2}$ and $\coth s = 1/\sqrt{1-\xi^2}$, so with $A(\xi)\equiv -\xi\sqrt{1-\xi^2}$,

$$G'(s) = A\,G_\xi, \qquad G''(s) = A(A\,G_\xi)_\xi = A^2\,G_{\xi\xi} + A\,A'\,G_\xi, \tag{54.13}$$

with $A^2=\xi^2(1-\xi^2)$ and $AA'=\xi(1-2\xi^2)$, while $d\coth s\,G'(s) = d\cdot(1-\xi^2)^{-1/2}\cdot(-\xi\sqrt{1-\xi^2})\,G_\xi = -d\,\xi\,G_\xi$. Substituting into Eq. (54.12) and collecting,

$$\xi^2(1-\xi^2)\,G_{\xi\xi} + \xi\big[(1-d)-2\xi^2\big]\,G_\xi - m^2\,G = 0. \tag{54.14}$$

The behaviour at large separation, $\xi\to 0$, is governed by the leading balance $\xi^2 G_{\xi\xi}+(1-d)\xi G_\xi - m^2 G\approx 0$; trying $G\sim\xi^p$ gives $p(p-1)+(1-d)p-m^2 = p(p-d)-m^2=0$, the mass–dimension equation Eq. (53.112) once more. Its roots are $p=\Delta$ and $p=d-\Delta$, and *normalizability* selects the decaying root $G\sim\xi^{\Delta}$.

The hypergeometric solution. Strip the leading power by writing $G(\xi) = \xi^{\Delta}\, y(\xi)$. With $G' = \Delta\xi^{\Delta-1}y + \xi^{\Delta}y'$ and $G'' = \Delta(\Delta-1)\xi^{\Delta-2}y + 2\Delta\xi^{\Delta-1}y' + \xi^{\Delta}y''$, equation Eq. (54.14) divided by ξ^{Δ} becomes, after the y-coefficient bracket $\big[\Delta(\Delta-1) + (1-d)\Delta - m^2\big] = \Delta(\Delta-d) - m^2$ vanishes by Eq. (53.112),

$$(1-\xi^2)\,y'' + \Big[\frac{2\Delta+1-d}{\xi} - (2\Delta+2)\,\xi\Big]y' - \Delta(\Delta+1)\,y = 0. \tag{54.15}$$

Now pass to the variable $t = \xi^2$, so that $y' = 2\sqrt{t}\,y_t$ and $y'' = 2\,y_t + 4t\,y_{tt}$. Substituting and dividing by 4,

$$t(1-t)\,y_{tt} + \Big[(\Delta+1-\tfrac{d}{2}) - (\Delta+\tfrac{3}{2})t\Big]\,y_t - \tfrac{1}{4}\Delta(\Delta+1)\,y = 0. \tag{54.16}$$

This is the hypergeometric equation $t(1-t)y_{tt} + [c - (a+b+1)t]y_t - ab\,y = 0$ with parameters read off directly:

$$c = \Delta - \frac{d}{2} + 1, \qquad a+b = \Delta + \tfrac{1}{2}, \qquad ab = \tfrac{1}{4}\Delta(\Delta+1). \tag{54.17}$$

The quadratic $X^2 - (\Delta+\frac{1}{2})X + \frac{1}{4}\Delta(\Delta+1) = 0$ has discriminant $(\Delta+\frac{1}{2})^2 - \Delta(\Delta+1) = \frac{1}{4}$, so its roots are $a = \frac{\Delta}{2}$ and $b = \frac{\Delta}{2} + \frac{1}{2}$. The interior-regular, normalizable solution is therefore

$$G_{\Delta}(\xi) \;=\; \mathcal{C}_{\Delta}\,\xi^{\Delta}\,{}_2F_1\Big(\frac{\Delta}{2},\,\frac{\Delta}{2}+\frac{1}{2};\,\Delta-\frac{d}{2}+1;\,\xi^2\Big), \tag{54.18}$$

the second solution behaving as $\xi^{d-\Delta}$ near $\xi = 0$ and discarded as non-normalizable.

Fixing the normalization by the short-distance singularity. The constant $\mathcal{C}_{\Delta}$ is fixed by the unit-strength delta source in Eq. (54.8), which is the statement that, at short distance, G_{Δ} must reduce to the flat-space Green's function: near coincidence the AdS metric is locally flat and the curvature and mass terms are subleading. In D Euclidean dimensions the Green's function of $-\nabla^2$ is $\mathcal{G}_{\text{flat}}(r) = A_D\, r^{2-D}$ with A_D fixed by Gauss's law, $1 = \int_{\text{ball}}(-\nabla^2\mathcal{G}) = -\oint \partial_r\mathcal{G}\,\mathrm{d}S = A_D(D-2)\,\Omega_{D-1}$, where $\Omega_{D-1} = 2\pi^{D/2}/\Gamma(D/2)$ is the unit-sphere area; hence

$$A_D = \frac{1}{(D-2)\,\Omega_{D-1}} = \frac{\Gamma(\frac{D}{2}-1)}{4\,\pi^{D/2}}, \qquad D = d+1: \quad \mathcal{G}_{\text{flat}}(s) = \frac{\Gamma(\frac{d-1}{2})}{4\,\pi^{(d+1)/2}}\,s^{\,1-d}. \tag{54.19}$$

On the other side, the coincidence limit $s \to 0$ is $\xi \to 1$, i.e. $t \to 1$. The hypergeometric function diverges there as $c-a-b = -\frac{d-1}{2} < 0$, and by the standard connection formula ${}_2F_1(a,b;c;t) \to \frac{\Gamma(c)\Gamma(a+b-c)}{\Gamma(a)\Gamma(b)}(1-t)^{c-a-b}$. Using $1-t = 1-\xi^2 = \tanh^2 s \simeq s^2$, $a+b-c = \frac{d-1}{2}$, and the Legendre duplication identity $\Gamma(\frac{\Delta}{2})\Gamma(\frac{\Delta}{2}+\frac{1}{2}) = 2^{1-\Delta}\sqrt{\pi}\,\Gamma(\Delta)$,

$$G_{\Delta}(\xi) \;\xrightarrow{\;s\to 0\;}\; \mathcal{C}_{\Delta}\,\frac{\Gamma(\Delta-\frac{d}{2}+1)\,\Gamma(\frac{d-1}{2})}{2^{1-\Delta}\sqrt{\pi}\,\Gamma(\Delta)}\;s^{\,1-d}. \tag{54.20}$$

Matching Eq. (54.20) to Eq. (54.19) cancels the common $\Gamma(\frac{d-1}{2})s^{1-d}$ and fixes

$$\boxed{\mathcal{C}_\Delta \;=\; \frac{\Gamma(\Delta)}{2^{\Delta+1}\,\pi^{d/2}\,\Gamma(\Delta-\frac{d}{2}+1)}\,.} \tag{54.21}$$

Equations Eq. (54.18) and Eq. (54.21) are the bulk-to-bulk propagator in closed form. The same object is occasionally written in the chordal variable u of Eq. (54.9) as $G_\Delta \propto (2u)^{-\Delta}\,{}_2F_1(\Delta,\Delta-\frac{d-1}{2};2\Delta-d+1;-2/u)$; this is Eq. (54.18) after a quadratic hypergeometric transformation and is the form used downstream in Section 54.3.3. The two agree term by term, as the matching of their large-separation falloffs $\propto \xi^{\Delta} \propto u^{-\Delta}$ already guarantees.

54.1.3 The bulk-to-boundary propagator as a boundary limit

The bulk-to-boundary propagator K_Δ of Eq. (54.5) is the kernel that carries a boundary source into the interior; it is what an external leg of a Witten diagram is made of. It is most cleanly obtained as the boundary limit of G_Δ: a source placed at a bulk point Y becomes a boundary source as Y is pushed to the conformal boundary, $w \to 0$. The precise statement is that the normalizable falloff of G_Δ in its second argument factors out a bulk-to-boundary propagator,

$$K_\Delta(X;y) \;=\; (2\Delta-d)\,\lim_{w\to 0}\; w^{-\Delta}\,G_\Delta(X;\,w,y). \tag{54.22}$$

We carry out the limit explicitly and recover both the closed form of K_Δ and the normalization constant c_Δ that Theorem 53.30 obtained independently by the inversion method. As $w \to 0$, the chordal variable Eq. (54.10) vanishes, $\xi = 2zw/(z^2+w^2+|x-y|^2) \to 2w\cdot z/(z^2+|x-y|^2) \to 0$, so the hypergeometric factor in Eq. (54.18) tends to unity and only the leading power survives:

$$G_\Delta(X;w,y) \;\xrightarrow{w\to 0}\; \mathcal{C}_\Delta\,\xi^{\Delta} \;=\; \mathcal{C}_\Delta\,(2w)^{\Delta}\Big(\frac{z}{z^2+|x-y|^2}\Big)^{\Delta}. \tag{54.23}$$

Multiplying by $w^{-\Delta}$ removes the w-dependence, and the prefactor in Eq. (54.22) is chosen precisely to clean up the constant:

$$K_\Delta(X;y) \;=\; (2\Delta-d)\,2^{\Delta}\,\mathcal{C}_\Delta\,\Big(\frac{z}{z^2+|x-y|^2}\Big)^{\Delta} \;=\; c_\Delta\,\Big(\frac{z}{z^2+|x-y|^2}\Big)^{\Delta}. \tag{54.24}$$

The constant assembles to exactly c_Δ: using $(2\Delta-d)\Gamma(\Delta-\frac{d}{2}) = 2\,\Gamma(\Delta-\frac{d}{2}+1)$,

$$(2\Delta-d)\,2^{\Delta}\,\mathcal{C}_\Delta = (2\Delta-d)\,2^{\Delta}\,\frac{\Gamma(\Delta)}{2^{\Delta+1}\pi^{d/2}\Gamma(\Delta-\frac{d}{2}+1)} = \frac{\Gamma(\Delta)}{\pi^{d/2}\,\Gamma(\Delta-\frac{d}{2})} \;=\; c_\Delta, \tag{54.25}$$

in exact agreement with the value $c_\Delta = \Gamma(\Delta)/[\pi^{d/2}\Gamma(\Delta-\frac{d}{2})]$ of Eq. (53.177). This is a genuine cross-check: Theorem 53.30 fixed c_Δ by demanding $K_\Delta \to$

$z^{d-\Delta}\delta^d(x-y)$ at the boundary, whereas here the same constant emerges from the short-distance strength of the bulk-to-bulk delta source in Eq. (54.21). Two independent normalizations of two different propagators land on the same number; the perturbation theory is internally consistent.

Two properties of K_Δ make it the correct external leg, and both are visible in Eq. (54.24). First, it solves the *homogeneous* wave equation $(-\Box_{\mathrm{AdS}}+m^2)K_\Delta = 0$ everywhere in the interior — it must, being the $w \to 0$ limit of $G_\Delta(X;Y)$ away from coincidence — so attaching it to a vertex turns on no spurious bulk source. (One checks this directly: $\phi = z^\Delta$ solves the free equation by the computation in Eq. (53.177), and K_Δ is its image under the inversion isometry Eq. (53.178).) Second, it carries a *delta-function boundary source*: as $z \to 0$ at fixed $x \neq y$ it vanishes as z^Δ, the normalizable mode, while integrated against a test function it develops the non-normalizable $z^{d-\Delta}$ piece localized at $x = y$,

$$K_\Delta(z,x;y) \xrightarrow{z\to 0} z^{\,d-\Delta}\,\delta^d(x-y) \;+\; z^\Delta\,\frac{c_\Delta}{|x-y|^{2\Delta}} \;+\; \cdots\,, \tag{54.26}$$

the coefficient of $z^{d-\Delta}$ being a delta function precisely because c_Δ was fixed by the integral Eq. (53.179). The first term identifies K_Δ as the response to a unit boundary source $\phi_0 = \delta^d(x-y)$, justifying Eq. (54.5); the coefficient of the second, normalizable term, $c_\Delta/|x-y|^{2\Delta}$, is already the seed of the two-point function that Section 54.2 extracts in full.

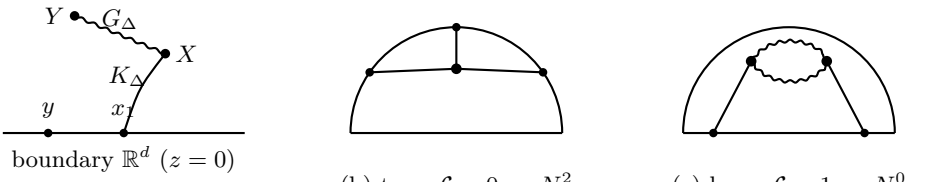
54.1.4 The Witten rules

We can now state the Feynman rules of perturbative holography. They are the diagrammatic encoding of the recursive solution of Section 54.1.1: each functional derivative in Eq. (54.2) attaches an external boundary leg, each interaction vertex of Eq. (54.3) produces an integrated bulk point, and the lines joining vertices are bulk-to-bulk propagators. A diagram drawn on a slice of the Poincaré patch — external points on the boundary, vertices in the interior — is called a *Witten diagram* (Fig. 54.1).

Theorem 54.2 (Witten-diagram rules)**.** *In the supergravity limit the connected n-point function $\langle \mathcal{O}_1(x_1)\cdots\mathcal{O}_n(x_n)\rangle_{\mathrm{c}}$ of single-trace boundary primaries is the sum over connected Witten diagrams, evaluated by the following position-space rules in Euclidean* AdS_{d+1}*:*

1. ***External legs.*** *Each boundary insertion $\mathcal{O}_i(x_i)$ is attached to a bulk vertex by a bulk-to-boundary propagator $K_{\Delta_i}(X;x_i) = c_{\Delta_i}\big(z/(z^2+|x-x_i|^2)\big)^{\Delta_i}$ Eq. (54.24), with $\Delta_i(\Delta_i-d) = m_i^2$.*

2. ***Internal lines.*** *Each internal line carrying a field of dimension Δ is a bulk-to-bulk propagator $G_\Delta(X,Y)$ Eq. (54.18), the normalizable Green's function Eq. (54.8).*



(a) propagators

(b) tree, $\mathcal{L}=0$, $\sim N^2$

(c) loop, $\mathcal{L}=1$, $\sim N^0$

Figure 54.1: The ingredients of perturbative holography. *(a)* A bulk-to-boundary propagator K_Δ (solid) reaches from a boundary insertion to an interior bulk point; a bulk-to-bulk propagator G_Δ (wavy) joins two interior points. *(b)* A tree-level Witten diagram — here a cubic contact vertex (filled dot) integrated over the bulk, with three external K_Δ legs — contributes at order N^2. *(c)* A one-loop diagram, with two internal bulk-to-bulk propagators forming a closed loop, is suppressed by $G_N \propto N^{-2}$ and drops out of the leading-order correlator. Solid horizontal lines are the conformal boundary; the half-disk is a slice of Euclidean AdS_{d+1}.

3. ***Vertices.*** *Each vertex is the corresponding coupling of the bulk action Eq. (54.3) integrated over the bulk with the invariant measure, $-g_k\int \mathrm{d}^{d+1}X\,\sqrt{g}$, with $\sqrt{g}=z^{-(d+1)}$ (in units $L=1$), and the appropriate symmetry factor.*

4. ***Loop counting.*** *A diagram with $\mathcal{L}$ closed bulk loops is suppressed by $G_N^{\mathcal{L}} \propto N^{-2\mathcal{L}}$ relative to the tree level Eq. (54.7). At leading order in $1/N$ only tree diagrams contribute.*

The overall normalization (one factor of $1/G_N \propto N^2$) and the sign are those of Eq. (54.1), fixed for the two-point case in Section 53.6.5.

Proof. The rules are a transcription of the recursive solution of the equations of motion and the resulting on-shell action. The first-order solution Eq. (54.5) attaches one K_Δ per unit of source, giving rule 1; the second- and higher-order solutions Eq. (54.6) convolve the inhomogeneity against G_Δ at each integrated bulk vertex, giving rules 2 and 3, with the measure $\sqrt{g}\,\mathrm{d}^{d+1}X$ inherited from the action Eq. (54.3). Resubstituting into the action and differentiating n times with respect to the source extracts the connected n-point function as the sum of trees with n external legs; the only freedom — combinatorial vertex weights — is the symmetry-factor bookkeeping of ordinary Feynman rules (Theorem 15.9), unchanged here because it is purely combinatorial. Rule 4 is the loop-counting Eq. (54.7), equivalently the genus expansion Theorem 53.2. □

The simplest diagram of all has no vertex: two external legs are sewn directly, which is the statement that the quadratic on-shell action computes the two-point function. We isolate that case as the bridge to the next section, but first we

exhibit the rules at work on the simplest *interacting* diagram, the cubic contact, which makes the calculus concrete and names the integral that Section 54.3 will evaluate.

Worked Example 54.3 (The cubic contact diagram)**.** Take three bulk scalars ϕ_1, ϕ_2, ϕ_3 of dimensions $\Delta_1, \Delta_2, \Delta_3$ with a single cubic vertex $g_3\,\phi_1\phi_2\phi_3$ in the action Eq. (54.3), dual to three boundary primaries $\mathcal{O}_1, \mathcal{O}_2, \mathcal{O}_3$. We assemble their connected three-point function at leading (tree) order.

By Theorem 54.2 the only connected tree topology is a single bulk vertex with three external legs (Fig. 54.1b). Each source $\phi_{0,i}$ pulls down one bulk-to-boundary propagator $K_{\Delta_i}(X; x_i)$, the three meet at the vertex point X, and X is integrated over the bulk with the invariant measure. With three distinct fields the vertex carries no symmetry factor, and Eq. (54.2) gives

$$\langle \mathcal{O}_1(x_1)\mathcal{O}_2(x_2)\mathcal{O}_3(x_3)\rangle_{\mathrm{c}} \;=\; -\,g_3 \int \mathrm{d}^{d+1}X\,\sqrt{g}\;K_{\Delta_1}(X;x_1)\,K_{\Delta_2}(X;x_2)\,K_{\Delta_3}(X;x_3). \tag{54.27}$$

This is a contact Witten diagram: every line is a K_Δ, there is a single integrated vertex, no bulk-to-bulk propagator appears, and there is manifestly no loop. The entire content of the calculation is now the bulk integral on the right, a function of the three boundary points x_1, x_2, x_3 alone. Two of its features are forced before any integration is done. The integrand is built from isometry-covariant objects, so translations, rotations, dilations and the inversion Eq. (53.178) of AdS_{d+1} act on Eq. (54.27) as the conformal group acts on a CFT three-point function; the integral is therefore proportional to the conformally fixed structure $|x_{12}|^{-(\Delta_1+\Delta_2-\Delta_3)}|x_{23}|^{-(\Delta_2+\Delta_3-\Delta_1)}|x_{13}|^{-(\Delta_1+\Delta_3-\Delta_2)}$ of Theorem 47.21's three-point companion. And its overall coefficient — the holographic OPE coefficient C_{123} — is a definite ratio of Gamma functions built from g_3, the Δ_i, and the c_{Δ_i}. Evaluating the integral and extracting that coefficient is the work of Section 54.3, where the contact integral Eq. (54.27) is given the name D-function and computed by Schwinger parameters; here we have shown only that the Witten rules assemble it with no ambiguity left over. The reader should note how little freedom remains: the bulk action fixes g_3, the masses fix the Δ_i, and the diagram then *predicts* the OPE coefficient that, on the CFT side, is an independent piece of dynamical data.

The carried example of this Part is its honest namesake. The bulk scalars and gravitons whose Witten diagrams we have just learned to draw are the supergravity duals of the single-trace operators of $\mathcal{N} = 4$ super-Yang–Mills — the maximally symmetric, large-N cousin of Yang–Mills theory (Chapter 25) — so the rules of Theorem 54.2 are, concretely, the rules for computing strong-coupling correlators of that gauge theory, a regime no perturbative Yang–Mills expansion can reach. We defer the actual $\mathcal{N} = 4$ numbers — the free energy and the shear-viscosity ratio — to Sections 54.4 and 54.5, where the thermal state and its transport are computed; here the thread is only set in place.

With the propagators built and the rules stated, the apparatus is complete. The lightest possible use of it — two external legs and no vertex, equivalently the quadratic on-shell action — is the scalar two-point function. Its evaluation requires one more ingredient that the contact and exchange diagrams above quietly assumed finite: the on-shell action is divergent at the conformal boundary, and rendering it finite is holographic renormalization. We turn the bulk-to-boundary propagator K_Δ Eq. (54.24) and the rule "quadratic on-shell action = two-point function" over to the next section, which builds that renormalization machinery and recovers the conformally fixed correlator $\langle \mathcal{O}(x)\mathcal{O}(y)\rangle \propto |x-y|^{-2\Delta}$ with its coefficient computed from the bulk.

54.2 The Holographic Two-Point Function and Holographic Renormalization

The previous section turned the GKP–Witten saddle relation Eqs. (53.162) and (53.163) into position-space Feynman rules in AdS: every boundary insertion of a primary $\mathcal{O}$ is attached to the interior by a bulk-to-boundary propagator K_Δ Eq. (53.177), vertices are integrated over the bulk, and the connected correlators are functional derivatives of the classical on-shell action with respect to the boundary sources Theorem 54.2. The simplest such rule, with no vertex at all, is that the *quadratic* on-shell action is the two-point function. We now execute that rule in full, and in doing so build the renormalization machinery that the rest of the chapter cannot do without.

There is a subtlety the rule glosses over, and it is the whole content of this section. The on-shell action of a field on AdS is divergent: the warp factor $\sqrt{g} = (L/z)^{d+1}$ blows up at the conformal boundary $z \to 0$, and the naive boundary term picks up power-law divergences as the regulator is removed. These divergences are not a flaw in the duality; they are the bulk image of the familiar ultraviolet divergences of the boundary field theory — the radial coordinate is the renormalization scale (Section 53.4), so $z \to 0$ is the deep UV, and a cutoff at $z = \epsilon$ is a UV cutoff at energy $\sim 1/\epsilon$. The cure is the one the boundary theory already taught us in Section 19.1: the divergences are *local*, so they are removed by *local* covariant counterterms, and what remains is a finite, scheme-independent, separated-point correlator. The systematic version of this program on the gravity side is *holographic renormalization*. We develop it here for the scalar two-point function, because that is where the algebra is cleanest and the result is checkable against pure conformal symmetry; the same counterterm structure, in its gravitational guise, will renormalize the on-shell action that computes the free energy in Section 54.4.

Three ingredients make up the toolkit, and we take them in turn. First, the *near-boundary (Fefferman–Graham) expansion*: any bulk solution is, near $z = 0$, an asymptotic series in z whose two seeds are the source and the response,

with everything in between determined locally by the source. Second, the *regulated on-shell action* at a radial cutoff and the precise form of its divergences. Third, the *covariant counterterms* that cancel them, packaged as a theorem (Theorem 54.5). With the toolkit assembled we recompute the two-point function directly in position space — the computation Section 53.6.5 did in momentum space via Bessel functions, now done in the Witten-diagram language and giving an independent check of the coefficient — and read off the renormalized statement $\langle \mathcal{O}(x)\mathcal{O}(y)\rangle = (2\Delta - d)\, c_\Delta / |x-y|^{2\Delta}$.

54.2.1 The near-boundary expansion

We work in Euclidean Poincaré AdS_{d+1} Eq. (53.161) with flat boundary $\mathbb{R}^d$, radius L, and a free scalar of mass m dual to a primary $\mathcal{O}$ of dimension Δ. The classical field equation is the Euclidean Klein–Gordon equation Eq. (53.167),

$$z^2\,\partial_z^2\phi - (d-1)\,z\,\partial_z\phi + z^2\,\partial_x^2\phi - m^2L^2\,\phi = 0, \qquad \partial_x^2 \equiv \delta^{\mu\nu}\partial_\mu\partial_\nu, \tag{54.28}$$

and the analysis of Section 53.4 established that near $z=0$ every solution is a superposition of two power laws z^{Δ_-} and z^{Δ_+}, the exponents being the roots of the indicial (mass–dimension) equation $\Delta(\Delta-d) = m^2L^2$ Eq. (53.112). We recall the roots, since they organize everything that follows:

$$\Delta_\pm = \frac{d}{2} \pm \sqrt{\frac{d^2}{4} + m^2L^2}, \qquad \nu \equiv \Delta_+ - \frac{d}{2} = \sqrt{\frac{d^2}{4} + m^2L^2}, \tag{54.29}$$

so that $\Delta \equiv \Delta_+ = \frac{d}{2} + \nu$ is the dimension of the dual operator and $\Delta_- = d - \Delta = \frac{d}{2} - \nu$ its shadow. The square root is real precisely above the Breitenlohner–Freedman floor $m^2L^2 \geq -d^2/4$ Eq. (53.122), the bulk avatar of the requirement that Δ be real in a unitary CFT (Theorem 47.18).

The structural statement of Eq. (53.116) — two leading powers — is not the whole story, and the rest of the story is what holographic renormalization rests on. We need the *full* asymptotic series, because the divergences of the on-shell action live in the subleading terms. The systematic expansion is due to Fefferman and Graham; we derive it as a recursion.

Definition 54.4 (Near-boundary expansion)**.** For a free scalar dual to $\mathcal{O}$ of dimension $\Delta = \frac{d}{2} + \nu$, the *near-boundary* (Fefferman–Graham) *expansion* of a bulk solution is the double asymptotic series

$$\phi(z,x) \;\xrightarrow{z\to 0}\; z^{\,d-\Delta}\sum_{n\geq 0} a_n(x)\, z^{2n} \;+\; z^{\,\Delta}\sum_{n\geq 0} b_n(x)\, z^{2n}, \qquad a_0 = \alpha, \quad b_0 = \beta, \tag{54.30}$$

in which $\alpha(x)$ is the coefficient of the leading falloff $z^{d-\Delta}$ and $\beta(x)$ the coefficient of the subleading falloff z^{Δ}.

The two series are not on the same footing, and the difference is the crux. Insert Eq. (54.30) into Eq. (54.28) and collect the coefficient of a given power. Take a single monomial $a_n(x)\, z^p$ with $p = d - \Delta + 2n$. The first three terms of Eq. (54.28) act algebraically: $z^2\partial_z^2$ gives $p(p-1)$, $-(d-1)z\,\partial_z$ gives $-(d-1)p$, and $-m^2L^2$ is a multiplier, so together they contribute

$$[p(p-1) - (d-1)p - m^2L^2]a_n\, z^p = [p^2 - dp - m^2L^2]a_n\, z^p. \tag{54.31}$$

Using $m^2L^2 = \Delta(\Delta - d)$, the bracket factorizes,

$$p^2 - dp - \Delta(\Delta - d) = (p - \Delta)(p + \Delta - d), \tag{54.32}$$

as one checks by expanding the right side, $p^2 + (\Delta - d - \Delta)p - \Delta(\Delta - d) = p^2 - dp - \Delta(\Delta - d)$. The remaining term $z^2\partial_x^2$ raises the power by two, so the monomial $a_{n-1}z^{p-2}$ feeds $\partial_x^2 a_{n-1}\, z^p$ into the same order. Setting the total coefficient of z^p to zero gives the recursion

$$(p - \Delta)(p + \Delta - d)\, a_n + \partial_x^2 a_{n-1} = 0, \qquad p = d - \Delta + 2n. \tag{54.33}$$

Now evaluate the prefactor: $p - \Delta = d - 2\Delta + 2n = 2n - 2\nu$ and $p + \Delta - d = 2n$, so $(p - \Delta)(p + \Delta - d) = 4n(n - \nu)$ and

$$\boxed{a_n = -\frac{\partial_x^2\, a_{n-1}}{4\, n\, (n - \nu)}, \qquad n \geq 1,} \tag{54.34}$$

with $a_0 = \alpha$ free. The first coefficient is therefore

$$a_1 = -\frac{\partial_x^2 \alpha}{4(1 - \nu)} = \frac{\partial_x^2 \alpha}{2\,(2\Delta - d - 2)}, \tag{54.35}$$

using $4(1-\nu) = -2(2\Delta - d - 2)$. The pattern is the whole point: *every coefficient a_n of the leading series is a local differential operator acting on the single datum α.* The leading falloff and its entire analytic tail are fixed, with no further input, by the boundary source.

The subleading series is governed by the same algebra with $\Delta \to d - \Delta$, i.e. $\nu \to -\nu$: writing $q = \Delta + 2n$ one finds $(q - \Delta)(q + \Delta - d) = 4n(n + \nu)$ and

$$b_n = -\frac{\partial_x^2 b_{n-1}}{4\, n\, (n + \nu)}, \qquad n \geq 1, \tag{54.36}$$

with $b_0 = \beta$ free. Crucially, the recursion Eq. (54.34) *never* reaches the order $z^\Delta = z^{d-\Delta+2\nu}$ for non-integer ν: the two series stay disjoint, and β is a genuinely independent integration constant, not determined by α through any local relation. The equation of motion is second order, so a solution carries two free functions of x, and the near-boundary expansion exhibits them cleanly as α and β. What ties β to α is not the near-boundary analysis at all but the *global* condition

of regularity in the interior $z \to \infty$; that is the content of the modified-Bessel solution Eq. (53.176), which fixed the ratio

$$\beta(k) = \mathcal{B}(k)\,\alpha(k), \qquad \mathcal{B}(k) = \frac{\Gamma(-\nu)}{\Gamma(\nu)}\Big(\frac{k}{2}\Big)^{2\nu}, \tag{54.37}$$

the single *non-local* (in x) piece of information in the whole problem. This split — local data α determines the divergent structure, global data β carries the physics — is exactly why the divergences can be subtracted by local counterterms without touching the answer.

Source and response; the two quantizations. The dictionary of Section 53.5 identifies the leading coefficient α with the field-theory *source* coupling to $\mathcal{O}$, $\alpha = \phi_0$, and we will prove below that β is, up to a fixed factor, the operator's *vacuum expectation value*: $\langle\mathcal{O}\rangle \propto \beta$. This is the *standard quantization*, available for all $\Delta \geq d/2$. In the Breitenlohner–Freedman window $-d^2/4 \leq m^2L^2 < -d^2/4 + 1$, equivalently $0 \leq \nu < 1$, the normalizability analysis Theorem 53.18 found that *both* falloffs are normalizable, and one is free to exchange their roles: declaring β the source and α the response defines the *alternative quantization*, dual to an operator of dimension $\Delta_- = d - \Delta$. The two quantizations are related by a Legendre transform of the renormalized action; we treat the standard one and note the dual under $\Delta \to d - \Delta$.

Caution

The recursion Eq. (54.34) has a vanishing denominator when $n = \nu$, i.e. when ν (equivalently $\Delta - \frac{d}{2}$) is a non-negative integer. There the leading series would generate a term $z^{d-\Delta+2\nu} = z^{\Delta}$, colliding with the seed of the subleading series, and the resolution is a logarithm: the expansion acquires a term $\propto z^{\Delta}\log z$, as flagged already in Eq. (53.116) and seen in the Bessel expansion of Theorem 53.32. This logarithm is not a pathology; it is the seed of the holographic conformal anomaly, and we account for it in Theorem 54.6. For now take ν generic.

54.2.2 The regulated on-shell action and its divergences

We evaluate the bulk action of the free scalar on the solution. Integrating by parts and using the equation of motion, the bulk integral collapses to a boundary term, regulated at $z = \epsilon$; this was carried out in Eq. (53.181), giving

$$S_{\mathrm{reg}}[\epsilon] = -\frac{\mathcal{N}}{2}\int_{z=\epsilon} \mathrm{d}^d x\; z^{1-d}\,\phi\,\partial_z\phi\Big|_{z=\epsilon}, \qquad \mathcal{N} \equiv \mathcal{N}_\phi L^{d-1}, \tag{54.38}$$

where $\mathcal{N}_\phi \propto 1/G_{d+1} \propto N^2$ is the matter normalization of Section 53.6.2 and the sign is that of the outward normal pointing to decreasing z. The interior boundary

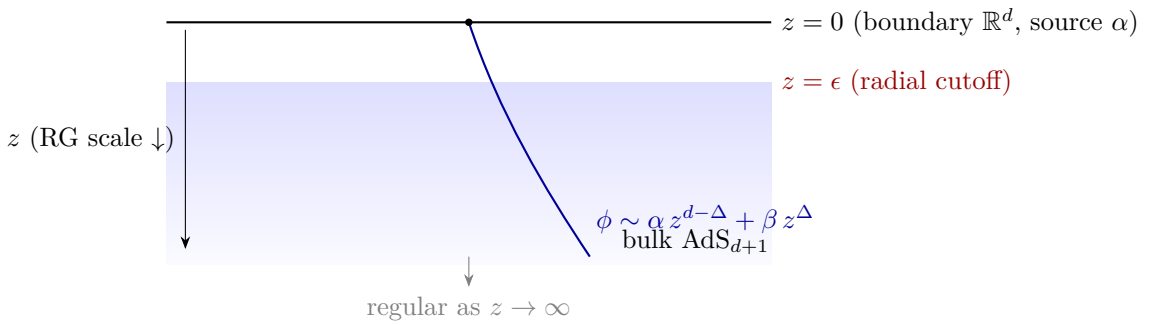


Figure 54.2: Holographic renormalization at a glance. A boundary source α at $z = 0$ launches a bulk profile whose near-boundary form Eq. (54.30) contains the leading mode $z^{d-\Delta}$ (with its locally determined tail) and the subleading mode z^{Δ} with coefficient β; interior regularity at $z \to \infty$ fixes β in terms of α Eq. (54.37). The on-shell action is evaluated at the radial cutoff $z = \epsilon$ (dashed) and its $\epsilon \to 0$ divergences — local functionals of α — are removed by covariant counterterms living on that slice.

contributes nothing because the regular solution decays there. Everything now hinges on the small-ϵ behaviour of the boundary flux $z^{1-d}\phi\,\partial_z\phi$, which the near-boundary expansion delivers.

Write $\phi = \alpha z^{d-\Delta}(1 + \cdots) + \beta z^{\Delta}(1 + \cdots)$ with the dots the local tails of Eq. (54.30). The leading piece of the flux comes from the source mode alone: with $\phi \simeq \alpha z^{d-\Delta}$ one has $\partial_z\phi \simeq (d-\Delta)\alpha z^{d-\Delta-1}$, so

$$z^{1-d}\,\phi\,\partial_z\phi \;\simeq\; (d-\Delta)\,\alpha^2\, z^{\,2(d-\Delta)-d} = (d-\Delta)\,\alpha^2\, z^{-2\nu}, \tag{54.39}$$

a divergence as $z \to 0$ for every $\nu > 0$. The first analytic correction $a_1 \propto \partial_x^2\alpha$ promotes this to a term $z^{-2\nu+2}$ with coefficient $\propto \alpha\,\partial_x^2\alpha$, the next to $z^{-2\nu+4}$ with coefficient built from $\alpha\,\partial_x^4\alpha$, and so on. Organizing the flux by powers of z,

$$z^{1-d}\phi\,\partial_z\phi = (d-\Delta)\,\alpha^2\,\epsilon^{-2\nu} + c_2\,\alpha\,\partial_x^2\alpha\,\epsilon^{-2\nu+2} + \cdots + d\,\alpha\beta + (\text{vanishing as } \epsilon \to 0), \tag{54.40}$$

where the coefficient of the single finite, ϵ-independent term is computed exactly as in Eq. (53.183) and equals $d\,\alpha\beta$ (the cross term of the two falloffs). Two features are decisive.

First, the divergences are local. Each divergent power $\epsilon^{-2\nu+2k}$ comes multiplied by a coefficient that is a *local* differential polynomial in α: α^2, then $\alpha\,\partial_x^2\alpha$, then $\alpha\,\partial_x^4\alpha$, and so forth — precisely the structure forced by the local recursion Eq. (54.34). There is no $\alpha\beta$ in any divergent coefficient, because β first appears at the finite order. Locality is what licenses a local covariant subtraction, exactly as the local divergences of a one-loop boundary diagram licensed the local counterterms of Section 19.2.6 and Eq. (19.23).

Second, the finite piece $d\,\alpha\beta$ is not yet the answer. It is contaminated by the very regulator we are about to remove: subtracting the divergence will necessarily reach into the finite part, because the counterterm, expanded near the boundary, also produces an $\alpha\beta$ term. The bare coefficient d is wrong; the renormalized one is what we now compute.

54.2.3 Covariant counterterms and the holographic-renormalization theorem

The subtraction must be *covariant* and *local on the cutoff surface*, for the same reason a good regulator's counterterms must respect the symmetries: a subtraction that did not could spoil conformal invariance and inject spurious physics into the separated-point correlator. The cutoff slice $z = \epsilon$ carries an induced metric $\gamma_{\mu\nu} = (L/\epsilon)^2\delta_{\mu\nu}$, with $\sqrt{\gamma} = (L/\epsilon)^d$, and the boundary value of the field is $\phi_\epsilon(x) \equiv \phi(\epsilon, x)$. The available local covariant scalars built from these of the right dimension are ϕ_ϵ^2, $\phi_\epsilon\,\Box_\gamma\phi_\epsilon$ (where $\Box_\gamma$ is the Laplacian of γ), $R[\gamma]\,\phi_\epsilon^2$, and so on. The counterterm action is their covariant sum.

Theorem 54.5 (Holographic renormalization of the scalar two-point function)**.** *Let ϕ be a free scalar of dimension $\Delta = \frac{d}{2} + \nu$ (with $\nu > 0$ non-integer) on Euclidean AdS_{d+1}, with source α and response β as in Eq. (54.30). Define the covariant counterterm action on the cutoff slice*

$$S_{\rm ct}[\epsilon] = \frac{\mathcal{N}_\phi}{2}\int_{z=\epsilon} \mathrm{d}^d x\,\sqrt{\gamma}\,\Big[\frac{d-\Delta}{L}\,\phi_\epsilon^2 + \frac{L}{2(2\Delta-d-2)}\,\phi_\epsilon\,\Box_\gamma\phi_\epsilon + \cdots\Big], \tag{54.41}$$

the displayed terms cancelling the divergences $\epsilon^{-2\nu}$ and $\epsilon^{-2\nu+2}$ and the dots being the finitely many higher curvature/derivative terms needed for the remaining power divergences. Then the renormalized action

$$S_{\rm ren} = \lim_{\epsilon\to 0}\big(S_{\rm reg}[\epsilon] + S_{\rm ct}[\epsilon]\big) \tag{54.42}$$

is finite, and the renormalized one-point function is the subleading mode,

$$\langle\mathcal{O}(x)\rangle = (2\Delta - d)\,\mathcal{N}\,\beta(x), \qquad \mathcal{N} = \mathcal{N}_\phi L^{d-1}. \tag{54.43}$$

With the canonical normalization $\mathcal{N} = 1$ fixed by the dictionary Eq. (53.190), $\langle\mathcal{O}\rangle = (2\Delta - d)\beta$.

Proof. We track the leading term explicitly; the higher ones work identically order by order. Evaluate the leading counterterm on the solution. With $\phi_\epsilon = \alpha\,\epsilon^{d-\Delta}(1 + 2\,(\beta/\alpha)\epsilon^{2\nu} + \cdots)$ one has $\phi_\epsilon^2 = \alpha^2\epsilon^{2(d-\Delta)}\big[1 + 2\,(\beta/\alpha)\,\epsilon^{2\nu} + \cdots\big]$, hence

$$\frac{\mathcal{N}_\phi}{2}\int \mathrm{d}^d x\,\sqrt{\gamma}\,\frac{d-\Delta}{L}\,\phi_\epsilon^2 = \frac{\mathcal{N}_\phi L^{d-1}}{2}\,(d-\Delta)\int \mathrm{d}^d x\;\epsilon^{-d}\,\alpha^2\,\epsilon^{2(d-\Delta)}\big[1 + 2(\beta/\alpha)\epsilon^{2\nu} + \cdots\big]$$

$$= \frac{\mathcal{N}}{2}\,(d-\Delta)\int \mathrm{d}^d x\,\left[\alpha^2\,\epsilon^{-2\nu} + 2\,\alpha\beta + \cdots\right], \tag{54.44}$$

using $\sqrt{\gamma}/L = L^{d-1}\epsilon^{-d}$ and $-d + 2(d-\Delta) = d - 2\Delta = -2\nu$. Meanwhile Eq. (54.38) fed by Eq. (54.40) reads

$$S_{\mathrm{reg}}[\epsilon] = -\frac{\mathcal{N}}{2}\int \mathrm{d}^d x\,\left[(d-\Delta)\,\alpha^2\,\epsilon^{-2\nu} + \cdots + d\,\alpha\beta + \cdots\right]. \tag{54.45}$$

The divergent $\epsilon^{-2\nu}$ pieces cancel between Eqs. (54.44) and (54.45) by construction — this is what fixed the counterterm coefficient $(d-\Delta)/L$. The $\epsilon^{-2\nu+2}$ divergence is cancelled, identically, by the second term of Eq. (54.41), whose coefficient $L/[2(2\Delta - d - 2)]$ is exactly the one that reproduces c_2 in Eq. (54.40) after the $\Box_\gamma = (\epsilon/L)^2\partial_x^2$ rescaling and the FG coefficient Eq. (54.35); the higher dots proceed the same way and exhaust the finite tower of power divergences. What survives the limit is finite, with the finite $\alpha\beta$ coefficient collapsing from the bare $-d$ to

$$2(d-\Delta) - d = d - 2\Delta = -(2\Delta - d), \tag{54.46}$$

the first contribution coming from Eq. (54.44) (the $2\alpha\beta$ reach of the counterterm) and the second from Eq. (54.45) (the $d\,\alpha\beta$ of the bare flux). Therefore

$$S_{\mathrm{ren}} = -\frac{\mathcal{N}}{2}\,(2\Delta - d)\int \mathrm{d}^d x\,\mathrm{d}^d y\;\alpha(x)\,R(x,y)\,\alpha(y) + (\text{local, scheme}), \tag{54.47}$$

where we have written the nonlocal $\alpha\beta$ pairing as a quadratic form in the source through $\beta(x) = \int \mathrm{d}^d y\,R(x,y)\,\alpha(y)$, the response kernel Eq. (54.37). The renormalized one-point function follows from Eq. (53.164), $\langle\mathcal{O}(x)\rangle = -\,\delta S_{\mathrm{ren}}/\delta\alpha(x)$. Varying Eq. (54.47) once (the quadratic form is symmetric, giving a factor of two against the $\frac{1}{2}$),

$$\langle\mathcal{O}(x)\rangle = (2\Delta - d)\,\mathcal{N}\int \mathrm{d}^d y\,R(x,y)\,\alpha(y) = (2\Delta - d)\,\mathcal{N}\,\beta(x), \tag{54.48}$$

which is Eq. (54.43). The local, scheme-dependent remainder in Eq. (54.47) is supported at coincident points; it shifts contact terms only and we keep it implicit. □

The mechanism deserves to be named because it recurs everywhere in holographic renormalization: *the counterterm introduced to kill a divergence carries a finite remainder of just the right size to correct the answer.* The naive finite coefficient d of Eq. (54.40) is meaningless; only the combination Eq. (54.46) that survives the subtraction is physical, and it is exactly $-(2\Delta - d)$. This is the holographic face of the statement that, in the boundary theory, the value of a renormalized correlator depends on the subtraction scheme through contact terms but not through its separated-point structure.

The gravitational counterterms. The same logic, applied to the metric rather than a probe scalar, supplies the counterterms that will renormalize the free energy in Section 54.4. The bulk gravitational action — Einstein–Hilbert plus negative cosmological constant plus the Gibbons–Hawking boundary term — evaluated on an asymptotically-AdS solution diverges because the proper volume near the boundary is infinite. The leading divergence is a pure volume term: on shell the Lagrangian density is constant ($R - 2\Lambda = -2d/L^2$ for AdS_{d+1} with $\Lambda = -d(d-1)/2L^2$), so the bulk integral $\int_\epsilon \mathrm{d}z\,(L/z)^{d+1} \sim \epsilon^{-d}$ diverges as ϵ^{-d}, a divergence proportional to the boundary volume $\int \mathrm{d}^d x\sqrt{\gamma}$. It is cancelled by a *cosmological-constant counterterm* on the slice; the subleading divergences, proportional to the boundary curvature, by an *Einstein (curvature) counterterm*:

$$S_{\mathrm{ct}}^{\mathrm{grav}} = \frac{1}{8\pi G_{d+1}} \int_{z=\epsilon} \mathrm{d}^d x\,\sqrt{\gamma}\,\Big[\frac{d-1}{L} + \frac{L}{2(d-2)}\,R[\gamma] + \cdots\Big], \tag{54.49}$$

the constant $(d-1)/L$ fixing the volume divergence and the $R[\gamma]$ term the next one; for higher d further curvature-squared terms follow, all local and covariant. The coefficients are universal — they depend only on the asymptotics, not on the particular solution — which is why they are computed once and reused for every black-brane background. We quote them here as the metric-sector members of the same toolkit; their explicit deployment, and the resulting finite on-shell action whose value is the free energy, is the business of Section 54.4.

Remark 54.6 (The logarithmic divergence and the holographic Weyl anomaly). When $\nu = \Delta - \frac{d}{2}$ is a non-negative integer the recursion Eq. (54.34) resonates at $n = \nu$ and the on-shell action develops, alongside the powers, a divergence $\propto \log\epsilon$. A logarithm cannot be removed by any covariant *power* counterterm; subtracting it requires a counterterm of the form $\log\epsilon$ times a local covariant integral, and such a counterterm *breaks scale invariance*: under a rescaling of the cutoff $\epsilon \to \lambda\epsilon$, equivalently a Weyl rescaling of the boundary metric, $\log\epsilon$ shifts by a constant and the renormalized action is not invariant. The non-invariance is finite, local, and unremovable — it is the holographic conformal (Weyl) anomaly, and the local integral multiplying $\log\epsilon$ is precisely the trace anomaly $\langle T^{\mu}{}_{\mu}\rangle$ of the boundary CFT (Chapter 37). In the scalar two-point function this is the integer-ν logarithm of Theorem 53.31, made concrete in the $d = 4$, $\Delta = 4$ computation of Theorem 53.32, where the response degenerated to $(k^2)^2\log(k^2/\mu^2)$ and a renormalization scale μ entered through the log counterterm. In the gravitational sector the same logarithm, present only in *even* boundary dimension d, multiplies the curvature invariant that is the bulk computation of the boundary central charges — the holographic derivation of the a- and c-anomalies. The pattern is uniform: power divergences are scheme, the logarithm is physics.

54.2.4 The two-point function in position space

We now assemble the connected two-point function and read off its coefficient directly in position space, the language in which the higher-point Witten diagrams of Section 54.3 are built. The starting point is the renormalized vev Eq. (54.43): differentiating once more with respect to the source produces the two-point function,

$$\langle \mathcal{O}(x)\,\mathcal{O}(y)\rangle = \frac{\delta\,\langle \mathcal{O}(x)\rangle}{\delta\alpha(y)} = (2\Delta - d)\,\mathcal{N}\,\frac{\delta\beta(x)}{\delta\alpha(y)}, \tag{54.50}$$

so the entire content is the response kernel $\delta\beta/\delta\alpha$, the position-space version of $\mathcal{B}(k)$. We extract it from the bulk-to-boundary propagator without re-solving the radial equation. The regular bulk solution sourced by α is the smearing

$$\phi(z,x) = \int \mathrm{d}^d y\; K_\Delta(z,x;y)\,\alpha(y), \qquad K_\Delta(z,x;y) = c_\Delta\,\frac{z^\Delta}{(z^2+|x-y|^2)^\Delta}, \tag{54.51}$$

with K_Δ the source-normalized propagator Eq. (53.177) and $c_\Delta = \Gamma(\Delta)/[\pi^{d/2}\Gamma(\Delta - \frac{d}{2})]$. Recall how this propagator was normalized: $K_\Delta \to z^{d-\Delta}\,\delta^d(x-y)$ as $z\to 0$, which guarantees that Eq. (54.51) has the correct leading falloff $\phi \to z^{d-\Delta}\alpha(x)$, identifying the smearing's seed with the source. We need its *subleading* coefficient, the z^Δ term, which is by definition β.

The extraction is immediate from the explicit form. Split the y-integral into a coincident region $y \approx x$ and a separated region $y \neq x$. For $y \neq x$, the limit $z \to 0$ of K_Δ is taken with $z^2 \ll |x-y|^2$, so the denominator becomes $|x-y|^{2\Delta}$ and

$$K_\Delta(z,x;y) \xrightarrow{z\to 0,\; y\neq x} c_\Delta\,\frac{z^\Delta}{|x-y|^{2\Delta}}. \tag{54.52}$$

This is a pure z^Δ term: it is exactly the response mode, with coefficient $c_\Delta/|x-y|^{2\Delta}$. The coincident region $y \approx x$ reproduces, together with the analytic tail of Eq. (54.51), the leading $z^{d-\Delta}$ delta function and the local FG tower $a_n[\alpha]$ — all of it local, all of it absorbed into the scheme-dependent contact part already set aside in Eq. (54.47). Reading off the z^Δ coefficient of Eq. (54.51) therefore gives the response as a smearing of the source against the kernel Eq. (54.52):

$$\beta(x) = \int \mathrm{d}^d y\;\frac{c_\Delta}{|x-y|^{2\Delta}}\,\alpha(y) + (\text{local in } \alpha), \qquad \Longrightarrow \qquad \frac{\delta\beta(x)}{\delta\alpha(y)} = \frac{c_\Delta}{|x-y|^{2\Delta}} \quad (x\neq y). \tag{54.53}$$

Substituting into Eq. (54.50) gives the renormalized two-point function,

$$\boxed{\langle \mathcal{O}(x)\,\mathcal{O}(y)\rangle = \frac{(2\Delta-d)\,\mathcal{N}\,c_\Delta}{|x-y|^{2\Delta}} = \mathcal{N}\,\frac{(2\Delta-d)\,\Gamma(\Delta)}{\pi^{d/2}\,\Gamma(\Delta-\frac{d}{2})}\,\frac{1}{|x-y|^{2\Delta}}\,,} \tag{54.54}$$

with $\mathcal{N} = \mathcal{N}_\phi L^{d-1}$, and the canonical choice $\mathcal{N} = 1$ giving the unit-normalized CFT coefficient $C_\Delta = (2\Delta - d)\,c_\Delta$.

This is the same number as the momentum-space computation of Eq. (53.195), reached by a route that touches neither Bessel functions nor a Fourier transform: the position-space response kernel is literally the subleading term of the bulk-to-boundary propagator, and the coefficient $2\Delta - d$ is the universal factor that the renormalization theorem Theorem 54.5 attached to the vev. The agreement of the two derivations is a check that the holographic-renormalization machinery is internally consistent — the divergent intermediaries (the $\Gamma(-\nu)$ that cancelled between kernel and transform in Eq. (53.194), the $\epsilon^{-2\nu}$ that cancelled against the counterterm here) leave no trace in the finite separated-point answer.

Matching conformal symmetry, and the thread. Compare Eq. (54.54) with the form that pure conformal symmetry forces on any scalar primary two-point function, derived with no dynamics in Theorem 47.21,

$$\langle \mathcal{O}(x)\, \mathcal{O}(y)\rangle = \frac{C_{\mathcal{O}}}{|x-y|^{2\Delta}}, \tag{54.55}$$

the structure of Eq. (47.120). Holography reproduces it exactly: the power is 2Δ with Δ the mass–dimension value Eq. (54.29), and the would-be free function of $|x-y|$ is pinned to a pure power by the same conformal invariance that, in the bulk, was the AdS isometry group. What symmetry left undetermined — the coefficient $C_{\mathcal{O}}$ — is now *computed*: $C_\Delta = (2\Delta - d)c_\Delta$, manifestly positive for $\Delta > d/2$ (since $\Gamma(\Delta - \frac{d}{2}) > 0$ there), in accord with reflection positivity and the unitarity bound $\Delta \geq (d-2)/2$ of Theorem 47.18. The overall $\mathcal{N}_\phi \propto N^2$ is the holographic image of large-N factorization: connected single-trace correlators scale as N^2, the same $1/G_{d+1}$ that sets the central charge of the dual.

This same conformally fixed two-point structure is where ϕ^4 theory ended. At the Wilson–Fisher fixed point of Chapter 52, the order-parameter primary's two-point function was pinned by scale and conformal invariance to $\langle \mathcal{O}(x)\mathcal{O}(0)\rangle \sim |x|^{-2\Delta}$ Eq. (52.38), with Δ read off from a critical exponent and the coefficient fixed by the normalization of $\mathcal{O}$ — the structure was *imposed* by symmetry, and the number was an input. Here the identical structure emerges *dynamically* from a bulk wave equation, with the coefficient C_Δ *output* by the geometry. The two perspectives are complementary faces of the same conformal datum: the fixed point is a CFT whose two-point function symmetry constrains, and a holographic CFT is one whose two-point function a classical bulk computes. Where a theory admits both descriptions — a large-N, large-gap CFT with a weakly curved dual, the role played for Yang–Mills theory's maximally symmetric cousin $\mathcal{N} = 4$ super-Yang–Mills — the symmetry-fixed form and the bulk computation must, and do, agree.

With the two-point function in hand and the renormalization toolkit assembled — the near-boundary expansion Eq. (54.30), the radial cutoff and its local divergences Eq. (54.40), the covariant counterterms Eqs. (54.41) and (54.49), the

identification of the vev with the subleading mode Eq. (54.43), and the normalized bulk-to-boundary propagator Eq. (54.51) whose subleading term is the response kernel — we are equipped to turn on interactions. The next section integrates cubic and quartic bulk vertices against these propagators to compute three- and four-point functions, where the finite renormalized action of Theorem 54.5 again removes the boundary divergences, now of contact and exchange diagrams, and delivers OPE coefficients and the double-trace spectrum.

54.3 Three- and Four-Point Functions and OPE Data

The two-point function of Section 53.6.5 used only the quadratic part of the bulk action: a single field propagating freely from one boundary insertion to another, its renormalized on-shell action read off by the holographic-renormalization toolkit assembled in the previous section. That toolkit — the near-boundary expansion, the radial cutoff at $z = \epsilon$, the local counterterms, and the normalized bulk-to-boundary propagator K_Δ of Eq. (53.177) — is now in hand and will not be rebuilt. What changes here is the action. The bulk Lagrangian generically contains interaction vertices, cubic and quartic in the fields, that we suppressed when all we wanted was $\langle \mathcal{O}\mathcal{O} \rangle$. Switching them on, the classical saddle that dominates the GKP–Witten partition function Eq. (53.162) is no longer a single free profile but a tree of propagators tied together at integrated bulk vertices. Functional differentiation of the on-shell action with respect to the boundary sources then produces connected correlators of three and more operators, organized diagrammatically by the Witten rules of Theorem 54.2. This section computes the first two such correlators. The three-point contact diagram will reproduce, with no freedom left over, the conformally fixed structure of Eq. (47.137), and hand us its single undetermined coefficient — the OPE coefficient C_{123} — as an explicit ratio of Gamma functions built from the bulk coupling. The four-point exchange diagram will then be decomposed into conformal blocks, exposing not only the single-trace operator dual to the exchanged bulk field but an entire tower of *double-trace* operators whose dimensions, and whose interaction-induced shifts, are the holographic image of the operator data that the bootstrap of Chapters 49 and 50 carves out from crossing alone.

54.3.1 The contact diagram and the D-function

Every tree-level Witten diagram is assembled from two ingredients: the bulk-to-boundary propagator K_Δ, which carries a boundary insertion into the interior, and the integrated bulk vertex. The simplest non-trivial assembly is the *contact diagram*: all external legs meet at one bulk point, which is integrated over AdS_{d+1}. The basic integral it produces deserves a name.

Definition 54.7 (Contact D-function)**.** For boundary points $x_1,\dots,x_n\in\mathbb{R}^d$ and dimensions $\Delta_1,\dots,\Delta_n$, the contact D-function is the bulk integral of n unnormalized bulk-to-boundary propagators,

$$D_{\Delta_1\cdots\Delta_n}(x_1,\dots,x_n)\;\equiv\;\int_0^\infty\frac{\mathrm{d}z}{z^{d+1}}\int_{\mathbb{R}^d}\mathrm{d}^dx\;\prod_{i=1}^n\widehat{K}_{\Delta_i}(z,x;x_i),\qquad \widehat{K}_\Delta(z,x;x_i)=\Big(\frac{z}{z^2+|x-x\tag{54.56}$$

where $\widehat{K}_\Delta=K_\Delta/c_\Delta$ strips the normalization $c_\Delta=\Gamma(\Delta)/[\pi^{d/2}\Gamma(\Delta-\frac{d}{2})]$ of Eq. (53.177), and the measure $\mathrm{d}z\,\mathrm{d}^dx/z^{d+1}$ is the AdS_{d+1} volume element in units $L=1$ (the factor L^{d+1} from $\sqrt{g}$ is restored at the end).

The whole content of any contact Witten diagram is a D-function times the coupling and the normalizations c_{Δ_i}. It is worth reducing Eq. (54.56) once and for all to a single integral over a simplex of Feynman-like parameters; this is the Symanzik trick, and it works for any n.

Introduce a Schwinger parameter t_i for each propagator,

$$\frac{1}{(z^2+|x-x_i|^2)^{\Delta_i}}=\frac{1}{\Gamma(\Delta_i)}\int_0^\infty\mathrm{d}t_i\,t_i^{\Delta_i-1}\,e^{-t_i(z^2+|x-x_i|^2)}.\tag{54.57}$$

Write $\Sigma\equiv\sum_i\Delta_i$ and $T\equiv\sum_i t_i$. Collecting the numerators z^{Δ_i} into z^Σ, the D-function becomes

$$D_{\Delta_1\cdots\Delta_n}=\frac{1}{\prod_i\Gamma(\Delta_i)}\int_0^\infty\Big[\prod_i\mathrm{d}t_i\,t_i^{\Delta_i-1}\Big]\int_0^\infty\mathrm{d}z\,z^{\Sigma-d-1}\int_{\mathbb{R}^d}\mathrm{d}^dx\;\exp\Big[-Tz^2-\sum_i t_i|x-x_i|^2\Big].\tag{54.58}$$

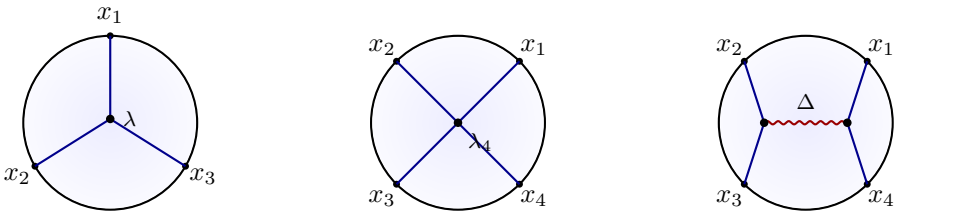
The boundary integral is Gaussian. Completing the square, $\sum_i t_i|x-x_i|^2=T\,|x-\bar{x}|^2+\frac{1}{T}\sum_{i<j}t_it_j|x_{ij}|^2$ with $\bar{x}=T^{-1}\sum_i t_ix_i$ and $x_{ij}\equiv x_i-x_j$, so

$$\int_{\mathbb{R}^d}\mathrm{d}^dx\,e^{-\sum_i t_i|x-x_i|^2}=\Big(\frac{\pi}{T}\Big)^{d/2}\exp\Big[-\frac{1}{T}\sum_{i<j}t_it_j|x_{ij}|^2\Big].\tag{54.59}$$

The radial integral is a Gamma function, $\int_0^\infty\mathrm{d}z\,z^{\Sigma-d-1}e^{-Tz^2}=\frac{1}{2}\Gamma(\frac{\Sigma-d}{2})T^{-(\Sigma-d)/2}$. Together with $(\pi/T)^{d/2}$ this gives an overall $T^{-\Sigma/2}$. Finally rescale $t_i=\rho\,\alpha_i$ with $\rho\in(0,\infty)$ and $\sum_i\alpha_i=1$; then $T=\rho$, the measure factorizes as $\prod_i\mathrm{d}t_i=\rho^{n-1}\,\mathrm{d}\rho\,\delta(1-\sum_i\alpha_i)\prod_i\mathrm{d}\alpha_i$, and the ρ-integral $\int_0^\infty\mathrm{d}\rho\,\rho^{\Sigma/2-1}e^{-\rho P}=\Gamma(\frac{\Sigma}{2})P^{-\Sigma/2}$ with $P=\sum_{i<j}\alpha_i\alpha_j|x_{ij}|^2$. The result is the Symanzik representation

$$\boxed{D_{\Delta_1\cdots\Delta_n}=\frac{\pi^{d/2}\,\Gamma(\frac{\Sigma-d}{2})\,\Gamma(\frac{\Sigma}{2})}{2\,\prod_i\Gamma(\Delta_i)}\int_{\Delta_{n-1}}\Big[\prod_i\mathrm{d}\alpha_i\,\alpha_i^{\Delta_i-1}\Big]\,\delta\Big(1-\sum_i\alpha_i\Big)\,\Big(\sum_{i<j}\alpha_i\alpha_j\,|x_{ij}|^2\Big)^{-\Sigma/2},}\tag{54.60}$$

the integral running over the $(n-1)$-simplex $\Delta_{n-1}=\{\alpha_i\ge0,\sum\alpha_i=1\}$. Every contact Witten diagram is Eq. (54.60) dressed by couplings; the remaining work is the simplex integral, which we now do for $n=3$ in closed form and reduce, for $n=4$, to a function of cross-ratios.



(a) cubic contact (b) quartic contact (c) s-channel exchange

Figure 54.3: Tree-level Witten diagrams. The disk is a constant-time slice of Euclidean AdS_{d+1}; its boundary circle is (a compactification of) the CFT space $\mathbb{R}^d$. Solid lines are bulk-to-boundary propagators K_Δ Eq. (53.177) reaching from a boundary insertion to an integrated bulk vertex (filled dot). *(a)* The cubic contact vertex $\lambda\,\phi_1\phi_2\phi_3$ gives the three-point function Eq. (54.62). *(b)* The quartic contact vertex $\lambda_4\,\phi^4$ gives the contact D-function $D_{\Delta_\phi\Delta_\phi\Delta_\phi\Delta_\phi}$. *(c)* An internal bulk-to-bulk propagator (wavy) of the exchanged field of dimension Δ between two cubic vertices gives the s-channel exchange diagram Eq. (54.72).

54.3.2 The three-point function and the OPE coefficient

Let three bulk scalars ϕ_1, ϕ_2, ϕ_3, dual to primaries $\mathcal{O}_1, \mathcal{O}_2, \mathcal{O}_3$ of dimensions $\Delta_1, \Delta_2, \Delta_3$, be coupled by the cubic vertex $\lambda\,\phi_1\phi_2\phi_3$ added to the bulk action of Section 53.6.5, which we write with the common matter normalization $\mathcal{N}_\phi$,

$$S = \sum_i \frac{\mathcal{N}_\phi}{2}\int \mathrm{d}^{d+1}X\sqrt{g}\,\left[(\partial\phi_i)^2 + m_i^2\phi_i^2\right] + \mathcal{N}_\phi\,\lambda\int \mathrm{d}^{d+1}X\sqrt{g}\;\phi_1\phi_2\phi_3. \quad (54.61)$$

Each field's mass is tied to its dual dimension by the mass–dimension relation $\Delta_i(\Delta_i - d) = m_i^2 L^2$ of Eq. (53.112). By the Witten rules of Theorem 54.2, the connected three-point function is minus the third functional derivative of the on-shell action with respect to the three boundary sources; with three distinct fields the vertex carries no symmetry factor, each source pulls down one bulk-to-boundary propagator, and the single bulk vertex is integrated:

$$\langle \mathcal{O}_1(x_1)\mathcal{O}_2(x_2)\mathcal{O}_3(x_3)\rangle = -\,\mathcal{N}_\phi\,\lambda\,L^{d+1}\,c_{\Delta_1}c_{\Delta_2}c_{\Delta_3}\;D_{\Delta_1\Delta_2\Delta_3}(x_1,x_2,x_3), \quad (54.62)$$

the factor L^{d+1} being the one promised in Theorem 54.7, coming from $\sqrt{g}\,\mathrm{d}^{d+1}X = L^{d+1}\,\mathrm{d}z\,\mathrm{d}^d x/z^{d+1}$.

The form is forced by symmetry. Before computing $D_{\Delta_1\Delta_2\Delta_3}$ we observe that its functional form is fixed. Translations and rotations of $\mathbb{R}^d$ are isometries of AdS_{d+1} under which the measure is invariant and each $\widehat{K}_{\Delta_i}$ depends only on $x - x_i$, so D depends only on the separations x_{ij}. Under a dilation $x \to \mu x$, $z \to \mu z$ (also an isometry) the measure is invariant while $\widehat{K}_{\Delta_i} \to \mu^{-\Delta_i}\widehat{K}_{\Delta_i}$, so $D \to \mu^{-\Sigma}D$: the function is homogeneous of degree $-\Sigma = -\sum_i \Delta_i$. Finally, under the inversion

Eq. (53.178), which is the isometry that completes the conformal group, the bulk-to-boundary propagator transforms covariantly. Writing $\bar{x}_i = x_i/|x_i|^2$ for the inverted boundary points and $\bar{X}$ for the inverted bulk point, a direct computation using $z^2+|x-x_i|^2 = (z'^2+|x'-\bar{x}_i|^2)/(|X'|^2|\bar{x}_i|^2)$ (with $|X'|^2 = z'^2+|x'|^2$) gives

$$\widehat{K}_{\Delta_i}(z,x;x_i) = |x_i|^{-2\Delta_i}\,\widehat{K}_{\Delta_i}(z',x';\bar{x}_i), \tag{54.63}$$

while the measure is again invariant. Hence D transforms exactly as a product of three primaries of dimensions Δ_i. The unique function of three points with these three properties is the conformal three-point structure of Eq. (47.137),

$$D_{\Delta_1\Delta_2\Delta_3}(x_1,x_2,x_3) = \frac{b(\Delta_i)}{|x_{12}|^{\Delta_1+\Delta_2-\Delta_3}\,|x_{13}|^{\Delta_1+\Delta_3-\Delta_2}\,|x_{23}|^{\Delta_2+\Delta_3-\Delta_1}}, \tag{54.64}$$

with $b(\Delta_i)$ a pure number. The bulk integral cannot produce anything but the conformally mandated structure — the same lesson the two-point function taught, now at three points.

The coefficient. To extract $b(\Delta_i)$ we exploit the freedom just established and choose convenient kinematics. Translate so that $x_3 = 0$, then perform the inversion. The propagator to $x_3 = 0$ collapses: $\widehat{K}_{\Delta_3}(z,x;0) = (z/(z^2+|x|^2))^{\Delta_3} = z'^{\Delta_3}$ in inverted coordinates, a pure power of the new radial variable with no dependence on the new boundary position. The other two propagators transform by Eq. (54.63) with $|x_i| = |x_{i3}|$, and after a further translation that places one of them at the origin the integral reduces to

$$D_{\Delta_1\Delta_2\Delta_3} = |x_{13}|^{-2\Delta_1}|x_{23}|^{-2\Delta_2}\,B(r), \qquad B(r) = \int_0^\infty \frac{\mathrm{d}z}{z^{d+1}}\, z^{\Delta_3}\,\widehat{K}_{\Delta_1}(z,x;b)\,\widehat{K}_{\Delta_2}(z,x;0)\,\mathrm{d}^d x, \tag{54.65}$$

where $r = |b| = |\bar{x}_1 - \bar{x}_2|$ is the single remaining separation and we have dropped primes. The integral $B(r)$ is now a textbook Schwinger computation. Parametrize both denominators as in Eq. (54.57), do the Gaussian x-integral Eq. (54.59) (two points only), and the radial integral:

$$B(r) = \frac{\pi^{d/2}\,\Gamma\!\left(\frac{\Sigma-d}{2}\right)}{2\,\Gamma(\Delta_1)\Gamma(\Delta_2)} \int_0^\infty \mathrm{d}t\,\mathrm{d}s\; t^{\Delta_1-1}s^{\Delta_2-1}\,(t+s)^{-\Sigma/2}\,\exp\!\Big[-\frac{ts}{t+s}\,r^2\Big]. \tag{54.66}$$

Substitute $t=\rho\xi$, $s=\rho(1-\xi)$ with $\rho\in(0,\infty)$, $\xi\in(0,1)$ and $\mathrm{d}t\,\mathrm{d}s = \rho\,\mathrm{d}\rho\,\mathrm{d}\xi$; then $t+s=\rho$, $ts/(t+s) = \rho\,\xi(1-\xi)$, and the ρ-integral gives $\Gamma\!\left(\frac{\Delta_1+\Delta_2-\Delta_3}{2}\right)\big[\xi(1-\xi)r^2\big]^{-(\Delta_1+\Delta_2-\Delta_3)/2}$, using $\Delta_1+\Delta_2-\frac{\Sigma}{2} = \frac{\Delta_1+\Delta_2-\Delta_3}{2}$. The remaining ξ-integral is an Euler Beta integral,

$$\int_0^1 \mathrm{d}\xi\;\xi^{\frac{\Delta_1+\Delta_3-\Delta_2}{2}-1}(1-\xi)^{\frac{\Delta_2+\Delta_3-\Delta_1}{2}-1} = \frac{\Gamma\!\left(\frac{\Delta_1+\Delta_3-\Delta_2}{2}\right)\Gamma\!\left(\frac{\Delta_2+\Delta_3-\Delta_1}{2}\right)}{\Gamma(\Delta_3)}, \tag{54.67}$$

where the exponents follow from $\Delta_1 - \frac{\Delta_1+\Delta_2-\Delta_3}{2} = \frac{\Delta_1+\Delta_3-\Delta_2}{2}$ and the denominator from $\frac{\Delta_1+\Delta_3-\Delta_2}{2} + \frac{\Delta_2+\Delta_3-\Delta_1}{2} = \Delta_3$. Collecting the pieces, $B(r) = b(\Delta_i)\, r^{-(\Delta_1+\Delta_2-\Delta_3)}$ with the same power of r that Eq. (54.64) demands after restoring $|\bar{x}_1 - \bar{x}_2|^2 = |x_{12}|^2/(|x_{13}|^2|x_{23}|^2)$, and the coefficient is

$$\boxed{b(\Delta_i) = \frac{\pi^{d/2}}{2}\, \frac{\Gamma\!\left(\frac{\Delta_1+\Delta_2-\Delta_3}{2}\right)\Gamma\!\left(\frac{\Delta_1+\Delta_3-\Delta_2}{2}\right)\Gamma\!\left(\frac{\Delta_2+\Delta_3-\Delta_1}{2}\right)\Gamma\!\left(\frac{\Delta_1+\Delta_2+\Delta_3-d}{2}\right)}{\Gamma(\Delta_1)\,\Gamma(\Delta_2)\,\Gamma(\Delta_3)}\,.} \tag{54.68}$$

Although the derivation singled out the third point, the answer is manifestly symmetric in $1, 2, 3$ — a strong internal check. The three Gamma functions of the half-differences $\frac{\Delta_i+\Delta_j-\Delta_k}{2}$ are the hallmark of the conformal three-point structure; the fourth, $\Gamma(\frac{\Sigma-d}{2})$, is the radial integral that distinguishes the AdS computation from a flat-space one.

Reading off C_{123}. The OPE coefficient is the coefficient of the conformal structure when the operators are normalized to unit two-point functions, as in Eq. (47.208). With the canonical bulk normalization $\mathcal{N}_\phi L^{d-1} = 1$ that reproduced the dictionary in Section 53.6.4, the two-point coefficient is $C_{\Delta_i} = (2\Delta_i - d)\, c_{\Delta_i}$ from Eq. (53.195); rescaling $\mathcal{O}_i \to \mathcal{O}_i/\sqrt{C_{\Delta_i}}$ to unit normalization, the structure constant extracted from Eqs. (54.62) and (54.64) is

$$\boxed{C_{123} = -\,\frac{\lambda\, L^2\, b(\Delta_i)}{\sqrt{\mathcal{N}_\phi L^{d-1}}}\,\sqrt{\frac{c_{\Delta_1}\, c_{\Delta_2}\, c_{\Delta_3}}{(2\Delta_1 - d)(2\Delta_2 - d)(2\Delta_3 - d)}}\,,} \tag{54.69}$$

with $b(\Delta_i)$ given by Eq. (54.68) and all L-dependence collected into the prefactor (it cancels the dimension of the bulk coupling λ, so C_{123} is dimensionless). Two features deserve emphasis. First, the OPE coefficient is *computed*, not merely allowed: conformal symmetry left C_{123} free, and holography fixes it through the single bulk number λ and a universal ratio of Gamma functions of the dimensions. Second, the scaling with N is exactly right. The matter normalization inherits the gravitational $\mathcal{N}_\phi L^{d-1} \propto 1/G_N \propto N^2$ of Eq. (53.162) (the same factor that made $C_\Delta \propto N^2$ in the two-point function), so Eq. (54.69) carries $C_{123} \propto 1/\sqrt{\mathcal{N}_\phi L^{d-1}} \propto 1/N$. A three-point function of single-trace operators is suppressed by one power of $1/N$ relative to the two-point function — precisely the statement of large-N factorization, that single-trace operators behave at leading order like generalized free (Gaussian) fields whose connected higher correlators are $1/N$-suppressed. The bulk cubic vertex is the leading correction to that Gaussianity.

54.3.3 Four points: contact versus exchange

At four points conformal symmetry no longer fixes the answer: the correlator of four identical scalars $\mathcal{O}$ of dimension Δ_ϕ is, by Eq. (47.145),

$$\langle \mathcal{O}(x_1)\mathcal{O}(x_2)\mathcal{O}(x_3)\mathcal{O}(x_4)\rangle = \frac{\mathcal{G}(u,v)}{|x_{12}|^{2\Delta_\phi}\,|x_{34}|^{2\Delta_\phi}}, \qquad u=\frac{x_{12}^2\,x_{34}^2}{x_{13}^2\,x_{24}^2}, \quad v=\frac{x_{14}^2\,x_{23}^2}{x_{13}^2\,x_{24}^2}, \tag{54.70}$$

with u, v the cross-ratios of Eq. (47.138) and $\mathcal{G}(u,v)$ an undetermined function. Two distinct bulk processes feed $\mathcal{G}$ at tree level. A quartic contact vertex $\lambda_4\,\phi^4$ gives the contact D-function $D_{\Delta_\phi\Delta_\phi\Delta_\phi\Delta_\phi}$ of Fig. 54.3(b); a cubic coupling $\phi\phi\sigma$ to a second bulk field σ gives, at the same order, the exchange diagram of Fig. 54.3(c) in which σ is propagated internally between two cubic vertices.

The contact piece. The four-point contact diagram is read off from Eq. (54.60) with $n=4$, $\Sigma = 4\Delta_\phi$. The simplex integral can no longer be done in elementary closed form for all dimensions, but it always reduces to a function of the cross-ratios alone once the kinematic prefactor is stripped: by the same homogeneity-plus-inversion argument as at three points, $D_{\Delta_\phi\Delta_\phi\Delta_\phi\Delta_\phi}$ equals a power of the x_{ij} fixing the overall conformal weight times a function $\bar{D}(u,v)$,

$$D_{\Delta_\phi\Delta_\phi\Delta_\phi\Delta_\phi}(x_i) = \frac{\pi^{d/2}\,\Gamma\!\left(2\Delta_\phi-\frac{d}{2}\right)\Gamma(2\Delta_\phi)}{2\,\Gamma(\Delta_\phi)^4}\,\frac{1}{(x_{13}^2\,x_{24}^2)^{\Delta_\phi}}\,\bar{D}_{\Delta_\phi\Delta_\phi\Delta_\phi\Delta_\phi}(u,v). \tag{54.71}$$

The reduced $\bar{D}$-functions are the standard building blocks of contact Witten diagrams; for integer or half-integer dimensions they evaluate to combinations of ${}_2F_1$ hypergeometrics and, in the simplest cases, to logarithms and dilogarithms. Their key qualitative property, which we exploit below, is that a contact diagram contains *no* single-trace conformal block: with no field propagating internally, no new primary is exchanged, and the only operators that can appear in the $\mathcal{O}\times\mathcal{O}$ OPE are the composites built from two $\mathcal{O}$'s.

The exchange piece. Let σ be a scalar bulk field of mass m_σ, dual to a single-trace primary $\mathcal{O}_\Delta$ of dimension Δ, $\Delta(\Delta-d) = m_\sigma^2 L^2$, coupled to the external field by $\lambda\,\phi\phi\sigma$. The s-channel exchange diagram is

$$A^{s}_{\text{exch}}(x_i) = (\mathcal{N}_\phi\lambda)^2 L^{2(d+1)}\,c_{\Delta_\phi}^4 \int \frac{\mathrm{d}Z_1}{z_1^{d+1}}\frac{\mathrm{d}Z_2}{z_2^{d+1}}\,\widehat{K}_{\Delta_\phi}(Z_1;x_1)\widehat{K}_{\Delta_\phi}(Z_1;x_2)\,G_\Delta(Z_1,Z_2)\,\widehat{K}_{\Delta_\phi}(Z_2;x_3 \tag{54.72}$$

with $\mathrm{d}Z_a = \mathrm{d}z_a\,\mathrm{d}^d x_a$ and $G_\Delta(Z_1,Z_2)$ the *bulk-to-bulk* propagator of σ: the Green's function of the bulk wave operator,

$$(-\Box_{Z_1} + m_\sigma^2)\,G_\Delta(Z_1,Z_2) = \frac{1}{\sqrt{g}}\,\delta^{d+1}(Z_1-Z_2), \tag{54.73}$$

regular in the interior and normalizable ($\sim z^{\Delta}$, not $z^{d-\Delta}$) at the boundary, so that no source for $\mathcal{O}_\Delta$ is turned on. In terms of the chordal distance $\zeta \equiv [(z_1-z_2)^2+|x_1-x_2|^2]/(2z_1z_2)$ it has the closed hypergeometric form $G_\Delta(\zeta) \propto (2\zeta)^{-\Delta}\,{}_2F_1(\Delta, \Delta-\frac{d}{2}+\frac{1}{2}; 2\Delta-d+1; -2/\zeta)$; the only property we need is its behaviour as one argument approaches the boundary, $z_1 \to 0$, where the normalizable falloff factors out a bulk-to-boundary propagator,

$$G_\Delta(Z_1,Z_2) \xrightarrow{z_1\to 0} \frac{1}{2\Delta-d}\, z_1^{\Delta}\, K_\Delta(Z_2;x_1) + O(z_1^{\Delta+2}). \tag{54.74}$$

This is the same coefficient $2\Delta-d$ that appeared in the two-point function, and it is what ties the exchange to the OPE coefficient.

54.3.4 The conformal-block decomposition of the exchange diagram

The double bulk integral in Eq. (54.72) looks intractable, but the equation of motion Eq. (54.73) collapses one of the two integrations and, with it, organizes the answer into conformal blocks. Define the field sourced by the first vertex,

$$\Phi(Z_2) \equiv \int \frac{\mathrm{d}Z_1}{z_1^{d+1}}\, G_\Delta(Z_2,Z_1)\, \widehat{K}_{\Delta_\phi}(Z_1;x_1)\, \widehat{K}_{\Delta_\phi}(Z_1;x_2). \tag{54.75}$$

Acting with the wave operator and using Eq. (54.73) turns the integral equation into a differential one,

$$(-\Box_{Z_2} + m_\sigma^2)\,\Phi(Z_2) = \widehat{K}_{\Delta_\phi}(Z_2;x_1)\,\widehat{K}_{\Delta_\phi}(Z_2;x_2) \equiv \mathcal{J}(Z_2), \tag{54.76}$$

so Φ is the bulk field generated by the bilinear source $\mathcal{J}$ built from two external legs, and the exchange amplitude is the single remaining integral $A^s_{\text{exch}} \propto \int \mathrm{d}Z_2\, z_2^{-(d+1)}\, \widehat{K}_{\Delta_\phi}(Z_2;x_3)\widehat{K}_{\Delta_\phi}(Z_2;x_4)\,\Phi(Z_2)$.

Now read off the structure of Φ from Eq. (54.76). The full solution is the sum of a particular solution and a homogeneous solution. The source $\mathcal{J}$, by conformal covariance, behaves near the boundary point $x \to x_1 \approx x_2$ like a power $z^{2\Delta_\phi}$; the particular solution inherits powers $z^{2\Delta_\phi+2n}$, $n=0,1,2,\dots$, generated by acting with $\Box^{-1}$ on the analytic tail of the source. The homogeneous solutions of $(-\Box+m_\sigma^2)\Phi_{\text{hom}}=0$ carry the two indicial powers of the wave operator, z^{Δ} and $z^{d-\Delta}$, exactly as in the two-point analysis of Section 53.6.3; normalizability and the boundary conditions inherited from G_Δ select the z^{Δ} branch. Thus the small-z expansion of Φ contains *two species of falloff*:

$$\Phi(z,x) \xrightarrow{z\to 0} \underbrace{a_\Delta\, z^{\Delta}\, f_\Delta(x;x_1,x_2)}_{\text{homogeneous (single-trace)}} + \sum_{n\ge 0} \underbrace{b_n\, z^{\,2\Delta_\phi+2n}\, f_n(x;x_1,x_2)}_{\text{particular (double-trace)}}. \tag{54.77}$$

When this is fed into the second vertex, each power z^{δ} produces, after the Z_2 integral, a contribution to $\mathcal{G}(u,v)$ that begins at $u^{\delta/2}$ in the OPE limit $u \to 0$.

Comparison with the block expansion makes the identification immediate. The s-channel decomposition of Eq. (54.70) into the conformal blocks of Theorem 47.49 reads, by Eq. (47.227),

$$\mathcal{G}(u,v) = \sum_{\mathcal{O}'} C^2_{\mathcal{O}\mathcal{O}\mathcal{O}'}\, G_{\Delta_{\mathcal{O}'},\ell_{\mathcal{O}'}}(u,v), \qquad G_{\Delta',\ell'}(u,v) \xrightarrow{u\to 0} u^{(\Delta'-\ell')/2}, \tag{54.78}$$

each block beginning with the power $u^{\tau'/2}$, $\tau' = \Delta' - \ell'$ the twist. Matching powers in Eqs. (54.77) and (54.78):

- The homogeneous z^{Δ} term produces $u^{\Delta/2}$, the leading power of the conformal block of the single-trace primary $\mathcal{O}_\Delta$ itself — the operator dual to the exchanged bulk field σ. Its coefficient is, by the boundary limit Eq. (54.74), exactly the product of the two cubic OPE coefficients computed in Section 54.3.2: $C^2_{\mathcal{O}\mathcal{O}\mathcal{O}_\Delta}$. A single bulk field exchanges *exactly one* single-trace primary, and one conformal block (which already packages all of $\mathcal{O}_\Delta$'s descendants) accounts for it. This is the precise sense in which the equation of motion *truncates* the single-trace content of the block sum: the second-order wave operator Eq. (54.73) has a two-dimensional space of indicial behaviours and boundary conditions pick out one dimension Δ, not a tower.
- The particular-solution powers $z^{2\Delta_\phi+2n}$ produce $u^{\Delta_\phi+n}$, the leading powers of an infinite tower of *double-trace* operators of twist $2\Delta_\phi + 2n$. Spin enters once the external legs are allowed to carry derivatives (or the exchanged field carries spin): each twist $2\Delta_\phi+2n$ supports a whole family of spins ℓ, and the general double-trace primary $[\mathcal{O}\mathcal{O}]_{n,\ell}$ has dimension $\Delta_{n,\ell} = 2\Delta_\phi + 2n + \ell$.

Assembling the two species of falloff, the s-channel exchange diagram has the block decomposition

$$\mathcal{G}^{s}_{\text{exch}}(u,v) = C^2_{\mathcal{O}\mathcal{O}\mathcal{O}_\Delta}\, G_{\Delta,0}(u,v) \;+\; \sum_{n=0}^{\infty}\sum_{\ell} p_{n,\ell}\, G_{\,2\Delta_\phi+2n+\ell,\,\ell}(u,v), \qquad \Delta_{n,\ell} = 2\Delta_\phi + 2n + \tag{54.79}$$

The single-trace block is the genuinely new physics of the exchange; the double-trace tower is, dimension for dimension, the very spectrum that the bootstrap finds in any unitary correlator of identical scalars. Indeed these are exactly the double-twist operators $[\mathcal{O}\mathcal{O}]_{n,\ell}$ of dimension $2\Delta_\phi + 2n + \ell$ that crossing forced into the mean-field solution of Eq. (49.130) and Section 49.5.1 — recovered here from the bulk, with their leading $1/N$ corrections supplied by the exchange and contact diagrams.

Worked Example 54.8 (Double-trace operators as two-particle states in AdS)**.** The double-trace tower has a transparent bulk meaning that the block decomposition obscures. In the strict large-N limit, $G_N \to 0$, the bulk theory is free: a

single bulk scalar ϕ of mass m on rigid AdS_{d+1}, with no interactions. Quantize it in global AdS, where the timelike boundary makes AdS a box and the spectrum of the wave operator is discrete: a single quantum has energies $\omega = \Delta + 2k + j$, $k, j \geq 0$, with Δ the dual dimension and j the angular momentum on the spatial S^{d-1}. Because energy in global AdS equals scaling dimension under the state–operator map (Section 47.5), the one-particle states are exactly $\mathcal{O}$ and its descendants. A *two*-particle state, two quanta with relative excitation n and total spin ℓ, has energy

$$E_{n,\ell} = 2\Delta + 2n + \ell + O(G_N), \tag{54.80}$$

the free sum of the two single-particle energies. Under the dictionary this is a primary of dimension $2\Delta_\phi + 2n + \ell$ — precisely the double-trace operator $[\mathcal{O}\mathcal{O}]_{n,\ell}$. The operator $[\mathcal{O}\mathcal{O}]_{n,\ell}$ is the boundary image of a pair of bulk particles; that is why it is present in every holographic correlator independently of any interaction, and why its mean-field dimension is the free sum.

Now restore the interaction. The two bulk particles attract or repel through the exchange of σ (or the contact ϕ^4 vertex), shifting the two-particle energy by a binding energy of order $G_N \propto 1/N^2$,

$$\Delta_{n,\ell} = 2\Delta_\phi + 2n + \ell + \frac{1}{N^2}\,\gamma^{(1)}_{n,\ell} + O(N^{-4}). \tag{54.81}$$

The anomalous dimension $\gamma^{(1)}_{n,\ell}$ is literally the binding energy of the two-particle state in AdS units. An attractive bulk force — gravity is universally attractive — gives $\gamma^{(1)}_{n,\ell} < 0$: the bound pair is lighter than the sum of its parts, exactly as two masses are lighter when gravitationally bound. This sign is not optional; it is fixed by bulk causality and is the holographic face of the same positivity that the conformal bootstrap and the chaos bound impose on $\gamma_{n,\ell}$ in the large-spin expansion of Chapter 51.

Reading the anomalous dimension off the correlator. The shift Eq. (54.81) leaves an unmistakable fingerprint. A block of dimension $\Delta_{n,\ell} = 2\Delta_\phi + 2n + \ell + \gamma$ contributes a power $u^{(\Delta_{n,\ell}-\ell)/2} = u^{\Delta_\phi + n}\, u^{\gamma/2}$, and expanding $u^{\gamma/2} = 1 + \frac{\gamma}{2}\log u + \cdots$ for the small $\gamma \propto 1/N^2$ shows that the anomalous dimension appears as the coefficient of a *logarithm* of the cross-ratio:

$$\mathcal{G}(u,v) \;\supset\; \tfrac{1}{2}\, a^{(0)}_{n,\ell}\, \gamma^{(1)}_{n,\ell}\, u^{\Delta_\phi + n}\, \log u, \tag{54.82}$$

with $a^{(0)}_{n,\ell}$ the mean-field (squared) OPE coefficient. A tree-level Witten diagram is an analytic function of the cross-ratios except for exactly such logarithms; the contact and exchange diagrams generate them, and the coefficient of $\log u$ at order $u^{\Delta_\phi+n}$ is $\frac{1}{2}a^{(0)}_{n,\ell}\gamma^{(1)}_{n,\ell}$. This is how anomalous dimensions of double-trace operators are extracted in practice, and it is the holographic signal that the bulk fields interact: were the bulk free, $\mathcal{G}$ would be the pure mean-field correlator of Eq. (49.127) with no logarithm and no anomalous dimensions at all.

54.3.5 The Mellin amplitude and the link to the bootstrap

The cross-ratio functions $\bar{D}(u,v)$ are cumbersome, and the block decomposition Eq. (54.79) hides the simplicity of the underlying diagram. The natural variable is the Mellin transform. Strip the leading prefactor and write the reduced correlator as a double inverse-Mellin integral,

$$\mathcal{G}(u,v) = \int_{-i\infty}^{i\infty} \frac{\mathrm{d}s\,\mathrm{d}t}{(4\pi i)^2}\, u^{s/2}\, v^{(t-2\Delta_\phi)/2}\, M(s,t)\,\Gamma^2\!\Big(\Delta_\phi - \tfrac{s}{2}\Big)\,\Gamma^2\!\Big(\Delta_\phi - \tfrac{t}{2}\Big)\,\Gamma^2\!\Big(\Delta_\phi - \tfrac{\tilde{u}}{2}\Big), \qquad \tilde{u} = 4\Delta_\phi \tag{54.83}$$

the Gamma functions forming the universal Mellin measure and $M(s,t)$ the *Mellin amplitude*. The Mellin variables $s,t,\tilde{u}$ are the conformal analogues of Mandelstam invariants, satisfying $s+t+\tilde{u} = 4\Delta_\phi$, and $M(s,t)$ plays the role of a flat-space scattering amplitude. In this variable the Witten diagrams become elementary:

- a contact diagram from a non-derivative ϕ^4 vertex has a *constant* Mellin amplitude, $M(s,t) = \text{const}$; derivative vertices give polynomials in s,t;
- an s-channel exchange of $\mathcal{O}_\Delta$ has a Mellin amplitude with *poles* at the locations of the exchanged twist and its descendants,

$$M(s,t) = \sum_{m=0}^{\infty} \frac{R_m}{s-(\Delta-\ell)-2m} + (\text{regular}), \tag{54.84}$$

  the single tower of poles at $s = \Delta - \ell + 2m$ encoding the one single-trace primary and its descendants.

The double-trace operators are not poles of M at all: they are the poles of the Mellin measure — the Gamma functions $\Gamma^2(\Delta_\phi - \frac{s}{2})$ have double poles at $s = 2\Delta_\phi + 2n$, and a double pole is precisely the $\log u$ of Eq. (54.82), i.e. an anomalous dimension. The kinematic, always-present double-trace spectrum is built into the measure; interactions move and split those poles. A tree-level Witten diagram is thus a *rational* (for contact) or *meromorphic* (for exchange) function of s,t — the simplest analytic object the correlator can be, and the reason the Mellin representation is the workhorse of modern holographic computation.

Crossing. The assembled four-point function is the sum over channels: the disconnected mean-field piece (the identity plus its double-trace shadow) at $O(N^0)$, and at $O(1/N^2)$ the sum of s-, t-, and u-channel exchanges together with the contact terms. No single Witten diagram is crossing symmetric: the s-channel exchange Eq. (54.79) manifestly distinguishes the pair (12)(34). But the full correlator must be invariant under permutations of the four identical insertions, in particular under the $1 \leftrightarrow 3$ exchange that swaps $u \leftrightarrow v$ and yields the bootstrap

equation Eq. (49.15). The justification is structural rather than diagram-by-diagram: the bulk is a consistent local theory, so its boundary correlators are genuine correlators of a single CFT, and any genuine CFT correlator satisfies crossing by associativity of the OPE (Theorem 49.13). In Mellin space the statement is sharp and immediate: crossing symmetry is the total symmetry of $M(s,t)$ under permutations of $(s,t,\tilde{u})$, which the sum of the three channel exchanges plus the symmetric contact term manifestly possesses. The individual diagrams conspire, channel against channel, exactly as the infinite double-trace tower conspired in the mean-field solution of Section 49.5.1 to reproduce a single crossed-channel term.

Contact with the numerical bootstrap. This closes the loop opened in Chapters 49 and 50. The bootstrap takes crossing Eq. (49.15) and unitarity as the only inputs and, with no Lagrangian, carves out the allowed operator data $\{\Delta,\, C\}$ — for the three-dimensional Ising universality class, the endpoint of ϕ^4 theory, pinning Δ_σ and Δ_ϵ to the island recorded in Table 50.1. Holography computes the same kind of data from the opposite direction: when a CFT possesses a weakly curved gravity dual, its single-trace OPE coefficients are the Gamma-function ratios of Eq. (54.69) and its double-trace anomalous dimensions are the binding energies of Eq. (54.81), all read off from tree-level diagrams. The two methods meet on the crossing equation, the one constraint both must satisfy. They are not, however, the same theory: the canonical holographic example is $\mathcal{N}=4$ super-Yang–Mills at large N and large 't Hooft coupling — the maximally symmetric large-N cousin of Yang–Mills theory — whose sparse spectrum and large gap make a local bulk possible, whereas the 3D Ising CFT has order-one central charge and no parametrically light single-trace tower, hence no weakly coupled gravity dual. What is universal, and what this section has exhibited, is the *structure*: every unitary CFT four-point function decomposes into single-trace (or, for Ising, simply low-lying) primaries plus the double-trace tower $[\mathcal{O}\mathcal{O}]_{n,\ell}$ at $2\Delta_\phi + 2n + \ell$, and the bulk computation and the bootstrap are two windows onto the same operator content.

With the vacuum correlators of the holographic CFT now under control — two-, three-, and four-point functions, their conformally fixed structures, their OPE coefficients, and the double-trace spectrum that the bootstrap independently demands — the zero-temperature story is complete. The same bulk fields whose tree-level diagrams we have just resummed must next be quantized on a different geometry: heating the boundary CFT corresponds to replacing pure AdS by a black-brane background, and the renormalized on-shell action that here gave correlators will there give a free energy. Section 54.4 turns to that thermal state.

54.4 Black Holes and Finite Temperature

The previous three sections quantized bulk fields on *empty* anti–de Sitter space and read off the vacuum correlators of the dual conformal field theory: two-, three-, and four-point functions, their conformally fixed structures, and the operator data they encode. That entire computation lived at zero temperature, on the single geometry Eq. (53.161). We now heat the boundary theory. In ordinary quantum field theory the thermal partition function $Z(\beta) = \mathrm{Tr}\, e^{-\beta H}$ is computed by putting the Euclidean theory on a time circle of circumference $\beta = 1/T$ (Eq. (10.136)); the holographic question is therefore sharp and inevitable. The GKP–Witten relation Eq. (53.162) equates Z_{CFT} with a bulk gravitational partition function, and at large N and large 't Hooft coupling that partition function is dominated by a classical saddle. So the question becomes: *which bulk geometry, with a Euclidean time circle of circumference β on its conformal boundary, dominates the gravitational path integral?* The answer is the single most consequential geometry in this book. For high enough temperature it is not empty AdS with a periodically identified time, but a *black brane* — a planar black hole whose horizon sits at a finite radial depth. Its temperature is the Hawking temperature, fixed entirely by the demand that the Euclidean geometry close off smoothly at the horizon; the renormalized on-shell gravitational action — rendered finite by exactly the counterterms of Section 54.2.3 — is the free energy; and the area of the horizon, divided by $4G$, is the entropy. This section establishes all of that, carries every term of the on-shell action, and ends by exhibiting the gravitational dual of confinement: the Hawking–Page transition.

54.4.1 The planar AdS–Schwarzschild black brane

We work in Euclidean signature, where the partition function is a genuine convergent integral and the boundary condition is a Dirichlet problem, exactly as in Section 53.6.1. The bulk dynamics is pure gravity with a negative cosmological constant — the metric sector of the supergravity theory whose probe scalars supplied the correlators of the previous sections. Its action, in $D = d+1$ bulk dimensions, is the Einstein–Hilbert action with the Gibbons–Hawking boundary term and the holographic counterterms,

$$S_E \;=\; -\frac{1}{16\pi G}\int_{\mathcal{M}} \mathrm{d}^{d+1}x\,\sqrt{g}\,(R-2\Lambda) \;-\; \frac{1}{8\pi G}\int_{\partial\mathcal{M}} \mathrm{d}^{d}x\,\sqrt{\gamma}\,K \;+\; S_{\mathrm{ct}}, \tag{54.85}$$

with $G \equiv G_{d+1}$ the bulk Newton constant, Λ the cosmological constant, $\gamma_{\mu\nu}$ the induced metric on the regulating boundary slice, K the trace of its extrinsic curvature, and S_{ct} the local covariant counterterms of Eq. (54.49). The Gibbons–Hawking term is the standard addition that makes the Dirichlet variational problem well posed: without it, varying Eq. (54.85) would leave a boundary term proportional to the normal derivative of the metric, and the action would

not be stationary on solutions with the metric (rather than its derivative) fixed at the boundary. We take its presence as established; what we owe here is the evaluation, not the derivation of the boundary term, and we carry that evaluation in full below.

The cosmological constant is fixed by demanding that empty AdS_{d+1} of radius L solve the equations of motion. Varying Eq. (54.85) gives the Einstein equation $R_{\mu\nu} - \frac{1}{2}g_{\mu\nu}R + \Lambda g_{\mu\nu} = 0$; tracing it in $D = d+1$ dimensions,

$$R\Big(1 - \frac{D}{2}\Big) + D\Lambda = 0 \quad \Longrightarrow \quad R = \frac{2D}{D-2}\Lambda = \frac{2(d+1)}{d-1}\Lambda, \tag{54.86}$$

and matching to the known curvature of AdS_{d+1}, $R = -d(d+1)/L^2$, fixes

$$\Lambda = -\frac{d(d-1)}{2L^2}. \tag{54.87}$$

We will use one consequence of Eq. (54.86) repeatedly: on *any* solution the on-shell Lagrangian density is a spacetime constant. From Eq. (54.86) and Eq. (54.87),

$$R - 2\Lambda = \frac{2(d+1)}{d-1}\Lambda - 2\Lambda = 2\Lambda\,\frac{(d+1)-(d-1)}{d-1} = \frac{4\Lambda}{d-1} = -\frac{2d}{L^2}, \tag{54.88}$$

the same constant $-2d/L^2$ already flagged for the counterterm analysis in Section 54.2.3. The bulk integrand of Eq. (54.85) is therefore proportional to the volume element alone; all the work in evaluating the action is the (divergent) volume integral and the boundary terms.

Among the solutions with conformal boundary $\mathbb{R}\times\mathbb{R}^{d-1}$ (flat space, the setting of the previous sections, now to be given a thermal circle) there is a one-parameter family of *planar black holes*. We state the metric and then verify it solves the equations.

Definition 54.9 (Planar AdS–Schwarzschild black brane)**.** The *planar AdS–Schwarzschild metric*, or *black brane*, in Poincaré-like coordinates with radial coordinate z is

$$\mathrm{d}s^2 \;=\; \frac{L^2}{z^2}\left[-f(z)\,\mathrm{d}t^2 + \mathrm{d}\mathbf{x}^2 + \frac{\mathrm{d}z^2}{f(z)}\right], \qquad f(z) = 1 - \Big(\frac{z}{z_h}\Big)^d, \tag{54.89}$$

with $\mathbf{x}\in\mathbb{R}^{d-1}$, conformal boundary at $z\to 0$, and a horizon at $z = z_h$ where the *blackening factor* f vanishes. As $z_h\to\infty$, $f\to 1$ and Eq. (54.89) reduces to the Poincaré patch Eq. (53.59), up to the overall sign of the metric: that equation is written in the book's mostly-minus signature, whereas Eq. (54.89) and every other Lorentzian metric of this and the following two sections use mostly-plus, as the notationwatch below records.

Notation Watch

Signature in the black-hole and real-time sections. The book's global convention is mostly-minus, $\eta_{\mu\nu} = \mathrm{diag}(+, -, \ldots, -)$ (Appendix A; fixed for Part XV in Section 53.3). The zero-temperature correlators of Sections 54.1 and 54.3 were computed in Euclidean signature, where the question does not arise. For the Lorentzian black-hole, transport, and holographic-RG computations of Sections 54.4 to 54.6 we adopt instead the *mostly-plus* signature $\mathrm{diag}(-, +, \ldots, +)$ standard in general relativity and the holography literature, with the Wald curvature convention in which AdS has negative scalar curvature. The departure is deliberate: mostly-plus is the natural convention for black-hole geometry, keeping $\sqrt{-g}$ real in every bulk dimension $D = d + 1$ and the horizon and causal structure transparent, and it matches the references a reader of this material will consult. The translation to the book's mostly-minus form is the overall sign flip of every metric (so Eq. (54.89) is the mostly-minus Eq. (53.59) with its sign reversed and a blackening factor inserted), and no physical conclusion depends on the choice: the Euclidean thermodynamics of this section is signature-blind, and the mass–dimension and transport relations are invariant. We state the convention once here and carry it through Section 54.6.

That Eq. (54.89) solves Einstein's equation with Eq. (54.87) is a direct computation; the structure that makes it work is worth seeing. The function f multiplies $\mathrm{d}t^2$ and divides $\mathrm{d}z^2$, the hallmark of a static black hole, and the specific power z^d is the unique one for which the (t, z) part of the Ricci tensor stays proportional to the metric while the flat boundary directions $\mathbf{x}$ are left undisturbed. The single integration constant z_h labels the family: it is the position of the horizon, and — as we are about to show — it is in one-to-one correspondence with the temperature. The metric is asymptotically AdS: near $z = 0$, $f \to 1$ and Eq. (54.89) approaches Eq. (53.59) (in the mostly-plus form of the notationwatch above), so the holographic dictionary, the falloff analysis, and the counterterms of the previous sections all apply unchanged in the near-boundary region. The black brane differs from empty AdS only deep in the interior, at $z \sim z_h$ — which is exactly the statement, in the language of Section 53.4, that turning on a temperature is an *infrared* deformation of the boundary theory, invisible in the deep ultraviolet at $z \to 0$.

Physical Insight

The radial coordinate is the renormalization scale (Section 53.4): $z \to 0$ is the deep ultraviolet, $z \to \infty$ the deep infrared. Temperature is an infrared scale — it is invisible to short-distance physics and dominates

long-distance physics. The black brane realizes this perfectly: it is identical to the AdS vacuum near the boundary and is modified only in the far interior, where the geometry simply *ends* at a horizon. The horizon is the geometric incarnation of the thermal infrared cutoff; the spacetime has nowhere deeper to go, because the temperature has screened it.

To make $Z = \mathrm{Tr}\, e^{-\beta H}$ we Wick-rotate $t \to -i\tau$ (Theorem 5.30), turning Eq. (54.89) into the Euclidean black brane

$$\mathrm{d}s_E^2 \;=\; \frac{L^2}{z^2}\left[\, f(z)\,\mathrm{d}\tau^2 + \mathrm{d}\mathbf{x}^2 + \frac{\mathrm{d}z^2}{f(z)}\,\right], \qquad f(z) = 1 - \Big(\frac{z}{z_h}\Big)^d, \tag{54.90}$$

on which the boundary Euclidean time τ runs over a circle whose circumference we must now determine. It is not free. Demanding that the geometry Eq. (54.90) be smooth at $z = z_h$ — where the coefficient of $\mathrm{d}\tau^2$ vanishes — fixes the period of τ, and that period is $\beta = 1/T$.

54.4.2 The Hawking temperature from Euclidean regularity

The coefficient of $\mathrm{d}\tau^2$ in Eq. (54.90) is $\frac{L^2}{z^2} f(z)$, which vanishes at $z = z_h$. A metric in which a circle direction shrinks to zero size is, generically, *singular* there — it has a conical defect, like the tip of a cone — unless the period of the angular coordinate is tuned to exactly the value that makes the tip smooth. This is the same elementary fact that fixes the period of the angle in polar coordinates: $\mathrm{d}R^2 + R^2\,\mathrm{d}\theta^2$ is smooth flat space at $R = 0$ only if θ has period exactly 2π; any other period leaves a cone with an opening-angle deficit and a curvature delta-function at the tip. The Euclidean black brane closes off smoothly at the horizon for one and only one period β of τ, and that period is the inverse temperature.

We carry out the near-horizon expansion explicitly. Write $z = z_h - \rho$ with $\rho \to 0^+$ approaching the horizon from the boundary side. Expanding f to first order,

$$f(z) \simeq f'(z_h)\,(z - z_h) = -f'(z_h)\,\rho, \qquad f'(z) = -\frac{d\, z^{d-1}}{z_h^d} \;\Longrightarrow\; f'(z_h) = -\frac{d}{z_h}, \tag{54.91}$$

so $f \simeq (d/z_h)\,\rho > 0$, vanishing linearly as it must. Near the horizon the two-dimensional (τ, z) part of Eq. (54.90) is, to leading order (the prefactor $L^2/z^2 \to L^2/z_h^2$ is smooth and we evaluate it at z_h),

$$\mathrm{d}s^2_{(2)} \;\simeq\; \frac{L^2}{z_h^2}\left[\, \frac{d}{z_h}\,\rho\,\mathrm{d}\tau^2 + \frac{z_h}{d\,\rho}\,\mathrm{d}\rho^2\,\right], \tag{54.92}$$

using $\mathrm{d}z^2 = \mathrm{d}\rho^2$ and $1/f \simeq z_h/(d\rho)$. This is not yet in the recognizable polar form, because the radial part is $\mathrm{d}\rho^2/\rho$, not $\mathrm{d}R^2$. Introduce the proper radial distance R from the horizon,

$$R = \int \frac{L}{z_h}\frac{\mathrm{d}\rho}{\sqrt{f}} = \frac{L}{z_h}\sqrt{\frac{z_h}{d}}\int \frac{\mathrm{d}\rho}{\sqrt{\rho}} = \frac{2L}{z_h}\sqrt{\frac{z_h\,\rho}{d}}, \tag{54.93}$$

so that by construction $\frac{L^2}{z_h^2}\frac{\mathrm{d}\rho^2}{f} = \mathrm{d}R^2$. Inverting, $\rho = \frac{d\,z_h}{4L^2}R^2$, and the $\mathrm{d}\tau^2$ coefficient becomes

$$\frac{L^2}{z_h^2}\frac{d}{z_h}\rho = \frac{L^2}{z_h^2}\frac{d}{z_h}\frac{d\,z_h}{4L^2}R^2 = \frac{d^2}{4z_h^2}R^2. \tag{54.94}$$

The near-horizon metric is therefore

$$\mathrm{d}s^2_{(2)} \;\simeq\; \mathrm{d}R^2 + \frac{d^2}{4z_h^2}R^2\,\mathrm{d}\tau^2 \;=\; \mathrm{d}R^2 + R^2\,\mathrm{d}\theta^2, \qquad \theta \equiv \frac{d}{2z_h}\tau, \tag{54.95}$$

which is flat $\mathbb{R}^2$ in polar coordinates — a smooth disk capping off the geometry — precisely when the angle θ has period 2π. Since $\theta = \frac{d}{2z_h}\tau$, the period of τ for which this holds is

$$\frac{d}{2z_h}\beta = 2\pi \quad\Longrightarrow\quad \boxed{\beta = \frac{4\pi z_h}{d}\,, \qquad T = \frac{1}{\beta} = \frac{d}{4\pi z_h}\,.} \tag{54.96}$$

Any other period $\beta' \neq \beta$ would leave a conical singularity at z_h with deficit angle $2\pi(1-\beta'/\beta)$ and a curvature singularity that no smooth solution of Einstein's equation can have. *Smoothness alone fixes the temperature.* This is the Hawking temperature, and the derivation by Euclidean regularity is the cleanest route to it: there is no need to track Bogoliubov coefficients or compute a particle flux (the Lorentzian-signature derivation we give for a genuine collapsing star in Chapter 65); the temperature is read off the geometry as the unique period that avoids a conical defect. Equivalently, using the general formula $T = |f'(z_h)|/4\pi$ that Eq. (54.91) makes explicit — a relation the next section's infalling analysis Eq. (54.143) reuses verbatim — the surface gravity of the horizon is $\kappa = \frac{1}{2}|f'(z_h)|\cdot(z_h/L)\cdots$; we will not need the surface-gravity packaging, since Eq. (54.96) is already the result.

54.4.3 The renormalized free energy

With the geometry and its temperature fixed, the free energy follows from the GKP–Witten saddle. In the supergravity limit the gravitational partition function is dominated by the on-shell action of the black brane, $Z_{\rm grav} \approx e^{-S_E^{\text{on-shell}}}$ (Eq. (53.163)), and the standard thermodynamic identity $Z = e^{-\beta F}$ identifies

$$\beta F = S_E^{\text{on-shell}}[\,\text{black brane}\,]. \tag{54.97}$$

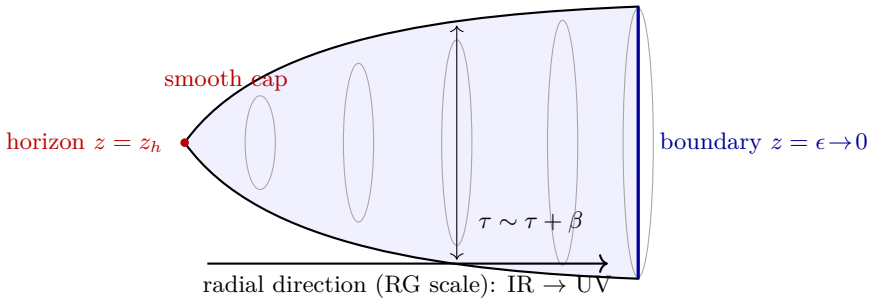


Figure 54.4: The Euclidean black brane as a "cigar." The Euclidean time direction τ is a circle of circumference β fibered over the radial coordinate. Near the boundary $z \to 0$ the circle has its full size; as one moves into the interior the circle shrinks, and at the horizon $z = z_h$ it closes off to a point. The geometry caps smoothly there (no conical defect) for exactly one period, $\beta = 4\pi z_h/d$, which is the inverse Hawking temperature Eq. (54.96). The tip is the tip of the disk $\mathrm{d}R^2 + R^2\mathrm{d}\theta^2$ of Eq. (54.95); this is the "cigar" whose smoothness the Lorentzian infalling boundary condition of Section 54.5.1 continues into causality.

The whole content of this subsection is the careful evaluation of the right-hand side, term by term, with the radial cutoff at $z = \epsilon$ kept until the very end. Three pieces contribute — bulk, Gibbons–Hawking, counterterm — and the divergences cancel between them, exactly as the scalar computation of Theorem 54.5 promised for the gravitational sector. We work with the Euclidean metric Eq. (54.90). Throughout, $V_{d-1} = \int \mathrm{d}^{d-1}x$ is the (infinite, regulated) coordinate volume of the spatial boundary directions, and we will report intensive densities per unit V_{d-1}.

The square root of the metric determinant is the same as for empty AdS, because the two factors f and $1/f$ cancel:

$$\sqrt{g} = \sqrt{\left(\tfrac{L^2}{z^2}\right)^{d+1} f \cdot \tfrac{1}{f}} = \left(\frac{L}{z}\right)^{d+1}. \tag{54.98}$$

Bulk term. Using Eq. (54.88), the bulk integrand is the constant $-\frac{1}{16\pi G}(R - 2\Lambda) = \frac{1}{16\pi G}\frac{2d}{L^2} = \frac{d}{8\pi G L^2}$, so

$$S_{\text{bulk}} = \frac{d}{8\pi G L^2}\int_0^\beta \mathrm{d}\tau \int \mathrm{d}^{d-1}x \int_\epsilon^{z_h} \mathrm{d}z \left(\frac{L}{z}\right)^{d+1} = \frac{d\,\beta V_{d-1} L^{d-1}}{8\pi G}\int_\epsilon^{z_h} \frac{\mathrm{d}z}{z^{d+1}}. \tag{54.99}$$

The radial integral runs from the cutoff $z = \epsilon$ down to the horizon $z = z_h$, which is the lower edge of the spacetime — the geometry simply ends there, so there is nothing below the horizon to integrate. Evaluating,

$$\int_\epsilon^{z_h} \frac{\mathrm{d}z}{z^{d+1}} = \Big[-\frac{1}{d\,z^d}\Big]_\epsilon^{z_h} = \frac{1}{d}\Big(\frac{1}{\epsilon^d} - \frac{1}{z_h^d}\Big), \tag{54.100}$$

so, writing the common prefactor $\mathcal{N} \equiv \dfrac{\beta V_{d-1} L^{d-1}}{8\pi G}$,

$$S_{\text{bulk}} = \mathcal{N}\Big(\frac{1}{\epsilon^d} - \frac{1}{z_h^d}\Big). \tag{54.101}$$

The ϵ^{-d} piece is the expected power divergence: it is proportional to the infinite proper volume near the boundary and must be cancelled.

Gibbons–Hawking term. The boundary slice is $z = \epsilon$, with induced metric $\gamma_{\mu\nu} = \frac{L^2}{\epsilon^2}\,\mathrm{diag}\big(f(\epsilon), 1, \dots, 1\big)$ and $\sqrt{\gamma} = (L/\epsilon)^d \sqrt{f(\epsilon)}$. The outward unit normal points toward decreasing z (out of the bulk, toward the boundary): $n^z = -\sqrt{g^{zz}} = -\frac{z}{L}\sqrt{f}$. The extrinsic-curvature trace is the covariant divergence of the normal,

$$K = \nabla_\mu n^\mu = \frac{1}{\sqrt{g}}\,\partial_z\big(\sqrt{g}\, n^z\big). \tag{54.102}$$

With $\sqrt{g}\, n^z = (L/z)^{d+1}\big(-\frac{z}{L}\sqrt{f}\big) = -L^d z^{-d}\sqrt{f}$,

$$\partial_z\big(\sqrt{g}\, n^z\big) = -L^d\Big(-d\, z^{-d-1}\sqrt{f} + z^{-d}\frac{f'}{2\sqrt{f}}\Big), \tag{54.103}$$

and multiplying by $1/\sqrt{g} = z^{d+1}/L^{d+1}$,

$$K = \frac{1}{L}\Big(d\sqrt{f} - \frac{z\, f'}{2\sqrt{f}}\Big). \tag{54.104}$$

Therefore the integrand of the Gibbons–Hawking term is

$$\sqrt{\gamma}\, K = \Big(\frac{L}{\epsilon}\Big)^d \sqrt{f}\cdot\frac{1}{L}\Big(d\sqrt{f} - \frac{\epsilon f'}{2\sqrt{f}}\Big) = \frac{L^{d-1}}{\epsilon^d}\Big(d\, f(\epsilon) - \frac{\epsilon f'(\epsilon)}{2}\Big). \tag{54.105}$$

Insert $f(\epsilon) = 1 - (\epsilon/z_h)^d$ and $\epsilon f'(\epsilon) = -d(\epsilon/z_h)^d$:

$$d\, f(\epsilon) - \frac{\epsilon f'(\epsilon)}{2} = d - d\Big(\frac{\epsilon}{z_h}\Big)^d + \frac{d}{2}\Big(\frac{\epsilon}{z_h}\Big)^d = d - \frac{d}{2}\Big(\frac{\epsilon}{z_h}\Big)^d, \tag{54.106}$$

so the Gibbons–Hawking contribution, with the $-\frac{1}{8\pi G}$ prefactor of Eq. (54.85) folded into $\mathcal{N}$, is

$$S_{\text{GH}} = -\frac{\beta V_{d-1}}{8\pi G}\, L^{d-1}\Big(\frac{d}{\epsilon^d} - \frac{d}{2}\,\frac{1}{z_h^d}\Big) = \mathcal{N}\Big(-\frac{d}{\epsilon^d} + \frac{d}{2 z_h^d}\Big). \tag{54.107}$$

Counterterm. For the flat planar boundary the only relevant counterterm of Eq. (54.49) is the cosmological-constant (volume) counterterm; the curvature counterterm $\propto R[\gamma]$ vanishes because the boundary metric is flat. Thus

$$S_{\rm ct} = \frac{1}{8\pi G}\,\frac{d-1}{L}\int \mathrm{d}^d x\,\sqrt{\gamma} = \frac{(d-1)\beta V_{d-1}}{8\pi G\,L}\Big(\frac{L}{\epsilon}\Big)^d\sqrt{f(\epsilon)}. \tag{54.108}$$

Expand the square root, $\sqrt{f(\epsilon)} = \big(1-(\epsilon/z_h)^d\big)^{1/2} = 1 - \tfrac{1}{2}(\epsilon/z_h)^d + O(\epsilon^{2d})$. The higher terms vanish as $\epsilon \to 0$, leaving

$$S_{\rm ct} = \mathcal{N}\,(d-1)\Big(\frac{1}{\epsilon^d} - \frac{1}{2z_h^d}\Big). \tag{54.109}$$

Summing the three pieces. Add Eqs. (54.101), (54.107) and (54.109). The coefficients of the divergent ϵ^{-d} collect to

$$1 - d + (d-1) = 0, \tag{54.110}$$

so the divergence cancels identically — the volume counterterm is engineered to do exactly this, and that it works with the same universal coefficient $(d-1)/L$ that renormalized the scalar two-point function in Theorem 54.5 is the promised gravitational deployment of holographic renormalization. The finite coefficients of z_h^{-d} collect to

$$-1 + \frac{d}{2} - \frac{d-1}{2} = -1 + \frac{d-(d-1)}{2} = -1 + \frac{1}{2} = -\frac{1}{2}, \tag{54.111}$$

so the renormalized on-shell action is finite:

$$S_E^{\text{on-shell}} = -\frac{\mathcal{N}}{2z_h^d} = -\frac{\beta V_{d-1} L^{d-1}}{16\pi G\,z_h^d}. \tag{54.112}$$

By Eq. (54.97) the free energy is $F = S_E^{\text{on-shell}}/\beta$, and the free energy density $f \equiv F/V_{d-1}$ is

$$f = -\frac{L^{d-1}}{16\pi G\,z_h^d}. \tag{54.113}$$

Finally, trade z_h for the temperature via Eq. (54.96), $z_h = d/(4\pi T)$, so $z_h^{-d} = (4\pi T/d)^d$:

$$\boxed{\,f = -\frac{L^{d-1}}{16\pi G}\Big(\frac{4\pi}{d}\Big)^d T^d\,.\,} \tag{54.114}$$

The temperature dependence $f \propto T^d$ is exactly what conformal invariance demands: a CFT in d spacetime dimensions has no scale but T, and the free energy density, of mass dimension d, can only be a pure number times T^d. Holography has computed that pure number. Its sign is negative, as a free energy

must be (the pressure $p = -f > 0$), and its magnitude is controlled by L^{d-1}/G — which, by the dictionary $1/G \sim N^2$ (Chapter 35, and Theorem 53.33 for the precise $\mathcal{N} = 4$ coefficient), scales as N^2. This N^2 is the headline: it is the number of *deconfined* degrees of freedom, the gluonic $N^2 - 1 \approx N^2$ color components all contributing freely to the thermodynamics. We return to its physical weight in Section 54.4.6.

54.4.4 Entropy and the Bekenstein–Hawking area law

The entropy density follows from the free energy by the elementary thermodynamic relation $s = -\partial f/\partial T$. Differentiating Eq. (54.114),

$$s = -\frac{\partial f}{\partial T} = \frac{L^{d-1}}{16\pi G}\Big(\frac{4\pi}{d}\Big)^{d} d\, T^{d-1} = \frac{L^{d-1}}{4G}\Big(\frac{4\pi T}{d}\Big)^{d-1}, \tag{54.115}$$

where in the last step we used $\frac{1}{16\pi G}(\frac{4\pi}{d})^d\, d = \frac{1}{4G}(\frac{4\pi}{d})^{d-1}$. The energy density is then $\varepsilon = f + Ts$, and using $Ts = d\,|f|$ from Eqs. (54.114) and (54.115),

$$\varepsilon = f + Ts = (d-1)\,|f| = (d-1)\frac{L^{d-1}}{16\pi G}\Big(\frac{4\pi}{d}\Big)^{d} T^{d}. \tag{54.116}$$

The relation $\varepsilon = (d-1)\,p$ with $p = -f$ is the conformal equation of state, equivalent to the tracelessness of the stress tensor, $\varepsilon - (d-1)p = T^{\mu}{}_{\mu} = 0$. The first law is automatic: with all quantities homogeneous in T, $\mathrm{d}\varepsilon = (d-1)d\,|f|\,\mathrm{d}T/T = T\,\mathrm{d}s$, which the reader can confirm by differentiating Eqs. (54.115) and (54.116) and comparing. The thermodynamics is therefore fully consistent, and entirely fixed by the single number L^{d-1}/G.

The deeper statement is geometric. The entropy density Eq. (54.115) is, on its face, a boundary quantity computed from a free energy. It is also — and this is the Bekenstein–Hawking miracle — the *area of the horizon*, per unit boundary volume, divided by $4G$. We now show this, and elevate it to the central theorem of the section.

Theorem 54.10 (Bekenstein–Hawking area law)**.** *The thermal entropy of the holographic CFT, computed from the renormalized on-shell gravitational action, equals one quarter of the horizon area in bulk Planck units:*

$$S = \frac{A}{4G}, \tag{54.117}$$

where A is the area of the horizon $z = z_h$ in the induced metric, and $G \equiv G_{d+1}$ is the bulk Newton constant.

Proof. The horizon is the surface $z = z_h$ at fixed Euclidean time (equivalently, the bifurcation surface). Its induced metric is read off Eq. (54.90) by setting

$z = z_h$ (where $f = 0$, so the τ direction has shrunk away) and restricting to the spatial directions $\mathbf{x}$:

$$\mathrm{d}s^2\big|_{\mathrm{hor}} = \frac{L^2}{z_h^2}\,\mathrm{d}\mathbf{x}^2, \tag{54.118}$$

a flat $(d-1)$-dimensional metric with constant conformal factor $(L/z_h)^2$. The induced volume element is $\sqrt{h} = (L/z_h)^{d-1}$, so the horizon area — the proper volume of this $(d-1)$-dimensional surface — is

$$A = \int \mathrm{d}^{d-1}x \left(\frac{L}{z_h}\right)^{d-1} = V_{d-1}\left(\frac{L}{z_h}\right)^{d-1}. \tag{54.119}$$

Now compute the total entropy $S = s\,V_{d-1}$ from Eq. (54.115), using $4\pi T/d = 1/z_h$ from Eq. (54.96):

$$S = s\,V_{d-1} = \frac{L^{d-1}}{4G}\,\frac{1}{z_h^{d-1}}\,V_{d-1} = \frac{1}{4G}\,V_{d-1}\left(\frac{L}{z_h}\right)^{d-1} = \frac{A}{4G}, \tag{54.120}$$

the last equality being Eq. (54.119). The entropy obtained from the free energy is identically the horizon area over $4G$. □

Physical Insight

Theorem 54.10 is the holographic incarnation of black-hole thermodynamics. The entropy of a strongly coupled thermal gauge theory — a boundary, field-theoretic quantity — has turned out to be the *area* of a horizon in one higher dimension. That the answer is an area, not a volume, is the original "holographic" observation of 't Hooft and Susskind, and it is the reason the duality bears that name: the number of degrees of freedom of the boundary theory is bounded by the bulk horizon area in Planck units. Here we have not merely matched the scaling; we computed both sides and found them *equal*, coefficient included, with the Bekenstein–Hawking $1/4$ emerging from the Gibbons–Hawking boundary term and the counterterms with no further input.

54.4.5 The $\mathcal{N} = 4$ plasma and the factor of $\frac{3}{4}$

We now make the headline N^2 concrete on the carried example, $\mathcal{N} = 4$ super-Yang–Mills with gauge group $\mathrm{SU}(N)$ — the maximally symmetric large-N cousin of Yang–Mills theory (Chapter 25), whose holographic dual is type IIB string theory on $\mathrm{AdS}_5 \times S^5$ (Theorem 53.6). This is the $d = 4$, AdS_5 case. The computation reproduces a celebrated result: at infinite coupling the entropy is exactly $\frac{3}{4}$ of its free-field value. The factor of $\frac{3}{4}$ is the cleanest single number through which holography is checked against an honest field-theory count, and we carry it in full.

Worked Example 54.11 (The strong/weak factor $\frac{3}{4}$ for $\mathcal{N}=4$ SYM)**. Strong coupling (holography).** Set $d=4$ in Eqs. (54.114) and (54.115). The horizon radius is $z_h = 4/(4\pi T) = 1/(\pi T)$, and

$$f_{\text{strong}} = -\frac{L^3}{16\pi G_5}\Big(\frac{4\pi}{4}\Big)^4 T^4 = -\frac{\pi^3 L^3}{16\,G_5}\,T^4, \qquad s_{\text{strong}} = \frac{L^3}{4G_5}\,(\pi T)^3 = \frac{\pi^3 L^3}{4G_5}\,T^3. \tag{54.121}$$

The dictionary converts L^3/G_5 into a gauge-theory quantity. From the central-charge match of Theorem 53.33, the gravity side gives $a = c = \dfrac{\pi L^3}{8G_5} = \dfrac{N^2}{4}$ exactly (Eq. (53.208)), while the field-theory value is $\frac{N^2-1}{4}$ (Eq. (53.201)), the two agreeing at leading order in large N; hence

$$\frac{L^3}{G_5} = \frac{2N^2}{\pi}. \tag{54.122}$$

Substituting,

$$f_{\text{strong}} = -\frac{\pi^3 T^4}{16}\cdot\frac{2N^2}{\pi} = -\frac{\pi^2}{8}N^2T^4, \qquad s_{\text{strong}} = \frac{\pi^3 T^3}{4}\cdot\frac{2N^2}{\pi} = \frac{\pi^2}{2}N^2T^3. \tag{54.123}$$

Weak coupling (free-field count). At zero coupling, $\mathcal{N}=4$ SYM is a free gas of its constituent fields, one copy per generator of SU(N), i.e. $N^2-1 \approx N^2$ copies. The $\mathcal{N}=4$ vector multiplet contains, per generator: one gauge field (2 physical polarizations), six real scalars (6 bosonic states), and four Weyl fermions ($4\times 2 = 8$ fermionic states). So the bosonic and fermionic on-shell counts are

$$n_b = 2+6 = 8, \qquad n_f = 8. \tag{54.124}$$

The free energy density of a single massless real bosonic degree of freedom in four dimensions is the Stefan–Boltzmann result

$$f_{\text{boson}} = T\int \frac{\mathrm{d}^3k}{(2\pi)^3}\,\ln\!\big(1-e^{-k/T}\big) = -\frac{\pi^2}{90}T^4, \tag{54.125}$$

the integral being the standard $\int_0^\infty \mathrm{d}x\, x^2\ln(1-e^{-x}) = -\pi^4/45$ divided by $2\pi^2$. A single fermionic degree of freedom contributes $\frac{7}{8}$ of this (the Fermi–Dirac integral $\int_0^\infty \mathrm{d}x\, x^2\ln(1+e^{-x}) = \frac{7}{8}\cdot\pi^4/45$). Hence the free $\mathcal{N}=4$ free energy density is

$$f_{\text{free}} = -\frac{\pi^2}{90}T^4\,(n_b + \tfrac{7}{8}n_f)(N^2-1) \approx -\frac{\pi^2}{90}T^4\,(8+7)\,N^2 = -\frac{\pi^2}{6}N^2T^4, \tag{54.126}$$

using $n_b + \frac{7}{8}n_f = 8 + \frac{7}{8}\cdot 8 = 15$ and $15/90 = 1/6$. The corresponding entropy density is $s_{\text{free}} = -\partial f_{\text{free}}/\partial T = \frac{2\pi^2}{3}N^2T^3$.

The ratio. Dividing the strong-coupling result Eq. (54.123) by the free-field result Eq. (54.126),

$$\boxed{\frac{f_{\text{strong}}}{f_{\text{free}}} = \frac{\pi^2N^2/8}{\pi^2N^2/6} = \frac{6}{8} = \frac{3}{4}, \qquad \frac{s_{\text{strong}}}{s_{\text{free}}} = \frac{\pi^2/2}{2\pi^2/3} = \frac{3}{4}.} \tag{54.127}$$

The result $f_{\text{strong}} = \frac{3}{4} f_{\text{free}}$ is due to Gubser, Klebanov, and Tseytlin (1996). Several features deserve emphasis, in the honest spirit this book keeps about the frontier. First, the two numbers are computed in *opposite* regimes of the same theory: f_{free} at $\lambda = g^2 N \to 0$ where the gauge theory is a free gas, f_{strong} at $\lambda \to \infty$ where the classical gravity dual is reliable. There is no contradiction in their differing — a strongly interacting plasma has fewer thermally active states than a free gas of the same field content — and the factor of $\frac{3}{4}$ is precisely the interpolation between the two ends, a genuine prediction of the duality, not a consistency check fixed by symmetry. Second, the leading correction in $1/\lambda$ has been computed from the first α'-correction to type IIB supergravity, $f_{\text{strong}}/f_{\text{free}} = \frac{3}{4} + \frac{45}{32}\zeta(3)\lambda^{-3/2} + \cdots$, which rises back toward unity as the coupling is dialed down, smoothly connecting the two regimes; this is the same α'-correction that lifts η/s above $1/4\pi$ in Section 54.5. Third, the $\frac{3}{4}$ is not derivable from conformal symmetry alone: conformal invariance fixes the T^4 scaling and the equation of state $\varepsilon = 3p$, but the coefficient is dynamics, and matching $\frac{3}{4}$ between gravity and a (resummed) field-theory computation remains one of the most quoted pieces of evidence for the correspondence as of the mid-2020s.

Historical Note

The $\frac{3}{4}$ was found by Gubser, Klebanov, and Tseytlin in 1996, before the correspondence was even stated in its modern form — it was one of the near-extremal black-brane entropy computations that, in hindsight, were AdS/CFT thermodynamics avant la lettre. That a black hole's Bekenstein–Hawking entropy could be matched (up to the celebrated $\frac{3}{4}$) to a weak-coupling gauge-theory state count was among the first quantitative hints that a black brane and a thermal gauge plasma are the same object.

54.4.6 Global AdS and the Hawking–Page transition

The planar brane of Theorem 54.9 describes the CFT on flat space $\mathbb{R}^{d-1}$, which has no intrinsic scale: by conformal invariance every temperature is equivalent, the free energy is forced to be $\propto T^d$ at *all* $T > 0$, and the N^2 degrees of freedom are deconfined at any nonzero temperature. There is no phase transition because there is nothing for a transition to happen *at*. To see a genuine confinement/deconfinement transition — and thereby to make holographic contact with the confinement criterion of Yang–Mills theory — we must give the boundary theory a scale. The simplest way is to put it on a sphere: take the boundary to be $\mathbb{R}_\tau \times S^{d-1}$ with the sphere of radius set, by conformal invariance, to a reference value (we set it to the AdS radius L). The sphere radius is a length, and the dimensionless combination $T \times (\text{radius})$ is now a physical control parameter. The bulk dual of this boundary is *global* AdS rather than the Poincaré patch,

and the thermal physics involves a competition between two saddles.

The two saddles. The two relevant Euclidean geometries with boundary $S^1_\beta \times S^{d-1}$ are:

- *Thermal AdS*: global AdS_{d+1} with the Euclidean time periodically identified, $\tau \sim \tau + \beta$. Its metric is

$$\mathrm{d}s^2 = \Big(1 + \frac{r^2}{L^2}\Big)\mathrm{d}\tau^2 + \frac{\mathrm{d}r^2}{1 + r^2/L^2} + r^2\,\mathrm{d}\Omega^2_{d-1}, \tag{54.128}$$

  smooth everywhere; the time circle never shrinks, so β is unconstrained. This is "empty" AdS at temperature T — a thermal gas of supergravity modes in a fixed geometry.

- *Global AdS–Schwarzschild*: a black hole sitting at the center of global AdS,

$$\mathrm{d}s^2 = f(r)\,\mathrm{d}\tau^2 + \frac{\mathrm{d}r^2}{f(r)} + r^2\,\mathrm{d}\Omega^2_{d-1}, \qquad f(r) = 1 + \frac{r^2}{L^2} - \frac{\mu}{r^{d-2}}, \tag{54.129}$$

  with a horizon at the largest root r_+ of f, where the same Euclidean-regularity argument as in Section 54.4.2 fixes β.

The parameter μ measures the black-hole mass. From $f(r_+) = 0$, $\mu = r_+^{d-2}(1 + r_+^2/L^2)$, and the temperature follows from $T = f'(r_+)/4\pi$. Differentiating Eq. (54.129), $f'(r) = \frac{2r}{L^2} + (d-2)\frac{\mu}{r^{d-1}}$, and substituting $\mu/r_+^{d-1} = (1 + r_+^2/L^2)/r_+$ gives

$$T = \frac{1}{4\pi}\Big(\frac{d\,r_+}{L^2} + \frac{d-2}{r_+}\Big). \tag{54.130}$$

This temperature, unlike the planar case, has a *minimum*. Setting $\mathrm{d}T/\mathrm{d}r_+ = 0$ gives $r_{+,\min} = L\sqrt{(d-2)/d}$ and

$$T_{\min} = \frac{1}{4\pi}\Big(\frac{d\,r_{+,\min}}{L^2} + \frac{d-2}{r_{+,\min}}\Big) = \frac{\sqrt{d(d-2)}}{2\pi L}, \tag{54.131}$$

($T_{\min} = \sqrt{2}/\pi L$ for $d = 4$). Below $T_{\min}$ no black hole exists at all; above it there are two branches — a small black hole ($r_+ < r_{+,\min}$, with negative specific heat, thermodynamically unstable) and a large one ($r_+ > r_{+,\min}$, stable). Only the large branch can compete with thermal AdS.

Which saddle dominates. The competition is decided by the free energies, i.e. by the renormalized on-shell actions. We compute the *difference* $\Delta I = I_{\mathrm{BH}} - I_{\mathrm{AdS}}$ by the background-subtraction method, which is cleaner here than introducing counterterms term by term: both geometries share the same conformal boundary, so their Gibbons–Hawking and counterterm contributions are identical and cancel

in the difference, leaving only the difference of bulk integrals. Using the on-shell density Eq. (54.88) (the constant $-2d/L^2$, valid for both geometries) and $\sqrt{g} = r^{d-1}\sqrt{g_{S^{d-1}}}$, the regulated bulk actions out to a common cutoff $r = \mathcal{R}$ are

$$I_{\rm BH} = \frac{d}{8\pi G L^2}\,\beta\,\Omega_{d-1}\int_{r_+}^{\mathcal{R}} r^{d-1}\,{\rm d}r = \frac{\beta\,\Omega_{d-1}}{8\pi G L^2}(\mathcal{R}^d - r_+^d), \tag{54.132}$$

$$I_{\rm AdS} = \frac{\beta'\,\Omega_{d-1}}{8\pi G L^2}\,\mathcal{R}^d, \tag{54.133}$$

where $\Omega_{d-1} = {\rm Vol}(S^{d-1})$, the black-hole integral starts at the horizon (the spacetime ends there), and the thermal-AdS integral starts at $r = 0$. The two periods are *not* equal: β is fixed by black-hole regularity, while β' is the thermal-AdS period chosen so that the two geometries have the *same proper length of the time circle at the common cutoff* $r = \mathcal{R}$ — the physical matching condition that they describe the same boundary,

$$\beta'\sqrt{1+\mathcal{R}^2/L^2} = \beta\sqrt{f(\mathcal{R})} \;\Longrightarrow\; \beta' = \beta\sqrt{\frac{1+\mathcal{R}^2/L^2-\mu/\mathcal{R}^{d-2}}{1+\mathcal{R}^2/L^2}} \xrightarrow{\mathcal{R}\to\infty} \beta\Big(1-\frac{\mu L^2}{2\mathcal{R}^d}+\cdots\Big). \tag{54.134}$$

Now form the difference and take $\mathcal{R}\to\infty$. The $\mathcal{R}^d$ pieces cancel up to the matching correction:

$$\Delta I = \frac{\Omega_{d-1}}{8\pi G L^2}\lim_{\mathcal{R}\to\infty}\Big[\beta(\mathcal{R}^d - r_+^d) - \beta'\mathcal{R}^d\Big] = \frac{\Omega_{d-1}\beta}{8\pi G L^2}\Big(-r_+^d + \frac{\mu L^2}{2}\Big), \tag{54.135}$$

where the surviving finite piece $\frac{\mu L^2}{2}$ comes from the $\mathcal{R}\to\infty$ limit of $\beta'\mathcal{R}^d = \beta\mathcal{R}^d - \beta\frac{\mu L^2}{2} + \cdots$. Insert $\mu = r_+^{d-2} + r_+^d/L^2$:

$$-r_+^d + \frac{\mu L^2}{2} = -r_+^d + \frac{L^2 r_+^{d-2}}{2} + \frac{r_+^d}{2} = \frac{r_+^{d-2}}{2}(L^2 - r_+^2), \tag{54.136}$$

so the on-shell action difference is

$$\boxed{\Delta I = \frac{\Omega_{d-1}\,\beta\,r_+^{d-2}(L^2 - r_+^2)}{16\pi G\,L^2}\,.} \tag{54.137}$$

This is the Hawking–Page result. Its sign is the whole story:

- For $r_+ < L$ (which, via Eq. (54.130), is the low-temperature regime), $\Delta I > 0$, so $I_{\rm BH} > I_{\rm AdS}$ and *thermal AdS* dominates the path integral e^{-I}. The dominant saddle has no horizon.
- For $r_+ > L$ (high temperature), $\Delta I < 0$ and the *black hole* dominates.

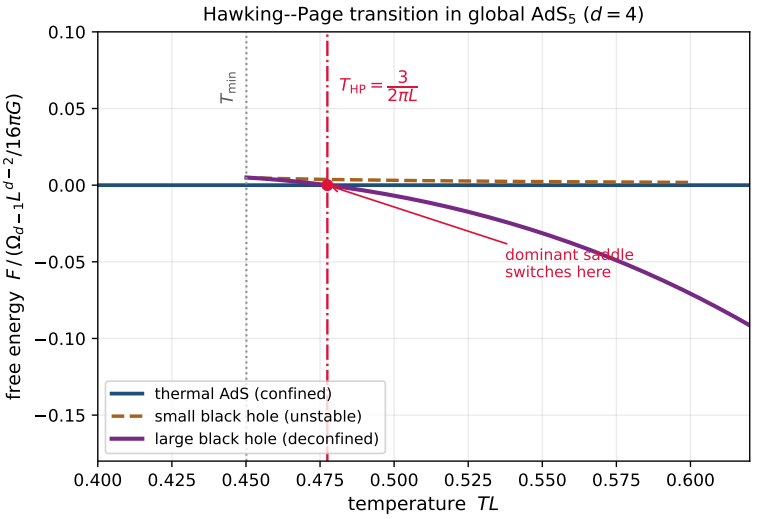

Figure 54.5: Free energy of the competing saddles for the CFT on S^{d-1} ($d = 4$, AdS_5). Thermal AdS has $F = 0$ (the reference). The black-hole branch appears only above $T_{\min} = \sqrt{2}/\pi L$ Eq. (54.131), splitting into a small (unstable, dashed) and a large (stable) branch. The large-black-hole free energy crosses zero at the Hawking–Page temperature $T_{\rm HP} = 3/2\pi L$ Eq. (54.138): below it thermal AdS dominates (confined, $F \sim N^0$), above it the black hole dominates (deconfined, $F \sim N^2$). The jump in $\partial F/\partial T$ at $T_{\rm HP}$ is the first-order deconfinement transition.

- The transition is at $\Delta I = 0$, i.e. $r_+ = L$ exactly. Substituting $r_+ = L$ into Eq. (54.130) gives the *Hawking–Page temperature*

$$T_{\rm HP} = \frac{1}{4\pi}\Big(\frac{d}{L} + \frac{d-2}{L}\Big) = \frac{d-1}{2\pi L}, \tag{54.138}$$

  which is $T_{\rm HP} = 3/2\pi L$ for $d = 4$. Note $T_{\rm HP} > T_{\min}$, so the transition occurs on the stable large-black-hole branch, as a first-order jump.

Figure 54.5 plots the free energy $F_{\rm BH} = \Delta I/\beta$ of the two saddles for $d = 4$, exhibiting the minimum temperature, the unstable small-black-hole branch, and the first-order crossing at $T_{\rm HP}$.

Confinement and deconfinement. The Hawking–Page transition is the gravity dual of the confinement/deconfinement transition of the boundary gauge theory — the observation of Witten (1998), and the strong-coupling face of the confinement criterion proved at weak coupling in Section 27.7. The order parameter is the scaling of the free energy with N. In the low-temperature (thermal-AdS) phase, the free energy relative to the vacuum is $O(N^0)$: it is the free energy of a gas of supergravity modes, i.e. of color-singlet glueball-like states,

with an $O(1)$ number of thermally active degrees of freedom — the hallmark of *confinement*, where color is locked into singlets and the count of light states does not grow with N. In the high-temperature (black-hole) phase, $F \sim 1/G \sim N^2$ by Eq. (54.114) and Theorem 53.33: the full N^2 gluonic degrees of freedom are liberated, the hallmark of *deconfinement*. The transition between an $O(N^0)$ and an $O(N^2)$ free energy is exactly the large-N deconfinement transition, and here it is a sharp, first-order geometric event: the nucleation of a horizon.

Physical Insight

Yang–Mills theory established confinement at weak coupling through the Wilson-loop area law (Theorem 27.20): a linear quark–antiquark potential, color flux squeezed into a tube. That criterion is genuinely non-perturbative but was accessible there only qualitatively, in lattice language. Holography supplies the complementary strong-coupling, large-N statement: confinement is the phase in which the dominant bulk geometry has *no horizon*, deconfinement the phase in which a black hole has formed, and the free energy's scaling with N is the order parameter. The same physics — color confinement — is seen from two opposite ends of the coupling, neither computation reachable by the other's methods. This is the deepest payoff of the duality for gauge theory: a controlled handle on the strongly coupled, deconfined plasma that perturbative Yang–Mills (Chapter 27) cannot touch.

Caution

The clean Hawking–Page transition requires the boundary sphere. On flat space (the planar brane that carries the rest of this chapter) the deconfined black-brane phase exists for all $T > 0$ and there is no transition — this is not a failure but a feature: a scale-invariant theory on scale-invariant space cannot have a preferred transition temperature. $\mathcal{N} = 4$ SYM, being exactly conformal, confines only when placed on a sphere, where the sphere radius provides the scale; a confining theory like pure Yang–Mills would confine on flat space too, and its holographic dual replaces pure AdS in the infrared by a geometry that caps off smoothly even at zero temperature. The honest statement is that the Hawking–Page transition is the deconfinement transition *of the conformal theory on a sphere*; modeling the genuine QCD deconfinement transition requires deforming the geometry, a subject beyond this chapter.

We have built the thermal state from the ground up: a planar black brane Eq. (54.89) as the dominant saddle, its Hawking temperature Eq. (54.96) from Euclidean regularity, its renormalized free energy Eq. (54.114) and entropy obeying the Bekenstein–Hawking area law Theorem 54.10, the strong/weak

factor of $\frac{3}{4}$ for $\mathcal{N}=4$ SYM, and the Hawking–Page transition Eq. (54.137) as the gravity dual of deconfinement. All of this was equilibrium thermodynamics, computed from a Euclidean on-shell action that knows nothing of time. The plasma is, however, a dynamical medium, and its real-time response — how it relaxes, how it dissipates — is encoded in the propagation of the very same bulk fields on the very same geometry, now in Lorentzian signature with a boundary condition imposed at the horizon. Section 54.5 takes the metric Eq. (54.89), the temperature Eq. (54.96), and the entropy density Eq. (54.115) handed over here, and extracts from them the shear viscosity and the universal ratio $\eta/s = 1/4\pi$.

54.5 Real-Time Correlators and the Shear Viscosity Bound

The previous section handed us a thermal state and its coarse data: the planar AdS–Schwarzschild black brane Eq. (54.89), its Hawking temperature Eq. (54.96) fixed by Euclidean regularity, and the entropy density s delivered by the area law Theorem 54.10. Those are equilibrium quantities — they are computed from a Euclidean on-shell action and know nothing of time. The plasma described by this geometry is, however, a dynamical medium: perturb it and it relaxes, push it and it resists, and the rates at which it does so are real-time transport coefficients. To compute them we must leave Euclidean signature, where everything so far has lived, and confront Lorentzian time directly. This is not a cosmetic change. A Euclidean correlator is real and symmetric and encodes no arrow of time; a transport coefficient is an intrinsically dissipative, causal quantity, the imaginary part of a *retarded* response. The bulk geometry now has a feature it lacked at zero temperature — a horizon — and we will see that it is precisely the boundary condition imposed at that horizon, the demand that nothing escape it, that injects causality into the bulk computation and selects the retarded correlator. The chain of this section is short and inevitable: build the Lorentzian dictionary (the infalling prescription), feed it the one perturbation that controls momentum transport (the transverse graviton, which we show is a massless scalar), and read off the shear viscosity. The answer, $\eta/s = 1/4\pi$, is the single most quoted number in holography, and we will compute it twice — once by a horizon-flux argument that makes its universality transparent, and once as a check from the hydrodynamic pole of the correlator — and then say honestly what it is and is not.

54.5.1 From Euclidean to retarded: the infalling prescription

At zero temperature the GKP–Witten relation Eq. (53.162) computed Euclidean correlators, and Euclidean correlators were all we needed: conformal data is signature-blind, and the Wick rotation back to Lorentzian signature is, for

the vacuum, an unambiguous analytic continuation. At finite temperature the situation is different in a way that matters. The thermal field theory possesses a whole family of two-point functions — Euclidean (Matsubara), Feynman (time-ordered), Wightman, retarded, advanced — which agree in the vacuum but are genuinely distinct in a medium, related by the fluctuation–dissipation theorem and distinguished by their analytic structure in the complex frequency plane. Transport is governed by exactly one of them.

Recall the object we are after. The *retarded* two-point function of an operator $\mathcal{O}$ is

$$G^R(\omega,\mathbf{k}) = -i\int \mathrm{d}t\,\mathrm{d}^{d-1}x\; e^{i\omega t - i\mathbf{k}\cdot\mathbf{x}}\,\theta(t)\,\big\langle\,[\,\mathcal{O}(t,\mathbf{x}),\,\mathcal{O}(0,\mathbf{0})\,]\,\big\rangle_T, \tag{54.139}$$

the thermal expectation value of the commutator, retarded by the step function $\theta(t)$ so that the response at time t depends only on disturbances in its past. Causality makes $G^R(\omega)$ analytic in the upper half ω-plane; its imaginary part is the spectral density,

$$\rho(\omega,\mathbf{k}) = -2\,\mathrm{Im}\,G^R(\omega,\mathbf{k}), \tag{54.140}$$

a non-negative measure of the dissipation the medium exerts on a probe of frequency ω. This is the same physics — and, structurally, the same object — as the imaginary part of the photon self-energy $\Pi^{\mu\nu}(q)$ of Eq. (19.4): there the transverse form factor's imaginary part was, by the optical theorem (Section 14.7), a sum over physical on-shell intermediate states, i.e. a production rate. Here it is the rate at which a slow perturbation deposits energy into the plasma. The retarded correlator is the unique one whose poles encode the decay (not the growth) of perturbations, and it is the one transport sees.

The Euclidean correlator $G_E(\omega_n,\mathbf{k})$, by contrast, is defined only at the discrete Matsubara frequencies $\omega_n = 2\pi n T$ (bosonic), and the retarded function is its analytic continuation from the upper half-plane,

$$G^R(\omega,\mathbf{k}) = G_E(\omega_n \to -i\omega + 0^+,\,\mathbf{k}), \qquad \omega_n > 0, \tag{54.141}$$

with the 0^+ fixing the continuation to come from above the real axis. In a generic interacting theory Eq. (54.141) is impractical: one has data at isolated points ω_n and must reconstruct an analytic function, an ill-posed inversion. Holography circumvents it entirely by working in Lorentzian signature from the start — but then the bulk computation must itself encode the choice of retarded over Feynman, and the question is how.

The bulk solutions and the horizon. Consider, as the universal warm-up, a massless scalar ϕ probing the black brane; in Section 54.5.3 we show that the perturbation controlling viscosity *is* such a scalar. Write the planar brane metric Eq. (54.89) in the form

$$\mathrm{d}s^2 = \frac{L^2}{z^2}\left[-f(z)\,\mathrm{d}t^2 + \mathrm{d}\mathbf{x}^2 + \frac{\mathrm{d}z^2}{f(z)}\right], \qquad f(z) = 1 - \left(\frac{z}{z_h}\right)^d, \tag{54.142}$$

with the conformal boundary at $z \to 0$ and the horizon at $z = z_h$, where $f(z_h) = 0$; the Hawking temperature is $T = |f'(z_h)|/4\pi = d/4\pi z_h$ from Eq. (54.96). The wave equation $\Box\phi = 0$ in this background, Fourier-transformed as $\phi(z, t, \mathbf{x}) = e^{-i\omega t + i\mathbf{k}\cdot\mathbf{x}}\,\phi_k(z)$, is a second-order ordinary differential equation in z, so it has a two-dimensional solution space. We must impose one condition at each end. At the boundary the structure is the familiar one of Section 53.6.3: two indicial powers, the non-normalizable z^0 (a constant, the source) and the normalizable z^d (the response). The new ingredient is the condition at the horizon.

Near $z = z_h$, set $f(z) \simeq f'(z_h)(z - z_h) = -4\pi T\,(z - z_h)$. The wave equation degenerates there, and its two local solutions are pure phases in the tortoise-like variable,

$$\phi_k(z) \;\sim\; (z_h - z)^{\mp\, i\omega/4\pi T} \;=\; f(z)^{\mp\, i\omega/4\pi T} \times (\text{regular}), \tag{54.143}$$

which we read off by substituting $\phi \sim f^\alpha$ into the leading near-horizon equation: $g^{zz} \sim f$ vanishes linearly while $g^{tt} \sim 1/f$ blows up, and balancing the $\partial_z(f\,\partial_z)$ term against the ω^2/f term forces $\alpha = \mp i\omega/4\pi T$. Restoring the time dependence, the two behaviours are

$$\phi \;\sim\; e^{-i\omega t}\,(z_h - z)^{-i\omega/4\pi T} \quad \text{(infalling)}, \qquad \phi \;\sim\; e^{-i\omega t}\,(z_h - z)^{+i\omega/4\pi T} \quad \text{(outgoing)}. \tag{54.144}$$

To see which is which, note that $z_h - z$ decreases toward the horizon, so a surface of constant phase $\omega t + (\omega/4\pi T)\log(z_h - z) = \text{const}$ moves toward larger z (toward the horizon) as t increases for the first branch: this wave falls *into* the horizon. The second branch emerges from it.

Causality selects infalling. A classical black-brane horizon is a one-way membrane: nothing, not even information about the wave, comes back out of it. A perturbation set up in the past propagates inward and is absorbed; nothing emerges. Discarding the outgoing branch and keeping only the infalling solution is the bulk statement of causality, and — this is the crucial claim — it is exactly equivalent to choosing the retarded correlator on the boundary. The argument is the analytic-continuation Eq. (54.141) made geometric. In Euclidean signature the horizon is not a one-way membrane at all: it is a smooth point (the tip of the cigar of Section 54.4) where the Euclidean time circle shrinks, and the only condition one can impose is *regularity* there. The Euclidean solution, regular at the tip, when continued in frequency by $\omega_n \to -i\omega + 0^+$ (continuation from the upper half-plane, which is where G^R is analytic), turns the regular behaviour $f^{\,\omega_n/4\pi T}$ into precisely $f^{-i\omega/4\pi T}$ — the infalling phase. Continuation from *below* ($\omega_n \to +i\omega$, the lower half-plane where G^A is analytic) would give the outgoing branch and the advanced correlator. So:

$$\boxed{\text{regular Euclidean at the tip} \;\xrightarrow{\omega_n \to -i\omega + 0^+}\; \text{infalling at the horizon} \;\Longleftrightarrow\; G^R.} \tag{54.145}$$

The infalling condition is the Lorentzian image of Euclidean regularity, and it is what makes the bulk computation deliver G^R rather than G^A or the time-ordered correlator.

Extracting the correlator: the Son–Starinets prescription. It remains to say how G^R is read off from the bulk solution, and here a subtlety of factor and signature must be faced squarely. Take the field with the canonical two-derivative action

$$S = -\frac{K}{2}\int \mathrm{d}^{d+1}X\,\sqrt{-g}\,g^{MN}\partial_M\phi\,\partial_N\phi, \tag{54.146}$$

where K is a normalization (for the graviton, $K = 1/16\pi G_N$, derived in Section 54.5.3). The equation of motion is $\partial_M(\sqrt{-g}\,g^{MN}\partial_N\phi) = 0$; on shell the action collapses to a boundary term,

$$S_{\text{on-shell}} = -\frac{K}{2}\int \mathrm{d}^{d}x\,\Big[\sqrt{-g}\,g^{zz}\,\phi\,\partial_z\phi\Big]_{z=z_h}^{z\to 0}, \tag{54.147}$$

the bulk integral having vanished by the equation of motion, leaving only the radial endpoints. Write the solution obeying the infalling condition and normalized to unit boundary value as $\phi_k(z) = f_k(z)\,\phi_0(k)$, $f_k(0) = 1$, so that $\phi_0(k)$ is the boundary source. In momentum space Eq. (54.147) becomes

$$S_{\text{on-shell}} = -\frac{1}{2}\int \frac{\mathrm{d}^d k}{(2\pi)^d}\,\phi_0(-k)\,\mathcal{F}_k(z)\,\phi_0(k)\Big|_{z=z_h}^{z\to 0}, \qquad \mathcal{F}_k(z) \equiv K\sqrt{-g}\,g^{zz}\,f_{-k}(z)\,\partial_z f_k(z). \tag{54.148}$$

Naively functional-differentiating twice would give $G^R = -2\mathcal{F}_k|_{z\to 0}$ symmetrized over the two endpoints and over $k \to -k$ — and that symmetrization is exactly the error. It produces a *real* result, killing the dissipative imaginary part, because the boundary and horizon contributions and their complex conjugates conspire to cancel it. The correct Lorentzian rule, due to Son and Starinets, is:

$$\boxed{G^R(\omega,\mathbf{k}) = -\,\mathcal{F}_k(z)\big|_{z\to 0} = -\,K\sqrt{-g}\,g^{zz}\,\frac{\partial_z f_k(z)}{f_k(z)}\Big|_{z\to 0}}, \tag{54.149}$$

with three explicit instructions that distinguish it from the Euclidean/Feynman recipe. *First*, keep only the boundary term at $z \to 0$; discard the horizon contribution at $z = z_h$ entirely (it would otherwise corrupt the answer with horizon data that is not part of the UV response). *Second*, do *not* symmetrize the two factors of ϕ_0 and do *not* add the complex conjugate — this is the missing "factor of two": the retarded function is the un-symmetrized coefficient $-\mathcal{F}_k$, not its real part $-\operatorname{Re}\mathcal{F}_k = -\frac{1}{2}(\mathcal{F}_k + \mathcal{F}_k^*)$. Because $f_k(z)$ is complex (it carries the infalling phase $f^{-i\omega/4\pi T}$), $\mathcal{F}_k$ is complex and its imaginary part survives, delivering the spectral density. *Third*, the result is to be renormalized by the same near-boundary counterterms of Section 53.6.4 that rendered the zero-temperature

two-point function finite; the divergent contact terms they remove are real and analytic in ω^2, so they never touch $\operatorname{Im} G^R$ — a fortunate fact that makes transport coefficients, which live in the imaginary part, automatically finite without any subtraction. The factor and the no-symmetrization rule are the entire content that separates the Lorentzian dictionary from the Euclidean one.

Caution

The temptation to compute G^R by analytically continuing a Euclidean (symmetrized) on-shell action is precisely the trap Eq. (54.149) avoids. The symmetric prescription returns $\operatorname{Re} G^R$ at best and, more often, nonsense, because it averages the infalling and outgoing solutions and so cannot know which way time runs. One must impose infalling boundary conditions on a genuinely complex Lorentzian solution and keep the unsymmetrized boundary term. The radially-conserved flux argument of Section 54.5.4 below is, in part, a way of seeing *why* only the boundary term and only the imaginary part are physical: the flux that carries dissipation is conserved from boundary to horizon, so its value can be computed at either end, and the horizon end makes its reality and sign manifest.

54.5.2 The Kubo formula for shear viscosity

We now specialize to the operator whose retarded correlator is the shear viscosity: the stress tensor $T^{\mu\nu}$, the conserved current of translations. Viscosity measures the medium's resistance to shear flow, and in linear-response theory it is extracted from the low-frequency limit of a stress-tensor two-point function by a Kubo formula. We import the statement as a result of the general linear-response theory of transport, of which the current–current correlator of Chapter 19 is the abelian prototype.

Definition 54.12 (Shear viscosity and the Kubo formula)**.** For a relativistic fluid in its rest frame at temperature T, the *shear viscosity* η is the transport coefficient in the constitutive relation $T^{ij} = p\,\delta^{ij} - \eta\,(\partial^i u^j + \partial^j u^i - \frac{2}{d-1}\delta^{ij}\partial\cdot u) + \dots$, the coefficient of the traceless symmetric gradient of the velocity field u. Equivalently, it is given by the Kubo formula as the zero-frequency slope of the spectral density of the off-diagonal stress component T^{xy} at zero spatial momentum,

$$\eta = -\lim_{\omega\to 0}\frac{1}{\omega}\operatorname{Im} G^R_{xy,xy}(\omega,\mathbf{k}=0), \qquad G^R_{xy,xy}(\omega,\mathbf{k}) = -i\int \mathrm{d}t\,\mathrm{d}^{d-1}x\; e^{i\omega t - i\mathbf{k}\cdot\mathbf{x}}\,\theta(t)\,\langle[\,T^{xy}(x), \tag{54.150}$$

The structure here is identical to the photon self-energy of Eq. (19.4): a conserved current ($T^{\mu\nu}$ in place of J^μ), whose two-point function is constrained to be transverse by the corresponding Ward identity ($\partial_\mu T^{\mu\nu} = 0$, the tensor analogue

of $\partial_\mu J^\mu = 0$ that gave $q_\mu \Pi^{\mu\nu} = 0$ in Theorem 19.5), and whose imaginary part is a non-negative spectral density measuring dissipation, just as $\operatorname{Im}\Pi(q^2)$ measured pair production. The T^{xy} component is the transverse-traceless ("shear") channel: at $\mathbf{k} = 0$ it is invariant under the rotations that fix the x–y plane orientation up to sign, decouples from the energy-density and pressure fluctuations (which sit in the scalar and sound channels), and therefore furnishes the cleanest single-function probe of momentum diffusion. The Kubo formula Eq. (54.150) is the precise statement that η is the linear-response coefficient relating the shear stress to an imposed shear strain rate — it is the coefficient of ω in the small-frequency expansion of the dissipative (Im) part of the response, exactly as a conductivity is the zero-frequency limit of $\operatorname{Im}\Pi/\omega$ in Chapter 19.

Holographically, $T^{\mu\nu}$ is the operator dual to the bulk metric $g_{\mu\nu}$ itself (the source for the stress tensor is the boundary metric, by the GKP–Witten relation Eq. (53.162) applied to the graviton). To compute $G^R_{xy,xy}$ we therefore perturb the bulk metric in the xy direction, solve the linearized Einstein equations with infalling conditions, and apply the prescription Eq. (54.149). The first task is to identify the bulk field and its equation.

54.5.3 The transverse graviton is a massless scalar

The metric fluctuation dual to T^{xy} is the off-diagonal spatial component h_{xy}. Raise an index to define the dimensionless perturbation

$$\phi(t, z) \equiv h^x{}_y = g^{xx} h_{xy}, \tag{54.151}$$

at zero spatial momentum, $\mathbf{k} = 0$, which is all the Kubo formula Eq. (54.150) requires. The perturbed line element is $\mathrm{d}s^2 \to \mathrm{d}s^2 + 2\, g_{xx}\, \phi\, \mathrm{d}x\, \mathrm{d}y$, with all other components of h set to zero. The central structural fact, which makes the whole viscosity computation tractable, is the following.

Proposition 54.13 (Shear graviton reduces to a massless minimally coupled scalar)**.** *On the planar black-brane background Eq. (54.142), the perturbation $\phi = h^x{}_y$ at $\mathbf{k} = 0$ satisfies the equation of a massless minimally coupled scalar,*

$$\frac{1}{\sqrt{-g}}\, \partial_M \Big(\sqrt{-g}\, g^{MN} \partial_N \phi \Big) = 0, \tag{54.152}$$

and its quadratic effective action is that of Eq. (54.146) with normalization $K = 1/16\pi G_N$.

Proof. We argue from symmetry, which fixes the form of the quadratic action completely, and then match the normalization. Three facts about $\phi = h^x{}_y$ on this background do all the work.

(i) ϕ is a scalar under the residual symmetry. The background Eq. (54.142) is invariant under translations and rotations of the spatial $\mathbf{x}$-directions and under

the reflection $R_y : y \to -y$. Under R_y the metric is unchanged, but the cross term $g_{xy}\,\mathrm{d}x\,\mathrm{d}y$ is odd, so $\phi \to -\phi$. Any other fluctuation of the metric — the diagonal components h_{tt}, h_{zz}, h_{ii}, the energy flux h_{ti}, the would-be scalar and vector modes — is *even* under R_y (or under the analogous reflection in another plane). A reflection-odd field cannot mix at quadratic order with reflection-even fields: the cross terms in the action are forbidden by the symmetry. Hence ϕ decouples from every other component of h_{MN} and obeys an equation involving ϕ alone. This is why the shear channel is clean — it is the unique parity-odd sector, protected from the constraint-tangle that snares the sound channel.

(ii) The action is two-derivative and reflection-even. Diffeomorphism invariance of the Einstein–Hilbert action $S = \frac{1}{16\pi G_N}\int \sqrt{-g}\,(R - 2\Lambda)$ descends to the quadratic action for ϕ. Expanding R to second order in h_{MN} and keeping only the decoupled ϕ produces a functional that is a scalar under the spatial isometries, even in ϕ (by (i)), and contains at most two derivatives (the curvature is two-derivative). The most general such quadratic functional of a single scalar on this background is

$$S^{(2)}[\phi] = -\frac{K}{2}\int \mathrm{d}^{d+1}X\,\sqrt{-g}\left(g^{MN}\partial_M\phi\,\partial_N\phi + m^2\phi^2\right), \tag{54.153}$$

for some constants K and m^2: no other reflection-even, two-derivative, diffeomorphism-scalar invariant of a single field exists. It remains to fix m^2 and K.

(iii) The mass vanishes: a constant ϕ is pure gauge. A spatially-constant, time-independent $\phi = c$ is not a physical excitation at all but a coordinate change. Under the linear redefinition $y \to y + c\,x$ of the flat boundary directions, $\mathrm{d}y^2 \to (\mathrm{d}y + c\,\mathrm{d}x)^2 = \mathrm{d}y^2 + 2c\,\mathrm{d}x\,\mathrm{d}y + c^2\mathrm{d}x^2$, which to first order in c generates exactly the off-diagonal term $2c\,\mathrm{d}x\,\mathrm{d}y$, i.e. $h^x{}_y = c$. Because this is a coordinate transformation, it leaves the Riemann tensor — hence the action — unchanged: a constant ϕ costs zero action. A mass term $\frac{Km^2}{2}\int\sqrt{-g}\,\phi^2$ would assign a nonzero action to a constant ϕ, so $m^2 = 0$. The perturbation ϕ is a genuine massless mode, the Goldstone-like avatar of the broken shear isometry, and its equation of motion is Eq. (54.152).

Normalization. The overall K is read off by comparing Eq. (54.153) to the explicit second-order expansion of the Einstein–Hilbert action. The kinetic term for a single off-diagonal metric component $h^x{}_y$ in $\frac{1}{16\pi G_N}\int\sqrt{-g}\,R$ is, after integration by parts, $-\frac{1}{16\pi G_N}\cdot\frac{1}{2}\int\sqrt{-g}\,g^{MN}\partial_M\phi\,\partial_N\phi$ — the standard result that each transverse-traceless graviton polarization is a canonically normalized scalar with the gravitational prefactor. Hence $K = 1/16\pi G_N$, as claimed. □

The reduction Theorem 54.13 is the technical heart of the universality of η/s: it says that for *any* bulk theory governed at two-derivative order by Einstein gravity, the shear graviton is the same massless scalar with the same prefactor $1/16\pi G_N$, regardless of the matter content that supports the geometry. The

computation that follows therefore returns the same number for every such background.

With $\mathbf{k}=0$ and $\phi = e^{-i\omega t}\phi_\omega(z)$, Eq. (54.152) reads, using $\sqrt{-g}=(L/z)^{d+1}$ (the factors of f cancel between g_{tt} and g_{zz}), $\sqrt{-g}\,g^{zz} = (L/z)^{d-1}f$, and $\sqrt{-g}\,g^{tt} = -(L/z)^{d-1}/f$,

$$\partial_z\Big[(L/z)^{d-1}f(z)\,\partial_z\phi_\omega\Big] + \frac{\omega^2}{f(z)}\,(L/z)^{d-1}\,\phi_\omega = 0. \tag{54.154}$$

This is the massless-scalar radial equation we will solve, with infalling conditions at z_h and unit source at $z\to 0$.

54.5.4 The horizon-flux computation of η

We could solve Eq. (54.154) order by order in ω and apply Eq. (54.149), and we will sketch that route as a check. But there is a far more illuminating argument, the *membrane-paradigm* computation, which extracts η from horizon data alone and exposes why the answer is universal. The idea is that the prescription Eq. (54.149) involves a radial quantity that is *conserved* along the flow from boundary to horizon in the $\omega\to 0$ limit, so its boundary value — which is G^R — equals its horizon value, where regularity fixes it completely.

Define the radial canonical momentum conjugate to ϕ and the response function it builds,

$$\Pi(z,\omega) \equiv -K\sqrt{-g}\,g^{zz}\,\partial_z\phi_\omega, \qquad \chi(z,\omega)\equiv \frac{\Pi(z,\omega)}{i\omega\,\phi_\omega(z)}. \tag{54.155}$$

The prescription Eq. (54.149) is exactly $G^R(\omega) = [\Pi/\phi]_{z\to 0} = i\omega\,\chi(0,\omega)$. The equation of motion Eq. (54.154) is $\partial_z\Pi = -K\,\partial_z(\sqrt{-g}\,g^{zz}\partial_z\phi) = -K\,\omega^2\sqrt{-g}\,g^{tt}\phi$ (using $\partial_t^2\to-\omega^2$ and the equation of motion), while $\partial_z\phi = -\Pi/(K\sqrt{-g}\,g^{zz})$ by definition. Differentiating $\chi=\Pi/(i\omega\phi)$ and substituting both relations gives a first-order flow equation in which the two derivatives combine into

$$\partial_z\chi = i\omega\left[\frac{\chi^2}{K\sqrt{-g}\,g^{zz}} + K\sqrt{-g}\,g^{tt}\right]. \tag{54.156}$$

Every step is algebra: $\partial_z\chi = \partial_z\Pi/(i\omega\phi) - \Pi\,\partial_z\phi/(i\omega\phi^2)$; the first term is $-K\omega^2\sqrt{-g}g^{tt}\phi/(i\omega\phi) = i\omega K\sqrt{-g}g^{tt}$, and the second is $-\Pi\cdot[-\Pi/(K\sqrt{-g}g^{zz})]/(i\omega\phi^2) = \Pi^2/(i\omega K\sqrt{-g}g^{zz}\phi^2) = i\omega\,\chi^2/(K\sqrt{-g}g^{zz})$, using $\Pi = i\omega\chi\phi$. Their sum is Eq. (54.156).

The flow equation Eq. (54.156) has the structure that makes the membrane paradigm work: its right-hand side is proportional to ω. Therefore, as $\omega\to 0$, $\partial_z\chi\to 0$ and χ becomes radially constant at leading order. The boundary value, which is what enters G^R, equals the horizon value,

$$\lim_{\omega\to0}\chi(0,\omega) = \lim_{\omega\to0}\chi(z_h,\omega), \tag{54.157}$$

and the horizon value is fixed by the infalling condition, with no need to solve the equation in between. This is the whole trick: a transport coefficient is a horizon quantity.

The horizon value. Impose infalling boundary conditions Eq. (54.144): near z_h, $\phi_\omega \sim f(z)^{-i\omega/4\pi T}$. Then

$$\partial_z \phi_\omega = -\frac{i\omega}{4\pi T}\,\frac{f'(z)}{f(z)}\,\phi_\omega \xrightarrow{z\to z_h} -\frac{i\omega}{4\pi T}\,\frac{(-4\pi T)}{f(z)}\,\phi_\omega = \frac{i\omega}{f(z)}\,\phi_\omega, \tag{54.158}$$

using $f'(z_h) = -4\pi T$. Substitute into Π from Eq. (54.155), with $\sqrt{-g}\,g^{zz} = (L/z)^{d-1} f(z)$:

$$\Pi(z_h,\omega) = -K\,(L/z)^{d-1} f(z)\cdot \frac{i\omega}{f(z)}\,\phi_\omega = -\,i\omega\,K\,(L/z_h)^{d-1}\,\phi_\omega, \tag{54.159}$$

the factors of f cancelling exactly — the cancellation that makes the horizon limit finite. Hence

$$\chi(z_h,\omega) = \left.\frac{\Pi}{i\omega\phi}\right|_{z_h} = -K\,(L/z_h)^{d-1}, \tag{54.160}$$

a real, ω-independent number. By the conservation Eq. (54.157), this is also the boundary value, so

$$G^R_{xy,xy}(\omega,\mathbf{0}) = i\omega\,\chi(0,\omega) = -\,i\omega\,K\,(L/z_h)^{d-1} + O(\omega^2), \tag{54.161}$$

and the Kubo formula Eq. (54.150) reads off the viscosity:

$$\eta = -\lim_{\omega\to 0}\frac{1}{\omega}\,\mathrm{Im}\,G^R_{xy,xy} = -\lim_{\omega\to 0}\frac{1}{\omega}\,\mathrm{Im}\Big[-i\omega K (L/z_h)^{d-1}\Big] = K\,(L/z_h)^{d-1}. \tag{54.162}$$

With $K = 1/16\pi G_N$ from Theorem 54.13,

$$\boxed{\eta = \frac{1}{16\pi G_N}\Big(\frac{L}{z_h}\Big)^{d-1} = \frac{a_h}{16\pi G_N},} \tag{54.163}$$

where $a_h = (L/z_h)^{d-1}$ is the *horizon area density* — the volume of the spatial horizon cross-section per unit boundary coordinate volume, $a_h = \sqrt{\det g_{ij}}\big|_{z_h}$ with $g_{ij} = (L/z_h)^2\delta_{ij}$ over the $d-1$ flat directions. The shear viscosity is the horizon area density divided by $16\pi G_N$: a purely horizon quantity, exactly as the membrane paradigm promised.

Historical Note

That a black-hole horizon behaves as a viscous membrane long predates AdS/CFT. In the 1970s and early 1980s Damour, and Price and Thorne, developed the *membrane paradigm*: an observer outside the horizon may replace it by a fictitious fluid membrane endowed with electrical resistivity, surface tension, and — relevantly here — a shear viscosity $\eta_{\rm mb} = 1/16\pi G_N$ per unit area and a negative bulk viscosity. The holographic computation Eq. (54.163) reproduces precisely this membrane shear viscosity, now reinterpreted as a transport coefficient of a genuine dual quantum field theory rather than a bookkeeping device. The dictionary turned a heuristic of classical relativity into a calculational tool for strongly coupled plasmas.

54.5.5 The universal ratio $\eta/s = 1/4\pi$

The viscosity Eq. (54.163) is proportional to the horizon area density — and so, by the area law Theorem 54.10 handed over from Section 54.4, is the entropy density. This is the entire reason the ratio is universal.

Theorem 54.14 (Universality of η/s)**.** *For any boundary theory dual to two-derivative (Einstein) gravity with a planar black-brane horizon, the ratio of shear viscosity to entropy density is*

$$\boxed{\frac{\eta}{s} = \frac{1}{4\pi} \qquad \Big(= \frac{\hbar}{4\pi k_B} \ \textit{with units restored} \Big).} \tag{54.164}$$

Proof. The entropy density is the horizon area density over $4G_N$ (Bekenstein–Hawking, Theorem 54.10),

$$s = \frac{a_h}{4G_N} = \frac{1}{4G_N}\Big(\frac{L}{z_h}\Big)^{d-1}. \tag{54.165}$$

Dividing Eq. (54.163) by Eq. (54.165), the area density $a_h = (L/z_h)^{d-1}$ and Newton's constant G_N cancel identically:

$$\frac{\eta}{s} = \frac{a_h/16\pi G_N}{a_h/4G_N} = \frac{4G_N}{16\pi G_N} = \frac{1}{4\pi}. \tag{54.166}$$

The cancellation is total: every feature of the particular geometry — the dimension d, the AdS radius L, the horizon location z_h (hence the temperature), and G_N itself — drops out. The result is a pure number, the same for every two-derivative gravity dual. Restoring units, the natural-unit $1/4\pi$ is $\hbar/4\pi k_B$: the only dimensionful combination that can appear in a viscosity-to-entropy-density ratio is $\hbar/k_B$, since η has dimensions of $\hbar$/volume$\times$ (rate) and s of k_B/volume, leaving $\eta/s \sim \hbar/k_B$. □

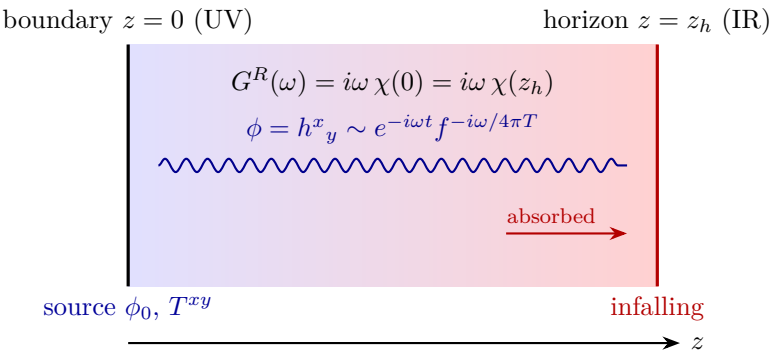

Figure 54.6: The Lorentzian setup. The shear graviton $\phi = h^x{}_y$, dual to the boundary stress component T^{xy}, is sourced at the conformal boundary $z = 0$ and obeys the infalling condition at the horizon $z = z_h$, where it is absorbed (causality, Eq. (54.145)). The response function χ of Eq. (54.155) is radially conserved as $\omega \to 0$ (Eq. (54.157)), so the retarded correlator read at the boundary equals a horizon quantity — the membrane-paradigm computation of η. The radial coordinate runs from the UV (boundary) to the IR (horizon), the interpolation that Section 54.4's successor promotes into the holographic renormalization group.

Physical Insight

Why is the ratio universal, when neither η nor s is? Because both are the *same* horizon area density, weighted by Newton's constant in the two characteristic ways gravity knows how: η counts the horizon as the source of dissipative flux ($1/16\pi G_N$, the graviton's kinetic normalization), and s counts it as the carrier of entropy ($1/4G_N$, Bekenstein–Hawking). The factor of 4π between them is the fixed ratio of these two ways of attaching $1/G_N$ to an area, and it is the same 4π that relates the surface gravity to the Hawking temperature. Holography turns the equality $\eta \propto s \propto$ (area) into a statement about a strongly coupled quantum fluid: the same horizon that carries the plasma's entropy sets the rate at which it dissipates momentum, and the proportionality is rigid.

The number for the $\mathcal{N} = 4$ plasma. The canonical realization is the thermal state of $\mathcal{N} = 4$ super-Yang–Mills with gauge group SU(N) at large N and large 't Hooft coupling $\lambda = g^2 N$, dual to the AdS_5 black brane ($d = 4$). Its free energy and entropy were computed in Section 54.4; its shear viscosity is now Eq. (54.162) with $d = 4$, and the ratio is $\eta/s = 1/4\pi$ exactly. Two things deserve emphasis. First, this is a number for a *strongly coupled* gauge theory: $\lambda \to \infty$ is the regime in which the gravity dual is classical, and it is exactly the regime that

the perturbative machinery of Yang–Mills theory cannot reach. The one-loop β-function and asymptotic freedom of Chapter 27 describe the weak-coupling ultraviolet, where η/s is instead *large* — a weakly coupled gas has long mean free paths, hence large viscosity, and kinetic theory gives $\eta/s \sim 1/(\lambda^2 \log \lambda^{-1}) \gg 1$ as $\lambda \to 0$. The holographic value $1/4\pi \approx 0.08$ is the opposite extreme, accessible by no resummation of the perturbative series. It is the cleanest illustration in this book of holography supplying a controlled answer in a regime where the Lagrangian-based methods of Parts VI and VII are powerless. Second, the same computation for $\mathcal{N} = 4$ shows that the leading correction at *finite* coupling raises the ratio: the first α'-correction to type IIB supergravity (a curvature-cubed R^4 term) gives

$$\frac{\eta}{s} = \frac{1}{4\pi}\left(1 + \frac{15\,\zeta(3)}{\lambda^{3/2}} + \cdots\right), \tag{54.167}$$

positive and decreasing toward $1/4\pi$ from above as $\lambda \to \infty$. The supergravity value $1/4\pi$ is thus approached from above along the strong-coupling axis, smoothly interpolating toward the large kinetic-theory value as the coupling is dialed down.

54.5.6 Quasinormal modes and hydrodynamic dispersion

The viscosity is the leading datum of an entire dynamical spectrum. The poles of the retarded correlator $G^R(\omega, \mathbf{k})$ in the complex ω-plane are the *quasinormal modes* (QNMs) of the black brane: frequencies at which the bulk supports a solution that is infalling at the horizon *and* normalizable at the boundary (no source, $\phi_0 = 0$), so that the response $G^R = [\Pi/\phi]_{z\to 0}$ diverges. They are the resonances of the dual plasma — the frequencies of its damped collective oscillations — and because the boundary condition is infalling (absorptive), they lie in the *lower* half ω-plane, $\mathrm{Im}\,\omega < 0$, encoding decay, consistent with G^R's analyticity in the upper half-plane.

The QNM spectrum splits into two families, shown in Fig. 54.7. A *gapped* tower sits at frequencies $|\omega| \sim 2\pi T$ with comparable real and imaginary parts; for the AdS_5 massless scalar these are the modes whose large-overtone asymptotics are $\omega_n/2\pi T \to n\,(\pm 1 - i)$, two rays descending at 45° into the lower half-plane. These set the relaxation time $\tau \sim 1/2\pi T$ on which the plasma returns to local equilibrium and have no analogue in hydrodynamics — they are the genuinely quantum, non-universal modes of the strongly coupled medium.

The physically decisive family is the *gapless*, hydrodynamic one: modes whose frequency vanishes as $\mathbf{k} \to 0$, $\omega(\mathbf{k}) \to 0$, because they are the long-wavelength relaxation of conserved densities, which cannot decay at zero wavenumber (conservation forbids it). Two such modes follow from $T^{\mu\nu}$ conservation. In the shear channel — the same T^{xy} channel that gave η, now at finite $\mathbf{k}$ — the conserved transverse momentum density obeys a diffusion equation, and the lowest QNM

is purely imaginary,

$$\omega = -\,i\,D\,k^2 + O(k^4), \qquad D = \frac{\eta}{\varepsilon + p}, \tag{54.168}$$

the momentum-diffusion (shear) mode, with D the diffusion constant and ε, p the energy density and pressure. In the sound channel the energy and longitudinal-momentum densities couple to give a propagating mode,

$$\omega = \pm\, c_s\, k - \frac{i}{2}\,\Gamma_s\, k^2 + O(k^3), \qquad c_s^2 = \frac{1}{d-1}, \quad \Gamma_s = \frac{2(d-2)}{d-1}\,\frac{\eta}{\varepsilon + p}, \tag{54.169}$$

the speed of sound $c_s^2 = \partial p/\partial\varepsilon = 1/(d-1)$ being fixed by conformal invariance (tracelessness $T^{\mu}{}_{\mu} = 0$ gives $\varepsilon = (d-1)p$), and the sound attenuation Γ_s again proportional to $\eta/(\varepsilon + p)$. That the holographic QNM dispersion relations take exactly the form predicted by relativistic hydrodynamics, with transport coefficients matching the Kubo result, is the statement that the long-distance, late-time dynamics of the strongly coupled plasma *is* hydrodynamics — a derivation of hydrodynamics from a microscopic (here, gravitational) description.

Worked Example 54.15 (The shear diffusion constant recovers $\eta/s = 1/4\pi$)**.** The diffusion pole Eq. (54.168) furnishes an independent route to the ratio, and a consistency check on Theorem 54.14. For a conformal plasma at zero chemical potential the Gibbs–Duhem relation gives $\varepsilon + p = Ts$ (the only extensive combination available when the sole scale is T and $\mu = 0$; equivalently, $p = -F/V$ and $\varepsilon = Ts - p$, of which the sum is Ts). Hence the shear diffusion constant is

$$D = \frac{\eta}{\varepsilon + p} = \frac{\eta}{Ts} = \frac{1}{T}\,\frac{\eta}{s}. \tag{54.170}$$

The diffusion constant of the AdS_5 black brane can also be computed directly, as the small-k limit of the shear-channel QNM: solving the finite-$\mathbf{k}$ analogue of Eq. (54.154) to the order that produces the pole Eq. (54.168) (the standard hydrodynamic-limit expansion of the bulk equation, infalling at the horizon and normalizable at the boundary) yields

$$D = \frac{1}{4\pi T}. \tag{54.171}$$

Equating Eq. (54.171) with Eq. (54.170) gives $\eta/s = T\,D = T \cdot \frac{1}{4\pi T} = \frac{1}{4\pi}$, in exact agreement with the horizon-flux computation Theorem 54.14. The two derivations probe the correlator differently — one its zero-frequency slope at $\mathbf{k} = 0$ (Kubo), the other its lowest pole at small $\mathbf{k}$ (hydrodynamics) — and their agreement is the internal check that the holographic plasma is a genuine relativistic fluid whose Kubo viscosity and hydrodynamic diffusion constant are the same physical η. The combination $D = 1/4\pi T$ also says the momentum-diffusion time over a thermal wavelength is the shortest the medium can sustain, the hallmark of a nearly perfect fluid.

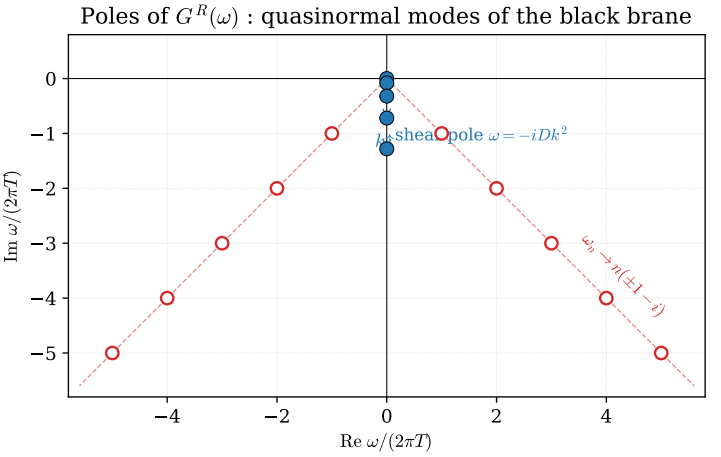

Figure 54.7: Poles of the retarded correlator $G^R(\omega)$ in the complex frequency plane (units $2\pi T$): the quasinormal-mode spectrum of the planar AdS_5 black brane. Open circles: the gapped non-hydrodynamic tower, with the exact large-overtone asymptotics $\omega_n \to n(\pm 1 - i)\, 2\pi T$ (dashed 45° rays). Filled circles: the hydrodynamic shear (momentum-diffusion) pole $\omega = -iDk^2$, which slides down the negative imaginary axis as the wavenumber k increases and pinches the origin as $k \to 0$ — the gapless mode whose small-k slope $D = \eta/(\varepsilon + p)$ encodes $\eta/s = 1/4\pi$.

54.5.7 The KSS bound: status, near-saturation, and violation

The value $\eta/s = 1/4\pi$ is strikingly small. Ordinary fluids have η/s orders of magnitude larger: water at room temperature sits near $400 \times (1/4\pi)$, helium near its superfluid transition — one of the lowest known laboratory values — still some $9 \times (1/4\pi)$. That every two-derivative gravity dual saturates the same small value, and that no ordinary substance comes near it, motivated Kovtun, Son, and Starinets to conjecture it as a universal lower bound.

Conjecture 54.16 (KSS bound)**.** *For all relativistic quantum field theories in flat space, in the regime where a hydrodynamic description applies, the shear-viscosity-to-entropy-density ratio satisfies*

$$\boxed{\frac{\eta}{s} \;\geq\; \frac{1}{4\pi} \qquad \Big(\frac{\hbar}{4\pi k_B} \text{ in restored units}\Big),} \tag{54.172}$$

with equality for theories dual to two-derivative Einstein gravity.

The physical heuristic for a *lower* bound is an uncertainty-principle estimate. In kinetic theory $\eta \sim \varepsilon\,\tau$ and $s \sim n$ (energy density times mean free time, particle density), so $\eta/s \sim \bar{\varepsilon}\,\tau \sim E\,\tau/\hbar$ in units — and a quasiparticle cannot have a relaxation time shorter than the inverse of its energy, $E\,\tau \gtrsim \hbar$, lest it not be a well-defined excitation at all. A fluid saturating the bound is one with *no* quasiparticles: the excitations are so strongly coupled that their lifetime is the minimum the uncertainty principle allows. This is exactly the holographic regime, where the absence of a sharp particle spectrum is the boundary face of the smooth bulk geometry.

Near-saturation by the quark–gluon plasma. The bound's empirical fame rests on a real fluid. The quark–gluon plasma produced in heavy-ion collisions at RHIC and the LHC, at temperatures $T \sim 0.2$–$0.5\,\mathrm{GeV}$ just above the QCD deconfinement transition, flows with an extraordinarily small η/s. Hydrodynamic fits to the observed anisotropic (elliptic) flow of the collision debris require η/s within a small multiple of $1/4\pi$ — the data, as understood in the mid-2020s, favour $\eta/s \approx (1\text{–}2.5) \times \frac{1}{4\pi}$, with the lower end near T_c. The quark–gluon plasma is thus the most nearly perfect fluid ever measured, and its near-saturation of the holographic value is the headline phenomenological success of AdS/CFT applied to QCD — all the more striking because QCD near T_c is strongly coupled and outside the reach of the perturbative β-function of Chapter 27, exactly the regime where $\mathcal{N} = 4$ SYM at strong coupling is the only tractable cousin. The match is qualitative-to-semiquantitative, not a theorem: QCD is neither conformal nor supersymmetric nor large-N, and the agreement says that the strong-coupling *value* of η/s is a more robust, more universal quantity than the details of the Lagrangian that produces it.

Violation by higher-derivative corrections. The honest status of Eq. (54.172) is that it is *not* a theorem, and it is now known to be violated. The universality theorem Theorem 54.14 relied on the shear graviton being a massless scalar with the Einstein-gravity normalization $1/16\pi G_N$ — a property of *two-derivative* gravity only. Finite-N and finite-coupling corrections in the dual gauge theory map to higher-derivative (curvature-squared and higher) terms in the bulk, which spoil the reduction Theorem 54.13: the graviton acquires a non-minimal coupling, and the cancellation that produced the pure number $1/4\pi$ no longer occurs. For Gauss–Bonnet gravity with coupling λ_{GB} (a curvature-squared theory whose linearized equations remain second order, hence ghost-free), the explicit computation gives

$$\frac{\eta}{s} = \frac{1}{4\pi}\,(1 - 4\lambda_{\mathrm{GB}} + \cdots), \tag{54.173}$$

which falls *below* $1/4\pi$ for positive λ_{GB}. The corresponding dual gauge theories (with $a \neq c$ central charges, i.e. away from the $\mathcal{N} = 4$ point) therefore violate the KSS bound. The violation is bounded: bulk causality and the absence of

superluminal graviton propagation constrain $\lambda_{\rm GB} \leq 9/100$ in five bulk dimensions, capping the violation at $\eta/s \geq \frac{1}{4\pi} \cdot \frac{16}{25}$. As understood in the mid-2020s, the situation is this: $1/4\pi$ is the exact value for Einstein gravity and is *approached from above* by the finite-coupling expansion Eq. (54.167) of any given theory like $\mathcal{N} = 4$ SYM; but across the space of *different* theories it is a strict lower bound only within two-derivative gravity, and is violated by higher-derivative duals, by a parametrically small amount controlled by causality. No sharp, universally valid lower bound on η/s is known; what survives is that $1/4\pi$ is a natural scale, that strongly coupled fluids cluster near it, and that ordinary fluids lie far above. The KSS bound is best stated as a near-saturated benchmark with known, controlled exceptions, not as a law.

Notation Watch

Throughout this section η denotes the shear viscosity (a transport coefficient), not the Minkowski metric $\eta_{\mu\nu}$ nor the conformal-anomaly central charge; the metric always carries indices and the viscosity never does. The ratio η/s is dimensionless in natural units; the restored form $\hbar/4\pi k_B$ makes the dependence on the two fundamental constants explicit and is the form in which the bound is compared to laboratory fluids.

The computation of this section has made one structural feature unavoidable, and it is the bridge to what follows. The retarded correlator was assembled from a single radial flow: a source planted at the boundary $z = 0$ and an infalling condition imposed at the horizon $z = z_h$, with the physics — the response function χ — flowing between them along the radial coordinate. The boundary end controlled the ultraviolet (the operator T^{xy} and its source), the horizon end the deep infrared (the thermal, dissipative, long-wavelength physics), and the radial direction interpolated between the two. This is no accident of the thermal problem: the same radial coordinate that here ran from UV operator to IR horizon is, in every holographic geometry, a geometric realization of energy scale. Section 54.4's successor promotes this observation into a precise statement — the holographic renormalization group — in which radial evolution of the bulk fields is the renormalization-group flow of the boundary couplings, closing the loop with the Wilsonian and Callan–Symanzik pictures of Part VI.

54.6 The Holographic Renormalization Group: the Radial Direction as Energy Scale

Every computation of this chapter has, on inspection, been a story told along the radial coordinate. In Section 54.5 the retarded correlator was assembled from a single radial flow — a source planted at the boundary $z = 0$, an infalling condition imposed at the horizon, and a response function carried between them;

the boundary end was the ultraviolet, the horizon end the deep infrared. In Theorem 54.5 the divergences of the on-shell action were power laws in the radial cutoff $z = \epsilon$, removed by local counterterms living on the cutoff slice — precisely the structure of an ultraviolet renormalization, with $z \to 0$ the deep UV because the warp factor $\sqrt{|g|} = (L/z)^{d+1}$ blows up there. Both facts pointed at one identification, which we now make precise and exploit: *the radial coordinate of an asymptotically-AdS geometry is the renormalization-group scale of the boundary theory, and radial evolution of the bulk fields is the RG flow of the boundary couplings.* This is the loop the chapter promised to close. We will build the geometry of a holographic RG flow (a domain wall interpolating between AdS asymptotics), recast the second-order bulk equations as first-order flow equations through a fake superpotential, define the holographic beta function and show it reproduces the operator dimensions of Section 53.4, prove a monotonicity theorem — the gravity dual of the a-theorem — from the bulk null energy condition, and finally identify the radial Hamilton–Jacobi equation with the Callan–Symanzik equation of Section 24.5, so that the Wilsonian shell-integration of Chapter 23 and the running couplings of Chapter 24 acquire a literal geometric meaning one dimension up.

Notation Watch

As declared in the notationwatch of Section 54.4.1 and used throughout Section 54.5, all *bulk geometry* in this section is written in the mostly-plus signature $\eta_{\mu\nu} = \mathrm{diag}(-,+,\dots,+)$ with the Wald curvature convention, in which AdS has negative scalar curvature — the deliberate local departure, adopted for the black-hole and real-time computations, from the book's mostly-minus convention (Section 53.3, Appendix A); the boundary *field-theory* statements (beta functions, dimensions, central charges) are signature-blind. The radial coordinate is $r \in (-\infty, +\infty)$ with the conformal boundary at $r \to +\infty$; it is related to the Fefferman–Graham coordinate z of Eq. (54.30) by $z \sim e^{-r/L}$ near a fixed point, so $r \to +\infty \Leftrightarrow z \to 0$ is the UV and decreasing r runs toward the IR.

54.6.1 The radial coordinate is the scale

The identification rests on a symmetry. The Poincaré metric of Eq. (53.59), written in the mostly-plus form

$$\mathrm{d}s^2 = \frac{L^2}{z^2}\Big(\eta_{\mu\nu}\,\mathrm{d}x^\mu \mathrm{d}x^\nu + \mathrm{d}z^2\Big), \qquad \eta_{\mu\nu} = \mathrm{diag}(-,+,\dots,+), \tag{54.174}$$

is invariant under the simultaneous rescaling

$$x^\mu \longmapsto \lambda\, x^\mu, \qquad z \longmapsto \lambda\, z, \qquad \lambda > 0, \tag{54.175}$$

because each factor of $\mathrm{d}x$ or $\mathrm{d}z$ scales as λ while the prefactor L^2/z^2 scales as λ^{-2}, leaving $\mathrm{d}s^2$ unchanged. On the boundary, $x^\mu \mapsto \lambda x^\mu$ is precisely a dilatation: a change of length unit, equivalently a change of energy scale by $\mu \mapsto \mu/\lambda$. The bulk realizes that dilatation as an isometry that also moves the radial coordinate, $z \mapsto \lambda z$. A bulk excitation localized near $z \sim 1/E$ in the radial direction therefore transforms under Eq. (54.175) as a boundary disturbance of energy E: small z (near the boundary) is large E (the ultraviolet), and large z (deep in the interior) is small E (the infrared). The dictionary is the quantitative statement

$$\mu \;\sim\; \frac{1}{z} \;=\; \frac{1}{L}\, e^{A(r)}, \qquad \ln \mu \;=\; A(r) + \text{const}, \tag{54.176}$$

where in the second form we have anticipated the general warped geometry below, writing the scale factor as $e^{A(r)}$ so that the dimensionless logarithm of the renormalization scale is the warp function A itself. The renormalization-group "time" $t = \ln \mu$ of Chapters 23 and 24 is, on the gravity side, literally the warp factor of the metric. This is no longer a heuristic: a bulk field's radial profile is a function of A, hence a function of $\ln \mu$, and its radial equation of motion will be an evolution equation in $\ln \mu$ — a renormalization-group equation. The remainder of the section turns this sentence into theorems.

54.6.2 Domain walls and the geometry of an RG flow

Pure AdS is dual to a conformal field theory: scale invariance Eq. (54.175) is an exact isometry, and nothing runs. To describe a theory that *does* run — a UV CFT deformed by a relevant operator, flowing to a distinct IR CFT — we need a geometry that looks like AdS near the boundary, looks like a (generally different) AdS deep in the interior, and interpolates smoothly in between, with the scale isometry broken along the way. The minimal bulk model that produces such a geometry is Einstein gravity coupled to a single scalar with a nontrivial potential. We take the bulk action in $D = d + 1$ dimensions,

$$S = \int \mathrm{d}^{d+1}x\, \sqrt{-g}\left[\frac{1}{2\kappa^2}\, R - \frac{1}{2}\, g^{MN}\partial_M\phi\, \partial_N\phi - V(\phi)\right], \qquad 2\kappa^2 = 16\pi G_N, \tag{54.177}$$

where ϕ is dual, by the field–operator map of Section 53.4, to a scalar boundary operator $\mathcal{O}$ whose dimension we will read off from V. The scalar's potential plays two roles at once: its value sets the local cosmological constant (hence the local AdS radius), and its shape away from the extrema drives the flow. We require V to possess at least two critical points $\phi_\star$ with $V'(\phi_\star) = 0$ and $V(\phi_\star) < 0$; each is a candidate AdS vacuum.

The geometry that realizes the flow is the *domain wall*: a metric homogeneous and Poincaré-invariant along the boundary directions, with all dependence in the radial coordinate,

$$\mathrm{d}s^2 = \mathrm{d}r^2 + e^{2A(r)}\, \eta_{\mu\nu}\, \mathrm{d}x^\mu \mathrm{d}x^\nu, \qquad \phi = \phi(r), \tag{54.178}$$

with $\eta_{\mu\nu} = \mathrm{diag}(-,+,\dots,+)$ the flat boundary metric and $A(r)$ the warp function. The ansatz preserves d-dimensional Poincaré invariance (translations and Lorentz rotations of x^μ) but breaks the dilatation Eq. (54.175) unless A is linear in r; a position-dependent $A'(r)$ is exactly broken scale invariance, i.e. a running coupling. A pure-AdS region is recovered wherever ϕ sits at a critical point $\phi_\star$ and A is linear, $A(r) = r/L_\star$, with the radius $L_\star$ fixed by $V(\phi_\star)$, as we now verify.

Definition 54.17 (Holographic RG flow)**.** A *holographic renormalization-group flow* is a solution $(A(r), \phi(r))$ of the equations of motion of Eq. (54.177) in the domain-wall form Eq. (54.178) for which $\phi(r)$ interpolates between two critical points of V: as $r \to +\infty$ (boundary, UV) the geometry approaches AdS of radius L_{UV} with $\phi \to \phi_{\mathrm{UV}}$, and as $r \to -\infty$ (interior, IR) it approaches AdS of radius L_{IR} with $\phi \to \phi_{\mathrm{IR}}$. The boundary CFT is the UV fixed point deformed by the operator dual to ϕ; the IR fixed point is the endpoint of the flow.

The reduced equations of motion. On the ansatz Eq. (54.178), the field equations of Eq. (54.177) collapse to ordinary differential equations in r. We need them explicitly, since the entire RG dictionary will be read off their structure. The Ricci tensor of Eq. (54.178) has the standard domain-wall components (Wald convention)

$$R_{rr} = -d(A''+A'^2), \qquad R_{\mu\nu} = -e^{2A}\eta_{\mu\nu}(A''+dA'^2), \qquad R = -2dA''-d(d+1)A'^2, \tag{54.179}$$

in which a prime denotes $\mathrm{d}/\mathrm{d}r$; for the AdS case $A = r/L$ (so $A'' = 0$, $A' = 1/L$) these give $R = -d(d+1)/L^2 < 0$, the negative curvature of mostly-plus AdS. The scalar equation $\nabla^2\phi = V'(\phi)$, with $\sqrt{-g} = e^{dA}$ and $g^{rr} = 1$, is

$$\phi'' + d\,A'\,\phi' = V'(\phi), \tag{54.180}$$

the radial wave equation with a friction term $dA'\phi'$ — formally the equation of a particle of position ϕ moving in the inverted potential $-V$ with Hubble-like damping dA', the radial coordinate playing the role of time. The Einstein equations $R_{MN} - \frac{1}{2}g_{MN}R = \kappa^2 T_{MN}$, with stress tensor $T_{MN} = \partial_M\phi\,\partial_N\phi - g_{MN}\big(\frac{1}{2}(\partial\phi)^2 + V\big)$, reduce to two independent components. The rr component gives the *Hamiltonian constraint*

$$\frac{d(d-1)}{2}\,A'^2 = \kappa^2\Big(\tfrac{1}{2}\,\phi'^2 - V\Big), \tag{54.181}$$

a first integral with no second derivatives — the bulk version of energy conservation along the radial flow. The $\mu\nu$ components give

$$(d-1)A'' + \frac{d(d-1)}{2}A'^2 = -\kappa^2\Big(\tfrac{1}{2}\,\phi'^2 + V\Big). \tag{54.182}$$

Subtracting Eq. (54.181) from Eq. (54.182) cancels both the A'^2 and the V terms and leaves a single, remarkably simple relation:

$$\boxed{A''(r) = -\frac{\kappa^2}{d-1}\,\phi'(r)^2 \;\le\; 0.} \tag{54.183}$$

This one line is the technical seed of everything that follows. It says the warp function is concave: $A'' \le 0$, with equality only where $\phi' = 0$, i.e. at a fixed point. We will see in Section 54.6.5 that Eq. (54.183) is exactly the bulk null energy condition, and that its sign is the sign of the a-theorem.

54.6.3 First-order flow equations from a fake superpotential

The system Eqs. (54.180), (54.181) and (54.183) is second order. Its solutions of interest — the smooth interpolating flows — can be obtained from a *first-order* system by the superpotential trick, familiar from supersymmetric domain walls but valid here as a purely classical device, for which reason the function W below is called a *fake* superpotential: it need not descend from any supersymmetry. The construction trades the second-order equations for a pair of first-order ones at the cost of solving an algebraic-differential consistency condition for W.

Theorem 54.18 (First-order flow equations)**.** *Suppose a function $W(\phi)$ — the fake superpotential — satisfies the consistency condition*

$$V(\phi) = \frac{1}{2}\big(W'(\phi)\big)^2 - \frac{d\,\kappa^2}{2(d-1)}\,W(\phi)^2, \tag{54.184}$$

where $W' \equiv \mathrm{d}W/\mathrm{d}\phi$. Then any solution of the first-order system

$$\boxed{\phi'(r) = W'(\phi), \qquad A'(r) = -\frac{\kappa^2}{d-1}\,W(\phi)} \tag{54.185}$$

solves the full second-order equations Eqs. (54.180), (54.181) and (54.183). Conversely, every domain-wall solution arises this way for an appropriate W.

Proof. We verify that Eq. (54.185) together with Eq. (54.184) implies each of the three reduced equations; the algebra is elementary and we show every step.

The concavity equation Eq. (54.183). Differentiate the second of Eq. (54.185): $A'' = -\frac{\kappa^2}{d-1}\,\frac{dW}{dr} = -\frac{\kappa^2}{d-1}\,W'\,\phi' = -\frac{\kappa^2}{d-1}\,W'\cdot W' = -\frac{\kappa^2}{d-1}(W')^2$, using $\phi' = W'$ from the first equation. Since $\phi' = W'$, this is exactly $A'' = -\frac{\kappa^2}{d-1}\phi'^2$, which is Eq. (54.183).

The Hamiltonian constraint Eq. (54.181). Substitute $A' = -\frac{\kappa^2}{d-1}W$ and $\phi' = W'$ into the left and right sides. The left side is $\frac{d(d-1)}{2}A'^2 = \frac{d(d-1)}{2}\cdot\frac{\kappa^4}{(d-1)^2}W^2 = \frac{d\,\kappa^4}{2(d-1)}W^2$. The right side is $\kappa^2\big(\frac{1}{2}W'^2 - V\big)$. Equality holds iff

$\frac{1}{2}W'^2 - V = \frac{d\kappa^2}{2(d-1)}W^2$, which is precisely the consistency condition Eq. (54.184) solved for V. So Eq. (54.181) holds by construction.

The scalar equation Eq. (54.180). The left side is $\phi'' + dA'\phi'$. Now $\phi'' = \frac{d}{dr}W'(\phi) = W''\phi' = W''W'$, and $dA'\phi' = d\cdot(-\frac{\kappa^2}{d-1}W)\cdot W' = -\frac{d\kappa^2}{d-1}WW'$, so the left side is $W''W' - \frac{d\kappa^2}{d-1}WW'$. The right side is V', which we compute by differentiating Eq. (54.184): $V' = W'W'' - \frac{d\kappa^2}{d-1}WW'$. The two sides coincide. Hence the scalar equation is automatically satisfied — it is the derivative of the Hamiltonian constraint, no new information.

The converse holds because the Hamiltonian constraint Eq. (54.181) can be solved pointwise for the quantity $-\frac{d-1}{\kappa^2}A'$ as a function of ϕ along any given monotonic flow, and that function, call it $W(\phi)$, then satisfies Eq. (54.184) and reproduces Eq. (54.185) by construction. □

The first-order equations Eq. (54.185) are the central computational object of holographic RG. They display the flow as a gradient flow: ϕ rolls along W', and the warp function is slaved to W. The radial coordinate is a monotonic clock because $\phi' = W'$ has fixed sign between critical points (where $W' = 0$), so ϕ moves monotonically from one extremum to the next, and by Eq. (54.183) A' decreases monotonically as well: the geometry never "turns around."

Fixed points are AdS vacua. At a critical point $\phi_\star$ of W ($W'(\phi_\star) = 0$) the first equation gives $\phi' = 0$, the second gives $A' = -\frac{\kappa^2}{d-1}W(\phi_\star) = \text{const}$, so $A = A'_\star r$ and the metric Eq. (54.178) is exactly AdS. Differentiating Eq. (54.184) shows $W'(\phi_\star) = 0 \Rightarrow V'(\phi_\star) = 0$: a critical point of the superpotential is a critical point of the potential, as it must be for the scalar to sit still. Taking $W(\phi_\star) < 0$ so that $A'_\star > 0$ (the warp factor grows toward the boundary), the AdS radius and cosmological constant are

$$\frac{1}{L_\star} = A'_\star = -\frac{\kappa^2}{d-1}\,W(\phi_\star), \qquad V(\phi_\star) = -\frac{d\,\kappa^2}{2(d-1)}\,W(\phi_\star)^2 = -\frac{d(d-1)}{2\kappa^2\,L_\star^2}, \tag{54.186}$$

the last equality being the standard relation $V_\star = \Lambda_\star/\kappa^2$ with $\Lambda_\star = -d(d-1)/2L_\star^2$ the cosmological constant of AdS_{d+1}, which one also reads directly off the Hamiltonian constraint Eq. (54.181) at $\phi' = 0$. Thus each extremum of V furnishes an AdS vacuum, hence a fixed-point CFT, and a flow is a bulk trajectory connecting two of them.

54.6.4 The holographic beta function and the operator dimensions

We can now define the running coupling and its beta function entirely from the geometry. The boundary coupling conjugate to $\mathcal{O}$ is the value of the scalar

(more precisely the coefficient of its leading near-boundary mode, Eq. (54.30)); to leading order the running coupling *is* ϕ as a function of scale. With the scale identified through Eq. (54.176) as $\ln \mu = A(r)$, the holographic beta function is the rate of change of ϕ per unit RG time, exactly the definition of Eq. (24.5) transplanted to the bulk:

$$\boxed{\beta(\phi) \;\equiv\; \frac{d\phi}{d\ln\mu} \;=\; \frac{\mathrm{d}\phi/\mathrm{d}r}{\mathrm{d}A/\mathrm{d}r} \;=\; \frac{\phi'}{A'} \;=\; -\frac{d-1}{\kappa^2}\,\frac{W'(\phi)}{W(\phi)}.} \tag{54.187}$$

The last equality used the flow equations Eq. (54.185). The structure is transparent: β vanishes wherever $W' = 0$, that is, at the AdS critical points where the scalar sits at an extremum of the potential. These are the zeros of the beta function — the fixed points of the RG flow — and they are the boundary CFTs. Between them β is nonzero and the coupling runs. The map "boundary = UV, deep interior = IR" of Section 54.6.1, anticipated qualitatively in Section 54.5 by the boundary/horizon split, is now the quantitative statement that the flow of ϕ from ϕ_{UV} (large r) to ϕ_{IR} (small r) is the RG trajectory of the boundary coupling from the ultraviolet fixed point to the infrared one.

Linearizing at a fixed point: dimensions from the slope. The physics of the fixed point is encoded in the slope of β there, just as in Chapter 24. Expand $\beta(\phi) \simeq \beta'(\phi_\star)(\phi - \phi_\star)$ near a zero. Differentiating Eq. (54.187) and using $W'(\phi_\star) = 0$,

$$\beta'(\phi_\star) = -\frac{d-1}{\kappa^2}\,\frac{W''(\phi_\star)}{W(\phi_\star)} = L_\star\, W''(\phi_\star), \tag{54.188}$$

where the second form used $-\frac{d-1}{\kappa^2 W(\phi_\star)} = L_\star$ from Eq. (54.186). The claim is that this slope is precisely the deviation of the operator dimension from marginality,

$$\beta'(\phi_\star) = \Delta - d, \tag{54.189}$$

exactly as a coupling for an operator of dimension Δ has a (dimensionless) beta function $\beta = (\Delta - d)\,(\text{coupling}) + \cdots$ in Chapters 23 and 24: relevant $\Delta < d$ gives $\beta' < 0$ (the coupling grows toward the IR), irrelevant $\Delta > d$ gives $\beta' > 0$ (the coupling dies in the IR), and marginal $\Delta = d$ gives $\beta' = 0$. To prove Eq. (54.189) and tie it to the mass–dimension relation of Theorem 53.17, compute the scalar mass at the fixed point, $m^2 = V''(\phi_\star)$, from the consistency condition. Differentiating Eq. (54.184) twice,

$$V'' = (W'')^2 + W'W''' - \frac{d\kappa^2}{d-1}(W'^2 + WW''), \tag{54.190}$$

and evaluating at $\phi_\star$ where $W' = 0$,

$$m^2 = V''(\phi_\star) = \big(W''(\phi_\star)\big)^2 - \frac{d\kappa^2}{d-1}\,W(\phi_\star)\,W''(\phi_\star) = (W''_\star)^2 + \frac{d}{L_\star}\,W''_\star, \tag{54.191}$$

the last step using $\frac{d\kappa^2}{d-1}W_\star = -d/L_\star$ from Eq. (54.186). Now write $W_\star'' = \beta'(\phi_\star)/L_\star$ from Eq. (54.188) and multiply through by $L_\star^2$:

$$m^2L_\star^2 = \big(\beta'(\phi_\star)\big)^2 + d\,\beta'(\phi_\star) = \beta'(\phi_\star)\big(\beta'(\phi_\star)+d\big). \tag{54.192}$$

This is identical to the mass–dimension relation $\Delta(\Delta-d) = m^2L^2$ of Eq. (53.112) under the substitution $\beta'(\phi_\star) = \Delta - d$, since then $\beta'(\beta'+d) = (\Delta-d)\Delta = \Delta(\Delta-d)$. The beta-function slope read off the bulk flow reproduces, on the nose, the conformal dimension assigned by the mass–dimension relation to the dual operator. The two computations — one a near-boundary falloff analysis (Section 53.4.3), the other a linearization of the RG flow — agree because they are the same boundary-value problem viewed from two ends.

A relevant deformation triggers the flow. The leading near-boundary behavior of the scalar follows directly from the linearized first-order equation $\phi' = W' \simeq W_\star''(\phi-\phi_\star)$, whose solution is $\phi-\phi_\star \propto e^{W_\star'' r} = e^{(\Delta-d)r/L_\star}$. Translating to the Fefferman–Graham coordinate $z \sim e^{-r/L_\star}$, this is $\phi - \phi_\star \propto z^{\,d-\Delta}$ — precisely the *source* (non-normalizable) mode of the near-boundary expansion Eq. (54.30), the leading falloff that turns on the deformation. The first-order flow equations capture exactly this source-driven part of the solution; the subleading *response* mode z^{Δ}, the vacuum expectation value $\langle\mathcal{O}\rangle$, is the one integration constant the first-order system leaves free, and it is fixed not by the boundary data but by the requirement of regularity in the deep interior (smoothness at the IR fixed point or, at finite temperature, the horizon regularity of Section 54.5). For a *relevant* operator, $\Delta < d$, the source mode $z^{d-\Delta}$ grows as z increases (toward the interior): a deformation that is arbitrarily small in the deep UV swells as one flows to lower scales and inevitably drives the geometry away from the UV AdS region. This is the geometric statement of the foundational fact of Theorem 23.23: relevant operators are the ones that matter in the infrared, the ones that trigger nontrivial flows; irrelevant operators ($\Delta > d$, mode $z^{d-\Delta}$ decaying) die away and leave the IR fixed point untouched. The bulk reproduces the relevant/marginal/irrelevant trichotomy as the growth/constancy/decay of a radial profile.

54.6.5 The holographic c-function and the a-theorem

The deepest structural fact about RG flows is that they are irreversible: a quantity counting the effective number of degrees of freedom decreases monotonically from the UV to the IR. In two dimensions this is Zamolodchikov's c-theorem; in four it is the a-theorem proved field-theoretically in Theorem 52.19 [301]. Holography supplies a one-line proof of the monotonicity, valid in any dimension, with the irreversibility traced directly to a positive-energy condition in the bulk.

Definition 54.19 (Holographic c-function)**.** Along a domain-wall flow Eq. (54.178) with $A'(r) > 0$, define

$$c(r) \;\equiv\; \frac{C_d}{\big(A'(r)\big)^{d-1}}, \qquad C_d = \frac{(d-1)^{d-1}\,\pi^{d/2}}{\Gamma\!\left(\frac{d}{2}\right)\kappa^2} \;\; (>0), \tag{54.193}$$

a positive constant $C_d \propto 1/G_N$ times the inverse $(d-1)$th power of the warp slope. At a fixed point, where $A' = 1/L_\star$, this evaluates to $c = C_d\, L_\star^{d-1} \propto L_\star^{d-1}/G_N$, the holographic central charge: the same combination $L^{d-1}/G_N \sim N^2$ that the parameter map of Section 53.4 identified as the number of boundary degrees of freedom, and, for even d, the coefficient of the Weyl anomaly — the a-charge for $d = 4$.

The normalization constant C_d is chosen so that c at a fixed point equals the standard CFT central charge; its precise value is immaterial to the monotonicity argument, which needs only $C_d > 0$, but we record it so that the endpoint values are the genuine anomaly coefficients that Theorem 52.19 constrains.

Theorem 54.20 (Holographic c-theorem)**.** *Let $(A(r), \phi(r))$ be a domain-wall solution of Eq. (54.177) whose matter satisfies the bulk* null energy condition *$T_{MN}\xi^M\xi^N \geq 0$ for every null vector ξ^M. Then the holographic c-function Eq. (54.193) is monotonically non-decreasing toward the boundary,*

$$c'(r) \;\geq\; 0, \tag{54.194}$$

with equality only where the flow is stationary ($\phi' = 0$). Consequently $c_{\mathrm{UV}} \geq c_{\mathrm{IR}}$: the central charge of the ultraviolet fixed point is never smaller than that of the infrared fixed point. This is the gravity dual of the a-theorem Theorem 52.19.

Proof. We first show that the null energy condition is exactly the concavity Eq. (54.183), then differentiate $c(r)$.

Null energy condition $\Rightarrow A'' \leq 0$. Choose the null vector ξ^M with a radial component and a single boundary time-like component, $\xi^r = 1$, $\xi^0 = e^{-A}$, and all other components zero. It is null: using $g_{rr} = 1$ and $g_{00} = e^{2A}\eta_{00} = -e^{2A}$,

$$g_{MN}\xi^M\xi^N = g_{rr}(\xi^r)^2 + g_{00}(\xi^0)^2 = 1 + (-e^{2A})\,e^{-2A} = 1 - 1 = 0. \tag{54.195}$$

Contract the Einstein equation $R_{MN} - \frac{1}{2}g_{MN}R = \kappa^2 T_{MN}$ with $\xi^M\xi^N$. Because ξ is null, the $\frac{1}{2}g_{MN}R$ term drops ($g_{MN}\xi^M\xi^N = 0$), leaving $R_{MN}\xi^M\xi^N = \kappa^2 T_{MN}\xi^M\xi^N$. The left side is computed from Eq. (54.179): $R_{rr}(\xi^r)^2 + R_{00}(\xi^0)^2 = -d(A'' + A'^2) + \big[-e^{2A}\eta_{00}(A'' + dA'^2)\big]e^{-2A}$. With $\eta_{00} = -1$ the second term is $+(A'' + dA'^2)$, so the sum is $-d(A'' + A'^2) + (A'' + dA'^2) = -(d-1)A''$. Therefore

$$-(d-1)\,A'' = \kappa^2\, T_{MN}\xi^M\xi^N \;\geq\; 0 \quad\Longrightarrow\quad A'' \leq 0, \tag{54.196}$$

the null energy condition delivering the concavity directly. For the scalar matter of Eq. (54.177) one checks $T_{MN}\xi^M\xi^N = \phi'^2 \geq 0$ explicitly — recovering Eq. (54.183) — but Eq. (54.196) shows $A'' \leq 0$ holds for *any* matter obeying the null energy condition, which is why the theorem is insensitive to the details of the bulk field content.

Monotonicity. Differentiate Eq. (54.193):

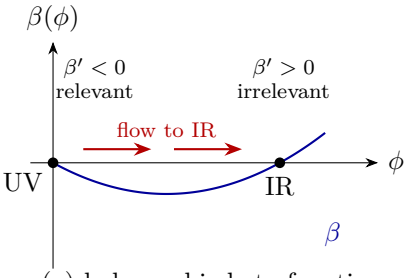
$$c'(r) = -(d-1)\,C_d\,\frac{A''(r)}{\big(A'(r)\big)^d} = \frac{(d-1)\,C_d}{\big(A'\big)^d}\cdot\big(-A''\big). \tag{54.197}$$

With $C_d > 0$, $A' > 0$ (warp growing toward the boundary), and $-A'' \geq 0$ by Eq. (54.196), every factor is non-negative: $c'(r) \geq 0$, with equality iff $A'' = 0$ iff $T_{MN}\xi^M\xi^N = 0$ iff $\phi' = 0$, a stationary point. Integrating from the IR ($r \to -\infty$) to the UV ($r \to +\infty$), c never decreases, so $c_{\rm UV} = c(+\infty) \geq c(-\infty) = c_{\rm IR}$. At the endpoints c equals the fixed-point central charges by Theorem 54.19, giving $c_{\rm UV} \geq c_{\rm IR}$. □

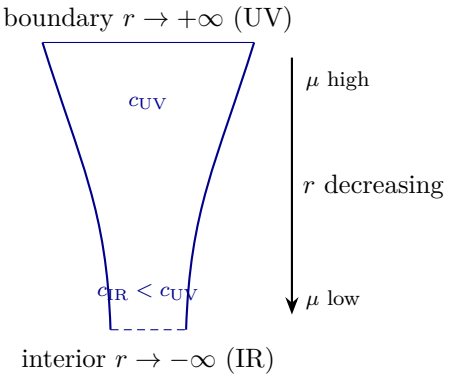
Physical Insight

The irreversibility of the renormalization group — a deep, scheme-independent statement about quantum field theory — is, holographically, the statement that a horizon-free gravitational geometry sourced by physical (positive-energy) matter cannot make its warp factor accelerate outward: $A'' \leq 0$. Degrees of freedom are lost along the flow because the bulk geometry funnels inward, the AdS throat narrowing from the wide UV boundary to the narrower IR. The same null energy condition that forbids traversable wormholes and underlies the area theorems of black-hole mechanics is, viewed through the dictionary, the engine of the a-theorem. A monotonicity that took decades and a subtle dilaton-effective-action argument to establish field-theoretically (Theorem 52.19) becomes, at strong coupling, a single contraction of the Einstein equations with a null vector.

Synthesis with the benchmark theories. The geometry of this section is the strong-coupling face of structures the book built perturbatively. The fixed-point/flow picture is the same one ϕ^4 theory traced from the Wilsonian shell-integration of Section 23.1.2 to the Wilson–Fisher fixed point of Theorem 23.36: a UV fixed point (there free-field Gaussian, here the UV AdS), a relevant deformation that triggers a flow (there the ϕ^2 mass operator, here the scalar's source mode $z^{d-\Delta}$ with $\Delta < d$), and an IR fixed point with fewer degrees of freedom. The relevant/marginal/irrelevant classification of Theorem 23.23 reappears intact as the sign of the beta-function slope Eq. (54.189), now derived from a bulk falloff rather than an engineering dimension. Yang–Mills theory contributes the complementary lesson: the asymptotically free running of Eq. (27.1)



(a) holographic beta function



(b) the RG throat, $A'' \leq 0$

Figure 54.8: The holographic renormalization group. (a) The beta function Eq. (54.187) of a flow with two fixed points: a UV fixed point at $\phi = 0$ with negative slope $\beta' = \Delta_{\mathrm{UV}} - d < 0$ (a relevant operator, Eq. (54.189)) that destabilizes it, and an IR fixed point where the same operator has become irrelevant ($\beta' > 0$). The radial coordinate carries the coupling from UV to IR. (b) The dual geometry: a domain wall Eq. (54.178) whose warp factor is concave, $A'' \leq 0$ Eq. (54.183), by the bulk null energy condition. The throat narrows from the wide UV boundary to the narrow IR interior, and the c-function Eq. (54.193) decreases monotonically along the way (Theorem 54.20) — the gravity dual of the a-theorem.

is a flow whose UV fixed point is the trivial (free) theory and which has *no* weakly coupled IR fixed point — the coupling grows without bound, confinement intervening. The holographic flows here are its strong-coupling counterparts, in which the IR is a genuine interacting CFT (a nontrivial AdS) reachable only because the gravity description resums the coupling. In both threads the abstract content — a beta function with zeros, a monotone counting function decreasing toward the IR — is identical; holography supplies the picture in which that content is visible as the literal shape of a higher-dimensional spacetime.

54.6.6 Wilsonian holography: the radial cutoff as a coarse-graining scale

The picture so far identifies radial *position* with scale and radial *evolution* with running. The Wilsonian viewpoint of Chapter 23 demands more: that integrating out the high-energy degrees of freedom down to a scale μ_c produce a definite effective action $S_{\mathrm{eff}}[\mu_c]$, and that lowering μ_c generate a flow equation for it. Holography realizes this literally. Cut the bulk at a finite radius $r = r_c$; integrate the bulk path integral over the region $r < r_c$ (from the deep interior or horizon out to the slice); the result is a functional of the field data on the slice r_c, and it *is* the

Wilsonian effective action of the boundary theory at the cutoff scale $\mu_c \sim e^{A(r_c)}$. The bulk region $r < r_c$ that has been integrated out is the holographic image of the modes with energy above μ_c; the slice carries the effective theory below it. We now make this precise and show that the radial evolution of the on-shell action is governed by a Hamilton–Jacobi equation that is the Callan–Symanzik equation of Theorem 24.19.

Radial canonical structure. Treat the radial coordinate r as "time" and foliate the bulk by constant-r slices, each carrying the induced metric $\gamma_{\mu\nu} = e^{2A}\eta_{\mu\nu}$ and the scalar ϕ. The extrinsic curvature of a slice measures how it bends as r advances,

$$K_{\mu\nu} = \tfrac{1}{2}\,\partial_r \gamma_{\mu\nu} = A'\,\gamma_{\mu\nu}, \qquad K \equiv \gamma^{\mu\nu}K_{\mu\nu} = d\,A', \tag{54.198}$$

so the warp slope A' is (up to the factor d) the trace of the extrinsic curvature. The momenta canonically conjugate to $\gamma_{\mu\nu}$ and ϕ in this radial Hamiltonian formulation are, from the gravitational and scalar parts of Eq. (54.177) respectively,

$$\pi^{\mu\nu} = \frac{1}{2\kappa^2}\sqrt{\gamma}\,(K^{\mu\nu} - K\gamma^{\mu\nu}), \qquad \pi_\phi = \sqrt{\gamma}\,\phi', \tag{54.199}$$

the standard ADM gravitational momentum and the radial momentum of the scalar. The on-shell action $S_{\rm cl}[\gamma,\phi]$ as a functional of the slice data is the Hamilton–Jacobi principal function, and the momenta are its functional gradients,

$$\pi^{\mu\nu} = \frac{\delta S_{\rm cl}}{\delta \gamma_{\mu\nu}}, \qquad \pi_\phi = \frac{\delta S_{\rm cl}}{\delta \phi}. \tag{54.200}$$

The Wilsonian action is the superpotential. For a flat, homogeneous slice the leading local part of the on-shell action is a spacetime integral of a local density,

$$S_{\rm cl} = \int \mathrm{d}^d x\,\sqrt{\gamma}\,W(\phi) + (\text{derivative terms}), \tag{54.201}$$

and we now show that this W is exactly the fake superpotential of Section 54.6.3, so that the Wilsonian effective potential at the cutoff slice and the function controlling the flow are one and the same object. Insert Eq. (54.201) into the Hamilton–Jacobi relations Eq. (54.200). For the scalar, using $\delta\sqrt{\gamma}/\delta\phi = 0$, $\delta S_{\rm cl}/\delta\phi = \sqrt{\gamma}\,W'(\phi)$, so Eq. (54.199) gives $\sqrt{\gamma}\,\phi' = \sqrt{\gamma}\,W'$, i.e.

$$\phi' = W'(\phi), \tag{54.202}$$

the first flow equation. For the metric, $\delta(\sqrt{\gamma})/\delta\gamma_{\mu\nu} = \tfrac{1}{2}\sqrt{\gamma}\,\gamma^{\mu\nu}$, so $\pi^{\mu\nu} = \tfrac{1}{2}\sqrt{\gamma}\,\gamma^{\mu\nu}W$; taking the trace, $\pi \equiv \gamma_{\mu\nu}\pi^{\mu\nu} = \tfrac{d}{2}\sqrt{\gamma}\,W$. The trace of the ADM

momentum Eq. (54.199) is $\pi = \frac{1}{2\kappa^2}\sqrt{\gamma}(K - dK) = -\frac{(d-1)}{2\kappa^2}\sqrt{\gamma}\,K = -\frac{d(d-1)}{2\kappa^2}\sqrt{\gamma}\,A'$, using $K = dA'$. Equating the two expressions for π and cancelling $\frac{d}{2}\sqrt{\gamma}$,

$$A' = -\frac{\kappa^2}{d-1}\,W(\phi), \tag{54.203}$$

the second flow equation. Thus the Hamilton–Jacobi relations Eq. (54.200) for the local ansatz Eq. (54.201) reproduce the first-order flow Eq. (54.185) exactly, and substituting them back into the radial Hamiltonian constraint (the bulk version of $H = 0$, which on the flat homogeneous slice is the constraint Eq. (54.181)) returns the consistency condition Eq. (54.184) as the *Hamilton–Jacobi equation for* W. The fake superpotential is the on-shell radial action density: the local part of the Wilsonian effective action at the cutoff slice.

Hamilton–Jacobi is Callan–Symanzik. The content of Eqs. (54.202) and (54.203) is that the radial derivative of the on-shell action is fixed by its slice data — a first-order evolution in the radial "time" $r = L\ln\mu$. Splitting the on-shell action into its local, divergent part (the counterterms of Theorem 54.5, which are exactly the terms Eq. (54.201)) and a finite remainder Γ identified through the GKP–Witten relation Eq. (53.162) with the boundary generating functional, the Hamilton–Jacobi equation organizes into an inhomogeneous first-order equation for Γ in $\ln\mu$, with the beta function Eq. (54.187) multiplying $\partial_\phi\Gamma$ and an anomalous-dimension term from the rescaling of $\sqrt{\gamma}$. This is structurally identical to the Callan–Symanzik equation Eq. (24.172) of Theorem 24.19: a scale derivative of a generating functional, plus the beta function times the coupling derivative, plus anomalous-dimension terms, equal to a (local, anomaly) inhomogeneity. The Wilsonian shell-integration of Theorems 23.13 and 23.15, which lowered a momentum cutoff and generated a flow of the effective action, is mirrored by lowering the radial slice r_c; the running couplings of Chapter 24 are the slice values of the bulk fields. The radial direction was the renormalization group all along, and the bulk equations of motion were its flow equations.

Worked Example 54.21 (A cubic superpotential: an explicit flow with $c_{\mathrm{IR}} < c_{\mathrm{UV}}$)**.** We exhibit a complete flow, compute the dimensions at both ends, verify that the deforming operator is relevant in the UV and irrelevant in the IR, and check the c-theorem inequality explicitly. To declutter the constants we adopt the normalization $\kappa^2 = d - 1$ (a choice of units for ϕ, stated once), in which the flow equations Eq. (54.185) read $\phi' = W'$, $A' = -W$, the beta function Eq. (54.187) is $\beta = -W'/W$, and the consistency condition Eq. (54.184) is $V = \frac{1}{2}W'^2 - \frac{d}{2}W^2$. Take the cubic superpotential

$$W(\phi) = -\frac{1}{L_0}\left(1 + \tfrac{1}{2}\,a\,\phi^2 - \tfrac{1}{3}\,b\,\phi^3\right), \qquad a, b > 0,\ \ L_0 > 0. \tag{54.204}$$

Its derivative $W' = -\frac{1}{L_0}(a\phi - b\phi^2) = -\frac{1}{L_0}\phi(a - b\phi)$ vanishes at $\phi = 0$ and at $\phi_{\mathrm{I}} = a/b$ — the two fixed points.

The UV fixed point ($\phi = 0$). Here $W(0) = -1/L_0$, so by Eq. (54.186) the AdS radius is $L_{\mathrm{UV}} = L_0$, and $W''(0) = -a/L_0$. The beta-function slope Eq. (54.188) is $\beta'(0) = L_{\mathrm{UV}} W''(0) = L_0 \cdot (-a/L_0) = -a$. Hence by Eq. (54.189) the dual operator has dimension $\Delta_{\mathrm{UV}} = d + \beta'(0) = d - a$. Since $a > 0$, $\Delta_{\mathrm{UV}} < d$: the operator is *relevant*, and the flow it triggers is genuine. As a check of Eq. (54.192), the scalar mass there is $m^2 = V''(0)$; from Eq. (54.190) with $\kappa^2 = d - 1$, $V''(0) = (W_0')^2 - d\, W_0 W_0'' = (a/L_0)^2 - d(-1/L_0)(-a/L_0) = \frac{a^2 - da}{L_0^2}$, so $m^2 L_{\mathrm{UV}}^2 = a^2 - da = (d-a)(-a) = \Delta_{\mathrm{UV}}(\Delta_{\mathrm{UV}} - d)$, the mass–dimension relation Eq. (53.112) confirmed.

The IR fixed point ($\phi_{\mathrm{I}} = a/b$). Evaluating Eq. (54.204),

$$W(\phi_{\mathrm{I}}) = -\frac{1}{L_0}\left(1 + \tfrac{1}{2} a\, \frac{a^2}{b^2} - \tfrac{1}{3} b\, \frac{a^3}{b^3}\right) = -\frac{1}{L_0}\left(1 + \frac{a^3}{6b^2}\right), \tag{54.205}$$

so $|W(\phi_{\mathrm{I}})| > |W(0)|$ and the IR AdS radius $L_{\mathrm{IR}} = 1/|W(\phi_{\mathrm{I}})| = L_0 (1 + \frac{a^3}{6b^2})^{-1}$ is *smaller* than $L_{\mathrm{UV}} = L_0$. The second derivative is $W''(\phi_{\mathrm{I}}) = -\frac{1}{L_0}(a - 2b\phi_{\mathrm{I}}) = -\frac{1}{L_0}(a - 2a) = +\frac{a}{L_0} > 0$, giving $\beta'(\phi_{\mathrm{I}}) = L_{\mathrm{IR}} W''(\phi_{\mathrm{I}}) = +a\,(1 + \frac{a^3}{6b^2})^{-1} > 0$. The same operator that was relevant at the UV is *irrelevant* at the IR ($\Delta_{\mathrm{IR}} = d + \beta'(\phi_{\mathrm{I}}) > d$), as it must be for the IR fixed point to be stable — nothing remains to drive the flow further. The trajectory is the gradient flow $\phi' = W' = -\frac{1}{L_0}\phi(a - b\phi)$: between the fixed points $\phi' < 0$, so as r decreases (UV→IR) the field climbs from 0 to a/b, reaching each endpoint exponentially, $\phi \sim e^{-(a/L_0)r}$ near the UV and $\phi - \phi_{\mathrm{I}} \sim e^{(a/L_0)r}$ near the IR. The radial coordinate is the monotone clock of Theorem 54.17.

The c-theorem inequality. The central charges are $c \propto L_\star^{d-1}$ by Theorem 54.19, so

$$\frac{c_{\mathrm{IR}}}{c_{\mathrm{UV}}} = \left(\frac{L_{\mathrm{IR}}}{L_{\mathrm{UV}}}\right)^{d-1} = \left(1 + \frac{a^3}{6b^2}\right)^{-(d-1)} < 1, \tag{54.206}$$

so $c_{\mathrm{IR}} < c_{\mathrm{UV}}$ strictly, in accordance with Theorem 54.20. The decrease is monotone along the whole flow, not merely between endpoints, because $A'' = -\phi'^2/(d-1) \le 0$ throughout (here $\kappa^2 = d - 1$). For a concrete number take $d = 4$, $a = 1$, $b = 1$: then $\Delta_{\mathrm{UV}} = 3$ (a relevant scalar, as for a mass operator), $L_{\mathrm{IR}}/L_{\mathrm{UV}} = (1 + \frac{1}{6})^{-1} = \frac{6}{7}$, and the IR central charge is reduced by the factor $(6/7)^3 \approx 0.63$ — the flow has shed roughly a third of its degrees of freedom in passing from the ultraviolet to the infrared.

The radial-direction-as-scale picture and the bulk/boundary split this section has made quantitative — UV physics at the boundary, IR physics deep in the interior, the warp factor counting degrees of freedom that only ever decrease inward — is also the seed of the deepest entry in the holographic dictionary, the one relating boundary entanglement to bulk geometry. The next chapters take it up: Chapter 55 develops the field-theoretic notion of entanglement entropy

that the radial geometry will turn out to encode, and Chapter 56 establishes the Ryu–Takayanagi prescription, in which a boundary region's entanglement entropy is the area of a bulk minimal surface reaching into exactly the radial depth — the scale — that this section has shown to be the renormalization group.

Further reading

The Witten-diagram calculus and the GKP–Witten relation originate in Gubser et al. [242] and Witten [522], following Maldacena [331]; the canonical pedagogical treatment of bulk propagators, contact and exchange diagrams, and D-functions is the TASI lectures of D'Hoker and Freedman [146], with the comprehensive review by Aharony et al. [9] surveying the whole subject. Holographic renormalization, the Fefferman–Graham expansion, and the covariant counterterms are developed systematically in Skenderis [444]. The conformal-block and Mellin organization of holographic correlators, and the bulk reading of the double-trace spectrum, are treated in Heemskerk et al. [261], Fitzpatrick et al. [194], and Penedones et al. [390]. Black-brane thermodynamics, the Hawking–Page transition, and its interpretation as confinement/deconfinement are due to Hawking and Page [258] and Witten [522], with the strong/weak factor of $\frac{3}{4}$ computed in Gubser et al. [241]. The Lorentzian (retarded) prescription and the shear viscosity are due to Son and Starinets [452] and Policastro et al. [405], with the universal ratio and its conjectured bound in Kovtun et al. [307]; the field-theoretic a-theorem the holographic c-theorem mirrors is Komargodski and Schwimmer [301]. Textbook accounts of the entire chapter are Nastase [359], Freedman and Van Proeyen [199], and — with the transport and condensed-matter emphasis — Hartnoll et al. [253].

Chapter 55

Entanglement Entropy in QFT

The vacuum is not empty. We have met this fact already in three guises: the zero-point fluctuations and normal ordering of Chapter 9, the short-distance singularity of the equal-time two-point function forced by microcausality, and the construction of the ground state, mode by mode, as the boundary value of a Euclidean path integral in Chapter 10. This chapter reframes that old observation in informational language. If the vacuum $|0\rangle$ is a correlated state and we agree to observe only the field within a spatial region A, discarding the complement, then what we keep is mixed — precisely because it was entangled with what we threw away. The number that quantifies this is the entanglement entropy S_A, and the chapter is the disciplined study of it: how to define it, how to compute it, what is universal in it, and — a theme we honor rather than hide — in what precise sense it is not, by itself, a finite observable at all.

The development imports little and builds much. From Chapter 9 we take the free scalar of ϕ^4 theory, its mode expansion, vacuum, and equal-time correlators, which become the explicit kernel of every free-field computation here; from Chapter 10 we take the Euclidean preparation of the vacuum, the single fact from which the entire path-integral construction of the reduced density matrix flows. The conformal apparatus of Chapter 47 — radial quantization, the state–operator map, correlators fixed by symmetry — and the two-dimensional machinery of Chapter 48 — the Virasoro algebra, the central charge, and the anomalous Schwarzian transformation of the stress tensor — supply the exactly solvable two-dimensional results, and the boost Noether charge of Chapter 7 furnishes the modular Hamiltonian of a half-space. The functional-determinant and zeta-regularization technology of Sections E.2 and E.3 underwrites the free-field area law, and Zamolodchikov's c-theorem from Chapter 52 reappears, recast as a statement about entanglement.

The arc runs from definition to computation to structure. Section 55.1 builds the reduced density matrix and the von Neumann and Rényi entropies in the safe finite-dimensional setting, proving the Schmidt decomposition, Klein's

inequality, concavity and subadditivity, and confronting at once the two features that make the field-theoretic problem genuinely subtle: the ultraviolet divergence of S_A and the failure of the Hilbert space to factorize across a sharp boundary. Section 55.2 converts the intractable operator logarithm into geometry — the replica trick: $\operatorname{Tr}\rho_A^n = Z_n/Z_1^n$ is a partition function on an n-sheeted branched cover, legitimized by Carlson's uniqueness theorem and, for a single interval, repackaged as a twist-operator correlator. Section 55.3 solves the one case where the geometry is trivial, the half-space, and reads the cut path integral as angular evolution by the boost: the vacuum restricted to a wedge is exactly thermal (Bisognano–Wichmann, Unruh), and its modular Hamiltonian is the local boost generator.

The remaining sections harvest these tools. Section 55.4 computes the twist dimension from the conformal anomaly and delivers the flagship result $S_A = \frac{c}{3}\log(\ell/\epsilon)$, together with its finite-size and finite-temperature deformations, and closes ϕ^4 theory on the entanglement side at the Ising value $c = \frac{1}{2}$. Section 55.5 establishes the higher-dimensional area law by an explicit Gaussian-state computation on the free scalar, dissects the full tower of ultraviolet divergences, and isolates the single universal term — a logarithm in even d, a constant in odd d — that counts degrees of freedom and runs monotonically under the renormalization group. Section 55.6 then builds the quantities that survive the continuum: relative entropy, its modular decomposition and ultraviolet finiteness, monotonicity and strong subadditivity, the first law of entanglement $\delta S_A = \delta\langle K_A\rangle$, and the bridge from information inequalities to energy conditions. These last structures are exactly the inputs that the holographic constructions of Chapters 56 and 57 will geometrize; the vacuum that Chapter 9 found correlated and Chapter 10 prepared as a path integral is shown here to carry an information-theoretic skeleton, and holography is the claim that the skeleton is spacetime.

55.1 Reduced Density Matrices and the Entanglement Entropy

The vacuum of an interacting — indeed of a free — quantum field is not the inert, structureless object the word "empty" suggests. We have already seen it fluctuate (the zero-point energy and normal ordering of Chapter 9), seen its short-distance correlations forced on us by microcausality, and seen it manufactured, mode by mode, as the boundary state of a Euclidean path integral (Chapter 10). The thread that runs through all of these facts is *correlation*: the field amplitude at one point is statistically tied to the amplitude at a neighbouring point, even with nothing present. The chapter's reframing of this old observation is informational. If the vacuum $|0\rangle$ is a correlated state, and if we agree to look only at the field within some spatial region A — a ball, a half-space, an interval — discarding all knowledge of the field in the complement, then the part we keep is not in a

pure state of its own. It is mixed, precisely because it was entangled with what we threw away. The question this section makes precise is: *how much* quantum correlation does a region share with its complement, and what is the right number to attach to it. The answer is the entanglement entropy, and building it cleanly — definitions first, then the structural facts, then the two features that make the field-theoretic version genuinely subtle — is the business of this section.

55.1.1 Bipartition and the reduced density matrix

Fix a quantum system whose Hilbert space factorizes into two tensor factors,

$$\mathcal{H} \;=\; \mathcal{H}_A \otimes \mathcal{H}_{\bar{A}}, \tag{55.1}$$

where A labels the degrees of freedom we retain and $\bar{A}$ (read "A-complement", also written A^{c}) the degrees of freedom we trace away. For a spin chain A is a set of sites and $\bar{A}$ the rest; for a quantum field, A is a spatial region and $\bar{A}$ its complement at fixed time — a partition we will have to handle with care, because Eq. (55.1) is exactly the assumption that fails in the continuum (Section 55.1.6). For now we take it as given and develop the formalism in the safe finite-dimensional setting, where every statement is a theorem of linear algebra.

The system is in a state described by a density operator ρ on $\mathcal{H}$: a positive semidefinite, Hermitian, unit-trace operator, $\rho \geq 0$, $\rho = \rho^\dagger$, $\operatorname{Tr}\rho = 1$. A pure state $|\Psi\rangle$ corresponds to the rank-one projector $\rho = |\Psi\rangle\langle\Psi|$. The observables accessible to an experimenter confined to A are the operators of the form $O_A \otimes \mathbf{1}_{\bar{A}}$. We want the single object on $\mathcal{H}_A$ that reproduces every such expectation value. That object is the reduced density matrix, and the operation that produces it is the partial trace.

Definition 55.1 (Partial trace)**.** Let $\{|j\rangle_{\bar{A}}\}_j$ be an orthonormal basis of $\mathcal{H}_{\bar{A}}$. The *partial trace over* $\bar{A}$ is the linear map $\operatorname{Tr}_{\bar{A}} \colon \mathcal{B}(\mathcal{H}_A \otimes \mathcal{H}_{\bar{A}}) \to \mathcal{B}(\mathcal{H}_A)$ defined by

$$\operatorname{Tr}_{\bar{A}}(M) \;=\; \sum_j (\mathbf{1}_A \otimes \langle j|_{\bar{A}})\, M\, (\mathbf{1}_A \otimes |j\rangle_{\bar{A}}). \tag{55.2}$$

On a product operator it acts as $\operatorname{Tr}_{\bar{A}}(O_A \otimes O_{\bar{A}}) = O_A \operatorname{Tr}(O_{\bar{A}})$, and it extends to all of $\mathcal{B}(\mathcal{H})$ by linearity.

The map Eq. (55.2) is independent of the chosen basis of $\mathcal{H}_{\bar{A}}$: a change of basis $|j\rangle_{\bar{A}} \mapsto \sum_k U_{jk}\,|k\rangle_{\bar{A}}$ with U unitary leaves the sum invariant, because $\sum_j U_{jk}\overline{U_{jk'}} = \delta_{kk'}$ collapses the two inserted resolutions back to one. It is the unique linear map satisfying $\operatorname{Tr}_A\!\big[(\operatorname{Tr}_{\bar{A}} M)\, O_A\big] = \operatorname{Tr}\!\big[M\,(O_A \otimes \mathbf{1}_{\bar{A}})\big]$ for all O_A, which is the property we actually need.

Definition 55.2 (Reduced density matrix)**.** For a global state ρ on $\mathcal{H}_A \otimes \mathcal{H}_{\bar{A}}$, the *reduced density matrix of* A is

$$\rho_A \;=\; \mathrm{Tr}_{\bar{A}}\, \rho. \tag{55.3}$$

When the global state is pure, $\rho = |\Psi\rangle\langle\Psi|$, we write $\rho_A = \mathrm{Tr}_{\bar{A}}\, |\Psi\rangle\langle\Psi|$.

Proposition 55.3 (ρ_A is a density matrix that encodes all of A's statistics)**.** *The reduced density matrix Eq. (55.3) is Hermitian, positive semidefinite, and has unit trace; and for every operator O_A acting on $\mathcal{H}_A$,*

$$\big\langle O_A \otimes \mathbf{1}_{\bar{A}} \big\rangle_\rho \;\equiv\; \mathrm{Tr}\big[\rho\,(O_A \otimes \mathbf{1}_{\bar{A}})\big] \;=\; \mathrm{Tr}_A\big(\rho_A\, O_A\big). \tag{55.4}$$

Proof. Hermiticity is immediate from Eq. (55.2): $(\mathrm{Tr}_{\bar{A}}\,\rho)^\dagger = \sum_j (\mathbf{1}\otimes\langle j|)\rho^\dagger(\mathbf{1}\otimes|j\rangle) = \mathrm{Tr}_{\bar{A}}\,\rho$ since $\rho^\dagger = \rho$. For positivity, let $|\chi\rangle \in \mathcal{H}_A$ be arbitrary; then

$$\langle\chi|\,\rho_A\,|\chi\rangle = \sum_j \big(\langle\chi|\otimes\langle j|\big)\,\rho\,\big(|\chi\rangle\otimes|j\rangle\big) \geq 0, \tag{55.5}$$

each term being the expectation of the positive operator ρ in the state $|\chi\rangle\otimes|j\rangle$. Unit trace follows from $\mathrm{Tr}_A\,\rho_A = \sum_i\sum_j (\langle i|\otimes\langle j|)\rho(|i\rangle\otimes|j\rangle) = \mathrm{Tr}_{\mathcal{H}}\,\rho = 1$, the inner double sum running over a full product basis of $\mathcal{H}$. Finally, taking $M = \rho(O_A\otimes\mathbf{1}_{\bar{A}})$ in the defining property of the partial trace, $\mathrm{Tr}_A[(\mathrm{Tr}_{\bar{A}}\,\rho)O_A] = \mathrm{Tr}[\rho(O_A\otimes\mathbf{1}_{\bar{A}})]$, which is exactly Eq. (55.4). □

Equation Eq. (55.4) is the operational meaning of ρ_A: *no measurement confined to A can distinguish the global state ρ from the local state ρ_A.* All accessible information about the region is packed into this one operator. The price of confinement is that even when the global state is pure — a state of maximal knowledge — the local state ρ_A is generically mixed. That mixedness is not classical ignorance about which pure state we prepared; it is the shadow cast on A by the entanglement between A and $\bar{A}$. Quantifying it is the next step.

55.1.2 The von Neumann and Rényi entropies

A density matrix is mixed to the extent that its spectrum is spread out, and the canonical functional that measures the spread of a probability distribution — here the spectrum $\{\lambda_i\}$ of ρ_A, a set of nonnegative eigenvalues summing to one — is the Shannon–von Neumann entropy.

Definition 55.4 (Entanglement entropy)**.** The *entanglement entropy* of the region A in the state ρ is the von Neumann entropy of the reduced density matrix,

$$S_A \;=\; -\,\mathrm{Tr}(\rho_A \log \rho_A) \;=\; -\sum_i \lambda_i \log \lambda_i, \tag{55.6}$$

where $\{\lambda_i\}$ are the eigenvalues of ρ_A, and $0\log 0 \equiv 0$ by the limit $x\log x \to 0$ as $x \to 0^+$.
