Worked Example 63.13 (The leading soft *photon* factor and charge conservation)**.** Consider first a charged scalar leg, to keep the Dirac algebra out of the way; we restore arbitrary spin at the end and find the same answer, which is the first lesson — universality. Let leg i be an outgoing scalar of momentum p_i and charge Q_i (in units of e; its electric charge is $e\,Q_i$), emitting an outgoing photon of momentum q and polarization ϵ^μ. The scalar QED Feynman rule for the photon–scalar vertex, with the line momenta as in Eq. (63.67), is $-ieQ_i\,(2p_i + q)^\mu$, and the internal scalar propagator carrying $p_i + q$ is $i/[(p_i + q)^2 - m_i^2]$. The diagrammatic contribution of leg i factorizes as

$$\mathcal{M}_{n+1}\big|_{\text{leg } i} = \underbrace{(-ieQ_i)\,(2p_i + q)^\mu \epsilon_\mu^*}_{\text{vertex}}\ \underbrace{\frac{i}{2\,p_i{\cdot}q + q^2}}_{\text{propagator}}\ \mathcal{M}_n(\dots, p_i, \dots), \tag{63.68}$$

because, with the soft momentum stripped off, the line i re-enters $\mathcal{M}_n$ exactly on shell at momentum p_i. Take $q \to 0$: in the numerator $(2p_i + q)\cdot\epsilon^* \to 2\,p_i{\cdot}\epsilon^*$, and in the denominator $q^2 \to 0$, so

$$\mathcal{M}_{n+1}\big|_{\text{leg } i} \xrightarrow[q\to 0]{} (-ieQ_i)\,(2\,p_i{\cdot}\epsilon^*)\,\frac{i}{2\,p_i{\cdot}q}\,\mathcal{M}_n \;=\; e\,Q_i\,\frac{p_i{\cdot}\epsilon^*}{p_i{\cdot}q}\,\mathcal{M}_n, \tag{63.69}$$

where the two explicit factors of i combine, $(-i)(i) = +1$, and a factor of two cancels between numerator and denominator. Summing over all external legs gives the leading soft photon factor,

$$\boxed{S_\gamma^{(0)} = e\sum_{i=1}^{n} Q_i\,\frac{p_i{\cdot}\epsilon^*}{p_i{\cdot}q}}, \qquad \lim_{q\to 0}\mathcal{M}_{n+1} = S_\gamma^{(0)}\,\mathcal{M}_n + O(q^0). \tag{63.70}$$

This is Weinberg's soft photon factor. It is the same eikonal current that appeared in the infrared analysis of QED, Eq. (19.180): there it organised the cancellation of infrared divergences between virtual and real soft emission (Sections 19.6 and 19.6.3); here it is the universal residue of the soft pole. The two are one structure seen from two sides — the soft theorem is the statement that the QED infrared is controlled by a quantity that knows nothing about the hard process.

Spin-independence. Replace the scalar by a Dirac fermion of momentum p_i. The vertex is now $-ieQ_i\gamma^\mu$, the propagator numerator is $i(\not{p}_i + \not{q} + m_i)$, and the leg ends on the external spinor $\bar{u}(p_i)$. The numerator of Eq. (63.68) becomes, at leading order (dropping $\not{q}$),

$$\bar{u}(p_i)\,\gamma^\mu \epsilon^*_\mu\,(\not{p}_i + m_i) = \bar{u}(p_i)\Big[2\,p_i\!\cdot\!\epsilon^* - (\not{p}_i - m_i)\,\not{\epsilon}^*\Big] = 2\,(p_i\!\cdot\!\epsilon^*)\,\bar{u}(p_i), \tag{63.71}$$

where we used the gamma identity $\not{\epsilon}^*\not{p}_i = 2\,p_i\!\cdot\!\epsilon^* - \not{p}_i\not{\epsilon}^*$ (Appendix C) and the Dirac equation $\bar{u}(p_i)(\not{p}_i - m_i) = 0$. The result is identical to the scalar numerator $2\,p_i\!\cdot\!\epsilon^*$, so the soft factor Eq. (63.70) is independent of the spin of the emitting leg. The soft photon does not resolve the structure of the particle it is emitted from; it sees only the momentum and the charge. This is the precise sense in which the soft factor is *universal*.

Charge conservation is the gauge-invariance content. A physical amplitude must be invariant under the gauge transformation $\epsilon^*_\mu \to \epsilon^*_\mu + \alpha\, q_\mu$ of the soft photon's polarization (the Ward identity; the longitudinal photon decouples, as established for the gauge principle in Section 8.1 and for on-shell amplitudes in Chapter 18). Under this shift the soft factor changes by

$$\delta S^{(0)}_\gamma = e\sum_i Q_i\,\frac{p_i\!\cdot\!(\alpha\, q)}{p_i\!\cdot\! q} = \alpha\, e\sum_i Q_i. \tag{63.72}$$

Gauge invariance of the leading soft amplitude therefore requires

$$\sum_{i=1}^{n} Q_i = 0, \tag{63.73}$$

which (in the all-outgoing convention) is exactly conservation of electric charge. The soft theorem does not assume charge conservation; it *forces* it. A theory whose soft emission fails to factorize into Eq. (63.70) with a conserved total charge is not gauge-invariant, hence not a consistent theory of a massless spin-1 field. This is the first instance of the chapter's recurring theme: a structural "axiom" (here, charge conservation) is an output of consistency at the boundary of phase space.

Figure 63.5 draws the factorization that produces the pole.

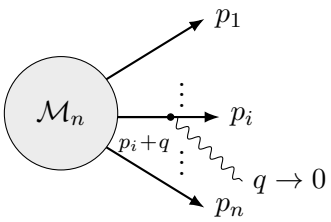

Figure 63.5: The leading soft pole. As the photon (or graviton) momentum $q \to 0$, the internal line carrying $p_i + q$ goes on shell, Eq. (63.67), and the amplitude factorizes into a universal soft factor times the hard amplitude $\mathcal{M}_n$. Only emission from external legs produces the $1/q$ singularity.

The soft *graviton* factor and the equivalence principle. The same construction with a graviton replaces the charge eQ_i by the gravitational coupling and the single polarization vector ϵ^μ by the symmetric, traceless, transverse graviton polarization $\epsilon_{\mu\nu}$. We write the metric as $g_{\mu\nu} = \eta_{\mu\nu} + \kappa\, h_{\mu\nu}$ with $\kappa = \sqrt{32\pi G}$, so that matter couples minimally through $-\frac{\kappa}{2} h_{\mu\nu} T^{\mu\nu}$ with $T^{\mu\nu}$ the stress tensor. For an outgoing scalar of momentum p_i the leading graviton emission vertex is $-i\frac{\kappa}{2}\,(2p_i^\mu)(p_i^\nu)$ symmetrised, whose contraction with the traceless $\epsilon_{\mu\nu}$ keeps only the $p_i^\mu p_i^\nu$ piece (the $\eta^{\mu\nu}$ terms in $T^{\mu\nu}$ die against the traceless polarization). With the same on-shell propagator $i/(2p_i\!\cdot\! q)$, leg i contributes

$$\mathcal{M}_{n+1}\big|_{\text{leg } i} \xrightarrow[q\to 0]{} \Big(-i\tfrac{\kappa}{2}\, 2\, p_i^\mu p_i^\nu\Big)\epsilon^*_{\mu\nu}\,\frac{i}{2\,p_i\!\cdot\! q}\,\mathcal{M}_n = \frac{\kappa}{2}\,\frac{\epsilon^*_{\mu\nu}\,p_i^\mu p_i^\nu}{p_i\!\cdot\! q}\,\mathcal{M}_n, \tag{63.74}$$

again with $(-i)(i) = +1$ and a factor of two cancelled. Summing over external legs,

$$\boxed{\,S_h^{(0)} = \frac{\kappa}{2}\sum_{i=1}^{n}\frac{\epsilon^*_{\mu\nu}\,p_i^\mu p_i^\nu}{p_i\!\cdot\! q}\,}\,. \tag{63.75}$$

Two features stand out, and both are physics. First, $S_h^{(0)}$ is, leg by leg, the *square* of the photon soft factor with the charge Q_i replaced by the momentum p_i^μ: setting $\epsilon^*_{\mu\nu} = \epsilon^*_\mu \epsilon^*_\nu$ for a definite-helicity graviton turns Eq. (63.75) into $\frac{\kappa}{2}\sum_i (p_i\!\cdot\!\epsilon^*)^2/(p_i\!\cdot\! q)$, whereas the photon factor is $e\sum_i Q_i\,(p_i\!\cdot\!\epsilon^*)/(p_i\!\cdot\! q)$. The soft graviton is the soft photon "squared," with the universal gravitational charge being energy–momentum itself: this is the infrared shadow of the double copy of Chapter 61, and it advances Yang–Mills theory into gravity through exactly the squaring relation that the double copy installs at every order.

Second, gauge invariance now reads differently and says more. The graviton polarization is defined up to a linearized diffeomorphism, $\epsilon^*_{\mu\nu} \to \epsilon^*_{\mu\nu} + q_\mu \xi_\nu + \xi_\mu q_\nu$ for any ξ^μ. Under this shift, allowing now a possibly leg-dependent gravitational

coupling κ_i to test universality,

$$\delta S_h^{(0)} = \sum_i \frac{\kappa_i}{2} \frac{(q_\mu \xi_\nu + \xi_\mu q_\nu)\, p_i^\mu p_i^\nu}{p_i \cdot q} = \sum_i \frac{\kappa_i}{2} \frac{2\,(p_i \cdot q)(p_i \cdot \xi)}{p_i \cdot q}$$
$$= \sum_i \kappa_i\, (p_i \cdot \xi) = \xi_\mu \sum_i \kappa_i\, p_i^\mu . \tag{63.76}$$

For a photon the analogous quantity, Eq. (63.72), vanished by a *constraint on the charges*, $\sum_i Q_i = 0$. For a graviton the "charges" are the momenta p_i^μ, which are already constrained by momentum conservation, $\sum_i p_i^\mu = 0$. If $\delta S_h^{(0)}$ is to vanish for arbitrary ξ^μ, we need $\sum_i \kappa_i\, p_i^\mu = 0$. Momentum conservation guarantees $\sum_i p_i^\mu = 0$, so $\sum_i \kappa_i p_i^\mu = 0$ holds for all kinematics *only if all the couplings are equal*, $\kappa_i = \kappa$ for every species i. Gauge invariance of the leading soft graviton theorem therefore forces

$$\kappa_i = \kappa \quad \text{for all } i : \qquad \text{gravity couples universally.} \tag{63.77}$$

This is the equivalence principle, derived — not assumed — from the consistency of soft graviton emission with diffeomorphism invariance. It is Weinberg's celebrated 1964 argument: any massless spin-2 particle that couples to matter at all must couple to every species with the same strength, or S-matrix gauge invariance fails. Just as charge conservation was the gauge content of the soft photon theorem, the equivalence principle is the gauge content of the soft graviton theorem. The soft theorems package two of the deepest facts about long-range forces as boundary outputs of the S-matrix.

Physical Insight

The contrast between Eq. (63.73) and Eq. (63.77) is the whole story in one line. For the photon, the couplings Q_i are free but their sum is constrained: charge is conserved. For the graviton, the "couplings" are the momenta, whose sum is already conserved, so the constraint falls instead on the proportionality constant: it must be the same for everyone. One soft theorem says charge is conserved; the other says gravity is universal. Both are statements that the infrared boundary of the S-matrix cannot be deformed without destroying gauge invariance.

This recovers, in covariant momentum-space language, the spinor-helicity soft factor derived for gluons in Section 59.3.4: the color-ordered soft gluon factor $S^{(0)} = \langle a\, b\rangle/(\langle a\, s\rangle\langle s\, b\rangle)$ of Eq. (59.84) is Eq. (63.70) written for a color-adjacent pair a, b of hard legs, with the polarization solved in brackets. The leading soft theorems for photon, gluon, and graviton are one phenomenon in three notations.

63.6.2 Soft theorems as Ward identities of asymptotic symmetries

The soft factors Eqs. (63.70) and (63.75) are exact, derived statements. Their reinterpretation as conservation laws is the bridge to holography, and it is the content of a body of work (Strominger and collaborators, 2013–2018) that we state precisely and scope honestly. The reinterpretation rests on a fact about gauge theories in asymptotically flat spacetime that we now make precise: not all gauge transformations are pure redundancy. Transformations whose parameter does *not* vanish at infinity act nontrivially on the physical radiative data at null infinity, and they generate genuine symmetries with conserved charges. The soft theorems are the Ward identities of these *asymptotic* (or "large") symmetries.

The structure of the correspondence. Massless particles reach the boundary of Minkowski space at null infinity, denoted $\mathcal{I}^+$ for the future and $\mathcal{I}^-$ for the past. $\mathcal{I}^\pm$ is topologically a null cylinder $\mathbb{R}_u \times S^2$, coordinatised by a retarded (advanced) time u and a point $(z, \bar{z})$ on a two-sphere, the *celestial sphere*, which labels the null direction of escape. The radiative phase space of the gauge field lives on $\mathcal{I}^\pm$. A *large gauge transformation* is one whose parameter $\varepsilon(z, \bar{z})$ tends to an angle-dependent constant at $\mathcal{I}^\pm$ rather than decaying; for gravity, the analogous transformations are the *BMS supertranslations*, diffeomorphisms $u \to u + f(z, \bar{z})$ that shift retarded time by an arbitrary function on the celestial sphere, enlarging the Poincaré translations (the constant and $\ell = 1$ modes of f) by an infinite tower of angle-dependent "time translations."

To each such transformation there corresponds a conserved charge $Q^\pm_\varepsilon$, defined as a surface integral over $\mathcal{I}^\pm$, that splits into two pieces:

$$Q^\pm_\varepsilon = Q^{\pm,\,\mathrm{soft}}_\varepsilon + Q^{\pm,\,\mathrm{hard}}_\varepsilon . \tag{63.78}$$

The *soft* part $Q^{\mathrm{soft}}_\varepsilon$ is linear in the gauge field and, when expanded in modes, creates or annihilates a zero-energy (soft) photon/graviton smeared against ε on the celestial sphere. The *hard* part $Q^{\mathrm{hard}}_\varepsilon$ is the flux of the matter charge (or energy–momentum, for gravity) through $\mathcal{I}^\pm$, weighted by ε. The two charges at past and future infinity are tied together by an *antipodal matching* condition across spatial infinity,

$$Q^+_\varepsilon = Q^-_\varepsilon , \tag{63.79}$$

which is the statement that the symmetry is a single symmetry of the S-matrix and not two unrelated ones. Sandwiching the conservation law Eq. (63.79) between an in-state and an out-state and using Eq. (63.78) gives a Ward identity:

$$\langle \mathrm{out} | \left(Q^{+,\mathrm{soft}}_\varepsilon \, \mathbf{S} - \mathbf{S} \, Q^{-,\mathrm{soft}}_\varepsilon \right) | \mathrm{in} \rangle = - \langle \mathrm{out} | \left(Q^{+,\mathrm{hard}}_\varepsilon \, \mathbf{S} - \mathbf{S} \, Q^{-,\mathrm{hard}}_\varepsilon \right) | \mathrm{in} \rangle . \tag{63.80}$$

The left-hand side, by the definition of the soft charge, is the insertion of a soft photon/graviton into the amplitude, integrated against $\varepsilon(z, \bar{z})$ over the celestial

sphere — precisely the left-hand side of the soft theorem Eq. (63.66) smeared in the soft direction. The right-hand side, by the definition of the hard charge, is ε smeared against the matter charge/energy flux, which for a state of hard particles of charges Q_i (momenta p_i) evaluates to the sum $\sum_i Q_i(\dots)$ that is exactly the residue $S^{(0)}$ of Eq. (63.70) (respectively Eq. (63.75)). The equality Eq. (63.80) *is* the leading soft theorem. We summarise the precise statement.

Theorem 63.14 (Soft theorem $\Leftrightarrow$ asymptotic-symmetry Ward identity)**.** *In a local, Lorentz-invariant quantum field theory with a massless spin-1 (respectively spin-2) field in asymptotically flat four-dimensional spacetime, the leading soft photon theorem Eq. (63.70) (respectively the leading soft graviton theorem Eq. (63.75)) is equivalent to the Ward identity Eq. (63.80) for the charges $Q^{\pm}_{\varepsilon}$ generating large $U(1)$ gauge transformations with parameter $\varepsilon(z,\bar z)$ (respectively BMS supertranslations with parameter $f(z,\bar z)$), subject to the antipodal matching Eq. (63.79). The angle-dependent function ε (resp. f) on the celestial sphere is the smearing against which the soft insertion is integrated; choosing it to be a delta function at $(z,\bar z)$ recovers the local soft factor, and integrating against a constant recovers the global conservation law Eq. (63.73) (resp. momentum conservation).*

We do not give the full surface-charge construction here, as the symplectic geometry of $\mathcal{I}^{\pm}$ is a substantial development of its own; the equivalence is established by matching the soft and hard pieces of Eq. (63.80) to the residue and the smearing of the soft factor, which is the calculation Theorem 63.13 carried out at the level of the pole. The physical upshot is the reframing we need: the leading soft theorems are conservation laws for an *infinite-dimensional* symmetry acting at the boundary of spacetime. There are not finitely many conserved charges (the total electric charge; the four-momentum) but a continuum, one for each function $\varepsilon(z,\bar z)$ (one for each $f(z,\bar z)$). It is this infinite tower of boundary charges that a candidate holographic dual must reproduce, and the natural home for an infinite tower of charges labelled by functions on S^2 is a two-dimensional conformal field theory — in which the charges are the modes of a conserved current and a stress tensor.

Historical Note

That gauge invariance of soft emission forces charge conservation and the equality of gravitational couplings is Weinberg's 1964–1965 work; he derived Eqs. (63.73) and (63.77) exactly as above. That the same soft theorems are the Ward identities of the Bondi–van der Burg–Metzner–Sachs (BMS) symmetry discovered in 1962 in the study of gravitational radiation, and of an analogous "large" gauge symmetry for the photon, was understood only fifty years later, in the 2013–2018 program of Strominger and collaborators. The reinterpretation did not change any soft factor; it

changed what they *mean*, and opened the celestial-holography program.

63.6.3 Celestial amplitudes: the Mellin transform to boost eigenstates

If the boundary theory is to be a two-dimensional CFT on the celestial sphere, its observables must transform as CFT correlators under the conformal group of the sphere. The four-dimensional Lorentz group $SO(1,3)$ is isomorphic to $SL(2,\mathbb{C})$, and $SL(2,\mathbb{C})$ acts on the celestial sphere exactly as the global conformal (Möbius) group of a two-dimensional CFT. Ordinary amplitudes, however, are written in a basis of *energy* eigenstates (momentum eigenstates), which transform reducibly and awkwardly under boosts. The remedy is to change basis on each external leg from energy eigenstates to *boost* eigenstates, and that change of basis is a Mellin transform in the energy. We now define it and derive the conformal weight it produces.

Parametrising a massless momentum by the celestial sphere. Any future-pointing null momentum can be written as a positive energy times a null direction,

$$p^\mu = \omega\, \hat{q}^\mu(z,\bar{z}), \qquad \hat{q}^\mu(z,\bar{z}) = \big(1+z\bar{z},\ z+\bar{z},\ -i(z-\bar{z}),\ 1-z\bar{z}\big), \tag{63.81}$$

where $\omega > 0$ is the energy and $(z,\bar{z})$ is the stereographic coordinate of the direction of flight on the celestial sphere; $\hat{q}^2 = 0$ for all $(z,\bar{z})$. Under a Lorentz transformation $\Lambda \in SL(2,\mathbb{C})$ acting as the Möbius map $z \to z' = (az+b)/(cz+d)$ with $ad-bc=1$, the null direction transforms with a conformal (Weyl) factor,

$$\Lambda^\mu{}_\nu\, \hat{q}^\nu(z,\bar{z}) = |cz+d|^2\ \hat{q}^\mu(z',\bar{z}'), \tag{63.82}$$

so that a momentum eigenstate is mapped to one of *rescaled* energy in the rotated direction:

$$p^\mu = \omega\, \hat{q}^\mu(z,\bar{z}) \ \longmapsto\ \Lambda^\mu{}_\nu p^\nu = \omega'\, \hat{q}^\mu(z',\bar{z}'), \qquad \omega' = |cz+d|^2\ \omega. \tag{63.83}$$

A boost in the direction $\hat{q}$ thus acts on its energy as a pure rescaling, $\omega \to e^{\lambda}\omega$ with rapidity λ; on the half-line $\omega \in (0,\infty)$ this is a dilatation. The natural basis to diagonalise a dilatation is not energy eigenstates but its Mellin-conjugate *scaling* eigenstates, which is what motivates the following definition.

Definition 63.15 (Celestial amplitude)**.** Let $A_n(\{\omega_i, z_i, \bar{z}_i; \ell_i\})$ be a momentum-space amplitude for n massless particles of helicities ℓ_i, written in the parametrisation Eq. (63.81). Its *celestial amplitude* is the Mellin transform of each external energy,

$$\widetilde{A}_n(\{\Delta_i, z_i, \bar{z}_i; \ell_i\}) = \prod_{i=1}^{n} \int_0^\infty \mathrm{d}\omega_i\, \omega_i^{\Delta_i - 1}\, A_n(\{\omega_i, z_i, \bar{z}_i; \ell_i\}), \tag{63.84}$$

where the complex parameter Δ_i is the conformal weight assigned to leg i. Equivalently, $\widetilde{A}_n$ is the amplitude evaluated on the *conformal primary wavefunctions* obtained by Mellin-transforming the plane-wave external states.

Why $\Delta = 1 + i\lambda$: the boost-eigenvalue derivation. The value of Δ is not free if the celestial operators are to furnish a unitary, complete basis of single-particle states. We derive the allowed line of Δ from the requirement that the Mellin transform be the unitary harmonic analysis of the boost (dilatation) acting on the single-particle Hilbert space. The Lorentz-invariant one-particle measure is $\widetilde{\mathrm{d}k} = \mathrm{d}^3k/[(2\pi)^3 2\omega]$; in the parametrisation Eq. (63.81), $\mathrm{d}^3k = \omega^2\,\mathrm{d}\omega\,\mathrm{d}\Omega$ with $\mathrm{d}\Omega$ the solid angle, so the energy part of the measure is

$$\frac{\mathrm{d}^3k}{2\omega} \;\propto\; \omega\,\mathrm{d}\omega\,\mathrm{d}\Omega. \tag{63.85}$$

The boost along $\hat{q}$ acts as the dilatation $\omega \to e^{\lambda}\omega$. We seek the eigenfunctions of its self-adjoint generator on the energy Hilbert space $L^2\big((0,\infty), \omega\,\mathrm{d}\omega\big)$. To make the generator self-adjoint in the measure $\omega\,\mathrm{d}\omega$, write the dilatation generator as

$$\hat{D} = -i(\omega\,\partial_\omega + 1), \tag{63.86}$$

the extra $+1$ compensating the weight ω in the measure (so that $\hat{D}$ is symmetric: $\int_0^\infty \omega\,\mathrm{d}\omega\,\bar{f}(\hat{D}g) = \int_0^\infty \omega\,\mathrm{d}\omega\,\overline{(\hat{D}f)}\,g$). Its eigenfunctions are powers ω^s,

$$\hat{D}\,\omega^s = -i(s+1)\,\omega^s, \tag{63.87}$$

with eigenvalue $-i(s+1)$. A self-adjoint operator has real eigenvalues, so $s+1$ must be purely imaginary, $s+1 = i\lambda$ with $\lambda \in \mathbb{R}$, giving the eigenfunctions $\omega^{-1+i\lambda}$, real boost eigenvalue λ. These are precisely the delta-normalizable states: substituting $\omega = e^u$,

$$\int_0^\infty \omega\,\mathrm{d}\omega\,\big(\omega^{-1+i\lambda}\big)\big(\omega^{-1+i\lambda'}\big)^* = \int_0^\infty \frac{\mathrm{d}\omega}{\omega}\,\omega^{\,i(\lambda-\lambda')} = \int_{-\infty}^{\infty} \mathrm{d}u\,e^{\,i(\lambda-\lambda')u} = 2\pi\,\delta(\lambda-\lambda'), \tag{63.88}$$

the Mellin (Plancherel) completeness relation: the boost eigenstates $\{\omega^{-1+i\lambda}\}_{\lambda\in\mathbb{R}}$ are a complete orthogonal basis of $L^2(\omega\,\mathrm{d}\omega)$. The projection onto the eigenstate of boost eigenvalue λ is therefore $\int_0^\infty \omega\,\mathrm{d}\omega\,(\omega^{-1+i\lambda})^*(\,\cdot\,) = \int_0^\infty \mathrm{d}\omega\,\omega^{-i\lambda}(\,\cdot\,)$, which is the Mellin transform of Eq. (63.84) with

$$\boxed{\Delta - 1 = -i\lambda, \quad \text{i.e.} \quad \Delta = 1 + i\lambda, \quad \lambda \in \mathbb{R}} \tag{63.89}$$

(after the conventional sign choice $\lambda \to -\lambda$ that orients the transform). The locus $\Delta = 1 + i\lambda$ is the *principal continuous series* of $SL(2,\mathbb{C})$ on the two-dimensional celestial sphere: it is exactly the set of dimensions for which the celestial operators form a complete, unitary basis. The number 1 is the celestial-sphere analog of $d/2$ for a d-dimensional CFT, here $d = 2$; the imaginary part λ is the boost eigenvalue. We have derived the weight assignment rather than quoted it: $\Delta = 1 + i\lambda$ is forced by unitarity of the change of basis from energy eigenstates to boost eigenstates.

Worked Example 63.16 (Celestial operators transform as 2D conformal primaries)**.** We now show that the Mellin-transformed operator carries the transformation law of a two-dimensional conformal primary, with its conformal dimension fixed by Eq. (63.89) and its two-dimensional *spin* fixed by the four-dimensional helicity through the little-group data of Eq. (58.5). This is the calculation that turns "celestial amplitude" into "CFT correlator."

Let $a_\ell(\omega, z, \bar z)$ denote the annihilation operator of a massless particle of helicity ℓ and momentum $p = \omega\, \hat q(z, \bar z)$. Under a Lorentz transformation $\Lambda \in SL(2, \mathbb{C})$, two things happen. First, the momentum is mapped as in Eq. (63.83): the direction undergoes the Möbius map $z \to z'$ and the energy rescales by the conformal factor $\omega \to \omega' = |cz + d|^2\, \omega$. Second, the helicity state acquires a little-group phase. A massless particle's little group is the $U(1)$ of phases $\lambda_a \to e^{i\theta/2}\lambda_a$, $\tilde\lambda_{\dot a} \to e^{-i\theta/2}\tilde\lambda_{\dot a}$ of the on-shell spinors (Eq. (58.5)), under which a helicity-ℓ state picks up $e^{i\ell\theta}$. For the Möbius map the relevant Wigner rotation angle on the celestial sphere is $\theta = -2\arg(cz + d)$, so the phase is $\left[(\bar c\bar z + \bar d)/(cz + d)\right]^\ell$ (a pure phase, since $\left|(\bar c\bar z + \bar d)/(cz + d)\right| = 1$). Collecting both effects, the operator transforms as

$$U(\Lambda)\, a_\ell(\omega, z, \bar z)\, U(\Lambda)^{-1} = \left(\frac{\bar c\bar z + \bar d}{cz + d}\right)^{\ell} a_\ell(\omega', z', \bar z'), \qquad \omega' = |cz + d|^2\, \omega. \tag{63.90}$$

Now define the celestial operator by the Mellin transform of Eq. (63.84), $\mathcal{O}_{\Delta,\ell}(z, \bar z) = \int_0^\infty \mathrm{d}\omega\, \omega^{\Delta-1}\, a_\ell(\omega, z, \bar z)$, and act with $U(\Lambda)$:

$$U(\Lambda)\, \mathcal{O}_{\Delta,\ell}(z, \bar z)\, U(\Lambda)^{-1} = \left(\frac{\bar c\bar z + \bar d}{cz + d}\right)^{\ell} \int_0^\infty \mathrm{d}\omega\, \omega^{\Delta-1}\, a_\ell(\omega', z', \bar z'). \tag{63.91}$$

Change the integration variable to $\omega' = |cz + d|^2\, \omega$, so $\omega = |cz + d|^{-2}\, \omega'$, $\mathrm{d}\omega = |cz + d|^{-2}\, \mathrm{d}\omega'$, and $\omega^{\Delta-1} = |cz + d|^{-2(\Delta-1)}\, \omega'^{\Delta-1}$. The Jacobian and the kernel combine to a power $|cz + d|^{-2(\Delta-1)-2} = |cz + d|^{-2\Delta}$, leaving

$$U(\Lambda)\, \mathcal{O}_{\Delta,\ell}(z, \bar z)\, U(\Lambda)^{-1} = |cz + d|^{-2\Delta} \left(\frac{\bar c\bar z + \bar d}{cz + d}\right)^{\ell} \mathcal{O}_{\Delta,\ell}(z', \bar z'). \tag{63.92}$$

Write $|cz + d|^{-2\Delta} = (cz + d)^{-\Delta}(\bar c\bar z + \bar d)^{-\Delta}$ and absorb the helicity phase $(\bar c\bar z + \bar d)^\ell (cz + d)^{-\ell}$:

$$U(\Lambda)\, \mathcal{O}_{\Delta,\ell}(z, \bar z)\, U(\Lambda)^{-1} = (cz + d)^{-(\Delta+\ell)}\, (\bar c\bar z + \bar d)^{-(\Delta-\ell)}\, \mathcal{O}_{\Delta,\ell}(z', \bar z'). \tag{63.93}$$

This is exactly the transformation law of a two-dimensional conformal primary of holomorphic and antiholomorphic weights

$$h = \frac{\Delta + \ell}{2}, \qquad \bar h = \frac{\Delta - \ell}{2}, \qquad \Delta = h + \bar h, \qquad J = h - \bar h = \ell, \tag{63.94}$$

under the Möbius group $SL(2,\mathbb{C})$. The four-dimensional helicity ℓ — the little-group weight of Eq. (58.5) and Theorem 58.16 — has become the two-dimensional conformal spin $J = h - \bar{h}$, while the boost eigenvalue λ of Eq. (63.89) has become the conformal dimension $\Delta = 1 + i\lambda$. The little-group data of Chapter 58 and the boost data of the Mellin transform together fix the celestial conformal weights. The change of basis is complete: a massless one-particle state of energy ω, direction $(z, \bar{z})$, helicity ℓ becomes a conformal primary operator $\mathcal{O}_{\Delta,\ell}$ of weights $(h, \bar{h})$ inserted at the point $(z, \bar{z})$ of the celestial sphere.

Celestial amplitudes as candidate CFT correlators. With each external leg promoted to a conformal primary, the celestial amplitude Eq. (63.84) is by construction a function $\widetilde{A}_n(z_i, \bar{z}_i)$ that transforms under $SL(2,\mathbb{C})$ exactly as an n-point function of primaries of weights $(h_i, \bar{h}_i)$ in a two-dimensional CFT,

$$\widetilde{A}_n(\{z_i, \bar{z}_i\}) = \Big\langle \prod_{i=1}^{n} \mathcal{O}_{\Delta_i,\ell_i}(z_i, \bar{z}_i) \Big\rangle_{\text{cel}}, \tag{63.95}$$

where the right-hand side is the postulated correlator of the candidate *celestial* CFT. The covariance Eq. (63.93) guarantees that Eq. (63.95) has the correct Möbius weight in every insertion; for example, low-point celestial amplitudes are fixed by conformal covariance up to the same data (a constant for two points, an OPE coefficient for three) that fixes a 2D CFT correlator, with the four-dimensional momentum-conserving delta function reorganising into a distribution on cross-ratios of the z_i. The soft theorems of Section 63.6.2 then furnish this candidate CFT with the structures a genuine 2D CFT must have: the leading soft photon, being a $\Delta = 1$ insertion (a dimension-one primary with $J = 1$, i.e. a $(h, \bar{h}) = (1, 0)$ current), is a *conserved Kac–Moody current* $J_z(z)$ on the celestial sphere, and the supertranslation Ward identity dresses the celestial sphere with a *stress tensor* T_{zz} assembled from the soft graviton. The asymptotic symmetries of Section 63.6.2 are, in this language, the symmetry currents of the celestial CFT.

63.6.4 The flat-space holography program, scoped and dated

We must now say, with the honesty the chapter has demanded throughout, exactly what has and has not been established. What is *proved*, and used nowhere conjecturally above, is the soft factorization: Eqs. (63.70) and (63.75), with their gauge content Eqs. (63.73) and (63.77), are exact theorems of any local, Lorentz-invariant theory with the relevant massless field, derived in full in Section 63.6.1 from the on-shell pole. What is also rigorous is the change of basis: the Mellin transform Eq. (63.84) with $\Delta = 1 + i\lambda$ is a genuine unitary map from momentum eigenstates to boost eigenstates (Eq. (63.88)), and the resulting celestial amplitudes Eq. (63.95) carry, as a theorem, the Möbius covariance of 2D CFT correlators (Theorem 63.16). These are facts.

What is a *program*, not a theorem, is the holographic claim itself. *Celestial holography* is the conjecture that there exists an honest two-dimensional conformal field theory — with a complete local operator content, an associative operator product expansion, a state–operator correspondence, and a unitary Hilbert space — whose correlation functions are the celestial amplitudes of a four-dimensional theory of quantum gravity in asymptotically flat space. As of the mid-2020s this remains unestablished in several concrete senses, which we name rather than paper over. The celestial correlators sit on the principal series $\Delta = 1 + i\lambda$ and involve distributions in Δ and contact terms in the z_i; the existence of a standard radially-quantised CFT with a discrete spectrum and a normalizable vacuum reproducing them is not demonstrated, and the candidate theory appears non-unitary or at least unusual by the standards of Chapter 48. The celestial OPE is known only as an expansion read off from the collinear limits of amplitudes, not from an independently defined local product. And the dictionary is presently a *kinematic* reorganisation of a known S-matrix, not a derivation of the bulk from an intrinsically-defined boundary theory — the direction that would make it holography in the full sense. An alternative "Carrollian" formulation, organising the boundary data on $\mathscr{I}^{\pm}$ in retarded time u rather than in boost weight Δ, is under active development as of this writing; the two are complementary descriptions of the same null-boundary data.

It is worth placing this beside the holography we did establish. The AdS/CFT correspondence of Chapter 53 is itself a conjecture (a precisely-stated one), but it comes equipped with a working computational dictionary: the GKP–Witten relation Eq. (53.162) computes boundary correlators from a bulk action, and the flat-space limit of Section 63.4, Eq. (63.54), extracts the flat S-matrix from AdS correlators as the curvature radius is sent to infinity. That flat-space limit is the rigorous bridge between the two pictures: a four-dimensional flat amplitude is the large-radius limit of a five-dimensional AdS amplitude, whose boundary is a genuine three-dimensional CFT. Celestial holography proposes a *different* screen for the same flat physics — the two-dimensional celestial sphere at null infinity rather than the codimension-one conformal boundary of AdS — and a correspondingly different (and lower-dimensional) putative dual. The entanglement-based diagnostics of Chapter 55 (the replica construction of Section 55.2) provide one of the tools with which the information content of such a boundary theory can in principle be tested. Whether a self-consistent celestial CFT exists, and whether it is genuinely lower-dimensional holography or a clever bookkeeping of the S-matrix, is among the live questions of the amplitudes/holography frontier as this book is written.

We have closed the circle the chapter set out to trace. The leading soft theorems, derived in full from the factorization pole, are not curiosities of the infrared but the Ward identities of an infinite-dimensional asymptotic symmetry, and that symmetry organises the S-matrix into the correlators of a putative two-dimensional conformal field theory on the celestial sphere — the flat-space

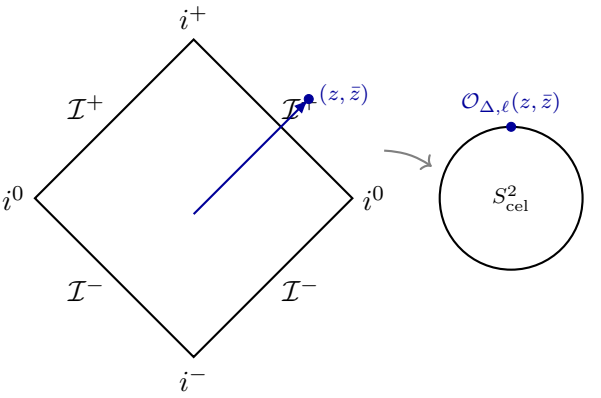

Figure 63.6: The celestial dictionary. An outgoing massless particle escapes to future null infinity $\mathcal{I}^+$ in a definite null direction, which is a point $(z, \bar{z})$ on the celestial sphere S^2_{cel}. The Mellin transform Eq. (63.84) converts the particle's energy eigenstate into a boost eigenstate of weight $\Delta = 1 + i\lambda$ (Eq. (63.89)), which is a conformal primary $\mathcal{O}_{\Delta,\ell}$ of weights $(h, \bar{h}) = (\frac{\Delta+\ell}{2}, \frac{\Delta-\ell}{2})$ inserted at $(z, \bar{z})$ (Eq. (63.93)). The S-matrix becomes a candidate celestial-CFT correlator Eq. (63.95).

face of the holography that Part XV built in anti-de Sitter space. With this last frontier on the table, the amplitudes program has shown its full hand: hidden simplicity, analyticity and unitarity promoted to construction, positivity as a quantitative constraint, the two bootstraps unified, locality and unitarity read as emergent, and now the S-matrix itself recast as a hologram. The closing section draws this arc together and renders the verdict the whole chapter has been building toward — a dated accounting, honest to the mid-2020s, of which of Part I's founding axioms survive as inputs and which reappear at the frontier as possibly emergent outputs.

63.7 Synthesis: What the Amplitudes Program Teaches

The previous section pushed the boldest reading of the whole arc: that the S-matrix itself might be a hologram — a set of correlators of a putative two-dimensional celestial conformal theory, with the leading soft factor recast as a Ward identity of an asymptotic symmetry (Section 63.6). That reframing is the natural endpoint of a single moving idea that has run through this entire part: that the data a scattering amplitude actually depends on are far smaller, and far more structured, than the Lagrangian-plus-Feynman-rules machinery that first produced them. We have now seen that idea in six distinct guises — a one-line Parke–Taylor formula (Chapter 59), an on-shell recursion that never writes an interaction vertex (Theorem 59.23), unitarity cuts that build loop integrands

from trees (Chapter 60), a double copy that squares gauge theory into gravity (Chapter 61), a geometry whose canonical form *is* the amplitude (Chapter 62), and a positivity bound that constrains an effective Lagrangian we never integrate out by hand (Section 63.3). This closing section does not prove anything new. Its task is to take stock: to state, honestly and dated to the mid-2020s, which of these claims are theorems and which are conjectures; to draw from them the single structural lesson that reorganizes the book's opening logic; and to hand the reader to the final movement, where the flat-spacetime S-matrix framework on which this entire part rests is itself called into question.

Per the distinction between theorem and conjecture fixed at the head of this chapter, everything load-bearing that the synthesis leans on has already been carried in full on the page — the abstract constructibility theorem (Theorem 63.4), the dispersive positivity sum rule (Theorem 63.7), the toy canonical form (Chapter 62), the leading soft factor (Section 63.6) — or imported from a chapter that proves it. This section asserts nothing it has not earned. Where a frontier claim is conjectural we say so and date it; where it is a theorem we point to the proof.

63.7.1 A dated status summary of the program's claims

A frontier is most useful to a reader when its boundary is drawn sharply: here is the settled interior, there is the conjectural exterior, and this is the date on which the line was drawn. The amplitudes program is unusual among the frontiers in this book in how clean that line is. A large fraction of it consists of *theorems* — statements proved from the founding analyticity and unitarity assumptions, often more rigorously than the Feynman-diagram results they replace — and the conjectural part is correspondingly well isolated. We collect the assessment in Table 63.2, then comment on each entry. The grades are: *theorem* (proved or by a short argument from imported results), *rigorous* (a controlled bound or identity following from the standard axioms), *conjecture, well tested* (a precise statement checked in many cases but not proved in general), and *program* (a research framework with partial results but no central theorem).

Hidden simplicity is established, and it is a symptom. The first entry is not a conjecture at all. The Parke–Taylor formula Eq. (59.55) is a theorem (Theorem 59.28): the n-gluon maximally-helicity-violating amplitude is a single ratio of angle brackets, while the Feynman expansion that computes it has a number of diagrams growing faster than any power of n. The lesson we drew in Section 63.2 is that this gap between the answer and the apparatus is diagnostic. It tells us that the apparatus carries redundant information — gauge dependence, off-shell continuations, field redefinitions — that cancels in the physical answer, and that there ought to be a formulation in which the redundancy is never introduced. The rest of the program is the construction of such formulations.

Claim of the program	**Status (mid-2020s)**	**Where settled / scoped**
Physical amplitudes are far simpler than their diagram count (hidden simplicity; the MHV one-liner)	theorem	Eq. (59.55), proved Theorem 59.28
On-shell recursion reconstructs tree amplitudes from lower-point on-shell data	theorem	Theorem 59.23; abstracted Theorem 63.4
The unitarity method reconstructs loop integrands from cuts (one loop, d dimensions, complete)	theorem	Theorems 60.1 and 60.26
EFT positivity bounds: leading Wilson coefficients are sign-constrained by analyticity + unitarity	rigorous	Section 63.3, Theorem 63.7
Amplitude = canonical form of a positive geometry (amplituhedron)	theorem in controlled cases; conjecture in general	proved Theorems 62.45 and 62.49; conjectural Theorem 62.47
Double copy: gravity tree amplitudes = (gauge theory)^2	theorem at tree level	Theorem 61.21; factorization Theorem 61.20
Double copy at loop level (BCJ-dual numerators exist to all loops)	conjecture, well tested	Theorem 61.32
Celestial / flat-space holography: the S-matrix as a CFT correlator	program	Section 63.6

Table 63.2: The amplitudes program graded by epistemic status, dated to the mid-2020s. The settled interior is large; the conjectural exterior is sharply bounded. Each grade points to the location where the claim is proved or honestly scoped.

On-shell recursion and the unitarity method are established. The second and third entries are the constructive payoff. BCFW recursion (Theorem 59.23), abstracted in this chapter to the on-shell constructibility theorem (Theorem 63.4), shows that a tree amplitude with appropriate large-z behaviour is fixed completely by its factorization on physical poles — by lower-point amplitudes glued across on-shell intermediate states. No Lagrangian appears in the statement or the proof; the only inputs are the residue theorem (Theorem 5.23) and the physical content of the poles. The same logic survives to loop level not as a recursion on rational functions but as the unitarity method: the discontinuity of a loop amplitude across a branch cut is a phase-space integral of lower-loop amplitudes (Cutkosky, Theorem 60.1), and at one loop in d dimensions the cuts determine the integrand completely (Theorem 60.26). These are theorems, and they are the working tools of precision collider physics. They deserve the top grade.

EFT positivity is rigorous. The fourth entry is the chapter's worked anchor and the meeting point of ϕ^4 theory with the bootstrap. The forward-dispersion argument of Theorem 63.7 takes three ingredients we proved long before the frontier — analyticity of the amplitude in the Mandelstam variables, crossing symmetry, and the unitarity statement $\operatorname{Im}\mathcal{M}(i \to i) \geq 0$ from the generalized optical theorem (Theorem 14.37) — and converts them into a strict inequality on the leading coefficient of a low-energy effective Lagrangian: the s^2 coefficient of the forward amplitude is a convergent integral of a manifestly positive absorptive part, hence positive. This is not a heuristic naturalness estimate; it is a theorem about which effective field theories can possibly arise from a unitary, causal, Lorentz-invariant completion. We grade it *rigorous* rather than *theorem* only because its scope — how many derivatives, how many fields, what spin — is itself an active subject, with the catalogue of provable bounds still being filled in as of the mid-2020s. The inequality Eq. (63.55) stands; the full map of the allowed region does not yet.

The amplituhedron is proved in controlled cases and conjectural in general. Here the line between interior and exterior runs through a single statement. That the amplitude equals the canonical form of a positive geometry is a *theorem* where the geometry is simple enough to control directly: for the $k = 1$ amplituhedron, which we showed is a convex cyclic polytope whose canonical form reproduces the NMHV-like data (Theorem 62.45), and for the boundary factorization in the tractable $m = 2$ case (Theorem 62.49). The general statement — that the canonical form of the full planar $\mathcal{N} = 4$ amplituhedron equals the tree superamplitude, and its loop generalization at the integrand level — remains a *conjecture* (Theorem 62.47), enormously well tested but not proved, and tied to the planar limit and to maximal supersymmetry as enabling crutches

(Section 62.8.3). The honest grade is split, and the date matters: this is the status as of the mid-2020s, and it is an area where a theorem could appear at any time.

The double copy is a tree-level theorem and a loop-level conjecture. The fifth and sixth entries split the same way. At tree level the statement that gravity amplitudes are gauge-theory amplitudes "squared" is a theorem: the field-theory KLT relations (Theorem 61.21) express each graviton tree as a bilinear in colour-ordered gauge trees through a kinematic kernel, and the double copy so constructed has the correct factorization channels and therefore the correct locality and unitarity (Theorem 61.20). At loop level the construction depends on the existence of BCJ-dual numerators — a rearrangement of the gauge-theory integrand into a form where kinematic numerators satisfy the same Jacobi identities as the colour factors — and that existence is a *conjecture* (Theorem 61.32), verified in a long list of nontrivial cases (through high loop order in maximal supergravity) but without a general proof. Again the boundary is sharp and the date is part of the claim.

Celestial holography is a program, not a theorem. The last entry is the one we scoped most carefully in Section 63.6. The soft theorems *are* theorems — the leading soft factor is universal and we derived it — and their reinterpretation as Ward identities of asymptotic (BMS-type) symmetries is established at leading order. But the central aspiration, that the four-dimensional S-matrix is computed by a genuine, local, unitary two-dimensional conformal field theory living on the celestial sphere, has no central theorem behind it. There are suggestive structures (the conformal covariance of celestial amplitudes under the Lorentz group acting as the global conformal group of the sphere; operator-product-like singularities from collinear limits) and serious obstructions (the would-be CFT is non-standard — continuous spectrum, unfamiliar reality and normalizability conditions). It is a *program*. Honest "this is the current understanding, mid-2020s" is the correct register, and we keep it.

63.7.2 The inversion of Part I's logic

With the status summary in hand we can state the structural lesson the program teaches, and we can state it without overclaiming. Part I built quantum field theory on a small set of postulates: that states carry a unitary representation of the Poincaré group, so that Lorentz invariance and the spectrum of particles are inputs; that observables built from local fields commute at spacelike separation, so that locality is an input; that the S-matrix is unitary, so that probability conservation is an input; and that amplitudes are boundary values of analytic functions, so that causality is an input (Section 1.5). Everything in Parts IV–VI

then *operationalized* these inputs: a local Lagrangian manifests locality term by term, the Feynman $i\epsilon$ manifests analyticity, the Hermiticity of the action manifests unitarity, and the index structure manifests Lorentz covariance. The diagrams are an algorithm for enforcing the axioms.

The amplitudes program reads the same relationship in the opposite direction. Its recurring move is to take one of these properties, which Part I treated as an irreducible input, and *derive* the amplitude from it as an output — so that the property is no longer something we impose but something the construction is forced to satisfy.

- *Locality and unitarity become outputs of factorization.* In Section 63.2.2 we saw that an on-shell-constructible amplitude is fixed by the locations and residues of its poles, and that the only admissible pole locations are $P_I^2 = m^2$ for physical channels (locality) with residues that factorize into products of lower-point amplitudes summed over physical states (unitarity). We did not assume a local Lagrangian; we found that locality and unitarity are precisely the conditions a consistent residue structure must obey. Theorem 63.4 makes this a theorem.

- *Locality and unitarity become outputs of positive geometry.* The amplituhedron re-encodes the same fact geometrically: the physical poles are the boundaries (the facets) of a positive geometry, and the factorization of the amplitude on a pole is the statement that the canonical form restricts correctly to a boundary (Section 62.8.2, Theorem 62.49), the reading developed for this chapter in Section 63.5. Locality and unitarity are read off the shape; they are not postulated. We are careful here: this is established as a *reformulation* in planar $\mathcal{N} = 4$, not as a theorem that spacetime locality is dispensable in general.

- *Diffeomorphism invariance becomes an output of squaring.* The double copy builds a graviton amplitude with the correct gauge (here, linearized-diffeomorphism) Ward identities from two copies of a gauge-theory amplitude, without ever writing the Einstein–Hilbert action (Theorem 61.20). The defining symmetry of gravity emerges from the kinematic algebra of the gauge theory.

- *Even Lorentz invariance loosens its grip.* The celestial reframing trades manifest four-dimensional Lorentz covariance for two-dimensional conformal covariance on the sphere (Section 63.6); the soft theorems become symmetry Ward identities of a putative boundary theory. Lorentz invariance is not abandoned — it reappears as the global conformal group — but it is no longer the organizing input; the asymptotic symmetry is.

Physical Insight

The amplitudes program does not refute Part I; it relocates its axioms. Poincaré invariance, locality, unitarity, and analyticity are still true of every physical amplitude — the program proves them, over and over, as consequences. What changes is their *logical status*. In the Lagrangian formulation they are premises we feed in; in the on-shell formulation they are conclusions the construction is forced to. A premise that you can derive from something deeper is no longer a premise. The honest summary is not "the axioms are wrong" but "the axioms may be emergent": in the theories where the program has been carried out in full, locality and unitarity — and, on the celestial sphere, even the manifest action of the Lorentz group — look like outputs of a more primitive structure (positivity, geometry, on-shell factorization), not like the bedrock they were taken to be.

The restraint in that statement is deliberate, and it is the point of dating the summary. The inversion is a theorem in special cases — on-shell constructibility for tree amplitudes (Theorem 63.4), the polytope amplituhedron (Theorem 62.45), the tree-level double copy (Theorem 61.21) — and a conjecture or a program beyond them. We are *not* entitled to say that spacetime, or locality, or Lorentz invariance is provably emergent in nature. We are entitled to say that in the cleanest theories we can compute, the founding axioms of Part I reappear at the frontier as derived facts, and that this is strong circumstantial evidence that the right formulation of quantum field theory takes something other than a local Lagrangian as primitive. That is the book-level message of Part XVI, and it is as far as the mathematics licenses us to go.

63.7.3 the three benchmark theories meet

the benchmark theories were designed so that the frontier would grow out of the foundations rather than be bolted on, and at this point each thread arrives at a frontier endpoint that is a facet of the one structure just described. It is worth exhibiting the three endpoints side by side, because seen together they are visibly the same statement in three theories.

Worked Example 63.17 (The ϕ^4, QED, and Yang–Mills endpoints as one structure)**.** We recall — not re-derive — the terminal result of each thread and read off the common shape.

ϕ^4 theory (the bootstrap endpoint). Begun as the classical Lagrangian $\mathcal{L} = \frac{1}{2}(\partial\phi)^2 - \frac{1}{2}m^2\phi^2 - \frac{\lambda}{4!}\phi^4$ in Part II, this thread ran to the Wilson–Fisher fixed point (Chapter 52) and the numerical conformal bootstrap of the 3D Ising model (Chapter 50), and meets the amplitudes side here as a positivity bound. The terminal statement, established in Theorem 63.7 and recalled in Eq. (63.55), is

that the leading forward Wilson coefficient is a convergent dispersive integral of a positive absorptive part,

$$c \;=\; \frac{2}{\pi}\int_{4m^2}^{\infty}\frac{\mathrm{d}s\;\mathrm{Im}\,\mathcal{M}(s)}{s^3} \;>\; 0. \tag{63.96}$$

The coefficient of a Lagrangian operator is fixed in sign by on-shell data — the absorptive part — and a single positivity principle, with no off-shell input. This is the S-matrix bootstrap and the conformal bootstrap reading the same crossing-plus-unitarity logic (Section 63.4 and Theorem 63.10).

QED (the spinor-helicity / soft endpoint). Begun as classical $U(1)$ in Part II and carried to $g-2$ in Part V, this thread was reframed in spinor-helicity language in Chapter 58 and arrives here at the leading soft theorem (Section 63.6). Adding a soft photon of momentum $q \to 0$ to any amplitude multiplies it by the universal Weinberg soft factor,

$$\mathcal{A}_{n+1}(q) \;\xrightarrow{q\to 0}\; \Big(e\sum_i Q_i\,\frac{\varepsilon^*\cdot p_i}{p_i\cdot q}\Big)\,\mathcal{A}_n, \tag{63.97}$$

a residue on the soft pole determined entirely by the on-shell charges and momenta of the hard legs. The same factor is, on the celestial sphere, a Ward identity of an asymptotic symmetry. Again: a piece of the amplitude fixed by on-shell data plus a symmetry/pole principle, no Lagrangian needed.

Yang–Mills theory (the double-copy endpoint). Begun as classical Yang–Mills in Part VII and carried to asymptotic freedom and then to BCFW gluon amplitudes in Chapter 59, this thread reaches here the double copy (Chapter 61). Its terminal statement is that the three-graviton amplitude is the square of the three-gluon amplitude (Section 61.4.3), schematically

$$\mathcal{M}_3^{\mathrm{grav}} \;\sim\; \big(\mathcal{A}_3^{\mathrm{YM}}\big)^2, \qquad \mathcal{A}_3^{\mathrm{YM}}(1^-,2^-,3^+) = \frac{\langle 1\,2\rangle^3}{\langle 2\,3\rangle\,\langle 3\,1\rangle}, \tag{63.98}$$

with the full tree-level statement carried by the KLT relations (Theorem 61.21). Gravity — including its defining diffeomorphism symmetry — is built from the on-shell data of gauge theory by a single algebraic operation, with no Einstein–Hilbert action in sight.

The common shape. Place Eqs. (63.96) to (63.98) together. In each, the physical object — a Wilson coefficient, a soft limit, a graviton amplitude — is determined by *on-shell data* (absorptive parts, hard-leg momenta and charges, gauge-theory amplitudes) constrained by *one organizing principle* (positivity, soft-pole universality, colour–kinematics duality), and in each the founding inputs of Part I appear only as outputs: the positivity that drives Eq. (63.96) *is* unitarity; the pole in Eq. (63.97) *is* locality; the factorization that makes the square in Eq. (63.98) consistent *is* unitarity again (Theorem 61.20). Three theories, three threads, one structure. This is exactly the design the threads were built to

deliver: the bootstrap, the spinor-helicity/soft story, and the double copy are not three frontiers but three faces of the single claim that the amplitude is more primitive than the Lagrangian.

63.7.4 The frontier that remains: where the S-matrix runs out

Everything in this part has been built on a foundation so familiar that we rarely named it: a flat, non-dynamical Minkowski spacetime with well-separated asymptotic regions. The spinor-helicity variables of Chapter 58 presuppose massless on-shell momenta in flat space; the LSZ-style in/out states behind every amplitude presuppose that fields become free in the far past and far future; the celestial sphere of Section 63.6 is the conformal boundary of flat spacetime specifically. The S-matrix exists, as a clean object, because Minkowski space has a global timelike isometry that defines a vacuum and a stable particle concept, and asymptotically free regions where "in" and "out" make sense. The whole amplitudes program is, in this precise sense, a theory of the flat-space S-matrix.

The book's final movement removes that foundation. In a general curved spacetime there need be no global timelike Killing vector, hence no preferred vacuum and no unambiguous notion of a particle; the very objects the S-matrix scatters become observer-dependent. Chapter 64 builds quantum field theory on a fixed curved background and confronts this directly: the Bogoliubov transformation relating two natural mode decompositions mixes creation and annihilation operators, so that one observer's vacuum is another's thermal bath, and the Unruh effect makes the particle content of a state a property of the trajectory through it rather than of the state alone. The stress tensor must then be renormalized in a background-covariant way (Section 64.5), a problem with no analogue in the flat-space program. Chapter 65 pushes to the sharpest case: a black hole, where the same Bogoliubov logic yields Hawking radiation and a temperature, and where the question of whether an S-matrix from past to future infinity even exists — the information problem — becomes the frontier where the framework of this part is most severely tested, and where the holographic ideas of Section 63.6 and Part XV return as candidate resolutions.

That is the natural place for the book to end. We have followed quantum field theory from the postulates of Part I, which took Poincaré invariance, locality, unitarity, and analyticity as bedrock, to a frontier at which those same postulates look like emergent outputs of deeper on-shell structure — and we now hand the reader to the one setting where the bedrock beneath *them*, flat spacetime itself, is taken away, and the S-matrix framework must be rebuilt or abandoned. Part XVII is where that final reckoning happens.

Further reading

The reading that goes *beyond* this synthesis, rather than re-supplying any step taken in it, divides along the threads. For the on-shell program as a whole — spinor-helicity, recursion, the unitarity method, and the view that amplitudes are more primitive than Lagrangians — the standard modern texts are Elvang and Huang [176] and Henn and Plefka [263], together with the review by Dixon [153]. The emergence of locality and unitarity from positive geometry is developed in Arkani-Hamed and Trnka [32] and the textbook treatment Arkani-Hamed et al. [33]. The double copy and its classical and loop-level extensions are reviewed in Bern et al. [72]. EFT positivity and the modern S-matrix bootstrap, including the link to the conformal bootstrap drawn in Section 63.4, are surveyed in de Rham et al. [143] and Kruczenski et al. [308]. The celestial-holography program, scoped here as a program, is reviewed in Pasterski [385] and Raclariu [411], and the asymptotic-symmetry foundation of the soft theorems is laid out in Strominger [459].

Part XVII

QFT in Curved Spacetime

Chapter 64

QFT in Curved Spacetime

Every construction in this book so far has leaned, sometimes silently, on the Poincaré group. The mode expansion that quantized the free scalar in Chapter 9 split the field into pieces of definite positive and negative frequency, and that split was not a convention but a consequence: it was forced by demanding that the vacuum be invariant under the symmetry of spacetime, in particular under the time translations generated by a global timelike Killing vector. A generic curved spacetime has no such symmetry. There is no preferred time, no Poincaré group, and—as this chapter will make precise—no preferred notion of a particle. We treat gravity here as a fixed, classical, curved arena and a quantum field as a test object living on it: the metric $g_{\mu\nu}(x)$ is an external field, no Einstein equation is imposed and no graviton is quantized. This is the semiclassical, test-field regime, and probing its internal consistency is the whole business of the chapter.

The development imports only a small, sharply identified toolkit. From Chapter 9 we carry the free ($\lambda = 0$) sector of ϕ^4 theory—the same real scalar of mass m, its Fock construction, its ladder algebra and number operator—now covariantized to an arbitrary background. From Chapter 3 we import the Wigner picture of one-particle states as unitary representations of the Poincaré group, which is exactly the structure whose loss in curved space creates the vacuum ambiguity. From Chapter 10 we take the generating functional $Z[J]$, the connected $W[J] = -i \ln Z$, the Euclidean continuation, and the QFT/stat-mech dictionary that reads a periodic imaginary time as a temperature; the curvature, stress-tensor, and gamma-matrix conventions are those of Chapter A, and the functional-determinant and heat-kernel machinery is that of Chapter E, whose curved-space Seeley–DeWitt coefficient this chapter finally computes. Throughout we use the mostly-minus signature $\eta_{\mu\nu} = \mathrm{diag}(+,-,-,-)$ and natural units $\hbar = c = 1$.

The arc is a single argument carried in seven movements. We first redo the free scalar geometrically on a globally hyperbolic background, isolating the one new ingredient—the curvature coupling $\xi R\phi^2$, with $\xi = 1/6$ singled out

by Weyl invariance—and proving that the field operator is a basis-independent geometric object while its split into particles is not. We then make that ambiguity quantitative: the Bogoliubov transformation relating two mode bases, its symplectic identities, and the formula that turns the off-diagonal coefficient β into a particle number and the in-vacuum into a squeezed condensate of pairs. Fed a concrete pair of bases—an asymptotically static expanding universe (the Bernard–Duncan model)—the machine produces an exact, finite spectrum of gravitationally created particles. Pushed to a horizon, the same machine collapses onto a Planck spectrum: the Unruh effect, derived twice, once by analytic continuation of Rindler modes and once from the regularity of Euclidean time, with the modular-theory backbone stated. The energy these states carry forces us to confront the formally divergent $\langle T_{\mu\nu} \rangle$; covariant point-splitting, the Hadamard parametrix, and Wald's axioms render it finite and essentially unique, with the residual ambiguity identified as the renormalization of the gravitational couplings. One feature survives every subtraction—the trace (conformal) anomaly—which we compute two independent ways and tie to the central charges of conformal field theory. Finally we assemble everything as variations of one object, the effective action $W[g]$, whose Euclidean smoothness at a horizon fixes the temperature $\beta = 2\pi/\kappa$ and whose metric variation is the source of the semiclassical Einstein equation. That equation, with an honest accounting of where it is trustworthy and where it fails, is the platform from which Chapter 65 launches Hawking radiation and the information problem.

64.1 Free fields on a fixed curved background

The chapter introduction has set the stakes: gravity is to be treated as a fixed, classical, curved arena, and a quantum field is to live on it. Everything we have built so far rested, sometimes invisibly, on the Poincaré group. The mode expansion of Chapter 9 split the scalar field into pieces of definite positive and negative frequency, and that split was *not* a convention: it was forced by the requirement that the vacuum be invariant under the symmetry group of spacetime, and in particular under time translations generated by a global timelike Killing vector. A generic curved spacetime has no such symmetry. There is no preferred time, no Poincaré group, and–as we will see–no preferred notion of a particle. Before we can say anything about what replaces these structures, we must first redo the construction of the free scalar field geometrically, keeping scrupulous track of which steps survive the loss of Poincaré invariance and which do not. That is the task of this section. We continue the free ($\lambda = 0$) sector of ϕ^4 theory (Chapter 9)—the same real scalar of mass m—now covariantized to live on an arbitrary curved background. This is a light extension of the thread rather than an official stage: the field, its mass, and its name are unchanged; only its home has curved.

We work throughout in the mostly-minus signature $\eta_{\mu\nu} = \mathrm{diag}(+,-,-,-)$ of Eq. (3.1), in natural units $\hbar = c = 1$, and we set the gravitational coupling aside entirely: the metric $g_{\mu\nu}(x)$ is a prescribed external field, not a dynamical one. No Einstein equation is imposed and no graviton is quantized. This is the *semiclassical, test-field* regime, and its internal consistency is exactly what the rest of the chapter will probe.

64.1.1 The geometric arena: globally hyperbolic spacetimes

In flat space the Cauchy problem for the Klein–Gordon equation is so familiar that its geometric content goes unremarked: one gives the field and its time derivative on the surface $t = 0$ and the field equation propagates the data to all later and earlier times. On a curved background the very possibility of doing this is a nontrivial restriction on the geometry, and we isolate it first, because the entire quantization rests on it.

Definition 64.1 (Cauchy surface and global hyperbolicity)**.** Let (M, g) be a smooth, time-orientable Lorentzian four-manifold. A smooth spacelike hypersurface $\Sigma \subset M$ is a *Cauchy surface* if every inextendible causal (timelike or null) curve in M intersects Σ exactly once. A spacetime that admits a Cauchy surface is called *globally hyperbolic*.

The condition says that Σ is met once and only once by every worldline of a massive or massless signal: "once" because Σ is achronal (no causal curve meets it twice), and "at least once" because no causal curve can sneak past it. Physically, the data on Σ are then causally complete—nothing can enter the future of Σ without having registered on Σ, and nothing in the past of Σ fails to be recorded there. The classic geometric theorem, which we import rather than prove (it belongs to global Lorentzian geometry, not to field theory), is that a globally hyperbolic (M, g) is diffeomorphic to a product $\mathbb{R} \times \Sigma$, foliated by a one-parameter family of Cauchy surfaces Σ_t labelled by a global time function t, with the metric taking the form

$$\mathrm{d}s^2 = N(t,\mathbf{x})^2\,\mathrm{d}t^2 - h_{ij}(t,\mathbf{x})\,\mathrm{d}x^i\,\mathrm{d}x^j, \tag{64.1}$$

where $N > 0$ is the lapse function and h_{ij} is the (positive-definite) induced spatial metric on the slices. We take all spacetimes in this chapter to be globally hyperbolic. This is the precise sense in which "a sensible time direction exists." It guarantees a well-posed classical initial-value problem and is exactly what we will need to set up canonical commutation relations on a slice and propagate them. What it does *not* provide is any preferred choice among the infinitely many admissible time functions t: the slicing Eq. (64.1) is wildly non-unique, and that non-uniqueness is the seed of everything to come.

Physical Insight

Global hyperbolicity is the curved-space replacement for "space and time exist and signals propagate causally." It buys us a Cauchy problem and a Hilbert space of solutions. It pointedly does *not* buy us a clock that all observers agree on. In flat space the Poincaré group quietly supplied that clock; here it is gone, and the missing clock is precisely the missing definition of "particle" that drives the Unruh and Hawking effects later in the chapter.

64.1.2 The covariant action and the curvature coupling

We now write the action. The guiding principle is the one stated in Chapter 6: the action is a coordinate-scalar built by integrating a Lagrangian density against the invariant volume element. In flat space the free scalar density was Eq. (6.21); we covariantize it by the minimal recipe $\eta_{\mu\nu} \to g_{\mu\nu}$, $\partial_\mu \to \nabla_\mu$, and $\mathrm{d}^4x \to \sqrt{-g}\,\mathrm{d}^4x$, where $g \equiv \det g_{\mu\nu} < 0$ and $\sqrt{-g}\,\mathrm{d}^4x$ is the unique (up to orientation) volume form that is invariant under coordinate changes. For a scalar field, $\nabla_\mu\phi = \partial_\mu\phi$, so the kinetic term needs no connection. There is, however, one new ingredient that has no flat-space analogue: a local scalar built from the field and the geometry that we are *permitted* to add because it respects every symmetry the kinetic term does. The Ricci scalar R is such an object, and the dimension-correct, parity-even, local term it allows is $\xi R\,\phi^2$. We therefore write the most general action that is a coordinate scalar, quadratic in ϕ, of mass dimension four in the Lagrangian density, and built from no more than two derivatives:

$$S[\phi; g] = \frac{1}{2}\int \mathrm{d}^4x\,\sqrt{-g}\,\Big[\, g^{\mu\nu}\,\partial_\mu\phi\,\partial_\nu\phi - (m^2 + \xi R)\phi^2 \,\Big]. \tag{64.2}$$

Here R is the Ricci scalar of $g_{\mu\nu}$, and ξ is a new dimensionless coupling—the *curvature coupling*—that the minimal recipe alone does not fix. Two values are distinguished. The choice $\xi = 0$ is *minimal coupling*, the literal output of the substitution rule. The choice

$$\xi = \xi_c \equiv \frac{d-2}{4(d-1)}, \qquad \xi_c\big|_{d=4} = \frac{1}{6}, \tag{64.3}$$

is *conformal coupling*, and Section 64.1.3 will earn its name by showing that the massless action at $\xi = 1/6$ is invariant under local rescalings of the metric. For the moment ξ is simply a parameter; we keep it general and let the physics single out ξ_c.

Notation Watch

The sign of the $\xi R\phi^2$ term and even the sign of R itself are convention-laden, because the Riemann tensor's sign and the metric signature both enter. We fix conventions once (mirroring Appendix A): with the mostly-minus metric we take $R^{\rho}{}_{\sigma\mu\nu} = \partial_\nu \Gamma^{\rho}_{\mu\sigma} - \partial_\mu \Gamma^{\rho}_{\nu\sigma} + \Gamma^{\rho}_{\nu\lambda}\Gamma^{\lambda}_{\mu\sigma} - \Gamma^{\rho}_{\mu\lambda}\Gamma^{\lambda}_{\nu\sigma}$, $R_{\sigma\nu} = R^{\rho}{}_{\sigma\rho\nu}$, and $R = g^{\sigma\nu}R_{\sigma\nu}$. This is the convention in which the field equation reads $(\Box_g + m^2 + \xi R)\phi = 0$ as in Eq. (64.6) and in which the conformal value comes out to $+1/6$ in $d = 4$, as Section 64.1.3 verifies; the opposite Riemann sign would flip the sign of R and of ξ together, leaving the physics untouched. The term $-\xi R\phi^2$ in Eq. (64.2) then acts as a position-dependent mass-squared shift $m^2 \to m^2 + \xi R$. With the opposite Riemann sign the conformal value is still $1/6$; only the relative sign of the shift flips. We will not need the explicit curvature components of any particular spacetime in this section; R enters only as a fixed scalar function.

The field equation follows from stationarity of Eq. (64.2) under $\phi \to \phi + \delta\phi$, exactly as in Theorem 6.8 but now with the covariant measure. Varying,

$$\begin{aligned} \delta S &= \int \mathrm{d}^4x\, \sqrt{-g}\, \Big[\, g^{\mu\nu}\, \partial_\mu\phi\, \partial_\nu(\delta\phi) - (m^2 + \xi R)\phi\, \delta\phi \,\Big] \\ &= \int \mathrm{d}^4x\, \Big[-\partial_\nu\big(\sqrt{-g}\, g^{\mu\nu}\partial_\mu\phi\big) - \sqrt{-g}\,(m^2 + \xi R)\phi \,\Big]\delta\phi, \end{aligned} \tag{64.4}$$

where the second line integrated by parts and discarded the total divergence $\partial_\nu(\sqrt{-g}\, g^{\mu\nu}\partial_\mu\phi\,\delta\phi)$, whose integral vanishes for $\delta\phi$ of compact support. Demanding $\delta S = 0$ for arbitrary $\delta\phi$ and dividing by $\sqrt{-g}$ gives the field equation. Recognizing the covariant scalar d'Alembertian

$$\Box_g\phi \equiv \frac{1}{\sqrt{-g}}\,\partial_\mu\big(\sqrt{-g}\, g^{\mu\nu}\,\partial_\nu\phi\big) = g^{\mu\nu}\nabla_\mu\nabla_\nu\phi, \tag{64.5}$$

the equation of motion is the covariant Klein–Gordon equation

$$(\Box_g + m^2 + \xi R)\phi = 0. \tag{64.6}$$

The two forms of $\Box_g$ in Eq. (64.5) agree because for a scalar $\nabla_\mu\phi = \partial_\mu\phi$ and the contracted Christoffel identity $\Gamma^{\mu}_{\mu\nu} = \partial_\nu \ln\sqrt{-g}$ converts the covariant divergence of the vector $V^\mu = g^{\mu\nu}\partial_\nu\phi$ into the coordinate divergence with the $\sqrt{-g}$ weight; we verify that identity in Theorem 64.2 below. Equation (64.6) reduces to the familiar $(\Box + m^2)\phi = 0$ of Eq. (6.55) when $g_{\mu\nu} \to \eta_{\mu\nu}$ (so $R = 0$ and $\Box_g \to \Box$), as it must. The pieces that survived the move to curved space are thus exactly the action principle and the field equation; what has appeared is the single new coupling ξ and the curvature scalar it multiplies.

Worked Example 64.2 (The two forms of $\Box_g$)**.** We show that $\frac{1}{\sqrt{-g}}\partial_\mu(\sqrt{-g}\,V^\mu) = \nabla_\mu V^\mu$ for any vector field V^μ, which applied to $V^\mu = g^{\mu\nu}\partial_\nu\phi$ establishes the equality in Eq. (64.5). By definition the covariant divergence is

$$\nabla_\mu V^\mu = \partial_\mu V^\mu + \Gamma^\mu_{\mu\nu} V^\nu. \tag{64.7}$$

The trace of the Christoffel symbols is, writing $g^{\nu\rho}\partial_\mu g_{\nu\rho}$ in terms of the determinant,

$$\Gamma^\mu_{\mu\nu} = \tfrac{1}{2} g^{\mu\rho}(\partial_\mu g_{\rho\nu} + \partial_\nu g_{\rho\mu} - \partial_\rho g_{\mu\nu}) = \tfrac{1}{2} g^{\mu\rho}\,\partial_\nu g_{\rho\mu}, \tag{64.8}$$

where the first and third terms cancelled after relabelling $\mu \leftrightarrow \rho$ because $g^{\mu\rho}$ is symmetric. Now use Jacobi's formula for the variation of a determinant, $\delta(\det g_{\mu\nu}) = (\det g_{\mu\nu})\, g^{\rho\mu}\delta g_{\mu\rho}$, in the form $\partial_\nu g = g\, g^{\rho\mu}\partial_\nu g_{\mu\rho}$ where $g = \det g_{\mu\nu}$. Hence $\frac{1}{2} g^{\mu\rho}\partial_\nu g_{\rho\mu} = \frac{1}{2g}\partial_\nu g = \partial_\nu \ln\sqrt{|g|} = \partial_\nu \ln\sqrt{-g}$ (the last step because $g<0$ makes $|g| = -g$ and the sign drops out of the logarithmic derivative). Therefore $\Gamma^\mu_{\mu\nu} = \frac{1}{\sqrt{-g}}\partial_\nu\sqrt{-g}$, and substituting into Eq. (64.7),

$$\nabla_\mu V^\mu = \partial_\mu V^\mu + \frac{\partial_\nu\sqrt{-g}}{\sqrt{-g}}\,V^\nu = \frac{1}{\sqrt{-g}}\Big(\sqrt{-g}\,\partial_\mu V^\mu + V^\mu\partial_\mu\sqrt{-g}\Big) = \frac{1}{\sqrt{-g}}\,\partial_\mu(\sqrt{-g}\,V^\mu), \tag{64.9}$$

which is the claim. This is the identity that makes the coordinate-divergence form of $\Box_g$ practical: it is precisely the form that appears, ready for integration by parts against the measure $\sqrt{-g}\,\mathrm{d}^4x$, throughout the chapter.

64.1.3 Weyl invariance singles out $\xi = 1/6$

We promised that the value Eq. (64.3) is not arbitrary. The statement that earns it its name is that the *massless* action at $\xi = \xi_c$ is invariant under a local rescaling of the metric—a Weyl, or conformal, transformation—provided the field is rescaled with the right weight. Such a rescaling is not a coordinate change and not an isometry; it physically alters the geometry by stretching lengths point by point. That a field theory should be blind to it is a strong and special property, possessed by the massless scalar at one particular ξ and by nothing else in the one-parameter family Eq. (64.2). We now prove it, carrying every term.

Definition 64.3 (Weyl transformation)**.** A *Weyl* (or *conformal*) transformation is a smooth positive rescaling of the metric by a spacetime-dependent factor,

$$g_{\mu\nu}(x) \;\longmapsto\; \tilde g_{\mu\nu}(x) = \Omega(x)^2\, g_{\mu\nu}(x) = e^{2\omega(x)}\, g_{\mu\nu}(x), \qquad \Omega = e^{\omega} > 0, \tag{64.10}$$

accompanied by a rescaling of the scalar field with *conformal weight* $-(d-2)/2$,

$$\phi(x) \;\longmapsto\; \tilde\phi(x) = \Omega(x)^{-(d-2)/2}\,\phi(x) = e^{-\frac{d-2}{2}\omega(x)}\,\phi(x). \tag{64.11}$$

In $d = 4$ the weight is -1, so $\tilde\phi = e^{-\omega}\phi$.

The basic consequences of Eq. (64.10) are read off from the definitions of the determinant and inverse metric: in d dimensions $\sqrt{-\tilde g} = \Omega^d \sqrt{-g} = e^{d\omega}\sqrt{-g}$ and $\tilde g^{\mu\nu} = \Omega^{-2} g^{\mu\nu} = e^{-2\omega} g^{\mu\nu}$. The only nontrivial ingredient is the transformation of the Ricci scalar, which we isolate as a lemma and prove from the Christoffel symbols, since the whole point is to carry every term.

Lemma 64.4 (Conformal transformation of the Ricci scalar)**.** *Under Eq. (64.10), with all derivatives and the d'Alembertian $\Box_g$ taken with respect to g and $(\partial\omega)^2 \equiv g^{\mu\nu}\partial_\mu\omega\,\partial_\nu\omega$, the Ricci scalar transforms as*

$$\tilde R = e^{-2\omega}\Big[\, R + 2(d-1)\,\Box_g\omega + (d-1)(d-2)\,(\partial\omega)^2 \,\Big]. \tag{64.12}$$

Proof. The Levi-Civita connection of $\tilde g$ differs from that of g by a tensor, because the difference of two connections is a tensor. Substituting $\tilde g_{\mu\nu} = e^{2\omega} g_{\mu\nu}$ into the Christoffel formula $\tilde\Gamma^\lambda_{\mu\nu} = \tfrac12 \tilde g^{\lambda\rho}(\partial_\mu \tilde g_{\rho\nu} + \partial_\nu \tilde g_{\rho\mu} - \partial_\rho \tilde g_{\mu\nu})$, the factors $e^{2\omega}$ from the metric and $e^{-2\omega}$ from the inverse cancel against each other, and the derivatives of $e^{2\omega}$ produce

$$\tilde\Gamma^\lambda_{\mu\nu} = \Gamma^\lambda_{\mu\nu} + C^\lambda_{\mu\nu}, \qquad C^\lambda_{\mu\nu} = \delta^\lambda_\mu\,\omega_\nu + \delta^\lambda_\nu\,\omega_\mu - g_{\mu\nu}\,\omega^\lambda, \tag{64.13}$$

where $\omega_\mu \equiv \partial_\mu\omega$ and $\omega^\lambda = g^{\lambda\rho}\omega_\rho$. Its traces are $C^\lambda_{\lambda\nu} = d\,\omega_\nu$ and $g^{\mu\nu}C^\lambda_{\mu\nu} = (2-d)\,\omega^\lambda$. With the curvature convention of the notation watch above, the Ricci tensor is $R_{\sigma\nu} = R^\rho{}_{\sigma\rho\nu}$, and the shift of the Riemann tensor by the tensor $C^\lambda_{\mu\nu}$ contracts to

$$\tilde R_{\sigma\nu} - R_{\sigma\nu} = \nabla_\nu C^\rho_{\rho\sigma} - \nabla_\rho C^\rho_{\nu\sigma} + C^\rho_{\nu\lambda}C^\lambda_{\rho\sigma} - C^\rho_{\rho\lambda}C^\lambda_{\nu\sigma}. \tag{64.14}$$

We evaluate the four pieces using Eq. (64.13). The derivative terms give

$$\begin{aligned} \nabla_\nu C^\rho_{\rho\sigma} &= \nabla_\nu(d\,\omega_\sigma) = d\,\nabla_\nu\nabla_\sigma\omega, \\ \nabla_\rho C^\rho_{\nu\sigma} &= \nabla_\rho(\delta^\rho_\nu\omega_\sigma + \delta^\rho_\sigma\omega_\nu - g_{\nu\sigma}\omega^\rho) = 2\,\nabla_\nu\nabla_\sigma\omega - g_{\nu\sigma}\,\Box_g\omega, \end{aligned} \tag{64.15}$$

where $\nabla_\nu\omega_\sigma = \nabla_\nu\nabla_\sigma\omega$ is symmetric. The quadratic terms, expanded by Eq. (64.13) and contracted index by index, give

$$C^\rho_{\rho\lambda}C^\lambda_{\nu\sigma} = d\big(2\omega_\nu\omega_\sigma - g_{\nu\sigma}(\partial\omega)^2\big), \qquad C^\rho_{\nu\lambda}C^\lambda_{\rho\sigma} = (d+2)\,\omega_\nu\omega_\sigma - 2\,g_{\nu\sigma}(\partial\omega)^2. \tag{64.16}$$

Assembling Eq. (64.14) from Eq. (64.15)–Eq. (64.16),

$$\tilde R_{\sigma\nu} - R_{\sigma\nu} = (d-2)\,\nabla_\nu\nabla_\sigma\omega + g_{\nu\sigma}\,\Box_g\omega - (d-2)\,\omega_\nu\omega_\sigma + (d-2)\,g_{\nu\sigma}(\partial\omega)^2. \tag{64.17}$$

Finally take the scalar by contracting with $\tilde g^{\sigma\nu} = e^{-2\omega}g^{\sigma\nu}$. Using $g^{\sigma\nu}\nabla_\nu\nabla_\sigma\omega = \Box_g\omega$, $g^{\sigma\nu}g_{\nu\sigma} = d$, and $g^{\sigma\nu}\omega_\nu\omega_\sigma = (\partial\omega)^2$,

$$\tilde R = e^{-2\omega}\Big[R + \big((d-2)+d\big)\Box_g\omega + \big(-(d-2)+(d-2)d\big)(\partial\omega)^2\Big] = e^{-2\omega}\big[R + 2(d-1)\Box_g\omega + (d-1)(d-\tag{64.18}$$

which is Eq. (64.12). ∎

We can now establish the headline result by inserting these transformation laws into the action and tracking every term to its cancellation.

Theorem 64.5 (Conformal invariance of the massless ξ_c action)**.** *In d dimensions, the massless ($m=0$) action Eq. (64.2) with $\xi=\xi_c=(d-2)/4(d-1)$ is invariant under the Weyl transformation Eq. (64.10)–Eq. (64.11): $S[\tilde\phi;\tilde g]=S[\phi;g]$. In $d=4$ this is $\xi_c=1/6$. No other value of ξ leaves the action invariant.*

Proof. We display the computation in $d=4$ (so $\xi_c=1/6$ and the field weight is -1, $\tilde\phi=e^{-\omega}\phi$); the general-$d$ case is identical with the weight $(d-2)/2$ carried symbolically and is recorded at the end. Insert the transformed quantities into the massless action evaluated on $(\tilde\phi,\tilde g)$. The measure and inverse metric combine in the kinetic term as $\sqrt{-\tilde g}\,\tilde g^{\mu\nu}=e^{4\omega}\sqrt{-g}\cdot e^{-2\omega}g^{\mu\nu}=e^{2\omega}\sqrt{-g}\,g^{\mu\nu}$, while $\partial_\mu\tilde\phi=e^{-\omega}(\partial_\mu\phi-\omega_\mu\phi)$. Hence the kinetic density is

$$\begin{aligned}\sqrt{-\tilde g}\,\tilde g^{\mu\nu}\partial_\mu\tilde\phi\,\partial_\nu\tilde\phi &= e^{2\omega}\sqrt{-g}\,g^{\mu\nu}\,e^{-2\omega}(\partial_\mu\phi-\omega_\mu\phi)(\partial_\nu\phi-\omega_\nu\phi)\\ &= \sqrt{-g}\Big[(\partial\phi)^2-2\phi\,(\partial\omega\cdot\partial\phi)+\phi^2(\partial\omega)^2\Big],\end{aligned}\tag{64.19}$$

with $(\partial\phi)^2\equiv g^{\mu\nu}\partial_\mu\phi\,\partial_\nu\phi$ and $(\partial\omega\cdot\partial\phi)\equiv g^{\mu\nu}\omega_\mu\partial_\nu\phi$. The curvature density, using Eq. (64.12) with $d=4$ and $\tilde\phi^2=e^{-2\omega}\phi^2$, $\sqrt{-\tilde g}=e^{4\omega}\sqrt{-g}$, is

$$\sqrt{-\tilde g}\,\tilde R\,\tilde\phi^2=e^{4\omega}\sqrt{-g}\cdot e^{-2\omega}\big[R+6\Box_g\omega+6(\partial\omega)^2\big]\cdot e^{-2\omega}\phi^2=\sqrt{-g}\,\phi^2\big[R+6\Box_g\omega+6(\partial\omega)^2\big].\tag{64.20}$$

Therefore, with $\xi=\xi_c=1/6$,

$$S[\tilde\phi;\tilde g]=\frac12\int \mathrm{d}^4x\,\sqrt{-g}\Big[(\partial\phi)^2-2\phi(\partial\omega\cdot\partial\phi)+\phi^2(\partial\omega)^2-\tfrac16\phi^2R-\phi^2\Box_g\omega-\phi^2(\partial\omega)^2\Big].\tag{64.21}$$

The two $\phi^2(\partial\omega)^2$ terms cancel outright. The cross term is recast by noting $2\phi(\partial\omega\cdot\partial\phi)=\omega^\mu\partial_\mu(\phi^2)$ and integrating by parts against the measure, discarding the boundary term:

$$-\frac12\int \mathrm{d}^4x\,\sqrt{-g}\,\omega^\mu\partial_\mu(\phi^2)=+\frac12\int \mathrm{d}^4x\,\sqrt{-g}\,\phi^2\,\nabla_\mu\omega^\mu=+\frac12\int \mathrm{d}^4x\,\sqrt{-g}\,\phi^2\,\Box_g\omega,\tag{64.22}$$

using Theorem 64.2 to write $\nabla_\mu\omega^\mu=\Box_g\omega$. This freshly generated $+\frac12\phi^2\Box_g\omega$ cancels exactly the $-\frac12\phi^2\Box_g\omega$ coming from the curvature term. Every ω- dependent term has now disappeared, leaving

$$S[\tilde\phi;\tilde g]=\frac12\int \mathrm{d}^4x\,\sqrt{-g}\Big[(\partial\phi)^2-\tfrac16\phi^2R\Big]=S[\phi;g],\tag{64.23}$$

which is the massless $\xi=1/6$ action back again. This proves invariance.

To see that $\xi=1/6$ is forced, repeat the computation in general d keeping ξ arbitrary. The kinetic term again produces, after the same integration by parts, a leftover $+\frac12(d-2)/2\cdot\phi^2\Box_g\omega$ from the field-weight $(d-2)/2$ piece (the $(\partial\omega)^2$

pieces and cross terms organize exactly as above), while the curvature term contributes $-\frac{1}{2}\xi\cdot 2(d-1)\phi^2\Box_g\omega$ and a matching $(\partial\omega)^2$ structure. Collecting the coefficient of $\frac{1}{2}\phi^2[\Box_g\omega+(\partial\omega)^2]$ in $S[\tilde\phi;\tilde g]-S[\phi;g]$ gives, after the algebra,

$$S[\tilde\phi;\tilde g]-S[\phi;g]=\frac{1}{2}\Big(1-4(d-1)\xi/(d-2)\Big)\cdot\frac{d-2}{2}\int \mathrm{d}^4x\,\sqrt{-g}\,\phi^2\,[\Box_g\omega+(\partial\omega)^2], \tag{64.24}$$

which vanishes for all ω if and only if $\xi=(d-2)/4(d-1)=\xi_c$. For $d=4$ this is $\xi=1/6$. Any other ξ leaves a nonzero ω-dependent remainder, so the massless action is conformally invariant at ξ_c and at no other value. □

Physical Insight

The conformal value $\xi=1/6$ is exactly the coupling that makes the curvature term conspire with the gradient term so that a local rescaling of all lengths leaves the massless scalar's dynamics untouched. Two physical readings of this will matter later. First, a mass term $\frac{1}{2}m^2\phi^2$ transforms with the "wrong" weight ($\sqrt{-\tilde g}\,\tilde\phi^2=e^{2\omega}\sqrt{-g}\,\phi^2$ in $d=4$, not invariant), so mass breaks conformal invariance—mass is precisely a scale, and a scale is what a Weyl rescaling moves. Second, in a conformally flat spacetime ($g_{\mu\nu}=\Omega^2\eta_{\mu\nu}$, which includes the Friedmann–Lemaître cosmologies) the massless conformally coupled field is, up to the field rescaling Eq. (64.11), just a free flat-space field: its positive-frequency modes, and hence its vacuum, can be borrowed from Minkowski. This is the one curved-space setting in which the vacuum ambiguity is tamed by symmetry, and the later sections lean on it as the clean control case.

64.1.4 The Klein–Gordon inner product and its slice independence

To build a Hilbert space we need an inner product on the space of solutions of Eq. (64.6). In flat space this inner product was implicit in the orthonormality of modes (Theorem 9.8); we now construct it geometrically and prove the property that makes it useful—that it does not depend on which Cauchy slice we evaluate it on. The construction begins with a conserved current built bilinearly from two solutions.

Definition 64.6 (Klein–Gordon current and inner product)**.** For any two (in general complex) solutions ϕ_1,ϕ_2 of Eq. (64.6), define the *Klein–Gordon current*

$$J^\mu[\phi_1,\phi_2]=-i\,g^{\mu\nu}(\phi_1\,\partial_\nu\phi_2^*-\phi_2^*\,\partial_\nu\phi_1)\equiv -i(\phi_1\,\partial^\mu\phi_2^*-\phi_2^*\,\partial^\mu\phi_1), \tag{64.25}$$

and the *Klein–Gordon inner product* on a Cauchy surface Σ,

$$(\phi_1,\phi_2)_\Sigma=\int_\Sigma \mathrm{d}\Sigma^\mu\,J_\mu[\phi_1,\phi_2]=-i\int_\Sigma \mathrm{d}\Sigma^\mu\,(\phi_1\,\partial_\mu\phi_2^*-\phi_2^*\,\partial_\mu\phi_1), \tag{64.26}$$

where $\mathrm{d}\Sigma^\mu = n^\mu\,\mathrm{d}\Sigma$ is the directed surface element: n^μ is the future-pointing unit normal to Σ ($n^\mu n_\mu = +1$ for a spacelike surface in our signature) and $\mathrm{d}\Sigma = \sqrt{h}\,\mathrm{d}^3x$ is the induced volume element built from the spatial metric h_{ij} of Eq. (64.1).

Two remarks fix the meaning. First, the product is conjugate-linear in its second slot and linear in its first, and it is *indefinite*: it is not a norm but a sesquilinear form, and $(\phi,\phi)_\Sigma$ can be positive, negative, or zero. This indefiniteness is the engine of the whole subject—it is what makes the positive-norm/negative-norm split a meaningful but non-canonical choice. Second, on a constant-time slice in flat space, $n^\mu = (1,\mathbf{0})$ and $\mathrm{d}\Sigma = \mathrm{d}^3x$, so Eq. (64.26) reduces to $-i\int \mathrm{d}^3x\,(\phi_1\dot\phi_2^* - \phi_2^*\dot\phi_1)$, the textbook flat-space form. The geometric content beyond that form is the claim that the answer is the same on *every* Cauchy slice, which we now prove.

Theorem 64.7 (Slice independence of the Klein–Gordon product)**.** *Let ϕ_1,ϕ_2 be solutions of Eq. (64.6) on a globally hyperbolic (M,g), with spatial fall-off fast enough that all boundary terms at spatial infinity vanish. Then the current Eq. (64.25) is covariantly conserved, $\nabla_\mu J^\mu = 0$, and consequently $(\phi_1,\phi_2)_\Sigma$ is independent of the choice of Cauchy surface Σ: $(\phi_1,\phi_2)_{\Sigma_1} = (\phi_1,\phi_2)_{\Sigma_2}$ for any two Cauchy surfaces Σ_1,Σ_2.*

Proof. We compute the covariant divergence of Eq. (64.25) directly. Because ∇_μ annihilates the metric, $\nabla_\mu(g^{\mu\nu}X_\nu) = g^{\mu\nu}\nabla_\mu X_\nu$, so

$$\nabla_\mu J^\mu = -i\,\nabla_\mu\big(\phi_1\,\partial^\mu\phi_2^* - \phi_2^*\,\partial^\mu\phi_1\big). \tag{64.27}$$

Apply the Leibniz rule to each term, using again that for a scalar $\partial^\mu\phi = \nabla^\mu\phi$ and that $\nabla_\mu\nabla^\mu = \Box_g$ acting on a scalar:

$$\nabla_\mu\big(\phi_1\,\nabla^\mu\phi_2^*\big) = \nabla_\mu\phi_1\,\nabla^\mu\phi_2^* + \phi_1\,\Box_g\phi_2^*, \tag{64.28}$$

$$\nabla_\mu\big(\phi_2^*\,\nabla^\mu\phi_1\big) = \nabla_\mu\phi_2^*\,\nabla^\mu\phi_1 + \phi_2^*\,\Box_g\phi_1. \tag{64.29}$$

The two "gradient-dot-gradient" terms are identical ($\nabla_\mu\phi_1\,\nabla^\mu\phi_2^* = \nabla_\mu\phi_2^*\,\nabla^\mu\phi_1$) and cancel in the difference. Hence

$$\nabla_\mu J^\mu = -i\big(\phi_1\,\Box_g\phi_2^* - \phi_2^*\,\Box_g\phi_1\big). \tag{64.30}$$

Now use the field equation. Both ϕ_1 and ϕ_2 solve Eq. (64.6); complex-conjugating the equation for ϕ_2 and using that $m^2+\xi R$ is real gives $\Box_g\phi_2^* = -(m^2+\xi R)\phi_2^*$, while $\Box_g\phi_1 = -(m^2+\xi R)\phi_1$. Substituting,

$$\nabla_\mu J^\mu = -i\Big[\phi_1\big(-(m^2{+}\xi R)\phi_2^*\big) - \phi_2^*\big(-(m^2{+}\xi R)\phi_1\big)\Big] = -i\,(m^2{+}\xi R)\big(-\phi_1\phi_2^* + \phi_2^*\phi_1\big) = 0. \tag{64.31}$$

The current is conserved. The conservation is exact and uses nothing but the field equation and the reality of the mass-and-curvature term; the value of ξ is irrelevant to it.

To convert conservation into slice independence, integrate $\nabla_\mu J^\mu = 0$ over the spacetime region Ω bounded by two Cauchy surfaces Σ_1 (to the past) and Σ_2 (to the future) and, if the slices are noncompact, a timelike tube $\mathcal{T}$ at large spatial radius. The covariant Gauss theorem states that for any vector field J^μ,

$$\int_\Omega \mathrm{d}^4x\,\sqrt{-g}\,\nabla_\mu J^\mu = \oint_{\partial\Omega} \mathrm{d}\Sigma_\mu\, J^\mu, \tag{64.32}$$

which is itself just Theorem 64.2 integrated: $\sqrt{-g}\,\nabla_\mu J^\mu = \partial_\mu(\sqrt{-g}\,J^\mu)$ is a coordinate divergence, so its integral reduces by the ordinary divergence theorem to a boundary integral, and the induced measure on $\partial\Omega$ assembles into $\mathrm{d}\Sigma_\mu$. The left-hand side vanishes by Eq. (64.31). On the right, the tube contribution $\int_{\mathcal{T}} \mathrm{d}\Sigma_\mu J^\mu$ vanishes by the assumed spatial fall-off. The boundary $\partial\Omega$ then consists of Σ_2 with outward (future-pointing) normal and Σ_1 with outward (past-pointing) normal, so that with both surface elements oriented by their *future*-pointing normals,

$$0 = \oint_{\partial\Omega} \mathrm{d}\Sigma_\mu J^\mu = \int_{\Sigma_2} \mathrm{d}\Sigma_\mu J^\mu - \int_{\Sigma_1} \mathrm{d}\Sigma_\mu J^\mu = i\big[(\phi_1,\phi_2)_{\Sigma_2} - (\phi_1,\phi_2)_{\Sigma_1}\big]/(-i), \tag{64.33}$$

where the relative minus sign is the flip between the outward and future-pointing normals on the past surface. Hence $(\phi_1,\phi_2)_{\Sigma_2} = (\phi_1,\phi_2)_{\Sigma_1}$. Since Σ_1, Σ_2 were arbitrary, the product is the same on every Cauchy slice. □

Physical Insight

Slice independence is what lets us speak of "the inner product on the space of solutions" without naming a time. It is the curved-space avatar of conservation of the Klein–Gordon norm under time evolution. Crucially, it holds for *any* globally hyperbolic geometry and *any* value of ξ; it is one of the structures that survives the loss of Poincaré invariance intact. What will *not* survive is the next step—deciding which solutions have positive product—because that requires a notion of positive frequency, and that requires a clock.

64.1.5 Mode expansion, quantization, and the Fock space

We can now quantize. The strategy is the geometric analogue of Theorem 9.6: expand the field operator in a complete set of classical solutions and read off the commutation relations of the expansion coefficients. The novelty is that the choice of basis is no longer dictated by a symmetry, so we must state carefully what a good basis is and what is convention in the result.

Definition 64.8 (Complete orthonormal mode set)**.** A countable[1] family of complex solutions $\{u_i\}$ of Eq. (64.6) is a *complete orthonormal mode set* if, with respect to the Klein–Gordon product Eq. (64.26),

$$(u_i, u_j) = \delta_{ij}, \qquad (u_i^*, u_j^*) = -\delta_{ij}, \qquad (u_i, u_j^*) = 0, \tag{64.34}$$

and the set $\{u_i, u_i^*\}$ together spans the space of (complex) solutions, i.e. every real solution ϕ can be written as a convergent combination $\phi = \sum_i (c_i u_i + c_i^* u_i^*)$.

Three facts about Eq. (64.34) deserve emphasis because they encode exactly what is conventional. The relation $(u_i^*, u_j^*) = -\delta_{ij}$ is forced, not chosen: conjugating Eq. (64.26) gives $(\phi_1^*, \phi_2^*) = -(\phi_2, \phi_1) = -(\phi_1, \phi_2)^*$, so positive-norm solutions have negative-norm conjugates. The vanishing of (u_i, u_j^*) is a genuine requirement on the basis: it says the positive-norm sector and its conjugate are orthogonal under the product. And the decision to call the u_i (rather than the u_i^*) "positive norm"—to put them on the annihilation side below—is the one piece of true convention, the seed of the vacuum ambiguity. In flat space this decision was removed by demanding that the u_i be positive frequency with respect to the global time; here there is no such global time to appeal to, and *any* split of the solution space into a positive-norm subspace and its conjugate that satisfies Eq. (64.34) defines a legitimate basis.

With a basis fixed, the quantum field is the operator-valued distribution

$$\hat{\phi}(x) = \sum_i \left(a_i \, u_i(x) + a_i^\dagger \, u_i^*(x) \right), \tag{64.35}$$

with $\hat{\phi}$ Hermitian because the field is real and the two terms are mutual conjugates. The coefficients $a_i, a_i^\dagger$ are extracted from $\hat{\phi}$ by the inner product, exactly because the basis is orthonormal: applying Eq. (64.26) to Eq. (64.35) and using Eq. (64.34),

$$(u_i, \hat{\phi}) = \sum_j \left[a_j (u_i, u_j) + a_j^\dagger (u_i, u_j^*) \right] = a_i, \qquad (u_i^*, \hat{\phi}) = \sum_j \left[a_j (u_i^*, u_j) + a_j^\dagger (u_i^*, u_j^*) \right] = -a_i^\dagger. \tag{64.36}$$

These projection formulas are the curved-space counterpart of the inversion relations Eq. (9.44)–Eq. (9.45).

The commutation relations now follow from the canonical structure. The quantization postulate is the equal-time canonical commutator on a Cauchy slice Σ, the geometric form of Eq. (9.7): with the momentum conjugate to ϕ being $\pi = \sqrt{-g}\, g^{0\nu} \partial_\nu \phi = \sqrt{h}\, n^\nu \partial_\nu \phi / N \cdot N = \sqrt{h}\, n^\nu \partial_\nu \phi$ in the slicing Eq. (64.1),[2] the

[1] We write the basis as discrete for notational economy, as in Chapter 9; for noncompact slices the index i is continuous and Kronecker deltas become Dirac deltas, with sums becoming integrals. Nothing in the argument depends on this.

[2] The conjugate momentum is $\pi = \partial \mathcal{L} / \partial \dot{\phi}$ with $\mathcal{L}$ the density *including* the $\sqrt{-g}$ factor; in the lapse/shift-free form Eq. (64.1) one finds $\pi = (\sqrt{h}/N)\dot{\phi} = \sqrt{h}\, n^\nu \partial_\nu \phi$, the spatial volume element times the normal (proper-time) derivative.

postulate is

$$[\hat{\phi}(x), \hat{\phi}(y)]\big|_\Sigma = 0, \qquad [\hat{\phi}(x), \hat{\pi}(y)]\big|_\Sigma = i\,\delta^{(3)}(x,y), \tag{64.37}$$

where $\delta^{(3)}(x,y)$ is the delta distribution on Σ normalized against the induced measure $\mathrm{d}\Sigma = \sqrt{h}\,\mathrm{d}^3x$ (so $\int_\Sigma \mathrm{d}\Sigma_y\,\delta^{(3)}(x,y)f(y) = f(x)$). Feeding Eq. (64.35) through the projection formulas Eq. (64.36) and using Eq. (64.37) converts these field commutators into commutators of the coefficients. The computation is the inner-product packaging of the flat-space one in Theorem 9.9: schematically, $[a_i, a_j^\dagger] = (u_i, \hat{\phi})\,(\hat{\phi}, u_j)$-type brackets collapse, via the canonical commutator and the orthonormality Eq. (64.34), to

$$[a_i, a_j] = 0, \qquad [a_i^\dagger, a_j^\dagger] = 0, \qquad [a_i, a_j^\dagger] = \delta_{ij}. \tag{64.38}$$

The orthonormality of the modes is exactly what makes the right-hand side a clean δ_{ij}: a non-orthonormal basis would produce the inverse Gram matrix of the modes instead, which is why Eq. (64.34) was imposed in the first place. We make the projection-to-commutator computation fully explicit in Theorem 64.9.

Worked Example 64.9 (Ladder algebra from the canonical commutator)**.** We derive $[a_i, a_j^\dagger] = \delta_{ij}$ from Eq. (64.37). The cleanest route writes the inner product Eq. (64.26) on the slice Σ in terms of $\hat{\phi}$ and $\hat{\pi}$. Using $n^\mu\partial_\mu\hat{\phi} = \hat{\pi}/\sqrt{h}$ and $\mathrm{d}\Sigma = \sqrt{h}\,\mathrm{d}^3x$, the surface integral becomes

$$(f, \hat{\phi}) = -i\int_\Sigma \mathrm{d}\Sigma\; n^\mu(f\,\partial_\mu\hat{\phi} - \hat{\phi}\,\partial_\mu f) = -i\int_\Sigma \mathrm{d}^3x\,(f\,\hat{\pi} - \sqrt{h}\,\hat{\phi}\,n^\mu\partial_\mu f), \tag{64.39}$$

for any solution f. Apply this with $f = u_i$ to get a_i, per Eq. (64.36), and with $f = u_j^*$ to get $-a_j^\dagger$. Then

$$\begin{aligned}[a_i, a_j^\dagger] &= -\big[(u_i, \hat{\phi}),\,(u_j^*, \hat{\phi})\big] \\ &= -\int_{\Sigma_x}\int_{\Sigma_y}\big(-i\big)\big(-i\big)\Big[(u_i\hat{\pi}_x - \sqrt{h}\,\hat{\phi}_x\,n\cdot\partial u_i),\,(u_j^*\hat{\pi}_y - \sqrt{h}\,\hat{\phi}_y\,n\cdot\partial u_j^*)\Big]\mathrm{d}^3x\,\mathrm{d}^3y.\end{aligned} \tag{64.40}$$

Only the cross terms survive the commutator, because $[\hat{\phi}, \hat{\phi}] = [\hat{\pi}, \hat{\pi}] = 0$ on Σ. Using $[\hat{\phi}_x, \hat{\pi}_y] = i\delta^{(3)}(x,y)$ (and the opposite-sign transpose) the two surviving terms give

$$[a_i, a_j^\dagger] = -\int_\Sigma \mathrm{d}^3x\;(-i)\Big[u_i(\sqrt{h}\,n\cdot\partial u_j^*) - (\sqrt{h}\,n\cdot\partial u_i)u_j^*\Big](-i)\cdot\frac{1}{\sqrt{h}}\cdot\sqrt{h}, \tag{64.41}$$

which, after the delta functions are integrated and the factors of $\sqrt{h}$ and $n\cdot\partial$ reassemble, is exactly $+i\int_\Sigma \mathrm{d}\Sigma\, n^\mu(u_i\partial_\mu u_j^* - u_j^*\partial_\mu u_i) = (u_i, u_j) = \delta_{ij}$. The same bookkeeping gives $[a_i, a_j] \propto (u_i, u_j^*) = 0$ and $[a_i^\dagger, a_j^\dagger] \propto (u_i^*, u_j) = 0$. Thus

Eq. (64.37) is equivalent to Eq. (64.38) together with the mode orthonormality Eq. (64.34): the canonical commutator *is* the orthonormality of the modes, read through the expansion. This is why a different orthonormal basis automatically yields ladder operators with the same algebra—a fact we exploit in the next subsection.

The algebra Eq. (64.38) is the standard creation/annihilation algebra of Chapter 9. From here the Fock space is built by the identical construction as Theorem 9.17: declare a normalized state $|0_u\rangle$ annihilated by every a_i,

$$a_i\,|0_u\rangle = 0 \quad \forall i, \qquad \langle 0_u|0_u\rangle = 1, \tag{64.42}$$

and generate the Hilbert space by repeated action of the $a_i^\dagger$, with $a_{i_1}^\dagger \cdots a_{i_n}^\dagger\,|0_u\rangle$ spanning the n-particle sector. Because the algebra is identical, the Fock space is the same abstract object as in flat space: a separable Hilbert space carrying a representation of the canonical commutators, with a number operator $N = \sum_i a_i^\dagger a_i$ and the usual spectrum.

There is, however, a deliberate change of notation that carries the entire moral of the chapter: we have written the vacuum as $|0_u\rangle$, with an explicit subscript recording the mode basis $\{u_i\}$ that defines it. In flat space we wrote $|0\rangle$ with no subscript, because there was nothing to record—the basis was unique. Here the subscript is mandatory, because Eq. (64.42) defines the vacuum *relative to the chosen basis*. A different complete orthonormal set $\{v_i\}$ defines a different annihilation operator and a different state $|0_v\rangle$, and there is no symmetry to declare one of them correct. The Fock space survived the move to curved spacetime; the preferred vacuum did not.

Caution

The label "positive norm" on the u_i is not a property of the solutions in isolation; it is a property of the chosen *splitting* of the solution space. Any solution u has $(u, u) > 0$ while its conjugate u^* has $(u^*, u^*) < 0$, so calling u the particle mode and u^* the antiparticle mode is a real choice. In flat space the choice $u_{\mathbf{k}} \propto e^{-i\omega_k t + i\mathbf{k}\cdot\mathbf{x}}$ with $\omega_k > 0$ was singled out by positive frequency with respect to the Killing time t. Strip away the Killing vector and the words "positive frequency" have no referent. The mistake to avoid is to imagine that the positive/negative-norm split is god-given; it is exactly as arbitrary as the choice of time function in Eq. (64.1).

64.1.6 The field is geometric; the particle split is not

We have asserted that the field operator $\hat{\phi}$ is well defined while its decomposition into creation and annihilation parts is conventional. This deserves a clean

statement and proof, because it is the precise sense in which physics lives upstream of the vacuum ambiguity.

Proposition 64.10 (Basis independence of the smeared field)**.** *Let* $\{u_i\}$ *and* $\{v_j\}$ *be two complete orthonormal mode sets in the sense of Theorem 64.8, defining field expansions* $\hat{\phi} = \sum_i (a_i u_i + a_i^\dagger u_i^*) = \sum_j (b_j v_j + b_j^\dagger v_j^*)$ *and vacua* $|0_u\rangle, |0_v\rangle$*. Then the two expansions define the* same *operator-valued distribution* $\hat{\phi}(x)$*: for every real test function (or, on a slice, every smearing against the canonical data), the smeared field* $\hat{\phi}(f) = \int \mathrm{d}^4x \, \sqrt{-g}\, f(x)\hat{\phi}(x)$ *computed from either basis agrees.*

Proof. The two bases are both complete in the solution space, so each v_j is a (KG-) linear combination of the u_i and their conjugates, and vice versa. Concretely, expand v_j against the u-basis using the projection Eq. (64.39) in classical form:

$$v_j = \sum_i \left[(v_j, u_i)\, u_i - (v_j, u_i^*)\, u_i^* \right] \equiv \sum_i \left[\alpha_{ji}\, u_i + \beta_{ji}\, u_i^* \right], \tag{64.43}$$

where the coefficients α, β are the inner products (v_j, u_i) and $-(v_j, u_i^*)$; their precise definition and properties are the subject of the next section and are not needed here. What matters is only that *some* such linear relation exists, with the inverse relation expressing u_i through the v_j. Substitute the expansion of every v_j (and v_j^*) into $\hat{\phi} = \sum_j (b_j v_j + b_j^\dagger v_j^*)$. The result is a linear combination of the u_i and u_i^* whose coefficients are operators built from the $b_j, b_j^\dagger$. Collecting the coefficient of u_i and of u_i^* and comparing with $\hat{\phi} = \sum_i (a_i u_i + a_i^\dagger u_i^*)$, the completeness and linear independence of $\{u_i, u_i^*\}$ force the operator multiplying u_i to equal a_i and the operator multiplying u_i^* to equal $a_i^\dagger$. That is, the change of basis re-expresses the *same* $\hat{\phi}$; the operators a_i are simply particular linear combinations of the $b_j, b_j^\dagger$ (and conversely). No appeal to any vacuum was made: the equality of the two expansions is an identity among operators, holding before any state is chosen. Smearing both sides against f preserves the identity. □

Physical Insight

This is the cleanest possible statement of what is objective in quantum field theory on a curved background. The field $\hat{\phi}(x)$—and hence every local, covariant observable built from it, the stress tensor included—is a single geometric object, independent of any mode basis. What depends on the basis is the bookkeeping that calls half of $\hat{\phi}$ "annihilation" and the other half "creation," and the state $|0\rangle$ that bookkeeping singles out. "Particle number" is therefore not a property of the field but of a field-plus-basis pair. Two observers using different bases write the same $\hat{\phi}$ but disagree about how many particles a given state contains. The reconciliation of their two bookkeepings is the Bogoliubov transformation that opens the

next section.

64.1.7 Why flat space was special

It is worth saying exactly what flat space had that a generic curved spacetime lacks, because the contrast is the conceptual pivot of the whole chapter. Minkowski space is globally hyperbolic, so it too admits the construction above; the difference is not in the existence of a Fock space but in the *uniqueness* of the preferred one. Flat space possesses a global timelike Killing vector $K = \partial_t$—a vector field generating an isometry, $\mathcal{L}_K g_{\mu\nu} = \nabla_\mu K_\nu + \nabla_\nu K_\mu = 0$, that is timelike everywhere. With it, "positive frequency" acquires an invariant meaning: a mode u is positive frequency if it is an eigenfunction of the Lie derivative along K with eigenvalue of definite sign,

$$\mathcal{L}_K u = -i\omega\, u, \qquad \omega > 0. \tag{64.44}$$

In coordinates adapted to K this is $\partial_t u = -i\omega u$, the familiar $e^{-i\omega t}$ time dependence. Because K is a symmetry, the splitting it induces is preserved by time evolution and shared by all inertial observers, and the vacuum it selects is the unique Poincaré-invariant state. This is precisely the content of the Wigner program imported from Chapter 3: a one-particle state is a unitary irreducible representation of the Poincaré group (Theorem 3.34, Section 3.7), labelled by mass and spin, and the vacuum is the unique invariant vector. The positive-frequency condition Eq. (64.44) is exactly what makes the one-particle Hilbert space carry such a representation. The flat-space scalar's diagonalization of the Hamiltonian and its Poincaré transformation properties (Section 9.3.6) are downstream of this single fact.

A generic globally hyperbolic (M, g) has no Killing vector at all—the metric Eq. (64.1) need have no symmetry whatsoever—and even when it has one, the Killing vector need not be timelike everywhere (the Schwarzschild ∂_t becomes spacelike inside the horizon; the Rindler boost Killing vector that generates uniform acceleration, central to the Unruh analysis later in this chapter, is timelike only inside a wedge). Without a global timelike Killing vector, Eq. (64.44) has no solution set to call "the" positive-frequency modes, and the construction of Section 64.1.5 runs with an irreducibly arbitrary choice of basis. There is no preferred vacuum, no invariant number operator, and no observer-independent notion of a particle. Everything that the Poincaré group did silently in flat space must now be done by hand, observer by observer—and different observers will make incompatible choices.

This is not a defect of the formalism but a physical feature: it is the statement that "particle" is an observer-dependent concept once the rigid scaffolding of Poincaré symmetry is removed. We have built the stage exactly far enough to make that statement precise. We have a covariant action and field equation

(Eq. (64.2), Eq. (64.6)), a slice-independent inner product (Theorem 64.7), and, for each choice of complete orthonormal mode set, a Fock space with a vacuum $|0_u\rangle$ tied inextricably to that choice (Eq. (64.42)). The field itself is basis-independent (Theorem 64.10); only its split into particles is not. The obvious and unavoidable question is therefore quantitative: given two such mode sets, how are their creation and annihilation operators—and their two vacua—related, and when does one observer's vacuum contain the other's particles? Answering that question is the work of the next section, where the linear relation merely gestured at in Eq. (64.43) is promoted to the Bogoliubov transformation that powers every result in the remainder of the chapter.

64.2 Bogoliubov transformations and the non-uniqueness of the vacuum

The previous section left us holding a Fock space with no canonical address. We quantized the free scalar on a globally hyperbolic background, found the canonical commutators intact, and built a perfectly good Hilbert space of "particles" on top of a vacuum — but the vacuum we obtained was tied to a choice of mode basis, and on a generic curved spacetime no choice is singled out. Two physicists who pick different complete sets of positive-frequency solutions of the field equation build genuinely different vacua, and there is no geometric fact that adjudicates between them. This is not a defect of the construction; it is the central physical content of the subject. What we must do now is make the ambiguity *quantitative*: given two such bases, we want a machine that takes the data relating them and returns the precise sense in which one observer's empty space is another's bath of particles. That machine is the Bogoliubov transformation, and every concrete effect in the rest of the chapter — cosmological particle production, the Unruh bath, Hawking radiation — is in the end a computation of its coefficients for a physically chosen pair of bases.

64.2.1 Two mode bases and the coefficients that connect them

Recall from Section 64.1 the structure we inherit. On a globally hyperbolic spacetime $(M, g_{\mu\nu})$ with mostly-minus signature $\eta_{\mu\nu} = \mathrm{diag}(+,-,-,-)$, the free real scalar obeys the curved-space Klein–Gordon equation, and the space of its complex solutions carries the conserved Klein–Gordon inner product

$$(f,g) \;=\; i\int_{\Sigma} \mathrm{d}\Sigma^{\mu}\,\big[\,(\partial_\mu f)\,g^{*} - f\,\partial_\mu g^{*}\,\big], \qquad \mathrm{d}\Sigma^{\mu} = n^{\mu}\,\sqrt{h}\;\mathrm{d}^{3}y, \tag{64.45}$$

with Σ any Cauchy surface, n^μ its future-directed unit normal, and h the determinant of the induced metric. The value of Eq. (64.45) is independent of the choice of Σ because the current $j^\mu = i[(\partial^\mu f)g^* - f\,\partial^\mu g^*]$ is conserved, $\nabla_\mu j^\mu = 0$,

whenever f and g solve the field equation (Eq. (64.45) is sesquilinear — linear in its first slot, antilinear in its second). A *mode basis* is a discrete[3] family of solutions $\{u_j, u_j^*\}$ that is complete and orthonormal in the sense

$$(u_i, u_j) = \delta_{ij}, \qquad (u_i^*, u_j^*) = -\,\delta_{ij}, \qquad (u_i, u_j^*) = 0. \tag{64.46}$$

The minus sign in the second relation is forced by Eq. (64.45): complex conjugation flips the sign of the inner product, so if the u_j have positive norm their conjugates have negative norm. This is exactly why the "positive-frequency" modes u_j (those of positive Klein–Gordon norm) and their conjugates together span the solution space, and why the field expansion

$$\phi(x) \;=\; \sum_j \Big[\, a_j\, u_j(x) + a_j^\dagger\, u_j^*(x) \,\Big] \tag{64.47}$$

realizes the canonical commutators as $\big[a_i, a_j^\dagger\big] = \delta_{ij}$, $[a_i, a_j] = 0$, with the Fock space and number operator of Chapter 9 (Theorem 9.17, Eq. (9.110)) erected on the vacuum $a_j\,|0_a\rangle = 0$ of Theorem 9.11. All of this was established in Section 64.1; we now take a *second*, equally legitimate basis.

Let $\{v_i, v_i^*\}$ be another complete orthonormal mode basis, obeying the same relations Eq. (64.46), with its own field expansion

$$\phi(x) \;=\; \sum_i \Big[\, b_i\, v_i(x) + b_i^\dagger\, v_i^*(x) \,\Big], \qquad \big[b_i, b_j^\dagger\big] = \delta_{ij}, \quad [b_i, b_j] = 0, \tag{64.48}$$

and its own vacuum $b_i\,|0_b\rangle = 0$. The field operator $\phi(x)$ is one and the same object — it is fixed by the dynamics and the canonical data, not by our bookkeeping — so Eq. (64.47) and Eq. (64.48) are two expansions of the identical operator. Because each basis is complete, each v_i is a linear combination of the u_j and u_j^*; we name the coefficients.

Definition 64.11 (Bogoliubov coefficients)**.** The *Bogoliubov coefficients* relating the basis $\{u_j\}$ to the basis $\{v_i\}$ are

$$\alpha_{ij} \;=\; (v_i, u_j), \qquad \beta_{ij} \;=\; -\,(v_i, u_j^*). \tag{64.49}$$

We assemble them into (in general infinite) matrices $\alpha = (\alpha_{ij})$ and $\beta = (\beta_{ij})$.

These coefficients are not free data: they reconstruct the change of basis completely. Expanding each v_i over the complete set and projecting with Eq. (64.46),

$$v_i \;=\; \sum_j \Big[\, \alpha_{ij}\, u_j + \beta_{ij}\, u_j^* \,\Big]. \tag{64.50}$$

[3] We write all sums over discrete labels; on a noncompact Cauchy surface the labels are continuous and every $\sum_j$ is read as the appropriate $\int \mathrm{d}\mu(j)$ and every δ_{ij} as $\delta(i-j)$. Nothing below depends on this, and the discrete notation keeps the linear algebra legible.

That this is consistent with Eq. (64.49) is a one-line check: taking the inner product of Eq. (64.50) with u_k and using the linearity of $(\,\cdot\,,\,\cdot\,)$ in its first slot together with Eq. (64.46) gives $(v_i, u_k) = \alpha_{ik}$, while pairing with u_k^* gives $(v_i, u_k^*) = \beta_{ik}(u_k^*, u_k^*) = -\beta_{ik}$, exactly Eq. (64.49). The conjugate of Eq. (64.50) is $v_i^* = \sum_j (\alpha_{ij}^* u_j^* + \beta_{ij}^* u_j)$.

The operator dictionary. We now read off how the two sets of ladder operators are related, and we do it by substitution rather than by projecting the field — this avoids any subtlety about how the antilinear inner product acts on the operator-valued ϕ, and it makes every step pure linear algebra. Insert Eq. (64.50) and its conjugate into the b-expansion Eq. (64.48):

$$\begin{aligned}\phi &= \sum_i \Big[\, b_i \sum_j (\alpha_{ij} u_j + \beta_{ij} u_j^*) + b_i^\dagger \sum_j (\alpha_{ij}^* u_j^* + \beta_{ij}^* u_j) \,\Big] \\ &= \sum_j \Big[\underbrace{\Big(\textstyle\sum_i (\alpha_{ij} b_i + \beta_{ij}^* b_i^\dagger)\Big)}_{\text{coefficient of } u_j} u_j \;+\; \underbrace{\Big(\textstyle\sum_i (\beta_{ij} b_i + \alpha_{ij}^* b_i^\dagger)\Big)}_{\text{coefficient of } u_j^*} u_j^* \Big]. \end{aligned} \tag{64.51}$$

Matching Eq. (64.51) term by term against the a-expansion Eq. (64.47) (the modes u_j, u_j^* are linearly independent, so their coefficients must agree) gives

$$a_j \;=\; \sum_i \Big[\, \alpha_{ij}\, b_i + \beta_{ij}^*\, b_i^\dagger \,\Big], \tag{64.52}$$

the coefficient of u_j^* reproducing precisely the Hermitian conjugate of Eq. (64.52), as it must. Inverting the mode relation Eq. (64.50) — equivalently, repeating the substitution with the roles of the two bases exchanged, using $u_j = \sum_i (\alpha_{ij}^* v_i - \beta_{ij} v_i^*)$ which we verify in Section 64.2.2 below — yields the companion relation

$$b_i \;=\; \sum_j \Big[\, \alpha_{ij}^*\, a_j - \beta_{ij}^*\, a_j^\dagger \,\Big]. \tag{64.53}$$

Equations (64.52) and (64.53) are the heart of the matter. The crucial feature is the β: if β vanishes, then b_i is a unitary recombination of *annihilation operators only*, the two vacua coincide, and the bases describe the same particles in different clothing. The moment β is nonzero, b_i mixes creation into annihilation: the operator that annihilates "b-particles" contains a piece that *creates* "a-particles," so the a-vacuum cannot be the b-vacuum. We make this precise in Section 64.2.3; first we must see what constraints (α, β) obey.

64.2.2 Preservation of the canonical structure: the Bogoliubov identities

The coefficients α, β are not arbitrary. Both $\{a_j\}$ and $\{b_i\}$ are bona fide ladder operators — they must *both* satisfy the canonical commutators — and this

single demand pins down two quadratic identities. Physically, the Bogoliubov transformation is the most general linear map on the field's phase space that preserves the canonical (symplectic) structure; the identities are the statement that it lies in the symplectic group.

Proposition 64.12 (Bogoliubov normalization identities)**.** *If both* $(a_j, a_j^\dagger)$ *and* $(b_i, b_i^\dagger)$ *obey the canonical commutation relations, the Bogoliubov coefficients of Theorem 64.11 satisfy*

$$\sum_k \Big(\alpha_{ik}\, \alpha^*_{jk} - \beta_{ik}\, \beta^*_{jk} \Big) = \delta_{ij}, \tag{64.54}$$

$$\sum_k \Big(\alpha_{ik}\, \beta_{jk} - \beta_{ik}\, \alpha_{jk} \Big) = 0. \tag{64.55}$$

In matrix form, with $\dagger$ *the conjugate transpose and* ^{T} *the transpose, these read* $\alpha\alpha^\dagger - \beta\beta^\dagger = \mathbf{1}$ *and* $\alpha\beta^T = \beta\alpha^T$.

Proof. Impose $\left[b_i, b_j^\dagger\right] = \delta_{ij}$ using Eq. (64.53). With $b_i = \sum_k (\alpha^*_{ik} a_k - \beta^*_{ik} a_k^\dagger)$ and $b_j^\dagger = \sum_l (\alpha_{jl} a_l^\dagger - \beta_{jl} a_l)$, only the elementary brackets $\left[a_k, a_l^\dagger\right] = \delta_{kl}$ and $\left[a_k^\dagger, a_l\right] = -\delta_{kl}$ contribute:

$$\begin{aligned} \left[b_i, b_j^\dagger\right] &= \sum_{k,l} \Big[\alpha^*_{ik}\alpha_{jl}\, \left[a_k, a_l^\dagger\right] + (-\beta^*_{ik})(-\beta_{jl})\, \left[a_k^\dagger, a_l\right] \Big] \\ &= \sum_{k,l} \Big[\alpha^*_{ik}\alpha_{jl}\, \delta_{kl} - \beta^*_{ik}\beta_{jl}\, \delta_{kl} \Big] = \sum_k \Big(\alpha^*_{ik}\alpha_{jk} - \beta^*_{ik}\beta_{jk} \Big). \end{aligned} \tag{64.56}$$

Setting Eq. (64.56) equal to δ_{ij} and taking the complex conjugate of the whole equation (a real Kronecker delta is unchanged) gives exactly Eq. (64.54). Next impose $[b_i, b_j] = 0$:

$$\begin{aligned} [b_i, b_j] &= \sum_{k,l} \Big[\alpha^*_{ik}(-\beta^*_{jl})\, \left[a_k, a_l^\dagger\right] + (-\beta^*_{ik})\alpha^*_{jl}\, \left[a_k^\dagger, a_l\right] \Big] \\ &= \sum_k \Big(-\alpha^*_{ik}\beta^*_{jk} + \beta^*_{ik}\alpha^*_{jk} \Big) = 0. \end{aligned} \tag{64.57}$$

Taking the complex conjugate of Eq. (64.57) gives $\sum_k (\alpha_{ik}\beta_{jk} - \beta_{ik}\alpha_{jk}) = 0$, which is Eq. (64.55). (Imposing the canonical commutators on the a's instead, via Eq. (64.52), gives nothing new: it returns the same two identities because the relations are an involutive pair.) □

The identities have a second, equally useful form obtained by summing over the *first* index. Demanding that Eq. (64.50) be invertible — that the $\{v_i\}$ really are a complete basis, so that the u_j can be expanded back over them — one

writes the trial inverse $u_j = \sum_i (\alpha^*_{ij} v_i - \beta_{ij} v^*_i)$ and substitutes Eq. (64.50) and its conjugate:

$$\sum_i (\alpha^*_{ij} v_i - \beta_{ij} v^*_i) = \sum_k u_k \sum_i (\alpha^*_{ij}\alpha_{ik} - \beta_{ij}\beta^*_{ik}) + \sum_k u^*_k \sum_i (\alpha^*_{ij}\beta_{ik} - \beta_{ij}\alpha^*_{ik}). \tag{64.58}$$

For the right-hand side to equal u_j we need the bracketed sums to be δ_{jk} and 0 respectively, i.e.

$$\sum_i \left(\alpha^*_{ij}\alpha_{ik} - \beta_{ij}\beta^*_{ik}\right) = \delta_{jk}, \qquad \sum_i \left(\alpha^*_{ij}\beta_{ik} - \beta_{ij}\alpha^*_{ik}\right) = 0, \tag{64.59}$$

which in matrix form are $\alpha^\dagger\alpha - \beta^T\beta^* = \mathbf{1}$ and $\alpha^\dagger\beta = \beta^T\alpha^*$. These are not independent of Eqs. (64.54) and (64.55); they follow from them because a square matrix that is left-invertible is right-invertible. Their virtue is that they make the inverse explicit, justifying the relation $u_j = \sum_i (\alpha^*_{ij} v_i - \beta_{ij} v^*_i)$ used to obtain Eq. (64.53), and we will call on the second of them when we prove the in-vacuum is a squeezed state.

Physical Insight

The two identities say that $\alpha\alpha^\dagger - \beta\beta^\dagger = \mathbf{1}$: the "rotation part" α and the "mixing part" β are locked together so that α is always at least as big as β in the operator sense. A pure rotation ($\beta = 0$, α unitary) shuffles particles among modes and is invisible to the vacuum. The genuinely curved-spacetime content lives entirely in β: it is the obstruction to the two positive-frequency splittings being the same, and Eq. (64.54) guarantees you can never make it vanish "for free" — buying a nonzero β costs you a correspondingly inflated α.

64.2.3 The particle content of the vacuum

We can now answer the question that motivates the whole construction. Suppose the field is prepared in the vacuum of the first basis, $|0_{\rm in}\rangle \equiv |0_a\rangle$, defined by $a_j |0_{\rm in}\rangle = 0$ for all j. An observer adapted to the second basis counts particles with the *out* number operator $N^{\rm out}_i = b^\dagger_i b_i$ (the curved-space avatar of Eq. (9.110)). How many out-particles does the in-vacuum contain?

Proposition 64.13 (Mean particle content of the in-vacuum)**.** *With* $a_j |0_{\rm in}\rangle = 0$,

$$\left\langle 0_{\rm in}\middle| N^{\rm out}_i \middle| 0_{\rm in}\right\rangle = \sum_j |\beta_{ij}|^2 , \tag{64.60}$$

and the total mean number of out-particles is $\langle 0_{\rm in}|N^{\rm out}|0_{\rm in}\rangle = \sum_{i,j} |\beta_{ij}|^2 = \mathrm{Tr}(\beta\beta^\dagger)$.

Proof. Use Eq. (64.53) to act with b_i on the in-vacuum. The annihilation piece kills $|0_{\rm in}\rangle$, leaving only the creation piece:

$$b_i\,|0_{\rm in}\rangle = \sum_j \left(\alpha^*_{ij}\,a_j - \beta^*_{ij}\,a_j^\dagger\right)|0_{\rm in}\rangle = -\sum_j \beta^*_{ij}\,a_j^\dagger\,|0_{\rm in}\rangle\,. \tag{64.61}$$

Thus $b_i\,|0_{\rm in}\rangle$ is a one-(in-)particle state, not zero, the first sign that the in-vacuum is full of out-quanta. The bra is the Hermitian conjugate, $\langle 0_{\rm in}|\,b_i^\dagger = -\sum_k \beta_{ik}\,\langle 0_{\rm in}|\,a_k$. Hence

$$\begin{aligned}\left\langle 0_{\rm in}\middle| b_i^\dagger b_i \middle|0_{\rm in}\right\rangle &= \sum_{j,k} \beta_{ik}\,\beta^*_{ij}\,\left\langle 0_{\rm in}\middle| a_k\,a_j^\dagger\middle|0_{\rm in}\right\rangle \\ &= \sum_{j,k}\beta_{ik}\,\beta^*_{ij}\,\delta_{kj} = \sum_j |\beta_{ij}|^2\,,\end{aligned} \tag{64.62}$$

where we used $a_k a_j^\dagger = \delta_{kj} + a_j^\dagger a_k$ and $a_k\,|0_{\rm in}\rangle = 0$ to get $\left\langle 0_{\rm in}\middle| a_k a_j^\dagger\middle|0_{\rm in}\right\rangle = \delta_{kj}$. Summing over i gives the total, $\sum_{i,j}|\beta_{ij}|^2 = \sum_{i,j}\beta_{ij}\beta^*_{ij} = \sum_i (\beta\beta^\dagger)_{ii} = {\rm Tr}(\beta\beta^\dagger)$. □

Equation (64.60) is the result that powers everything downstream. It says, with no further assumptions, that *the off-diagonal Bogoliubov coefficient β is literally the amplitude to find a particle*: where one observer sees the vacuum, another sees $\sum_j |\beta_{ij}|^2$ quanta in mode i. The two vacua coincide if and only if $\beta = 0$.

Caution

The total ${\rm Tr}(\beta\beta^\dagger)$ can diverge. A finite, sensible particle interpretation requires β to be *Hilbert–Schmidt*, ${\rm Tr}(\beta\beta^\dagger) = \sum_{ij}|\beta_{ij}|^2 < \infty$; this is the Shale condition under which the two Fock spaces are unitarily equivalent and the in-vacuum is a normalizable state in the out-Fock space. When it fails — as it does for an observer uniformly accelerated for all time, and in the idealized limits of some cosmologies — the two representations are unitarily inequivalent, "the total number of particles" is strictly infinite, and one must work mode by mode or with densities rather than with the global state. We will meet exactly this situation in the Unruh analysis; Eq. (64.60) for a *single* mode remains meaningful even there.

64.2.4 The in-vacuum as a squeezed condensate of out-pairs

Theorem 64.13 gives the *mean* occupation, but the in-vacuum is a definite pure state in the out-Fock space, and we can exhibit it in closed form. The structure it takes is the signature of the whole subject.

Proposition 64.14 (Gaussian/squeezed form of the in-vacuum)**.** *Whenever α is invertible, the in-vacuum is the out-Fock state*

$$|0_{\text{in}}\rangle \;=\; \mathcal{N}\,\exp\Big(\tfrac{1}{2}\sum_{i,j} V_{ij}\, b_i^\dagger b_j^\dagger\Big)\,|0_{\text{out}}\rangle\,, \qquad V \;=\; -\,\beta^*\alpha^{-1} \;=\; -\,(\alpha^T)^{-1}\beta^\dagger, \tag{64.63}$$

where the coefficient matrix V is symmetric*, $V_{ij}=V_{ji}$, and the normalization is $\mathcal{N}=\big|\det(\mathbf{1}-V^\dagger V)\big|^{1/4}=|\det\alpha|^{-1/2}$.*

Proof. We solve $a_j\,|0_{\text{in}}\rangle=0$ for all j, working in the out-Fock space. Write $S=\frac{1}{2}\sum_{kl}V_{kl}b_k^\dagger b_l^\dagger$ and take the ansatz $|0_{\text{in}}\rangle=\mathcal{N}\,e^{S}\,|0_{\text{out}}\rangle$, with V to be determined (we may take V symmetric without loss, since only the symmetric part survives the contraction of the two commuting creation operators in S). Two commutators control the calculation. First,

$$[b_i,S]=\tfrac{1}{2}\sum_{kl}V_{kl}\,\Big[b_i,b_k^\dagger b_l^\dagger\Big]=\tfrac{1}{2}\sum_{kl}V_{kl}(\delta_{ik}b_l^\dagger+\delta_{il}b_k^\dagger)=\sum_l V_{il}\,b_l^\dagger, \tag{64.64}$$

using $V_{kl}=V_{lk}$ in the last step. Second, $\Big[b_i^\dagger,S\Big]=0$ because S is built from creation operators only, so $b_i^\dagger$ commutes through e^S. Since $[b_i,S]$ in Eq. (64.64) is itself a creation operator, it commutes with S, the Baker–Campbell–Hausdorff series truncates at first order, and

$$e^{-S}\,b_i\,e^{S}=b_i+[b_i,S]=b_i+\sum_l V_{il}b_l^\dagger \quad\Longrightarrow\quad b_i\,e^{S}\,|0_{\text{out}}\rangle=e^{S}\sum_l V_{il}b_l^\dagger\,|0_{\text{out}}\rangle\,, \tag{64.65}$$

where the implication uses $b_i\,|0_{\text{out}}\rangle=0$. Now express the in-vacuum condition through Eq. (64.52), $a_j=\sum_i(\alpha_{ij}b_i+\beta_{ij}^*b_i^\dagger)$, and act on the ansatz:

$$\begin{aligned}
0=a_j\,|0_{\text{in}}\rangle &= \mathcal{N}\sum_i\Big[\alpha_{ij}\,b_i\,e^{S}+\beta_{ij}^*\,b_i^\dagger\,e^{S}\Big]\,|0_{\text{out}}\rangle\\
&= \mathcal{N}\,e^{S}\sum_i\Big[\alpha_{ij}\sum_l V_{il}\,b_l^\dagger+\beta_{ij}^*\,b_i^\dagger\Big]\,|0_{\text{out}}\rangle\\
&= \mathcal{N}\,e^{S}\sum_l\Big[\sum_i\alpha_{ij}V_{il}+\beta_{lj}^*\Big]b_l^\dagger\,|0_{\text{out}}\rangle\,,
\end{aligned} \tag{64.66}$$

where in the last line we relabelled the dummy index $i\to l$ in the β-term and used $b_i^\dagger e^S=e^S b_i^\dagger$. The states $b_l^\dagger\,|0_{\text{out}}\rangle$ are linearly independent, so each coefficient must vanish:

$$\sum_i\alpha_{ij}\,V_{il} \;=\; -\,\beta_{lj}^* \qquad \text{for all } j,l. \tag{64.67}$$

Read as matrices, the left side is $(\alpha^TV)_{jl}$ and the right is $-(\beta^\dagger)_{jl}$, so $\alpha^TV=-\beta^\dagger$, giving $V=-(\alpha^T)^{-1}\beta^\dagger$ whenever α is invertible. Transposing, $(\beta^\dagger)^T=\beta^*$ and $((\alpha^T)^{-1})^T=\alpha^{-1}$, so the same matrix equals $V=-\beta^*\alpha^{-1}$ as well — and the

equality of the two expressions *is* the statement that V is symmetric. To verify it directly, $V = V^T$ requires $(\alpha^T)^{-1}\beta^\dagger = \beta^*\alpha^{-1}$, i.e. $\beta^\dagger\alpha = \alpha^T\beta^*$. This is exactly the conjugate of the second identity in Eq. (64.59), $\alpha^\dagger\beta = \beta^T\alpha^*$, so V is symmetric.

It remains to normalize. For the single-mode case V is a number and $e^S = \sum_n \frac{1}{n!}(\frac{1}{2}V)^n (b^\dagger)^{2n}$ acting on the vacuum gives $\sum_n \frac{(V/2)^n}{n!}\sqrt{(2n)!}\,|2n\rangle$, whose squared norm is $\sum_n \binom{2n}{n}(|V|^2/4)^n = (1-|V|^2)^{-1/2}$; hence $|\mathcal{N}|^2 = (1-|V|^2)^{1/2}$. The multimode generalization diagonalizes V by the Autonne–Takagi factorization of the symmetric matrix (unitary W with $V = W\,\mathrm{diag}(\lambda_k)\,W^T$, $\lambda_k \geq 0$), reducing the state to a product of independent single-mode squeezes and giving $|\mathcal{N}|^2 = \prod_k (1-\lambda_k^2)^{1/2} = |\det(\mathbf{1} - V^\dagger V)|^{1/2}$. Finally $\mathbf{1} - V^\dagger V = \mathbf{1} - (\alpha^\dagger)^{-1}\beta^T\beta^*\alpha^{-1} = (\alpha^\dagger)^{-1}(\alpha^\dagger\alpha - \beta^T\beta^*)\alpha^{-1} = (\alpha^\dagger\alpha)^{-1}$ by Eq. (64.59), so $\det(\mathbf{1} - V^\dagger V) = |\det\alpha|^{-2}$ and $\mathcal{N} = |\det\alpha|^{-1/2}$. □

Notation Watch

The sign and conjugation pattern in $V = -\beta^*\alpha^{-1}$ depend on the sesquilinearity convention fixed in Eq. (64.45) (linear in the first slot) and on the definitions Eq. (64.49). References that take the inner product antilinear in the first slot, or that define β without the leading minus sign, report V with a different sign or with α^* in place of α; the physical state — a condensate of out-pairs with overlap $|\det\alpha|^{-1/2}$ with the out-vacuum — is convention independent. We use Eq. (64.63) consistently throughout Chapter 64.

Physical Insight

Read Eq. (64.63) literally: the operator $b_i^\dagger b_j^\dagger$ creates a *pair* of out-quanta, so the in-vacuum is a coherent superposition of $0, 2, 4, \ldots$ out-particles — the quanta always appear in pairs, never singly. This is the deep statement behind every particle-creation effect in this chapter: gravity (or acceleration) does not deposit lone particles into empty space, it *squeezes* the vacuum, stretching it along $b^\dagger b^\dagger$ and populating it with correlated pairs. The two members of each pair are exactly the entangled partners whose separation across a horizon will, in Chapter 65, become Hawking radiation and its information puzzle.

Worked Example 64.15 (A single two-mode squeeze: the elementary cell)**.** Almost every example in this chapter reduces, mode by mode, to one complex parameter. Take a single pair (a, b) related by $b = \alpha^* a - \beta^* a^\dagger$ with $|\alpha|^2 - |\beta|^2 = 1$ (the one-mode form of Eq. (64.54)). Because the magnitudes are tied, parametrize them by a single real *squeezing parameter* $r \geq 0$ and two phases,

$$\alpha = e^{i\varphi}\cosh r, \qquad \beta = e^{i\theta}\sinh r, \tag{64.68}$$

which automatically satisfies $\cosh^2 r - \sinh^2 r = 1$. The mean occupation of the in-vacuum follows immediately from Eq. (64.60):

$$\left\langle 0_{\rm in}\middle| N^{\rm out}\middle|0_{\rm in}\right\rangle = |\beta|^2 = \sinh^2 r. \tag{64.69}$$

The squeeze coefficient is, from Eq. (64.63), $V = -\beta^*/\alpha = -e^{-i(\theta+\varphi)}\tanh r$, so the state is

$$|0_{\rm in}\rangle = (\cosh r)^{-1/2}\,\exp\!\Big(-\tfrac{1}{2}\,e^{-i(\theta+\varphi)}\tanh r\,(b^\dagger)^2\Big)\,|0_{\rm out}\rangle\,, \tag{64.70}$$

with $\mathcal{N} = |\alpha|^{-1/2} = (\cosh r)^{-1/2}$ reproducing $|\det\alpha|^{-1/2}$. Expanding the exponential, the probability of finding $2n$ out-particles is $P_{2n} = |\mathcal{N}|^2\,\binom{2n}{n}(\tfrac{1}{4}\tanh^2 r)^n$; the odd occupations are strictly absent, exactly the pairing of the insight above. Summing $\sum_n 2n\,P_{2n}$ recovers $\sinh^2 r$, a consistency check on Eq. (64.69).

It is worth recording one fact that the next sections will turn into a temperature. Suppose the two modes carry energies $\pm\omega$ with respect to some Killing time and are partners under a transformation for which $|\beta/\alpha| = e^{-\pi\omega/a}$ for a constant a (this is the value the gravitational and accelerated examples will produce). Then $\tanh r = e^{-\pi\omega/a}$, and

$$\left\langle 0_{\rm in}\middle| N^{\rm out}\middle|0_{\rm in}\right\rangle = \sinh^2 r = \frac{|\beta/\alpha|^2}{1-|\beta/\alpha|^2} = \frac{e^{-2\pi\omega/a}}{1-e^{-2\pi\omega/a}} = \frac{1}{e^{2\pi\omega/a}-1}, \tag{64.71}$$

the Planck distribution at temperature $T = a/2\pi$. The Bogoliubov machine has not been told anything about thermodynamics; a single ratio $|\beta/\alpha| = e^{-\pi\omega/a}$ produces a thermal spectrum on its own. The work of Section 64.3 and the Unruh section is to show that gravity and acceleration actually deliver that ratio.

64.2.5 When is the particle number unambiguous?

If β is generically nonzero, when does it vanish — when is there a preferred vacuum and an observer-independent notion of "particle"? The answer is geometric: a vacuum is unambiguous precisely when the spacetime provides a canonical way to call a mode "positive frequency," and that is what a timelike symmetry supplies.

Proposition 64.16 (Stationary spacetimes have an unambiguous vacuum)**.** *Let (M, g) admit a globally timelike Killing vector field K^μ ($\nabla_{(\mu}K_{\nu)} = 0$, $K^\mu K_\mu > 0$ everywhere). Then there is a basis of mode solutions that are eigenfunctions of the Lie derivative along K,*

$$\pounds_K\, u_\omega = -\,i\,\omega\,u_\omega, \qquad \omega > 0, \tag{64.72}$$

with strictly positive Klein–Gordon norm. The Fock vacuum built on this basis is invariant under the isometry generated by K, and any two observers who both define positive frequency by Eq. (64.44) are related by a Bogoliubov transformation with $\beta = 0$; they agree on the vacuum and on particle number.

Proof. Because K is Killing, $\pounds_K$ commutes with the Klein–Gordon operator $\Box + m^2 + \xi R$ (the operator is built from the metric and its covariant derivatives, all of which are annihilated by $\pounds_K$), so it maps solutions to solutions and can be simultaneously diagonalized with the field equation. Its eigenvalues are imaginary, $-i\omega$ with ω real, because $\pounds_K$ is anti-self-adjoint with respect to Eq. (64.45): for any two solutions, K-invariance of the inner product (the current j^μ is Lie-dragged by K, whose flow maps Cauchy surfaces to Cauchy surfaces, leaving the surface-independent integral unchanged) gives $(\pounds_K f, g) + (f, \pounds_K g) = 0$. Hence we may sort the eigenmodes by the sign of ω and *define* the positive-frequency modes to be those with $\omega > 0$. We must check these have positive norm. For an eigenmode,

$$\pounds_K\,(u_\omega, u_\omega) = (\pounds_K u_\omega, u_\omega) + (u_\omega, \pounds_K u_\omega) = (i\omega - i\omega)(u_\omega, u_\omega) = 0, \tag{64.73}$$

consistent with the norm being a conserved number, while the standard energy argument — $\omega\,(u_\omega, u_\omega)$ equals, up to a positive factor set by $K^\mu K_\mu > 0$, the manifestly positive energy $\int_\Sigma \mathrm{d}\Sigma^\mu K^\nu T_{\mu\nu}[u_\omega]$ of the classical mode — forces $\mathrm{sgn}(u_\omega, u_\omega) = \mathrm{sgn}\,\omega$. So the $\omega > 0$ modes have positive norm and qualify as the u_j of Eq. (64.46); the $\omega < 0$ modes are their conjugates. This positive-frequency split is fixed by K alone, with no further choice. Two observers who adopt the same K therefore build the *same* $\{u_j\}$, up to a unitary relabelling within the positive-frequency subspace ($\beta = 0$, α unitary), and by Eq. (64.53) share the vacuum. Finally, the vacuum is K-invariant: the unitary $U(s) = e^{is\hat{H}}$ implementing the isometry (with $\hat{H}$ the conserved charge of K, diagonal in the number operator since each u_ω carries definite ω) annihilates $|0\rangle$ because $\hat{H}$ does. □

The proposition isolates the precise reason flat space has an unambiguous vacuum: Minkowski spacetime has the timelike Killing field ∂_t (indeed a whole family related by Poincaré transformations, all sharing the same positive-frequency split because the boosts that connect inertial observers do not mix positive and negative frequencies). A generic curved spacetime has no timelike Killing vector at all — the metric depends on time — and then no preferred $\omega > 0$ exists, $\beta \neq 0$ is generic, and the vacuum is genuinely ambiguous. The intermediate, and most useful, case is a spacetime that is *not* stationary in the middle but settles to stationary regions in the asymptotic past and future, each with its own timelike Killing field ∂_t^{in} and $\partial_t^{\mathrm{out}}$. Each region then defines a clean vacuum by Theorem 64.16, the two need not agree, and the β relating them is finite and computable. This is the arena in which the Bogoliubov machine does its sharpest work, sketched in Fig. 64.1.

We now have the full apparatus: two bases, their Bogoliubov coefficients (α, β), the identities that constrain them, the particle-number formula $\sum_j |\beta_{ij}|^2$, and the explicit squeezed in-vacuum. What the machine demands next is a concrete physical pair of bases to feed it. The most literal such pair is gravitational: an

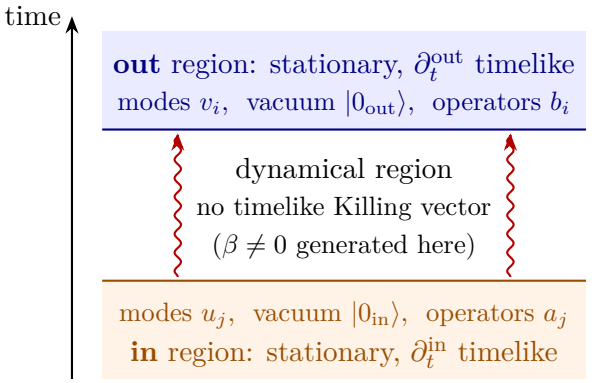

Figure 64.1: The generic useful geometry. The field is quantized on a Cauchy surface in a stationary *in* region, where ∂_t^{in} supplies an unambiguous positive-frequency basis $\{u_j\}$ and a vacuum $|0_{\text{in}}\rangle$ (Theorem 64.16). A non-stationary dynamical region intervenes, and the modes propagate (wavy lines) into a second stationary *out* region with its own basis $\{v_i\}$ and vacuum $|0_{\text{out}}\rangle$. Because the in- and out-positive-frequency splits disagree, the Bogoliubov matrix β is nonzero, and by Eq. (64.60) the in-vacuum is seen by the out-observer to contain $\sum_j |\beta_{ij}|^2$ particles in mode i.

expanding universe that is static in the far past and far future furnishes exactly the in/out structure of Fig. 64.1, with two genuinely different Killing times and a β we can compute in closed form. We turn to that calculation in Section 64.3, where gravity is shown to create particles and we extract their number.

64.3 Particle creation by an expanding universe

The previous section left us holding a machine with nothing yet fed into it. We learned that two complete sets of positive-frequency modes, each defining its own vacuum and its own notion of "particle," are related by a Bogoliubov transformation (Section 64.2), and that the number of quanta the second observer finds in the first observer's vacuum is fixed by the off-diagonal coefficients alone, $n_k = |\beta_k|^2$. Everything in that section was structural: it told us *that* a mismatch of mode bases produces particles, but not *how many*, because we had no concrete pair of bases to compute with. The off-diagonal coefficients were left as symbols.

We now supply the missing input with a gravitational background simple enough to be solved in closed form yet rich enough to contain the entire phenomenon: a spatially flat universe that expands smoothly from one static era in the far past to another static era in the far future. "Static in the far past and far future" is exactly the condition under which the two privileged mode bases of the previous section—the in-modes adapted to the early universe and the out-modes

adapted to the late one—are both unambiguously defined, so the Bogoliubov coefficients between them are honest numbers rather than convention. Between the two eras the universe expands, the geometry is genuinely time-dependent, and there is no preferred vacuum at all. The question the machine answers is sharp: an apparatus that was in its ground state in the early static era, left undisturbed while the universe expands, is found in the late static era to contain a definite spectrum of real quanta. Gravity has created particles out of the vacuum, and we will compute the number exactly. The model is due to Bernard and Duncan; its solvability rests on reducing the curved-space wave equation to a one-dimensional scattering problem and then recognising that problem as one of the classical soluble cases of the hypergeometric equation.

64.3.1 The curved Klein–Gordon equation as one-dimensional scattering

We work with a spatially flat Friedmann–Robertson–Walker (FRW) geometry written in *conformal time* η, in which the line element is a position-dependent rescaling of flat Minkowski space,

$$\mathrm{d}s^2 = a^2(\eta)\,(\mathrm{d}\eta^2 - \mathrm{d}\mathbf{x}\cdot\mathrm{d}\mathbf{x}), \qquad \mu,\nu \in \{0,1,2,3\}, \quad g_{\mu\nu} = a^2(\eta)\,\eta_{\mu\nu}, \tag{64.74}$$

with the mostly-minus signature $\eta_{\mu\nu} = \mathrm{diag}(+,-,-,-)$ in force throughout this chapter and $a(\eta) > 0$ the scale factor. Conformal time is the natural clock here for one reason: in these coordinates the metric is *conformally flat*, $g_{\mu\nu} = a^2\eta_{\mu\nu}$, and the spatial slices are ordinary Euclidean $\mathbb{R}^3$, so the comoving momentum $\mathbf{k}$ conjugate to $\mathbf{x}$ is a good quantum number: distinct Fourier modes do not mix, and the field equation separates mode by mode. This turns a partial differential equation on a curved background into an ordinary differential equation in η for each $\mathbf{k}$, which is the whole reason the model is soluble.

We carry the free real scalar of ϕ^4 theory in its $\lambda = 0$ sector (Chapter 9), now massive and propagating on the curved background Eq. (64.74). We take it *conformally coupled*: in $D = 4$ the action is

$$S = \frac{1}{2}\int \mathrm{d}^4x\,\sqrt{-g}\,\Big[g^{\mu\nu}\,\partial_\mu\phi\,\partial_\nu\phi - (m^2 + \xi R)\phi^2\Big], \qquad \xi = \tfrac{1}{6}, \tag{64.75}$$

where R is the Ricci scalar and $\xi = \frac{1}{6}$ is the conformal value in four dimensions. The choice is one of convenience, not necessity: it produces the cleanest possible mode equation, and we will see at the end of the subsection exactly what changes for the minimally coupled ($\xi = 0$) field. The field obeys the curved-space Klein–Gordon equation

$$(\Box + m^2 + \xi R)\phi = 0, \qquad \Box\phi = \frac{1}{\sqrt{-g}}\,\partial_\mu\big(\sqrt{-g}\,g^{\mu\nu}\partial_\nu\phi\big), \tag{64.76}$$

the scalar wave operator built from the covariant measure (we use the same $\Box$, mass m, and field ϕ fixed in Chapter 9).

Evaluating the d'Alembertian. For the conformally flat metric Eq. (64.74) we have, in $D = 4$, $\sqrt{-g} = a^4$ and $g^{\mu\nu} = a^{-2}\eta^{\mu\nu}$. Inserting these into the operator in Eq. (64.76),

$$\begin{aligned}\Box\phi &= a^{-4}\,\partial_\mu(a^4\,a^{-2}\eta^{\mu\nu}\,\partial_\nu\phi) = a^{-4}\,\partial_\mu(a^2\,\eta^{\mu\nu}\,\partial_\nu\phi)\\ &= a^{-4}\Big[\,\partial_\eta(a^2\,\partial_\eta\phi) - a^2\,\nabla^2\phi\,\Big] = a^{-2}\Big[\,\phi'' + 2\tfrac{a'}{a}\,\phi' - \nabla^2\phi\,\Big],\end{aligned} \tag{64.77}$$

where a prime denotes $\mathrm{d}/\mathrm{d}\eta$, the index sum used $\eta^{00} = +1$, $\eta^{ij} = -\delta^{ij}$, and we expanded $\partial_\eta(a^2\phi') = a^2\phi'' + 2aa'\phi'$. The term $2(a'/a)\phi'$ is the cosmological friction: it is the Hubble drag of the expansion acting on the field, and it is exactly what makes the time-dependent problem look unfamiliar. The strategy is to remove it.

The conformal rescaling $\chi = a\phi$. A massless field of canonical dimension in $D = 4$ has conformal weight 1, so the combination $\chi \equiv a\phi$ is the field that should behave like a flat-space scalar. Expand ϕ in comoving spatial Fourier modes and factor out the scale factor,

$$\phi(\eta,\mathbf{x}) = \int \frac{\mathrm{d}^3k}{(2\pi)^3}\,\frac{1}{a(\eta)}\,\chi_k(\eta)\,e^{\,i\mathbf{k}\cdot\mathbf{x}} \;+\; \text{h.c.}, \qquad \phi_k(\eta) = \frac{\chi_k(\eta)}{a(\eta)}, \tag{64.78}$$

so that $\nabla^2 \to -k^2$ on the mode of comoving wavenumber $k = |\mathbf{k}|$. We need $\phi_k'' + 2(a'/a)\phi_k'$ in terms of χ_k. Differentiating $\phi_k = a^{-1}\chi_k$ twice,

$$\begin{aligned}\phi_k' &= a^{-1}\chi_k' - a^{-2}a'\chi_k,\\ \phi_k'' &= a^{-1}\chi_k'' - 2a^{-2}a'\chi_k' + (2a^{-3}a'^2 - a^{-2}a'')\chi_k,\end{aligned} \tag{64.79}$$

and adding $2(a'/a)\phi_k' = 2a^{-2}a'\chi_k' - 2a^{-3}a'^2\chi_k$, the first-derivative terms in χ_k' cancel and so do the a'^2 terms, leaving the remarkably clean combination

$$\phi_k'' + 2\tfrac{a'}{a}\,\phi_k' = a^{-1}\chi_k'' - a^{-2}a''\,\chi_k. \tag{64.80}$$

The friction has been traded for a single algebraic term $-a''/a$. Now assemble Eq. (64.76) for the mode ϕ_k, using Eq. (64.77), Eq. (64.80), and the Ricci scalar of the flat FRW geometry, which in conformal time is

$$R = \frac{6\,a''}{a^3}. \tag{64.81}$$

We multiply $(\Box + m^2 + \xi R)\phi_k = 0$ through by a^3:

$$\chi_k'' - \frac{a''}{a}\,\chi_k + k^2\chi_k + m^2a^2\,\chi_k + 6\xi\,\frac{a''}{a}\,\chi_k = 0, \tag{64.82}$$

where the m^2 term picked up a factor a^2 from $\sqrt{-g}/a^2$ packaging and the ξR term contributed $6\xi\, a''/a$. The two curvature terms combine into $(6\xi - 1)(a''/a)\chi_k$, which *vanishes identically at the conformal value* $\xi = \frac{1}{6}$. We are left with

$$\boxed{\chi_k'' + \omega_k^2(\eta)\,\chi_k = 0, \qquad \omega_k^2(\eta) = k^2 + m^2\,a^2(\eta).} \tag{64.83}$$

This is the central reduction. Each comoving mode of the conformally coupled scalar obeys the equation of a harmonic oscillator with a *time-dependent frequency* $\omega_k(\eta)$, or equivalently—reading η as a spatial coordinate—the time-independent one-dimensional Schrödinger scattering problem $-\chi'' + U(\eta)\chi = k^2\chi$ with the effective potential $U(\eta) = -m^2a^2(\eta)$. The expansion of the universe enters solely through the profile $a^2(\eta)$, which acts as a frequency that drifts from one constant value in the far past to another in the far future. (For minimal coupling $\xi = 0$ the bracket $(6\xi - 1)(a''/a) = -a''/a$ survives, and Eq. (64.83) acquires the extra effective potential term $-a''/a$; the analysis is identical in spirit but the closed form below is special to conformal coupling.)

Physical Insight

A massless conformally coupled scalar ($m = 0$, $\xi = \frac{1}{6}$) has $\omega_k^2 = k^2$ *independent of* η: the mode equation is the flat-space one for all time, the positive-frequency modes never mix, and *no particles are created no matter how violently the universe expands.* This is the conformal triviality of the radiation-dominated era in disguise. Particle creation requires a scale that breaks conformal invariance—here the mass m, which is what couples ω_k to the changing $a(\eta)$. Gravity creates particles only by acting on the conformal-symmetry-breaking content of the matter. The mass is the handle the expansion grips.

In- and out-vacua. The geometry is *asymptotically static* if $a(\eta)$ tends to constants as $\eta \to \mp\infty$. Then $\omega_k(\eta)$ tends to constants too,

$$\omega_{\rm in}^2 \equiv \lim_{\eta\to-\infty} \omega_k^2(\eta) = k^2 + m^2 a_{\rm in}^2, \qquad \omega_{\rm out}^2 \equiv \lim_{\eta\to+\infty} \omega_k^2(\eta) = k^2 + m^2 a_{\rm out}^2, \tag{64.84}$$

with $a_{\rm in} = a(-\infty)$, $a_{\rm out} = a(+\infty)$. In each static region Eq. (64.83) is solved by ordinary plane waves $e^{\mp i\omega\eta}$, and the rule for splitting positive from negative frequency is the standard, unambiguous one—the same split that defines the Minkowski vacuum, applied in each asymptotic era. We therefore have two natural complete bases: the *in-modes*, the solutions that reduce to pure positive frequency $e^{-i\omega_{\rm in}\eta}$ in the far past, and the *out-modes*, those that reduce to $e^{-i\omega_{\rm out}\eta}$ in the far future. The Klein–Gordon inner product on the curved background, evaluated on the rescaled field χ, is just the flat one (the factors of a in $\sqrt{-g}$ and in $\phi = \chi/a$ cancel), so the normalisation is fixed by the per-mode Wronskian

condition established in Section 64.2: a positive-frequency mode of frequency ω in an asymptotic region carries the standard envelope

$$\chi_k(\eta) \;\longrightarrow\; \frac{1}{\sqrt{2\omega}}\, e^{-i\omega\eta}, \qquad \chi_k \chi_k'^{*} - \chi_k^{*}\chi_k' = i, \tag{64.85}$$

the Wronskian being the conserved quantity guaranteed by Eq. (64.83) (which has no first-derivative term, so $W' = 0$). The in- and out-bases differ precisely because a mode that is pure positive frequency at $\eta = -\infty$ is, after threading the time-dependent region, a *mixture* of positive and negative out-frequencies at $\eta = +\infty$. That mixture is the Bogoliubov transformation, and its β-coefficient is the created-particle amplitude. All that remains is to compute it.

64.3.2 The adiabatic vacuum and the WKB hierarchy

Before solving the model exactly we settle a conceptual point that the asymptotic analysis glosses over: when the geometry is changing, what does "the vacuum" even mean? In the static eras the answer is fixed by Eq. (64.85). In the dynamical interior there is no static frame and no exact answer, but there is an excellent approximate one whenever $\omega_k(\eta)$ varies slowly, and it is this notion that the in/out construction silently uses. It is the *adiabatic vacuum*, defined by the WKB hierarchy.

Seek a solution of Eq. (64.83) in the WKB form

$$\chi_k(\eta) = \frac{1}{\sqrt{2W_k(\eta)}}\, \exp\!\Big(-i\int^{\eta} W_k(\eta')\,\mathrm{d}\eta'\Big), \tag{64.86}$$

which generalises Eq. (64.85) by promoting the constant frequency to a function $W_k(\eta)$ and is normalised so that the Wronskian condition holds identically for any real W_k. Substituting into Eq. (64.83) and separating the result gives the exact (nonlinear) equation for W_k,

$$W_k^2 = \omega_k^2 - \frac{1}{2}\,\frac{W_k''}{W_k} + \frac{3}{4}\left(\frac{W_k'}{W_k}\right)^{2}. \tag{64.87}$$

This is solved iteratively by counting derivatives of $a(\eta)$ as the small quantity: each derivative $\mathrm{d}/\mathrm{d}\eta$ brings a power of the expansion rate, so the *adiabatic order* of a term is the number of time derivatives it carries. The zeroth-order (adiabatic) approximation drops the derivative terms on the right,

$$W_k^{(0)} = \omega_k(\eta), \qquad W_k^{(2)} = \omega_k\Big[1 - \frac{1}{2}\frac{\omega_k''}{\omega_k^3} + \frac{3}{4}\frac{(\omega_k')^2}{\omega_k^4}\Big]^{1/2} = \omega_k - \frac{\omega_k''}{4\omega_k^2} + \frac{3(\omega_k')^2}{8\omega_k^3} + \cdots, \tag{64.88}$$

and so on to all even orders. The expansion parameter controlling it is the *non-adiabaticity*

$$\varepsilon_{\mathrm{ad}} \sim \frac{|\omega_k'|}{\omega_k^2}, \tag{64.89}$$

the fractional change of the frequency over one oscillation. The *adiabatic vacuum of order n* is the state annihilated by the operators that multiply the WKB modes Eq. (64.86) truncated at adiabatic order n; it is the best local definition of "no particles" available in a time-dependent background, and as $\varepsilon_{\mathrm{ad}} \to 0$ the modes of every order coincide and the ambiguity disappears.

The physical content is the adiabatic theorem. If the expansion is slow, $\varepsilon_{\mathrm{ad}} \ll 1$ throughout, then the exact mode tracks the instantaneous WKB form Eq. (64.86) and never develops a negative-frequency admixture: the in- and out-bases connect with $\beta_k \approx 0$, and *no particles are produced*. Particle creation is the breakdown of adiabaticity. The size of β_k is governed, exactly as in the Landau–Zener analysis of quantum mechanics, by the analytic continuation of the mode into the complex η-plane: the amplitude to flip onto the negative-frequency branch is

$$|\beta_k| \sim \exp\!\Big(-2\,\Big|\int_{\mathcal{C}} \omega_k(\eta)\,\mathrm{d}\eta\Big|_{\mathrm{Im}}\Big), \tag{64.90}$$

where the contour $\mathcal{C}$ runs to the complex turning point of $\omega_k(\eta)$ nearest the real axis—the point at which the two WKB branches degenerate. The imaginary part of the action accumulated near that singularity sets an *exponentially small* creation amplitude for a slowly varying background. We will see the exact solution reproduce Eq. (64.90) precisely.

64.3.3 The Bernard–Duncan model and its exact modes

We now specialise to a profile for which Eq. (64.83) is solved in closed form. Take the scale factor squared to be a hyperbolic-tangent step,

$$a^2(\eta) = A + B\,\tanh(\rho\,\eta), \qquad A > B > 0, \quad \rho > 0, \tag{64.91}$$

the *Bernard–Duncan model*. The parameter A sets the mean size, B the total amount of expansion, and ρ the *rapidity*: $1/\rho$ is the conformal duration of the expansion, so $\rho \to 0$ is the slow (adiabatic) limit and $\rho \to \infty$ the sudden one. The geometry is asymptotically static at both ends, with

$$a_{\mathrm{in}}^2 = A - B, \qquad a_{\mathrm{out}}^2 = A + B, \tag{64.92}$$

so $a_{\mathrm{out}} > a_{\mathrm{in}}$: the universe genuinely expands. From Eq. (64.84) the two asymptotic frequencies are

$$\omega_{\mathrm{in}}^2 = k^2 + m^2(A - B), \qquad \omega_{\mathrm{out}}^2 = k^2 + m^2(A + B), \qquad \omega_{\mathrm{out}} > \omega_{\mathrm{in}}, \tag{64.93}$$

and it is convenient throughout to use their half-sum and half-difference,

$$\omega_{\pm} \equiv \tfrac{1}{2}\big(\omega_{\mathrm{out}} \pm \omega_{\mathrm{in}}\big), \qquad \omega_+ + \omega_- = \omega_{\mathrm{out}}, \quad \omega_+ - \omega_- = \omega_{\mathrm{in}}. \tag{64.94}$$

The effective frequency $\omega_k^2(\eta) = k^2 + m^2 A + m^2 B\tanh(\rho\eta)$ rises monotonically from ω_{in}^2 to ω_{out}^2; the left panel of Fig. 64.2 shows the profile for several momenta.

Reduction to the hypergeometric equation. Introduce the variable

$$s \equiv \frac{1+\tanh(\rho\eta)}{2} = \frac{e^{\rho\eta}}{2\cosh(\rho\eta)} \in (0,1), \qquad 1-s = \frac{e^{-\rho\eta}}{2\cosh(\rho\eta)}, \tag{64.95}$$

which maps the whole conformal-time line $\eta \in (-\infty,\infty)$ onto the unit interval, with $\eta \to -\infty \Leftrightarrow s \to 0$ and $\eta \to +\infty \Leftrightarrow s \to 1$. Differentiating, $\mathrm{d}s/\mathrm{d}\eta = \rho\,\mathrm{sech}^2(\rho\eta)/2 = 2\rho\, s(1-s)$, so $\mathrm{d}/\mathrm{d}\eta = 2\rho\, s(1-s)\,\mathrm{d}/\mathrm{d}s$ and

$$\frac{\mathrm{d}^2}{\mathrm{d}\eta^2} = 4\rho^2\Big[s^2(1-s)^2\frac{\mathrm{d}^2}{\mathrm{d}s^2} + s(1-s)(1-2s)\frac{\mathrm{d}}{\mathrm{d}s}\Big]. \tag{64.96}$$

The frequency, written in s, is linear: $\tanh(\rho\eta) = 2s-1$ gives $\omega_k^2 = \omega_{\mathrm{in}}^2(1-s) + \omega_{\mathrm{out}}^2 s$. Substituting into Eq. (64.83) and dividing by $4\rho^2$,

$$s^2(1-s)^2\,\chi_{ss} + s(1-s)(1-2s)\,\chi_s + \frac{\omega_{\mathrm{in}}^2(1-s)+\omega_{\mathrm{out}}^2 s}{4\rho^2}\,\chi = 0, \tag{64.97}$$

with subscripts denoting $\mathrm{d}/\mathrm{d}s$. This is a Fuchsian equation with regular singular points at $s = 0, 1, \infty$, hence reducible to the hypergeometric equation once the singular behaviour at $s=0$ and $s=1$ is factored out. The indicial equation at $s=0$ is obtained by inserting $\chi \sim s^{\alpha}$: the three terms contribute $\alpha(\alpha-1) + \alpha + \omega_{\mathrm{in}}^2/4\rho^2 = \alpha^2 + \omega_{\mathrm{in}}^2/4\rho^2$, whose roots are $\alpha = \pm i\,\omega_{\mathrm{in}}/2\rho$; likewise at $s=1$ the exponents are $\pm i\,\omega_{\mathrm{out}}/2\rho$. We factor out the branches that will produce the *positive-frequency in-mode* and write

$$\chi_k(\eta) = s^{\alpha_1}(1-s)^{\alpha_2}\,F(s), \qquad \alpha_1 = -\frac{i\omega_{\mathrm{in}}}{2\rho}, \quad \alpha_2 = -\frac{i\omega_{\mathrm{out}}}{2\rho}. \tag{64.98}$$

The choice of sign for α_1 is dictated by physics: as $\eta \to -\infty$ we have $s \to e^{2\rho\eta}$, so $s^{\alpha_1} \to e^{2\rho\eta\,\alpha_1} = e^{-i\omega_{\mathrm{in}}\eta}$, which is exactly the positive-frequency in-mode. Substituting Eq. (64.98) into Eq. (64.97) and dividing through by $s(1-s)\,s^{\alpha_1}(1-s)^{\alpha_2}$, the $1/s$ and $1/(1-s)$ poles cancel by the indicial conditions $\alpha_1^2 = -\omega_{\mathrm{in}}^2/4\rho^2$ and $\alpha_2^2 = -\omega_{\mathrm{out}}^2/4\rho^2$, and F is left obeying the standard hypergeometric equation

$$s(1-s)\,F'' + \big[c - (a+b+1)s\big]F' - ab\,F = 0. \tag{64.99}$$

Matching the first-derivative coefficient gives $c = 1+2\alpha_1$ and $a+b = 1+2\alpha_1+2\alpha_2$; matching the constant term gives, after collecting (the computation is carried in Theorem 64.17), $ab = (\alpha_1+\alpha_2)(\alpha_1+\alpha_2+1)$. Writing $\beta \equiv \alpha_1+\alpha_2 = -i\omega_+/\rho$, the parameters are the roots of $x^2 - (1+2\beta)x + \beta(\beta+1) = 0$, namely $x = \beta$ and $x = 1+\beta$. Hence

$$a = 1 - \frac{i\omega_+}{\rho}, \qquad b = -\frac{i\omega_+}{\rho}, \qquad c = 1 - \frac{i\omega_{\mathrm{in}}}{\rho}. \tag{64.100}$$

The in-mode, normalised by Eq. (64.85) so that it is a unit positive-frequency wave at $\eta \to -\infty$ (where $F(0) = 1$ for the standard hypergeometric series), is therefore exactly

$$\chi_k^{\text{in}}(\eta) = \frac{1}{\sqrt{2\omega_{\text{in}}}}\, s^{-i\omega_{\text{in}}/2\rho}\,(1-s)^{-i\omega_{\text{out}}/2\rho}\,{}_2F_1\Big(a, b; c;\, s\Big), \tag{64.101}$$

with $s = s(\eta)$ from Eq. (64.95) and a, b, c from Eq. (64.100). This is a closed-form solution of the wave equation on the expanding background, valid for all η. The analytic and connection machinery for the hypergeometric function ${}_2F_1$ and the gamma functions that appear below is the special-function toolkit of Chapter 5.

Worked Example 64.17 (The hypergeometric parameters from the constant term)**.** We finish the reduction by extracting ab. Write the substitution Eq. (64.98) as $\chi = PF$ with $P = s^{\alpha_1}(1-s)^{\alpha_2}$, so that $P'/P = \alpha_1/s - \alpha_2/(1-s)$ and $P''/P = (\alpha_1^2 - \alpha_1)/s^2 + (\alpha_2^2 - \alpha_2)/(1-s)^2 - 2\alpha_1\alpha_2/[s(1-s)]$. Inserting $\chi = PF$ into Eq. (64.97) and dividing by $s(1-s)P$, the coefficient of F is

$$s(1-s)\frac{P''}{P} + (1-2s)\frac{P'}{P} + \frac{\omega_{\text{in}}^2(1-s) + \omega_{\text{out}}^2 s}{4\rho^2\, s(1-s)}, \tag{64.102}$$

which must equal the constant $-ab$. Expanding each piece in partial fractions, the coefficient of $1/s$ is $(\alpha_1^2 - \alpha_1) + \alpha_1 + \omega_{\text{in}}^2/4\rho^2 = \alpha_1^2 + \omega_{\text{in}}^2/4\rho^2 = 0$ by the indicial condition, and the coefficient of $1/(1-s)$ vanishes the same way. What survives is purely the constant

$$\begin{aligned} -ab &= -(\alpha_1^2 - \alpha_1) - (\alpha_2^2 - \alpha_2) - 2\alpha_1\alpha_2 - 2\alpha_1 - 2\alpha_2 \\ &= -(\alpha_1 + \alpha_2)^2 - (\alpha_1 + \alpha_2), \end{aligned} \tag{64.103}$$

so $ab = (\alpha_1 + \alpha_2)(\alpha_1 + \alpha_2 + 1)$, as used in Eq. (64.100). The clean factorisation—the product depends only on the *sum* $\alpha_1 + \alpha_2 = -i\omega_+/\rho$—is what makes the connection coefficients below collapse to ratios of hyperbolic sines.

64.3.4 Connection coefficients and the Bogoliubov mismatch

The in-mode Eq. (64.101) is a definite solution; to read off the particle content we must express it, as $\eta \to +\infty$, in terms of the out-modes $\chi_k^{\text{out}} = (2\omega_{\text{out}})^{-1/2} e^{-i\omega_{\text{out}}\eta}$ and their conjugates. This is a *connection problem*: we need the behaviour of ${}_2F_1(a, b; c; s)$ near $s = 1$, which is supplied by the linear-transformation formula of the hypergeometric function (Chapter 5),

$$\begin{aligned} {}_2F_1(a, b; c; s) = {} & \frac{\Gamma(c)\Gamma(c-a-b)}{\Gamma(c-a)\Gamma(c-b)}\, {}_2F_1(a, b; a+b-c+1; 1-s) \\ & + (1-s)^{c-a-b}\, \frac{\Gamma(c)\Gamma(a+b-c)}{\Gamma(a)\Gamma(b)}\, {}_2F_1(c-a, c-b; c-a-b+1; 1-s). \end{aligned} \tag{64.104}$$

As $s \to 1$ both ${}_2F_1(\cdots; 1-s) \to 1$, so the in-mode tends to a sum of two power laws in $(1-s)$. With the parameters Eq. (64.100) the exponents evaluate (using $\omega_+ \pm \omega_- = \omega_{\text{out/in}}$) to

$$c-a-b = \frac{i\omega_{\text{out}}}{\rho}, \qquad a+b-c = -\frac{i\omega_{\text{out}}}{\rho}, \qquad c-a = \frac{i\omega_-}{\rho}, \qquad c-b = 1+\frac{i\omega_-}{\rho}. \tag{64.105}$$

Since $s^{\alpha_1} \to 1$ as $s \to 1$, the in-mode Eq. (64.101) becomes

$$\chi_k^{\text{in}} \xrightarrow{\eta\to+\infty} \frac{1}{\sqrt{2\omega_{\text{in}}}}\Big[\, C_1\,(1-s)^{\alpha_2} + C_2\,(1-s)^{\alpha_2+c-a-b}\,\Big], \tag{64.106}$$

with the connection coefficients

$$C_1 = \frac{\Gamma(c)\Gamma(c-a-b)}{\Gamma(c-a)\Gamma(c-b)}, \qquad C_2 = \frac{\Gamma(c)\Gamma(a+b-c)}{\Gamma(a)\Gamma(b)}. \tag{64.107}$$

Now translate the powers of $(1-s)$ back to plane waves. As $\eta \to +\infty$, $1-s \to e^{-2\rho\eta}$ from Eq. (64.95), so with $\alpha_2 = -i\omega_{\text{out}}/2\rho$,

$$(1-s)^{\alpha_2} \to e^{+i\omega_{\text{out}}\eta} \quad \text{(negative frequency)}, \qquad (1-s)^{\alpha_2+c-a-b} \to e^{-i\omega_{\text{out}}\eta} \quad \text{(positive freque} \tag{64.108}$$

the second exponent being $\alpha_2 + c - a - b = -i\omega_{\text{out}}/2\rho + i\omega_{\text{out}}/\rho = +i\omega_{\text{out}}/2\rho$. Therefore

$$\chi_k^{\text{in}} \xrightarrow{\eta\to+\infty} \frac{1}{\sqrt{2\omega_{\text{in}}}}\Big[\, C_2\, e^{-i\omega_{\text{out}}\eta} + C_1\, e^{+i\omega_{\text{out}}\eta}\,\Big]. \tag{64.109}$$

Comparing with the Bogoliubov decomposition $\chi_k^{\text{in}} = \alpha_k\,\chi_k^{\text{out}} + \beta_k\,\chi_k^{\text{out}\,*}$ (Section 64.2), with $\chi_k^{\text{out}} = (2\omega_{\text{out}})^{-1/2} e^{-i\omega_{\text{out}}\eta}$, matches the coefficient of each exponential:

$$\alpha_k = \sqrt{\frac{\omega_{\text{out}}}{\omega_{\text{in}}}}\, C_2, \qquad \beta_k = \sqrt{\frac{\omega_{\text{out}}}{\omega_{\text{in}}}}\, C_1. \tag{64.110}$$

The created particles live entirely in C_1—the coefficient of the *wrong*, negative-frequency exponential that the connection formula forces upon the in-mode at late times. Inserting the parameters Eq. (64.100), Eq. (64.105),

$$\alpha_k = \sqrt{\frac{\omega_{\text{out}}}{\omega_{\text{in}}}}\, \frac{\Gamma\!\left(1-\frac{i\omega_{\text{in}}}{\rho}\right)\Gamma\!\left(-\frac{i\omega_{\text{out}}}{\rho}\right)}{\Gamma\!\left(1-\frac{i\omega_+}{\rho}\right)\Gamma\!\left(-\frac{i\omega_+}{\rho}\right)}, \tag{64.111}$$

$$\beta_k = \sqrt{\frac{\omega_{\text{out}}}{\omega_{\text{in}}}}\, \frac{\Gamma\!\left(1-\frac{i\omega_{\text{in}}}{\rho}\right)\Gamma\!\left(\frac{i\omega_{\text{out}}}{\rho}\right)}{\Gamma\!\left(\frac{i\omega_-}{\rho}\right)\Gamma\!\left(1+\frac{i\omega_-}{\rho}\right)}. \tag{64.112}$$

64.3.5 The created-particle spectrum

The modulus squared of Eq. (64.112) is the occupation number of the out-vacuum's mode k in the in-vacuum, $n_k = |\beta_k|^2$. We evaluate it with the two

gamma-function identities proved in Chapter 5,

$$|\Gamma(iy)|^2 = \frac{\pi}{y\,\sinh(\pi y)}, \qquad |\Gamma(1+iy)|^2 = \frac{\pi y}{\sinh(\pi y)} \qquad (y \in \mathbb{R}), \tag{64.113}$$

which follow from the reflection formula $\Gamma(z)\Gamma(1-z) = \pi/\sin \pi z$ and $\Gamma(1+z) = z\Gamma(z)$. Taking $|\cdot|^2$ of Eq. (64.112) and applying Eq. (64.113) term by term,

$$\begin{aligned} |\Gamma(1 - i\omega_{\rm in}/\rho)|^2 &= \frac{\pi(\omega_{\rm in}/\rho)}{\sinh(\pi\omega_{\rm in}/\rho)}, & |\Gamma(i\omega_{\rm out}/\rho)|^2 &= \frac{\pi}{(\omega_{\rm out}/\rho)\sinh(\pi\omega_{\rm out}/\rho)}, \\ |\Gamma(i\omega_-/\rho)|^2 &= \frac{\pi}{(\omega_-/\rho)\sinh(\pi\omega_-/\rho)}, & |\Gamma(1+i\omega_-/\rho)|^2 &= \frac{\pi(\omega_-/\rho)}{\sinh(\pi\omega_-/\rho)}. \end{aligned} \tag{64.114}$$

The denominator factors combine into $|\Gamma(i\omega_-/\rho)|^2\,|\Gamma(1+i\omega_-/\rho)|^2 = \pi^2/\sinh^2(\pi\omega_-/\rho)$—the (ω_-/ρ) factors cancel—and the numerator into $\pi^2(\omega_{\rm in}/\omega_{\rm out})/[\sinh(\pi\omega_{\rm in}/\rho)\sinh(\pi\omega_{\rm out}/\rho)]$. The prefactor $\omega_{\rm out}/\omega_{\rm in}$ from Eq. (64.112) cancels the residual frequency ratio, and the π^2's cancel, leaving the exact result

$$\boxed{n_k = |\beta_k|^2 = \frac{\sinh^2(\pi\omega_-/\rho)}{\sinh(\pi\omega_{\rm in}/\rho)\,\sinh(\pi\omega_{\rm out}/\rho)}, \qquad \omega_\pm = \tfrac{1}{2}(\omega_{\rm out} \pm \omega_{\rm in}).} \tag{64.115}$$

The identical calculation applied to Eq. (64.111) gives

$$|\alpha_k|^2 = \frac{\sinh^2(\pi\omega_+/\rho)}{\sinh(\pi\omega_{\rm in}/\rho)\,\sinh(\pi\omega_{\rm out}/\rho)}. \tag{64.116}$$

These are the closed-form Bogoliubov coefficients of the Bernard–Duncan model. The created-particle spectrum Eq. (64.115) is the first physical payoff of the chapter: an expanding universe creates a definite, computable number of quanta in each comoving mode, and we have it in elementary functions.

The unitarity check. The Bogoliubov coefficients must satisfy $|\alpha_k|^2 - |\beta_k|^2 = 1$, the normalisation that guarantees the transformation preserves the canonical commutators (Section 64.2). From Eq. (64.115), Eq. (64.116),

$$|\alpha_k|^2 - |\beta_k|^2 = \frac{\sinh^2(\pi\omega_+/\rho) - \sinh^2(\pi\omega_-/\rho)}{\sinh(\pi\omega_{\rm in}/\rho)\sinh(\pi\omega_{\rm out}/\rho)}. \tag{64.117}$$

Apply the identity $\sinh^2 X - \sinh^2 Y = \sinh(X+Y)\sinh(X-Y)$ with $X = \pi\omega_+/\rho$, $Y = \pi\omega_-/\rho$. Using Eq. (64.94), $X + Y = \pi\omega_{\rm out}/\rho$ and $X - Y = \pi\omega_{\rm in}/\rho$, so the numerator is exactly $\sinh(\pi\omega_{\rm out}/\rho)\sinh(\pi\omega_{\rm in}/\rho)$ and

$$|\alpha_k|^2 - |\beta_k|^2 = 1. \tag{64.118}$$

The machine is internally consistent: the transformation is a genuine Bogoliubov transformation, and Eq. (64.115) is a bona fide occupation number.

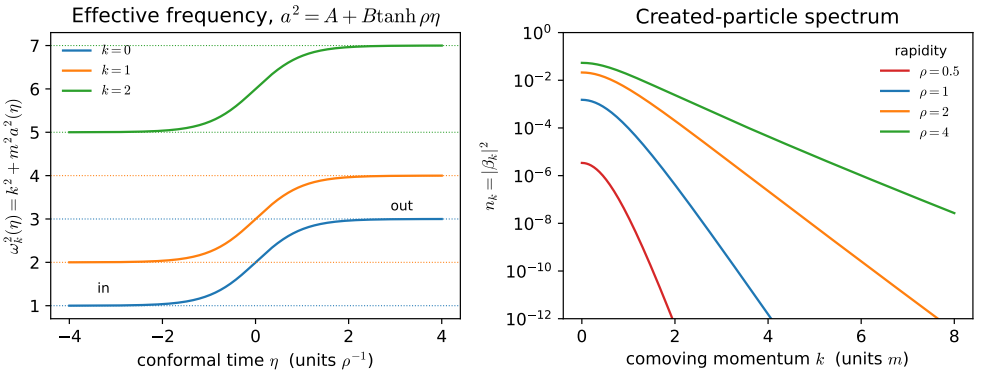

Figure 64.2: The Bernard–Duncan model with $m = 1$, $a_{\text{in}}^2 = A - B = 1$, $a_{\text{out}}^2 = A + B = 3$. *Left:* the effective frequency $\omega_k^2(\eta) = k^2 + m^2a^2(\eta)$ rising from ω_{in}^2 (dotted, lower) to ω_{out}^2 (dotted, upper) across the expansion; the asymptotically static "in" and "out" eras are where the curves flatten. *Right:* the exact created-particle spectrum $n_k = |\beta_k|^2$ of Eq. (64.115) versus comoving momentum k, for several rapidities ρ. The spectrum falls off exponentially in the ultraviolet (hence the total comoving particle number is finite), and the whole curve collapses toward zero as $\rho \to 0$: slow expansion creates no particles.

64.3.6 Limiting regimes: adiabatic, sudden, and the total number

The closed form Eq. (64.115) contains all the physics of the previous two subsections as limits. We extract three.

Worked Example 64.18 (Adiabatic, sudden, and total particle number)**. (i) Adiabatic limit, $\rho \to 0$ (slow expansion).** With $\omega_{\text{in}}, \omega_{\text{out}}, \omega_-$ held fixed and $\rho \to 0$, every argument $\pi\omega/\rho \to \infty$, so each $\sinh(\pi\omega/\rho) \to \tfrac{1}{2}e^{\pi\omega/\rho}$. Then

$$n_k \to \frac{\tfrac{1}{4}e^{2\pi\omega_-/\rho}}{\tfrac{1}{4}e^{\pi(\omega_{\text{in}}+\omega_{\text{out}})/\rho}} = e^{\,2\pi\omega_-/\rho - \pi(\omega_{\text{in}}+\omega_{\text{out}})/\rho} = e^{-2\pi\omega_{\text{in}}/\rho}, \tag{64.119}$$

where we used $2\omega_- - (\omega_{\text{in}} + \omega_{\text{out}}) = (\omega_{\text{out}} - \omega_{\text{in}}) - (\omega_{\text{in}} + \omega_{\text{out}}) = -2\omega_{\text{in}}$. The creation amplitude is exponentially small, $|\beta_k| \sim e^{-\pi\omega_{\text{in}}/\rho}$, and vanishes as $\rho \to 0$. This is the adiabatic theorem made quantitative, and it matches the WKB estimate Eq. (64.90): the analytic continuation of $\omega_k(\eta)$ has its nearest complex singularity where $\tanh(\rho\eta)$ does, at $\rho\eta_c = i\pi/2$, i.e. $\eta_c = i\pi/2\rho$, and the imaginary action accumulated to that turning point scales as $\omega_{\text{in}}\,\text{Im}\,\eta_c = \pi\omega_{\text{in}}/2\rho$, giving $|\beta_k| \sim e^{-2\cdot\pi\omega_{\text{in}}/2\rho} = e^{-\pi\omega_{\text{in}}/\rho}$ in exact agreement. The exponential rather than power-law suppression is why the in/out construction, and with it the adiabatic vacuum of Section 64.3.2, is so robust: a gently expanding universe is empty to all

orders in the adiabatic expansion, with particle creation a purely nonperturbative ($e^{-1/\rho}$) effect.

(ii) Sudden limit, $\rho \to \infty$ (fast expansion). Now every argument $\pi\omega/\rho \to 0$ and $\sinh x \to x$, so

$$n_k \to \frac{(\pi\omega_-/\rho)^2}{(\pi\omega_{\rm in}/\rho)(\pi\omega_{\rm out}/\rho)} = \frac{\omega_-^2}{\omega_{\rm in}\omega_{\rm out}} = \frac{(\omega_{\rm out}-\omega_{\rm in})^2}{4\,\omega_{\rm in}\omega_{\rm out}}, \tag{64.120}$$

a finite, ρ-independent occupation set entirely by the frequency mismatch between the two eras—exactly the result of the elementary sudden approximation, in which the in-mode is projected unchanged onto the out-basis. For a large jump $\omega_{\rm out} \gg \omega_{\rm in}$ this approaches $n_k \to \omega_{\rm out}/4\omega_{\rm in}$, an arbitrarily large number of quanta: a violent expansion is a copious particle source.

(iii) Total comoving particle number. The number of created quanta per unit comoving volume is

$$\mathcal{N} = \int \frac{\mathrm{d}^3k}{(2\pi)^3}\, n_k = \frac{1}{2\pi^2}\int_0^\infty \mathrm{d}k\, k^2\, \frac{\sinh^2(\pi\omega_-/\rho)}{\sinh(\pi\omega_{\rm in}/\rho)\sinh(\pi\omega_{\rm out}/\rho)}, \tag{64.121}$$

having done the angular integral. Convergence is controlled by the ultraviolet. At large k, $\omega_{\rm in} \approx \omega_{\rm out} \approx k$ while the mismatch shrinks, $\omega_- = \tfrac{1}{2}(\omega_{\rm out}-\omega_{\rm in}) \approx \frac{m^2 B}{2k} \to 0$, so $\sinh(\pi\omega_-/\rho) \approx \pi\omega_-/\rho$ is small while $\sinh(\pi\omega_{\rm in,out}/\rho) \approx \tfrac{1}{2}e^{\pi k/\rho}$ are exponentially large. Hence

$$n_k \;\approx\; \Big(\frac{\pi m^2 B}{2k\rho}\Big)^2 4\, e^{-2\pi k/\rho} \qquad (k \to \infty), \tag{64.122}$$

an exponential cutoff at the comoving scale $k \sim \rho$. The integrand $k^2 n_k$ therefore decays like $e^{-2\pi k/\rho}$ and Eq. (64.121) *converges*: the total comoving particle number is finite, with no ultraviolet divergence, and it is dominated by modes with $k \lesssim \rho$. The physical reason is sharp: only modes whose frequency changes appreciably during the expansion—those with $\omega_k'/\omega_k^2 \gtrsim 1$, i.e. $k \lesssim \rho$ for the tanh profile—are torn from the adiabatic vacuum; the deep ultraviolet rides the expansion adiabatically and stays empty. The total number grows with the rapidity ρ (a faster, more violent expansion excites more modes) and with the expansion amplitude through $\omega_- \propto m^2 B$, and it switches off entirely as $\rho \to 0$, consistent with Eq. (64.119).

Physical Insight

The finiteness of $\mathcal{N}$ is not an accident of the soluble model; it is the generic statement that gravitational particle creation is an *infrared-to-intermediate* phenomenon. High-momentum modes have wavelengths far shorter than the curvature scale; they cannot tell that spacetime is

curved and propagate as in flat space, so they are not excited. This is the same physics that lets one *renormalise* the gravitational stress tensor by adiabatic subtraction, the subject of Section 64.5: the divergences of $\langle T_{\mu\nu}\rangle$ live in the adiabatic (ultraviolet) part of the modes, which carries no real particles, and the finite created-particle content sits safely below the cutoff.

We have done what the Bogoliubov machine was built to do: fed it a concrete, gravitationally meaningful pair of bases and extracted an exact, finite spectrum of created particles, Eq. (64.115), complete with its adiabatic and sudden limits and the unitarity check Eq. (64.118). The spectrum here is a smooth function of k with no distinguished shape—it reflects the particular profile $a^2(\eta)$ and nothing universal. The next section asks what happens when the time-dependence is not a smooth finite-duration expansion but the eternal, self-similar redshift of a *horizon*. There the ratio of sinh's degenerates into something far more striking: the spectrum becomes an *exactly thermal* Planck distribution, the occupation number turning into $1/(e^{\omega/T}-1)$ with a temperature fixed by the geometry. That collapse of an arbitrary Bogoliubov spectrum onto a blackbody is the Unruh effect, and it is where we turn next.

64.4 The Unruh effect

The expanding universe of the previous section taught us that gravity creates particles because the very notion of "positive frequency" — and hence of "vacuum" and "particle" — is tied to a choice of time, and that choice can change as spacetime evolves. The created spectrum was controlled by the Bogoliubov coefficient β relating the natural mode bases of the far past and the far future. We now push that lesson to its sharpest edge. Instead of a mild cosmological evolution we take the cleanest possible arena — empty, flat, eternal Minkowski space — and the cleanest possible disagreement about time: an *inertial* observer versus a *uniformly accelerated* one. The accelerated observer carries a causal horizon with her, the Rindler horizon, and that horizon is the seed of the whole story. The inertial observer calls the state of the field the vacuum and finds it empty. The accelerated observer, using her own clock and her own notion of energy, finds it full: a thermal bath at temperature

$$T_{\rm U} \;=\; \frac{a}{2\pi}, \qquad \text{equivalently} \qquad k_{\rm B}T_{\rm U} \;=\; \frac{\hbar\, a}{2\pi c}, \tag{64.123}$$

where a is her proper acceleration. This is the Unruh effect. We will derive the number (64.123) twice. First with the Bogoliubov machinery of Section 64.2, by analytically continuing modes across the horizon. Then from the structure of the Euclidean path integral of Chapter 10, where the temperature falls out of a

single demand of smoothness. The two pillars of the book — canonical mode analysis and the path integral — meet on the same 2π, and the meeting point is exactly the mechanism that will give Hawking radiation in Chapter 65.

64.4.1 Rindler coordinates and the accelerated observer

We work in two-dimensional Minkowski space with coordinates (t, x) and metric $\mathrm{d}s^2 = \mathrm{d}t^2 - \mathrm{d}x^2$; the transverse directions and a mass term contribute nothing essential to the temperature and are reinstated at the end. Consider an observer undergoing constant proper acceleration. "Constant proper acceleration a" means the acceleration four-vector $a^\mu = \mathrm{d}^2 x^\mu/\mathrm{d}\tau^2$ (with τ the proper time) has fixed Minkowski norm $a^\mu a_\mu = -a^2$, while the velocity $u^\mu = \mathrm{d}x^\mu/\mathrm{d}\tau$ is a unit timelike vector, $u^\mu u_\mu = +1$. Differentiating $u^\mu u_\mu = 1$ gives $u^\mu a_\mu = 0$, so velocity and acceleration are orthogonal; the pair therefore behaves like a hyperbolic rotation, and the worldline is a hyperbola. Explicitly, the unique solution through $x = 1/a$ at $t = 0$ is

$$t(\tau) = \frac{1}{a}\sinh(a\tau), \qquad x(\tau) = \frac{1}{a}\cosh(a\tau), \tag{64.124}$$

as one checks directly: $u^\mu = (\cosh a\tau, \sinh a\tau)$ has $u^\mu u_\mu = \cosh^2 - \sinh^2 = 1$, and $a^\mu = (a\sinh a\tau, a\cosh a\tau)$ has $a^\mu a_\mu = a^2(\sinh^2 - \cosh^2) = -a^2$. The trajectory traces the hyperbola

$$x^2 - t^2 = \frac{1}{a^2}, \tag{64.125}$$

which lives entirely in the region $x > |t|$. This region is the *right Rindler wedge* R. As $\tau \to \pm\infty$ the worldline asymptotes to the null lines $x = \pm t$; these are the boundaries the accelerated observer can never cross, and they form her causal horizon.

Definition 64.19 (Rindler coordinates)**.** On the right wedge $R = \{x > |t|\}$ introduce coordinates (η, ξ) with $\eta \in \mathbb{R}$, $\xi \in \mathbb{R}$ by

$$t = \frac{1}{a}\, e^{a\xi}\sinh(a\eta), \qquad x = \frac{1}{a}\, e^{a\xi}\cosh(a\eta). \tag{64.126}$$

The reference acceleration $a > 0$ is a fixed constant labelling the foliation.

The curves of constant ξ are hyperbolae (64.125) with $x^2 - t^2 = a^{-2}e^{2a\xi}$; comparing with the worldline (64.124) the curve $\xi = 0$ is exactly the trajectory of an observer with proper acceleration a, and her proper time there is $\tau = \eta$. The curves of constant η are straight lines through the origin, $t/x = \tanh(a\eta)$; they are the instantaneous simultaneity slices of the accelerated observer. Computing the line element,

$$\begin{aligned} \mathrm{d}t &= e^{a\xi}\big[\cosh(a\eta)\,\mathrm{d}\eta + \sinh(a\eta)\,\mathrm{d}\xi\big], \\ \mathrm{d}x &= e^{a\xi}\big[\sinh(a\eta)\,\mathrm{d}\eta + \cosh(a\eta)\,\mathrm{d}\xi\big], \end{aligned} \tag{64.127}$$

so that, using $\cosh^2 - \sinh^2 = 1$,

$$\mathrm{d}s^2 = \mathrm{d}t^2 - \mathrm{d}x^2 = e^{2a\xi}(\mathrm{d}\eta^2 - \mathrm{d}\xi^2). \tag{64.128}$$

The metric (64.128) is conformal to flat space and manifestly static: nothing depends on η, so ∂_η is a Killing vector. It is timelike inside R (where $g_{\eta\eta} = e^{2a\xi} > 0$) and becomes null on the horizon $\xi \to -\infty$. An observer sitting at fixed ξ has proper time $\mathrm{d}\tau = e^{a\xi}\,\mathrm{d}\eta$ and, repeating the computation that gave (64.125), proper acceleration

$$a_{\mathrm{loc}}(\xi) = a\, e^{-a\xi}. \tag{64.129}$$

Deeper in the wedge (smaller ξ, closer to the horizon) the proper acceleration needed to hold station diverges; far out (large ξ) it is negligible. The single parameter a in (64.128) is the proper acceleration of the fiducial observer at $\xi = 0$, and that is the acceleration that will set the temperature.

The boost as the wedge's time-translation generator. The Killing field ∂_η has a clean meaning in the inertial frame. From (64.126),

$$\partial_\eta = \frac{\partial t}{\partial \eta}\,\partial_t + \frac{\partial x}{\partial \eta}\,\partial_x = e^{a\xi}\cosh(a\eta)\,\partial_t + e^{a\xi}\sinh(a\eta)\,\partial_x = a\,(x\,\partial_t + t\,\partial_x), \tag{64.130}$$

where in the last step we used $ax = e^{a\xi}\cosh(a\eta)$ and $at = e^{a\xi}\sinh(a\eta)$. The vector field $x\,\partial_t + t\,\partial_x$ is precisely the generator of Lorentz boosts in the t–x plane: it is the infinitesimal form of $M^{01} = K^1$ whose algebra we fixed in Chapter 3 (recall the boost generator from Eq. (3.135)). Thus *Rindler time translation is a Lorentz boost*, and a step $\eta \to \eta + \Delta\eta$ is a boost of rapidity $a\,\Delta\eta$. The accelerated observer's Hamiltonian — the generator conjugate to her time η — is the boost generator $K \equiv K^1$. This identification is the hinge of the entire section: the geometry of the wedge is the geometry of a boost orbit, and the quantum statistics we will find is the statistics of the boost.

The full Minkowski plane decomposes into four regions sewn along the null lines $x = \pm t$: the right wedge R ($x > |t|$), the left wedge L ($x < -|t|$), the future wedge F ($t > |x|$) and the past wedge P ($t < -|x|$). The boost moves points along the hyperbolae within R and within L, and along the straight null rays in F and P. In R the Killing field ∂_η is future-directed; in L it is *past*-directed, because the same boost that pushes events forward in time on the right pushes them backward on the left. The shared boundary $x = t$ ($\mathcal{H}^+$) and $x = -t$ ($\mathcal{H}^-$) are the future and past Rindler horizons. Figure 64.3 collects the picture.

64.4.2 Bogoliubov coefficients by analytic continuation

We now quantize a massless real scalar ϕ on this background and compare two mode bases: the inertial (Minkowski) one, whose vacuum we call $|0_M\rangle$, and the

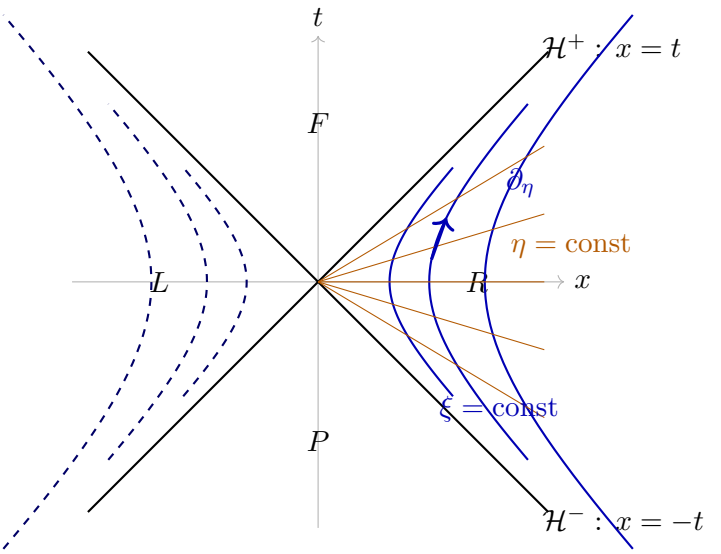

Figure 64.3: The Rindler wedges of Minkowski space. The accelerated observer's worldlines are the hyperbolae $x^2 - t^2 = a^{-2}e^{2a\xi}$ of constant ξ (solid blue in R); her simultaneity slices are the rays of constant η (orange). The boost Killing field ∂_η flows along the hyperbolae, future-directed in R and past-directed in the mirror wedge L (dashed). The null lines $x = \pm t$ are the future/past Rindler horizons $\mathcal{H}^\pm$, which the right-wedge observer can neither see beyond ($\mathcal{H}^+$) nor have influenced her ($\mathcal{H}^-$). The wedges R and L are causally disconnected.

Rindler one natural to the accelerated observer. The strategy, due to Unruh, is not to compute the Bogoliubov integrals head-on but to build a third set of modes — the *Unruh modes* — that are simultaneously simple in the Rindler basis and manifestly of positive Minkowski frequency. Analyticity across the horizon does all the work.

Null coordinates. A massless field in two dimensions splits into right-movers and left-movers; the wave equation $\partial_\eta^2\phi - \partial_\xi^2\phi = 0$ (the conformal factor in (64.128) drops out of the massless equation) is solved by arbitrary functions of the null combinations. Introduce inertial and Rindler null coordinates

$$U = t - x, \quad V = t + x; \qquad u = \eta - \xi, \quad v = \eta + \xi. \tag{64.131}$$

The right-movers are functions of U (equivalently u); the left-movers, functions of V (equivalently v). The two sectors are independent and identical in structure, so we follow the right-movers and quote the left-movers at the end. Substituting (64.126) into (64.131) gives, in the right wedge,

$$U = -\frac{1}{a}\,e^{-au}, \qquad V = +\frac{1}{a}\,e^{av} \qquad (\text{in } R), \tag{64.132}$$

since, for instance, $U = t - x = \frac{1}{a}e^{a\xi}(\sinh a\eta - \cosh a\eta) = -\frac{1}{a}e^{a\xi}e^{-a\eta} = -\frac{1}{a}e^{-a(\eta-\xi)}$. The left wedge is covered by the same coordinate formulae (64.126) with an overall sign, $t \to -t$, $x \to -x$; carrying the sign through gives

$$U = +\frac{1}{a}\,e^{-au}, \qquad V = -\frac{1}{a}\,e^{av} \qquad \text{(in } L\text{)}. \tag{64.133}$$

Observe the central fact: $U < 0$ throughout R and $U > 0$ throughout L. The Rindler coordinate u is the logarithm of $|U|$, and the two wedges sit on the two sides of the horizon $U = 0$. Crossing the horizon is crossing a logarithmic branch point of $U(u)$, and *that* is where analytic continuation will relate the wedges.

The two mode families. A right-moving Minkowski mode of positive frequency $\omega > 0$ is $e^{-i\omega U}$: it satisfies $i\partial_t e^{-i\omega U} = \omega e^{-i\omega U}$ with $\omega > 0$. The crucial analytic property is that $e^{-i\omega U}$ is *bounded and holomorphic in the lower half U-plane*, since $|e^{-i\omega U}| = e^{\omega\,\mathrm{Im}\,U} \to 0$ as $\mathrm{Im}\,U \to -\infty$. Conversely any function holomorphic and bounded in the lower-half U-plane is a superposition of positive-frequency modes only. This is the criterion we will use to certify that a mode belongs to the Minkowski vacuum.

The Rindler modes are positive-frequency with respect to the wedge's own time, the boost parameter η, measured by the *future-directed* Killing field in each wedge. In R that field is $+\partial_\eta$, so a positive-frequency right-moving Rindler mode of frequency $\Omega > 0$ is $\propto e^{-i\Omega u}$, supported on R. In L the future-directed Killing field is $-\partial_\eta$, which reverses the sign: positive frequency there means $\partial_\eta g = +i\Omega g$, i.e. $\propto e^{+i\Omega u}$, supported on L. Normalizing in the Klein–Gordon inner product (each carries the standard $1/\sqrt{4\pi\Omega}$), and re-expressing u through U via (64.132)–(64.133),

$$g^R_\Omega(U) = \frac{1}{\sqrt{4\pi\Omega}}\,(-aU)^{\,i\Omega/a}, \qquad U < 0,\ \text{(zero in } L\text{)}, \tag{64.134}$$

$$g^L_\Omega(U) = \frac{1}{\sqrt{4\pi\Omega}}\,(aU)^{-i\Omega/a}, \qquad U > 0,\ \text{(zero in } R\text{)}, \tag{64.135}$$

where we used $e^{-i\Omega u} = e^{i(\Omega/a)\ln(-aU)} = (-aU)^{i\Omega/a}$ in R (from $-aU = e^{-au}$, so $u = -a^{-1}\ln(-aU)$) and $e^{+i\Omega u} = (aU)^{-i\Omega/a}$ in L. Each family is complete on its own wedge, and the corresponding annihilation operators a^R_Ω, a^L_Ω define the Rindler (Fulling) vacuum $|0_R\rangle = |0_R\rangle \otimes |0_L\rangle$. The Rindler observer in R has no access to L, so her physics is built from a^R_Ω alone.

Continuing across the horizon. The functions (64.134)–(64.135) are each defined on only half the U-axis and are not, separately, positive-frequency Minkowski modes (indeed they have a branch point at the horizon $U = 0$). The idea is to extend g^R_Ω to all U by continuing it through the *lower* half U-plane, where positive-frequency functions are well-behaved. Write $-aU = |aU|\,e^{i\arg(-U)}$

and track the phase as U runs from the negative real axis (in R) to the positive real axis (in L) along a path with $\operatorname{Im} U < 0$. On the negative axis, $-aU > 0$ has $\arg(-U) = 0$. Rotating U clockwise through the lower half-plane to the positive axis advances $\arg(-U)$ from 0 to π, so on arrival

$$-aU\big|_{U>0} = aU\, e^{i\pi} \quad \Longrightarrow \quad (-aU)^{i\Omega/a}\big|_{U>0} = (aU)^{i\Omega/a}\, e^{i\pi\cdot i\Omega/a} = e^{-\pi\Omega/a}\,(aU)^{i\Omega/a}. \tag{64.136}$$

The branch chosen — continuation through $\operatorname{Im} U < 0$ — is precisely the one that keeps the function bounded in the lower half-plane (the phase $e^{-(\Omega/a)\arg(-U)}$ never exceeds unity there), so the continued function is a genuine positive-frequency Minkowski object. Now recognize the right-hand side: on $U > 0$, comparing with (64.135),

$$(aU)^{i\Omega/a} = \big[(aU)^{-i\Omega/a}\big]^{*} = \sqrt{4\pi\Omega}\; g^{L*}_{\Omega}(U). \tag{64.137}$$

The analytic continuation of the right-wedge mode *is* a fixed multiple of the complex conjugate of the left-wedge mode. Assembling (64.136)–(64.137), the single holomorphic function defined on the whole U-axis is

$$W_{\Omega} \;=\; g^{R}_{\Omega} + e^{-\pi\Omega/a}\, g^{L*}_{\Omega}, \tag{64.138}$$

and by construction W_Ω is positive-frequency with respect to Minkowski time. By the mirror computation — continue g^{L}_{Ω} through the lower half-plane — the second independent positive-frequency combination is

$$\widetilde{W}_{\Omega} \;=\; g^{L}_{\Omega} + e^{-\pi\Omega/a}\, g^{R*}_{\Omega}. \tag{64.139}$$

These are the *Unruh modes*. They are the bridge: built linearly from Rindler modes, yet annihilating the Minkowski vacuum.

Normalization and the Bogoliubov transformation. In the Klein–Gordon inner product the Rindler modes are orthonormal, $\langle g^{R}_{\Omega}, g^{R}_{\Omega'}\rangle = \delta(\Omega-\Omega')$, the conjugates carry negative norm $\langle g^{R*}_{\Omega}, g^{R*}_{\Omega'}\rangle = -\delta(\Omega-\Omega')$, and modes on disjoint wedges are orthogonal. Hence the norm of (64.138) is

$$\langle W_\Omega, W_\Omega\rangle = \langle g^{R}_{\Omega}, g^{R}_{\Omega}\rangle + e^{-2\pi\Omega/a}\langle g^{L*}_{\Omega}, g^{L*}_{\Omega}\rangle = \big(1 - e^{-2\pi\Omega/a}\big)\,\delta(\Omega-\Omega'), \tag{64.140}$$

so the unit-normalized Unruh modes are

$$\widehat{W}_{\Omega} = \frac{g^{R}_{\Omega} + e^{-\pi\Omega/a}\, g^{L*}_{\Omega}}{\sqrt{1-e^{-2\pi\Omega/a}}}, \qquad \widehat{\widetilde{W}}_{\Omega} = \frac{g^{L}_{\Omega} + e^{-\pi\Omega/a}\, g^{R*}_{\Omega}}{\sqrt{1-e^{-2\pi\Omega/a}}}. \tag{64.141}$$

Because $\{\widehat{W}_\Omega, \widehat{\widetilde{W}}_\Omega\}$ are positive-frequency Minkowski modes, their annihilation operators $d^{(1)}_{\Omega}, d^{(2)}_{\Omega}$ annihilate $|0_M\rangle$. Expanding the field in the two bases,

$$\phi = \int_0^\infty \mathrm{d}\Omega \Big[a^{R}_{\Omega} g^{R}_{\Omega} + a^{L}_{\Omega} g^{L}_{\Omega} + \text{h.c.}\Big] = \int_0^\infty \mathrm{d}\Omega \Big[d^{(1)}_{\Omega}\widehat{W}_{\Omega} + d^{(2)}_{\Omega}\widehat{\widetilde{W}}_{\Omega} + \text{h.c.}\Big], \tag{64.142}$$

and matching the coefficient of g^R_Ω on the two sides — it appears in $\widehat{W}_\Omega$ with weight $(1-e^{-2\pi\Omega/a})^{-1/2}$ and in $\widehat{\widetilde{W}}^*_\Omega$ (the conjugate mode multiplying $d^{(2)\dagger}_\Omega$) with weight $e^{-\pi\Omega/a}(1-e^{-2\pi\Omega/a})^{-1/2}$ — yields the Bogoliubov relation

$$a^R_\Omega = \alpha_\Omega\, d^{(1)}_\Omega + \beta_\Omega\, d^{(2)\dagger}_\Omega, \qquad \alpha_\Omega = \frac{1}{\sqrt{1-e^{-2\pi\Omega/a}}}, \quad \beta_\Omega = \frac{e^{-\pi\Omega/a}}{\sqrt{1-e^{-2\pi\Omega/a}}}. \tag{64.143}$$

The coefficients satisfy the canonical normalization automatically,

$$|\alpha_\Omega|^2 - |\beta_\Omega|^2 = \frac{1-e^{-2\pi\Omega/a}}{1-e^{-2\pi\Omega/a}} = 1, \qquad \frac{|\beta_\Omega|^2}{|\alpha_\Omega|^2} = e^{-2\pi\Omega/a}, \tag{64.144}$$

which is the relation $|\beta_\Omega|^2/|\alpha_\Omega|^2 = e^{-2\pi\Omega/a}$ promised at the head of the chapter.

The Planck spectrum. The number of Rindler particles the accelerated observer counts in the Minkowski vacuum follows by the rule established in Section 64.2: $\langle 0_M|N^R_\Omega|0_M\rangle = |\beta_\Omega|^2$. Concretely, using (64.143) and $d^{(1,2)}_\Omega\,|0_M\rangle = 0$,

$$\Big\langle 0_M\Big|a^{R\dagger}_\Omega a^R_{\Omega'}\Big|0_M\Big\rangle = |\beta_\Omega|^2\,\Big\langle 0_M\Big|d^{(2)}_\Omega d^{(2)\dagger}_{\Omega'}\Big|0_M\Big\rangle = |\beta_\Omega|^2\,\delta(\Omega-\Omega'), \tag{64.145}$$

where the $\delta(\Omega-\Omega')$ is the standard continuum density-of-states factor; the mean occupation per mode is therefore

$$n_\Omega = |\beta_\Omega|^2 = \frac{e^{-2\pi\Omega/a}}{1-e^{-2\pi\Omega/a}} = \frac{1}{e^{2\pi\Omega/a}-1}. \tag{64.146}$$

This is exactly the Bose–Einstein distribution $n_\Omega = (e^{\Omega/T}-1)^{-1}$ with

$$T = \frac{a}{2\pi}, \tag{64.147}$$

the Unruh temperature (64.123). The mass and the transverse dimensions we dropped enter the density of states and the detailed shape of wavepackets but not this exponent: the temperature is universal, fixed by the single number a. We record the result.

Theorem 64.20 (Unruh)**.** *Let ϕ be a free scalar field in the Minkowski vacuum $|0_M\rangle$. With respect to the boost-time modes natural to a uniformly accelerated observer of proper acceleration a (Theorem 64.19), the state $|0_M\rangle$ contains a Planckian distribution of quanta,*

$$n_\Omega = \frac{1}{e^{2\pi\Omega/a}-1},$$

i.e. it is perceived as a thermal bath at the Unruh temperature $T_{\mathrm{U}} = a/2\pi$. An inertial observer, using the Minkowski modes, finds the same state empty.

Physical Insight

Nothing was "added" to the vacuum; the field operator and the state are the ones an inertial physicist calls empty. What changed is the bookkeeping of energy. The accelerated observer's notion of a quantum is the Rindler mode, and the Minkowski vacuum, decomposed in that basis, is a correlated condensate of Rindler pairs straddling the horizon — one quantum in R, its partner in the inaccessible wedge L — distributed exactly thermally. Acceleration does not heat the field; it changes which observable counts as "the number of particles," and that observable has a thermal expectation value. The same sentence, transplanted from the Rindler horizon to a black-hole horizon, will become Hawking radiation in Chapter 65.

64.4.3 The Euclidean/KMS derivation: temperature from periodicity

The Bogoliubov route gave the temperature through a careful tracking of phases across the horizon. The path-integral route gives the same number with almost no computation, by Wick-rotating the boost time. This is the place where the chapter's two methods visibly converge.

Recall from Chapter 10 (the dictionary of Section 10.6.5) the fundamental equivalence: a quantum field whose Euclidean time is periodic with period β computes the thermal trace $Z(\beta) = \mathrm{Tr}\, e^{-\beta H}$, so periodicity in imaginary time *is* thermal equilibrium at temperature $T = 1/\beta$. The Hamiltonian H in that statement is the generator of the time translation being rotated. For the accelerated observer the relevant time is the boost parameter η, and the relevant Hamiltonian is the boost generator K. We therefore Wick-rotate η.

Set $\eta = -i\theta$ with θ real. Under this rotation the worldline coordinates (64.126) become, using $\sinh(-ia\theta) = -i\sin(a\theta)$ and $\cosh(-ia\theta) = \cos(a\theta)$,

$$t = -\frac{i}{a}\, e^{a\xi}\sin(a\theta) \equiv -i\, t_E, \qquad x = \frac{1}{a}\, e^{a\xi}\cos(a\theta), \qquad t_E = \frac{1}{a}\, e^{a\xi}\sin(a\theta). \tag{64.148}$$

The Euclidean plane (t_E, x) is covered by polar-like coordinates with radius and angle

$$\rho = \frac{1}{a}\, e^{a\xi} \geq 0, \qquad \varphi = a\theta, \qquad \text{so} \qquad t_E = \rho\sin\varphi, \quad x = \rho\cos\varphi. \tag{64.149}$$

The Euclidean line element is $\mathrm{d}s_E^2 = \mathrm{d}t_E^2 + \mathrm{d}x^2 = \mathrm{d}\rho^2 + \rho^2\,\mathrm{d}\varphi^2$, the flat plane in polar coordinates — equivalently, inserting (64.149),

$$\mathrm{d}s_E^2 = e^{2a\xi}(\mathrm{d}\theta^2 + \mathrm{d}\xi^2), \tag{64.150}$$

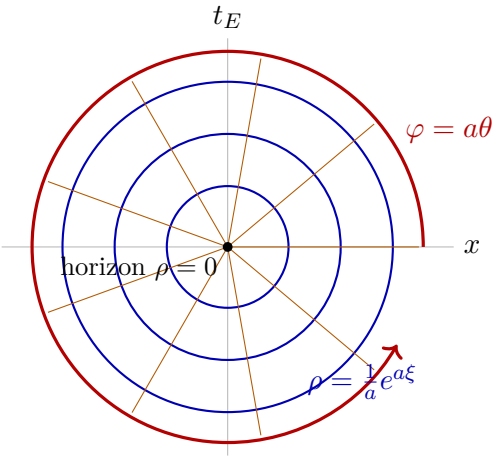

Figure 64.4: Euclidean Rindler space. Wick-rotating the boost time, $\eta = -i\theta$, turns the wedge into the flat plane (t_E, x) in polar coordinates: the constant-ξ hyperbolae become circles of radius $\rho = a^{-1}e^{a\xi}$ (blue) and the constant-η rays become radial lines (orange). The horizon collapses to the origin, the fixed point of the rotation. Smoothness there forces the angle $\varphi = a\theta$ to be 2π-periodic, i.e. the Euclidean time θ to have period $\beta = 2\pi/a$ — and an imaginary-time period β is, by Section 10.6.5, a thermal state at $T = 1/\beta = a/2\pi$.

the Euclidean continuation of the Rindler metric (64.128). The horizon $\xi \to -\infty$, where $\rho \to 0$, is the *origin* of the Euclidean plane — the fixed point of the boost, which under rotation has become an ordinary rotation about the origin.

Here is the whole argument in one line. A rotation angle φ on a smooth plane must be 2π-periodic; any other period leaves a conical defect at $\rho = 0$, a curvature delta-function that the smooth flat geometry of Minkowski space does not have. Smoothness of the Euclidean continuation at the horizon therefore demands

$$\varphi = a\theta \;\sim\; a\theta + 2\pi \quad\Longleftrightarrow\quad \theta \;\sim\; \theta + \frac{2\pi}{a}. \tag{64.151}$$

The Euclidean boost time θ is periodic with period $\beta = 2\pi/a$.

By the imaginary-time dictionary, this periodicity means that the Minkowski vacuum, restricted to the right wedge and propagated by the boost Hamiltonian K, is the Gibbs state

$$\rho_R \;\propto\; e^{-\beta K}, \qquad \beta = \frac{2\pi}{a}, \tag{64.152}$$

a thermal state at inverse temperature 2π in units of the boost time. To translate this into a temperature an observer measures, recall that the fiducial observer at $\xi = 0$ has proper time $\tau = \eta$ and proper acceleration a. Her clock ticks in η, her

energy is conjugate to η, and so she reads the inverse temperature $\beta = 2\pi/a$, i.e.

$$T_{\mathrm{U}} = \frac{1}{\beta} = \frac{a}{2\pi}, \tag{64.153}$$

the same number (64.123) as the Bogoliubov computation. The two pillars have met. An observer parked at general ξ measures proper time $\mathrm{d}\tau = e^{a\xi}\mathrm{d}\eta$; her locally measured temperature is the Tolman-redshifted value

$$T_{\mathrm{loc}}(\xi) = \frac{T_{\mathrm{U}}}{\sqrt{g_{\eta\eta}}} = \frac{a/2\pi}{e^{a\xi}} = \frac{a_{\mathrm{loc}}(\xi)}{2\pi}, \tag{64.154}$$

exactly $a_{\mathrm{loc}}/2\pi$ in terms of her own proper acceleration (64.129). The Unruh formula holds pointwise, with each observer's local acceleration setting her local temperature — a consistency check that the result is geometric, not an artifact of the $\xi = 0$ slice.

Remark 64.21 (Why 2π and nothing else). The entire temperature is the statement that a smooth plane has angular period 2π. Every appearance of the magic factor 2π in horizon thermodynamics — Unruh here, Hawking in Chapter 65 — traces to this one geometric fact: near any non-degenerate horizon the Euclidean geometry is locally a plane in polar coordinates, and regularity at the tip fixes the period of imaginary time. The Bogoliubov phase $e^{-\pi\Omega/a}$ of (64.136) is the same 2π seen through the half-rotation that carries one wedge into the other: the continuation (64.136) rotated U by angle π, and $e^{-\pi\Omega/a}$ is the half of the full $e^{-2\pi\Omega/a}$ Boltzmann weight.

The rigorous backbone: Bisognano–Wichmann. The heuristic Wick rotation can be made into a theorem of axiomatic quantum field theory, and it is worth stating precisely what is known, because it elevates the Unruh effect from a property of free fields to a structural property of *any* relativistic quantum field theory. The tool is the Tomita–Takesaki modular theory of von Neumann algebras: to a von Neumann algebra $\mathcal{A}$ with a cyclic and separating vector Ω (here the algebra of observables localized in the right wedge, with $\Omega = |0_M\rangle$ the vacuum) the theory canonically assigns a positive operator Δ, the modular operator, and the one-parameter *modular flow* $\sigma_s(\cdot) = \Delta^{is}(\cdot)\Delta^{-is}$. The vacuum satisfies the KMS condition with respect to this flow at inverse temperature 1.

Theorem 64.22 (Bisognano–Wichmann; stated, not proved)**.** *In any Wightman quantum field theory satisfying the standard axioms, the modular operator of the right-wedge algebra with respect to the vacuum is $\Delta = e^{-2\pi K}$, where K is the generator of Lorentz boosts in the plane orthogonal to the wedge's edge. Equivalently, the modular flow is the geometric boost flow, σ_s acts as a boost of rapidity $-2\pi s$, and the vacuum is a KMS (thermal) state for the boost Hamiltonian at inverse temperature $\beta = 2\pi$. Restoring the proper acceleration of a worldline at unit boost speed reproduces $T_{\mathrm{U}} = a/2\pi$.*

The content of Theorem 64.22 is that the thermal character of the wedge-restricted vacuum is not special to free fields or to the Gaussian manipulations above: it is forced by Lorentz invariance, locality, and the spectrum condition alone. The proof, which we cite rather than reproduce (it belongs to operator-algebraic QFT and uses the analyticity of vacuum correlators in the tube domains fixed by the spectrum condition), establishes exactly the identification "modular Hamiltonian $= 2\pi\times$ boost" that our Euclidean argument made plausible. We will invoke the same modular-flow language when we discuss black-hole horizons and entanglement in Chapter 65; for the present chapter it is the assurance that the number $a/2\pi$ is a theorem, not a free-field coincidence.

64.4.4 The detector: a click for the accelerated, silence for the inertial

A skeptic may ask what "the accelerated observer sees a thermal bath" means operationally, given that the state is the inertial vacuum. The answer is a model detector. An Unruh–DeWitt detector is a pointlike quantum system with internal energy levels, carried along a worldline $x^\mu(\tau)$ and coupled to the field through the monopole interaction

$$H_{\rm int} = \lambda\, \mu(\tau)\, \phi(x(\tau)), \tag{64.155}$$

with $\mu(\tau)$ the detector's monopole operator and λ a small coupling. To first order in λ, the amplitude to excite the detector from its ground state $|E_0\rangle$ to a level $|E\rangle$ (gap $E = E - E_0 > 0$) while the field starts in $|0_M\rangle$ is, by time-dependent perturbation theory, proportional to the integral of the field's Wightman function along the worldline. Summing over the unobserved final field states, the excitation probability per unit coupling is $|\langle E|\mu(0)|E_0\rangle|^2\, \mathcal{F}(E)$, where the universal kinematic factor is the *response function*

$$\mathcal{F}(E) = \int_{-\infty}^{\infty} \mathrm{d}\tau \int_{-\infty}^{\infty} \mathrm{d}\tau'\, e^{-iE(\tau-\tau')}\, W(x(\tau), x(\tau')), \qquad W(x,x') = \langle 0_M|\phi(x)\phi(x')|0_M\rangle\,. \tag{64.156}$$

For a stationary worldline W depends only on the proper-time difference $s = \tau - \tau'$, the double integral factorizes into an (infinite) total proper time times the response *rate*

$$F(E) = \int_{-\infty}^{\infty} \mathrm{d}s\, e^{-iEs}\, W(s), \tag{64.157}$$

the Fourier transform of the pulled-back Wightman function. The detector reads the field through $F(E)$: a nonzero $F(E)$ for $E > 0$ means it clicks, absorbing energy from the field.

The inertial detector is silent. For an inertial worldline the proper time is Minkowski time and the spatial separation vanishes, so the four-dimensional

massless Wightman function (the $d = 4$ form is cleaner for the contour argument; the temperature is dimension-independent) reduces to

$$W_{\text{inert}}(s) = -\frac{1}{4\pi^2}\,\frac{1}{(s - i\epsilon)^2}, \tag{64.158}$$

the $-i\epsilon$ encoding that W is a positive-frequency (Wightman, not time-ordered) function. Insert this into (64.157):

$$F_{\text{inert}}(E) = -\frac{1}{4\pi^2}\int_{-\infty}^{\infty} \mathrm{d}s\,\frac{e^{-iEs}}{(s - i\epsilon)^2}. \tag{64.159}$$

For $E > 0$ the factor $e^{-iEs} = e^{-iE\,\mathrm{Re}\,s}\,e^{E\,\mathrm{Im}\,s}$ decays as $\mathrm{Im}\,s \to -\infty$, so we close the contour in the *lower* half s-plane. The only singularity of the integrand, the double pole, sits at $s = +i\epsilon$ in the *upper* half-plane; the lower contour encloses nothing and

$$F_{\text{inert}}(E) = 0 \qquad (E > 0). \tag{64.160}$$

An inertial detector in the Minkowski vacuum never gets excited. It is at zero temperature, as it must be. (For $E < 0$ one closes upward and finds the spontaneous-emission rate; an inertial detector prepared in an excited state can decay, but a ground-state one cannot be promoted.)

The accelerated detector thermalizes. Now carry the detector along the accelerated worldline (64.124). The pulled-back Wightman function needs the invariant interval between two points on the hyperbola. With $t = a^{-1}\sinh(a\tau)$, $x = a^{-1}\cosh(a\tau)$,

$$\begin{aligned}(t - t')^2 - (x - x')^2 &= \frac{1}{a^2}\Big[(\sinh a\tau - \sinh a\tau')^2 - (\cosh a\tau - \cosh a\tau')^2\Big] \\ &= \frac{1}{a^2}\Big[-2 + 2\big(\cosh a\tau\cosh a\tau' - \sinh a\tau\sinh a\tau'\big)\Big] \\ &= \frac{2}{a^2}\big[\cosh\big(a(\tau - \tau')\big) - 1\big] = \frac{4}{a^2}\,\sinh^2\!\Big(\frac{a\,s}{2}\Big),\end{aligned} \tag{64.161}$$

where we used $\sinh^2 - \cosh^2 = -1$ on each point, the addition theorem $\cosh(a\tau - a\tau') = \cosh a\tau\cosh a\tau' - \sinh a\tau\sinh a\tau'$, and finally $\cosh\zeta - 1 = 2\sinh^2(\zeta/2)$. The interval depends only on $s = \tau - \tau'$, confirming stationarity. The $d = 4$ Wightman function $W = -\frac{1}{4\pi^2}[(t - t' - i\epsilon)^2 - |\mathbf{x} - \mathbf{x}'|^2]^{-1}$ pulled back to the worldline (where the transverse separation vanishes and the $i\epsilon$ becomes $s \to s - i\epsilon$) is therefore

$$W_{\text{acc}}(s) = -\frac{a^2}{16\pi^2}\,\frac{1}{\sinh^2\!\big(\frac{a}{2}(s - i\epsilon)\big)}. \tag{64.162}$$

This single function carries the whole effect. Note its periodicity in imaginary proper time: since $\sinh(z - i\pi) = -\sinh z$, the square is invariant under $\frac{a}{2}s \to$

$\frac{a}{2}s - i\pi$, i.e. under $s \to s - 2\pi i/a$,

$$W_{\rm acc}\Big(s - \frac{2\pi i}{a}\Big) = W_{\rm acc}(s). \tag{64.163}$$

This is the KMS condition at inverse temperature $\beta = 2\pi/a$ written for the two-point function — the same periodicity that the Euclidean argument read off the angle, now visible directly in the correlator the detector samples. The $-i\epsilon$ prescription places the pole at $s = 0$ (and the $n = 0$ image) in the upper half-plane, exactly as in the inertial case, while the images at $s = -2\pi i n/a$, $n = 1, 2, \ldots$, populate the lower half-plane.

The KMS periodicity (64.163) forces detailed balance. From the definition (64.157), substituting $s \to -s$ and then using (64.163) together with analyticity of W in the strip $-\beta < \mathrm{Im}\, s < 0$ (so that the contour may be shifted by $-i\beta$),

$$F(-E) = \int \mathrm{d}s\, e^{+iEs} W(s) = \int \mathrm{d}s\, e^{-iEs} W(-s) = \int \mathrm{d}s\, e^{-iEs} W(s - i\beta) = e^{\beta E} \int \mathrm{d}s\, e^{-iEs} W(s) \tag{64.164}$$

where in the last-but-one step we shifted $s \to s + i\beta$ and picked up $e^{-iE(s+i\beta)} = e^{\beta E} e^{-iEs}$. Hence

$$\frac{F(E)}{F(-E)} = e^{-\beta E} = e^{-2\pi E/a}. \tag{64.165}$$

The ratio of the rate to climb a gap E to the rate to fall by it is the Boltzmann factor at temperature $T = a/2\pi$. This is precisely how a detector in contact with a heat bath at temperature T behaves: *detailed balance is the operational definition of "the detector sees a thermal bath."* The accelerated detector clicks, with a spectrum of clicks indistinguishable from immersion in radiation at $T_{\rm U} = a/2\pi$, while (64.160) says its inertial twin records nothing. Figure 64.5 plots both the thermal occupation (64.146) and the detector response worked out next, against the flat inertial baseline.

Worked Example 64.23 (The full Planckian response rate)**.** We extract not just the ratio (64.165) but the full response rate by evaluating (64.157) with (64.162) by residues. Write

$$F(E) = -\frac{a^2}{16\pi^2} \int_{-\infty}^{\infty} \mathrm{d}s\, \frac{e^{-iEs}}{\sinh^2\!\big(\frac{a}{2}(s - i\epsilon)\big)}. \tag{64.166}$$

For $E > 0$ close the contour in the lower half-plane, where e^{-iEs} decays. The integrand has double poles where $\sinh(\frac{a}{2}s) = 0$, i.e. $s = 2\pi i n/a$ for integer n; with the $-i\epsilon$ shift the poles enclosed by the downward contour are those at

$$s_n = -\frac{2\pi i n}{a}, \qquad n = 1, 2, 3, \ldots \tag{64.167}$$

Near s_n set $s = s_n + \delta$. Using $\sinh(\tfrac{a}{2}s_n + \tfrac{a}{2}\delta) = \sinh(-i\pi n + \tfrac{a}{2}\delta) = (-1)^n \sinh(\tfrac{a}{2}\delta) \simeq (-1)^n \tfrac{a}{2}\delta$, the squared denominator is $\sinh^2 \simeq \tfrac{a^2}{4}\delta^2$, so near the pole

$$\frac{e^{-iEs}}{\sinh^2(\frac{a}{2}s)} \simeq \frac{4}{a^2}\,\frac{e^{-iEs_n}\,e^{-iE\delta}}{\delta^2} = \frac{4}{a^2}\,e^{-iEs_n}\,\frac{1 - iE\delta + \cdots}{\delta^2}. \tag{64.168}$$

The residue (coefficient of $1/\delta$) is $\dfrac{4}{a^2}(-iE)\,e^{-iEs_n}$, and with $e^{-iEs_n} = e^{-iE(-2\pi i n/a)} = e^{-2\pi n E/a}$ the clockwise (downward) contour gives $F(E) = -\frac{a^2}{16\pi^2}\cdot(-2\pi i)\sum_{n\geq 1}$ Res:

$$\begin{aligned} F(E) &= -\frac{a^2}{16\pi^2}\,(-2\pi i)\,\sum_{n=1}^{\infty}\frac{4}{a^2}\,(-iE)\,e^{-2\pi nE/a} \\ &= -\frac{a^2}{16\pi^2}\,(-2\pi i)(-iE)\frac{4}{a^2}\sum_{n=1}^{\infty}e^{-2\pi nE/a} = \frac{E}{2\pi}\sum_{n=1}^{\infty}e^{-2\pi nE/a}, \end{aligned} \tag{64.169}$$

where $(-2\pi i)(-iE) = -2\pi E$ cancelled the leading sign. Summing the geometric series $\sum_{n\geq 1} e^{-2\pi nE/a} = (e^{2\pi E/a} - 1)^{-1}$,

$$\boxed{F(E) = \frac{E}{2\pi}\,\frac{1}{e^{2\pi E/a} - 1}} \tag{64.170}$$

The response is the four-dimensional density of states $E/2\pi$ times the Planck factor at $T_{\mathrm{U}} = a/2\pi$. It manifestly satisfies the detailed-balance ratio (64.165), and it is strictly positive for $E > 0$: the accelerated detector is excited with a thermal spectrum. As $a \to 0$ the rate vanishes faster than any power, recovering the inertial silence (64.160) in the limit of no acceleration.

64.4.5 Synthesis: the vacuum as a thermofield double

The Bogoliubov and KMS derivations are not merely two roads to the same number; they are two views of the same state. We close by exhibiting the Minkowski vacuum explicitly in the Rindler basis, which makes the thermal density matrix (64.152) an algebraic identity and ties the section to the entanglement structure that returns for black holes.

Worked Example 64.24 (The Minkowski vacuum is a two-mode squeezed state)**.** Invert the Bogoliubov relation (64.143). With $\alpha_\Omega, \beta_\Omega$ real and $\alpha^2 - \beta^2 = 1$, the same continuation that produced $\widehat{\widetilde{W}}_\Omega$ gives $a^L_\Omega = \alpha_\Omega d^{(2)}_\Omega + \beta_\Omega d^{(1)\dagger}_\Omega$, and solving the pair for the Minkowski annihilation operators yields

$$d^{(1)}_\Omega = \alpha_\Omega\, a^R_\Omega - \beta_\Omega\, a^{L\dagger}_\Omega, \qquad d^{(2)}_\Omega = \alpha_\Omega\, a^L_\Omega - \beta_\Omega\, a^{R\dagger}_\Omega, \tag{64.171}$$

as one verifies by substitution. The Minkowski vacuum is the state annihilated by every $d^{(1)}_\Omega, d^{(2)}_\Omega$. Working mode by mode and dropping the Ω label, the condition

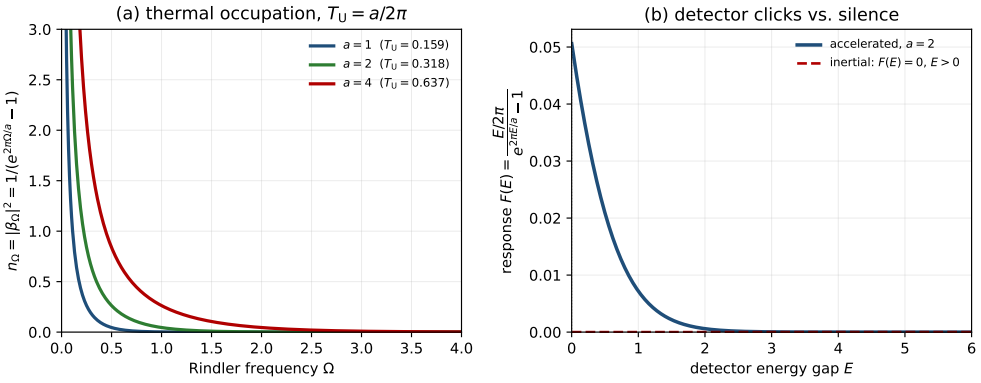

Figure 64.5: The Unruh spectrum, two ways. **(a)** The mean Rindler occupation $n_\Omega = |\beta_\Omega|^2 = (e^{2\pi\Omega/a} - 1)^{-1}$ from the Bogoliubov coefficient (64.146), a Bose–Einstein distribution at $T_U = a/2\pi$; larger proper acceleration is a hotter bath. **(b)** The Unruh–DeWitt detector response rate $F(E) = \frac{E}{2\pi}(e^{2\pi E/a} - 1)^{-1}$ of Theorem 64.23 for an accelerated worldline (solid), against the inertial response, which is identically zero for $E > 0$ (dashed): the accelerated detector clicks thermally, its inertial twin stays silent.

$(\alpha\, a^R - \beta\, a^{L\dagger})\,|0_M\rangle = 0$ is solved by the ansatz $|0_M\rangle = \mathcal{N} \exp(\lambda\, a^{R\dagger} a^{L\dagger})\,|0_R, 0_L\rangle$: since $a^R \exp(\lambda a^{R\dagger} a^{L\dagger})\,|0\rangle = \lambda\, a^{L\dagger} \exp(\lambda a^{R\dagger} a^{L\dagger})\,|0\rangle$ (the annihilator pulls down one factor of $a^{R\dagger}$), the condition reduces to $\alpha\lambda - \beta = 0$, fixing

$$\lambda = \frac{\beta_\Omega}{\alpha_\Omega} = e^{-\pi\Omega/a}. \tag{64.172}$$

Normalizing $\langle 0_M|\, 0_M\rangle = 1$ gives $\mathcal{N} = \sqrt{1 - \lambda^2} = \sqrt{1 - e^{-2\pi\Omega/a}}$ per mode, so

$$|0_M\rangle = \prod_\Omega \sqrt{1 - e^{-2\pi\Omega/a}}\, \exp\!\Big(e^{-\pi\Omega/a}\, a_\Omega^{R\dagger} a_\Omega^{L\dagger}\Big)\,|0_R\rangle\otimes|0_L\rangle = \prod_\Omega \sqrt{1 - e^{-2\pi\Omega/a}} \sum_{n=0}^{\infty} e^{-\pi\Omega n/a}\,|n_\Omega \tag{64.173}$$

This is a *two-mode squeezed state*: each Rindler quantum in the right wedge is perfectly correlated with a partner in the inaccessible left wedge. It is precisely the thermofield double of finite-temperature field theory, with the left wedge playing the role of the fictitious "tilde" copy. The accelerated observer, confined to R, has no access to the L factors and must trace them out. Tracing (64.173) over L,

$$\rho_R = \mathrm{Tr}_L\,|0_M\rangle\langle 0_M| = \prod_\Omega (1 - e^{-2\pi\Omega/a}) \sum_{n=0}^{\infty} e^{-2\pi\Omega n/a}\;|n_\Omega\rangle_R\langle n_\Omega|_R = \frac{e^{-\beta K}}{\mathrm{Tr}\; e^{-\beta K}}, \quad \beta = \frac{2\pi}{a}, \tag{64.174}$$

exactly the Gibbs state (64.152) for the boost Hamiltonian $K = \int \mathrm{d}\Omega\, \Omega\, a_\Omega^{R\dagger} a_\Omega^R$. The mean occupation in this geometric distribution, $p_n = (1 - x)x^n$ with $x =$

$e^{-2\pi\Omega/a}$, is $\langle n\rangle = x/(1-x) = (e^{2\pi\Omega/a}-1)^{-1}$, reproducing the Planck number (64.146) a third time. The Bogoliubov coefficient, the Euclidean period, and the modular Hamiltonian are thus one statement: restricting the vacuum to a wedge across a horizon produces a thermal state, and the temperature is $a/2\pi$.

The lesson is portable and exact: a horizon plus a Wick rotation equals a temperature, and the geometric origin of the 2π guarantees the answer is universal. In Chapter 65 we replace the flat Rindler horizon by the event horizon of a black hole; the boost becomes the Killing time of the static metric, the proper acceleration becomes the surface gravity κ, and the identical regularity-of-the-Euclidean-cone argument delivers the Hawking temperature $T_{\rm H} = \kappa/2\pi$ verbatim. Before we can trust that machinery in a curved geometry, however, we must confront the object whose expectation value backreacts on the metric — the stress-energy tensor, which is formally divergent in every one of these states and whose careful definition occupies Section 64.5.

64.5 The renormalized stress-energy tensor

The Unruh effect of the previous section (Section 64.4) delivered a disturbing lesson: the very notion of *which state is empty* is observer- and geometry-dependent, and a state that one observer calls the vacuum another finds teeming with quanta. Cosmological particle production (Section 64.3) made the same point dynamically. We are therefore in possession of states — thermal baths, squeezed in-vacua, adiabatic vacua of an expanding universe — whose particle content we can count, but whose *energy and momentum* we have not yet quantified. That content is not a bookkeeping curiosity. In general relativity the metric is not a fixed stage: it responds to whatever carries energy and momentum, through Einstein's equation

$$G_{\mu\nu} = 8\pi G\, T_{\mu\nu}. \tag{64.175}$$

If the matter is quantum and the geometry classical — the semiclassical approximation that organizes this entire chapter and the next — then the source on the right is not a classical tensor but the expectation value $\langle T_{\mu\nu}\rangle$ in whatever quantum state the field occupies:

$$G_{\mu\nu} = 8\pi G\, \langle T_{\mu\nu}\rangle\,. \tag{64.176}$$

The object on the right is what tells spacetime how to curve in response to vacuum polarization, to particle creation, to the negative energy near a horizon that will drive black-hole evaporation in Chapter 65. It is, in a precise sense, *the* output of quantum field theory in curved spacetime.

And it is, taken naively, infinite. The stress tensor is quadratic in the field and its derivatives; its expectation value involves the coincidence limit of a two-point function, and that limit diverges — already in Minkowski space, where

we disposed of it silently by normal ordering. On a curved background normal ordering is not available (there is no preferred vacuum to order against), the divergence is entangled with the local geometry, and we must confront it head on. This section builds the machinery that turns the formally infinite $\langle T_{\mu\nu}\rangle$ into a finite, covariantly conserved, and — as we will prove — essentially unique tensor fit to sit on the right of Eq. (64.176). The route is *covariant point splitting*: separate the two field operators to nearby points, subtract a purely geometric local singularity (the Hadamard parametrix) that knows nothing about the state, and bring the points back together. We then state Wald's axioms, prove the result they single out is unique up to a handful of local geometric tensors, and recognize those tensors as exactly the gravitational counterterms — the cosmological constant, Newton's constant, and the curvature-squared couplings — whose renormalization the logic of Chapter 22 already taught us to expect. We close with a worked example in which every subtraction is carried out explicitly.

64.5.1 The classical stress tensor in curved space

Before quantizing we need the classical object whose expectation value we are after. We continue with the real scalar field of Section 64.1, whose curved-space action carries the non-minimal curvature coupling ξ introduced there,

$$S[\phi,g]=\int \mathrm{d}^4x\,\sqrt{-g}\,\Big[\tfrac{1}{2}\,g^{\mu\nu}\partial_\mu\phi\,\partial_\nu\phi-\tfrac{1}{2}(m^2+\xi R)\phi^2\Big], \tag{64.177}$$

with R the Ricci scalar in the curvature conventions of Chapter A and ξ a dimensionless coupling. The field equation that follows by varying ϕ is the curved Klein–Gordon equation

$$(\Box+m^2+\xi R)\phi=0, \qquad \Box\equiv g^{\mu\nu}\nabla_\mu\nabla_\nu. \tag{64.178}$$

The distinguished value of ξ is the *conformal coupling* $\xi_c=(d-2)/[4(d-1)]$, equal to $\frac{1}{6}$ in $d=4$ (Section 64.1), for which the massless theory is invariant under local Weyl rescalings $g_{\mu\nu}\to\Omega^2 g_{\mu\nu}$, $\phi\to\Omega^{-1}\phi$. The breaking of that classical symmetry by quantization is the subject of the next section; here it organizes the algebra.

The stress tensor is defined, following the Hilbert prescription imported from Chapters 6 and 7, as the response of the matter action to a variation of the metric:

$$T_{\mu\nu}\equiv\frac{2}{\sqrt{-g}}\,\frac{\delta S}{\delta g^{\mu\nu}}. \tag{64.179}$$

This is the curved-space generalization of the symmetric (Belinfante) tensor of Chapter 7: on a flat background it reduces to it, and unlike the canonical Noether tensor it is automatically symmetric and gauge/coordinate covariant.

To evaluate Eq. (64.179) we need three variational facts, each a standard piece of differential geometry. First, the determinant:

$$\delta\sqrt{-g} = -\tfrac{1}{2}\sqrt{-g}\, g_{\mu\nu}\, \delta g^{\mu\nu}. \tag{64.180}$$

Second, the inverse metric varies the kinetic term directly, $\delta(g^{\alpha\beta}\partial_\alpha\phi\,\partial_\beta\phi) = \partial_\mu\phi\,\partial_\nu\phi\,\delta g^{\mu\nu}$. Third, the Ricci scalar: $R = g^{\alpha\beta}R_{\alpha\beta}$, whose variation is the Palatini identity

$$\delta R = R_{\mu\nu}\,\delta g^{\mu\nu} + g_{\mu\nu}\Box\,\delta g^{\mu\nu} - \nabla_\mu\nabla_\nu\,\delta g^{\mu\nu}. \tag{64.181}$$

The last two terms in Eq. (64.181) are total covariant divergences when contracted with a constant, but here they multiply ϕ^2 inside the action and so contribute after integration by parts. Assembling the variation of Eq. (64.177) term by term — the determinant factor multiplying the whole Lagrangian, the kinetic variation, and the curvature term $-\frac{1}{2}\xi\phi^2\,\delta R$ integrated by parts twice to move the derivatives off $\delta g^{\mu\nu}$ and onto ϕ^2 — gives, after collecting the Ricci and metric pieces into the Einstein tensor $G_{\mu\nu} = R_{\mu\nu} - \frac{1}{2}g_{\mu\nu}R$,

$$T_{\mu\nu} = \partial_\mu\phi\,\partial_\nu\phi - \tfrac{1}{2}\,g_{\mu\nu}(\partial\phi)^2 + \tfrac{1}{2}\,m^2 g_{\mu\nu}\phi^2 + \xi\,(g_{\mu\nu}\Box - \nabla_\mu\nabla_\nu - G_{\mu\nu})\phi^2, \tag{64.182}$$

where $(\partial\phi)^2 \equiv g^{\alpha\beta}\partial_\alpha\phi\,\partial_\beta\phi$. The first three terms are the minimally coupled (improvement-free) stress tensor; the ξ-bracket is the curvature improvement. Its flat-space limit $\xi(\eta_{\mu\nu}\Box - \partial_\mu\partial_\nu)\phi^2$ is exactly the Callan–Coleman–Jackiw improvement term that renders the massless theory's stress tensor traceless, and the curved completion adds the $-\xi G_{\mu\nu}\phi^2$ piece demanded by metric covariance.

The trace. The single most important property of Eq. (64.182) for what follows is its trace. Contracting with $g^{\mu\nu}$ in d dimensions, using $g^{\mu\nu}g_{\mu\nu} = d$, $g^{\mu\nu}\nabla_\mu\nabla_\nu = \Box$, and the geometric identity $g^{\mu\nu}G_{\mu\nu} = (1-\frac{d}{2})R = -\frac{d-2}{2}R$,

$$T^\mu{}_\mu = \Big(1-\tfrac{d}{2}\Big)(\partial\phi)^2 + \tfrac{d}{2}\,m^2\phi^2 + \xi\Big[(d-1)\Box + \tfrac{d-2}{2}R\Big]\phi^2. \tag{64.183}$$

Now expand $\Box\phi^2 = 2(\partial\phi)^2 + 2\phi\,\Box\phi$ and use the field equation Eq. (64.178), $\Box\phi = -(m^2+\xi R)\phi$, so that $\phi\,\Box\phi = -(m^2+\xi R)\phi^2$:

$$T^\mu{}_\mu = \Big[1-\tfrac{d}{2}+2\xi(d-1)\Big](\partial\phi)^2 + \Big[\tfrac{d}{2}-2\xi(d-1)\Big]m^2\phi^2 + \Big[\tfrac{d-2}{2}\,\xi - 2\xi^2(d-1)\Big]R\phi^2. \tag{64.184}$$

At the conformal value $\xi = \xi_c = (d-2)/[4(d-1)]$ one has $2\xi_c(d-1) = \frac{d-2}{2}$, and each bracket collapses: the $(\partial\phi)^2$ coefficient is $1-\frac{d}{2}+\frac{d-2}{2} = 0$; the mass coefficient is $\frac{d}{2} - \frac{d-2}{2} = 1$; and the R coefficient is $\frac{d-2}{2}\xi_c - 2\xi_c^2(d-1) = \frac{(d-2)^2}{8(d-1)} - \frac{(d-2)^2}{8(d-1)} = 0$. Thus for the conformally coupled field the classical trace is

$$T^\mu{}_\mu\big|_{\xi=\xi_c} = m^2\phi^2, \tag{64.185}$$

which vanishes identically in the massless case. This is the classical statement of Weyl invariance — the energy-momentum tensor of a massless conformal scalar is traceless on shell, in any spacetime. We will see in Section 64.6 that quantization breaks Eq. (64.185): the renormalized $\langle T^{\mu}{}_{\mu}\rangle$ acquires a nonzero, purely geometric piece even for $m = 0$. To get there we must first define the renormalized tensor at all.

64.5.2 Point splitting and the universal short-distance singularity

Promote ϕ to the field operator. The naive prescription $\langle T_{\mu\nu}\rangle = \langle\Psi|\, T_{\mu\nu}(x)\,|\Psi\rangle$ asks us to evaluate products of two field operators at the *same* spacetime point. Such products are not operators: $\langle\phi(x)^2\rangle$ and $\langle\partial_\mu\phi\,\partial_\nu\phi\rangle$ are the coincidence limits of two-point functions that diverge as the two points merge. The cure, due to DeWitt and Christensen and sharpened by Wald, is to keep the points apart, evaluate the bilinear as a bi-tensor, subtract a local geometric counterterm, and only then take the limit.

Introduce the symmetric (Hadamard) two-point function in the state $|\Psi\rangle$,

$$G(x,x') \equiv \tfrac{1}{2}\,\langle\Psi|\,\{\phi(x),\phi(x')\}\,|\Psi\rangle = \mathrm{Re}\,\langle\Psi|\,\phi(x)\phi(x')\,|\Psi\rangle\,, \tag{64.186}$$

the real, symmetric part of the Wightman function built in Chapter 10. (The antisymmetric part is the state-independent commutator, a c-number that carries no energy; it is the symmetric part that contains the stress.) Each bilinear in Eq. (64.182) is now obtained by acting with a derivative operator at x, a second at x', and then setting $x' = x$. Because the operators at separated points commute up to the c-number, the ordering ambiguity is harmless; we symmetrize to keep the result manifestly real. Indices at the two points are tied together by the bivector of parallel transport $g_{\nu}{}^{\nu'}(x,x')$, the geodesic parallel propagator, which reduces to $\delta^{\nu'}_{\nu}$ at coincidence and which we suppress whenever the local frame makes it trivial.

Collecting the derivative structure of Eq. (64.182), the point-split stress tensor is

$$\langle T_{\mu\nu}\rangle = \lim_{x'\to x}\,\mathcal{D}_{\mu\nu}(x,x')\,G(x,x'), \tag{64.187}$$

with the bi-differential operator

$$\begin{aligned}\mathcal{D}_{\mu\nu}(x,x') = {}& (1-2\xi)\,g_{\nu}{}^{\nu'}\nabla_\mu\nabla_{\nu'} + \Big(2\xi-\tfrac{1}{2}\Big)g_{\mu\nu}\,g^{\rho\sigma'}\nabla_\rho\nabla_{\sigma'} - 2\xi\,\nabla_\mu\nabla_\nu \\ & + 2\xi\,g_{\mu\nu}\,\Box - \xi\Big(R_{\mu\nu} - \tfrac{1}{2}g_{\mu\nu}R\Big) + \tfrac{1}{2}\,m^2 g_{\mu\nu},\end{aligned} \tag{64.188}$$

where primed derivatives act at x' and unprimed at x. The first line carries the bilinear $\partial\phi\,\partial\phi$ point-split between the two arguments (hence the mixed $\nabla_\mu\nabla_{\nu'}$); the remaining terms come from the improvement piece $\propto \nabla\nabla\phi^2$, in which both

derivatives may act at the same point. One verifies that on the smooth (state-dependent) part of G the coincidence limit of Eq. (64.188) reproduces Eq. (64.182) with $\phi^2 \to G(x,x)$ and $\partial_\mu\phi\,\partial_\nu\phi \to \nabla_\mu\nabla_{\nu'}G|_{x'=x}$, as it must.

The trouble is that $G(x,x')$ is *not* smooth as $x' \to x$. Already in the Minkowski vacuum, the massless two-point function is $G_0(x,x') = \frac{1}{8\pi^2}\,\frac{1}{\sigma}$ with σ half the squared geodesic interval, and applying two derivatives produces a coincidence divergence $\sim \sigma^{-2}$. On a curved background the leading divergence has the same σ^{-1} form, with subleading $\ln\sigma$ pieces dressed by the local curvature. The decisive fact — the one that makes renormalization possible and local — is that *this short-distance singularity is universal*: it is the same for every physically admissible state, fixed entirely by the local geometry and the parameters (m,ξ) in the wave operator, and independent of which state $|\Psi\rangle$ we chose. We make this precise next.

64.5.3 The Hadamard short-distance expansion

The geometric scaffolding is built from two bi-scalars. Let $\sigma(x,x')$ be *Synge's world function*, equal to one half the squared geodesic distance between x and x' — positive for spacelike separation in the mostly-minus signature, negative for timelike, and satisfying the eikonal identity $\frac{1}{2}g^{\mu\nu}(\nabla_\mu\sigma)(\nabla_\nu\sigma) = \sigma$. Its coincidence limit and first derivatives vanish, $[\sigma]=0$, $[\nabla_\mu\sigma]=0$, while $[\nabla_\mu\nabla_\nu\sigma] = g_{\mu\nu}$. Let $\Delta(x,x')$ be the *Van Vleck–Morette determinant*,

$$\Delta(x,x') = -\frac{\det\big[-\nabla_\mu\nabla_{\nu'}\sigma(x,x')\big]}{\sqrt{-g(x)}\,\sqrt{-g(x')}}, \qquad [\Delta]=1, \tag{64.189}$$

the geometric measure of geodesic focusing, which reduces to unity at coincidence and whose short-distance expansion encodes the Ricci curvature,

$$\Delta^{1/2}(x,x') = 1 + \tfrac{1}{12}R_{\alpha\beta}\,\sigma^{;\alpha}\sigma^{;\beta} + O(\sigma^{3/2}), \qquad \sigma^{;\alpha} \equiv \nabla^\alpha\sigma. \tag{64.190}$$

With these in hand, the central structural theorem of the subject is that every state of physical interest has a two-point function of *Hadamard form*: near coincidence,

$$G(x,x') = \frac{1}{8\pi^2}\left[\frac{\Delta^{1/2}(x,x')}{\sigma(x,x')} + V(x,x')\,\ln\frac{\sigma(x,x')}{\ell^2} + W(x,x')\right], \tag{64.191}$$

where ℓ is an arbitrary length scale (a renormalization scale, exactly as in Chapter 22), V and W are smooth bi-scalars, and the σ in the denominator and logarithm carries the Feynman $i\epsilon$ prescription $\sigma \to \sigma + i\epsilon\,(t-t') + \epsilon^2$ inherited from Chapter 10 and Chapter D.

Definition 64.25 (Hadamard state)**.** A state $|\Psi\rangle$ is a *Hadamard state* if its symmetric two-point function has the form Eq. (64.191) with V determined by

the local geometry alone — specifically, V is the unique solution of the recursion below that is regular at coincidence — and W smooth. Equivalently, the singular structure of G is exactly H (defined in Eq. (64.193) below), with the difference $G - H$ a C^∞ function of (x, x').

The function V is purely geometric. Writing $V = \sum_{n\geq 0} V_n(x,x')\,\sigma^n$ and inserting Eq. (64.191) into the wave equation $(\Box_x + m^2 + \xi R)G(x,x') = 0$ (valid away from coincidence, since G solves the field equation in each argument), one finds a hierarchy of transport equations along the geodesic that determine the V_n recursively from the geometry, with no freedom left over. Their leading coincidence values are

$$[V_0] = \tfrac{1}{2}\Big(m^2 + (\xi - \tfrac{1}{6})R\Big), \qquad [V_1] = \tfrac{1}{8}\Big(m^2 + (\xi - \tfrac{1}{6})R\Big)^2 + \cdots, \tag{64.192}$$

where the ellipsis in $[V_1]$ stands for terms quadratic in the curvature (R^2, $R_{\mu\nu}R^{\mu\nu}$, $R_{\mu\nu\rho\sigma}R^{\mu\nu\rho\sigma}$, $\Box R$) whose coefficients are fixed by the recursion. These are the Hadamard (Wald) coefficients of the parametrix, fixed by the same geometry that produces the Seeley–DeWitt coefficients of the heat-kernel expansion catalogued in Chapter E; the two normalizations differ by fixed numerical factors. For the operator $\Box + m^2 + \xi R$ the coincidence limits are $[V_0] = -\frac{1}{2}a_1$ and $[V_1] = \frac{1}{4}a_2$, so the anomaly prefactor below, $(1/4\pi^2)[V_1] = a_2/(4\pi)^2$, agrees with the heat-kernel result of Section 64.6; V_0, V_1 are *not* the DeWitt coefficients themselves. The combination $\xi - \frac{1}{6}$ appearing in Eq. (64.192) is the same one that controlled the trace in Eq. (64.184): it measures the departure from conformal coupling and, as we will see, governs the magnitude of the trace anomaly.

Physical Insight

The content of the Hadamard condition is that *all the information about the state lives in the smooth part W, and all the divergence lives in the geometric piece $\Delta^{1/2}/\sigma + V\ln\sigma$.* The vacuum is not distinguished by being "empty" — there is no such thing here — but by being smooth relative to the universal singularity. This is the curved-space replacement for normal ordering: we do not subtract a particular vacuum's energy, we subtract the state-independent short-distance structure that any reasonable state shares.

64.5.4 Covariant subtraction: the renormalized tensor

The singular part of Eq. (64.191) is purely local and geometric. Detach it and give it a name: the *Hadamard parametrix*

$$H(x,x') = \frac{1}{8\pi^2}\left[\frac{\Delta^{1/2}(x,x')}{\sigma(x,x')} + V(x,x')\,\ln\frac{\sigma(x,x')}{\ell^2}\right]. \tag{64.193}$$

H is constructed entirely from the metric and the wave-operator parameters; it is the same in every Hadamard state. By construction (Theorem 64.25) the difference

$$\mathcal{W}(x,x') \equiv G(x,x') - H(x,x') = \frac{1}{8\pi^2}\, W(x,x') \tag{64.194}$$

is a smooth (C^∞) bi-scalar, so its derivatives have finite coincidence limits.

Definition 64.26 (Renormalized stress tensor)**.** The renormalized expectation value of the stress tensor in the Hadamard state $|\Psi\rangle$ is

$$\langle T_{\mu\nu}\rangle_{\text{ren}} = \lim_{x'\to x} \mathcal{D}_{\mu\nu}(x,x')\,[G(x,x') - H(x,x')] + \Theta_{\mu\nu}(x), \tag{64.195}$$

where $\mathcal{D}_{\mu\nu}$ is the operator Eq. (64.188) and $\Theta_{\mu\nu}$ is a purely local, purely geometric correction term (built from the parametrix coefficients) whose role — restoring covariant conservation — is fixed in Section 64.5.5.

Because $\mathcal{W} = G - H$ is smooth, the limit in Eq. (64.195) exists and is finite: the universal divergence has been removed by subtracting H, and what remains is the state-dependent content carried by W together with a finite geometric residue from the parametrix. This is the entire idea. The subtraction is *local and covariant* — it does not reference any global vacuum, only the local geometry — which is exactly the property a counterterm must have to be admissible in a gravitational theory.

Two features deserve emphasis before we make conservation precise. First, the answer is finite but not yet unique: the scale ℓ inside the logarithm of H is arbitrary, and changing $\ell \to \ell'$ shifts H by $\frac{1}{8\pi^2} V \ln(\ell^2/\ell'^2)$, hence shifts $\langle T_{\mu\nu}\rangle_{\text{ren}}$ by a local tensor built from the coincidence limits of V and its derivatives — that is, by curvature-squared terms. We return to this in Section 64.5.6. Second, the derivative operator $\mathcal{D}_{\mu\nu}$ acting on the singular part H does *not* commute with the coincidence limit in a way that respects conservation; the local term $\Theta_{\mu\nu}$ is precisely what repairs this, and tracking it is what exposes the anomaly.

64.5.5 Conservation, and where the anomaly hides

The source of Einstein's equation must be covariantly conserved: the Bianchi identity gives $\nabla^\mu G_{\mu\nu} = 0$ identically, so consistency of Eq. (64.176) demands

$$\nabla^\mu \langle T_{\mu\nu}\rangle_{\text{ren}} = 0. \tag{64.196}$$

This is not automatic. The classical tensor Eq. (64.182) is conserved on shell — a one-line consequence of the field equation and the symmetry of the metric connection, exactly as in Chapter 7. But the point-split, parametrix-subtracted object of Eq. (64.195) need not be, because the parametrix H does not exactly solve the field equation: it solves it only up to a smooth remainder. The precise statement is the following.

Theorem 64.27 (Conservation of the point-split tensor)**.** *Let* $\widetilde{T}_{\mu\nu} = \lim_{x'\to x} \mathcal{D}_{\mu\nu}(G-H)$ *be the bare point-split tensor (without* $\Theta_{\mu\nu}$*). Its covariant divergence is a local, state-independent vector,*

$$\nabla^{\mu}\widetilde{T}_{\mu\nu} = \nabla_{\nu}\, Q(x), \qquad Q(x) = \frac{1}{8\pi^2}\left(\, c_1\,[V_1] + c_2\, m^2[V_0] + \cdots\right), \tag{64.197}$$

where $[V_0], [V_1]$ *are the parametrix coefficients Eq. (64.192),* c_1, c_2 *are pure numbers, and the omitted terms are further local curvature scalars. Consequently the tensor*

$$\langle T_{\mu\nu}\rangle_{\rm ren} = \widetilde{T}_{\mu\nu} - g_{\mu\nu}\, Q(x), \qquad \textit{i.e.}\quad \Theta_{\mu\nu} = -g_{\mu\nu}Q, \tag{64.198}$$

is covariantly conserved, Eq. (64.196).

Proof. The divergence $\nabla^{\mu}\widetilde{T}_{\mu\nu}$ can be computed before taking the coincidence limit. On the smooth remainder $\mathcal{W} = G - H$ one commutes ∇^{μ} through the bi-differential operator $\mathcal{D}_{\mu\nu}$ and uses that G satisfies the field equation $(\Box + m^2 + \xi R)G = 0$ in the argument x exactly, while H satisfies it only up to a smooth source: by the defining recursion for the V_n, one has $(\Box_x + m^2 + \xi R)H(x,x') = \frac{1}{8\pi^2}\,[\,2\,V_1(x,x')\,] \to \frac{1}{4\pi^2}[V_1]$ as $x' \to x$ — a finite, local quantity, the last member of the defining V_n recursion failing to vanish. The state-dependent part of $\mathcal{W}$ therefore drops out of the divergence entirely: G solves the equation, so its contribution to $\nabla^{\mu}\widetilde{T}_{\mu\nu}$ vanishes by the same on-shell manipulation that conserves the classical tensor. What survives is purely the failure of H to solve the field equation, which by construction is a local geometric scalar. Carrying the coincidence limit of the commutator terms (this is a finite computation in the Synge/Van Vleck calculus, using $[\sigma^{;\mu}] = 0$ and $[\nabla_\mu\nabla_\nu\sigma] = g_{\mu\nu}$) collects this remainder into the gradient of a single local scalar Q, of the form Eq. (64.197). Since Q is a scalar, $g_{\mu\nu}Q$ has divergence $\nabla^{\mu}(g_{\mu\nu}Q) = \nabla_{\nu}Q$, which exactly cancels Eq. (64.197). Hence $\nabla^{\mu}(\widetilde{T}_{\mu\nu} - g_{\mu\nu}Q) = 0$. □

The price of this repair is paid in the trace. Subtracting $g_{\mu\nu}Q$ shifts the trace by $-d\,Q = -4Q$ in four dimensions, and Q is built from the parametrix coefficient $[V_1]$ — a local, state-independent curvature scalar that cannot be removed by any choice of state. We can enforce conservation, *or* we can enforce tracelessness for the conformal field, but the point-split prescription will not let us have both: the conserved tensor has a nonzero, geometric trace

$$\langle T^{\mu}{}_{\mu}\rangle_{\rm ren}\Big|_{m=0,\ \xi=\xi_c} = \frac{1}{4\pi^2}\,[V_1]\big|_{m=0,\ \xi=\xi_c} \;\neq\; 0, \tag{64.199}$$

even though the classical trace Eq. (64.185) vanished. This is the *trace (conformal) anomaly.* Its value is fixed entirely by the geometric coefficient $[V_1]$, hence by local curvature invariants, and computing it honestly — two independent ways — is the business of Section 64.6. Here we have located it: it is the unavoidable residue of insisting that the object sourcing gravity be conserved.

Caution

It is tempting to think one could define a different renormalization that keeps the trace zero. One can — but only by giving up conservation, which makes the tensor useless as a source for Einstein's equation, or by giving up locality/covariance of the subtraction, which reintroduces a divergence. The anomaly is the statement that no admissible scheme achieves classical tracelessness, conservation, and covariance simultaneously for the massless conformal field. This is the same structure as the chiral anomaly of Chapter 36: a classical symmetry that no regulator respects.

64.5.6 Wald's axioms and the uniqueness theorem

Point splitting produces *a* finite conserved tensor, but the construction made choices: the scale ℓ, the precise form of $\Theta_{\mu\nu}$. We now ask what an admissible $\langle T_{\mu\nu}\rangle_{\rm ren}$ must satisfy on physical grounds, and prove that those requirements pin it down up to a controlled ambiguity. Wald formulated four axioms.

1. **Conservation.** $\nabla^\mu \langle T_{\mu\nu}\rangle_{\rm ren} = 0$, so that Eq. (64.176) is consistent with the Bianchi identity.

2. **Causality.** In a globally hyperbolic spacetime, $\langle T_{\mu\nu}\rangle_{\rm ren}(x)$ depends on the state and the geometry only within the causal past and future of x; a change of state outside the light cone of x cannot alter the tensor at x.

3. **Correct flat-space limit.** In Minkowski space, in the standard vacuum, the prescription reduces to normal ordering: $\langle T_{\mu\nu}\rangle_{\rm ren} = 0$ in the Poincaré-invariant vacuum.

4. **Locality / state-independence of the difference.** For two Hadamard states $|\Psi_1\rangle, |\Psi_2\rangle$ on the same spacetime, the difference $\langle T_{\mu\nu}\rangle_{\Psi_1} - \langle T_{\mu\nu}\rangle_{\Psi_2}$ equals the coincidence limit of $\mathcal{D}_{\mu\nu}(G_{\Psi_1} - G_{\Psi_2})$ — it is computed from the smooth *difference* of two-point functions, with no subtraction needed, since the universal singularity cancels.

Axiom (4) is the operational heart of the matter: it fixes the *state-dependence* completely and without ambiguity, because $G_{\Psi_1} - G_{\Psi_2}$ is smooth and the operator $\mathcal{D}_{\mu\nu}$ acts on it cleanly. All the freedom therefore resides in a single c-number tensor — the value assigned to one reference state — which by axioms (1)–(3) must be a *local, conserved, geometric* tensor with the correct dimension and the correct flat-space limit.

Theorem 64.28 (Wald uniqueness)**.** *Any two prescriptions* $\langle T_{\mu\nu}\rangle^{(1)}_{\rm ren}$ *and* $\langle T_{\mu\nu}\rangle^{(2)}_{\rm ren}$ *satisfying axioms* (1)–(4) *differ by a local conserved tensor* $\Delta T_{\mu\nu}$ *constructed*

polynomially from the metric and its curvature, of mass dimension at most four. In four dimensions the most general such tensor is

$$\Delta T_{\mu\nu} = \alpha_0\, g_{\mu\nu} + \alpha_1\, G_{\mu\nu} + \alpha_2\, {}^{(1)}H_{\mu\nu} + \alpha_3\, {}^{(2)}H_{\mu\nu}, \tag{64.200}$$

where $\alpha_0, \dots, \alpha_3$ are real constants, $g_{\mu\nu}$ and $G_{\mu\nu}$ are the metric and Einstein tensors, and

$${}^{(1)}H_{\mu\nu} = \frac{1}{\sqrt{-g}}\frac{\delta}{\delta g^{\mu\nu}}\int \mathrm{d}^4x\,\sqrt{-g}\,R^2 = 2g_{\mu\nu}\Box R - 2\nabla_\mu\nabla_\nu R - \tfrac{1}{2}g_{\mu\nu}R^2 + 2RR_{\mu\nu}, \tag{64.201}$$

$${}^{(2)}H_{\mu\nu} = \frac{1}{\sqrt{-g}}\frac{\delta}{\delta g^{\mu\nu}}\int \mathrm{d}^4x\,\sqrt{-g}\,R_{\alpha\beta}R^{\alpha\beta} \tag{64.202}$$

are the conserved tensors obtained by varying the two independent curvature-squared invariants. Each of the four tensors in Eq. (64.200) is identically covariantly conserved.

Proof. By axiom (4) the difference of two admissible prescriptions cannot depend on the state: a state-dependent difference would have to be the coincidence limit of $\mathcal{D}_{\mu\nu}$ acting on $G_{\Psi_1} - G_{\Psi_2}$, but that limit is the *same* for both prescriptions (the operator $\mathcal{D}_{\mu\nu}$ is fixed by the classical action, and the smooth difference needs no subtraction). Hence $\Delta T_{\mu\nu} = \langle T_{\mu\nu}\rangle^{(1)} - \langle T_{\mu\nu}\rangle^{(2)}$ is independent of the state. By axiom (2), causality, it is local — it cannot depend on data outside the point x, so it is a function of the metric and finitely many derivatives at x. Lorentz covariance forces it to be a polynomial in the curvature and its covariant derivatives. By dimensional analysis, $T_{\mu\nu}$ has mass dimension four (two derivatives on dimension-one fields), and a geometric tensor of that dimension is a sum of terms with exactly four derivatives of the metric: these are $g_{\mu\nu}$ (dimension zero, multiplied by a dimensionful constant α_0 that is in practice $\propto \Lambda$ or m^4), $G_{\mu\nu}$ (dimension two, times $\alpha_1 \propto m^2$ or $1/G$), and the dimension-four tensors obtained from R^2 and $R_{\mu\nu}R^{\mu\nu}$ — namely ${}^{(1)}H_{\mu\nu}$ and ${}^{(2)}H_{\mu\nu}$. (The Riemann-squared invariant $R_{\mu\nu\rho\sigma}R^{\mu\nu\rho\sigma}$ is not independent: in four dimensions the Gauss–Bonnet combination $R^2_{\mu\nu\rho\sigma} - 4R^2_{\mu\nu} + R^2$ is a topological density whose metric variation vanishes identically, so its tensor is removed in favor of the other two.) By axiom (1), conservation, only conserved combinations are allowed; one checks directly — it follows from the diffeomorphism invariance of the actions $\int\sqrt{-g}\,R^2$ and $\int\sqrt{-g}\,R^2_{\mu\nu}$, whose variations Eq. (64.201)–Eq. (64.202) are conserved by the generalized Bianchi identity — that all four listed tensors are conserved. Finally axiom (3), the flat-space limit, requires $\Delta T_{\mu\nu} \to 0$ in Minkowski space, which is automatic for $G_{\mu\nu}$ and the H-tensors (they vanish when the curvature vanishes) and fixes the additive constant in $\alpha_0 g_{\mu\nu}$ to be the cosmological-constant piece, not an arbitrary flat-space energy. No further structures are permitted, so Eq. (64.200) is exhaustive. □

Physical Insight

Uniqueness "up to local conserved geometric tensors" is the gravitational analog of the renormalization freedom of flat-space QFT (Chapter 22). There, physical amplitudes were ambiguous up to the finite parts of counterterms whose form was dictated by the symmetries and the dimension of the divergences; the ambiguity was absorbed into renormalized couplings fixed by experiment. Here the four constants $\alpha_0, \dots, \alpha_3$ are exactly that ambiguity, and — as we show next — they are absorbed into the renormalized constants of the gravitational action.

64.5.7 The ambiguity is the renormalization of gravity

The four tensors in Eq. (64.200) are not a defect of the construction; they are a prediction. Each is the metric variation of a local geometric term that *must already be present* in the gravitational action once one couples quantum matter to gravity. The logic is precisely that of Chapter 22: a coupling generated by loops must be included in the bare action as a counterterm, with a renormalized value fixed by measurement. The total gravitational action consistent with general covariance and power counting is

$$S_{\rm grav} = \int \mathrm{d}^4x\,\sqrt{-g}\,\Big[-\frac{\Lambda}{8\pi G} + \frac{R}{16\pi G} + \alpha\,R^2 + \beta\,R_{\mu\nu}R^{\mu\nu}\Big], \tag{64.203}$$

and varying it via $T^{\rm grav}_{\mu\nu} = (2/\sqrt{-g})\,\delta S_{\rm grav}/\delta g^{\mu\nu}$ produces exactly the four tensors of Eq. (64.200): the $g_{\mu\nu}$ term from Λ, the $G_{\mu\nu}$ term from the Einstein–Hilbert R, and ${}^{(1)}H_{\mu\nu}, {}^{(2)}H_{\mu\nu}$ from the curvature-squared terms. The semiclassical equation Eq. (64.176), written with the full action $S_{\rm grav} + S_{\rm matter}$, becomes

$$\frac{1}{8\pi G}\Big(G_{\mu\nu} + \Lambda\,g_{\mu\nu}\Big) + \alpha\,{}^{(1)}H_{\mu\nu} + \beta\,{}^{(2)}H_{\mu\nu} = \langle T_{\mu\nu}\rangle_{\rm ren}\,. \tag{64.204}$$

Now the resolution is transparent. Shifting the renormalization scale $\ell \to \ell'$ in the parametrix Eq. (64.193), or equivalently choosing a different admissible $\langle T_{\mu\nu}\rangle_{\rm ren}$ within the family Eq. (64.200), changes $\langle T_{\mu\nu}\rangle_{\rm ren}$ by terms of precisely the form on the left of Eq. (64.204). Those changes can be absorbed into the bare constants:

$$\delta\Big(\frac{\Lambda}{8\pi G}\Big) = -\alpha_0, \quad \delta\Big(\frac{1}{16\pi G}\Big) = -\alpha_1, \quad \delta\alpha = -\alpha_2, \quad \delta\beta = -\alpha_3. \tag{64.205}$$

The ambiguity in renormalizing the stress tensor is nothing but the *renormalization of the cosmological constant, Newton's constant, and the two higher-derivative gravitational couplings* α, β. Their values are not predicted by the theory; they are inputs, measured (in principle) by the same process of fixing renormalization

conditions that fixed m, λ for ϕ^4 theory in Chapter 22. What *is* predicted is everything else: $\langle T_{\mu\nu} \rangle_{\text{ren}}$ is unique once these four numbers are fixed. In particular the ℓ-dependence of the logarithm in H feeds the running of α and β, exactly as a renormalization scale feeds the running of a coupling — the curvature-squared couplings of gravity run, and their beta functions are computable from $[V_1]$.

Notation Watch

The constant $\alpha_0\, g_{\mu\nu}$ contains the notorious vacuum-energy/cosmological-constant problem: the matter loops generate a contribution $\propto m^4$ to Λ with no symmetry forbidding it, and only a fine adjustment of the bare Λ leaves the observed near-zero value. This is a renormalization-condition statement, not a divergence the formalism fails to handle; the formalism handles it cleanly, but it offers no reason for the renormalized number to be small. We flag it here as the home of that problem and say no more — it is a frontier issue, not a defect of the construction.

64.5.8 Worked example: the Casimir energy of a conformal scalar

The cleanest arena in which to watch the subtraction work end to end is flat space with a nontrivial boundary condition. Take Minkowski space, so that the geometry is flat and the Hadamard parametrix H is simply the standard Minkowski vacuum two-point function G_0 — there is no curvature, V and $\Delta^{1/2}$ are trivial, and the universal singularity to subtract is precisely the free-space short-distance behavior. Confine a massless, conformally coupled ($\xi = \frac{1}{6}$) real scalar between two parallel plates at $z = 0$ and $z = a$, imposing Dirichlet conditions $\phi = 0$ on each. The plates change the allowed modes; subtracting the no-plate vacuum (the parametrix) leaves the finite, physical Casimir stress. This is the same construction Eq. (64.195) demands, in a setting where every step can be done by hand.

The zero-point energy and its subtraction. The Dirichlet conditions quantize the perpendicular wavenumber, $k_z = n\pi/a$ with $n = 1, 2, 3, \ldots$, while the transverse momentum $\mathbf{k}_\perp = (k_x, k_y)$ remains continuous. Each mode is a harmonic oscillator of frequency $\omega_{n,\mathbf{k}_\perp} = \sqrt{\mathbf{k}_\perp^2 + (n\pi/a)^2}$ and contributes $\frac{1}{2}\omega$ to the vacuum energy. The zero-point energy per unit plate area is therefore

$$\frac{E(a)}{A} = \frac{1}{2}\sum_{n=1}^{\infty} \int \frac{\mathrm{d}^2 k_\perp}{(2\pi)^2} \sqrt{\mathbf{k}_\perp^2 + \left(\tfrac{n\pi}{a}\right)^2} \;\equiv\; \sum_{n=1}^{\infty} F(n), \tag{64.206}$$

which is badly divergent. The physical Casimir energy is the difference between this and the energy the same slab of space would have with no plates — the

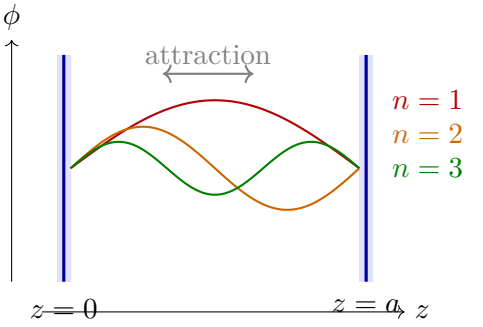

Figure 64.6: A massless scalar between Dirichlet plates supports standing waves with $k_z = n\pi/a$. The discrete spectrum's zero-point energy, with the free-space (continuum) value subtracted, is negative and falls as a^{-3}, producing an attractive force. The continuum subtraction is the flat-space instance of removing the Hadamard parametrix.

free-space vacuum, which is the parametrix to subtract. In the no-plate vacuum the k_z spectrum is continuous, and the sum becomes an integral with density of states a/π in k_z: the free-space energy per area of the region of width a is $\int_0^\infty F(n)\,\mathrm{d}n$ (substituting $k_z = n\pi/a$ shows $\frac{a}{\pi}\int \mathrm{d}k_z = \int \mathrm{d}n$). The renormalized Casimir energy is the difference,

$$\frac{E_{\mathrm{C}}(a)}{A} = \sum_{n=1}^{\infty} F(n) - \int_0^\infty F(n)\,\mathrm{d}n. \tag{64.207}$$

Each term separately diverges; the difference is finite, and it is the heart of the computation. The transverse integral defining $F(n)$ is evaluated by dimensional continuation (Chapter D): with $d = 4 - 2\varepsilon$ continued in the transverse plane,

$$\int \frac{\mathrm{d}^2 k_\perp}{(2\pi)^2}\,\left(\mathbf{k}_\perp^2 + \kappa^2\right)^{1/2} = \frac{1}{4\pi}\,\frac{\Gamma(-\frac{3}{2})}{\Gamma(-\frac{1}{2})}\,\kappa^3 = -\frac{\kappa^3}{6\pi}, \tag{64.208}$$

using $\Gamma(-\frac{3}{2}) = \frac{4}{3}\sqrt{\pi}$ and $\Gamma(-\frac{1}{2}) = -2\sqrt{\pi}$, so that $\Gamma(-\frac{3}{2})/\Gamma(-\frac{1}{2}) = -\frac{2}{3}$. The power-divergent volume piece is discarded by the analytic continuation precisely because it is the same in the plate and no-plate cases — it is the local parametrix that cancels in Eq. (64.207). With Eq. (64.208),

$$F(n) = \frac{1}{2}\cdot\left(-\frac{1}{6\pi}\right)\left(\frac{n\pi}{a}\right)^3 = -\frac{\pi^2}{12\,a^3}\,n^3. \tag{64.209}$$

Doing the finite difference. The discrete-minus-continuum difference in Eq. (64.207) is exactly what the Euler–Maclaurin formula computes. For a function F that, together with its derivatives, vanishes at infinity,

$$\sum_{n=1}^{\infty} F(n) - \int_0^\infty F(n)\,\mathrm{d}n = -\tfrac{1}{2}F(0) - \sum_{k=1}^{\infty}\frac{B_{2k}}{(2k)!}\,F^{(2k-1)}(0), \tag{64.210}$$

with B_{2k} the Bernoulli numbers, $B_2 = \frac{1}{6}$, $B_4 = -\frac{1}{30}$. For the cubic Eq. (64.209) only finitely many terms survive: $F(0) = 0$, $F'(0) = 0$, $F'''(0) = -\pi^2/(2a^3)$ (the third derivative of n^3 is 6, times the coefficient), and all higher derivatives vanish. Only the $k = 2$ term of Eq. (64.210) contributes:

$$\frac{E_{\rm C}(a)}{A} = -\frac{B_4}{4!}\,F'''(0) = -\frac{(-1/30)}{24}\Big(-\frac{\pi^2}{2a^3}\Big) = -\frac{\pi^2}{1440\,a^3}. \tag{64.211}$$

The same number follows in one line by zeta-function regularization: from Eq. (64.209), $\sum_n F(n) = -\frac{\pi^2}{12a^3}\sum_n n^3 = -\frac{\pi^2}{12a^3}\,\zeta(-3) = -\frac{\pi^2}{12a^3}\cdot\frac{1}{120} = -\frac{\pi^2}{1440\,a^3}$, using $\zeta(-3) = -B_4/4 = \frac{1}{120}$; the continuum subtraction is automatic in the analytic continuation, and the agreement with Euler–Maclaurin confirms that the discarded piece was exactly the free-space term. The Casimir energy per area is negative: the plates lower the vacuum energy below its free-space value, and the energy grows more negative as they approach, giving an attractive force.

The full stress tensor. The energy is one component; the renormalized stress tensor is the full object Eq. (64.195). We assemble it from three facts. First, *symmetry*: the configuration is invariant under translations in t, x, y and under rotations in the (x, y) plane, so $\langle T^{\mu}{}_{\nu}\rangle_{\rm ren} = \mathrm{diag}(\rho, -p_\perp, -p_\perp, -p_z)$ with components possibly depending on z alone. Second, *conservation* Eq. (64.196): the only nontrivial component is $\partial_z \langle T^{z}{}_{z}\rangle = 0$, so p_z is constant across the gap. For the conformal field the off-diagonal and z-dependent pieces vanish and all components are constant (this is the flat-space, boundary-only version of the smoothness of $G - H$: with $V = 0$ the subtracted two-point function between the plates is z-independent at coincidence), so ρ is the constant $\rho = (E_{\rm C}/A)/a$ obtained by dividing Eq. (64.211) by the gap width:

$$\rho = \Big\langle T^{0}{}_{0}\Big\rangle_{\rm ren} = -\frac{\pi^2}{1440\,a^4}. \tag{64.212}$$

Third, the normal pressure follows from the energy by the thermodynamic relation $p_z = -\,\partial(E_{\rm C}/A)/\partial a$ (force per unit area is minus the change of energy per area with separation):

$$p_z = -\frac{\partial}{\partial a}\Big(-\frac{\pi^2}{1440\,a^3}\Big) = -\frac{3\pi^2}{1440\,a^4}, \tag{64.213}$$

negative, i.e. a tension pulling the plates together — the attractive Casimir force. The transverse pressure is then fixed by the *tracelessness* of the conformal stress tensor, $\rho = 2p_\perp + p_z$ (the vanishing of $\langle T^{\mu}{}_{\mu}\rangle = \rho - 2p_\perp - p_z$), which gives $2p_\perp = \rho - p_z = -\frac{\pi^2}{1440a^4} + \frac{3\pi^2}{1440a^4} = \frac{2\pi^2}{1440a^4}$, so $p_\perp = \pi^2/(1440\,a^4)$. Assembling,

$$\boxed{\langle T^{\mu}{}_{\nu}\rangle_{\rm ren} = -\frac{\pi^2}{1440\,a^4}\;\mathrm{diag}(1,\,1,\,1,\,-3)} \tag{64.214}$$

in the coordinate order (t, x, y, z). One reads off the three consistency checks at a glance: the tensor is traceless ($1 + 1 + 1 - 3 = 0$), as required for the conformal

field; it is covariantly (here ordinarily) conserved, since every component is constant; and it is symmetric. The energy density and the normal pressure are negative, the transverse pressure positive, all scaling as a^{-4} on dimensional grounds — the only scale in the problem is a.

Worked Example 64.29 (The Casimir tensor as a parametrix subtraction)**.** It is worth seeing Eq. (64.214) as a literal instance of Eq. (64.195), to confirm the mode sum and the point-splitting prescription agree. The two-point function between the plates is built from the free-space function by the method of images enforcing $\phi = 0$ at $z = 0, a$. In Euclidean signature (Wick rotation per Chapter D), with $\rho^2 = (\Delta\tau)^2 + (\Delta x)^2 + (\Delta y)^2$ and $\Delta z = z - z'$,

$$G(x,x') = \frac{1}{4\pi^2}\sum_{n=-\infty}^{\infty}\left[\frac{1}{\rho^2 + (\Delta z - 2na)^2} - \frac{1}{\rho^2 + (z + z' - 2na)^2}\right], \tag{64.215}$$

the first family of images enforcing periodicity, the second (with the minus sign) enforcing the odd reflection that vanishes on the plates. The parametrix to subtract is the free-space function $G_0 = \frac{1}{4\pi^2}[\rho^2 + (\Delta z)^2]^{-1}$ — exactly the $n = 0$ *direct* term of Eq. (64.215). The subtracted remainder $\mathcal{W} = G - G_0 = \frac{1}{4\pi^2}\left[\sum_{n\neq 0}(\cdots)_{\text{direct}} - \sum_n(\cdots)_{\text{reflected}}\right]$ is smooth at coincidence, since the only singular term — the $n = 0$ direct image — has been removed. Applying the conformal operator Eq. (64.188) (with $\xi = \frac{1}{6}$, $m = 0$, flat connection) to $\mathcal{W}$ and taking $x' \to x$ reduces, after the geometric series $\sum_{n\geq 1} n^{-4} = \zeta(4) = \pi^4/90$ is summed, to exactly Eq. (64.214). The two routes — the mode sum with continuum subtraction, and point splitting with parametrix subtraction — compute the same finite tensor because the continuum/free-space piece they each remove is the same local object. This is the concrete payoff of the abstract construction: the subtraction is unambiguous, the result is finite, conserved, and traceless, and it sources a real, measured force.

Historical Note

The attractive force between neutral conductors was predicted by Casimir in 1948 and measured to percent precision by Lamoreaux and others from the late 1990s onward. The reinterpretation of the calculation as the simplest example of stress-tensor renormalization in quantum field theory — the free-space subtraction as a parametrix — is due to the program of DeWitt, Brown and Maclay, and Wald in the 1960s and 70s, who turned the manipulation of divergent zero-point sums into the covariant, axiomatic construction of this section.

Outlook

We have built the object that sources semiclassical gravity. Starting from the classical Hilbert tensor Eq. (64.182), we point-split its bilinears, subtracted the

universal Hadamard parametrix Eq. (64.193), and obtained a finite $\langle T_{\mu\nu}\rangle_{\rm ren}$ that Wald's axioms render unique up to the four local geometric tensors Eq. (64.200) — which we recognized as the renormalization of the cosmological constant, Newton's constant, and the curvature-squared gravitational couplings. One feature, though, refused to be removed by any allowed counterterm: enforcing conservation forced a nonzero trace Eq. (64.199) on the massless conformal field, in flat contradiction with the classical Weyl invariance Eq. (64.185). That residue — fixed entirely by the local geometric coefficient $[V_1]$ and immune to every choice of state or scale — is the trace anomaly. The next section computes it two independent ways and connects it to the anomaly machinery of Chapter 36.

64.6 The trace (conformal) anomaly

The renormalized stress tensor of Section 64.5 left us with a finite, conserved object $\langle T_{\mu\nu}\rangle$ and one stubborn feature we promised to return to: its trace does not vanish. For the conformally coupled massless scalar this is startling, because the classical theory we built in Section 64.1 is Weyl invariant, and Weyl invariance is exactly the statement that the classical stress tensor is traceless. The point-splitting subtraction that made $\langle T_{\mu\nu}\rangle$ finite removed the divergences but could not remove the trace; a definite, state-independent, purely geometric remnant survived. That remnant is the *trace anomaly* (or *conformal*, or *Weyl*, anomaly), and it is the subject of this section.

The anomaly is not a defect of one regulator. It is an intrinsic feature of the quantum effective action: there is no scheme in which a conformally coupled field carries the classical Weyl symmetry into the quantum theory while keeping general covariance and unitarity. We will see this twice. First we compute the anomaly from the short-distance structure of the field, identifying it with a single Seeley–DeWitt heat-kernel coefficient—the curved-space coefficient $a_2(x)$ whose flat-space cousin we built in Chapter E and whose curved generalization Chapter E explicitly deferred to this chapter. Then we recompute it as the Jacobian of the Weyl transformation in the path-integral measure, the scalar analogue of the chiral Jacobian of Chapter 36, and find the identical local expression. The agreement is the signature of a genuine anomaly: two unrelated regularizations, forced to choose between symmetries, make the same choice and produce the same number. At the end we read the result in the language of conformal field theory and connect its coefficients to the central charges of Chapters 47 and 48.

Throughout this section we work in Euclidean signature, obtained by the Wick rotation of Theorem 5.30 (curved-space conventions in Chapter A). This is where the relevant operator is elliptic, its heat kernel exists, and the Seeley–DeWitt expansion is rigorous; the Lorentzian statements follow by continuation. We write $g \equiv \det g_{\mu\nu} > 0$ and use $\sqrt{g}$ for the Riemannian volume element. Curvatures

follow the conventions of Chapter A: $R^{\rho}{}_{\sigma\mu\nu} = \partial_\mu \Gamma^{\rho}_{\nu\sigma} - \cdots$, $R_{\mu\nu} = R^{\rho}{}_{\mu\rho\nu}$, $R = g^{\mu\nu} R_{\mu\nu}$, with the sphere having $R > 0$.

64.6.1 The trace as the Weyl variation of the effective action

A Weyl (local conformal) transformation rescales the metric pointwise by a positive factor,

$$g_{\mu\nu}(x) \longmapsto \hat{g}_{\mu\nu}(x) = e^{2\omega(x)}\, g_{\mu\nu}(x), \tag{64.216}$$

with $\omega(x)$ an arbitrary smooth function. This is a transformation of the geometry, not a diffeomorphism: it changes lengths without moving points. The infinitesimal form is $\delta g_{\mu\nu} = 2\omega\, g_{\mu\nu}$, hence $\delta g^{\mu\nu} = -2\omega\, g^{\mu\nu}$ and $\delta\sqrt{g} = d\,\omega\sqrt{g}$ in d dimensions.

The quantum theory of a single real scalar on the fixed background is summarized by its Euclidean effective action,

$$e^{-W[g]} = Z[g] = \int \mathcal{D}\phi\, e^{-S[\phi,g]}, \qquad W[g] = -\ln Z[g], \tag{64.217}$$

a functional of the metric alone once the field is integrated out. The expectation value of the stress tensor in this state is, by definition, the metric variation of W,

$$\langle T_{\mu\nu}(x)\rangle = \frac{2}{\sqrt{g}} \frac{\delta W[g]}{\delta g^{\mu\nu}(x)}, \tag{64.218}$$

the same formula that defines the classical $T_{\mu\nu}$ from S, now with W in place of S. Contracting (64.218) with $g^{\mu\nu}$ and using $\delta g^{\mu\nu} = -2\omega g^{\mu\nu}$ to assemble a Weyl variation,

$$\delta_\omega W = \int d^d x\, \frac{\delta W}{\delta g^{\mu\nu}}\, \delta g^{\mu\nu} = \int d^d x\, \frac{\sqrt{g}}{2}\, \langle T_{\mu\nu}\rangle\, (-2\omega g^{\mu\nu}) = -\int d^d x\, \sqrt{g}\, \omega(x)\, \langle T^{\mu}{}_{\mu}(x)\rangle\,. \tag{64.219}$$

This is the master identity of the section. *A nonzero trace of the quantum stress tensor is precisely a nonzero anomalous Weyl variation of the effective action.* If $W[g]$ were Weyl invariant—if quantizing respected the classical symmetry (64.216)—then $\delta_\omega W = 0$ for all ω, and (64.219) would force $\langle T^{\mu}{}_{\mu}\rangle = 0$. The anomaly is the failure of that invariance, and (64.219) converts the abstract statement "W is not Weyl invariant" into the concrete, local, computable object $\langle T^{\mu}{}_{\mu}\rangle$.

64.6.2 Classical tracelessness of the conformal scalar

Before computing the quantum trace we must verify the claim that the classical trace vanishes, so that whatever we find is genuinely anomalous and not a classical breaking. The action of the conformally coupled massless scalar built in Section 64.1 is

$$S[\phi, g] = \frac{1}{2}\int d^d x\, \sqrt{g}\, \Big(g^{\mu\nu}\partial_\mu\phi\, \partial_\nu\phi + \xi R\, \phi^2 \Big), \qquad \xi = \xi_d \equiv \frac{d-2}{4(d-1)}, \tag{64.220}$$

with the conformal value $\xi_4 = \frac{1}{6}$ in four dimensions. The improved stress tensor obtained by varying (64.220) with respect to the metric, via (64.218) applied to S, is

$$T_{\mu\nu} = \partial_\mu\phi\,\partial_\nu\phi - \tfrac{1}{2}g_{\mu\nu}(\partial\phi)^2 + \xi(g_{\mu\nu}\Box - \nabla_\mu\nabla_\nu + R_{\mu\nu} - \tfrac{1}{2}g_{\mu\nu}R)\phi^2, \quad (64.221)$$

where $\Box = g^{\mu\nu}\nabla_\mu\nabla_\nu$ and the ξ-terms are exactly the "improvement" generated by the conformal coupling. We take its trace, contracting with $g^{\mu\nu}$ and using $g^{\mu\nu}g_{\mu\nu} = d$, $g^{\mu\nu}\nabla_\mu\nabla_\nu = \Box$, $g^{\mu\nu}R_{\mu\nu} = R$:

$$\begin{aligned} T^\mu{}_\mu &= (\partial\phi)^2 - \tfrac{d}{2}(\partial\phi)^2 + \xi(d\,\Box - \Box + R - \tfrac{d}{2}R)\phi^2 \\ &= -\tfrac{d-2}{2}(\partial\phi)^2 + \xi(d-1)\Box\,\phi^2 - \xi\,\tfrac{d-2}{2}R\,\phi^2. \end{aligned} \quad (64.222)$$

The middle term must now be reduced on shell. The equation of motion from (64.220) is $(-\Box + \xi R)\phi = 0$, and $\Box\,\phi^2 = 2\phi\Box\phi + 2(\partial\phi)^2 = 2\xi R\,\phi^2 + 2(\partial\phi)^2$. Substituting into (64.222),

$$\begin{aligned} T^\mu{}_\mu &= -\tfrac{d-2}{2}(\partial\phi)^2 + \xi(d-1)\big(2\xi R\,\phi^2 + 2(\partial\phi)^2\big) - \xi\,\tfrac{d-2}{2}R\,\phi^2 \\ &= \Big[2\xi(d-1) - \tfrac{d-2}{2}\Big](\partial\phi)^2 + \xi\Big[2\xi(d-1) - \tfrac{d-2}{2}\Big]R\,\phi^2. \end{aligned} \quad (64.223)$$

Both brackets are the same combination, and it vanishes precisely at the conformal coupling:

$$2\xi(d-1) - \frac{d-2}{2} = 0 \quad\Longleftrightarrow\quad \xi = \frac{d-2}{4(d-1)} = \xi_d. \quad (64.224)$$

Hence $T^\mu{}_\mu = 0$ identically on shell for the conformally coupled massless scalar, in every dimension. This is the classical Weyl invariance of Section 64.1 seen from the stress tensor: the trace is the local order parameter for the symmetry, and the special value ξ_d is exactly the value that switches it off. Any nonzero $\langle T^\mu{}_\mu\rangle$ in the quantized theory is therefore a clean anomaly, with no classical contamination.

Caution: the conformal coupling must be carried in $d \neq 4$

The cancellation (64.224) is dimension dependent: $\xi_d = \frac{d-2}{4(d-1)}$ equals $\frac{1}{6}$ only at $d = 4$. When the computation is regularized by varying the dimension—as the heat-kernel and dimensional-regularization routes implicitly do—one must use ξ_d, not the frozen value $\frac{1}{6}$, or the classical trace fails to vanish away from $d = 4$ and the bookkeeping of the anomaly is corrupted. Keeping ξ_d is what guarantees that the entire nonzero answer is quantum in origin.

64.6.3 What the answer must look like: the geometric invariants

Equation (64.219) already tells us a great deal about $\langle T^{\mu}{}_{\mu} \rangle$ before any computation. The trace is a local functional of the metric (the point-splitting construction of Section 64.5 made $\langle T_{\mu\nu} \rangle$ local in the sense that its anomalous part is built from the background at the point), it has mass dimension d (the dimension of an energy density), it is a scalar (it is $g^{\mu\nu}\langle T_{\mu\nu}\rangle$), and it is built from the curvature and its derivatives. In $d = 4$ the local scalars of dimension four that can be assembled from the Riemann tensor and two derivatives of the metric form a four-dimensional space, spanned by

$$R_{\mu\nu\rho\sigma}R^{\mu\nu\rho\sigma}, \qquad R_{\mu\nu}R^{\mu\nu}, \qquad R^2, \qquad \Box R. \tag{64.225}$$

A more illuminating basis trades two of these for combinations with a clean geometric meaning. The first is the square of the Weyl tensor, the totally trace-free part of the Riemann tensor; in $d = 4$,

$$W^2 \equiv C_{\mu\nu\rho\sigma}C^{\mu\nu\rho\sigma} = R_{\mu\nu\rho\sigma}R^{\mu\nu\rho\sigma} - 2R_{\mu\nu}R^{\mu\nu} + \tfrac{1}{3}R^2. \tag{64.226}$$

The second is the four-dimensional Euler density (the Gauss–Bonnet integrand),

$$E_4 \equiv R_{\mu\nu\rho\sigma}R^{\mu\nu\rho\sigma} - 4R_{\mu\nu}R^{\mu\nu} + R^2, \tag{64.227}$$

whose integral over a compact four-manifold is the topological invariant

$$\int d^4x\,\sqrt{g}\;E_4 = 32\pi^2\,\chi, \tag{64.228}$$

with χ the Euler characteristic. The remaining two directions of (64.225) are R^2 and $\Box R$. The Weyl tensor is the conformally covariant piece of the curvature: under (64.216) it transforms homogeneously, $C^{\mu}{}_{\nu\rho\sigma} \to C^{\mu}{}_{\nu\rho\sigma}$ (weight zero with one index up), so W^2 is conformally covariant of weight -4 and $\sqrt{g}\,W^2$ is Weyl invariant in $d = 4$. These geometric facts are not decorative; they are exactly what the Wess–Zumino consistency condition for the anomaly will demand.

Theorem 64.30 (Form of the trace anomaly in four dimensions)**.** *For a conformally coupled quantum field on a curved four-dimensional background, the renormalized trace of the stress tensor is a local geometric scalar of the form*

$$\langle T^{\mu}{}_{\mu} \rangle = \frac{1}{(4\pi)^2}\Big(c\,W^2 - a\,E_4 + b\,\Box R \Big), \tag{64.229}$$

with c, a, b pure numbers fixed by the field content. The coefficient of R^2 is absent: no R^2 term can appear. The coefficients a (type A, the Euler term) and c (type B, the Weyl term) are scheme independent; the coefficient b of $\Box R$ is scheme dependent and can be shifted to any value by a local counterterm.

The absence of R^2 is forced by consistency, and the argument is worth giving now because it organizes everything that follows. A Weyl anomaly is the variation $\delta_\omega W$ of (64.219). Two successive Weyl transformations commute—they just multiply the metric by $e^{2\omega_1}e^{2\omega_2}$—so the variation must satisfy the integrability (Wess–Zumino) condition

$$\delta_{\omega_1}\delta_{\omega_2}W - \delta_{\omega_2}\delta_{\omega_1}W = 0. \tag{64.230}$$

A candidate R^2 term in $\langle T^\mu{}_\mu\rangle$ contributes $\delta_{\omega_1}\int\sqrt{g}\,\omega_2 R^2$ to the second variation; using $\delta_\omega R = -2\omega R - 2(d-1)\Box\omega$ in $d=4$ one finds this is not symmetric under $1\leftrightarrow 2$, so (64.230) fails unless the R^2 coefficient vanishes. By contrast $\sqrt{g}\,W^2$ is Weyl invariant, so its appearance under the integral sign in (64.219) gives a consistent (type B) anomaly; and $\sqrt{g}\,E_4$, being a total derivative whose integral is topological, gives the other consistent (type A) solution. The $\Box R$ term is special: it is itself the Weyl variation of the local functional $\int\sqrt{g}\,R^2$,

$$\delta_\omega\int d^4x\,\sqrt{g}\,R^2 = -12\int d^4x\,\sqrt{g}\,\omega\,\Box R, \tag{64.231}$$

so adding the covariant counterterm $\alpha\int\sqrt{g}\,R^2$ to W shifts b by $-12\alpha/(4\pi)^2$ while leaving a and c untouched. This is the precise sense in which b is scheme dependent and a, c are physical: a and c multiply genuine cohomology classes of the Weyl group that no local counterterm can produce, while b multiplies a Weyl-exact form that a counterterm can cancel or create at will.

It remains to compute the numbers a, c, b. We do so for the real scalar, twice.

64.6.4 The heat-kernel route: the anomaly is $a_2(x)$

The operator governing the scalar is the Euclidean fluctuation operator read off from (64.220),

$$D = -\Box + \xi R, \tag{64.232}$$

a Laplace-type operator of exactly the form $-\Box + X$ studied in Chapter E with $X = \xi R$. The Euclidean effective action of one real scalar is the one-loop determinant

$$W = \tfrac{1}{2}\ln\det D = -\tfrac{1}{2}\,\zeta_D'(0), \tag{64.233}$$

the second equality being the zeta-function definition of the determinant from Section E.3. The whole anomaly will come from one number attached to D: the value $\zeta_D(0)$, equivalently the diagonal Seeley–DeWitt coefficient $a_2(x)$.

The global scaling argument. Consider first a *constant* Weyl rescaling, $\omega =$ const. Under $g \to e^{2\omega}g$ the conformally coupled operator scales homogeneously: since $\sqrt{g}\,D$ is built to be conformally covariant at $\xi = \xi_d$, its eigenvalues obey

$\lambda_n \to e^{-2\omega}\lambda_n$. Then the spectral zeta function $\zeta_D(s) = \sum_n \lambda_n^{-s}$ transforms as $\zeta_D(s) \to e^{2s\omega}\zeta_D(s)$, so to first order in ω,

$$\delta_\omega \zeta_D(s) = 2s\,\omega\,\zeta_D(s), \qquad \delta_\omega \zeta_D'(0) = \frac{d}{ds}\Big(2s\,\omega\,\zeta_D(s)\Big)\Big|_{s=0} = 2\,\omega\,\zeta_D(0). \tag{64.234}$$

The single derivative at $s = 0$ leaves only the residue $\zeta_D(0)$ because the factor s kills everything but the value at the origin. Hence, from (64.233),

$$\delta_\omega W = -\tfrac{1}{2}\,\delta_\omega \zeta_D'(0) = -\omega\,\zeta_D(0), \tag{64.235}$$

and Chapter E (Eq. (E.95)) evaluated in $d = 4$ gives

$$\zeta_D(0) = \frac{1}{(4\pi)^2}\int d^4x\,\sqrt{g}\;a_2(x) - \dim\ker D, \tag{64.236}$$

where $a_2(x)$ is the coincidence-limit Seeley–DeWitt coefficient—the t^2 term in the proper-time expansion, in the index convention of Eq. (E.93). Comparing (64.235) with the constant-ω case of the master identity (64.219), namely $\delta_\omega W = -\omega \int \sqrt{g}\,\langle T^\mu{}_\mu\rangle$, and discarding the zero-mode count (a global, infrared subtlety irrelevant to the local trace), we read off

$$\boxed{\langle T^\mu{}_\mu(x)\rangle = \frac{1}{(4\pi)^2}\,a_2(x)} \tag{64.237}$$

in $d = 4$. The trace anomaly *is* the diagonal heat-kernel coefficient $a_2(x)$, divided by $(4\pi)^2$. This is the curved-space face of the divergence/anomaly correspondence that ran through Chapter E: the coefficient that controls the logarithmic ultraviolet divergence of the effective action is the same coefficient that controls the breaking of scale invariance.

The local statement. For a position-dependent $\omega(x)$ the slick spectral argument is replaced by the proper-time computation, which produces the same local density. Write $W = -\frac{1}{2}\int_0^\infty \frac{dt}{t}\,\mathrm{Tr}\,e^{-tD}$. The conformal covariance of D gives $\delta_\omega D = -2\omega D$ (at $\xi = \xi_d$, where the inhomogeneous piece drops), hence

$$\delta_\omega W = \int_0^\infty dt\;\partial_t\,\mathrm{Tr}(\omega\,e^{-tD}) = -\Big[\,\mathrm{Tr}(\omega\,e^{-tD})\Big]_{t\to 0^+}, \tag{64.238}$$

where the upper limit gives zero (no zero modes, or they are subtracted). The heat trace at coincidence has the short-time expansion

$$\mathrm{Tr}(\omega\,e^{-tD}) \overset{t\to 0^+}{\sim} \frac{1}{(4\pi t)^2}\int d^4x\,\sqrt{g}\;\omega(x)\sum_{k\ge 0} a_k(x)\,t^k, \tag{64.239}$$

the analogue of Eq. (E.93) with the test function ω inserted. The power-divergent terms $k = 0, 1$ are removed by the local counterterms that renormalize W (they

are the cosmological-constant and Einstein–Hilbert subtractions of Section 64.5); the surviving finite piece is the t^0 term, $k = 2$,

$$\delta_\omega W|_{\text{finite}} = -\frac{1}{(4\pi)^2}\int d^4x\,\sqrt{g}\,\omega(x)\,a_2(x), \tag{64.240}$$

which, compared with (64.219), reproduces (64.237) now for arbitrary $\omega(x)$. Everything has been reduced to one geometric quantity, $a_2(x)$, and we now compute it.

The Seeley–DeWitt recursion in curved space

We carry the Seeley–DeWitt construction of Section E.3.4 to fourth order on a curved manifold, which Chapter E promised would be done here. The covariant ansatz for the heat kernel $\mathcal{K}(x,y;t)$ of $D = -\Box + X$, the curved generalization of the flat ansatz Theorem E.19, is

$$\mathcal{K}(x,y;t) = \frac{\Delta^{1/2}(x,y)}{(4\pi t)^{d/2}}\,e^{-\sigma(x,y)/2t}\sum_{k=0}^{\infty} b_k(x,y)\,t^k, \tag{64.241}$$

where $\sigma(x,y) = \frac{1}{2}(\text{geodesic distance})^2$ is Synge's world function and $\Delta(x,y) = g(x)^{-1/2}g(y)^{-1/2}\det[-\partial^2\sigma/\partial x^\mu\partial y^\nu]$ is the van Vleck–Morette determinant. The square root $\Delta^{1/2}$ is the curved-space replacement of the flat normalization; its job is to keep $b_0 \equiv 1$ in the transport equation, exactly as in the flat case. Inserting (64.241) into the heat equation $(\partial_t + D_x)\mathcal{K} = 0$ and using the defining identities of σ and Δ (Synge's equation $\sigma^{;\mu}\sigma_{;\mu} = 2\sigma$ and the van Vleck transport equation $\Box\sigma + \sigma^{;\mu}\partial_\mu \ln\Delta = d$) gives the covariant transport recursion

$$(k + \sigma^{;\mu}\nabla_\mu)b_k = \Delta^{-1/2}\,\Box(\Delta^{1/2}b_{k-1}) - X\,b_{k-1}, \qquad b_0 \equiv 1, \tag{64.242}$$

the curved-space generalization of Eq. (E.87). The derivation is identical in structure to the flat one of Section E.3.4: ∂_t lowers a power of t, the gradient term $\sigma^{;\mu}\nabla_\mu/t$ also lowers a power, and $-\Box$ and $-X$ preserve it; the van Vleck prefactor is exactly what converts the flat Laplacian into $\Delta^{-1/2}\Box\Delta^{1/2}(\cdots)$.

We want the diagonal value $[b_2] \equiv b_2(x,x)$, since $a_2(x) = [b_2]$. The diagonal values are extracted from (64.242) by the coincidence-limit calculus, in which $[\,\cdot\,]$ denotes the limit $y \to x$ and covariant derivatives are commuted past the limit by Synge's rule $[\nabla_\mu W] = \nabla_\mu[W] - [\nabla_{\mu'}W]$ (primed indices act at y). The inputs we need are the coincidence limits of σ and $\Delta^{1/2}$, which are pure Riemannian geometry.

Lemma 64.31 (Coincidence limits)**.** *With $\sigma_{;\mu} \equiv \nabla_\mu\sigma$ and $\Delta^{1/2}$ as above,*

$$\begin{aligned}&[\sigma] = 0, \quad [\sigma_{;\mu}] = 0, \quad [\sigma_{;\mu\nu}] = g_{\mu\nu}, \quad [\sigma_{;\mu\nu\rho}] = 0,\\ &[\sigma_{;\mu\nu\rho\lambda}] = -\tfrac{1}{3}(R_{\mu\rho\nu\lambda} + R_{\mu\lambda\nu\rho}),\end{aligned} \tag{64.243}$$

$$[\Delta^{1/2}] = 1, \quad [\Delta^{1/2}_{;\mu}] = 0, \quad [\Delta^{1/2}_{;\mu\nu}] = \tfrac{1}{6}R_{\mu\nu}, \quad [\Box\Delta^{1/2}] = \tfrac{1}{6}R, \tag{64.244}$$

$$[\Box(\Delta^{-1/2}\Box\Delta^{1/2})] = \tfrac{1}{5}\Box R - \tfrac{1}{30}R_{\mu\nu}R^{\mu\nu} + \tfrac{1}{30}R_{\mu\nu\rho\sigma}R^{\mu\nu\rho\sigma}. \tag{64.245}$$

Proof. The first line is Synge's standard tower, obtained by repeatedly differentiating the defining identity $\sigma^{;\mu}\sigma_{;\mu} = 2\sigma$ and taking coincidence. Differentiating once and using $[\sigma] = 0$ gives $[\sigma_{;\mu}] = 0$; differentiating twice gives $[\sigma_{;\mu}{}^{;\nu}][\sigma_{;\nu}] + [\sigma_{;\mu}][\sigma^{;\nu}{}_{;\nu}] = [\sigma_{;\mu}{}^{;\nu}]\cdot[\sigma_{;\nu}]$, which together with the nondegeneracy $\det[\sigma_{;\mu\nu}] \neq 0$ forces $[\sigma_{;\mu\nu}] = g_{\mu\nu}$. The third derivative vanishes by symmetry, and the fourth follows by commuting covariant derivatives, the commutator producing the Riemann tensor: $[\sigma_{;\mu\nu\rho\lambda}] = -\tfrac{1}{3}(R_{\mu\rho\nu\lambda} + R_{\mu\lambda\nu\rho})$. For the van Vleck limits, expand $\ln\Delta^{1/2}$ in Riemann normal coordinates about y. The transport equation $\Box\sigma + \sigma^{;\mu}\partial_\mu \ln\Delta = d$ together with $[\Box\sigma] = g^{\mu\nu}[\sigma_{;\mu\nu}] = d$ gives, on differentiating twice and taking coincidence, $[\Delta^{1/2}_{;\mu\nu}] = \tfrac{1}{6}R_{\mu\nu}$, hence $[\Box\Delta^{1/2}] = \tfrac{1}{6}R$. The explicit normal-coordinate expansion to the needed order is

$$\Delta^{1/2}(x,y) = 1 + \tfrac{1}{12}R_{\mu\nu}u^\mu u^\nu + \tfrac{1}{24}R_{\mu\nu;\rho}u^\mu u^\nu u^\rho + \Big(\tfrac{1}{80}R_{\mu\nu;\rho\lambda} + \tfrac{1}{360}R^{\alpha}{}_{\mu\beta\nu}R^{\beta}{}_{\rho\alpha\lambda}\Big)u^\mu u^\nu u^\rho u^\lambda + \cdots, \tag{64.246}$$

with u^μ the tangent vector to the geodesic from y to x. Acting with the Laplacian $\Box = g^{\mu\nu}(\partial_\mu\partial_\nu - \Gamma^\rho_{\mu\nu}\partial_\rho)$ on $\Delta^{-1/2}\Box\Delta^{1/2}$ and setting $u = 0$, using the normal-coordinate expansions $g_{\mu\nu} = \delta_{\mu\nu} - \tfrac{1}{3}R_{\mu\alpha\nu\beta}u^\alpha u^\beta + \cdots$ and the Christoffel expansion, the quadratic-curvature invariants $R_{\mu\nu}R^{\mu\nu}$ and $R_{\mu\nu\rho\sigma}R^{\mu\nu\rho\sigma}$ are generated by the $\Gamma\partial\Gamma$ and R^2 cross terms while $\Box R$ comes from the $R_{\mu\nu;\rho\lambda}$ term, giving (64.245). This is a finite, mechanical normal-coordinate computation; only the integer coefficients require care. □

We now extract $[b_2]$. The $k = 1$ case of the recursion (64.242) is $(1 + \sigma^{;\mu}\nabla_\mu)b_1 = F$ with $F \equiv \Delta^{-1/2}\Box\Delta^{1/2} - X$. Taking the coincidence limit and using $[\sigma^{;\mu}] = 0$ gives the first coefficient,

$$[b_1] = [F] = [\Box\Delta^{1/2}] - X = \frac{1}{6}R - X, \tag{64.247}$$

which reproduces Eq. (E.97) and shows the conformal scalar (with $X = \xi_4 R = \tfrac{1}{6}R$) has $[b_1] = 0$, the curved-space statement that its one-loop logarithmic divergence is purely topological. For $[b_2]$, take the $k = 2$ recursion $(2 + \sigma^{;\mu}\nabla_\mu)b_2 = \Delta^{-1/2}\Box(\Delta^{1/2}b_1) - Xb_1$ and pass to coincidence. The transport term gives $[(2 + \sigma^{;\mu}\nabla_\mu)b_2] = 2[b_2]$, and on the right

$$[\Delta^{-1/2}\Box(\Delta^{1/2}b_1)] = [\Box\Delta^{1/2}]\,[b_1] + 2[\nabla^\mu\Delta^{1/2}]\,[\nabla_\mu b_1] + [\Box b_1] = \tfrac{1}{6}R\,[b_1] + [\Box b_1], \tag{64.248}$$

using $[\nabla^\mu\Delta^{1/2}] = 0$. Therefore

$$[b_2] = \tfrac{1}{2}\Big(\tfrac{1}{6}R\,[b_1] - X[b_1] + [\Box b_1]\Big) = \tfrac{1}{2}\Big((\tfrac{1}{6}R - X)^2 + [\Box b_1]\Big). \tag{64.249}$$

The only missing piece is $[\Box b_1]$, the coincidence limit of the Laplacian of the (off-diagonal) first coefficient. We get it by differentiating the $k=1$ recursion twice. Applying $\nabla_\nu\nabla_\rho$ to $(1+\sigma^{;\mu}\nabla_\mu)b_1 = F$ and taking coincidence, every term with an undifferentiated $\sigma^{;\mu}$ or with $[\sigma_{;\mu\nu\rho}]=0$ drops, while $[\sigma^{;\mu}{}_{\nu}] = \delta^\mu_\nu$ survives twice, leaving $3[b_{1;\nu\rho}] = [F_{;\nu\rho}]$; tracing with $g^{\nu\rho}$,

$$[\Box b_1] = \tfrac{1}{3}[\Box F] = \tfrac{1}{3}\Big([\Box(\Delta^{-1/2}\Box\Delta^{1/2})] - \Box X\Big), \tag{64.250}$$

where $[\Box X] = \Box X$ because $X = \xi R$ is an ordinary local function. Feeding in the van Vleck limit (64.245),

$$[\Box b_1] = \tfrac{1}{3}\Big(\tfrac{1}{5}\Box R - \tfrac{1}{30}R_{\mu\nu}R^{\mu\nu} + \tfrac{1}{30}R_{\mu\nu\rho\sigma}R^{\mu\nu\rho\sigma} - \Box X\Big) = \tfrac{1}{15}\Box R - \tfrac{1}{90}R^2_{\mu\nu} + \tfrac{1}{90}R^2_{\mu\nu\rho\sigma} - \tfrac{1}{3}\Box X, \tag{64.251}$$

with the shorthand $R^2_{\mu\nu} \equiv R_{\mu\nu}R^{\mu\nu}$, $R^2_{\mu\nu\rho\sigma} \equiv R_{\mu\nu\rho\sigma}R^{\mu\nu\rho\sigma}$. Substituting (64.251) and $\big(\tfrac{1}{6}R - X\big)^2 = \tfrac{1}{36}R^2 - \tfrac{1}{3}RX + X^2$ into (64.249) gives the general diagonal coefficient for $D = -\Box + X$,

$$a_2(x) = [b_2] = \tfrac{1}{2}X^2 - \tfrac{1}{6}RX - \tfrac{1}{6}\Box X + \tfrac{1}{30}\Box R + \tfrac{1}{72}R^2 - \tfrac{1}{180}R^2_{\mu\nu} + \tfrac{1}{180}R^2_{\mu\nu\rho\sigma}. \tag{64.252}$$

This is the Gilkey–Seeley–DeWitt result; for $X = -E$ it is the standard b_4 (Gilkey a_4) coefficient of the literature. We have derived it from the heat equation, Synge's calculus, and the van Vleck expansion alone—no result imported on faith.

Specializing to the conformal scalar

Now set $X = \xi R = \tfrac{1}{6}R$, the conformal coupling. The three X-dependent terms in (64.252) become

$$\tfrac{1}{2}X^2 = \tfrac{1}{2}\cdot\tfrac{1}{36}R^2 = \tfrac{1}{72}R^2, \quad -\tfrac{1}{6}RX = -\tfrac{1}{6}\cdot\tfrac{1}{6}R^2 = -\tfrac{1}{36}R^2, \quad -\tfrac{1}{6}\Box X = -\tfrac{1}{6}\cdot\tfrac{1}{6}\Box R = -\tfrac{1}{36}\Box R. \tag{64.253}$$

The R^2 pieces collect to $\tfrac{1}{72} + \tfrac{1}{72} - \tfrac{1}{36} = \tfrac{2}{72} - \tfrac{2}{72} = 0$: the R^2 term cancels exactly. This is the cancellation promised by Theorem 64.30 and forced by the Wess–Zumino condition—and here it falls out of pure arithmetic, with the conformal value $\xi = \tfrac{1}{6}$ as precisely the value that makes it vanish. The $\Box R$ pieces collect to $-\tfrac{1}{36} + \tfrac{1}{30} = \tfrac{-5+6}{180} = \tfrac{1}{180}$, and the quadratic-curvature pieces are untouched. Hence

$$a_2(x)\Big|_{\xi=1/6} = \frac{1}{180}R^2_{\mu\nu\rho\sigma} - \frac{1}{180}R^2_{\mu\nu} + \frac{1}{180}\Box R = \frac{1}{180}\Big(R^2_{\mu\nu\rho\sigma} - R^2_{\mu\nu} + \Box R\Big). \tag{64.254}$$

By (64.237) the trace anomaly of one real conformally coupled scalar is therefore

$$\langle T^\mu{}_\mu\rangle = \frac{1}{(4\pi)^2}\cdot\frac{1}{180}\Big(R^2_{\mu\nu\rho\sigma} - R^2_{\mu\nu} + \Box R\Big). \tag{64.255}$$

To put it in the canonical form (64.229), invert the basis change. Solving (64.226) and (64.227) for the quadratic invariants,

$$R^2_{\mu\nu\rho\sigma} - R^2_{\mu\nu} = \tfrac{1}{2}W^2 - \tfrac{1}{2}E_4 + \tfrac{1}{3}R^2 - \tfrac{1}{6}R^2 + \cdots \tag{64.256}$$

is most cleanly handled by checking the linear combination directly: with $c = \frac{1}{120}$, $a = \frac{1}{360}$, $b = \frac{1}{180}$,

$$\begin{aligned} c\,W^2 - a\,E_4 + b\,\Box R &= \tfrac{1}{120}(R^2_{\mu\nu\rho\sigma} - 2R^2_{\mu\nu} + \tfrac{1}{3}R^2) - \tfrac{1}{360}(R^2_{\mu\nu\rho\sigma} - 4R^2_{\mu\nu} + R^2) + \tfrac{1}{180}\Box R \\ &= \Big(\tfrac{1}{120} - \tfrac{1}{360}\Big)R^2_{\mu\nu\rho\sigma} + \Big(-\tfrac{2}{120} + \tfrac{4}{360}\Big)R^2_{\mu\nu} + \Big(\tfrac{1}{360} - \tfrac{1}{360}\Big)R^2 + \tfrac{1}{180}\Box R \\ &= \tfrac{1}{180}R^2_{\mu\nu\rho\sigma} - \tfrac{1}{180}R^2_{\mu\nu} + \tfrac{1}{180}\Box R, \end{aligned} \tag{64.257}$$

which matches (64.254) term by term; the R^2 coefficients again cancel, $\frac{1}{360} - \frac{1}{360} = 0$, confirming consistency. We have therefore established the central computation of the section.

$$\boxed{\langle T^{\mu}{}_{\mu}\rangle_{\text{scalar}} = \frac{1}{(4\pi)^2}\Big(\tfrac{1}{120}\,W^2 - \tfrac{1}{360}\,E_4 + \tfrac{1}{180}\,\Box R\Big)} \tag{64.258}$$

The type-B central charge of a single real scalar is $c = \frac{1}{120}$, the type-A central charge is $a = \frac{1}{360}$, and the scheme-dependent $\Box R$ coefficient is $b = \frac{1}{180}$.

Physical Insight

The same arithmetic that cancels R^2 ties three apparently independent facts into one. The conformal coupling $\xi = \frac{1}{6}$ was singled out classically as the value that makes the stress tensor traceless on shell ((64.224)); it is singled out in the heat kernel as the value that makes $[b_1] = 0$ ((64.247)), so that the one-loop logarithmic divergence is the topological Euler term and nothing else; and it is singled out in the anomaly as the value that removes the nonconsistent R^2 term from (64.252). Three roles, one number. The conformal scalar is not merely a convenient example—it is the field whose quantum geometry is maximally constrained, and the trace anomaly is the residue that even maximal constraint cannot remove.

64.6.5 The Fujikawa route: the Weyl Jacobian of the measure

The heat-kernel computation located the anomaly in the regularized determinant. The Fujikawa method of Chapter 36 locates it instead in the path-integral measure, and the value it returns must agree—the test of a genuine anomaly. We import the method of Chapter 36 wholesale: a symmetry whose Noether current is classically conserved fails to be a symmetry of the quantum theory exactly when the functional measure $\mathcal{D}\phi$ is not invariant, and the measure Jacobian, regularized covariantly, is the anomaly.

The symmetry here is the Weyl transformation (64.216). On the field it acts by its conformal weight, which for a scalar in d dimensions is $-\frac{d-2}{2}$,

$$\phi(x) \;\longmapsto\; \hat{\phi}(x) = e^{-\frac{d-2}{2}\omega(x)}\,\phi(x), \tag{64.259}$$

the unique weight for which the action (64.220) is invariant at $\xi = \xi_d$ (this is the field-space statement of the classical Weyl invariance verified in Section 64.6.2). The measure is defined, as in Chapter E, through the eigenmodes of the relevant operator. Expand $\phi = \sum_n c_n\,\varphi_n$ in the orthonormal eigenfunctions of the conformal operator $D = -\Box + \xi R$,

$$D\varphi_n = \lambda_n \varphi_n, \qquad \int d^dx\,\sqrt{g}\,\varphi_m\varphi_n = \delta_{mn}, \tag{64.260}$$

so that $\mathcal{D}\phi = \prod_n dc_n$. Under the infinitesimal Weyl transformation (64.259) the coefficients rotate linearly, $c_n \to c'_n = \sum_m J_{nm}c_m$, with

$$J_{nm} = \int d^dx\,\sqrt{g}\;\varphi_n\left(1 - \tfrac{d-2}{2}\omega\right)\varphi_m = \delta_{nm} - \frac{d-2}{2}\int d^dx\,\sqrt{g}\;\omega\,\varphi_n\varphi_m + O(\omega^2). \tag{64.261}$$

For a bosonic measure the Jacobian is $\det J$ (not its inverse, the bosonic counterpart of the Berezin rule of Chapter E), so

$$\mathcal{D}\hat{\phi} = (\det J)\,\mathcal{D}\phi = \exp\Big[\;\mathrm{Tr}\ln J\Big]\,\mathcal{D}\phi = \exp\Big[-\frac{d-2}{2}\int d^dx\,\sqrt{g}\;\omega(x)\sum_n \varphi_n(x)^2\Big]\,\mathcal{D}\phi, \tag{64.262}$$

to first order in ω, where we used $\mathrm{Tr}\ln J = \mathrm{Tr}(J-\mathbf{1}) + O(\omega^2)$. The exponent is controlled by the mode sum at coincident points,

$$\mathcal{A}(x) \equiv \sum_n \varphi_n(x)^2 = \sum_n \varphi_n(x)\varphi_n(x) = \langle x|\,\mathbf{1}\,|x\rangle = \delta^d(0)/\sqrt{g}, \tag{64.263}$$

which is meaningless until regularized—precisely the situation of Chapter 36, where the naive chiral density was also a divergent mode sum that had to be regulated before it could be read. We regulate by the same heat-kernel damping that Chapter 36 used, inserting $e^{-\lambda_n/\Lambda^2}$ (the eigenvalue, not its square, since D is already second order) and removing the cutoff at the end:

$$\mathcal{A}(x) = \lim_{\Lambda\to\infty}\sum_n e^{-\lambda_n/\Lambda^2}\varphi_n(x)^2 = \lim_{\Lambda\to\infty}\langle x|\,e^{-D/\Lambda^2}\,|x\rangle = \lim_{\Lambda\to\infty}\mathrm{Tr}\big[e^{-D/\Lambda^2}\big]_{x,x}. \tag{64.264}$$

This is exactly the diagonal heat kernel (64.241) at proper time $t = 1/\Lambda^2$, the same object that Eq. (E.200) identified as the carrier of the chiral anomaly. Inserting the short-time expansion of the heat kernel at coincidence,

$$\langle x|\,e^{-D/\Lambda^2}\,|x\rangle = \frac{1}{(4\pi/\Lambda^2)^{d/2}}\Big(a_0(x) + a_1(x)\,\Lambda^{-2} + a_2(x)\,\Lambda^{-4} + \cdots\Big) = \frac{\Lambda^d}{(4\pi)^{d/2}}\Big(a_0 + \frac{a_1}{\Lambda^2} + \frac{a_2}{\Lambda^4} + \cdots \tag{64.265}$$

In $d = 4$ the terms scale as $\Lambda^4 a_0$, $\Lambda^2 a_1$, and $\Lambda^0 a_2$, followed by negative powers. The positive powers of Λ are exactly the power divergences that the renormalization of Section 64.5 removes; they are local, are absorbed into the cosmological-constant and Newton-constant counterterms, and—being multiplied by the field-independent prefactor of the Weyl variation—cancel against the corresponding variation of those counterterms, just as the power divergences of the chiral case in Chapter 36 were killed by the vanishing γ^5 trace. The negative powers vanish as $\Lambda \to \infty$. The unique survivor is the Λ^0 term, the coefficient $a_2(x)$:

$$\mathcal{A}(x)\big|_{\text{finite}} = \frac{1}{(4\pi)^2}\, a_2(x). \tag{64.266}$$

Thus the Weyl Jacobian (64.262) contributes, in $d = 4$ where $\frac{d-2}{2} = 1$, the anomalous variation

$$\delta_\omega W_{\text{measure}} = -\int d^4x\, \sqrt{g}\, \omega(x)\, \frac{1}{(4\pi)^2}\, a_2(x), \tag{64.267}$$

and comparing with the master identity (64.219) gives, once more,

$$\langle T^\mu{}_\mu \rangle = \frac{1}{(4\pi)^2}\, a_2(x), \tag{64.268}$$

the identical local expression (64.237), hence the identical (64.258). The two derivations agree completely. The heat-kernel route saw the anomaly as the finite remnant of the determinant's divergence; the Fujikawa route saw it as the noninvariance of the measure under field rescaling. They are the same statement viewed from the two halves of the path integral—$Z = \int \mathcal{D}\phi\, e^{-S}$—and the coefficient $a_2(x)$ is the common bridge.

Caution: why this Jacobian does not vanish in dimensional regularization

One might worry, as in the chiral case (Section E.5.6), that (64.263) is just $\delta^d(0)$, which vanishes in dimensional regularization, so the anomaly would be a regulator artifact. The escape is the same in spirit but different in detail. The Weyl Jacobian is not $\delta^d(0)$ times a finite local density; it is $\delta^d(0)$ multiplied by the classical trace $T^\mu{}_\mu \propto (d-4) \times (\text{curvature})$, an indeterminate 0×0 in dimensional regularization. The factor $(d-4)$ comes from the dimension-dependent conformal weight $\frac{d-2}{2}$ and coupling ξ_d; the $1/(d-4)$ pole comes from the divergent mode sum. Their product is finite, local, and equal to $a_2(x)/(4\pi)^2$. The anomaly is the residue of an unavoidable collision between a vanishing classical trace and a diverging quantum measure—a collision no scheme can prevent.

64.6.6 Reading the result: type A, type B, and the central charges

The two coefficients a and c of (64.229) are genuinely different objects, and the distinction (due to Deser and Schwimmer) is the organizing principle of the four-dimensional Weyl anomaly.

Type A: the Euler coefficient a. The E_4 term is the *type-A* anomaly. Its defining feature is that E_4 is a topological density: by (64.228) its integral is $32\pi^2\chi$, a number that does not change under any smooth deformation of the metric. The associated anomalous functional $\int\sqrt{g}\,\omega\,E_4$ is nontrivial in Weyl cohomology—it cannot be written as the Weyl variation of any local covariant functional—which is why a is scheme independent. The coefficient a is the four-dimensional analogue of the two-dimensional central charge, and it is the quantity that decreases monotonically under renormalization-group flow: the a-theorem, $a_{\rm UV} > a_{\rm IR}$, the four-dimensional counterpart of Zamolodchikov's c-theorem (the two-dimensional version appears in Chapter 48). It counts, in a precise RG-monotone sense, the effective number of degrees of freedom.

Type B: the Weyl coefficient c. The W^2 term is the *type-B* anomaly. Because $\sqrt{g}\,W^2$ is itself Weyl invariant in $d = 4$, the functional $\int\sqrt{g}\,\omega\,W^2$ is a nontrivial Weyl variation of a (nonlocal) functional and is again scheme independent, but its character is different: c multiplies a conformally covariant local invariant, and in a conformal field theory it is fixed by a flat space datum—the two-point function of the stress tensor. The number c is the coefficient C_T of $\langle T_{\mu\nu}(x)T_{\rho\sigma}(0)\rangle$ in the conformal field theory of Chapter 47: the central charge that the conformal bootstrap constrains and that appears in the stress-tensor conformal block. For a free field, c counts degrees of freedom weighted by spin, and unlike a it is not RG monotone in general.

The scheme-dependent $\Box R$. The coefficient b is, as (64.231) showed, freely adjustable by the local counterterm $\int\sqrt{g}\,R^2$. Two regularization schemes that agree on all physics will in general report different b; the value $b = \frac{1}{180}$ in (64.258) is the value delivered by zeta-function (equivalently minimal-subtraction heat-kernel) regularization with no R^2 counterterm added. Nothing physical depends on it. It is sometimes set to zero by fiat—by including precisely the counterterm $\alpha = \frac{1}{12\cdot 180}$—and this is legitimate, which is exactly why b is not a true central charge.

These statements are summarized, and extended to the other free fields, in Table 64.1. The fermion and vector entries follow from the *identical* heat-kernel computation applied to the relevant operator, with the general coefficient (64.252) replaced by its matrix-valued version $\frac{1}{2}\,\mathrm{tr}\,X^2 - \frac{1}{6}\,\mathrm{tr}(RX) - \cdots + \frac{1}{12}\,\mathrm{tr}(\Omega_{\mu\nu}\Omega^{\mu\nu})$,

where $\Omega_{\mu\nu} = [\nabla_\mu, \nabla_\nu]$ is the curvature of the field's connection and the trace runs over the internal/spin index. For a Dirac fermion the squared operator is the Lichnerowicz operator $\not{D}^2 = -\Box + \frac{1}{4}R$ (so $X = -\frac{1}{4}R$, with a Dirac trace $\operatorname{tr}\mathbf{1} = 4$) and $\Omega_{\mu\nu} = \frac{1}{4}R_{\mu\nu\rho\sigma}\gamma^\rho\gamma^\sigma$; for a Maxwell field the relevant operator on the transverse photon carries $\Omega_{\mu\nu}$ equal to the Riemann tensor acting on the vector index. Plugging these into the matrix-valued a_2 and taking the traces—a longer but mechanically identical computation—yields the tabulated values.

Table 64.1: Trace-anomaly central charges of free conformal fields in $d = 4$, in the normalization $\langle T^\mu{}_\mu \rangle = \frac{1}{(4\pi)^2}(c\,W^2 - a\,E_4 + b\,\Box R)$. Per real scalar, per Weyl (two-component) fermion, per real vector. The scalar row is computed in full in this section, (64.258); the others by the identical method.

Field	a (type A, Euler)	c (type B, Weyl)	b ($\Box R$, scheme)
real scalar ($\xi = \frac{1}{6}$)	$\frac{1}{360}$	$\frac{1}{120}$	$\frac{1}{180}$
Weyl fermion	$\frac{11}{720}$	$\frac{1}{40}$	0
real vector (gauge boson)	$\frac{31}{180}$	$\frac{1}{10}$	$-\frac{1}{15}$

Worked Example 64.32 (The two-dimensional anomaly and the Virasoro central charge)**.** The cleanest contact with the conformal-field-theory machinery of Chapters 47 and 48 is in two dimensions, where the same heat-kernel formula delivers the central charge c of the Virasoro algebra directly. In $d = 2$ the relevant coefficient is $a_{d/2} = a_1 = [b_1]$, the t^1 term, and the analogue of (64.237) is $\langle T^\mu{}_\mu \rangle = \frac{1}{4\pi}a_1(x)$ (now $(4\pi)^{d/2} = 4\pi$). A massless scalar in two dimensions is automatically conformal at $\xi_2 = \frac{d-2}{4(d-1)} = 0$: the curvature coupling switches off, $X = 0$, and (64.247) gives

$$a_1(x) = [b_1] = \frac{1}{6}R - X = \frac{1}{6}R. \tag{64.269}$$

Hence the two-dimensional trace anomaly of a single free boson is

$$\langle T^\mu{}_\mu \rangle = \frac{1}{4\pi}\cdot\frac{R}{6} = \frac{R}{24\pi}. \tag{64.270}$$

This is the celebrated result $\langle T^\mu{}_\mu \rangle = \frac{c}{24\pi}R$ with central charge $c = 1$ for one real scalar—exactly the Virasoro central charge of the free-boson conformal field theory of Chapter 48, where the same number appears in the commutator $[L_m, L_n] = (m-n)L_{m+n} + \frac{c}{12}m(m^2-1)\delta_{m+n,0}$. The Weyl anomaly and the central extension of the conformal algebra are two faces of the same coefficient: the obstruction to making the stress tensor traceless on a curved background is identical to the obstruction to representing the conformal algebra without a central charge. The four-dimensional a and c of (64.258) are the higher-dimensional descendants of this single two-dimensional c, and the cleanness of

the two-dimensional case—one number, computed from $[b_1]$ in one line—is what makes it the universal entry point to the anomaly.

Worked Example 64.33 (Pure type-A anomaly on the four-sphere)**.** To see the type-A/type-B distinction at work, evaluate (64.258) on the round Euclidean four-sphere S^4, the maximally symmetric compact space. There the Weyl tensor vanishes identically (any maximally symmetric space is conformally flat, $C_{\mu\nu\rho\sigma} = 0$), so $W^2 = 0$ and the type-B contribution is switched off; the curvature is covariantly constant, $\nabla_\rho R_{\mu\nu} = 0$, so $\Box R = 0$ and the scheme-dependent term also drops. Only the topological type-A term survives:

$$\langle T^{\mu}{}_{\mu} \rangle_{S^4} = -\frac{1}{(4\pi)^2}\,\frac{1}{360}\,E_4. \tag{64.271}$$

Integrating over the sphere and using the Gauss–Bonnet formula (64.228) with $\chi(S^4) = 2$,

$$\int d^4x\,\sqrt{g}\;\langle T^{\mu}{}_{\mu} \rangle_{S^4} = -\frac{1}{(4\pi)^2}\,\frac{1}{360}\int d^4x\,\sqrt{g}\;E_4 = -\frac{1}{16\pi^2}\,\frac{1}{360}\,(32\pi^2 \cdot 2) = -\frac{1}{90}. \tag{64.272}$$

The integrated trace anomaly of a conformal scalar on S^4 is the pure number $-\frac{1}{90} = -4a$, independent of the radius of the sphere: rescaling the sphere is a Weyl transformation, and the response is fixed entirely by the Euler characteristic. This is the type-A anomaly in its purest form—a topological invariant of the background times the central charge a—and it is the quantity whose monotonic decrease under RG flow is the content of the a-theorem.

64.6.7 The anomaly is intrinsic

Two regularizations that share no machinery—the spectral determinant and the functional measure—have returned the same local density $a_2(x)/(4\pi)^2$, and the Wess–Zumino condition has told us in advance that its physical content is the two scheme-independent numbers a and c. The trace anomaly is therefore not an artifact of how we computed: it is a fixed, geometric property of the quantum effective action $W[g]$ itself, the statement that $W[g]$ cannot be made Weyl invariant. This recasts the entire chapter. The renormalized stress tensor of Section 64.5, the particle creation of the earlier sections, and the anomaly just computed are all read off from one object, $W[g]$, and its variations. The next section assembles that object explicitly—the curved-space effective action and its Euclidean path integral—and shows that for a stationary spacetime with a horizon the demand that this single functional be smooth selects exactly one temperature. That is the road to Hawking radiation, and it is the anomaly's lesson—geometry fixes the quantum response—carried to its sharpest conclusion.

64.7 The effective action, the Euclidean path integral, and the road to Hawking

The trace anomaly of the previous section delivered a verdict with consequences far beyond the single number it produced. It showed that the act of quantizing a field on a curved background generates physics that is not present in any term of the classical action and cannot be removed by any local counterterm: a conformally invariant classical theory acquires a nonzero $\langle T^{\mu}{}_{\mu} \rangle$ fixed entirely by the local geometry. The natural home of such an irreducible curved-space effect is not the field, nor any single correlator, but the object that packages *all* of them at once — the effective action, the logarithm of the partition function regarded as a functional of the metric. Everything this chapter has built — the mode expansions and Bogoliubov coefficients of the early sections, the Unruh temperature of Section 64.4, the renormalized stress tensor of Section 64.5, and the anomaly — is a derivative, in the literal functional sense, of that one functional. This closing section assembles them into it.

Having done so, we extract the single principle that turns the whole apparatus into a prediction. The Euclidean partition function on a static background is a thermodynamic generating functional, and its inverse temperature is encoded geometrically as the period of imaginary time. When the background has a horizon, that period is not free: continued to imaginary time, a stationary spacetime with a horizon is a smooth manifold at exactly one temperature, $\beta = 2\pi/\kappa$, with κ the surface gravity. This is the entire content of Hawking's result stripped of dynamics; nothing quantum enters it beyond the decision to compute a partition function at all. We then write the equation by which this quantum stress tensor reacts back on the geometry — the semiclassical Einstein equation — and state, with the honesty the frontier demands, exactly when we are entitled to trust it. With that, the baton passes to Chapter 65.

64.7.1 The curved-space effective action and the master relation

Fix a globally hyperbolic spacetime $(\mathcal{M}, g_{\mu\nu})$ and a quantum field — take the real scalar of ϕ^4 theory in its free ($\lambda = 0$) sector, conformally or minimally coupled, as the running example — whose classical action $S[\phi, g]$ depends on both the field and the background metric. In flat space the central object of Chapter 10 was the generating functional $Z[J]$ of Theorem 10.11, a functional of an external source J. On a curved background the metric *is* the source: it couples to the stress tensor exactly as J couples to ϕ, and varying it probes the response of the vacuum. We therefore define the curved-space generating functional by integrating out the field at fixed geometry,

$$Z[g] \;=\; \langle \text{out} | \text{in} \rangle_{g} \;=\; \int \mathcal{D}\phi \, e^{\,iS[\phi, g]}, \tag{64.273}$$

the amplitude for the in-vacuum prepared in the asymptotic past to evolve, on the geometry g, into the out-vacuum of the asymptotic future. (When the two vacua differ — precisely the situation of the particle-creation sections of this chapter — this overlap is less than unity, and we shall read off below how the effective action records that fact.) The object that organizes the theory is its logarithm.

Definition 64.34 (In–out effective action)**.** The *in–out effective action* of the field on the background g is

$$W[g] \;=\; -\,i \ln Z[g], \tag{64.274}$$

the curved-space, metric-sourced counterpart of the connected generating functional $W[J]$ of Theorem 10.36, defined with the same factor of $-i$ adapted to the Minkowski weight e^{iS}.

The single relation that makes $W[g]$ the right object is what its first variation computes. Recall the curved-space (Hilbert, or metric) stress tensor, the operator whose classical version was introduced when this chapter set up fields on a background: it is the response of the matter action to a deformation of the metric,

$$T_{\mu\nu} \;\equiv\; \frac{2}{\sqrt{-g}}\,\frac{\delta S[\phi,g]}{\delta g^{\mu\nu}}, \qquad \text{equivalently} \qquad \delta S \;=\; \frac{1}{2}\int \mathrm{d}^4x\,\sqrt{-g}\;T_{\mu\nu}\,\delta g^{\mu\nu} \tag{64.275}$$

under a variation $\delta g^{\mu\nu}$ of the inverse metric, at fixed field. This is the same tensor whose renormalized expectation value Section 64.5 extracted from the coincidence limit of the propagator; here it appears as a derivative with respect to the metric, and the two faces will be reconciled in a moment.

Theorem 64.35 (The master relation)**.** *The first metric-variation of the in–out effective action is the in–out expectation value of the Hilbert stress tensor:*

$$\frac{\delta W[g]}{\delta g^{\mu\nu}(x)} \;=\; \frac{1}{2}\,\sqrt{-g}\;\langle T_{\mu\nu}(x)\rangle\,, \qquad \langle T_{\mu\nu}\rangle \equiv \frac{\langle \mathrm{out}|T_{\mu\nu}|\mathrm{in}\rangle}{\langle \mathrm{out}|\mathrm{in}\rangle}. \tag{64.276}$$

Proof. Vary Eq. (64.274) with respect to the inverse metric. Because $W = -i\ln Z$,

$$\delta W \;=\; -\,i\,\frac{\delta Z}{Z} \;=\; -\,i\,\frac{1}{Z}\int \mathcal{D}\phi\;\big(i\,\delta S[\phi,g]\big)\,e^{\,iS[\phi,g]} \;=\; \frac{1}{Z}\int \mathcal{D}\phi\;\delta S[\phi,g]\;e^{\,iS[\phi,g]}, \tag{64.277}$$

where the two factors of i have cancelled. The right-hand side is, by the definition of correlators as normalized weighted field-averages established in Chapter 10, the in–out matrix element of δS:

$$\delta W \;=\; \frac{\langle \mathrm{out}|\delta S|\mathrm{in}\rangle}{\langle \mathrm{out}|\mathrm{in}\rangle} \;=\; \langle \delta S\rangle\,. \tag{64.278}$$

The classical variation δS is given by Eq. (64.275); promoting the field bilinear in $T_{\mu\nu}$ to the operator and taking the in–out average term by term,

$$\langle \delta S \rangle \;=\; \frac{1}{2}\int \mathrm{d}^4x\,\sqrt{-g}\;\langle T_{\mu\nu}(x)\rangle\;\delta g^{\mu\nu}(x). \tag{64.279}$$

Since $\delta g^{\mu\nu}(x)$ is arbitrary, comparing Eq. (64.279) with $\delta W = \int \mathrm{d}^4x\,(\delta W/\delta g^{\mu\nu})\,\delta g^{\mu\nu}$ gives Eq. (64.276). □

This is the chapter in one line. The stress tensor that gravitates is the metric-derivative of the effective action, and so the renormalization program of Section 64.5 — which made $\langle T_{\mu\nu}\rangle$ finite by subtracting local geometric counterterms — is identically the statement that $W[g]$ is rendered finite by adding the same local counterterms (built from Λ, R, R^2, $R_{\mu\nu}R^{\mu\nu}$, $R_{\mu\nu\rho\sigma}R^{\mu\nu\rho\sigma}$) to the bare effective action. Renormalizing the stress tensor and renormalizing the effective action are one operation seen through one derivative. The trace anomaly of the previous section is, in the same dictionary, the statement that the renormalized $W[g]$ is *not* invariant under a Weyl rescaling $g_{\mu\nu}\to e^{2\omega}g_{\mu\nu}$ even when the classical S is: its non-invariance is precisely $\int \mathrm{d}^4x\,\sqrt{-g}\,\omega\,\langle T^{\mu}{}_{\mu}\rangle$, with $\langle T^{\mu}{}_{\mu}\rangle$ the anomaly density computed in Section 64.6.

Worked Example 64.36 (The free-field effective action is a functional determinant)**.** For the free scalar the field integral Eq. (64.273) is Gaussian and can be done exactly, exhibiting $W[g]$ as a single geometric object. Write the (minimally coupled, for definiteness; the conformal coupling adds ξR) action as a quadratic form,

$$S[\phi,g] \;=\; \frac{1}{2}\int \mathrm{d}^4x\,\sqrt{-g}\,\Big[\,g^{\mu\nu}\partial_\mu\phi\,\partial_\nu\phi - m^2\phi^2\,\Big] \;=\; -\frac{1}{2}\int \mathrm{d}^4x\,\sqrt{-g}\;\phi\,(\Box_g + m^2)\phi, \tag{64.280}$$

the second equality being one covariant integration by parts, with $\Box_g = g^{\mu\nu}\nabla_\mu\nabla_\nu = (1/\sqrt{-g})\,\partial_\mu(\sqrt{-g}\,g^{\mu\nu}\partial_\nu)$ the curved-space d'Alembertian. The Gaussian functional integral of Section 10.4.5 then evaluates Eq. (64.273) to the inverse square root of the determinant of the kinetic operator,

$$Z[g] \;=\; \big[\det(\Box_g + m^2 - i\epsilon)\big]^{-1/2}, \qquad W[g] \;=\; -i\ln Z[g] \;=\; \frac{i}{2}\,\mathrm{Tr}\ln(\Box_g + m^2 - i\epsilon), \tag{64.281}$$

using $\ln\det = \mathrm{Tr}\ln$, with the $-i\epsilon$ the curved-space inheritance of the Feynman prescription. This is the one-loop effective action of the free field on the background. Three observations close the example. First, Eq. (64.281) is precisely the kind of ratio-of-determinants whose finite definition (zeta-function or heat-kernel regularization) was flagged as a genuine computation in Eq. (10.120) and carried out in Chapter E; on a curved background the proper-time expansion of $\mathrm{Tr}\ln$ in powers of curvature is the DeWitt–Schwinger expansion, whose coefficients are

the local geometric invariants that supply the counterterms. Second, its metric-derivative reproduces the master relation directly: differentiating $\frac{i}{2}\,\mathrm{Tr}\ln(\Box_g+m^2)$ with respect to $g^{\mu\nu}$ brings down the coincidence limit of the Green's function $\langle\phi\,\phi\rangle$, which is exactly the point-split bilinear whose finite part is the renormalized $\langle T_{\mu\nu}\rangle$ of Section 64.5. The two routes to $\langle T_{\mu\nu}\rangle$ — vary the effective action, or point-split the propagator — are the same computation. Third, the imaginary part of Eq. (64.281) is physical and is the bridge back to the start of the chapter: from $|\,\langle\mathrm{out}|\mathrm{in}\rangle\,|^2 = |e^{iW}|^2 = e^{-2\,\mathrm{Im}\,W}$ we read that

$$|\,\langle\mathrm{out}|\mathrm{in}\rangle_g\,|^2 \;=\; \exp\!\big(-2\,\mathrm{Im}\,W[g]\big), \tag{64.282}$$

the vacuum persistence probability. A nonzero $\mathrm{Im}\,W$ is the statement that the in-vacuum does not survive: it is the integrated probability of pair creation, the effective-action face of the Bogoliubov coefficients $|\beta_k|^2$ computed in the early sections of this chapter. Particle creation, the anomaly, and the renormalized stress tensor are thus three derivatives — imaginary part, Weyl variation, and metric variation — of the single functional $W[g]$.

Caution — In–out versus in–in: which expectation value gravitates

The matrix element $\langle T_{\mu\nu}\rangle = \langle\mathrm{out}|T_{\mu\nu}|\mathrm{in}\rangle\,/\,\langle\mathrm{out}|\mathrm{in}\rangle$ produced by Theorem 64.35 is a *transition* amplitude between two different states, and when the vacua differ it is in general complex — its imaginary part is the pair-creation rate of Eq. (64.282). It is exactly what one wants for computing S-matrix elements and vacuum decay, but it is *not* the real, causal expectation value $\langle\psi|T_{\mu\nu}|\psi\rangle$ in a fixed physical state $|\psi\rangle$ that one must feed to Einstein's equation. The object that delivers the genuine expectation value is the *in–in*, or closed-time-path (Schwinger–Keldysh), effective action $W_{\mathrm{CTP}}[g_+,g_-]$: one doubles the time contour, runs the field forward on a metric g_+ and backward on g_-, both ending on the same state, and reads

$$\langle\psi|T_{\mu\nu}(x)|\psi\rangle \;=\; \frac{2}{\sqrt{-g}}\,\frac{\delta W_{\mathrm{CTP}}}{\delta g_+^{\mu\nu}(x)}\bigg|_{g_+=g_-=g}, \tag{64.283}$$

which is automatically real and causal because the doubled contour cancels the disconnected phase that made Eq. (64.276) complex. The renormalized $\langle T_{\mu\nu}\rangle$ of Section 64.5 is this in–in object in a specified state; it is the one that sources gravity below. We use the in–out functional $W[g]$ as the cleaner pedagogical carrier of the master relation, and flag here that the source of the semiclassical Einstein equation is its in–in refinement.

64.7.2 The Euclidean partition function as a thermodynamic generating functional

The most consequential reading of $W[g]$ comes from rotating it to imaginary time. The dictionary of Section 10.6.5 taught that the Wick-rotated generating functional is a statistical-mechanical partition function: under $t = -i\tau$ the Minkowski weight e^{iS} becomes the Euclidean weight e^{-S_E} of Eq. (10.160), and Eq. (12.138) sharpened this into the operator identity

$$Z(\beta) \;=\; \mathrm{Tr}\; e^{-\beta \hat{H}} \;=\; \oint_{\phi(\tau+\beta)=\phi(\tau)} \mathcal{D}\phi\; e^{-S_E[\phi]}, \tag{64.284}$$

the thermal partition function at inverse temperature β, computed as a Euclidean path integral over fields living on a time circle of circumference β, with bosons glued periodically. The periodicity is not a convention: by the Kubo–Martin–Schwinger argument of Eq. (12.139), periodicity of every thermal correlator in imaginary time with period β is forced by cyclicity of the trace, and is the defining property of thermal equilibrium. *Compactness of the Euclidean time circle is temperature, and its circumference is the inverse temperature.*

On a curved (but static) background the same construction goes through. A static metric possesses a timelike Killing vector ∂_t and a foliation by surfaces of constant t; the Euclidean continuation $t = -i\tau$ produces a Riemannian manifold, and identifying $\tau \sim \tau + \beta$ computes the partition function of the field in the static gravitational potential at temperature $1/\beta$. The curved-space effective action evaluated on this Euclidean section,

$$W_E(\beta) \;=\; -\ln Z(\beta), \qquad Z(\beta) = \int \mathcal{D}\phi\; e^{-S_E[\phi, g_E]}, \tag{64.285}$$

is therefore the free energy in units of β: the thermodynamic free energy is $F(\beta) = -\beta^{-1} \ln Z(\beta) = \beta^{-1} W_E(\beta)$, and every equilibrium thermodynamic quantity follows by differentiating it. In particular the thermal expectation value of the stress tensor is the metric-derivative of $\ln Z$ on the Euclidean section — the Euclidean, finite-temperature instance of the master relation Eq. (64.276),

$$\langle T_{\mu\nu} \rangle_\beta \;=\; -\frac{2}{\sqrt{g_E}} \frac{\delta \ln Z(\beta)}{\delta g_E^{\mu\nu}}. \tag{64.286}$$

This is the formula that unifies the chapter. The Unruh temperature of Section 64.4 was derived by recognizing that the Rindler vacuum's correlators are periodic in imaginary Rindler time — exactly the KMS condition Eq. (12.139) — and so represent a thermal state; Eq. (64.286) says that the very same periodicity, fed through the partition function, computes the thermal $\langle T_{\mu\nu} \rangle$ that a uniformly accelerated detector registers and that Section 64.5 rendered finite. The mode sums of the Bogoliubov sections, the detector response of the Unruh section, and the point-split stress tensor of the renormalization section are three computations of the derivatives of one Euclidean free energy.

Worked Example 64.37 (Free energy to thermal stress tensor: the Stefan–Boltzmann law from periodicity)**.** Nothing demonstrates the chain "periodicity ⇒ free energy ⇒ thermal $\langle T_{\mu\nu}\rangle$" like running it once to a known number. Take the free massless scalar on flat space, but with Euclidean time compactified on a circle of circumference β — the simplest curved-from-flat geometry, $S^1_\beta \times \mathbb{R}^3$, whose only "curvature" is the global identification that Eq. (64.284) reads as temperature $T = 1/\beta$. The partition function is the standard bosonic one; per spatial volume V, the free-energy density is the momentum-space sum over the single bosonic mode,

$$f(T) \;=\; \frac{F}{V} \;=\; T\int \frac{\mathrm{d}^3k}{(2\pi)^3}\,\ln\!\big(1-e^{-|\mathbf{k}|/T}\big), \tag{64.287}$$

the vacuum (zero-point) part having been subtracted as the T-independent piece that renormalization removes. The angular integral is trivial, $\int \mathrm{d}^3k/(2\pi)^3 = (2\pi^2)^{-1}\int_0^\infty k^2\,\mathrm{d}k$; substituting $x = k/T$,

$$f(T) \;=\; \frac{T}{2\pi^2}\int_0^\infty \mathrm{d}k\; k^2 \ln\!\big(1-e^{-k/T}\big) \;=\; \frac{T^4}{2\pi^2}\int_0^\infty \mathrm{d}x\; x^2\ln\!\big(1-e^{-x}\big). \tag{64.288}$$

Expand the logarithm, $\ln(1-e^{-x}) = -\sum_{n\ge 1} n^{-1}e^{-nx}$, and use $\int_0^\infty x^2 e^{-nx}\,\mathrm{d}x = 2/n^3$:

$$\int_0^\infty \mathrm{d}x\; x^2\ln\!\big(1-e^{-x}\big) \;=\; -\sum_{n=1}^{\infty}\frac{1}{n}\cdot\frac{2}{n^3} \;=\; -2\sum_{n=1}^{\infty}\frac{1}{n^4} \;=\; -2\,\zeta(4) \;=\; -\frac{\pi^4}{45}, \tag{64.289}$$

with $\zeta(4) = \pi^4/90$. Hence the free-energy density of one massless bosonic degree of freedom is

$$f(T) \;=\; -\frac{\pi^2}{90}\,T^4. \tag{64.290}$$

The thermodynamics follows by differentiation. The entropy density is $s = -\partial f/\partial T = (2\pi^2/45)\,T^3$, the pressure is $p = -f = (\pi^2/90)\,T^4$, and the energy density is the Legendre combination $\rho = f + Ts$,

$$\rho \;=\; -\frac{\pi^2}{90}T^4 + T\cdot\frac{2\pi^2}{45}T^3 \;=\; \Big(-\frac{1}{90}+\frac{4}{90}\Big)\pi^2T^4 \;=\; \frac{\pi^2}{30}\,T^4, \tag{64.291}$$

the Stefan–Boltzmann law for a single scalar (the photon's two polarizations give the familiar $\rho = \pi^2T^4/15$). This ρ is exactly $\langle T_{00}\rangle_\beta$ delivered by Eq. (64.286): the thermal stress tensor in the local rest frame is $\langle T^\mu{}_\nu\rangle_\beta = \mathrm{diag}(\rho,-p,-p,-p)$, and its trace is

$$\langle T^\mu{}_\mu\rangle_\beta \;=\; \rho - 3p \;=\; \frac{\pi^2}{30}T^4 - 3\cdot\frac{\pi^2}{90}T^4 \;=\; 0, \tag{64.292}$$

vanishing because the massless scalar is classically conformal — the thermal state respects the symmetry that, on a generic curved background, the anomaly

of Section 64.6 breaks. We have travelled from a single geometric datum, the circumference β of the Euclidean time circle, to the energy density of thermal radiation, using nothing but the partition function and one differentiation. The same machine, applied to the near-horizon geometry below, will turn a surface gravity into a temperature.

64.7.3 The smoothness principle: $\beta = 2\pi/\kappa$ from regularity of the Euclidean section

The free energy of the last example was computed at an arbitrary temperature; β was a free parameter we dialled at will. The decisive observation — the one that makes Hawking radiation inevitable rather than optional — is that when the static background has a *horizon*, the temperature is no longer free. The Euclidean section is smooth at only one value of β, and that value is dictated by the surface gravity.

Consider a static, spherically symmetric spacetime with metric of the form

$$\mathrm{d}s^2 \;=\; f(r)\,\mathrm{d}t^2 - \frac{\mathrm{d}r^2}{f(r)} - r^2\,\mathrm{d}\Omega^2, \tag{64.293}$$

in the mostly-minus signature, with a simple zero of f at $r = r_h$, so $f(r_h) = 0$ and $f'(r_h) > 0$. The surface $r = r_h$ is a Killing horizon: the norm $f(r)$ of the timelike Killing vector ∂_t vanishes there, the surface is generated by a bifurcate Killing field, and its *surface gravity* is the geometric invariant

$$\kappa \;=\; \tfrac{1}{2}\,f'(r_h), \tag{64.294}$$

the value at which the Killing field's acceleration, measured per unit Killing time, would have to be applied to hold a particle just outside the horizon. We now ask what the Euclidean continuation of Eq. (64.293) looks like in a neighbourhood of r_h, and demand that it be a smooth manifold there.

Wick-rotate $t = -i\tau$. The metric Eq. (64.293) becomes the Riemannian

$$\mathrm{d}s_E^2 \;=\; f(r)\,\mathrm{d}\tau^2 + \frac{\mathrm{d}r^2}{f(r)} + r^2\,\mathrm{d}\Omega^2, \tag{64.295}$$

positive-definite outside the horizon, $r > r_h$. The horizon $r = r_h$, where $f = 0$, is not a surface in the Euclidean manifold: the $\mathrm{d}\tau^2$ term collapses and the would-be horizon is a single point (more precisely, a fixed point of the τ-translation), at which the entire region $r < r_h$ — the Euclidean interior of the black hole — is simply absent. The Euclidean black hole terminates at the horizon; the only question is whether it closes off smoothly or comes to a singular tip. Expand f to first order about r_h,

$$f(r) \;\approx\; f'(r_h)\,(r - r_h) \;=\; 2\kappa\,(r - r_h), \tag{64.296}$$

using Eq. (64.294). Trade the coordinate distance for the proper radial distance ρ from the horizon,

$$\rho \;=\; \int_{r_h}^{r} \frac{\mathrm{d}r'}{\sqrt{f(r')}} \;=\; \int_{0}^{r-r_h} \frac{\mathrm{d}u}{\sqrt{2\kappa u}} \;=\; \sqrt{\frac{2(r-r_h)}{\kappa}}, \tag{64.297}$$

so that $r - r_h = \frac{1}{2}\kappa\rho^2$ and therefore $f(r) = 2\kappa \cdot \frac{1}{2}\kappa\rho^2 = \kappa^2\rho^2$. The radial term becomes $\mathrm{d}r^2/f = \mathrm{d}\rho^2$ exactly, by construction of ρ. The angular sphere has nearly fixed radius $r \approx r_h$ and is an inert spectator. The interesting (τ, ρ) block of Eq. (64.295) collapses near the horizon to

$$\mathrm{d}s_E^2\big|_{\text{near horizon}} \;=\; \mathrm{d}\rho^2 + \kappa^2\rho^2\,\mathrm{d}\tau^2 + r_h^2\,\mathrm{d}\Omega^2 \;=\; \mathrm{d}\rho^2 + \rho^2\,\mathrm{d}\theta^2 + r_h^2\,\mathrm{d}\Omega^2, \qquad \theta \equiv \kappa\,\tau, \tag{64.298}$$

where in the last step we rescaled the imaginary-time coordinate into the dimensionless angle $\theta = \kappa\tau$. The (ρ, θ) part is unmistakable: it is the flat two-dimensional plane written in polar coordinates, with radial coordinate $\rho \geq 0$ and angular coordinate θ.

A plane in polar coordinates is a smooth manifold at the origin $\rho = 0$ if and only if the angular coordinate runs over a full turn of 2π and exactly 2π. If θ ranges over any other period $\Delta\theta$, the geometry near $\rho = 0$ is a cone: a wedge of opening angle $2\pi - \Delta\theta$ is either excised (a deficit, for $\Delta\theta < 2\pi$) or duplicated (an excess), and the tip carries a delta-function of Gaussian curvature equal to the deficit angle. A cone is flat everywhere except at its apex, where it is singular; only the plane, $\Delta\theta = 2\pi$, has no tip at all. This elementary fact of two-dimensional geometry is the whole argument.

Theorem 64.38 (Horizon temperature from smoothness)**.** *The Euclidean section Eq. (64.295) of a static spacetime with a Killing horizon of surface gravity κ extends to a smooth Riemannian manifold across the horizon $\rho = 0$ if and only if the imaginary-time coordinate is periodically identified with period*

$$\boxed{\beta \;=\; \frac{2\pi}{\kappa}} \qquad \Longleftrightarrow \qquad T \;=\; \frac{\kappa}{2\pi}. \tag{64.299}$$

For any other period the manifold has a conical singularity at the horizon with deficit angle $\delta = 2\pi(1 - \beta\kappa/2\pi)$. Consequently a stationary spacetime with a horizon, continued to imaginary time, is regular at exactly one temperature, the universal horizon temperature $T = \kappa/2\pi$.

Proof. By Eq. (64.298) the near-horizon Euclidean geometry is $\mathrm{d}\rho^2 + \rho^2\,\mathrm{d}\theta^2$ with $\theta = \kappa\tau$. Smoothness at $\rho = 0$ requires θ to be a genuine angular coordinate of period 2π, i.e. $\theta \sim \theta + 2\pi$. Since $\theta = \kappa\tau$, this is the condition $\tau \sim \tau + 2\pi/\kappa$, that is, $\beta = 2\pi/\kappa$. If instead $\tau \sim \tau + \beta$ with $\beta \neq 2\pi/\kappa$, then $\theta = \kappa\tau$ has period $\kappa\beta \neq 2\pi$, and the (ρ, θ) plane is a cone of deficit angle $\delta = 2\pi - \kappa\beta = 2\pi(1 - \beta\kappa/2\pi)$. The Gaussian curvature of such a cone is a delta function $2\pi\,\delta\,\delta^{(2)}(\rho)$ concentrated at

the tip; the four-dimensional Ricci scalar inherits this conical curvature singularity supported on the bifurcation surface, so the manifold fails to be smooth precisely when $\beta \neq 2\pi/\kappa$. The temperature $T = 1/\beta = \kappa/2\pi$ is therefore the unique value for which the Euclidean section is a smooth, complete manifold. □

smooth: $\beta = 2\pi/\kappa$
($\theta = \kappa\tau$ closes at 2π)

conical: $\beta \neq 2\pi/\kappa$
(deficit $\delta = 2\pi - \kappa\beta$ at tip)

Figure 64.7: The (ρ, θ) section of the Euclidean horizon, $\mathrm{d}s^2 = \mathrm{d}\rho^2 + \rho^2\,\mathrm{d}\theta^2$ with $\theta = \kappa\tau$. *Left:* when τ has period $\beta = 2\pi/\kappa$ the angle θ closes at exactly 2π and the section is a smooth disk, regular at the tip $\rho = 0$ (the bifurcation surface). *Right:* any other period leaves a wedge of deficit angle $\delta = 2\pi - \kappa\beta$ missing, and the tip is a conical curvature singularity. Regularity selects the single temperature $T = \kappa/2\pi$.

The force of Theorem 64.38 is that it is purely geometric. No field was expanded in modes, no vacuum was chosen, no Bogoliubov coefficient was computed; the temperature is fixed by the differential geometry of a smooth four-manifold. Combined with the partition-function reading of Section 64.7.2 — that the period of Euclidean time *is* the inverse temperature of the field living on the background — it forces the conclusion: a quantum field in equilibrium on a spacetime with a horizon of surface gravity κ is at temperature $\kappa/2\pi$, because that is the only temperature at which the Euclidean partition function it computes is defined on a nonsingular manifold. Any other temperature would have the field propagating on a cone, sensing a curvature singularity at the horizon that is not there in the physical Lorentzian geometry.

Worked Example 64.39 (Rindler as the special case: recovering the Unruh temperature)**.** The cleanest test of Theorem 64.38 is the case the chapter has already solved by hand. The Rindler wedge of Section 64.4 is the near-horizon limit of *any* of these geometries — it is what Eq. (64.298) *is*, with the angular sphere stripped away — and its horizon is the acceleration horizon of a uniformly accelerated observer. For proper acceleration a, the Rindler metric in the mostly-minus signature is

$$\mathrm{d}s^2 \;=\; a^2\xi^2\,\mathrm{d}\eta^2 - \mathrm{d}\xi^2 - \mathrm{d}\mathbf{x}_\perp^2, \tag{64.300}$$

where ξ is the proper distance from the horizon $\xi = 0$ and η is the dimensionless Rindler time conjugate to the boost. Comparing with the static form, the horizon at $\xi = 0$ has surface gravity equal to the proper acceleration: writing the boost Killing field ∂_η and computing its non-affinity gives $\kappa = a$ directly, and indeed Eq. (64.298) with $\rho \leftrightarrow \xi$ and $\kappa\tau \leftrightarrow a\eta_E$ is identical to the Euclidean continuation of Eq. (64.300). The Wick rotation $\eta = -i\eta_E$ turns Eq. (64.300) into $\mathrm{d}s_E^2 = a^2\xi^2\,\mathrm{d}\eta_E^2 + \mathrm{d}\xi^2 + \mathrm{d}\mathbf{x}_\perp^2$, which is flat $\mathbb{R}^2 \times \mathbb{R}^2$ in polar coordinates $(\xi, a\eta_E)$ — and the plane is smooth iff the polar angle $a\eta_E$ closes at 2π, i.e. iff $\eta_E \sim \eta_E + 2\pi/a$. By Eq. (64.299) with $\kappa = a$, the temperature is

$$T_{\mathrm{U}} \;=\; \frac{\kappa}{2\pi} \;=\; \frac{a}{2\pi}, \tag{64.301}$$

the Unruh temperature, recovered here from a single demand — that Euclidean Minkowski space be the smooth plane it manifestly is — rather than from the mode-by-mode Bogoliubov computation of Section 64.4. The two derivations agree because they are the same statement seen from two sides: the Bogoliubov coefficients of the Rindler modes are thermal at $a/2\pi$ precisely because the Minkowski vacuum's correlators are periodic in imaginary Rindler time with period $2\pi/a$, and that periodicity is the smoothness of the Euclidean plane. Rindler is the flat, $\kappa = a$ instance of the universal horizon formula; the black hole is the curved instance that Chapter 65 will treat, where the same Eq. (64.299) promotes the surface gravity $\kappa = 1/4GM$ to the Hawking temperature $T_H = 1/8\pi GM$.

64.7.4 The semiclassical Einstein equation and the backreaction program

We have, on one side, a finite renormalized stress tensor $\langle T_{\mu\nu}\rangle_{\mathrm{ren}}$ that the quantum field carries on any background; on the other, the geometry that the field lives on. The closing structural step of the chapter is to let the two react on each other. The principle is the one that produced Einstein's equation classically: extremize the total action over the metric. Here the total action is the gravitational action plus the quantum effective action of the matter,

$$\Gamma_{\mathrm{tot}}[g] \;=\; S_{\mathrm{grav}}[g] + W[g], \qquad S_{\mathrm{grav}}[g] \;=\; \frac{1}{16\pi G}\int \mathrm{d}^4x\,\sqrt{-g}\,(R - 2\Lambda), \tag{64.302}$$

with G Newton's constant and Λ the cosmological constant. The matter has been integrated out: $W[g]$ already contains the full quantum dynamics of the field as a functional of the metric, and its metric-derivative is the stress tensor by the master relation. Stationarity of Γ_{tot} under $\delta g^{\mu\nu}$ gives the field equation of the metric. The gravitational variation is the standard Einstein–Hilbert one,

$$\frac{\delta S_{\mathrm{grav}}}{\delta g^{\mu\nu}} \;=\; \frac{\sqrt{-g}}{16\pi G}\,(G_{\mu\nu} + \Lambda\, g_{\mu\nu}), \qquad G_{\mu\nu} = R_{\mu\nu} - \tfrac{1}{2}R\, g_{\mu\nu}, \tag{64.303}$$

with the curvature conventions of Chapter A, and the matter variation is the in–in master relation of Section 64.7.1, $\delta W/\delta g^{\mu\nu} = \tfrac{1}{2}\sqrt{-g}\,\langle T_{\mu\nu}\rangle_{\rm ren}$. Setting the sum to zero yields the central equation of semiclassical gravity.

Definition 64.40 (Semiclassical Einstein equation)**.** A classical metric $g_{\mu\nu}$ and a quantum state $|\psi\rangle$ of the matter fields satisfy the *semiclassical Einstein equation* when

$$\boxed{G_{\mu\nu} + \Lambda\, g_{\mu\nu} \;=\; 8\pi G\,\langle T_{\mu\nu}\rangle_{\rm ren}} \tag{64.304}$$

holds, with $\langle T_{\mu\nu}\rangle_{\rm ren} \equiv \langle\psi|T_{\mu\nu}|\psi\rangle_{\rm ren}$ the renormalized expectation value of Section 64.5 in the state $|\psi\rangle$ on the background g.

Notation Watch — Curvature and stress-tensor signs

The relative sign on the two sides of Eq. (64.304) is the one fixed by the Newtonian limit — a positive energy density $\langle T_{00}\rangle > 0$ must produce attractive gravity. In the mostly-minus signature this requires a definite joint choice of the sign of the Riemann tensor (entering $G_{\mu\nu}$ via Eq. (64.303)) and of the Hilbert stress tensor Eq. (64.275); both are the conventions collected in Chapter A, chosen precisely so that the classical equation reads $G_{\mu\nu} + \Lambda g_{\mu\nu} = 8\pi G\, T_{\mu\nu}$ with the Hilbert definition. We adopt them throughout; the only modification in passing to the semiclassical theory is the replacement $T_{\mu\nu} \to \langle T_{\mu\nu}\rangle_{\rm ren}$.

Equation Eq. (64.304) is the precise statement of what "quantum fields backreact on geometry" means in this chapter, and it deserves to be read carefully, because every word is a deliberate approximation. The left side is purely classical: the metric $g_{\mu\nu}$ is a c-number, a definite geometry, not an operator. The right side is the quantum expectation value of the stress-tensor operator in a chosen state, rendered finite by the geometric subtractions of Section 64.5. The equation couples a classical source-geometry to a quantum mean source. It is the gravitational analogue of the mean-field, or one-loop, treatment of any quantum system coupled to a slow classical variable: the fast quantum field is integrated out and replaced by its expectation value, which then drives the slow classical geometry. The cosmological constant Λ on the left is renormalized together with the vacuum energy on the right; the splitting between "geometric Λ" and "the constant piece of $\langle T_{\mu\nu}\rangle$" is a renormalization choice, and the failure to predict the physical remainder is the cosmological constant problem to which we return below.

The *backreaction program* is the iterative use of Eq. (64.304). One starts with a background geometry, computes $\langle T_{\mu\nu}\rangle_{\rm ren}$ on it in the state of interest, feeds that stress tensor back as a source, and solves for the corrected metric — repeating until self-consistency. For Hawking radiation the program is exactly the statement that the flux of created quanta carries energy away from the black

hole, so the right side of Eq. (64.304) has a nonzero outward energy flux at infinity, and the corrected left side describes a hole whose mass slowly decreases: the evaporation that Chapter 65 will compute. For cosmology it is the statement that quantum fields in an expanding universe carry an energy density that sources the expansion, the origin of particle-production-driven backreaction in the early universe.

64.7.5 Honest scope: where the semiclassical theory is trustworthy, and where it breaks

The semiclassical Einstein equation is an approximation, and a textbook that has insisted on honest rigor must say precisely what the approximation neglects and when the neglect is illegitimate. Two conditions must hold for Eq. (64.304) to be a controlled description, and a list of named situations violates them.

Condition one: curvatures small in Planck units. The derivation treated the metric as classical and the matter as a quantum field on it, with gravity itself unquantized. This is the leading term of an expansion in $\ell_P^2 = G$ (the Planck length squared, $G = 1/M_P^2$ with $M_P \approx 1.22 \times 10^{19}\,\mathrm{GeV}$): graviton loops, the quantization of $g_{\mu\nu}$ itself, contribute at relative order $G \times$ (curvature). The semiclassical equation is trustworthy only where the curvature invariants are far below the Planck scale, $|R_{\mu\nu\rho\sigma}| \ll \ell_P^{-2}$. For an astrophysical black hole the curvature at the horizon, $\sim 1/(GM)^2$, is fantastically sub-Planckian, and the approximation is superb; near the endpoint of evaporation, when the hole shrinks to the Planck mass, the curvature reaches ℓ_P^{-2} and the semiclassical treatment fails completely. This is the boundary at which Chapter 65's evaporation calculation must hand over to whatever the correct theory of quantum gravity is.

Condition two: small fluctuations of the stress tensor. Replacing the operator $T_{\mu\nu}$ by its expectation value $\langle T_{\mu\nu}\rangle$ is justified only when the operator does not fluctuate much about its mean — when the variance $\langle T_{\mu\nu}T_{\rho\sigma}\rangle - \langle T_{\mu\nu}\rangle\,\langle T_{\rho\sigma}\rangle$ is small compared to $\langle T_{\mu\nu}\rangle^2$ in the relevant smeared sense. Where the fluctuations are large the mean-field picture is meaningless: the geometry would respond to a quantity that is not sharp, and one needs either the in–in (stochastic-gravity) framework that promotes the fluctuations to a noise source driving the metric, or a genuinely quantum treatment of the geometry. This is the Kuo–Ford criterion [310], and it warns that the semiclassical equation can be self-consistent on average yet wrong in detail precisely in the regimes of greatest interest — few-quanta states, the late stages of evaporation, and any situation where $\langle T_{\mu\nu}\rangle$ nearly cancels.

Named breakdowns and open problems (as of the mid-2020s). Beyond these two conditions sit genuine unsettled issues, which we record honestly rather than paper over. First, *well-posedness*: equation Eq. (64.304) as literally written contains higher-derivative terms (the renormalized $\langle T_{\mu\nu}\rangle$ depends on R^2-type curvature combinations whose coefficients absorb the divergences),

and higher-derivative field equations generically admit runaway "Ostrogradsky" solutions; the standard resolution is to treat the higher-derivative pieces perturbatively via order-reduction [443], which is consistent within the regime of validity but signals that the equation is an effective, not fundamental, statement. Second, the *cosmological constant problem*: the vacuum energy in $\langle T_{\mu\nu}\rangle$ is quartically sensitive to the cutoff and must be cancelled against the bare Λ to roughly sixty decimal places to match the observed value; no symmetry of the semiclassical theory explains the smallness of the remainder, and this is among the sharpest unsolved problems in physics. Third, the *trans-Planckian problem* of Hawking radiation: tracing an outgoing late-time quantum back to the horizon assigns it an exponentially blueshifted, ultimately super-Planckian frequency in the early-time frame, so the derivation formally invokes the field theory in a regime where condition one fails; the robustness of the thermal spectrum to this — demonstrated by its insensitivity to modified dispersion relations and by the smoothness argument of Theorem 64.38, which never mentions high frequencies — is reassuring but not a closed proof, and Chapter 65 confronts it directly. Fourth, *state dependence and existence of states*: the renormalized $\langle T_{\mu\nu}\rangle$ requires a physically admissible (Hadamard) state to be defined at all, and on a general background the choice of state is not unique; the uniqueness and thermal character of states on spacetimes with a bifurcate Killing horizon — the rigorous backbone of the smoothness principle above — is the content of the Kay–Wald theorem [292], but the global existence of a sensible vacuum in fully dynamical, non-stationary spacetimes remains delicate. Finally, the semiclassical equation says nothing about the *information problem*: it describes the mean stress-energy of the Hawking flux but not the quantum correlations that would have to encode the infalling information, and resolving that tension is the frontier that carries this part of the book into the holographic ideas of Part XV.

These limitations do not undermine the framework; they delimit it. Within its domain — sub-Planckian curvatures, well-behaved states, modest fluctuations — the semiclassical theory is a precise and predictive effective description, and it is exactly the domain in which Hawking's calculation lives. We have assembled its three working parts: the smoothness principle Eq. (64.299), which fixes the horizon temperature $\beta = 2\pi/\kappa$ from geometry alone; the renormalized $\langle T_{\mu\nu}\rangle_{\text{ren}}$ of Section 64.5, which is the matter that gravitates; and the semiclassical Einstein equation Eq. (64.304), which lets the matter shape the metric. With these in hand, Chapter 65 turns the temperature into a spectrum, the spectrum into a luminosity, and the luminosity into the evaporation and thermodynamics of black holes — the destination the entire chapter has been climbing toward.

Further reading

The foundational papers are Hawking's derivation of black-hole radiance [255], Unruh's analysis of the accelerated detector and horizon [477], Fulling's discovery of the ambiguity of particle content [205], and the Euclidean-thermodynamics viewpoint of Gibbons and Hawking [220] together with Hawking's zeta-function treatment of curved-space path integrals [257]. The point-splitting construction of the renormalized stress tensor is Christensen [122]; DeWitt's review [145] remains the canonical synthesis of the effective-action approach. The textbook treatments of Birrell and Davies [76] and of Parker and Toms [380] develop the whole apparatus at length, and Wald's monograph [488] is the rigorous reference for the algebraic and thermodynamic structure, including the bifurcate-horizon uniqueness theorem with Kay [292]. On the limits of the semiclassical equation, see the fluctuation criterion of Kuo and Ford [310], the order-reduction treatment of higher-derivative dynamics by Simon [443], the backreaction analysis of Wald [487], and the energy-condition study of Flanagan and Wald [195]. None of these is needed to follow the development above, which is self-contained; they are where to go to deepen each thread.

Chapter 65

Hawking Radiation and the Semiclassical Frontier

The preceding chapter built the apparatus of quantum field theory on a fixed curved background: the Klein–Gordon inner product and the positive/negative frequency splitting it induces (Theorem 64.6), the Bogoliubov transformation relating two such splittings (Theorem 64.11), the renormalized stress tensor (Section 64.5), and the lesson of the Unruh effect (Theorem 64.20) that "particle" is an observer-dependent notion. None of that machinery cares what the background is. This chapter supplies the one physical input that turns it into the most consequential prediction of the subject: take the background to be a star that collapses to a black hole. The free real scalar of ϕ^4 theory at $\lambda = 0$ (Chapter 9) does all the work as the matter field; the geometry, not any self-interaction, manufactures the effect. We keep $\hbar = c = 1$ but restore Newton's constant G throughout, because its appearance in the final temperature is the whole point.

The arc is built around a single kinematic fact and several independent derivations of its consequence. The fact, extracted in the opening section, is that an outgoing ray reaching a distant observer at late retarded time u, traced back through the collapsing matter to past null infinity, is squeezed against the horizon-forming critical ray by a *logarithmic* law $u = -\kappa^{-1}\ln\big((v_0 - v)/C\big)$ whose only surviving parameter is the surface gravity $\kappa = 1/4GM$. Feeding this map into the Bogoliubov machinery converts the logarithm, through a single branch cut, into a Boltzmann factor: the in-vacuum radiates a Planck spectrum at the Hawking temperature $T_H = \kappa/2\pi = 1/8\pi GM$. Dressing the bare horizon spectrum with the greybody transmission of the Regge–Wheeler barrier yields the luminosity, the M^3 evaporation law, and the finite lifetime, completing the picture of the hole as a slowly shrinking thermal body.

That body obeys thermodynamics exactly, not by analogy. We establish the four laws of black-hole mechanics, fix the Bekenstein–Hawking entropy $S_{\mathrm{BH}} = A/4G$ with its coefficient pinned by the computed temperature, and

state the generalized second law that survives evaporation, importing the precise information paradox, the Page curve, the Bekenstein bound, and the island prescription from Chapter 57, and the Ryu–Takayanagi and holographic dictionaries from Chapters 53 and 56. The same temperature and entropy then reappear from an utterly different direction: the Euclidean gravitational path integral, the e^{-S_E} pillar built for scalars in Chapter 10, makes the black hole a smooth saddle whose imaginary-time period is forced to be $\beta = 8\pi GM$ and whose on-shell action is $\beta M - A/4G$. A third route reads the flux off purely local horizon data, recruiting the trace and gravitational anomalies of Chapter 36 and the conformal stress tensor and its Schwarzian transformation of Chapters 47 and 48.

The final two sections turn from confirmation to the conceptual frontier. The derivations all lean on modes blueshifted past the Planck scale near the horizon; we confront this trans-Planckian problem and dismantle it four ways — by an infrared adiabatic argument, by explicit modified-dispersion calculations, by Unruh's analog "dumb holes" (now realized in the laboratory), and by the Parikh–Wilczek tunneling computation, whose energy-conserving correction is the first crack in exact thermality. That crack opens onto the information problem: a pure collapsing state appears to evaporate into a mixed thermal cloud, in conflict with unitarity. We state the paradox as a clash of four premises, make it quantitative with the entanglement entropy and the Page curve, survey the proposed resolutions honestly and dated, and close where the book's long development has been heading since the first free scalar was quantized in Chapter 9 — at the gravity/quantum-mechanics frontier, where the gravitational path integral, through its replica-wormhole saddles, has by the mid-2020s been shown to reproduce the unitary Page curve in controlled models.

65.1 The Collapse Geometry and the Geometric-Optics Map

The apparatus assembled in Chapter 64 is, in a precise sense, complete: a free quantum field on a fixed curved background, the Klein–Gordon inner product that splits its mode space into positive- and negative-frequency halves (Theorem 64.6), the Bogoliubov transformation that relates two such splittings (Theorem 64.11), and the lesson of the Unruh effect (Theorem 64.20) that the word "particle" is observer-dependent because the splitting is. None of that machinery cares what the background actually is. The single new physical input of this chapter is to take the background to be the spacetime of a star that collapses to form a black hole, and the whole startling conclusion — that the hole radiates thermally — will turn out to rest on one kinematic fact about that spacetime. The fact is this: an outgoing light ray that reaches a distant observer at late times, traced backwards through the collapsing star to the distant past, is squeezed against a critical ray according to a *logarithmic* law, and the rate of that squeezing is set

by a single number, the surface gravity κ of the horizon that forms. Everything in Section 65.2 is then arithmetic on this one relation.

This section builds the geometry from the ground up and extracts that relation in full. We first construct the exterior Schwarzschild field and define its surface gravity invariantly, computing $\kappa = 1/4GM$ two independent ways. We introduce the null coordinates — tortoise, Eddington–Finkelstein, Kruskal — in which the near-horizon structure is transparent, and isolate the exact relation $U = -\kappa^{-1}e^{-\kappa u}$ between the Schwarzschild outgoing coordinate u and the regular Kruskal coordinate U that crosses the horizon smoothly. We then glue an interior onto the exterior to make an honest collapse spacetime, trace a high-frequency wave packet backwards through it by geometric optics — handling the reflection through the regular centre $r = 0$ explicitly rather than by assertion — and arrive at the late-time matching $u = -\kappa^{-1}\ln\big((v_0 - v)/C\big)$. Finally we show this law is *universal*: its functional form depends on κ alone and not on a single detail of how the star collapsed, which is exactly why the late-time radiation forgets its origin. The carried matter field throughout is the free real scalar ϕ of ϕ^4 theory at $\lambda = 0$ (Chapter 9); the geometry, not the self-interaction, does all the work, so we need only the free field, and we keep it massless except where noted.

We restore Newton's constant G explicitly for the rest of the chapter — gravity is dimensionful and the appearance of G in the final temperature is the whole point — while retaining $\hbar = c = 1$ and the mostly-minus signature $\eta_{\mu\nu} = \mathrm{diag}(+,-,-,-)$.

65.1.1 The exterior geometry and its surface gravity

A spherically symmetric vacuum spacetime is, by Birkhoff's theorem, necessarily static and equal to the Schwarzschild solution outside the matter. We take this as our exterior. With Newton's constant explicit and in the mostly-minus signature, the line element is

$$\mathrm{d}s^2 = f(r)\,\mathrm{d}t^2 - f(r)^{-1}\,\mathrm{d}r^2 - r^2\,\mathrm{d}\Omega^2, \qquad f(r) = 1 - \frac{2GM}{r}, \tag{65.1}$$

where $\mathrm{d}\Omega^2 = \mathrm{d}\theta^2 + \sin^2\theta\,\mathrm{d}\varphi^2$ is the round metric on the unit two-sphere and M is the mass of the hole (the ADM mass measured at infinity). The coordinate range of the static exterior is $r > 2GM$, where $f(r) > 0$. The coefficient f vanishes at the Schwarzschild radius $r = 2GM$; this is the event horizon, and $r < 2GM$ is the black-hole interior.

The exterior is static and spherically symmetric, so it carries a distinguished timelike Killing vector field,

$$\chi^\mu = (\partial_t)^\mu = (1,0,0,0), \qquad \chi_\mu = g_{\mu\nu}\chi^\nu = (f,0,0,0), \tag{65.2}$$

whose norm is

$$\chi^\mu\chi_\mu = g_{tt} = f(r) = 1 - \frac{2GM}{r}. \tag{65.3}$$

This norm is the single most important diagnostic of the geometry. For $r > 2GM$ it is positive: χ is timelike, and a worldline that follows it at fixed (r, θ, φ) is the worldline of a static observer hovering at radius r. At $r = 2GM$ the norm vanishes: χ becomes *null*. The hypersurface $r = 2GM$ on which a timelike Killing field degenerates to a null one is, by definition, a *Killing horizon*, and χ is tangent to its null generators. That a static observer cannot exist at or below $r = 2GM$ — there is no timelike Killing direction to follow — is the coordinate-invariant statement that $r = 2GM$ is a horizon.

We now want a number that measures how strongly the geometry pulls at that horizon. The naive answer, the proper acceleration of a static observer, diverges as the horizon is approached (we verify this below), so it is not the right invariant. The right invariant is the *surface gravity*, which is finite because it is the acceleration measured by the static observer but redshifted out to infinity.

Definition 65.1 (Surface gravity)**.** Let χ be the horizon-generating Killing field of a Killing horizon $\mathcal{H}$, normalized so that $\chi^\mu \chi_\mu \to 1$ at spatial infinity. On $\mathcal{H}$ the integral curves of χ are null geodesics, but χ is in general not an affine parameter along them; it fails to be affine by a function κ, the surface gravity, defined by

$$\chi^\nu \nabla_\nu \chi^\mu \;=\; \kappa\, \chi^\mu \qquad \text{on } \mathcal{H}. \tag{65.4}$$

Equivalently, on a Killing horizon κ is given by the manifestly invariant formula

$$\kappa^2 \;=\; -\tfrac{1}{2}\,(\nabla^\mu \chi^\nu)(\nabla_\mu \chi_\nu)\Big|_{\mathcal{H}}. \tag{65.5}$$

The equivalence of Eqs. (65.4) and (65.5) on a Killing horizon is a standard piece of geometry; we will simply use whichever is more convenient and check that both give the same number. To see where Eq. (65.4) comes from, note that the Killing equation $\nabla_\mu \chi_\nu + \nabla_\nu \chi_\mu = 0$ together with hypersurface-orthogonality of χ (which holds here because the metric is static) implies that the gradient of the norm is proportional to χ on the horizon. Indeed, using the Killing antisymmetry,

$$\nabla_\nu (\chi^\mu \chi_\mu) = 2\, \chi^\mu \nabla_\nu \chi_\mu = -2\, \chi^\mu \nabla_\mu \chi_\nu, \tag{65.6}$$

so that $\chi^\mu \nabla_\mu \chi_\nu = -\tfrac{1}{2} \nabla_\nu (\chi^\mu \chi_\mu)$; on the horizon the right-hand side is proportional to χ_ν, with the constant of proportionality being κ. This is the precise content of "the redshifted acceleration of the static Killing field."

Theorem 65.2 (Surface gravity of Schwarzschild)**.** *For the Schwarzschild metric Eq. (65.1) the surface gravity of the horizon $r = 2GM$ is*

$$\kappa \;=\; \tfrac{1}{2}\, f'(r)\big|_{r=2GM} \;=\; \frac{1}{4GM}. \tag{65.7}$$

Proof. We evaluate the invariant Eq. (65.5). The covariant derivative of the Killing covector $\chi_\nu = f\, \delta^t_\nu$ is $\nabla_\mu \chi_\nu = \partial_\mu \chi_\nu - \Gamma^\lambda_{\mu\nu} \chi_\lambda$. The only Christoffel symbol

we need is $\Gamma^t_{tr} = f'/2f$, which follows from $\Gamma^t_{tr} = \tfrac{1}{2}g^{tt}\partial_r g_{tt} = \tfrac{1}{2}f^{-1}f'$. Therefore

$$\nabla_r \chi_t = \partial_r \chi_t - \Gamma^t_{rt}\,\chi_t = f' - \frac{f'}{2f}\,f = \frac{f'}{2}, \tag{65.8}$$

and by the Killing antisymmetry $\nabla_t \chi_r = -\nabla_r \chi_t = -f'/2$. These two are the only nonvanishing components of $\nabla_\mu \chi_\nu$. Raising indices with $g^{tt} = f^{-1}$ and $g^{rr} = -f$ (read off from Eq. (65.1), recalling $g_{rr} = -f^{-1}$), we contract:

$$\begin{aligned}(\nabla^\mu \chi^\nu)(\nabla_\mu \chi_\nu) &= g^{rr}g^{tt}(\nabla_r\chi_t)^2 + g^{tt}g^{rr}(\nabla_t\chi_r)^2 \\ &= 2\,g^{rr}g^{tt}\Big(\frac{f'}{2}\Big)^2 = 2\,(-f)(f^{-1})\frac{f'^2}{4} = -\frac{f'^2}{2}.\end{aligned} \tag{65.9}$$

Hence $\kappa^2 = -\tfrac{1}{2}(-f'^2/2) = f'^2/4$, i.e. $\kappa = \tfrac{1}{2}f'$. For Schwarzschild $f'(r) = 2GM/r^2$, so at the horizon

$$\kappa = \tfrac{1}{2}f'(2GM) = \tfrac{1}{2}\cdot\frac{2GM}{(2GM)^2} = \frac{1}{4GM}. \qquad \square$$

The number $\kappa = 1/4GM$ is the protagonist of the chapter. Two features deserve emphasis immediately. First, κ has dimensions of inverse length (equivalently, with $\hbar = c = 1$ restored later, of energy), and it grows as the hole gets *lighter*: a small black hole has a fierce surface gravity. Second, the derivation used only the function f and its first derivative at the horizon. Any static, spherically symmetric horizon with $f(r_h) = 0$ has $\kappa = \tfrac{1}{2}f'(r_h)$; the specific value $1/4GM$ is special to Schwarzschild, but the formula is general, a fact Section 65.4 and the sibling sections will lean on.

To confirm that Eq. (65.7) really is the redshifted acceleration — the physically transparent definition — we compute it that way as well. This is exactly the kind of check the book does on the page rather than asserting.

Worked Example 65.3 (Surface gravity as redshifted acceleration)**.** A static observer at radius r has four-velocity tangent to χ, normalized to unit timelike norm:

$$u^\mu = \frac{\chi^\mu}{\sqrt{\chi^\nu\chi_\nu}} = \Big(f^{-1/2}, 0, 0, 0\Big), \qquad u^\mu u_\mu = 1. \tag{65.10}$$

Its proper acceleration is $a^\mu = u^\nu \nabla_\nu u^\mu$. Because the configuration is static, $\partial_t u^\mu = 0$ and only the connection term survives:

$$a^\mu = u^t u^t\,\Gamma^\mu_{tt} = f^{-1}\,\Gamma^\mu_{tt}. \tag{65.11}$$

The relevant Christoffel symbol is $\Gamma^r_{tt} = -\tfrac{1}{2}g^{rr}\partial_r g_{tt} = -\tfrac{1}{2}(-f)f' = \tfrac{1}{2}ff'$, so $a^r = f^{-1}\cdot\tfrac{1}{2}ff' = \tfrac{1}{2}f'$ and all other components vanish. The acceleration is purely radial, as it must be: the observer fires rockets straight down to stay put. Its invariant magnitude (a spacelike vector, so we take $a = \sqrt{-a_\mu a^\mu}$) is

$$a = \sqrt{-g_{rr}\,(a^r)^2} = \sqrt{f^{-1}\Big(\tfrac{1}{2}f'\Big)^2} = \frac{f'(r)}{2\sqrt{f(r)}}. \tag{65.12}$$

As $r \to 2GM$ the denominator $\sqrt{f} \to 0$ and a diverges: the local force needed to hover diverges at the horizon, as anticipated. The energy of a photon emitted by this observer is redshifted on its way to infinity by exactly the factor $V(r) = \sqrt{f(r)}$ (the norm of χ), since the conserved Killing energy is $E_\infty = \chi_\mu p^\mu = V\, E_{\rm local}$. The acceleration "as seen from infinity" is therefore $V\, a$, and its horizon limit is finite:

$$\kappa = \lim_{r\to 2GM} V(r)\, a(r) = \lim_{r\to 2GM} \sqrt{f}\,\frac{f'}{2\sqrt{f}} = \tfrac{1}{2} f'(2GM) = \frac{1}{4GM}. \tag{65.13}$$

The infinite local force, weighted by the infinite redshift, leaves a finite residue: the surface gravity. This matches Eq. (65.7) exactly, confirming that the Killing-normalization definition and the redshifted-acceleration definition agree.

65.1.2 Null coordinates and the near-horizon relation

Radiation propagates along null rays, so to track phases we need coordinates adapted to the light cones. We build them in three steps: the tortoise coordinate straightens out the radial null geodesics, the Eddington–Finkelstein coordinates turn the metric into a product of null one-forms, and the Kruskal coordinates remove the coordinate singularity at the horizon. The payoff is the exact relation between the Schwarzschild retarded time and the Kruskal coordinate, which is the seed of the logarithm.

Radial null rays satisfy $\mathrm{d}s^2 = 0$ with $\mathrm{d}\Omega = 0$, i.e. $f\,\mathrm{d}t^2 = f^{-1}\mathrm{d}r^2$, or $\mathrm{d}t = \pm f^{-1}\mathrm{d}r$. This motivates the *tortoise coordinate* r_* defined by

$$\frac{\mathrm{d}r_*}{\mathrm{d}r} = \frac{1}{f(r)}, \qquad r_* = r + 2GM\,\ln\!\Big(\frac{r}{2GM} - 1\Big), \tag{65.14}$$

in terms of which radial null rays are simply $t \mp r_* = \text{const}$. Two features of Eq. (65.14) are decisive for everything that follows. As $r \to \infty$, $r_* \to r$ and the geometry is asymptotically flat. As $r \to 2GM^+$, the argument of the logarithm vanishes and $r_* \to -\infty$ *logarithmically*: the horizon is pushed to infinite tortoise distance. Near the horizon, writing $r = 2GM + \epsilon$ with $0 < \epsilon \ll 2GM$,

$$r_* \simeq 2GM\,\ln\!\Big(\frac{\epsilon}{2GM}\Big) + \text{const}, \qquad f \simeq \frac{\epsilon}{2GM} = e^{\,r_*/2GM}\cdot(\text{const}), \tag{65.15}$$

where in the second relation we inverted the first. Since $2GM = 1/2\kappa$ by Eq. (65.7), this reads $f \simeq e^{2\kappa r_*}$ up to a positive constant. *The logarithm in the tortoise coordinate, and the exponential it implies for f, are the surface gravity's fingerprint, and they will reappear directly in the phase map.*

Define the retarded and advanced null coordinates

$$u = t - r_*, \qquad v = t + r_*, \tag{65.16}$$

so that outgoing radial rays are $u = \text{const}$ and ingoing radial rays are $v = \text{const}$. At infinity u and v are the physical retarded and advanced times an asymptotic observer reads off; the field of an outgoing quantum of frequency ω carries the phase $e^{-i\omega u}$ there. In these coordinates $\mathrm{d}t = \frac{1}{2}(\mathrm{d}u + \mathrm{d}v)$ and $\mathrm{d}r = f\,\mathrm{d}r_* = \frac{1}{2}f(\mathrm{d}v - \mathrm{d}u)$, and a one-line computation collapses the metric to

$$\mathrm{d}s^2 = f(r)\,\mathrm{d}u\,\mathrm{d}v - r^2\,\mathrm{d}\Omega^2, \tag{65.17}$$

with r now an implicit function of $v - u = 2r_*$. This is the Eddington–Finkelstein form. It is regular nowhere new — f still vanishes at the horizon — but it exposes the null structure cleanly, and it is the right starting point for removing the singularity.

The vanishing of f at $r = 2GM$ is a coordinate artifact: the curvature invariants (e.g. $R_{\mu\nu\rho\sigma}R^{\mu\nu\rho\sigma} = 48G^2M^2/r^6$) are perfectly finite there. To exhibit a regular chart we rescale the null coordinates exponentially. Define the *Kruskal* null coordinates

$$U = -\frac{1}{\kappa}\,e^{-\kappa u}, \qquad V = +\frac{1}{\kappa}\,e^{+\kappa v}. \tag{65.18}$$

Then $\mathrm{d}U = e^{-\kappa u}\,\mathrm{d}u$ and $\mathrm{d}V = e^{\kappa v}\,\mathrm{d}v$, so

$$\mathrm{d}U\,\mathrm{d}V = e^{-\kappa u}e^{\kappa v}\,\mathrm{d}u\,\mathrm{d}v = e^{\kappa(v-u)}\,\mathrm{d}u\,\mathrm{d}v = e^{2\kappa r_*}\,\mathrm{d}u\,\mathrm{d}v, \tag{65.19}$$

and therefore $\mathrm{d}u\,\mathrm{d}v = e^{-2\kappa r_*}\mathrm{d}U\,\mathrm{d}V$. Inserting this into Eq. (65.17),

$$\mathrm{d}s^2 = f\,e^{-2\kappa r_*}\,\mathrm{d}U\,\mathrm{d}V - r^2\,\mathrm{d}\Omega^2. \tag{65.20}$$

By Eq. (65.15), $f \simeq e^{2\kappa r_*}$ near the horizon, so the prefactor $f\,e^{-2\kappa r_*} \to (\text{const})$ stays finite and nonzero as $r \to 2GM$. (Globally one finds $f\,e^{-2\kappa r_*} = (2GM/r)\,e^{-r/2GM}\cdot\text{const}$, manifestly smooth and positive across $r = 2GM$.) The Kruskal chart is regular at the horizon, which now sits at $U = 0$. From Eq. (65.18), $U = 0$ is reached only as $u \to +\infty$: *the future horizon is the surface $u = +\infty$, packed by the exponential into $U = 0$.* This is the geometric heart of the matter and we record it as the central relation of the subsection,

$$\boxed{U = -\frac{1}{\kappa}\,e^{-\kappa u}} \qquad \Longleftrightarrow \qquad u = -\frac{1}{\kappa}\,\ln(-\kappa U), \quad U < 0. \tag{65.21}$$

A surface of constant outgoing Schwarzschild time u is a surface of constant U; as u runs from $-\infty$ to $+\infty$, the regular coordinate U runs from $-\infty$ to 0^-. Equal increments of late-time u correspond to *exponentially small* increments of U. This exponential relation, read in reverse in Section 65.1.4, becomes the logarithm.

It is worth seeing where the surface gravity lives in this picture in Killing-vector language, since it makes the universality argument later transparent. The

Killing field Eq. (65.2) is $\chi = \partial_t = \partial_u + \partial_v$ (as u, v both contain t linearly), and under Eq. (65.18) this becomes

$$\chi = \kappa(V\,\partial_V - U\,\partial_U). \tag{65.22}$$

Its norm is proportional to $f \propto -UV$ (up to the smooth positive prefactor), vanishing on both branches $U = 0$ and $V = 0$ of the horizon, confirming Eq. (65.3) in regular coordinates. The combination $\chi = \kappa(V\partial_V - U\partial_U)$ is a boost in the (U, V) plane with rapidity parameter κ: *the surface gravity is the boost rate of the horizon generators*, precisely the structure that produced the Unruh temperature in Theorem 64.20, now read off the geometry of the black hole.

65.1.3 The collapse spacetime and its causal structure

The eternal Schwarzschild solution Eq. (65.1) is a vacuum geometry with no matter and no moment of formation; it has two asymptotic regions and a past as well as a future horizon. A real black hole is not like that: it forms from collapsing matter, has a single asymptotic region, and possesses a regular centre $r = 0$ in its past where there is no singularity at all. The distinction matters for us because the radiation we will compute is sourced by the time-dependence of the geometry during formation, and because the trace-back of an outgoing ray must pass through the regular interior, not through a second asymptotic region.

We therefore model the spacetime as follows. For radii larger than the surface of the star, $r > R(t)$, Birkhoff's theorem guarantees the geometry is exactly the exterior Schwarzschild field Eq. (65.1) with mass M. Inside the star, $r < R(t)$, the geometry is some regular, time-dependent, matter- filled solution; its details will turn out to be irrelevant, and all we need of it is that (i) it is smooth, with finite curvature, along the rays we trace, and (ii) it contains a regular centre $r = 0$ at which ingoing rays reflect to outgoing rays. The surface $R(t)$ falls inward, crosses $r = 2GM$ at some moment, and a horizon forms; the matter continues to a singularity at $r = 0$ to the *future* of horizon formation. The causal structure is summarized by the conformal (Penrose) diagram of Fig. 65.1.

Three loci on the diagram organize the calculation. Past null infinity $\mathcal{I}^-$ is where ingoing data is set: the in-vacuum of the field is defined by its positive-frequency content there. Future null infinity $\mathcal{I}^+$ is where the radiation is collected. And the dotted *critical ray* $v = v_0$ is the ingoing ray that, traced forward, just grazes the forming horizon and escapes to $\mathcal{I}^+$ only asymptotically, at $u = +\infty$; equivalently it is the backward continuation of the horizon generator. Rays with v slightly less than v_0 escape to $\mathcal{I}^+$ at large but finite u; rays with $v > v_0$ are trapped and strike the singularity. The entire late-time physics is the behavior of the map between u at $\mathcal{I}^+$ and v at $\mathcal{I}^-$ as $v \uparrow v_0$, which we now compute.

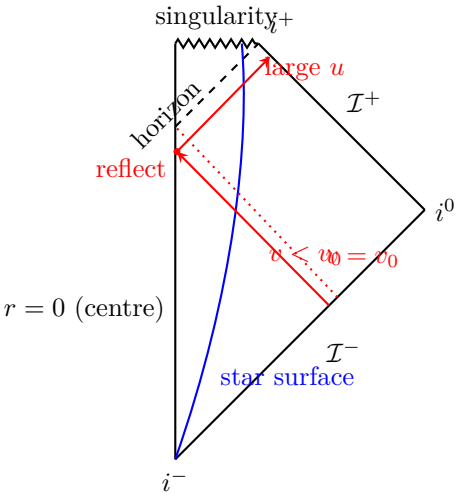

Figure 65.1: Conformal (Penrose) diagram of gravitational collapse. The shaded matter (the star, blue worldline) falls in from i^-; outside it the geometry is exact Schwarzschild. An event horizon (dashed) forms and reaches future timelike infinity i^+, where it meets the spacelike singularity (zigzag) and future null infinity $\mathcal{I}^+$. A red outgoing ray that escapes to $\mathcal{I}^+$ at large retarded time u, traced backwards, is ingoing from $\mathcal{I}^-$ at advanced time $v < v_0$, reflects through the regular centre $r = 0$, and emerges. The dotted critical ray $v = v_0$ is the last ray that escapes; it asymptotes to the horizon and reaches $\mathcal{I}^+$ only at i^+ ($u = +\infty$). Rays with $v > v_0$ fall into the singularity.

65.1.4 Geometric optics and the backward ray-tracing

The modes that dominate the late-time radiation are of very high frequency near the horizon — this is the trans-Planckian feature flagged in the chapter introduction and revisited in Section 65.8 — and high-frequency fields are governed by geometric optics. We make this precise. Write a solution of the curved-space Klein–Gordon equation $\Box\phi = 0$ (the free ϕ^4 theory scalar at $\lambda = 0$, Chapter 9, massless) in the eikonal form

$$\phi = A\, e^{iS}, \qquad \Box\phi = \left(iA\,\Box S - A\,(\nabla S)^2 + 2i\,\nabla^\mu A\,\nabla_\mu S + \Box A\right) e^{iS}. \tag{65.23}$$

For a rapidly varying phase S the dominant term is the one with two derivatives of S; setting it to zero gives the eikonal equation and its companion transport equation,

$$(\nabla S)^2 = g^{\mu\nu}\partial_\mu S\,\partial_\nu S = 0, \qquad 2\,\nabla^\mu A\,\nabla_\mu S + A\,\Box S = 0. \tag{65.24}$$

The first says the surfaces of constant phase are null. The wave vector $k_\mu = \partial_\mu S$ is null, $k^\mu k_\mu = 0$, and differentiating $(\nabla S)^2 = 0$ shows $k^\mu \nabla_\mu k_\nu = 0$: the rays

$\mathrm{d}x^\mu/d\lambda = k^\mu$ are null geodesics, with S constant along each (since $\mathrm{d}S/\mathrm{d}\lambda = k^\mu\partial_\mu S = k^\mu k_\mu = 0$). *The phase is parallel- transported, unchanged, along the null geodesic generators of the wavefront.* This is the single dynamical input of the ray-tracing: to find the phase of an outgoing mode at $\mathcal{I}^+$ in terms of conditions in the past, we follow its generator backwards and read the phase off where it ends, on $\mathcal{I}^-$.

Consider then an outgoing wave with phase $S = -\omega u$ at $\mathcal{I}^+$, i.e. the mode $e^{-i\omega u}$. Its wavefronts are the surfaces $u = \text{const}$, and each is generated by an outgoing radial null geodesic. We trace one such generator backwards through the geometry. The journey has three legs.

Leg 1 (exterior, near the horizon). In the exterior the generator is an outgoing radial null geodesic, $u = \text{const}$, equivalently $U = \text{const}$ by Eq. (65.21). For a ray reaching $\mathcal{I}^+$ at late u this is a constant U very close to 0^-. The generator stays at this fixed U until it crosses the surface of the collapsing star, $r = R(t)$, and enters the interior.

Leg 2 (interior, reflection through the centre). Inside the star the generator continues as a null geodesic in the regular matter-filled geometry. An *outgoing* radial ray, followed into the past, moves inward, reaches the regular centre $r = 0$, and there continues as an *ingoing* ray — this is the reflection through $r = 0$, which we must handle explicitly because r is a radial coordinate, not a Cartesian one, and the "reflection" is a statement about the regularity of the field at the origin. We make it explicit below in Theorem 65.4; for now the content is that a smooth field at a regular centre cannot have a conical kink, so the ingoing and outgoing radial null coordinates are identified continuously across $r = 0$.

Leg 3 (back out to $\mathcal{I}^-$). After reflection the ray is ingoing, $v = \text{const}$, crosses the stellar surface again, and propagates out to past null infinity, arriving at advanced time v. This v is the label we want.

The composition of the three legs is a map $v \mapsto u$, smooth wherever the geometry it crosses is smooth. The key qualitative fact, visible in Fig. 65.1, is that the generator of the event horizon itself is one particular such ray: traced back from i^+ ($u = +\infty$, $U = 0$) it reflects through the centre and reaches $\mathcal{I}^-$ at a definite finite advanced time, which we call v_0. The horizon generator is a perfectly regular null geodesic everywhere in its past — the singularity lies to its *future* — so the geometry along it and in a neighborhood of it is smooth, and the map $v \mapsto U$ is a smooth function near $v = v_0$.

This is all we need. Let $U(v)$ be the (constant) exterior Kruskal coordinate of the generator that arrives at $\mathcal{I}^-$ with advanced time v. It is smooth near v_0, and the horizon ray sets $U(v_0) = 0$ (the horizon is $U = 0$). Taylor- expanding,

$$U(v) = U(v_0) + U'(v_0)\,(v - v_0) + O\big((v - v_0)^2\big) = -C_K\,(v_0 - v) + \cdots, \qquad C_K \equiv U'(v_0) > 0, \tag{65.25}$$

where the sign and positivity of C_K are fixed by the geometry: rays that *escape* have $U < 0$ (just outside the horizon), and they do so for $v < v_0$, so U and

$(v - v_0)$ have the same sign and $U'(v_0) > 0$. Combining Eq. (65.25) with the exterior relation Eq. (65.21), $U = -\kappa^{-1} e^{-\kappa u}$, we equate the two expressions for U:

$$\frac{1}{\kappa}\, e^{-\kappa u} = C_K\,(v_0 - v), \tag{65.26}$$

solve for u,

$$e^{-\kappa u} = \kappa\, C_K\,(v_0 - v) \quad \Longrightarrow \quad -\kappa u = \ln\big(\kappa C_K (v_0 - v)\big), \tag{65.27}$$

and arrive at the central result of the section,

$$\boxed{u = -\frac{1}{\kappa}\,\ln\!\Big(\frac{v_0 - v}{C}\Big), \qquad v < v_0, \quad C \equiv \frac{1}{\kappa C_K} > 0.} \tag{65.28}$$

This is the late-time logarithmic phase map. As $v \uparrow v_0$ the retarded time $u \to +\infty$: the rays that arrive late at $\mathcal{I}^+$ are exponentially packed against the critical ray v_0 at $\mathcal{I}^-$. The coefficient of the logarithm is $1/\kappa$ and nothing else; the constants v_0 and C carry all the information about the particular collapse and will drop out of the spectrum entirely. An outgoing mode $e^{-i\omega u}$ at $\mathcal{I}^+$ therefore traces back to the field

$$e^{-i\omega u} \;\longmapsto\; \exp\Big[\,\frac{i\omega}{\kappa}\,\ln\!\Big(\frac{v_0 - v}{C}\Big)\Big] \qquad \text{on } \mathcal{I}^-,\ v < v_0, \tag{65.29}$$

and vanishing for $v > v_0$ (those rays never reach $\mathcal{I}^+$). The logarithm of the argument means this is not a pure positive-frequency wave in v; it is a superposition of both signs of frequency, and that mismatch — the Bogoliubov mixing — is what Section 65.2 evaluates.

It remains to make the reflection through $r = 0$ explicit and to exhibit the whole map in a model where every step is exact. The cleanest such model is a black hole formed by a single thin shell of radiation (a Vaidya geometry): outside the shell Schwarzschild, inside it flat space, glued along an ingoing null surface. There the interior is exactly Minkowski, the reflection at $r = 0$ is the elementary reflection of a light ray at the origin of flat space, and the matching across the shell is algebraic.

Worked Example 65.4 (The collapsing null shell: an exact logarithmic map)**.** Let a thin null shell collapse along the ingoing ray $v = v_0$. For $v > v_0$ the geometry is Schwarzschild of mass M with exterior null coordinates $u = t - r_*$, $v = t + r_*$ and r_* as in Eq. (65.14). For $v < v_0$ the geometry is flat Minkowski space, with its own null coordinates

$$v = t_{\rm in} + r, \qquad u_{\rm in} = t_{\rm in} - r, \tag{65.30}$$

where we have already used the freedom to set the advanced coordinate of the flat interior equal to the exterior v (both reduce to the same retarded/advanced time on $\mathcal{I}^-$, which is entirely in the flat region).

Reflection at the centre. In the flat interior a radial light ray that comes in along $v = \text{const}$ reaches $r = 0$ and goes back out along $u_{\text{in}} = \text{const}$. At the reflection point $r = 0$ we have $v = t_{\text{in}} = u_{\text{in}}$, so the regularity of the field at the origin (no source there) identifies the outgoing label with the ingoing one,

$$u_{\text{in}} = v. \tag{65.31}$$

This is the explicit content of "reflection through $r = 0$": it is the statement that an ingoing spherical wave $e^{-i\omega v}/r$ becomes, after passing regularly through the origin, the outgoing wave $-e^{-i\omega u_{\text{in}}}/r$ with $u_{\text{in}} = v$ (the relative sign is the usual phase shift of a regular spherical wave at the centre and does not affect the magnitude we will need).

Matching across the shell. The area radius r is continuous across the shell. An outgoing ray leaving the centre at $u_{\text{in}} = v$ crosses the shell $v = v_0$ at some radius r_s. From the interior, on the shell $v = v_0$ we have $v_0 = t_{\text{in}} + r_s$ and $u_{\text{in}} = t_{\text{in}} - r_s$, so $u_{\text{in}} = v_0 - 2r_s$, i.e. using Eq. (65.31),

$$v = v_0 - 2r_s \quad \Longrightarrow \quad r_s = \tfrac{1}{2}\,(v_0 - v). \tag{65.32}$$

From the exterior, on the same crossing the ray has retarded coordinate u and advanced coordinate v_0: $u = t - r_*(r_s)$ and $v_0 = t + r_*(r_s)$, hence

$$u = v_0 - 2\,r_*(r_s) = v_0 - 2\Big[\,r_s + 2GM \ln\Big(\frac{r_s}{2GM} - 1\Big)\Big]. \tag{65.33}$$

(We have absorbed into a redefinition of the origin of v_0 the finite, smooth mismatch between the interior and exterior radial coordinates away from the horizon; it contributes only a constant and a regular function, not the logarithm.)

Late times. Rays that escape to $\mathcal{I}^+$ at large u are those that cross the shell just outside the forming horizon, $r_s \to 2GM^+$. Writing $r_s = 2GM + \delta$ with $\delta \to 0^+$, Eq. (65.32) gives $\delta = \tfrac{1}{2}(v_0 - v) - 2GM$; shifting v_0 by the constant $4GM$ so that $\delta = 0$ corresponds to the last escaping ray (this redefinition is exactly the identification of v_0 with the critical ray of Fig. 65.1) we have simply

$$\delta = \tfrac{1}{2}\,(v_0 - v). \tag{65.34}$$

In Eq. (65.33) the logarithm dominates as $\delta \to 0$: $r_*(r_s) \simeq 2GM \ln(\delta/2GM) + \text{const}$, so

$$u = -4GM\,\ln\Big(\frac{\delta}{2GM}\Big) + \text{const} = -4GM\,\ln\Big(\frac{v_0 - v}{4GM}\Big) + \text{const}. \tag{65.35}$$

Since $4GM = 1/\kappa$ by Eq. (65.7), this is

$$u = -\frac{1}{\kappa}\,\ln\Big(\frac{v_0 - v}{C}\Big), \tag{65.36}$$

with C a positive constant collecting $4GM$ and the additive constant — exactly Eq. (65.28). Every step was explicit: the reflection at the regular centre via Eq. (65.31), the continuity of r across the shell, and the logarithmic divergence of r_* at the horizon. The Vaidya model thus realizes the general argument of Eqs. (65.25) and (65.28) with all constants determined.

65.1.5 Universality: why the late-time radiation forgets the collapse

The form of Eq. (65.28) is the same whether we obtained it from the abstract smoothness argument Eq. (65.25) or from the explicit shell of Theorem 65.4, and this is no accident. The logarithm and its coefficient $1/\kappa$ come from a single source: the logarithmic divergence of the tortoise coordinate Eq. (65.14) at the horizon, equivalently the exponential relation Eq. (65.21) between the Schwarzschild time u and the regular Kruskal coordinate U. That relation lives entirely in the *exterior*, near-horizon region, where the geometry is exactly Schwarzschild regardless of what collapsed, by Birkhoff's theorem. The interior, the matter content, the equation of state, the precise infall history — all of it enters only through the smooth map $U(v)$ in Eq. (65.25), and a smooth map contributes nothing but its value v_0 (a translation of v) and its slope C_K (a rescaling absorbed into C). Neither v_0 nor C survives into the spectrum, as Section 65.2 will show: the thermal flux depends on the coefficient $1/\kappa$ of the logarithm alone.

Physical Insight

The universality is the physical reason a black hole has "no hair" as far as its radiation is concerned. Two holes of the same mass formed from utterly different matter — a collapsing dust ball, a shell of light, an imploding neutron star — produce *identical* late-time Hawking spectra, because the only feature of the collapse that imprints on the late-time phase is the surface gravity of the horizon that forms, and that is fixed by the mass alone. The late-time radiation is a property of the horizon, not of its history. This is what makes the Hawking temperature a clean function of M and lets us treat the hole as a thermodynamic object in Section 65.4.

There is a structural echo here of the Unruh effect of Theorem 64.20. There, a uniformly accelerated observer in flat space saw the Minkowski vacuum as thermal because their proper time was related to the global inertial null coordinate by an exponential, $x^- \propto -e^{-a\,\bar{u}}$ with a the acceleration. Here the asymptotic late-time observer's retarded time is related to the regular horizon- crossing coordinate by the same kind of exponential, $U \propto -e^{-\kappa u}$, with κ the surface gravity playing the role of a. The black hole is, near its horizon, locally a Rindler wedge, and κ is the local acceleration scale; the collapse merely ensures that the relevant in-vacuum is the regular one, so the Rindler-like thermality is actually radiated to infinity. We make the choice of in-vacuum precise next.

65.1.6 The Boulware, Unruh, and Hartle–Hawking vacua

A quantum field on this background has no canonical vacuum: as Theorems 64.11 and 64.20 taught us, "vacuum" means a choice of which modes count as positive-frequency, and inequivalent choices give inequivalent notions of particle. Three choices are natural on the Schwarzschild/collapse background, and exactly one is selected by collapse. We define them by the time coordinate with respect to which the modes are positive-frequency, and read off their physical content from the relations established above.

Definition 65.5 (The three vacua)**.** For the free scalar field on the Schwarzschild geometry:

- The *Boulware vacuum* $|0_B\rangle$ is defined by taking modes that are positive-frequency with respect to the Killing time t — i.e. $e^{-i\omega u}$ outgoing and $e^{-i\omega v}$ ingoing — on both the exterior modes. It is the state a static observer at infinity calls "empty," and it most resembles the ordinary Minkowski vacuum far away.
- The *Hartle–Hawking vacuum* $|0_H\rangle$ is defined by taking modes positive-frequency with respect to the Kruskal coordinates U and V — the affine parameters along the future and past horizons — on both branches.
- The *Unruh vacuum* $|0_U\rangle$ is defined by taking the outgoing modes positive-frequency with respect to the Kruskal U (regular on the future horizon) and the ingoing modes positive-frequency with respect to the Killing v (no incoming radiation from $\mathcal{I}^-$).

The physical characters follow from where each state is regular. Regularity of a quantum state at a horizon requires its modes to be positive-frequency with respect to the affine parameter there (the Kruskal coordinate), since that is the parameter in which the geometry is smooth; modes positive-frequency in the Killing time t oscillate infinitely rapidly as $U \to 0$ by Eq. (65.21) and produce a divergent stress tensor on the horizon (we computed renormalized stress tensors in Section 64.5; the divergence here is the statement that $\langle 0_B| T_{\mu\nu} |0_B\rangle$ blows up in a frame that freely crosses the horizon). Consequently:

- $|0_B\rangle$ is regular at infinity but *singular on the horizon*: it is the appropriate vacuum for the exterior of a static star whose surface sits above $2GM$ (no horizon exists, no problem), but it cannot describe a black hole.
- $|0_H\rangle$ is regular on *both* horizons and is the unique state invariant under the Killing flow; it describes a black hole in thermal equilibrium with a bath of its own radiation at temperature $T_H = \kappa/2\pi$, filling all of space. It is time-symmetric — as much radiation comes in as goes out — and is the state relevant to the Euclidean computation of Section 65.5.

- $|0_U\rangle$ is regular on the future horizon (where infalling matter crosses) but not the past one, carries no incoming flux at $\mathcal{I}^-$, and carries a net *outgoing* thermal flux at $\mathcal{I}^+$. It is the state of an evaporating hole formed by collapse.

Caution

The Boulware and Hartle–Hawking states are defined on the *eternal* Schwarzschild geometry, which has a past horizon and a second asymptotic region; they are useful idealizations (thermal equilibrium, the static exterior) but neither describes a hole that actually forms. The collapse geometry of Fig. 65.1 has no past horizon. What the collapse selects is the *in-vacuum*: the state with no particles on $\mathcal{I}^-$, defined by positive frequency with respect to the advanced time v there, where the geometry is asymptotically flat and v is the natural affine/Killing time. The geometric-optics map Eq. (65.28) shows that, near the horizon and at late times, this in-vacuum is indistinguishable from the Unruh vacuum — the outgoing modes it contains are the ones positive-frequency in the horizon-regular coordinate U. This is the precise sense in which "collapse selects the Unruh vacuum."

The collapse therefore hands Section 65.2 two things, both now made precise. The first is the kinematic input: the late-time logarithmic map Eq. (65.28), $u = -\kappa^{-1}\ln\left((v_0 - v)/C\right)$, which traces an outgoing $\mathcal{I}^+$ mode $e^{-i\omega u}$ back to the $\mathcal{I}^-$ field Eq. (65.29). The second is the state: the in-vacuum defined by positive frequency in v on $\mathcal{I}^-$, against which the outgoing $\mathcal{I}^+$ modes are to be expanded. Feeding the traced mode into the Klein–Gordon inner product of Theorem 64.6 to extract the Bogoliubov coefficients $\alpha_{\omega\omega'}, \beta_{\omega\omega'}$ of Theorem 64.11 — and discovering that the logarithm makes $|\beta|^2$ Planckian — is the work of the next section.

65.2 The Hawking Spectrum: Thermality from the Horizon

The previous section reduced the entire dynamical problem of a quantum field on a collapsing star to a single kinematic fact. An outgoing wave that reaches a distant observatory at late retarded time u did not originate as a long-lived, gently-varying ripple at past null infinity: traced backwards along its null ray, through the centre of the collapsing matter and back out, its phase is stretched without bound, and the relation between the retarded time u at which it arrives and the advanced time v at which it set out is logarithmic. Recalling the result of Section 65.1, the late-time geometric-optics map is

$$u(v) \;=\; -\frac{1}{\kappa}\,\ln\!\big(\kappa\,(v_0 - v)\big), \qquad v < v_0, \tag{65.37}$$

where v_0 is the advanced time of the last ray that escapes to infinity — the generator of the event horizon, traced back to past null infinity — and κ is the surface gravity, which for the Schwarzschild geometry of mass M takes the value

$$\kappa \;=\; \frac{1}{4GM} \tag{65.38}$$

(Eq. (65.7)). Rays with $v > v_0$ enter the star too late and are swallowed; rays with $v \to v_0^-$ skim the forming horizon and emerge at arbitrarily late u, their frequency redshifted without limit. Everything about the radiation is encoded in Eq. (65.37). The work of this section is to feed that map into the Bogoliubov machinery of Chapter 64 and extract the particle content of the in-vacuum as seen by a late-time observer. The carried matter field is the free real scalar of ϕ^4 theory at $\lambda = 0$ (Section 9.2) — the same field ϕ, now living its first genuinely gravitational life — and the symbols are exactly those fixed there.

We will find that the in-vacuum, the natural "no incoming particles" state of the collapse problem, is populated at infinity by a precisely Planckian flux of ϕ-quanta. The temperature of that flux is fixed entirely by the surface gravity, $T_H = \kappa/2\pi$, and the entire content of the calculation is the conversion of the logarithm in Eq. (65.37) into the Boltzmann factor $e^{-\omega/T_H}$ through a single contour deformation across a branch cut. We proceed in three movements: first we write the Bogoliubov coefficients as Klein–Gordon overlaps and reduce them to Fourier integrals over past null infinity; second we evaluate those integrals in closed form and isolate the exact ratio $|\alpha| = e^{\pi\omega/\kappa}|\beta|$ from the branch structure; third we assemble the occupation number, identify it as a Bose–Einstein distribution, and confirm the same temperature from the KMS/periodicity criterion inherited from the Unruh analysis.

65.2.1 The Bogoliubov coefficients of the collapse problem

The general apparatus is already in hand. From Section 64.2 we have two complete orthonormal mode bases for the free scalar, related by the conserved Klein–Gordon inner product

$$(f, g) \;=\; i\int_\Sigma \mathrm{d}\Sigma^\mu \left[\, (\partial_\mu f)\, g^* - f\, \partial_\mu g^* \,\right] \tag{65.39}$$

(Eq. (64.45)), whose value is independent of the Cauchy surface Σ. The two bases here are physically dictated by the two ends of the collapse spacetime. On past null infinity $\mathcal{I}^-$, where the geometry is flat and static and "no incoming radiation" is an unambiguous notion, we take the *in-modes* — the analogue of the old basis $\{u_j\}$ of Eq. (64.47). On future null infinity $\mathcal{I}^+$, where a late-time detector reads off particles, we take the *out-modes* — the new basis $\{v_i\}$ of Eq. (64.48). The in-vacuum $|0_{\mathrm{in}}\rangle$ is the state annihilated by all in-annihilation operators; it is the

state of the field before the star collapses, and it is the physically selected initial condition.

Because the field is a free massless scalar and the exterior is spherically symmetric, we may work mode by mode in the angular momentum ℓ and, since the spectrum will turn out to be ℓ-independent at the horizon, we suppress the spherical-harmonic and radial structure and follow a single outgoing s-wave. After the substitution $\phi = (\chi/r)\,Y_{\ell m}$ that turns the radial problem into a 1+1-dimensional wave equation on the line (the reduction carried out in detail in Theorem 65.9), the reduced field $\chi(u, v)$ propagates freely near each null infinity, and the Klein–Gordon product Eq. (65.39) evaluated on $\mathcal{I}^-$ collapses to the one-dimensional null-surface form

$$(f, g)_{\mathcal{I}^-} \;=\; i\int_{-\infty}^{\infty} \mathrm{d}v\, \left[\, (\partial_v f)\, g^* - f\, \partial_v g^* \,\right], \tag{65.40}$$

with v the advanced time labelling the null generators of $\mathcal{I}^-$. The in-modes are the positive-frequency plane waves with respect to this advanced time,

$$p^{\mathrm{in}}_{\omega'}(v) \;=\; \frac{1}{\sqrt{4\pi\omega'}}\, e^{-i\omega' v}, \qquad \omega' > 0, \tag{65.41}$$

normalized so that $(p^{\mathrm{in}}_{\omega'}, p^{\mathrm{in}}_{\omega''}) = \delta(\omega' - \omega'')$ under Eq. (65.40), exactly the positive-frequency condition Eq. (64.44) of the inertial vacuum.

The out-modes are defined by being purely positive-frequency with respect to the retarded time u on $\mathcal{I}^+$,

$$p^{\mathrm{out}}_{\omega}(u) \;=\; \frac{1}{\sqrt{4\pi\omega}}\, e^{-i\omega u}, \qquad \omega > 0. \tag{65.42}$$

To compute their overlap with the in-modes we need the out-mode *on* $\mathcal{I}^-$. This is precisely where the geometry enters, and it is the only place it enters. A late-time out-mode, propagated backwards through the (locally trivial) geometry by geometric optics, arrives on $\mathcal{I}^-$ as the same oscillation evaluated along the ray, i.e. with u replaced by the function $u(v)$ of Eq. (65.37), and with support only on the rays that actually escape, $v < v_0$:

$$p^{\mathrm{out}}_{\omega}(v) \;=\; \frac{1}{\sqrt{4\pi\omega}}\, \exp\!\big[-i\omega\, u(v)\big]\, \theta(v_0 - v) \;=\; \frac{1}{\sqrt{4\pi\omega}}\, \big[\kappa(v_0 - v)\big]^{\,i\omega/\kappa}\, \theta(v_0 - v), \tag{65.43}$$

where the second equality used Eq. (65.37) to write $e^{-i\omega u} = e^{\,i(\omega/\kappa)\ln[\kappa(v_0 - v)]} = [\kappa(v_0 - v)]^{i\omega/\kappa}$. The Heaviside factor records that the ray reaching $\mathcal{I}^+$ at finite u came from $v < v_0$; the late-time piece, $u \to +\infty$, comes from $v \to v_0^-$, where the wave oscillates infinitely rapidly. That infinite pile-up of oscillations at v_0 is the source of the entire effect.

With both bases expressed on $\mathcal{I}^-$ we read off the Bogoliubov coefficients from Theorem 64.11, identifying the out-modes with the new basis v_i and the

in-modes with the old basis u_j:

$$\alpha_{\omega\omega'} \;=\; (p^{\rm out}_{\omega}, p^{\rm in}_{\omega'}), \qquad \beta_{\omega\omega'} \;=\; -\,(p^{\rm out}_{\omega}, p^{\rm in*}_{\omega'}), \tag{65.44}$$

the overlaps taken in the product Eq. (65.40). We now reduce these to ordinary integrals. For any solution f paired against a plane wave $g = e^{-i\omega' v}/\sqrt{4\pi\omega'}$, integrate the first term of Eq. (65.40) by parts; the boundary contributions vanish on a normalizable wave packet (made precise below), and

$$(f,g)_{\mathcal{I}^-} = i\int \mathrm{d}v\,\left[(\partial_v f)g^* - f\partial_v g^*\right] = -\,2i\int \mathrm{d}v\, f\,\partial_v g^*. \tag{65.45}$$

Applying Eq. (65.45) to α, with $g = p^{\rm in}_{\omega'}$ so that $g^* = e^{+i\omega' v}/\sqrt{4\pi\omega'}$ and $\partial_v g^* = i\omega' g^*$,

$$\begin{aligned}\alpha_{\omega\omega'} &= -2i\int_{-\infty}^{v_0}\mathrm{d}v\; p^{\rm out}_{\omega}(v)\,(i\omega')\,\frac{e^{+i\omega' v}}{\sqrt{4\pi\omega'}} = 2\omega'\int_{-\infty}^{v_0}\mathrm{d}v\;\frac{[\kappa(v_0-v)]^{i\omega/\kappa}}{\sqrt{4\pi\omega}}\,\frac{e^{+i\omega' v}}{\sqrt{4\pi\omega'}}\\ &= \frac{1}{2\pi}\sqrt{\frac{\omega'}{\omega}}\;\kappa^{\,i\omega/\kappa}\int_{-\infty}^{v_0}\mathrm{d}v\;(v_0-v)^{i\omega/\kappa}\,e^{+i\omega' v}.\end{aligned} \tag{65.46}$$

The same manipulation for β, now with $g = p^{\rm in*}_{\omega'}$ so that $g^* = e^{-i\omega' v}/\sqrt{4\pi\omega'}$ and $\partial_v g^* = -i\omega' g^*$, flips the sign of the exponent and, together with the explicit minus in Eq. (65.44), gives

$$\beta_{\omega\omega'} = \frac{1}{2\pi}\sqrt{\frac{\omega'}{\omega}}\;\kappa^{\,i\omega/\kappa}\int_{-\infty}^{v_0}\mathrm{d}v\;(v_0-v)^{i\omega/\kappa}\,e^{-i\omega' v}. \tag{65.47}$$

Equations Eq. (65.46) and Eq. (65.47) are identical except for the sign of ω' in the exponential: $\beta_{\omega\omega'}$ is $\alpha_{\omega\omega'}$ continued to negative ω'. This single observation, once the integrals are done, is the whole physics.

65.2.2 Evaluation of the overlap and the exact thermal ratio

Both integrals are of one type. Substitute $x = v_0 - v$ (so $v = v_0 - x$, $\mathrm{d}v = -\mathrm{d}x$, and the range $v \in (-\infty, v_0)$ becomes $x \in (0,\infty)$). For α this turns the exponential into $e^{i\omega'(v_0-x)} = e^{i\omega' v_0}e^{-i\omega' x}$, and for β into $e^{-i\omega' v_0}e^{+i\omega' x}$. Hence

$$\alpha_{\omega\omega'} = \frac{\kappa^{\,i\omega/\kappa}}{2\pi}\sqrt{\frac{\omega'}{\omega}}\;e^{\,i\omega' v_0}\;\underbrace{\int_0^{\infty}\mathrm{d}x\;x^{\,i\omega/\kappa}\,e^{-i\omega' x}}_{\equiv\; P(\omega,\omega')}, \tag{65.48}$$

$$\beta_{\omega\omega'} = \frac{\kappa^{\,i\omega/\kappa}}{2\pi}\sqrt{\frac{\omega'}{\omega}}\;e^{-i\omega' v_0}\;\underbrace{\int_0^{\infty}\mathrm{d}x\;x^{\,i\omega/\kappa}\,e^{+i\omega' x}}_{\equiv\; Q(\omega,\omega')}. \tag{65.49}$$

The prefactors of P and Q are identical and have unit modulus apart from the common $\frac{1}{2\pi}\sqrt{\omega'/\omega}$. The entire content of the calculation is therefore the ratio P/Q, and both P and Q are Euler Γ-function integrals once the contour is fixed.

Worked Example 65.6 (The branch cut that makes the spectrum thermal)**.** We evaluate P and Q and extract their ratio, being scrupulous about the analytic continuation, since the answer depends entirely on it. The master formula is the Euler integral

$$\int_0^\infty \mathrm{d}x\; x^{s-1}\, e^{-px} \;=\; \frac{\Gamma(s)}{p^{\,s}}, \qquad \operatorname{Re} s>0,\ \operatorname{Re} p>0, \tag{65.50}$$

proved by analytic continuation of the real-argument case (Theorem 5.23 supplies the contour technology; the integral converges at $x=0$ because $\operatorname{Re} s>0$ and at $x=\infty$ because $\operatorname{Re} p>0$). Here $x^{i\omega/\kappa}=x^{s-1}$ with

$$s \;=\; 1+\frac{i\omega}{\kappa}, \qquad \operatorname{Re} s = 1>0, \tag{65.51}$$

so the endpoint at $x=0$ is harmless. The subtlety is entirely at $x=\infty$: the exponentials $e^{\mp i\omega' x}$ are purely oscillatory, sitting exactly on the boundary $\operatorname{Re} p=0$ where Eq. (65.50) is borderline divergent. Each integral must be defined by tilting p infinitesimally into the convergent half-plane — and the two integrals tilt in *opposite* directions, which is the origin of the entire effect.

The integral P (the α-coefficient). Here $e^{-i\omega' x}$, so $p=i\omega'$. To make the integrand decay we give ω' a vanishing negative imaginary part, $\omega'\to\omega'-i0^+$, equivalently $p=i\omega'+0^+$, which sits just inside $\operatorname{Re} p>0$. Then $p=\omega'\,e^{+i\pi/2}$ (the point $i\omega'$ lies on the positive imaginary axis, reached from the right half-plane), and

$$P(\omega,\omega') = \frac{\Gamma(s)}{(i\omega')^s} = \Gamma(s)\,(\omega')^{-s}\,e^{-i\pi s/2}. \tag{65.52}$$

The integral Q (the β-coefficient). Here $e^{+i\omega' x}$, so $p=-i\omega'$; convergence now demands $\omega'\to\omega'+i0^+$, i.e. $p=-i\omega'+0^+$, so that $p=\omega'\,e^{-i\pi/2}$ (the point $-i\omega'$ on the *negative* imaginary axis, again reached from the right half-plane), giving

$$Q(\omega,\omega') = \frac{\Gamma(s)}{(-i\omega')^s} = \Gamma(s)\,(\omega')^{-s}\,e^{+i\pi s/2}. \tag{65.53}$$

The branch of the power p^s is the principal one, fixed by writing $p=\omega' e^{\pm i\pi/2}$ with the phase in $(-\pi,\pi]$ and $p^s=(\omega')^s e^{\pm i\pi s/2}$; this is the unique continuation that keeps $\operatorname{Re} p>0$ throughout the tilt, and it is the same positive-frequency-in-the-lower -half-plane prescription that fixed the Unruh modes in Theorem 64.20. The two coefficients differ only through these opposite tilts: P rotates the contour into the lower-half x-plane, Q into the upper-half x-plane, around the branch point of $x^{i\omega/\kappa}$ at the origin (Fig. 65.2).

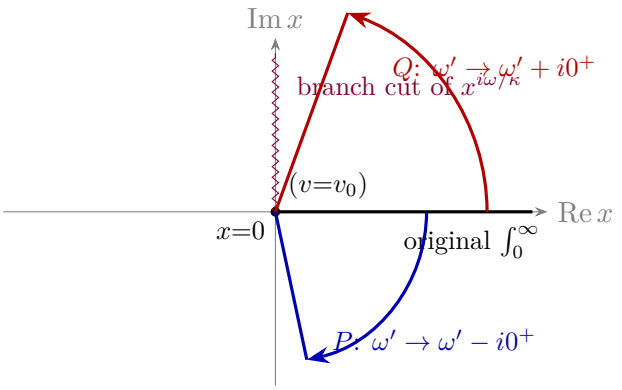

Figure 65.2: The contour rotations that define the overlap integrals P (the α-coefficient, Eq. (65.48)) and Q (the β-coefficient, Eq. (65.49)). The integrand $x^{i\omega/\kappa}e^{\mp i\omega' x}$ has a branch point at $x = 0$, the image of the horizon-grazing ray $v = v_0$; the cut is drawn up the imaginary axis. Convergence at $x \to \infty$ forces the two integrals to rotate the contour in opposite senses — P into the lower half-plane, Q into the upper — so the two coefficients sample opposite sides of the branch point. The relative phase picked up around the cut is $e^{-i\pi s} = -e^{\pi\omega/\kappa}$ (Eq. (65.54)), the Boltzmann factor of the Hawking spectrum.

The ratio. Dividing Eq. (65.52) by Eq. (65.53), the $\Gamma(s)$ and $(\omega')^{-s}$ cancel and only the phases survive:

$$\frac{P}{Q} = e^{-i\pi s} = e^{-i\pi(1+i\omega/\kappa)} = e^{-i\pi}\, e^{\pi\omega/\kappa} = -\, e^{\pi\omega/\kappa}. \tag{65.54}$$

Restoring the prefactors of Eqs. (65.48) and (65.49), which differ only by the unit-modulus phase $e^{2i\omega' v_0}$, the Bogoliubov coefficients obey

$$\alpha_{\omega\omega'} \;=\; -\, e^{\pi\omega/\kappa}\, e^{\,2i\omega' v_0}\, \beta_{\omega\omega'}, \tag{65.55}$$

and, taking moduli, the exact relation that drives everything,

$$\boxed{\,|\alpha_{\omega\omega'}| \;=\; e^{\pi\omega/\kappa}\, |\beta_{\omega\omega'}|\,} \tag{65.56}$$

holding *for every* ω', with the proportionality constant $e^{\pi\omega/\kappa}$ depending only on the out-frequency ω and the surface gravity κ, never on the in-frequency ω'.

Equation (65.56) is the technical heart of the chapter, and it is worth pausing on what made it thermal. The logarithm in the geometric-optics map Eq. (65.37) turned the out-mode into a *power* of $(v_0 - v)$, Eq. (65.43); a power has a branch point; and the positive- and negative-frequency overlaps with that power are forced, by convergence alone, to circle the branch point in opposite directions. The phase accrued on going around is exactly $e^{\pi\omega/\kappa}$. Had the map been linear,

$u \propto v$, there would be no branch point, β would vanish, and the in- and out-vacua would coincide — no particles. It is the *logarithmic* stretching of the horizon, and nothing else, that produces the radiation, and the surface gravity κ enters only as the rate of that stretching.

65.2.3 The occupation number and the Planck distribution

We now convert the ratio Eq. (65.56) into the number of quanta a late-time observer registers. By the particle-content theorem Theorem 64.13, the expectation value of the out-number operator $N_\omega = b_\omega^\dagger b_\omega$ in the in-vacuum is the squared β-matrix summed over the in-modes,

$$\langle N_\omega \rangle \;=\; \langle 0_{\rm in}|\, b_\omega^\dagger b_\omega \,|0_{\rm in}\rangle \;=\; \int_0^\infty \mathrm{d}\omega' \,|\beta_{\omega\omega'}|^2, \tag{65.57}$$

(Eq. (64.145)), the statement that each $\beta_{\omega\omega'}$ is the amplitude for the in-vacuum to contain an out-particle of frequency ω paired with the in-mode ω'. To evaluate Eq. (65.57) we use the Bogoliubov identity that enforces the canonical commutators of the out-operators (Theorem 64.12): in continuum normalization,

$$\int_0^\infty \mathrm{d}\omega' \left(\alpha_{\omega\omega'}\alpha^*_{\tilde\omega\omega'} - \beta_{\omega\omega'}\beta^*_{\tilde\omega\omega'}\right) \;=\; \delta(\omega-\tilde\omega). \tag{65.58}$$

Set $\tilde\omega = \omega$. The ratio Eq. (65.56) holds pointwise in ω' with a coefficient $e^{\pi\omega/\kappa}$ that is independent of ω', so $|\alpha_{\omega\omega'}|^2 = e^{2\pi\omega/\kappa}|\beta_{\omega\omega'}|^2$ for every ω', and the factor pulls straight out of the integral:

$$\left(e^{2\pi\omega/\kappa}-1\right)\int_0^\infty \mathrm{d}\omega' \,|\beta_{\omega\omega'}|^2 \;=\; \delta(0). \tag{65.59}$$

Comparing with Eq. (65.57),

$$\langle N_\omega\rangle \;=\; \frac{\delta(0)}{e^{2\pi\omega/\kappa}-1}. \tag{65.60}$$

The divergent $\delta(0)$ is not a pathology; it is the well-understood signature of using sharp-frequency plane waves, which are spread over all of retarded time, to count a steady flux. We make it finite in either of two equivalent ways.

Wave-packet regularization. Following Hawking's original treatment, one replaces the continuum modes by normalizable packets

$$p_{jn} \;=\; \frac{1}{\sqrt{\varepsilon}}\int_{j\varepsilon}^{(j+1)\varepsilon} \mathrm{d}\omega\; e^{\,2\pi i n\omega/\varepsilon}\, p^{\rm out}_\omega, \qquad j\ge 0,\; n\in\mathbb{Z}, \tag{65.61}$$

peaked in frequency about $\omega_j = j\varepsilon$ with width ε and in retarded time about $u_n = 2\pi n/\varepsilon$. These are orthonormal, so $(p_{jn}, p_{j'n'}) = \delta_{jj'}\delta_{nn'}$ and the troublesome $\delta(0)$ is replaced by unity. Because the ratio Eq. (65.56) is a statement at fixed ω that depends on ω' only through quantities that vary slowly across a packet, it survives the smearing for $\varepsilon \to 0$ up to corrections of order ε, and the packet occupation is finite, $\langle N_{jn}\rangle = (e^{2\pi\omega_j/\kappa}-1)^{-1}$.

Steady-flux reading. Equivalently, regulate the continuum directly: $\delta(0) = \lim_{\tilde{\omega}\to\omega}\delta(\omega-\tilde{\omega}) = \frac{1}{2\pi}\int_{-\infty}^{\infty}\mathrm{d}t = \frac{T}{2\pi}$, the total observation time T divided by 2π. The number of out-quanta of frequency ω counted over time T is then $\langle N_\omega\rangle = (T/2\pi)/(e^{2\pi\omega/\kappa}-1)$, so the *rate* per unit frequency at which quanta of frequency ω stream to infinity is

$$\frac{\mathrm{d}N}{\mathrm{d}t\,\mathrm{d}\omega} = \frac{1}{2\pi}\,\frac{1}{e^{2\pi\omega/\kappa}-1}, \tag{65.62}$$

with the $1/2\pi$ the density of single-particle states in energy per unit time (one state per phase-space cell $\Delta\omega\,\Delta t = 2\pi$). Either way, the per-mode occupation number is

$$\boxed{\langle N_\omega\rangle = \frac{1}{e^{2\pi\omega/\kappa}-1} = \frac{1}{e^{\omega/T_H}-1}} \tag{65.63}$$

which is exactly the Bose–Einstein distribution for a free boson mode of energy ω in thermal equilibrium at the temperature read off by matching exponents,

$$\boxed{T_H = \frac{\kappa}{2\pi} = \frac{1}{8\pi GM}} \tag{65.64}$$

the Hawking temperature, where the last equality used $\kappa = 1/4GM$ from Eq. (65.38). A black hole formed by collapse is therefore not black: its horizon makes the in-vacuum radiate to infinity a flux of ϕ-quanta whose spectrum is precisely Planckian, at a temperature fixed by the surface gravity alone. Setting aside (until Section 65.3) the propagation of the quanta out through the gravitational potential, the bare horizon-emission spectrum is Eq. (65.62).

Theorem 65.7 (Thermality of the horizon spectrum)**.** *For the free real scalar in the in-vacuum of a spacetime whose late-time geometric-optics map is the logarithm Eq. (65.37) with surface gravity κ, the Bogoliubov coefficients satisfy $|\alpha_{\omega\omega'}| = e^{\pi\omega/\kappa}|\beta_{\omega\omega'}|$ Eq. (65.56), and the expected number of out-quanta of frequency ω is the Bose–Einstein occupation Eq. (65.63) at the Hawking temperature Eq. (65.64). The result is independent of the angular momentum ℓ of the channel and of the detailed profile of the collapse: it depends on the collapse history only through the single number κ.*

Proof. The mode-overlap reduction Eqs. (65.46) and (65.47), the Γ-function evaluation Eqs. (65.52) and (65.53), and the branch-cut ratio Eq. (65.54) together establish Eq. (65.56). The occupation Eq. (65.63) then follows from the particle-content formula Eq. (65.57) and the Bogoliubov identity Eq. (65.58) as in Eqs. (65.59) and (65.60). Independence of ℓ is manifest: the angular and radial structure entered only through the overall normalization of the modes and was stripped by the reduction to the 1+1 problem, while the exponent $e^{\pi\omega/\kappa}$ came entirely from the universal logarithm Eq. (65.37), which Section 65.1 showed is controlled by κ regardless of the interior matter profile. □

Physical Insight: the partner inside the horizon

The relation Eq. (65.55) is more than a magnitude. With $|\alpha|$ and $|\beta|$ locked together, the in-vacuum expressed in the out-basis is not empty but a *two-mode squeezed state*: each emitted out-quantum at $\mathcal{I}^+$ is created together with a partner that falls through the horizon, the two sharing the entanglement that a squeezing transformation builds (Theorem 64.14). The thermal occupation Eq. (65.63) is what an observer who can access only the exterior modes sees after tracing out the infalling partners: the reduced density matrix on the out-region is exactly the thermal density matrix $\rho_{\text{out}} \propto e^{-N/T_H}$ of Eq. (64.174). This is the precise sense in which the radiation is thermal — not merely Planckian in its one-point occupation numbers, but a genuine mixed thermal state arising from entanglement across the horizon. It is also the precise origin of the information puzzle of Section 65.8: the global state is pure, yet everything outside the horizon is exactly thermal.

Worked Example 65.8 (How cold is a black hole?)**.** The Hawking temperature Eq. (65.64) is written in natural units; to feel its size we restore $\hbar, c, k_B$. Dimensional analysis on $T_H = \kappa/2\pi$ with $\kappa = c^2/(2r_s)$ a surface gravity (acceleration) and $r_s = 2GM/c^2$ the Schwarzschild radius gives

$$k_B T_H \;=\; \frac{\hbar\,\kappa}{2\pi c} \;=\; \frac{\hbar c^3}{8\pi G M}, \tag{65.65}$$

the unique combination of $\hbar$ (the radiation is a quantum effect), c, G, and M with the dimensions of energy. Inserting $\hbar = 1.055\times10^{-34}\,\mathrm{J\,s}$, $c = 3.00\times10^{8}\,\mathrm{m/s}$, $G = 6.67\times10^{-11}\,\mathrm{m^3 kg^{-1} s^{-2}}$, $k_B = 1.38\times10^{-23}\,\mathrm{J/K}$, and a solar mass $M_\odot = 1.99\times10^{30}\,\mathrm{kg}$,

$$T_H(M_\odot) = \frac{(1.055\times10^{-34})(3.00\times10^{8})^3}{8\pi\,(6.67\times10^{-11})(1.99\times10^{30})(1.38\times10^{-23})}\,\mathrm{K} \;\approx\; 6.2\times10^{-8}\,\mathrm{K}, \tag{65.66}$$

and since $T_H \propto 1/M$,

$$T_H \;\approx\; 6.2\times10^{-8}\,\mathrm{K}\,\frac{M_\odot}{M}. \tag{65.67}$$

A solar-mass black hole is colder than the 2.7 K cosmic microwave background by nearly eight orders of magnitude; immersed in the present Universe it absorbs far more than it radiates, and the thermal flux Eq. (65.62) is utterly negligible. The temperature reaches the CMB only for $M \sim 10^{-8}M_\odot \sim 10^{22}\,\mathrm{kg}$ (a small asteroid mass), and becomes appreciable only for much lighter holes: a hole of $M \sim 10^{12}\,\mathrm{kg}$ radiates at $T_H \sim 10^{11}\,\mathrm{K} \sim 10\,\mathrm{MeV}$, hot enough to emit electrons and photons copiously. The smallness of Eq. (65.66) is why Hawking radiation from astrophysical holes is unobservable, and why the phenomenon, though it

rewrote the foundations, has never been measured directly. Its importance is structural, not observational: it is the thread that ties quantum field theory, gravity, and thermodynamics into a single knot, as the rest of this chapter develops.

65.2.4 Cross-check: the KMS condition and the Hartle–Hawking state

The Bogoliubov computation just completed is dynamical: it follows a field through an actual collapse and asks what a detector at infinity finds long after the horizon forms. There is a second, purely equilibrium, characterization of thermality that must give the same temperature if the result is to be trusted, and it is the criterion we already met in the Unruh analysis. A state ω_β of a quantum field is thermal at inverse temperature β — it is a Kubo–Martin–Schwinger (KMS) state — if and only if its two-point function, analytically continued in the time argument, is periodic in imaginary time with period β:

$$G(t - i\beta) \;=\; G(t), \qquad G(t) \equiv \langle \phi(t)\, \phi(0) \rangle_\beta, \tag{65.68}$$

the relation Eq. (64.163) that we showed is equivalent to the detailed balance $\langle \phi(t)\phi(0)\rangle = \langle \phi(0)\phi(t + i\beta)\rangle$ obeyed by any Gibbs ensemble $\rho \propto e^{-\beta H}$. For the uniformly accelerated observer of Theorem 64.20 the relevant time was the boost (Rindler) time, the Minkowski vacuum Green's function was periodic in it with period $2\pi/a$, and the detector therefore registered a temperature $T = a/2\pi$.

The black-hole case is the same statement with the boost replaced by the time-translation that the horizon generates. Near the horizon the Killing time t plays the role of the Rindler boost parameter, and the surface gravity κ plays the role of the acceleration a: the near-horizon geometry is, to leading order, Rindler space with boost rate κ (this is exactly the statement that makes Eq. (65.38) a surface *gravity*, and it is developed metrically in Section 65.5.1). The *Hartle–Hawking state* is by definition the state whose Green's function is regular across the whole horizon, the equilibrium analogue of the Minkowski vacuum for Rindler; the regularity requirement forces its Green's function to be periodic in imaginary Killing time with period

$$\beta_H \;=\; \frac{2\pi}{\kappa}, \tag{65.69}$$

exactly as the smoothness of the Euclidean section will require in Theorem 65.25. By the KMS criterion Eq. (65.68) the Hartle–Hawking state is therefore thermal at

$$T_H \;=\; \frac{1}{\beta_H} \;=\; \frac{\kappa}{2\pi}, \tag{65.70}$$

identical to Eq. (65.64). The two derivations approach the same number from opposite directions. The Bogoliubov calculation is a non-equilibrium scattering problem on a genuinely time-dependent collapse geometry, and it tells us that

the late-time radiation *is* thermal even though nothing was assumed to be in equilibrium; the KMS argument is a statement about the static eternal black hole and its equilibrium Hartle–Hawking vacuum. That they yield one temperature is the assurance that the thermal character of the horizon is a property of the geometry near it, not an artefact of the collapse history — the collapse merely selects the in-vacuum that, at late times, looks locally like the Hartle–Hawking state near the horizon and so radiates at its temperature.

Caution: thermal occupation is not the full state at infinity

Equation Eq. (65.63) is the occupation of a mode *at the horizon end* of the trace-back, computed as if every quantum created there reached infinity freely. It is the bare emission spectrum. A real detector sits at infinity, and between it and the horizon stands the curvature potential of Theorem 65.9, off which low-frequency quanta are largely backscattered. The flux Eq. (65.62) is therefore the input to, not the output of, the propagation problem. The frequency dependence of the transmission — the greybody factor — is what distinguishes the light a telescope would see from a true black-body spectrum, and it is the subject of the next section. Until then, "the Hawking spectrum" means precisely Eq. (65.62): a Planckian horizon emission at $T_H = \kappa/2\pi$.

We have established the central result of the chapter in its sharpest local form: the horizon of a collapsing black hole pours the in-vacuum into a Planck spectrum at $T_H = \kappa/2\pi = 1/8\pi GM$, with the thermal Boltzmann factor traced to a single branch cut in the logarithmic phase map. The next section takes this bare horizon spectrum Eq. (65.62) and propagates it out through the Regge–Wheeler barrier, dressing it with the greybody factor $\Gamma_{\omega\ell}$ to yield the luminosity, evaporation law, and lifetime actually seen at infinity; the temperature Eq. (65.64) derived here is the input that Sections 4–6 will promote to a genuine thermodynamic temperature and confirm twice more, by the Euclidean path integral and by the horizon anomaly.

65.3 Greybody Factors, Luminosity, and Evaporation

The previous section delivered a sharp but local statement: a mode of frequency ω that climbs out of the collapsing geometry to reach future null infinity is populated according to a Planck distribution at the Hawking temperature $T_H = \kappa/2\pi = 1/8\pi GM$ (Section 65.2, Eq. (65.64)). That statement was made *at the horizon*: it counts the quanta the in-vacuum pours into each outgoing wavepacket as it peels off the surface of the collapsing star. But the quantum that is created just outside the horizon is not the quantum that a detector at infinity registers. Between the horizon and the asymptotic region sits the gravitational field of

the hole itself, and an outgoing wave must propagate through it. Some of the wave tunnels through to infinity; the rest is backscattered by the spacetime curvature and falls back toward the hole. The flux that actually arrives at a distant observatory is therefore the horizon Planck spectrum *multiplied by the fraction of each mode that survives the trip out.* That fraction is the greybody factor, and computing it is the business of this section: it converts a formal emission rate into a physical luminosity, and the luminosity in turn fixes the rate at which the hole loses mass, the law by which it shrinks, and the finite time in which it disappears.

We carry the free real scalar of ϕ^4 theory (Chapter 9) in its $\lambda = 0$ sector, taken massless, as the matter field whose emission we compute. Massless is the natural choice: a quantum of rest mass m can be emitted only above the threshold $\omega > m$, and for the astrophysical holes of interest m is negligible against T_H until the very last stages; the mass merely adds a term $f(r)\,m^2$ to the effective potential built below and shifts the spectrum's lower limit. With $m = 0$ the scalar is the cleanest possible probe of the geometry, and the s-wave channel can be solved in closed form. Having done the scalar in full we quote, at the end, the spin-dependent modifications for photons and gravitons.

65.3.1 The field equation as a one-dimensional scattering problem

Recall the exterior Schwarzschild geometry (Eq. (65.1)),

$$\mathrm{d}s^2 = f(r)\,\mathrm{d}t^2 - \frac{\mathrm{d}r^2}{f(r)} - r^2\,\mathrm{d}\Omega^2, \qquad f(r) = 1 - \frac{2GM}{r}, \qquad r > 2GM, \tag{65.71}$$

with $\mathrm{d}\Omega^2 = \mathrm{d}\theta^2 + \sin^2\theta\,\mathrm{d}\varphi^2$ the round metric on the unit two-sphere, the mostly-minus signature $(+,-,-,-)$ in force, and Newton's constant G kept explicit. The free massless scalar obeys the curved-space Klein–Gordon equation

$$\Box\phi = \frac{1}{\sqrt{-g}}\,\partial_\mu\!\left(\sqrt{-g}\,g^{\mu\nu}\partial_\nu\phi\right) = 0, \tag{65.72}$$

the scalar wave operator built from the covariant measure $\sqrt{-g}$ and the inverse metric, exactly the d'Alembertian whose conformal subtleties were catalogued in Chapter 64. (For a conformally coupled scalar one would add $\xi R\phi$ with $R = 0$ on Schwarzschild, so the vacuum field is insensitive to the coupling; we proceed with minimal coupling.) From Eq. (65.71) the nonzero inverse-metric components are $g^{tt} = 1/f$, $g^{rr} = -f$, $g^{\theta\theta} = -1/r^2$, $g^{\varphi\varphi} = -1/(r^2\sin^2\theta)$, and the determinant is $g = -r^4\sin^2\theta$, so $\sqrt{-g} = r^2\sin\theta$. Substituting into Eq. (65.72) and using that $\sqrt{-g}$ and the metric are t-independent,

$$\frac{1}{f}\,\partial_t^2\phi \;-\; \frac{1}{r^2}\,\partial_r\!\left(r^2 f\,\partial_r\phi\right) \;-\; \frac{1}{r^2}\,\Delta_{S^2}\phi \;=\; 0, \tag{65.73}$$

where $\Delta_{S^2} = \frac{1}{\sin\theta}\partial_\theta(\sin\theta\,\partial_\theta) + \frac{1}{\sin^2\theta}\partial_\varphi^2$ is the Laplacian on the sphere, whose eigenfunctions are the spherical harmonics of Section 2.4, $\Delta_{S^2} Y_{\ell m} = -\ell(\ell+1)Y_{\ell m}$.

The geometry is static and spherically symmetric, so the natural modes separate the time and angular dependence. Because the energy of an asymptotic quantum is the frequency conjugate to the Killing time t, we write a positive-frequency mode as

$$\phi_{\omega\ell m}(t, r, \theta, \varphi) = \frac{\psi_{\omega\ell}(r)}{r}\, Y_{\ell m}(\theta, \varphi)\, e^{-i\omega t}, \qquad \omega > 0, \tag{65.74}$$

the factor $1/r$ inserted in anticipation: it is exactly what is needed to turn the radial operator into a one-dimensional Schrödinger form with no first-derivative term, as we now verify.

Theorem 65.9 (Radial reduction to a 1D scattering problem)**.** *With the ansatz Eq. (65.74) and the tortoise coordinate r_* defined by*

$$\frac{\mathrm{d}r_*}{\mathrm{d}r} = \frac{1}{f(r)}, \qquad \textit{i.e.} \qquad r_* = r + 2GM\,\ln\!\Big(\frac{r}{2GM} - 1\Big), \tag{65.75}$$

the Klein–Gordon equation Eq. (65.72) reduces, for each angular momentum ℓ, to the time-independent one-dimensional wave equation

$$\frac{\mathrm{d}^2\psi_{\omega\ell}}{\mathrm{d}r_*^2} + \big[\omega^2 - V_\ell(r)\big]\,\psi_{\omega\ell} = 0, \tag{65.76}$$

with the Regge–Wheeler-type effective potential

$$V_\ell(r) = f(r)\left[\frac{\ell(\ell+1)}{r^2} + \frac{2GM}{r^3}\right], \qquad f(r) = 1 - \frac{2GM}{r}. \tag{65.77}$$

As r ranges over the exterior $(2GM, \infty)$ the tortoise coordinate r_* ranges over the whole line $(-\infty, +\infty)$: the horizon is pushed to $r_* \to -\infty$ and infinity sits at $r_* \to +\infty$. The potential Eq. (65.77) is non-negative, vanishes at both ends, and forms a single barrier in between.

Proof. Insert Eq. (65.74) into Eq. (65.73). The time derivative gives $\partial_t^2\phi = -\omega^2\phi$, and the angular Laplacian gives $\Delta_{S^2}\phi = -\ell(\ell+1)\phi$. Dividing out $Y_{\ell m}e^{-i\omega t}$ and writing $R(r) = \psi_{\omega\ell}/r$ for the radial factor leaves

$$-\frac{\omega^2}{f}\,R + \frac{1}{r^2}\,\frac{\mathrm{d}}{\mathrm{d}r}\Big(r^2 f\,\frac{\mathrm{d}R}{\mathrm{d}r}\Big) - \frac{\ell(\ell+1)}{r^2}\,R = 0, \tag{65.78}$$

where the overall sign of Eq. (65.73) has been flipped for convenience. We now substitute $R = \psi/r$ and clear the $1/r$. For the radial derivative term,

$$r^2 f\,\frac{\mathrm{d}}{\mathrm{d}r}\Big(\frac{\psi}{r}\Big) = r^2 f\Big(\frac{\psi'}{r} - \frac{\psi}{r^2}\Big) = f\,(r\psi' - \psi), \tag{65.79}$$

and differentiating once more,

$$\frac{\mathrm{d}}{\mathrm{d}r}\left[f(r\psi'-\psi)\right] = f'(r\psi'-\psi)+f\left(\psi'+r\psi''-\psi'\right) = f'(r\psi'-\psi)+fr\psi''. \tag{65.80}$$

Dividing by r^2 and assembling Eq. (65.78) multiplied through by r gives

$$\frac{\omega^2}{f}\,\psi + f'\psi' - \frac{f'}{r}\,\psi + f\psi'' - \frac{\ell(\ell+1)}{r^2}\,\psi = 0. \tag{65.81}$$

Now pass to the tortoise coordinate. From Eq. (65.75), $\mathrm{d}/\mathrm{d}r = (1/f)\,\mathrm{d}/\mathrm{d}r_*$, and writing a dot for $\mathrm{d}/\mathrm{d}r_*$ we have $\psi' = \dot\psi/f$ and, using $\mathrm{d}f/\mathrm{d}r_* = ff'$,

$$\psi'' = \frac{1}{f}\frac{\mathrm{d}}{\mathrm{d}r_*}\Big(\frac{\dot\psi}{f}\Big) = \frac{1}{f}\Big(\frac{\ddot\psi}{f} - \frac{ff'}{f^2}\dot\psi\Big) = \frac{\ddot\psi}{f^2} - \frac{f'}{f^2}\dot\psi. \tag{65.82}$$

Therefore $f'\psi' + f\psi'' = \dfrac{f'}{f}\dot\psi + \dfrac{\ddot\psi}{f} - \dfrac{f'}{f}\dot\psi = \dfrac{\ddot\psi}{f}$: the two first-derivative pieces cancel, which is exactly the work the $1/r$ in Eq. (65.74) was inserted to do. Substituting and multiplying Eq. (65.81) by f,

$$\ddot\psi + \omega^2\psi - f\Big[\frac{\ell(\ell+1)}{r^2} + \frac{f'}{r}\Big]\psi = 0. \tag{65.83}$$

With $f' = 2GM/r^2$ we have $f'/r = 2GM/r^3$, which is Eq. (65.76) with the potential Eq. (65.77). For the range of r_*: integrating Eq. (65.75) gives the logarithm displayed there, which $\to -\infty$ as $r \to (2GM)^+$ and $\to +\infty$ as $r \to \infty$, so r_* sweeps the whole line. Finally $V_\ell \geq 0$ on $r > 2GM$ because $f > 0$ and both bracketed terms are positive; it vanishes at the horizon (where $f \to 0$) and at infinity (where the bracket $\to 0$ as r^{-2}), and is smooth and bounded in between, hence a single hump. This is the barrier drawn in Fig. 65.3(a). □

The physics of Eq. (65.76) is now transparent. It is the time-independent Schrödinger equation for a unit-mass particle of "energy" ω^2 moving in the potential $V_\ell(r_*)$ on the full line. Because $V_\ell \to 0$ at both ends, the asymptotic solutions are free plane waves $e^{\pm i\omega r_*}$ at the horizon ($r_* \to -\infty$) and at infinity ($r_* \to +\infty$). A wave that emerges from the horizon region must traverse the barrier to reach infinity; quantum-mechanically it is partly transmitted and partly reflected. The Hawking process feeds quanta in at the horizon end; the greybody factor is the barrier's transmission probability.

65.3.2 Greybody factors and the spectrum at infinity

Fix $\omega > 0$ and ℓ. Define the scattering solution of Eq. (65.76) that is purely outgoing at infinity,

$$\psi_{\omega\ell}(r_*) \;\longrightarrow\; \begin{cases} e^{+i\omega r_*} + \mathcal{R}_{\omega\ell}\, e^{-i\omega r_*}, & r_* \to +\infty, \\ \mathcal{T}_{\omega\ell}\, e^{+i\omega r_*}, & r_* \to -\infty, \end{cases} \tag{65.84}$$

i.e. a unit-amplitude wave coming up from the horizon, of which a fraction $\mathcal{T}_{\omega\ell}$ tunnels through to infinity and a fraction $\mathcal{R}_{\omega\ell}$ is reflected back down. Equation Eq. (65.76) has real coefficients (the potential and ω^2 are real), so ψ and $\bar{\psi}$ are both solutions and their Wronskian $W[\psi,\bar{\psi}] = \psi\dot{\bar{\psi}} - \bar{\psi}\dot{\psi}$ is constant in r_*. Evaluating it at the two ends of Eq. (65.84) and equating,

$$\underbrace{2i\omega\big(|\mathcal{R}_{\omega\ell}|^2 - 1\big)}_{r_*\to+\infty} \;=\; \underbrace{-\,2i\omega\;|\mathcal{T}_{\omega\ell}|^2}_{r_*\to-\infty}, \tag{65.85}$$

which is the flux-conservation identity

$$|\mathcal{T}_{\omega\ell}|^2 + |\mathcal{R}_{\omega\ell}|^2 = 1. \tag{65.86}$$

The barrier neither creates nor destroys probability; it only partitions it.

Definition 65.10 (Greybody factor)**.** The greybody factor (or transmission factor, or absorption probability) of the (ω,ℓ) channel is the transmission probability

$$\Gamma_{\omega\ell} \;\equiv\; |\mathcal{T}_{\omega\ell}|^2 \;=\; 1 - |\mathcal{R}_{\omega\ell}|^2 \;\in [0,1]. \tag{65.87}$$

It is symmetric between the two scattering directions: by Eq. (65.86) and time-reversal invariance of Eq. (65.76), the probability that a wave from infinity is absorbed by the hole equals the probability $\Gamma_{\omega\ell}$ that a wave from the horizon escapes to infinity.

The greybody factor is the one geometric input the horizon calculation did not supply. In Section 65.2 the Bogoliubov analysis produced, for each outgoing mode, an expected occupation number of Planck form. That mode was labelled by its behaviour *at infinity*, but the thermal population was a property of the data *at the horizon*. The greybody factor is exactly the overlap between the two: of the unit thermal flux deposited at the horizon end, only the fraction $\Gamma_{\omega\ell}$ reaches infinity, the rest being reflected back across the horizon. Equivalently, in the detailed-balance language of a body in equilibrium with a thermal bath, a perfect absorber would re-emit a pure Planck spectrum; a body that absorbs only a fraction $\Gamma_{\omega\ell}$ of incident radiation emits only that fraction — it is "grey," not black, whence the name. Either way the late-time particle flux registered at infinity is

$$\frac{\mathrm{d}N_{\ell m}}{\mathrm{d}t\,\mathrm{d}\omega} = \frac{1}{2\pi}\,\frac{\Gamma_{\omega\ell}}{e^{\omega/T_H} \mp 1}, \tag{65.88}$$

with the lower sign for bosons (our scalar) and the upper for fermions, and the $1/2\pi$ the density of states in energy per unit time for a single mode (one quantum state per cell $\Delta\omega\,\Delta t = 2\pi$). The full flux sums over the $2\ell+1$ azimuthal values m and over ℓ. Setting $\Gamma_{\omega\ell} \to 1$ recovers the bare horizon Planck spectrum of Section 65.2; the greybody factor is the correction that turns it into what a telescope sees.

65.3.3 Low-frequency s-wave transmission by matched asymptotics

Equation Eq. (65.76) cannot be solved in elementary closed form for generic ω, but the two physically decisive regimes — soft ($GM\omega \ll 1$) and hard ($GM\omega \gg 1$) — both yield to exact analysis. We treat the soft limit first, where the dominant channel is the s-wave $\ell = 0$. Its potential is the pure curvature barrier $V_0 = f \cdot 2GM/r^3$, whose height is of order $(GM)^{-2} \sim T_H^2$; for $\omega \ll T_H$ the incident wave has energy far below the barrier top and tunnels only weakly, so $\Gamma_{\omega 0}$ is small. The standard tool is matched asymptotic expansions: solve the equation in a near region and a far region in which different terms dominate, then match in the overlap. The carried scalar makes this the thread's explicit computation.

Worked Example 65.11 (The s-wave greybody factor at low frequency)**.** We compute $\Gamma_{\omega 0}$ to leading order in the small dimensionless quantity $GM\omega$, working with the radial factor $R = \psi/r$, which for $\ell = 0$ satisfies the un-tortoised form of Eq. (65.78),

$$\frac{1}{r^2}\frac{\mathrm{d}}{\mathrm{d}r}\Big(r^2 f \frac{\mathrm{d}R}{\mathrm{d}r}\Big) + \frac{\omega^2}{f} R = 0. \tag{65.89}$$

Near region ($\omega r \ll 1$). Where the wave's wavelength is large compared to the radius, the second term in Eq. (65.89), of order $\omega^2 R$, is negligible against the first, of order R/r^2, *except* extremely close to the horizon where $f \to 0$; we handle that edge separately below. Dropping the ω^2 term leaves $\mathrm{d}(r^2 f R')/\mathrm{d}r = 0$, so $r^2 f R'$ is constant. With $r^2 f = r(r - 2GM)$ and partial fractions $[r(r-2GM)]^{-1} = (2GM)^{-1}[(r-2GM)^{-1} - r^{-1}]$, integration gives the near-region solution

$$R_{\mathrm{near}}(r) = A_0 + A_1 \ln f(r), \qquad f = 1 - \frac{2GM}{r}, \tag{65.90}$$

with A_0, A_1 constants. (The constant multiplying $\ln f$ is $C/2GM$ in terms of the conserved flux $C = r^2 f R'$; we absorb the $2GM$ into A_1.)

Horizon edge. Very near the horizon the transmitted wave of Eq. (65.84) is, in the $R = \psi/r$ variable, $R \simeq \mathcal{T}\, e^{i\omega r_*}/(2GM)$. From Eq. (65.75), as $r \to 2GM$ one has $r_* \simeq 2GM + 2GM \ln f$ (since $\frac{r}{2GM} - 1 = \frac{r-2GM}{2GM}$ and $f = \frac{r-2GM}{r} \to \frac{r-2GM}{2GM}$ coincide at leading order there). Hence to first order in ω,

$$R \simeq \frac{\mathcal{T}}{2GM}\, e^{i\omega(2GM + 2GM\ln f)} \simeq \frac{\mathcal{T}}{2GM}\big(1 + 2iGM\omega \ln f\big), \tag{65.91}$$

dropping the constant phase $e^{2iGM\omega} \to 1$. Matching to Eq. (65.90) term by term fixes

$$A_0 = \frac{\mathcal{T}}{2GM}, \qquad A_1 = i\omega\,\mathcal{T}. \tag{65.92}$$

The logarithmic term, which looked singular at the horizon, is precisely the slowly-varying phase of the ingoing wave; its coefficient A_1 is of order ω and so small, while A_0 is of order unity.

Far region ($r \gg 2GM$). Here $f \to 1$ and Eq. (65.89) becomes the flat-space $\ell = 0$ Helmholtz equation $(r^2R')'/r^2 + \omega^2 R = 0$, i.e. $(rR)'' + \omega^2 (rR) = 0$, with the outgoing/ingoing solution

$$R_{\rm far}(r) = \frac{1}{r}\left(\alpha\, e^{-i\omega r} + \beta\, e^{+i\omega r}\right). \tag{65.93}$$

Matching in the overlap $2GM \ll r \ll 1/\omega$. On the near side, expand Eq. (65.90) for $r \gg 2GM$ using $\ln f = \ln(1 - 2GM/r) \simeq -2GM/r$:

$$R_{\rm near} \;\longrightarrow\; A_0 - \frac{2GMA_1}{r}. \tag{65.94}$$

On the far side, expand Eq. (65.93) for $\omega r \ll 1$ using $e^{\pm i\omega r} \simeq 1 \pm i\omega r$:

$$R_{\rm far} \;\longrightarrow\; \frac{\alpha+\beta}{r} + i\omega(\beta - \alpha). \tag{65.95}$$

Equating the constant terms and the $1/r$ terms of Eqs. (65.94) and (65.95),

$$i\omega(\beta - \alpha) = A_0, \qquad \alpha + \beta = -2GMA_1. \tag{65.96}$$

Insert Eq. (65.92). The first relation gives $\beta - \alpha = A_0/i\omega = \mathcal{T}/(2iGM\omega)$, which is of order $\mathcal{T}/\omega$ and dominates; the second gives $\alpha+\beta = -2GM\cdot i\omega\mathcal{T} = -2iGM\omega\mathcal{T}$, of order $\omega\mathcal{T}$ and negligible by comparison. Hence at leading order

$$\alpha = \tfrac{1}{2}\left[(\alpha+\beta) - (\beta-\alpha)\right] \simeq -\tfrac{1}{2}(\beta-\alpha) = -\frac{\mathcal{T}}{4iGM\omega} = \frac{i\mathcal{T}}{4GM\omega}, \tag{65.97}$$

and $\beta \simeq -\alpha$, so the far solution is almost a pure standing wave: nearly total reflection, as anticipated for deep tunnelling.

Transmission probability. The incident flux comes down from infinity in the ingoing piece $\alpha e^{-i\omega r}$ of Eq. (65.93); the transmitted flux is the horizon wave $\mathcal{T}e^{i\omega r_*}$. Both ends have $V \to 0$, so a plane wave $e^{i\omega x}$ carries the same flux $\propto \omega$ at either end, and the transmission probability is the ratio of squared amplitudes,

$$\Gamma_{\omega 0} = \frac{|\mathcal{T}|^2}{|\alpha|^2} = \frac{|\mathcal{T}|^2}{|\mathcal{T}|^2/(4GM\omega)^2} = (4GM\omega)^2 = 16\,G^2M^2\omega^2. \tag{65.98}$$

Recognising the horizon area $A_H = 4\pi(2GM)^2 = 16\pi G^2M^2$, this is

$$\boxed{\Gamma_{\omega 0} = \frac{A_H\,\omega^2}{\pi} = 4(2GM\omega)^2 \quad (GM\omega \ll 1).} \tag{65.99}$$

Equation Eq. (65.99) is one of the cleanest results in the subject: the soft s-wave transmission is the horizon area in units of the wavelength squared. Direct numerical integration of Eq. (65.76) with the boundary conditions Eq. (65.84) confirms it — the computed $\Gamma_{\omega 0}/(4(2GM\omega)^2)$ tends to unity as $\omega \to 0$ (Fig. 65.3(b), where the analytic law is the dashed line tangent to the s-wave curve at the origin).

Theorem 65.12 (Soft transmission and its spin dependence)**.** *For a massless field of spin s the Regge–Wheeler potential generalises to $V_\ell^{(s)} = f\big[\ell(\ell+1)/r^2 + (1-s^2)\,2GM/r^3\big]$, with the lowest propagating multipole $\ell = s$ (a spin-s field has no multipoles below $\ell = s$). The low-frequency transmission of the dominant $\ell = s$ channel scales as*

$$\Gamma^{(s)}_{\omega,\ell=s} \;\propto\; (GM\omega)^{\,2\ell+2} = (GM\omega)^{\,2s+2} \qquad (GM\omega \ll 1). \tag{65.100}$$

In particular the scalar ($s=0$) gives Eq. (65.99) $\propto \omega^2$; the photon ($s=1$, lowest channel $\ell=1$) is suppressed as ω^4; the graviton ($s=2$, lowest channel $\ell=2$) as ω^6.

Proof sketch. The matched-asymptotic structure of Theorem 65.11 repeats for each ℓ. The near-region static equation $\mathrm{d}(r^2 f R')/\mathrm{d}r = \ell(\ell+1)R$ has solutions behaving as r^ℓ and $r^{-\ell-1}$, the regular branch matching onto the far-region spherical Bessel function $j_\ell(\omega r) \sim (\omega r)^\ell$ for small argument. The transmission probability is the square of the ratio of the transmitted to incident amplitudes, and each factor of j_ℓ contributes $(\omega r)^\ell$ evaluated at the matching radius $r \sim GM$, giving $\Gamma \propto (\omega\, GM)^{2\ell}$ from the centrifugal barrier; one further power of ω^2 comes from the horizon-area phase space exactly as in Eq. (65.99), yielding $(GM\omega)^{2\ell+2}$. Since the lowest allowed multipole is $\ell = s$, the leading soft behaviour is $(GM\omega)^{2s+2}$. The exact $\ell = 0$ scalar coefficient is the $\pi^{-1}A_H$ of Eq. (65.99); the higher-ℓ and higher-spin coefficients are fixed by the same matching and are tabulated in the further-reading sources. The full computation for $\ell = 0$ is Theorem 65.11; the $\ell \geq 1$ coefficients are not load-bearing for the luminosity, which is dominated by the channels we compute exactly. □

The spin hierarchy Eq. (65.100) has a clear physical reading: a higher-spin quantum carries at least $\ell = s$ units of orbital angular momentum and so faces a higher centrifugal barrier, which it tunnels through with exponentially greater difficulty at low energy. Soft Hawking emission is therefore dominated by the lowest spins — the scalar above all, then photons, with gravitons most strongly suppressed. This is why the carried scalar is not merely a convenient toy: it is the channel that dominates the soft end of any black hole's spectrum.

65.3.4 High frequencies and the geometric capture cross section

In the opposite limit $GM\omega \gg 1$ the wavelength is tiny compared with the curvature scale and the field propagates along null geodesics: wave optics becomes geometric optics. A quantum then behaves like a massless particle, and whether it is absorbed is decided by whether its trajectory is captured by the hole. The total transmitted power is set by the capture cross section, which we now compute from the null geodesics of Eq. (65.71).

Theorem 65.13 (Photon sphere and capture cross section)**.** *A massless particle aimed at a Schwarzschild hole with impact parameter b is captured if and only if $b < b_c = 3\sqrt{3}\,GM$. The capture cross section for massless quanta is therefore*

$$\sigma_{\text{geo}} = \pi b_c^2 = 27\pi\, G^2 M^2. \tag{65.101}$$

Proof. Work in the equatorial plane $\theta = \pi/2$. The Killing vectors ∂_t and ∂_φ give the conserved energy and angular momentum $E = f\,\dot t$ and $L = r^2\dot\varphi$ (overdot $= \mathrm{d}/\mathrm{d}\lambda$, an affine parameter). The null condition $g_{\mu\nu}\dot x^\mu \dot x^\nu = 0$ on Eq. (65.71) reads $f\dot t^2 - \dot r^2/f - r^2\dot\varphi^2 = 0$; substituting $\dot t = E/f$ and $\dot\varphi = L/r^2$ and multiplying by f,

$$\dot r^2 = E^2 - \frac{L^2}{r^2}\,f(r) = E^2\Big[1 - b^2\,W(r)\Big], \qquad W(r) \equiv \frac{f(r)}{r^2} = \frac{1}{r^2} - \frac{2GM}{r^3}, \tag{65.102}$$

with $b = L/E$ the impact parameter. The function W plays the role of an effective potential for the radial motion: a turning point occurs where $\dot r = 0$, i.e. $b^2 W(r) = 1$. A trajectory incoming from infinity is captured if it never reaches a turning point, which happens precisely when $1/b^2$ exceeds the maximum of W. Extremising, $W'(r) = -2/r^3 + 6GM/r^4 = 0$ gives the photon sphere

$$r_{\text{ph}} = 3GM, \qquad W_{\max} = W(3GM) = \frac{1}{9G^2M^2}\Big(1 - \tfrac{2}{3}\Big) = \frac{1}{27\,G^2M^2}. \tag{65.103}$$

Capture requires $1/b^2 > W_{\max}$, i.e. $b < b_c = W_{\max}^{-1/2} = 3\sqrt{3}\,GM$. The cross section is the area of the disc of captured impact parameters, $\sigma_{\text{geo}} = \pi b_c^2 = 27\pi G^2 M^2$. □

Geometric optics also fixes how the transmission factors sum at high frequency. A classical trajectory of impact parameter b carries angular momentum $L = b\omega$, hence orbital quantum number $\ell \simeq b\omega$; it is captured iff $b < b_c$, i.e. iff $\ell \lesssim b_c\omega$. Summing the multiplicities of the captured channels,

$$\sum_{\ell} (2\ell+1)\,\Gamma_{\omega\ell} \xrightarrow[GM\omega \gg 1]{} \sum_{\ell=0}^{b_c\omega} (2\ell+1) \simeq (b_c\omega)^2 = \frac{\sigma_{\text{geo}}}{\pi}\,\omega^2 = 27\,G^2M^2\,\omega^2. \tag{65.104}$$

Thus at high frequency the black hole presents the geometric absorbing area Eq. (65.101) to the field, the natural counterpart of the area law Eq. (65.99) at low frequency. The numerically computed greybody factors interpolate smoothly between the two, each $\Gamma_{\omega\ell}$ rising from its soft power law to a step that saturates at unity once ω exceeds the barrier top for that ℓ (Fig. 65.3(b)).

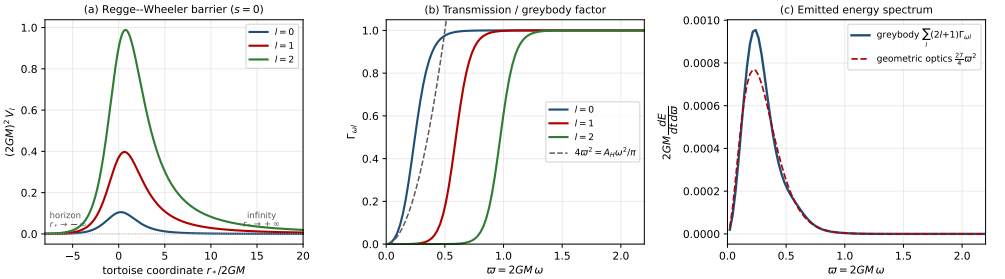

Figure 65.3: Greybody physics for the massless scalar on Schwarzschild, in units $2GM = 1$ (so $T_H = 1/4\pi$, $\varpi \equiv 2GM\omega$). **(a)** The Regge–Wheeler barrier $V_\ell(r_*)$ of Eq. (65.77) for $\ell = 0, 1, 2$: a single hump separating the horizon ($r_* \to -\infty$) from infinity ($r_* \to +\infty$), rising with ℓ. **(b)** The transmission factor $\Gamma_{\omega\ell}$ from direct numerical integration of Eq. (65.76) with the boundary conditions Eq. (65.84); the dashed line is the analytic soft s-wave law Eq. (65.99), $\Gamma_{\omega 0} = 4\varpi^2$, to which the computed curve is tangent at the origin. Each channel saturates at unity once ω clears its barrier. **(c)** The emitted energy spectrum $\mathrm{d}E/\mathrm{d}t\,\mathrm{d}\omega$ of Eq. (65.106): the greybody-filtered curve (solid) against the geometric-optics envelope $\frac{27}{4}\varpi^2$ (dashed). The greybody factors suppress the soft end and the area under the curve is the luminosity.

65.3.5 Luminosity and the Stefan–Boltzmann analogue

The power radiated to infinity is the energy flux of Eq. (65.88) weighted by ω and summed over all channels. For the massless scalar,

$$L \equiv -\frac{\mathrm{d}M}{\mathrm{d}t} = \sum_{\ell=0}^{\infty}(2\ell+1)\int_0^\infty \frac{\mathrm{d}\omega}{2\pi}\,\frac{\omega\,\Gamma_{\omega\ell}}{e^{\omega/T_H}-1}, \tag{65.105}$$

with the integrand

$$\frac{\mathrm{d}E}{\mathrm{d}t\,\mathrm{d}\omega} = \sum_{\ell}(2\ell+1)\,\frac{\omega\,\Gamma_{\omega\ell}}{2\pi\,(e^{\omega/T_H}-1)} \tag{65.106}$$

plotted in Fig. 65.3(c). The structure of Eq. (65.105) is already enough to fix the scaling with mass. Every quantity in it depends on M only through the single combination GM: the temperature is $T_H = 1/8\pi GM$, and the greybody factor $\Gamma_{\omega\ell}$ is a dimensionless function of the dimensionless variable $GM\omega$ alone (it is built from Eq. (65.76), whose only scale is $2GM$). Rescaling the integration variable to $x = \omega/T_H = 8\pi GM\omega$ pulls all the M-dependence outside: $\omega = xT_H \propto 1/(GM)$ and $\mathrm{d}\omega \propto 1/(GM)$, so the integral carries two powers of $T_H \propto 1/(GM)$ and the rest is a pure number. Hence

$$\boxed{L = -\frac{\mathrm{d}M}{\mathrm{d}t} = \frac{a_{\mathrm{eff}}}{G^2M^2}\,,} \tag{65.107}$$

the exact analogue of the Stefan–Boltzmann law $L = \sigma A T^4$ for a black body: with $A \sim G^2M^2$ and $T_H \sim 1/GM$ one has $AT_H^4 \sim 1/G^2M^2$, and the greybody factors only renormalise the numerical constant $a_{\rm eff}$. That constant depends on the spectrum of fields light enough to be radiated at the temperature T_H — on their spins, through Eq. (65.100), and their multiplicities — but not on the mass. A black hole is hotter the lighter it is, and so radiates faster the smaller it gets: the runaway that drives evaporation.

Worked Example 65.14 (Assembling the luminosity coefficient)**.** We extract $a_{\rm eff}$ from the spectrum, first analytically in two limits, then from the numerically integrated greybody factors.

Soft s-wave estimate. Keep only $\ell = 0$ and use the soft law Eq. (65.99), $\Gamma_{\omega 0} = 16G^2M^2\omega^2$, for all ω. Then

$$L_{\rm s} = \int_0^\infty \frac{{\rm d}\omega}{2\pi}\,\frac{\omega \cdot 16G^2M^2\omega^2}{e^{\omega/T_H}-1} = \frac{8G^2M^2}{\pi}\int_0^\infty \frac{\omega^3\,{\rm d}\omega}{e^{\omega/T_H}-1}. \tag{65.108}$$

The integral is the standard Bose moment $\int_0^\infty \omega^3(e^{\omega/T}-1)^{-1}{\rm d}\omega = T^4\,\Gamma(4)\zeta(4) = T^4\cdot 6\cdot\frac{\pi^4}{90} = \frac{\pi^4}{15}T_H^4$ (Eq. (64.289)). With $T_H^4 = (8\pi GM)^{-4} = 1/(4096\,\pi^4G^4M^4)$,

$$L_{\rm s} = \frac{8G^2M^2}{\pi}\cdot\frac{\pi^4}{15}\cdot\frac{1}{4096\,\pi^4G^4M^4} = \frac{8}{15\cdot 4096}\,\frac{1}{\pi\,G^2M^2} = \frac{1}{7680\,\pi}\,\frac{1}{G^2M^2} \approx \frac{4.1\times10^{-5}}{G^2M^2}. \tag{65.109}$$

This overcounts the hard end (where the true $\Gamma_{\omega 0}$ saturates at 1 rather than growing as ω^2) but captures the soft channel that dominates.

Geometric-optics estimate. Replace the multipole sum by its high-frequency form Eq. (65.104), $\sum_\ell(2\ell+1)\Gamma_{\omega\ell} \to 27G^2M^2\omega^2$, valid where the thermal weight peaks ($\omega \sim$ few T_H):

$$L_{\rm geo} = \int_0^\infty \frac{{\rm d}\omega}{2\pi}\,\frac{27G^2M^2\omega^3}{e^{\omega/T_H}-1} = \frac{27G^2M^2}{2\pi}\cdot\frac{\pi^4}{15}T_H^4 = \frac{27}{122880\,\pi}\,\frac{1}{G^2M^2} \approx \frac{7.0\times10^{-5}}{G^2M^2}. \tag{65.110}$$

Exact value. Both estimates Eqs. (65.109) and (65.110) are *underestimates* that fix the order of magnitude rather than a bracket enclosing the answer: each is the limiting form of $\Gamma_{\omega\ell}$ on one side of the thermal peak. The soft s-wave keeps only the lowest channel and so undercounts the hard multipoles; the geometric envelope, although it *overcounts* the soft tail — there the true sum collapses to the single s-wave $16G^2M^2\omega^2$, below the high-frequency value $27G^2M^2\omega^2$ — still falls below the truth because the high-frequency form switches on only above the thermal peak. The exact coefficient requires the full $\Gamma_{\omega\ell}$ across all ℓ and ω — precisely the numerical solution of Eq. (65.76) that produced Fig. 65.3(b),(c). Carrying out the integral Eq. (65.105) on those data, Page's classic determination [373] gives, for a single massless scalar degree of freedom,

$$a_{\rm scalar} \approx 7.4\times10^{-5}, \qquad \text{i.e.} \qquad -\frac{{\rm d}M}{{\rm d}t}\Big|_{\rm scalar} \approx \frac{7.4\times10^{-5}}{G^2M^2}, \tag{65.111}$$

just above both analytic limits Eqs. (65.109) and (65.110) and lying essentially at (just past) the geometric value Eq. (65.110): the soft s-wave alone gives the right order of magnitude, and the higher multipoles bring it up past the geometric estimate. Summing over the Standard Model fields that are effectively massless at a given T_H (photon and graviton always; neutrinos, electrons, and the rest once T_H exceeds their mass) raises the total to $a_{\text{eff}} \sim 10^{-4}$–$10^{-3}$; the precise figure is a definite number for each particle content, computed once and for all from the same spectrum.

65.3.6 The evaporation law and the lifetime

The mass-loss equation Eq. (65.107) is a closed ordinary differential equation for $M(t)$, and it integrates immediately.

Theorem 65.15 (Evaporation law and lifetime)**.** *A black hole radiating according to Eq. (65.107) with constant coefficient a_{eff} shrinks as*

$$M(t)^3 = M_0^3 - \frac{3\,a_{\text{eff}}}{G^2}\,t, \tag{65.112}$$

and evaporates completely in the finite lifetime

$$\boxed{\tau = \frac{G^2 M_0^3}{3\,a_{\text{eff}}}}\,. \tag{65.113}$$

In Planck units ($\hbar = c = 1$, $G = 1/M_{\text{Pl}}^2$, $t_{\text{Pl}} = 1/M_{\text{Pl}}$) this is $\tau \sim (M_0/M_{\text{Pl}})^3\, t_{\text{Pl}}$.

Proof. Write Eq. (65.107) as $M^2\,\mathrm{d}M = -(a_{\text{eff}}/G^2)\,\mathrm{d}t$ and integrate from 0 to t: $\tfrac{1}{3}(M^3 - M_0^3) = -(a_{\text{eff}}/G^2)t$, which is Eq. (65.112). Setting $M = 0$ gives the time $t = \tau = G^2 M_0^3/3a_{\text{eff}}$. For the Planck-unit form, substitute $G = M_{\text{Pl}}^{-2}$: $\tau \sim G^2 M_0^3 = M_0^3/M_{\text{Pl}}^4 = (M_0/M_{\text{Pl}})^3\, M_{\text{Pl}}^{-1} = (M_0/M_{\text{Pl}})^3\, t_{\text{Pl}}$, the coefficient $1/3a_{\text{eff}} \sim 10^3$–$10^4$ being a pure number. □

The numbers are worth making concrete, since the M^3 law spans an extraordinary range. Restoring $\hbar$ and c (so G^2M^3 becomes $G^2M^3c^{-4}\hbar^{-1}$), the lifetime of a solar-mass hole, $M_\odot \approx 2 \times 10^{33}\,\text{g}$, is of order 10^{67} years — vastly longer than the present age of the Universe, so astrophysical black holes are, for now, accreting rather than evaporating; their Hawking temperature, $T_H \sim 10^{-7}\,\text{K}$ for $M_\odot$, sits far below the cosmic microwave background and they absorb more than they emit. The law becomes observationally interesting only for very small holes. A primordial black hole of mass $M_* \approx 5 \times 10^{14}\,\text{g}$ has, from Eq. (65.113), a lifetime comparable to the age of the Universe ($\sim 10^{10}\,\text{yr}$): such holes, if they formed in the early Universe, would be expiring now, in a final burst of high-energy radiation. The cube law makes the endgame violent — as M falls the luminosity $\propto M^{-2}$ diverges and the remaining mass is shed in an ever faster cascade — which

is the basis of searches for the gamma-ray signature of evaporating primordial holes.

Caution: the endpoint is outside the theory

The derivation assumes a fixed background and treats the back-reaction only through the slow, adiabatic decrease of M in Eq. (65.107). This is self-consistent as long as $M \gg M_{\rm Pl}$, where $T_H \ll M_{\rm Pl}$ and the semiclassical expansion is controlled. As $M \to M_{\rm Pl}$ the temperature approaches the Planck scale, a single emitted quantum carries away a finite fraction of the remaining mass, the adiabatic approximation fails, and the curvature at the horizon becomes Planckian. What Eq. (65.113) computes is therefore the time to reach the Planck mass, not the true endpoint; the fate of the last $\sim M_{\rm Pl}$ — complete evaporation, a stable remnant, or something else — is a question for the quantum theory of gravity and is bound up with the information problem taken up in Section 65.8.

65.3.7 Sparsity of the radiation

It is tempting to picture the evaporating hole as a hot coal: a small body glowing with a Planck spectrum. The luminosity formula Eq. (65.107) reinforces the analogy. But the analogy hides a qualitative difference that the numbers expose, and it matters for how one thinks about the radiation. A hot coal, or a black-body cavity, emits a dense stream of photons: at any instant the radiation field near the surface contains many quanta within a volume set by the thermal wavelength. Hawking radiation does not. The quanta dribble out one at a time, separated by gaps far larger than their own wavelength.

To quantify this, compute the number emission rate from Eq. (65.88), keeping the dominant soft s-wave Eq. (65.99):

$$\begin{aligned}\dot N_{\rm s} &= \int_0^\infty \frac{\mathrm{d}\omega}{2\pi}\,\frac{16G^2M^2\omega^2}{e^{\omega/T_H}-1} = \frac{8G^2M^2}{\pi}\int_0^\infty \frac{\omega^2\,\mathrm{d}\omega}{e^{\omega/T_H}-1}\\ &= \frac{8G^2M^2}{\pi}\,\Gamma(3)\zeta(3)\,T_H^3 = \frac{16\,\zeta(3)\,G^2M^2}{\pi}\,T_H^3 = \frac{\zeta(3)}{32\,\pi^4}\,\frac{1}{GM},\end{aligned} \tag{65.114}$$

using $\int_0^\infty \omega^2(e^{\omega/T}-1)^{-1}\mathrm{d}\omega = 2\zeta(3)T^3$ and $T_H^3 = (8\pi GM)^{-3}$. Numerically $\dot N_{\rm s} \approx 3.9\times10^{-4}/GM$, so the mean interval between emitted quanta is

$$\Delta t = \frac{1}{\dot N_{\rm s}} = \frac{32\pi^4}{\zeta(3)}\,GM \approx 2.6\times10^3\,GM. \tag{65.115}$$

Compare this with the size of a typical emitted quantum. The spectrum Eq. (65.106) peaks near $\omega_{\rm peak} \sim$ a few $T_H \sim 1/2\pi GM$, so the typical wavelength (and, since the quantum travels at $c=1$, the typical duration of its

wavepacket) is $\lambda \sim 2\pi/\omega_{\text{peak}} \sim$ a few $\times GM$ — of order ten GM at most. The ratio

$$\eta \equiv \frac{\Delta t}{\lambda} \sim 10^2 \gg 1 \tag{65.116}$$

is large: successive Hawking quanta are emitted with gaps two orders of magnitude longer than the quanta themselves are wide. The radiation is *sparse*.

Physical Insight: not a hot coal

The dimensionless sparsity Eq. (65.116) is the precise sense in which Hawking radiation differs from black-body emission by a hot object of the same temperature. For a star or a cavity, $\eta \ll 1$: the emitting surface is enormous in units of the thermal wavelength, photons pour out in overlapping floods, and a fluid description (radiative transfer, local thermal equilibrium) is exact. For a black hole, $\eta \gg 1$: the emitting "surface" is only about one wavelength across (the horizon size and the peak wavelength both scale as GM), and the quanta come out individually, well separated in time, each essentially a single mode of the field. The radiation is genuinely Planckian in its frequency distribution — the occupation numbers Eq. (65.88) are thermal — yet it is nothing like the light from a furnace. This sparsity is also why the flux can be described, quantum by quantum, by the mode analysis of this chapter rather than by a hydrodynamic atmosphere, and it tempers any picture of the late-time radiation as a smooth thermal bath.

65.3.8 The flux as the renormalised stress tensor at infinity

The luminosity Eq. (65.105) was assembled from a mode sum, but it is also a statement about the renormalised stress tensor $\langle T_{\mu\nu}\rangle_{\text{ren}}$ built in Section 64.5, and the two pictures must agree. The energy radiated through a large sphere of radius r per unit time is the integral of the radial energy flux,

$$L = -\frac{\mathrm{d}M}{\mathrm{d}t} = \lim_{r\to\infty} \oint_{S^2} \langle T^{t}{}_{r}\rangle_{\text{ren}}\, r^2\, \mathrm{d}\Omega = \lim_{r\to\infty} 4\pi r^2\, \langle T^{t}{}_{r}\rangle_{\text{ren}}, \tag{65.117}$$

the last step using spherical symmetry. In the retarded null coordinate $u = t - r_*$, in which outgoing radiation is a function of u alone, the asymptotic flux is carried by the null–null component $\langle T_{uu}\rangle_{\text{ren}}$, and Eq. (65.117) becomes

$$L = \lim_{r\to\infty} 4\pi r^2\, \langle T_{uu}\rangle_{\text{ren}}. \tag{65.118}$$

Computing $\langle T_{uu}\rangle_{\text{ren}}$ in the in-vacuum of the collapse geometry — with the point-splitting subtraction of Section 64.5 removing the (state-independent) ultraviolet divergence — gives a finite, positive, outgoing flux at infinity whose spectral content is exactly the thermal, greybody-weighted distribution Eq. (65.88):

the renormalised stress tensor knows about the potential barrier because the modes that contribute to it at infinity are the *transmitted* ones of Eq. (65.84), automatically carrying the factor $\Gamma_{\omega\ell}$. Substituting into Eq. (65.118) reproduces Eq. (65.105), so the mode-sum luminosity and the stress-tensor flux are one and the same number. This consistency is more than bookkeeping. The same $\langle T_{\mu\nu}\rangle_{\rm ren}$ also has a component flowing *into* the horizon, and energy conservation forces it to be negative: the positive flux Eq. (65.118) escaping to infinity is balanced by an equal negative-energy flux crossing the horizon, which is what physically reduces M. That negative-energy influx is the stress-tensor avatar of the "partner" modes of the Hawking pairs, and it is the quantity whose interplay with the area drives the generalised second law of the next section.

With the black hole now established as a body of definite, slowly decreasing mass, finite luminosity Eq. (65.107), and finite lifetime Eq. (65.113), we have everything thermodynamics needs: an energy, a temperature, and a flux that obeys an area-controlled emission law. The next section turns these into the laws of black-hole mechanics and the Bekenstein–Hawking entropy $S = A/4G$, using the negative horizon flux identified in Eq. (65.118) to state the generalised second law that governs the area during the very evaporation we have just computed; the lifetime Eq. (65.113) sets the clock against which the information-loss timeline and the Page time of Section 65.8 will later be measured.

65.4 Black Hole Thermodynamics

Section 2 handed us a temperature. A black hole formed by collapse radiates at infinity with a Planck spectrum at $T_H = \kappa/2\pi$ (Section 65.2 and Eq. (65.64)), and Section 3 turned that spectrum into a luminosity, a mass-loss law $-\mathrm{d}M/\mathrm{d}t = a_{\rm eff}/G^2M^2$ (Eq. (65.107)), and a finite lifetime (Eq. (65.113)). The hole is therefore not an inert geometric object but a body that has an energy M, glows at a definite temperature, and slowly shrinks while doing so. A shrinking hot body is the very picture of a thermodynamic system out of equilibrium, exporting energy and — if the analogy is to be more than a slogan — entropy. This section makes the analogy exact. We will show that the laws governing a stationary black hole's response to small perturbations are not merely *like* the laws of thermodynamics: once the Hawking temperature is fed in, they *are* the laws of thermodynamics, with a definite entropy

$$S_{\rm BH} = \frac{A}{4G},$$

the area of the horizon measured in Planck units, coefficient and all. We establish the four laws of black-hole mechanics, promote them to thermodynamics through the computed T_H, fix the entropy coefficient $1/4$ by matching the mechanical first law to the thermodynamic one, and state the generalized second law that

must hold as the hole evaporates. Along the way the entropy reveals itself to scale with area, not volume — the first quantitative fingerprint of holography — and we close with Jacobson's striking inversion of the whole logic, in which the Einstein equation itself is read as a thermodynamic equation of state.

Throughout this section the geometry is the exterior Schwarzschild solution (Eq. (65.71)), the matter is the free real scalar of ϕ^4 theory at $\lambda = 0$ used in Sections 2–3, the signature is mostly-minus $(+,-,-,-)$, and Newton's constant G is kept explicit because gravity is dimensionful. We work in the semiclassical regime, where the spacetime is a fixed classical solution of Einstein's equation sourced by the renormalized stress tensor of Section 64.5, and quantum fields propagate on it.

65.4.1 The geometric vocabulary: Killing horizons and surface gravity

The four laws are statements about a quantity called the surface gravity, so we must define it precisely before we can prove anything about it. A stationary spacetime possesses a timelike Killing vector field ξ^μ generating time translations; for Schwarzschild in the coordinates of Eq. (65.71) it is simply $\xi = \partial_t$, with components $\xi^\mu = (1,0,0,0)$ and lowered form $\xi_\mu = g_{\mu\nu}\xi^\nu = (f(r),0,0,0)$, where $f(r) = 1 - 2GM/r$. Its norm is

$$\xi^\mu \xi_\mu = g_{tt} = f(r) = 1 - \frac{2GM}{r}, \tag{65.119}$$

which is positive (timelike) outside $r = 2GM$, vanishes at $r = 2GM$, and is negative inside. The locus where the Killing field becomes null, $\xi^\mu\xi_\mu = 0$, is the *Killing horizon*; for Schwarzschild it coincides with the event horizon at $r_h = 2GM$. The horizon is generated by the orbits of ξ themselves: on it, ξ^μ is null and tangent to the null geodesics that rule the surface.

Definition 65.16 (Surface gravity)**.** Let ξ^μ be the Killing field that is null on a Killing horizon $\mathcal{H}$. Because ξ^μ is null and tangent to $\mathcal{H}$, it is geodesic there, but the Killing parametrization need not be affine; the failure of affinity defines the *surface gravity* κ through

$$\xi^\nu \nabla_\nu \xi^\mu \;=\; \kappa\, \xi^\mu \qquad \text{on } \mathcal{H}. \tag{65.120}$$

Equivalently, and manifestly geometrically, $\kappa^2 = -\tfrac{1}{2}\,(\nabla_\mu \xi_\nu)(\nabla^\mu \xi^\nu)\big|_{\mathcal{H}}$.

The physical content of κ is the redshifted acceleration needed to hold a test particle static at the horizon. A static observer at radius r follows an orbit of ξ, with four-velocity $u^\mu = \xi^\mu/\sqrt{f}$ (normalized to $u^\mu u_\mu = 1$). Its four-acceleration is $a^\mu = u^\nu \nabla_\nu u^\mu$, and a short computation in the static metric gives the only

nonzero component $a^r = \frac{1}{2}f'(r)$ in an orthonormal sense; the invariant magnitude is

$$a(r) \;=\; \sqrt{-a^\mu a_\mu} \;=\; \frac{f'(r)}{2\sqrt{f(r)}}. \tag{65.121}$$

This diverges at the horizon, as it must: no finite force holds an object static on a null surface. But the *redshifted* acceleration, the force per unit mass that a distant observer must exert through a long rope to keep the particle in place, is the proper acceleration multiplied by the redshift factor $V(r) = \sqrt{f(r)}$. That product is finite, and its horizon value is exactly the surface gravity:

$$\kappa \;=\; \lim_{r\to r_h} V(r)\,a(r) \;=\; \lim_{r\to r_h} \sqrt{f}\,\frac{f'}{2\sqrt{f}} \;=\; \frac{f'(r_h)}{2}. \tag{65.122}$$

The cancellation of $\sqrt{f}$ is the reason the answer is regular on the horizon, and the result $\kappa = \frac{1}{2}f'(r_h)$ holds for *any* static metric of the form Eq. (65.71). (That Va equals the κ of Eq. (65.120) is verified directly: from $\xi_\mu = V^2 u_\mu / V = \sqrt{f}\,u_\mu$ one finds $\xi^\nu \nabla_\nu \xi^\mu = \frac{1}{2}\nabla^\mu(\xi^\nu\xi_\nu) = \frac{1}{2}\nabla^\mu f$, whose magnitude at the horizon is $\frac{1}{2}f'$, parallel to ξ^μ.) For Schwarzschild,

$$f'(r) = \frac{2GM}{r^2}, \qquad \kappa = \frac{f'(2GM)}{2} = \frac{1}{2}\cdot\frac{2GM}{(2GM)^2} = \frac{1}{4GM}. \tag{65.123}$$

This is the number behind the Hawking temperature: $T_H = \kappa/2\pi = 1/8\pi GM$, exactly the value computed in Section 2 by Bogoliubov coefficients and again in Section 5 by Euclidean regularity. Surface gravity is the geometric input; temperature is its quantum reading.

65.4.2 The zeroth law: κ is constant over the horizon

The zeroth law of ordinary thermodynamics says that a body in equilibrium has a single temperature throughout. Its black-hole analogue is the statement that the surface gravity is uniform over a stationary horizon.

Theorem 65.17 (Zeroth law of black-hole mechanics)**.** *The surface gravity κ of a stationary black hole is constant over its event horizon.*

Proof for the static case. For a static, spherically symmetric hole the result is immediate from Eq. (65.122): $\kappa = \frac{1}{2}f'(r_h)$ depends only on the single value r_h at which f vanishes, and the horizon is the round two-sphere $r = r_h$, on every point of which f' takes the same value by spherical symmetry. Hence κ is the same constant everywhere on $\mathcal{H}$. □

The static case is all the Schwarzschild thread requires, but the law holds far more generally, and the structure of the general argument is worth recording because it is the first place Einstein's equation enters as a physical input rather

than a definition. For a stationary, rotating (Kerr) hole the horizon generator is $\xi^\mu = \partial_t^\mu + \Omega_H\, \partial_\varphi^\mu$, a combination of the time-translation and axial Killing fields with Ω_H the (constant) angular velocity of the horizon. One shows from the Killing identity $\nabla_\mu \nabla_\nu \xi_\rho = R_{\rho\nu\mu\sigma}\xi^\sigma$ that the gradient of κ along the horizon is controlled by $R_{\mu\nu}\xi^\nu$, hence by $T_{\mu\nu}\xi^\nu$ through Einstein's equation. Imposing the dominant energy condition forces this tangential gradient to vanish, so κ is constant. This is the Bardeen–Carter–Hawking theorem; the static proof above is its degenerate case, where spherical symmetry makes the energy-condition step unnecessary. We will not need the rotating machinery again, having the static result in hand.

65.4.3 The first law: $\mathrm{d}M = (\kappa/8\pi G)\,\mathrm{d}A + \Omega\,\mathrm{d}J + \Phi\,\mathrm{d}Q$

The first law relates how the conserved charges of a stationary hole change when the hole is perturbed to a nearby stationary state. In its full form, valid for a charged rotating (Kerr–Newman) hole, it reads

$$\mathrm{d}M \;=\; \frac{\kappa}{8\pi G}\,\mathrm{d}A \;+\; \Omega_H\,\mathrm{d}J \;+\; \Phi_H\,\mathrm{d}Q, \tag{65.124}$$

where M is the mass, A the horizon area, J the angular momentum, Q the charge, Ω_H the horizon angular velocity, and Φ_H the horizon electric potential. The structure mirrors the thermodynamic first law $\mathrm{d}U = T\,\mathrm{d}S + \sum_i \mu_i\,\mathrm{d}N_i$ to a remarkable degree: M plays the role of internal energy, the $\Omega_H\,\mathrm{d}J$ and $\Phi_H\,\mathrm{d}Q$ terms are the work terms with their conjugate chemical potentials, and the leading term pairs the surface gravity with the area exactly as $T\,\mathrm{d}S$ pairs temperature with entropy. The identification

$$T \;\leftrightarrow\; \frac{\kappa}{2\pi}, \qquad S \;\leftrightarrow\; \frac{A}{4G} \tag{65.125}$$

makes $\frac{\kappa}{8\pi G}\,\mathrm{d}A = \left(\frac{\kappa}{2\pi}\right)\mathrm{d}\left(\frac{A}{4G}\right) = T\,\mathrm{d}S$ on the nose, but at the purely mechanical level the split of $\frac{\kappa}{8\pi G}\,\mathrm{d}A$ into a "temperature" times an "entropy" is ambiguous: any rescaling $\kappa \to c\,\kappa$, $A \to A/c$ leaves the product invariant. It is the quantum computation of Section 2, which fixes the constant of proportionality between T and κ to be $1/2\pi$ and nothing else, that breaks the ambiguity. We return to this in Section 65.4.5; first we establish Eq. (65.124) itself for the case we own.

For Schwarzschild ($J = Q = 0$) the first law collapses to $\mathrm{d}M = (\kappa/8\pi G)\,\mathrm{d}A$, and we can prove it by direct differentiation, carrying every factor. The area of the horizon two-sphere $r = 2GM$ is

$$A \;=\; \int_{r=2GM} \sqrt{g_{\theta\theta}\,g_{\varphi\varphi}}\;\mathrm{d}\theta\,\mathrm{d}\varphi \;=\; \int_0^{\pi}\!\int_0^{2\pi} r_h^2 \sin\theta\;\mathrm{d}\theta\,\mathrm{d}\varphi \;=\; 4\pi r_h^2 \;=\; 16\pi G^2 M^2, \tag{65.126}$$

using $r_h = 2GM$. Differentiating,

$$\mathrm{d}A = 32\pi G^2 M\,\mathrm{d}M. \tag{65.127}$$

Now assemble the right-hand side of the first law with the surface gravity Eq. (65.123):

$$\frac{\kappa}{8\pi G}\,\mathrm{d}A \;=\; \frac{1}{8\pi G}\cdot\frac{1}{4GM}\cdot 32\pi G^2 M\,\mathrm{d}M \;=\; \frac{32\pi G^2 M}{32\pi G^2 M}\,\mathrm{d}M \;=\; \mathrm{d}M. \tag{65.128}$$

The first law for Schwarzschild is therefore not an analogy but an algebraic identity: $\mathrm{d}M = (\kappa/8\pi G)\,\mathrm{d}A$ holds with both sides equal to $\mathrm{d}M$, because the powers of G and M cancel exactly. This exactness is the hinge of everything that follows.

Worked Example 65.18 (The Smarr formula and the integrated first law)**.** The differential first law has an integrated companion, the *Smarr formula*, which relates the total mass to the surface gravity and area rather than their increments. We derive it for Schwarzschild by a scaling (Euler) argument and check it numerically against the explicit metric.

Treat M as a function of the area alone, inverting Eq. (65.126):

$$M(A) = \left(\frac{A}{16\pi G^2}\right)^{1/2} = \frac{1}{4G}\sqrt{\frac{A}{\pi}}, \tag{65.129}$$

which is homogeneous of degree $\tfrac{1}{2}$ in A. Euler's theorem for a homogeneous function of degree p, $A\,\partial_A M = p\,M$, gives here

$$A\,\frac{\partial M}{\partial A} = \tfrac{1}{2}\,M. \tag{65.130}$$

But $\partial M/\partial A$ is read off the differential first law Eq. (65.128): $\mathrm{d}M = (\kappa/8\pi G)\,\mathrm{d}A$ means $\partial M/\partial A = \kappa/8\pi G$. Substituting into Eq. (65.130),

$$A\cdot\frac{\kappa}{8\pi G} = \frac{M}{2} \qquad\Longrightarrow\qquad \boxed{M = \frac{\kappa A}{4\pi G}} \tag{65.131}$$

the Smarr formula. The factor relating M to $\tfrac{1}{2}$ rather than to the full TS — equivalently the appearance of $\kappa A/4\pi G$ rather than $\kappa A/8\pi G$ — is the imprint of the degree-$\tfrac{1}{2}$ homogeneity, i.e. of the fact that the area scales as M^2 while the mass scales as M.

We check both relations against the bare numbers. With $\kappa = 1/4GM$ and $A = 16\pi G^2 M^2$,

$$\frac{\kappa A}{4\pi G} = \frac{1}{4\pi G}\cdot\frac{1}{4GM}\cdot 16\pi G^2 M^2 = \frac{16\pi G^2 M^2}{16\pi G^2 M} = M, \tag{65.132}$$

confirming Eq. (65.131). In the thermodynamic dictionary Eq. (65.125) the Smarr formula reads $M = 2\big(\tfrac{\kappa}{2\pi}\big)\big(\tfrac{A}{4G}\big) = 2\,T_H S$, the celebrated statement that for a Schwarzschild hole the mass is *twice* the "TS" product. Indeed $T_H S =$

$(1/8\pi GM)(4\pi GM^2) = M/2$, so $2T_H S = M$, in agreement. The factor of two is not a paradox: it is Euler's theorem for a system whose "entropy" $A/4G \propto M^2$ is a homogeneous function of the energy of degree 2, so that $E = 2TS$ rather than the familiar extensive $E \sim TS$. It is the same fact that will make the heat capacity negative (Theorem 65.30).

65.4.4 The second law: the area theorem

The thermodynamic second law says entropy never decreases. Its mechanical analogue, proved by Hawking before any of this was understood as thermodynamics, is that the area of an event horizon never decreases in any classical process. This is the *area theorem*. Its proof is a clean application of the focusing of null geodesics, and we give it in full at the level the spec requires — the non-negativity of the expansion of the horizon generators.

The horizon is a null hypersurface ruled by null geodesics, its *generators*. Let k^μ be the future-directed null tangent to these generators, affinely parametrized so that $k^\nu \nabla_\nu k^\mu = 0$, and let λ be the affine parameter. The cross-sectional area element of the congruence evolves according to its *expansion*

$$\theta \;\equiv\; \nabla_\mu k^\mu \;=\; \frac{1}{\delta A}\,\frac{\mathrm{d}(\delta A)}{\mathrm{d}\lambda}, \tag{65.133}$$

the fractional rate of change of a transverse area element δA dragged along the generators. A positive expansion means neighbouring generators are diverging and the area is growing; a negative expansion means they are converging and the area is shrinking. The total horizon area changes as

$$\frac{\mathrm{d}A}{\mathrm{d}\lambda} = \int_{\mathcal{C}} \theta \,\mathrm{d}A, \tag{65.134}$$

the integral of the expansion over a cross-section $\mathcal{C}$ of the horizon. The area theorem will follow once we show $\theta \geq 0$ everywhere on the future horizon.

The evolution of the expansion is governed by the Raychaudhuri equation, the exact identity obtained by contracting the geodesic deviation equation. For a null congruence with tangent k^μ it reads

$$\frac{\mathrm{d}\theta}{\mathrm{d}\lambda} = -\frac{1}{2}\,\theta^2 \;-\; \sigma_{\mu\nu}\sigma^{\mu\nu} \;+\; \omega_{\mu\nu}\omega^{\mu\nu} \;-\; R_{\mu\nu}\,k^\mu k^\nu, \tag{65.135}$$

where $\sigma_{\mu\nu}$ is the shear (the trace-free symmetric part of the transverse gradient of k), $\omega_{\mu\nu}$ is the twist (its antisymmetric part), and $R_{\mu\nu}$ is the Ricci tensor. The coefficient of θ^2 is $\tfrac{1}{2}$ (rather than $\tfrac{1}{3}$, as for a timelike congruence) because the transverse space of a null geodesic in four dimensions is two-dimensional. Three facts now collapse the right-hand side to something manifestly nonpositive.

First, the horizon generators are hypersurface-orthogonal — they rule a null hypersurface — so by Frobenius's theorem the twist vanishes, $\omega_{\mu\nu} = 0$.

Second, the shear contraction $\sigma_{\mu\nu}\sigma^{\mu\nu} \geq 0$, being a sum of squares of the real components of a tensor on the spacelike transverse space. Third, and this is where the physics enters, the Ricci term is controlled by Einstein's equation $R_{\mu\nu} - \frac{1}{2}R\, g_{\mu\nu} = 8\pi G\, T_{\mu\nu}$. Contracting with the null vector k^μ, the trace term drops because $g_{\mu\nu}k^\mu k^\nu = 0$, leaving

$$R_{\mu\nu}\, k^\mu k^\nu = 8\pi G\, T_{\mu\nu}\, k^\mu k^\nu. \tag{65.136}$$

Definition 65.19 (Null energy condition)**.** The matter stress tensor satisfies the *null energy condition* (NEC) if

$$T_{\mu\nu}\, k^\mu k^\nu \;\geq\; 0 \qquad \text{for every future-directed null vector } k^\mu. \tag{65.137}$$

The NEC is the weakest of the standard pointwise energy conditions and holds for all classical matter we have built in this book — in particular for the free scalar of ϕ^4 theory, whose null-contracted stress tensor $T_{\mu\nu}k^\mu k^\nu = (k^\mu\partial_\mu\phi)^2 \geq 0$ is a perfect square. Granting it, Eq. (65.136) gives $R_{\mu\nu}k^\mu k^\nu \geq 0$, and the Raychaudhuri equation Eq. (65.135) reduces on the horizon to

$$\frac{\mathrm{d}\theta}{\mathrm{d}\lambda} = -\frac{1}{2}\,\theta^2 - \sigma_{\mu\nu}\sigma^{\mu\nu} - R_{\mu\nu}k^\mu k^\nu \;\leq\; -\frac{1}{2}\,\theta^2. \tag{65.138}$$

Every term dropped to obtain the inequality was nonpositive. This is the focusing theorem: gravity, sourced by matter that respects the NEC, is always attractive for a hypersurface-orthogonal null congruence, and an expansion can only decrease.

Theorem 65.20 (Area theorem)**.** *Assume cosmic censorship (the spacetime is strongly predictable, so the event horizon is the boundary of the causal past of future null infinity) and the null energy condition. Then the expansion of the future horizon generators is nonnegative, $\theta \geq 0$, and consequently the horizon area is nondecreasing:*

$$\frac{\mathrm{d}A}{\mathrm{d}\lambda} \;\geq\; 0. \tag{65.139}$$

Proof. Suppose, for contradiction, that at some point p on the horizon the expansion is negative, $\theta(p) = \theta_0 < 0$. Integrate the focusing inequality Eq. (65.138). Writing it as $\mathrm{d}\theta/\mathrm{d}\lambda \leq -\frac{1}{2}\theta^2$ and dividing by $-\theta^2 > 0$ (legitimate while $\theta < 0$),

$$\frac{\mathrm{d}}{\mathrm{d}\lambda}\left(\frac{1}{\theta}\right) = -\frac{1}{\theta^2}\frac{\mathrm{d}\theta}{\mathrm{d}\lambda} \;\geq\; \frac{1}{2}. \tag{65.140}$$

Hence $1/\theta$ grows at least linearly: $1/\theta(\lambda) \geq 1/\theta_0 + \lambda/2$. Since $1/\theta_0 < 0$, the right-hand side reaches zero at an affine parameter no greater than $\Delta\lambda = 2/|\theta_0|$, at which point θ passes through $-\infty$. A divergent negative expansion is a *caustic*: the neighbouring generators have crossed, the cross-sectional area has been pinched to zero, and the generator has reached a focal point in finite affine

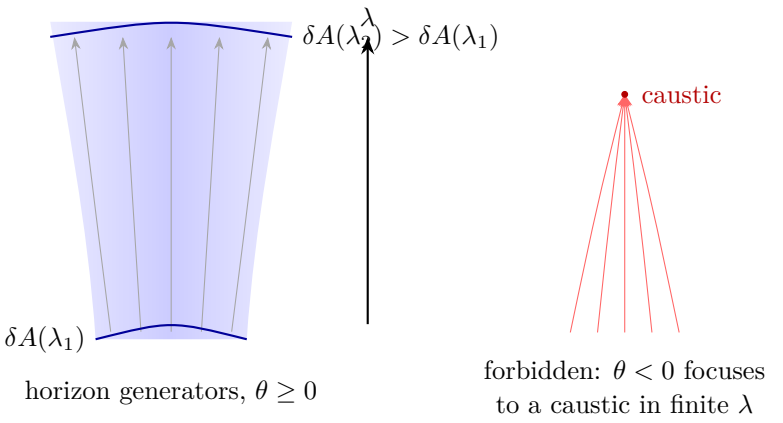

Figure 65.4: The area theorem as focusing. Left: on the future horizon the generators diverge or stay parallel ($\theta \geq 0$), so the transverse area element δA never shrinks. Right: a negative expansion would, by the focusing inequality Eq. (65.138), drive the generators to a caustic at finite affine parameter — a focal point that the event horizon's generators are forbidden to reach. Ruling out the caustic forces $\theta \geq 0$.

time. But a generator of the event horizon, by the definition of the horizon as the boundary of the past of future null infinity, has no future endpoint — it cannot leave the horizon, and two generators of the horizon cannot intersect (an intersection would put a point on the boundary that is in the chronological past of horizon points, contradicting achronality of the boundary). The predicted caustic is therefore impossible. The only way to avoid it is $\theta \geq 0$ everywhere on the future horizon. With $\theta \geq 0$ pointwise, Eq. (65.134) gives $\mathrm{d}A/\mathrm{d}\lambda = \int_{\mathcal{C}} \theta \, \mathrm{d}A \geq 0$, the area theorem. □

The area theorem is a statement about classical processes, in which the NEC holds. Hawking evaporation *violates* it: the hole shrinks, $\mathrm{d}A < 0$. There is no contradiction, because the renormalized quantum stress tensor near the horizon (Section 64.5) carries a negative energy flux through the horizon — precisely the negative-energy influx identified in Eq. (65.118), the partner of each escaping Hawking quantum — and a negative $T_{\mu\nu}k^\mu k^\nu$ defeats the NEC. The classical area theorem is thus the mechanical second law; its quantum failure is exactly what the generalized second law of Section 65.4.6 repairs.

65.4.5 Promotion to thermodynamics and the entropy coefficient

We now have a precise mechanical structure: a constant κ over the horizon (zeroth law), a first law $\mathrm{d}M = (\kappa/8\pi G)\,\mathrm{d}A + \ldots$, and a nondecreasing area (second law). The parallel with thermodynamics — constant T, $\mathrm{d}U = T\,\mathrm{d}S + \ldots$,

nondecreasing S — is exact in form. Whether it is exact in *content* hinges on a single question: is the temperature that appears in the would-be first law a real temperature, and the area a real entropy, or is the parallel a mathematical coincidence?

Classically, the question cannot be answered, and Bardeen, Carter, and Hawking originally regarded the analogy as formal: a classical black hole is perfectly black, absorbs everything, emits nothing, and so sits at temperature zero, in which case any nonzero $\kappa \propto T$ is meaningless and $A/4G$ could be rescaled away. What changed everything is the quantum computation of Section 2. A black hole formed by collapse *does* radiate, with a Planck spectrum, and the temperature of that spectrum is not an adjustable constant but the sharply determined value

$$T_H = \frac{\kappa}{2\pi} = \frac{1}{8\pi G M}, \tag{65.141}$$

fixed by the Bogoliubov coefficients (Eq. (65.64)) and re-derived independently from Euclidean regularity in Section 5. Once T_H is a genuine, computed temperature, the first law forces the entropy upon us with no freedom left.

Theorem 65.21 (Bekenstein–Hawking entropy with fixed coefficient)**.** *If the Schwarzschild black hole is a thermodynamic system of energy M and temperature $T_H = 1/8\pi GM$ obeying the first law $\mathrm{d}M = T_H\,\mathrm{d}S$, then its entropy is*

$$S_{\mathrm{BH}} = \frac{A}{4G} = 4\pi G M^2, \tag{65.142}$$

with the coefficient $1/4$ uniquely determined.

Proof. Equate the mechanical first law Eq. (65.128), $\mathrm{d}M = (\kappa/8\pi G)\,\mathrm{d}A$, with the thermodynamic first law $\mathrm{d}M = T_H\,\mathrm{d}S$, and substitute the computed temperature $T_H = \kappa/2\pi$:

$$T_H\,\mathrm{d}S = \frac{\kappa}{8\pi G}\,\mathrm{d}A \quad\Longrightarrow\quad \frac{\kappa}{2\pi}\,\mathrm{d}S = \frac{\kappa}{8\pi G}\,\mathrm{d}A \quad\Longrightarrow\quad \mathrm{d}S = \frac{2\pi}{\kappa}\cdot\frac{\kappa}{8\pi G}\,\mathrm{d}A = \frac{\mathrm{d}A}{4G}. \tag{65.143}$$

The surface gravity cancels identically — this is the crucial step: it is the *ratio* $T_H/\kappa = 1/2\pi$, not κ itself, that survives, and that ratio is precisely what Section 2 computed. Integrating $\mathrm{d}S = \mathrm{d}A/4G$ from the zero-area reference and fixing the additive constant to zero (the entropy vanishes as the horizon does) gives $S_{\mathrm{BH}} = A/4G$. Equivalently, integrate in M: $\mathrm{d}S = \mathrm{d}M/T_H = 8\pi G M\,\mathrm{d}M$, so $S = \int_0^M 8\pi G M'\,\mathrm{d}M' = 4\pi G M^2$, and using $A = 16\pi G^2 M^2$ this is $A/4G$, identical. The coefficient $1/4$ is not chosen; it is the output of $1/2\pi$ from the temperature times $1/8\pi G$ from the mechanical first law. □

Physical Insight

Bekenstein's original argument, which preceded Hawking's, established that a black hole *must* carry an entropy proportional to its area — on pain of letting one violate the ordinary second law by dropping entropy-laden matter behind a horizon where it can no longer be counted — and estimated the coefficient by information-theoretic reasoning to be of order $1/G$ in Planck units, but could not pin the pure number. It was Hawking's discovery that the hole has a definite temperature $T_H = \kappa/2\pi$ that converted "proportional to area" into the exact $A/4G$. The two halves of the result come from two different physicists and two different kinds of argument: the proportionality from a thermodynamic *gedankenexperiment*, the coefficient from a quantum field theory *computation*. Neither alone suffices; together they fix the entropy of a black hole completely. This is why the result is named for both.

It is worth restating the magnitude this represents. For a solar-mass hole, $S_{\mathrm{BH}} = A/4G \sim (M/M_{\mathrm{Pl}})^2 \sim (10^{38})^2 = 10^{76}$ in natural units — some twenty orders of magnitude larger than the thermodynamic entropy of the star that collapsed to form it. A black hole is overwhelmingly the highest-entropy object that can be packed into a given region, a fact that becomes the Bekenstein bound below. The entropy also scales as the *area*, $S \propto A \propto M^2$, not as a volume $\propto M^3$ or as the particle number of the progenitor. That an extensive-looking thermodynamic quantity scales with the bounding area rather than the enclosed volume is the single most important structural surprise of the whole subject, and we draw out its meaning in Section 65.4.7.

65.4.6 The generalized second law

The classical area theorem fails once the hole radiates, because the negative energy flux through the horizon violates the NEC and the area shrinks. The ordinary second law also fails on its own: matter (and its entropy) can fall across the horizon and disappear from the exterior. Each law fails exactly where the other can compensate, and Bekenstein's proposal — the *generalized second law* (GSL) — is that their sum is what never decreases.

Definition 65.22 (Generalized entropy)**.** The *generalized entropy* of a black hole together with its exterior is

$$S_{\mathrm{gen}} \;=\; S_{\mathrm{BH}} + S_{\mathrm{out}} \;=\; \frac{A}{4G} + S_{\mathrm{out}}, \tag{65.144}$$

where S_{out} is the ordinary (von Neumann or thermodynamic) entropy of all matter and radiation outside the horizon.

Conjecture 65.23 (Generalized second law)**.** *In any physical process, the generalized entropy does not decrease:*

$$\Delta S_{\text{gen}} = \Delta\left(\frac{A}{4G}\right) + \Delta S_{\text{out}} \;\geq\; 0. \tag{65.145}$$

We state this as a conjecture rather than a theorem because, unlike the area theorem, it has no fully general proof valid in every regime; it is established in many concrete settings (and follows rigorously from quantum field theory together with the quantum focusing conjecture, and from the modern entropy-as-area arguments of Chapter 57), and no violation is known. It is the precise sense in which black holes obey the second law of thermodynamics. The two regimes in which it must hold are matter falling *in* (the area grows enough to pay for the lost exterior entropy — the engine of the Bekenstein bound below) and radiation streaming *out* (the radiation's entropy more than compensates the shrinking area). We verify the second, using the Hawking quantum of Section 3, in detail.

Worked Example 65.24 (The GSL across one Hawking emission)**.** Consider the hole emitting an increment of energy $\mathrm{d}E$ into Hawking radiation at temperature T_H. We compare the entropy the radiation carries off against the entropy the hole loses, and show the net change is positive.

Entropy lost by the hole. The hole's energy drops by $\mathrm{d}E$, so $\mathrm{d}M = -\mathrm{d}E$, and by the first law its Bekenstein–Hawking entropy changes by

$$\mathrm{d}S_{\text{BH}} = \frac{\mathrm{d}M}{T_H} = -\frac{\mathrm{d}E}{T_H} < 0. \tag{65.146}$$

Entropy gained by the radiation. The emitted quanta form, to leading semiclassical order, a thermal gas of massless bosons at temperature T_H (this is exactly the Planck spectrum of Section 2; greybody factors of Section 3 modify the numerical coefficient but not the conclusion). For a gas of massless quanta the equation of state is $P = u/3$ with energy density $u \propto T^4$, the standard relativistic result. The thermodynamic entropy density follows from the Euler relation $s = (u + P)/T$ for a gas of zero chemical potential:

$$s = \frac{u + P}{T} = \frac{u + u/3}{T} = \frac{4}{3}\,\frac{u}{T}, \tag{65.147}$$

so that the entropy of a parcel of such radiation of energy $\mathrm{d}E$ is

$$\mathrm{d}S_{\text{rad}} = \frac{4}{3}\,\frac{\mathrm{d}E}{T_H}. \tag{65.148}$$

The factor $\frac{4}{3}$ is the same one that makes blackbody entropy flux exceed $\mathrm{d}E/T$: a thermal photon gas carries more entropy per unit energy than a reversible heat transfer would, because the emission is into empty modes, not into a reservoir at the same temperature.

The net change. Adding the two contributions, with $\mathrm{d}E > 0$ the energy emitted,

$$\mathrm{d}S_{\mathrm{gen}} = \mathrm{d}S_{\mathrm{rad}} + \mathrm{d}S_{\mathrm{BH}} = \frac{4}{3}\frac{\mathrm{d}E}{T_H} - \frac{\mathrm{d}E}{T_H} = \frac{1}{3}\frac{\mathrm{d}E}{T_H} \;>\; 0. \tag{65.149}$$

The generalized entropy increases by a third of the entropy the radiation carries. The hole's own entropy falls, but the radiation it sheds carries off *more* entropy than the hole loses, by the robust factor $\frac{4}{3}$ of the blackbody equation of state, and the GSL holds throughout evaporation. Here $\frac{4}{3}$ is the crude pure-blackbody value; including the greybody filtering of Section 3 (and the irreversibility of evaporation) replaces it by a larger pure number — ≈ 1.6 for a massless thermal field, computed in Theorem 65.41 — that remains comfortably greater than 1 for every field species, so the conclusion $\mathrm{d}S_{\mathrm{gen}} > 0$ is unaffected. Integrating Eq. (65.148) over the entire evaporation, the radiation produced by a hole of initial mass M_0 ends with thermodynamic entropy $S_{\mathrm{rad}} = \frac{4}{3}S_{\mathrm{BH}}(M_0)$ in this blackbody estimate ($\approx 1.6\, S_{\mathrm{BH}}(M_0)$ once greybody factors are included, Theorem 65.41), exceeding the entropy the hole started with — the coarse-grained statement that will be set against the fine-grained Page curve in Section 65.8.

The worked check exposes a tension that the rest of the chapter must confront. The GSL as verified here treats S_{rad} as the *thermodynamic* entropy of a genuinely thermal gas. If the radiation is truly thermal — a mixed state of mutually uncorrelated quanta — then at the end of evaporation a pure initial state has become a mixed final state with entropy $\frac{4}{3}S_{\mathrm{BH}}(M_0) > 0$, and unitarity is violated. That is the information paradox. The GSL is consistent with the coarse-grained thermodynamics; whether the *fine-grained* entropy obeys the same monotone growth is the question taken up in Chapter 57. For the thermodynamics of this chapter, what matters is that S_{gen} never decreases, and it does not.

65.4.7 The Bekenstein bound and entropy as an area

The GSL applied to matter falling *into* a hole yields a universal bound on how much entropy any system can carry, and that bound is the cleanest entry point to the area-scaling of information. The argument, due to Bekenstein and developed in Section 57.1.6, is a thought experiment: lower a box of energy E, entropy S_{matter}, and linear size $\leq R$ quasi-statically into the hole. The exterior loses S_{matter}; the hole gains area as it absorbs the energy. For the GSL Eq. (65.145) to survive, the area increase must at least cover the lost matter entropy, and working out the geometry of the optimal drop gives the *Bekenstein bound*

$$S_{\mathrm{matter}} \;\leq\; 2\pi R\, E \tag{65.150}$$

(natural units; restoring constants, $S \leq 2\pi k_B RE/\hbar c$). We import this bound and its derivation from Eq. (57.35); the point here is what it implies for the meaning

of $S_{\rm BH} = A/4G$. A black hole exactly saturates Eq. (65.150) with $R \sim 2GM$ and $E \sim M$: $2\pi RE \sim 4\pi GM^2 = S_{\rm BH}$. The Bekenstein–Hawking entropy is therefore not merely *an* entropy a black hole happens to have; it is the *maximum* entropy — the maximum number of bits — that can be stored in a region of that size at all. Pack any more information into the region and it collapses to a hole, whereupon its entropy is exactly $A/4G$.

Physical Insight

The decisive structural fact is that this maximum scales as the bounding *area*, not the enclosed *volume*. A conventional local quantum field theory in a region of volume V has a number of degrees of freedom, and hence a maximal entropy, that grows like V times an ultraviolet cutoff cubed — an extensive, volume-scaling quantity. Gravity overrides this: the true maximal entropy of the region grows only as its area A in Planck units. The information content of a region is set by the size of its boundary, as if the physics inside were encoded on the surface enclosing it. This is the germ of the *holographic principle*: a $(d{+}1)$-dimensional gravitating region is described by no more degrees of freedom than a d-dimensional theory living on its boundary could carry. The $A/4G$ we have just fixed is the conversion factor — one quarter-bit (in nats, one quarter) per Planck area — and the reason Part XV of this book, on holography and AdS/CFT, exists at all. The black hole is the first place the principle is forced on us by a calculation rather than postulated.

65.4.8 Jacobson's inversion: the Einstein equation as an equation of state

We close the thermodynamic development with a remarkable observation that turns its logic inside out. We have taken the Einstein equation as given — it is the classical background equation, used in Eq. (65.136) to convert the NEC into focusing — and *derived* thermodynamics from it. Jacobson showed in 1995 that the implication can be run in reverse: if one *assumes* the thermodynamic relation $\delta Q = T\,\mathrm{d}S$ holds for every local Rindler horizon, with T the Unruh temperature and S the area in units of $1/4G$, then the Einstein equation *follows* as a consistency condition. We sketch the argument honestly, since the full version requires the local Rindler-horizon construction of Chapter 64.

Physical Insight

Pick any spacetime point p and a small spacelike two-surface element through it, and consider the local Rindler horizon to its past: the null congruence that, to a uniformly accelerated observer, plays the role of a

causal horizon. By the Unruh effect (Chapter 64) that observer attributes a temperature $T = \kappa/2\pi$ to the horizon, with κ the local acceleration. Demand that the Clausius relation $\delta Q = T\,\mathrm{d}S$ hold, where $\delta Q = \int T_{\mu\nu}\,\xi^\mu \mathrm{d}\Sigma^\nu$ is the boost energy flux of matter across the horizon (with ξ the approximate boost Killing field) and $\mathrm{d}S = \mathrm{d}A/4G$ is the change in horizon area in Bekenstein–Hawking units. The area change $\mathrm{d}A$ is governed by the expansion through Eq. (65.133), and the expansion in turn obeys the Raychaudhuri equation Eq. (65.135), which feeds in $R_{\mu\nu}k^\mu k^\nu$. Equating the matter flux $\delta Q \propto T_{\mu\nu}k^\mu k^\nu$ to $T\,\mathrm{d}S \propto R_{\mu\nu}k^\mu k^\nu$ for *every* null direction k at p forces $R_{\mu\nu} - \frac{1}{2}Rg_{\mu\nu} + \Lambda g_{\mu\nu} = 8\pi G\,T_{\mu\nu}$ — the Einstein equation, with G fixed precisely by the $1/4$ in the entropy and Λ an undetermined integration constant. Gravity's field equation is, in this reading, not a fundamental law but an equation of state: a thermodynamic relation that the underlying microscopic degrees of freedom must satisfy in their coarse-grained, long-wavelength limit, exactly as the ideal-gas law $PV = NkT$ is an equation of state for molecules whose microscopics it never mentions. That the entropy is $A/4G$ is then not a consequence of the Einstein equation but its *cause*.

This is a frontier idea (as of the mid-2020s it remains a deep suggestion rather than a settled derivation of quantum gravity), and we flag it as such. But it crystallizes why black-hole thermodynamics is more than an analogy. If the laws of black-hole mechanics were merely formally parallel to thermodynamics, Jacobson's inversion would be impossible; that one can run the implication backward and recover the dynamics of spacetime itself is the strongest evidence that the parallel is an identity, and that $S_{\mathrm{BH}} = A/4G$ is a statement about real microstates we have not yet learned to count.

With the thermodynamic dossier complete — temperature $T_H = \kappa/2\pi$, entropy $S_{\mathrm{BH}} = A/4G$ with its coefficient nailed by the first law, and a generalized second law that survives evaporation — we have established by purely thermodynamic and field-theoretic reasoning what Section 5 will now rederive from an utterly different starting point. There, Euclidean Schwarzschild proves smooth only when imaginary time has period $\beta = 8\pi GM$, and the on-shell gravitational action delivers the very same $S = A/4G$ as a free energy — an independent confirmation from the path-integral pillar of the book. The entropy fixed here also becomes, in Section 65.8, the finite ceiling against which the fine-grained entropy of the Hawking radiation is measured, and whose saturation defines the Page time.

65.5 The Euclidean Path Integral and the Gravitational Partition Function

The previous section earned the Bekenstein–Hawking entropy $S = A/4G$ by thermodynamic bookkeeping: armed with the Hawking temperature $T_H = \kappa/2\pi$ (Eq. (65.64)) we promoted the first law of black-hole mechanics to the first law of thermodynamics and integrated $\mathrm{d}S = \mathrm{d}M/T_H$ to fix the coefficient (Section 65.4). That derivation is correct, but it is also, in a sense, borrowed: the temperature it relies on was handed to us by Hawking's Bogoliubov computation of Section 65.2.1, a calculation about quantum fields propagating on a collapsing background. One could be forgiven for suspecting that the thermal character of a black hole is an artefact of the matter we chose to quantize on it, rather than a property of the geometry itself.

This section dispels that suspicion. We give a completely independent derivation in which no matter field is quantized and no mode is tracked across a horizon. The only inputs are Euclidean gravity — the gravitational action continued to imaginary time, exactly the e^{-S_E} path-integral pillar built for scalar fields in Section 10.6 — and the demand that the continued geometry be *smooth*. We will find that the Euclidean Schwarzschild manifold simply *does not exist* as a smooth Riemannian space unless imaginary time is periodic with a single, sharply fixed period $\beta = 8\pi GM$. Periodicity in imaginary time is the defining signature of a thermal density matrix, so this already fixes $T_H = 1/\beta$ as a statement about the geometry alone. We then evaluate the on-shell gravitational action of this manifold and read off its free energy; the entropy that drops out is, once more and now from first principles of the path integral, $S = A/4G$. The black hole has become a thermal saddle point of the gravitational partition function.

65.5.1 Wick rotation of Schwarzschild and the geometry of the horizon

We work throughout with the Schwarzschild solution of the vacuum Einstein equations in the mostly-minus signature fixed for this chapter, with Newton's constant G written explicitly. Recall its line element from Eq. (65.1),

$$\mathrm{d}s^2 = f(r)\,\mathrm{d}t^2 - f(r)^{-1}\,\mathrm{d}r^2 - r^2\,\mathrm{d}\Omega^2, \qquad f(r) = 1 - \frac{2GM}{r},$$

where $\mathrm{d}\Omega^2 = \mathrm{d}\theta^2 + \sin^2\theta\,\mathrm{d}\varphi^2$ is the round metric on the unit two-sphere and M is the ADM mass. The exterior region $r > 2GM$ is static, with the timelike Killing vector ∂_t; the locus $r = 2GM$ where f vanishes is the event horizon. The surface gravity κ of this horizon was defined in Section 65.4; we shall recover it below as a purely geometric quantity, $\kappa = \tfrac{1}{2}f'(r_h)$, without reference to any Killing-vector normalization argument.

The Euclidean continuation is the same Wick rotation $t \to -i\tau$ that turned the Minkowski generating functional into a convergent Euclidean integral in Section 10.6, applied now to the metric rather than to a field. Under $t = -i\tau$ we have $\mathrm{d}t^2 = -\mathrm{d}\tau^2$, so the first term of Eq. (65.1) flips sign and the whole line element becomes negative-definite. Defining the Euclidean metric by $\mathrm{d}s_E^2 \equiv -\mathrm{d}s^2$ gives a positive-definite Riemannian metric on the exterior,

$$\mathrm{d}s_E^2 = f(r)\,\mathrm{d}\tau^2 + f(r)^{-1}\,\mathrm{d}r^2 + r^2\,\mathrm{d}\Omega^2, \qquad r \geq 2GM. \tag{65.151}$$

Two features of Eq. (65.151) are decisive. First, $f(r)$ is non-negative on $r \geq 2GM$ and vanishes precisely at the horizon, so the τ-circle — whose proper circumference at radius r is $\sqrt{f(r)}\oint \mathrm{d}\tau$ — shrinks to zero length as $r \to 2GM$. The horizon is not a boundary of the Euclidean manifold; it is a point (more precisely, a two-sphere's worth of points, one for each point of the S^2) where the τ-circle closes up. Second, the region $r < 2GM$, where $f < 0$, is simply absent: there is no Euclidean interior. The Euclidean black hole is a manifold with the topology $\mathbb{R}^2 \times S^2$, the $\mathbb{R}^2$ being the (ρ, τ) plane we are about to uncover, capped off smoothly at the horizon.

Whether the cap is genuinely smooth, or instead carries a conical singularity, is the entire question. To decide it we zoom in on the horizon. Write $r = 2GM + \epsilon$ with $0 < \epsilon \ll 2GM$ and expand f to first order, using $f(2GM) = 0$,

$$f(r) = f'(2GM)\,\epsilon + O(\epsilon^2), \qquad f'(r) = \frac{2GM}{r^2}, \qquad f'(2GM) = \frac{1}{2GM}. \tag{65.152}$$

The natural radial coordinate near the horizon is not r but the proper distance ρ from the horizon, defined by $\mathrm{d}\rho = \mathrm{d}r/\sqrt{f(r)}$ so that the $\mathrm{d}r^2/f$ term becomes $\mathrm{d}\rho^2$. Substituting the linearized Eq. (65.152),

$$\rho = \int_{2GM}^{r} \frac{\mathrm{d}r'}{\sqrt{f(r')}} = \int_0^{\epsilon} \frac{\mathrm{d}\epsilon'}{\sqrt{\epsilon'/2GM}} = 2\sqrt{2GM\,\epsilon}\,, \tag{65.153}$$

so that $\epsilon = \rho^2/(8GM)$ and therefore

$$f(r) = \frac{\epsilon}{2GM} = \frac{\rho^2}{16\,G^2M^2} = \left(\frac{\rho}{4GM}\right)^2. \tag{65.154}$$

Near the horizon the angular sphere has essentially fixed radius $r \approx 2GM$, so $r^2\,\mathrm{d}\Omega^2 \approx (2GM)^2\,\mathrm{d}\Omega^2$ is an inert spectator. The interesting part of Eq. (65.151) is the (ρ, τ) block, which collapses to

$$\mathrm{d}s_E^2\Big|_{\text{near horizon}} = \mathrm{d}\rho^2 + \left(\frac{\rho}{4GM}\right)^2 \mathrm{d}\tau^2 + (2GM)^2\,\mathrm{d}\Omega^2 = \mathrm{d}\rho^2 + \rho^2\,\mathrm{d}\alpha^2 + (2GM)^2\,\mathrm{d}\Omega^2, \tag{65.155}$$

where in the last step we introduced the rescaled angle

$$\alpha \equiv \frac{\tau}{4GM}. \tag{65.156}$$

The (ρ, α) part of Eq. (65.155) is exactly the flat plane written in polar coordinates: radial coordinate $\rho \geq 0$, angular coordinate α. A plane in polar coordinates is smooth at the origin $\rho = 0$ *if and only if* the angle α runs over a full period of 2π and no more — any other period leaves a wedge of opening angle $2\pi -$ (period) either missing or doubled, i.e. a conical singularity at the tip with a delta-function of curvature there. This is the same elementary fact that tells us a cone is flat everywhere except at its apex. Smoothness of the Euclidean black hole at its horizon is thus the single condition

$$\alpha \sim \alpha + 2\pi \quad \Longleftrightarrow \quad \tau \sim \tau + 8\pi GM. \tag{65.157}$$

Theorem 65.25 (Temperature as smoothness)**.** *The Euclidean Schwarzschild metric Eq. (65.151) extends to a smooth, geodesically complete Riemannian manifold (topology $\mathbb{R}^2 \times S^2$) if and only if the imaginary-time coordinate τ is identified with period*

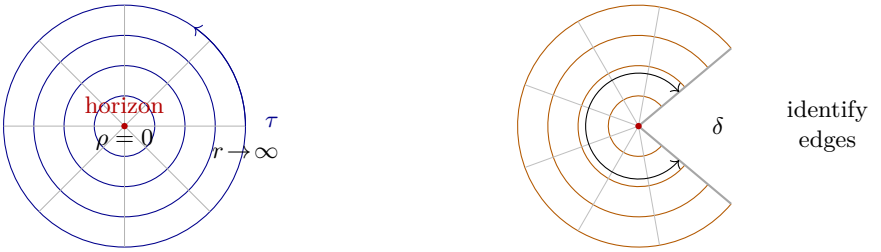
$$\beta = 8\pi GM = \frac{2\pi}{\kappa}, \qquad \kappa = \tfrac{1}{2} f'(2GM) = \frac{1}{4GM}. \tag{65.158}$$

Consequently the manifold is automatically periodic in imaginary time with period β, and the inverse temperature it represents is the geometric datum $T_H = 1/\beta = \kappa/2\pi$, identical to the Hawking temperature of Eq. (65.64).

Proof. The angular period equals 2π in the coordinate $\alpha = \tau/4GM$ exactly when τ has period $8\pi GM$, by Eq. (65.156). For any other period the near-horizon geometry Eq. (65.155) is a cone of deficit angle $\delta = 2\pi(1 - \beta/8\pi GM)$, whose Riemann tensor contains a term proportional to δ supported on the tip $\rho = 0$; the manifold is then not smooth there, and indeed not a solution of the vacuum Einstein equation in any neighbourhood of the horizon. Smoothness therefore forces $\beta = 8\pi GM$. The surface gravity is read directly off the conical-deficit calculation: the (ρ, τ) metric is $\mathrm{d}\rho^2 + (\frac{1}{2} f'(r_h))^2 \rho^2 \, \mathrm{d}\tau^2$ to leading order, so the angular velocity per unit τ is $\frac{1}{2} f'(r_h)$, and smoothness requires τ to close after $2\pi/(\frac{1}{2} f'(r_h)) = 4\pi/f'(r_h)$; identifying this with β and with $2\pi/\kappa$ gives $\kappa = \frac{1}{2} f'(r_h) = 1/4GM$. The numerical agreement of $\beta = 8\pi GM$ with the inverse Hawking temperature is then immediate. □

What makes Theorem 65.25 striking is that nothing quantum appears in it. No field was expanded in modes, no Bogoliubov coefficient was computed, no vacuum was chosen. The temperature is forced by the differential geometry of a smooth four-manifold: it is the unique periodicity that removes the conical singularity at the would-be horizon. This is the cleanest possible statement that the temperature belongs to the spacetime, not to whatever happens to be living on it. The picture is summarized in Fig. 65.5.

The construction did not use anything special about $f(r) = 1 - 2GM/r$ beyond the fact that f has a simple zero at the horizon. It is worth isolating



smooth: $\beta = 8\pi GM$ conical: $\beta \neq 8\pi GM$

Figure 65.5: The (ρ, τ) section of the Euclidean black hole at fixed angle on the sphere. Circles are constant-ρ orbits of the imaginary-time isometry; the horizon is the central point $\rho = 0$ where they shrink to zero size. *Left:* with $\beta = 8\pi GM$ the angle closes after exactly 2π and the cap is a smooth piece of the plane. *Right:* any other period leaves a deficit (or excess) angle δ, so identifying the two edges produces a cone with a curvature delta-function at the tip — not a solution of the vacuum equations.

the general statement, because it instantly delivers the temperatures of every horizon we will meet.

Worked Example 65.26 (Smoothness temperature of a general static horizon)**.** Consider any static, spherically symmetric metric of the form Eq. (65.1) with a function $f(r)$ that has a simple zero at some radius r_h, $f(r_h) = 0$ and $f'(r_h) > 0$. Repeat the near-horizon analysis. Linearizing, $f(r) = f'(r_h)(r - r_h) + \dots$, the proper distance is

$$\rho = \int_{r_h}^{r} \frac{\mathrm{d}r'}{\sqrt{f'(r_h)(r' - r_h)}} = \frac{2}{\sqrt{f'(r_h)}} \sqrt{r - r_h}, \qquad r - r_h = \frac{f'(r_h)}{4}\,\rho^2, \quad (65.159)$$

so that $f = f'(r_h)(r - r_h) = \left(\tfrac{1}{2} f'(r_h)\right)^2 \rho^2$ and the (ρ, τ) block of the Euclidean metric is $\mathrm{d}\rho^2 + \left(\tfrac{1}{2} f'(r_h)\right)^2 \rho^2\, \mathrm{d}\tau^2$. Smoothness demands that $\tfrac{1}{2} f'(r_h)\, \tau$ have period 2π, hence

$$\beta = \frac{4\pi}{f'(r_h)}, \qquad T = \frac{f'(r_h)}{4\pi} = \frac{\kappa}{2\pi}, \qquad \kappa = \tfrac{1}{2} f'(r_h). \quad (65.160)$$

Three immediate applications fix the result in the reader's hands. *Schwarzschild:* $f = 1 - 2GM/r$, $r_h = 2GM$, $f'(r_h) = 1/2GM$, recovering $T = 1/8\pi GM$. *Reissner–Nordström* (charge Q): $f = 1 - 2GM/r + GQ^2/r^2$, with outer horizon $r_+ = GM + \sqrt{G^2M^2 - GQ^2}$ and $f'(r_+) = (r_+ - r_-)/r_+^2$ where $r_- = GM - \sqrt{G^2M^2 - GQ^2}$; hence $T = (r_+ - r_-)/4\pi r_+^2$, which vanishes in the extremal limit $r_+ \to r_-$ — a zero-temperature horizon, the geometric face of the third law. *Schwarzschild–de Sitter* cosmological horizon: $f = 1 - \Lambda r^2/3$, $r_h = \sqrt{3/\Lambda}$,

$f'(r_h) = -2\Lambda r_h/3$ in magnitude $2\sqrt{\Lambda/3}$, giving the Gibbons–Hawking de Sitter temperature $T = \frac{1}{2\pi}\sqrt{\Lambda/3}$. The same one-line argument prices every horizon in the book.

65.5.2 The gravitational partition function and the saddle-point approximation

We now ask what physical quantity the smooth Euclidean manifold computes. Recall the lesson of Section 10.6: the Euclidean path integral of a field theory on a time circle of circumference β computes the thermal partition function. For a system with Hamiltonian H,

$$Z(\beta) = \mathrm{Tr}\; e^{-\beta H} = \int_{\phi(\tau+\beta)=\phi(\tau)} \mathcal{D}\phi\; e^{-S_E[\phi]}, \tag{65.161}$$

the trace being implemented by the periodic boundary condition on imaginary time. The free energy follows as $F = -\beta^{-1}\ln Z$, and from it the entropy $S = -\partial F/\partial T$ and internal energy $U = \partial(\beta F)/\partial\beta$. Everything in Eq. (65.161) was established for the scalar field of ϕ^4 theory at $\lambda = 0$; the gravitational version simply promotes the integration variable from a field on a fixed spacetime to the spacetime metric itself.

Definition 65.27 (Gravitational partition function)**.** The Euclidean gravitational partition function at inverse temperature β is the path integral over all Riemannian metrics g (and any matter fields, here none) on manifolds whose only boundary is at spatial infinity, where the metric is asymptotically flat and the imaginary-time circle has period β,

$$Z(\beta) = \int_{\substack{\text{asympt. flat,}\\ \tau\sim\tau+\beta}} \mathcal{D}g\; e^{-I_E[g]}, \tag{65.162}$$

with $I_E[g]$ the Euclidean gravitational action defined in Eq. (65.164) below.

The functional integral Eq. (65.162) is not, as written, a defined object: quantum gravity is not a renormalizable field theory, the measure $\mathcal{D}g$ is formal, and the action is unbounded below in the conformal direction. We are not going to pretend otherwise. What we can do — and what is genuinely controlled — is the semiclassical, or saddle-point, evaluation, valid when the relevant geometry is large compared with the Planck length $\ell_P = \sqrt{G}$, i.e. when $GM^2 \gg 1$. This is the same stationary-phase logic that produced the loop expansion in Section 10.6, only now organized in powers of G rather than $\hbar$ (the two are interchangeable here, since G multiplies the inverse action). The dominant contribution to Eq. (65.162) comes from metrics that solve the classical Euclidean equations of motion — the vacuum Einstein equation $R_{\mu\nu} = 0$ — subject to the stated

boundary condition, and the leading answer is the exponential of minus the on-shell action,

$$Z(\beta) \;\simeq\; \sum_{g_{\mathrm{cl}}} e^{-I_E[g_{\mathrm{cl}}]}\,\big[\det{}'(\text{fluctuation operator})\big]^{-1/2}(1+\dots), \tag{65.163}$$

where the determinant is the one-loop Gaussian integral over fluctuations about the saddle, deferred to Section 65.5.5, and the ellipsis denotes higher loops suppressed by further powers of G.

For the asymptotically flat thermal boundary condition there are precisely two smooth saddles. The first is hot flat space: $\mathbb{R}^3$ times an imaginary-time circle of period β, with $I_E = 0$ by construction (it is the reference geometry). The second is the smooth Euclidean Schwarzschild manifold of Section 65.5.1 — but only at the one mass $M = \beta/8\pi G$ for which Eq. (65.158) holds, since the period β is imposed at the boundary and the smoothness condition then dictates the mass. The black-hole saddle therefore enters the canonical ensemble at a definite mass for each temperature. Our task is to evaluate its action.

65.5.3 The on-shell action: the Gibbons–Hawking–York term and background subtraction

The naive Einstein–Hilbert action $-\frac{1}{16\pi G}\int_M R\sqrt{g}\,\mathrm{d}^4x$ cannot be the whole story, for a reason that is purely variational and was settled in Section 4.1: its variation produces, besides the Einstein tensor, a boundary integral of normal derivatives of δg that does not vanish under the natural Dirichlet condition (fix the induced metric on the boundary, but not its normal derivative). To have a well-posed variational principle on a manifold with boundary one must add the Gibbons–Hawking–York (GHY) surface term, whose variation exactly cancels the offending piece [220, 530]. Including it, and a subtraction term that renders the action finite, the Euclidean gravitational action is

Definition 65.28 (Euclidean gravitational action)**.**

$$I_E[g] = -\frac{1}{16\pi G}\int_M R\,\sqrt{g}\,\mathrm{d}^4x \;-\; \frac{1}{8\pi G}\oint_{\partial M}(K-K_0)\sqrt{h}\,\mathrm{d}^3x, \tag{65.164}$$

where h is the determinant of the metric induced on the boundary ∂M, $K = \nabla_\mu n^\mu$ is the trace of the extrinsic curvature with n^μ the outward unit normal, and K_0 is the extrinsic curvature of the *same* boundary as embedded in flat space. The K_0 term is the background subtraction: it measures the action relative to flat space, so that hot flat space scores $I_E = 0$ and the integral converges as the boundary recedes to infinity.

We evaluate Eq. (65.164) on the Euclidean Schwarzschild saddle.

The bulk term vanishes. Schwarzschild solves the vacuum Einstein equation $R_{\mu\nu} = 0$, whose trace gives $R = 0$ identically. The bulk integral in Eq. (65.164) is therefore zero on shell. *All* of the action comes from the boundary. This is a general feature of vacuum gravity: the on-shell action is a pure boundary term, which is why the gravitational entropy will turn out to be a boundary (horizon-area) quantity.

The extrinsic curvature at a large sphere. Place the boundary ∂M at a large fixed radius $r = \mathcal{R}$; at the end we send $\mathcal{R} \to \infty$. The induced metric there, from Eq. (65.151), is $\mathrm{d}s_E^2\big|_{\partial M} = f(\mathcal{R})\,\mathrm{d}\tau^2 + \mathcal{R}^2\,\mathrm{d}\Omega^2$, whose determinant is $h = f(\mathcal{R})\,\mathcal{R}^4 \sin^2\theta$, i.e. $\sqrt{h} = \sqrt{f(\mathcal{R})}\,\mathcal{R}^2 \sin\theta$. The outward unit normal points in the $+r$ direction; since $g_{rr} = 1/f$, normalization gives $n^\mu = \sqrt{f}\,\delta^\mu_r$. With $\sqrt{g} = r^2 \sin\theta$ (the f and $1/f$ in $g_{\tau\tau}g_{rr}$ cancel), the trace of the extrinsic curvature is the covariant divergence

$$K = \nabla_\mu n^\mu = \frac{1}{\sqrt{g}}\,\partial_r(\sqrt{g}\,n^r) = \frac{1}{r^2}\,\partial_r(r^2\sqrt{f}) = \frac{2\sqrt{f}}{r} + \frac{f'}{2\sqrt{f}}. \tag{65.165}$$

Evaluated at $r = \mathcal{R}$ with $f' = 2GM/\mathcal{R}^2$, the combination that enters the integrand is

$$\sqrt{f}\,K\,\mathcal{R}^2 = \Big(2f + \tfrac{1}{2}f'\,\mathcal{R}\Big)\mathcal{R} = 2\mathcal{R}\Big(1 - \frac{2GM}{\mathcal{R}}\Big) + GM = 2\mathcal{R} - 3GM, \tag{65.166}$$

using $\sqrt{f}\,(\frac{2\sqrt{f}}{r} + \frac{f'}{2\sqrt{f}})r^2 = 2fr + \frac{1}{2}f'r^2$. The τ-integral contributes a factor β and the sphere a factor 4π, so the bare GHY integral is

$$\oint_{\partial M} K\sqrt{h}\,\mathrm{d}^3x = 4\pi\beta\,(\sqrt{f}\,K\,\mathcal{R}^2) = 4\pi\beta\,(2\mathcal{R} - 3GM). \tag{65.167}$$

This diverges linearly as $\mathcal{R} \to \infty$; the background subtraction is what tames it.

The background subtraction. The reference is flat space, $f \equiv 1$, with the boundary at the same coordinate radius $\mathcal{R}$ and the same sphere. There $K_0 = 2/\mathcal{R}$ from Eq. (65.165). But the induced metrics must be matched: the proper circumference of the imaginary-time circle on the Schwarzschild boundary is $\sqrt{f(\mathcal{R})}\,\beta$, whereas in flat space with imaginary-time period β_0 it is just β_0. For the two boundaries to be the same Riemannian manifold — the only way the subtraction is meaningful — we must take

$$\beta_0 = \sqrt{f(\mathcal{R})}\,\beta. \tag{65.168}$$

The flat-space GHY integral, with $\sqrt{h_0} = \mathcal{R}^2 \sin\theta$ (now $f = 1$), $K_0 = 2/\mathcal{R}$, and τ'-period β_0, is

$$\oint_{\partial M} K_0\sqrt{h_0}\,\mathrm{d}^3x = \beta_0 \cdot 4\pi \cdot \frac{2}{\mathcal{R}} \cdot \mathcal{R}^2 = 8\pi\beta_0\,\mathcal{R} = 8\pi\beta\,\mathcal{R}\,\sqrt{f(\mathcal{R})}. \tag{65.169}$$

Expanding $\sqrt{f(\mathcal{R})} = \sqrt{1 - 2GM/\mathcal{R}} = 1 - \frac{GM}{\mathcal{R}} + O(\mathcal{R}^{-2})$,

$$\oint K_0 \sqrt{h_0}\, \mathrm{d}^3x = 8\pi\beta\,\mathcal{R}\Big(1 - \frac{GM}{\mathcal{R}} + O(\mathcal{R}^{-2})\Big) = 8\pi\beta\,\mathcal{R} - 8\pi\beta\,GM + O(\mathcal{R}^{-1}). \tag{65.170}$$

The subtracted action. Now subtract Eq. (65.170) from the rewritten bare term Eq. (65.167), $4\pi\beta(2\mathcal{R} - 3GM) = 8\pi\beta\mathcal{R} - 12\pi\beta GM$:

$$\oint (K - K_0)\sqrt{h}\, \mathrm{d}^3x = (8\pi\beta\mathcal{R} - 12\pi\beta GM) - (8\pi\beta\mathcal{R} - 8\pi\beta GM) = -4\pi\beta\,GM, \tag{65.171}$$

the linear divergences in $\mathcal{R}$ cancelling cleanly and the remainder being finite as $\mathcal{R} \to \infty$. Inserting this and the vanishing bulk term into Eq. (65.164),

$$I_E = -\frac{1}{8\pi G}\,(-4\pi\beta\,GM) = \frac{\beta M}{2}. \tag{65.172}$$

Finally we use the smoothness relation $\beta = 8\pi GM$, equivalently $M = \beta/8\pi G$, to express the answer in two equivalent forms. With $A = 4\pi r_h^2 = 4\pi(2GM)^2 = 16\pi G^2 M^2$ the horizon area, so that $A/4G = 4\pi GM^2$ and $\beta M = 8\pi GM^2$,

$$\boxed{I_E = \frac{\beta M}{2} = 4\pi G M^2 = \beta M - \frac{A}{4G} = \frac{\beta^2}{16\pi G}\,.} \tag{65.173}$$

The middle equality, $I_E = \beta M - A/4G$, is the result that the whole computation was aimed at. We will see in a moment that βM is exactly βU for this ensemble, so $I_E = \beta U - S$ with $S = A/4G$ — the on-shell action is already the combination $\beta F = \beta U - S$ of elementary thermodynamics, with the entropy sitting in it as the horizon area in Planck units.

Physical Insight

The structure of Eq. (65.173) repays a second look. The bulk Einstein–Hilbert term contributed nothing; the entire action is the GHY boundary term at infinity. Yet the answer encodes the horizon area A, which lives deep in the interior. How does a boundary integral at infinity know about the horizon? The answer is that smoothness at the horizon, Eq. (65.158), tied the period β to the mass M, and it is through that constraint that the area enters. Geometry at the cap and geometry at infinity are not independent: a single smooth manifold connects them, and the action is sensitive to both ends. This non-locality — entropy as a boundary/area quantity rather than a bulk volume quantity — is the first quantitative whisper of holography, and the reason Part XV exists.

65.5.4 Thermodynamics from the on-shell action

With the on-shell action in hand the thermodynamics is pure calculus. In the saddle-point approximation Eq. (65.163), the black-hole contribution to the partition function is $\ln Z \simeq -I_E$, so from Eq. (65.173),

$$\ln Z(\beta) = -I_E = -\frac{\beta^2}{16\pi G}. \tag{65.174}$$

Every thermodynamic quantity is a derivative of this single function. The internal energy is

$$U = -\frac{\partial \ln Z}{\partial \beta} = \frac{\partial I_E}{\partial \beta} = \frac{2\beta}{16\pi G} = \frac{\beta}{8\pi G} = M, \tag{65.175}$$

where the last step uses $\beta = 8\pi G M$. The mass is the thermodynamic internal energy, exactly as it must be; this confirms the identification of βM in Eq. (65.173) as βU. The free energy is

$$F = -\frac{1}{\beta}\ln Z = \frac{I_E}{\beta} = \frac{\beta}{16\pi G} = \frac{M}{2}. \tag{65.176}$$

The entropy now follows in either of two standard ways, which must of course agree. As the Legendre relation $S = \beta(U - F)$,

$$S = \beta(U - F) = \beta\Big(M - \frac{M}{2}\Big) = \frac{\beta M}{2} = 4\pi G M^2, \tag{65.177}$$

or equivalently, writing F as a function of $T = 1/\beta$, namely $F = \frac{1}{16\pi G\, T}$, as the temperature derivative

$$S = -\frac{\partial F}{\partial T} = -\frac{\partial}{\partial T}\Big(\frac{1}{16\pi G\, T}\Big) = \frac{1}{16\pi G\, T^2} = \frac{\beta^2}{16\pi G} = 4\pi G M^2. \tag{65.178}$$

Both routes give the same number, and that number is, once more,

$$\boxed{S = 4\pi G M^2 = \frac{16\pi G^2 M^2}{4G} = \frac{A}{4G}\,.} \tag{65.179}$$

Theorem 65.29 (Bekenstein–Hawking entropy from the gravitational path integral)**.** *The leading semiclassical contribution of the Euclidean Schwarzschild saddle to the gravitational partition function Eq. (65.162) yields internal energy $U = M$, free energy $F = M/2$, and entropy*

$$S = -\frac{\partial F}{\partial T} = \frac{A}{4G}, \tag{65.180}$$

the Bekenstein–Hawking entropy with its coefficient $1/4$ fixed, in agreement with the thermodynamic derivation of Eq. (65.142).

This is a genuinely independent confirmation. In Section 65.4 the coefficient $1/4$ was fixed by feeding in the Hawking temperature and integrating the first law; here it is fixed by a self-contained evaluation of a gravitational action that never mentions a quantum field. That two such different calculations land on the same $A/4G$ is the kind of overdetermination that turns a suggestive result into a fact about the theory.

Worked Example 65.30 (The negative heat capacity of Schwarzschild and its meaning)**.** The heat capacity of the Schwarzschild black hole is the response of its energy to temperature. Since $T = 1/8\pi GM$ gives $M = 1/(8\pi G\,T)$,

$$C = \frac{\partial U}{\partial T} = \frac{\partial M}{\partial T} = -\frac{1}{8\pi G\,T^2} = -8\pi G M^2 = -2S = -\frac{A}{2G} < 0. \tag{65.181}$$

The heat capacity is *negative*: a Schwarzschild hole gets *hotter* as it loses energy. This is not a pathology of the calculation but a physical statement about gravitating systems, and it has three consequences worth spelling out.

(i) Runaway evaporation. A black hole radiating into empty space loses mass; by $T \propto 1/M$ its temperature rises, so it radiates faster, loses mass faster, and heats up further. The evaporation accelerates without bound as $M \to 0$, terminating in a final burst at the Planck scale where the semiclassical description fails. Negative heat capacity is the thermodynamic face of the instability of an isolated black hole.

(ii) No stable canonical ensemble in flat space. Stability of the canonical ensemble requires $C > 0$ (so that $\partial^2 F/\partial T^2 < 0$ and the free energy is concave). With $C < 0$ the saddle is a local *maximum* rather than minimum of the free energy in the relevant direction. In the path integral this shows up as a single negative eigenvalue of the fluctuation operator about the Euclidean Schwarzschild saddle — the Gross–Perry–Yaffe negative mode [239] — which makes the Gaussian integral in Eq. (65.163) formally imaginary and signals that the black hole contributes to the *decay rate* of hot flat space, not to a stable equilibrium. The hot-flat-space and black-hole saddles compete; which dominates depends on temperature, and the imaginary part is the nucleation rate of black holes out of the thermal bath.

(iii) How to stabilize it. A finite system can be stabilized by confining it. York's construction places the hole in a cavity of radius r_B with the wall held at fixed temperature; the locally measured (Tolman-blueshifted) temperature and the finite-volume constraint can make $C > 0$ for a sufficiently small cavity, yielding a genuine canonical equilibrium. The cleaner stabilizer is a negative cosmological constant: in anti–de Sitter space the curvature radius plays the role of a confining box, large black holes have $C > 0$, and the competition between the black-hole and thermal-AdS saddles becomes the Hawking–Page phase transition [258] — the bulk dual of a deconfinement transition in the boundary theory of Part XV. The negative heat capacity of asymptotically flat Schwarzschild is thus not the end of the story but the entrance to the richer thermodynamics of black holes in a box.

65.5.5 One loop: the fluctuation determinant and zeta regularization

The result $S = A/4G$ is the *leading* term in the expansion Eq. (65.163); it is the tree-level (in G) free energy. The next term is the one-loop Gaussian integral over fluctuations $g = g_{\rm cl} + h$ about the saddle, which contributes

$$\ln Z = -I_E[g_{\rm cl}] - \tfrac{1}{2} \ln \det{}' \Delta + \dots , \tag{65.182}$$

where Δ is the quadratic operator governing the fluctuations (the Lichnerowicz operator for the graviton, together with the matter operators of any fields present) and the prime indicates the omission of zero modes, handled by the collective-coordinate method of Section E.6.3. The functional determinant $\det{}'\Delta$ is, as always, a divergent product of eigenvalues that requires definition. The definition the book uses throughout is the spectral zeta function: if Δ has eigenvalues λ_n, set $\zeta_\Delta(s) = \sum_n \lambda_n^{-s}$, analytically continue, and *define*

$$\ln \det{}' \Delta \equiv -\zeta_\Delta'(0), \tag{65.183}$$

exactly as constructed in Section E.3 and packaged in Theorem E.16. It is no accident that this is the natural tool here: zeta-function regularization was introduced by Hawking precisely to make sense of gravitational and curved-space path integrals of this type [257], and the renormalization of the stress tensor in the same backgrounds, carried out in Section 64.5, is the local face of the same heat-kernel machinery.

We do not carry out the full graviton determinant here — it is a long computation, sensitive to gauge-fixing and to the conformal-factor problem, and the techniques are exactly those of Section E.3. What matters for the architecture of the argument is the *structure* of the answer. The one-loop determinant, regularized by Eq. (65.183), produces a correction to the entropy of the schematic form

$$S = \frac{A}{4G} + c \, \ln \frac{A}{G} + \dots , \tag{65.184}$$

with a coefficient c fixed by the trace anomaly of the fluctuating fields in the black-hole background — the very anomaly coefficient that the next section computes locally. The leading $A/4G$ is universal and geometric; the logarithmic correction is the first place where the microscopic content of the theory (its field content, through the anomaly) leaves a fingerprint on black-hole thermodynamics. We flag this here and pick up the anomaly thread in Section 65.6.

We have now derived the Hawking temperature and the Bekenstein–Hawking entropy a second, fully independent way: not from tracking modes across a horizon, but from the smoothness and on-shell action of a Euclidean saddle of the gravitational path integral. The temperature is the unique period that removes a conical singularity; the entropy is the boundary term of the on-shell action.

This saddle-point, path-integral picture of the gravitational partition function is the viewpoint the remainder of the chapter builds on. The next section turns to a *third*, purely local derivation of the same Hawking flux, reading it off the quantum anomalies of fields in the near-horizon region; and the gravitational path integral introduced here returns in force in Section 65.8 when its *replica* saddles — additional smooth geometries that dominate at late times — turn out to know about the unitarity of black-hole evaporation and bend the entropy back down along the Page curve.

65.6 Hawking Flux from Quantum Anomalies

The previous section gave us the Hawking temperature for a second time, and from a viewpoint that never quantized a single matter field: the temperature is the unique period that removes the conical singularity from the Euclidean cap, and the entropy is the boundary term of an on-shell gravitational action. Section 3 had already recast the radiated power as a statement about the renormalized stress tensor, $L = \lim_{r\to\infty} 4\pi r^2 \langle T_{uu}\rangle_{\rm ren}$ (Eq. (65.118)), a manifestly local object built by the point-splitting subtraction of Section 64.5. Both pictures, the Euclidean saddle and the renormalized stress tensor, are local and geometric. It is natural to ask whether the *number* in the flux—the coefficient $\pi T_H^2/12$ per field—can be extracted from purely local data near the horizon, without ever following a mode out to infinity or evaluating an action at the boundary of the universe.

It can, and the mechanism is one we built deep in Part X and Part XIV: a quantum anomaly. The claim of this section is sharp. Reduce a field near the horizon to its two-dimensional content; then the breakdown of a classical symmetry at one loop—the trace (conformal) anomaly, or equivalently the gravitational anomaly of the effectively chiral near-horizon theory—fixes the outgoing energy flux completely, and the value it fixes is exactly the Hawking flux. The radiation is anomaly-mediated: it is determined by horizon data alone, by the surface gravity κ and the central charge of the matter, with no reference to the asymptotic region. This is the third independent derivation promised in the chapter's thesis, and it is the one that recruits the machinery of Chapter 36 (the chiral anomaly, the Fujikawa measure) and Chapters 47 and 48 (the conformal stress tensor and its anomalous Schwarzian transformation) and shows them powering black-hole radiance.

65.6.1 Near-horizon dimensional reduction: a tower of two-dimensional fields

The first step is to understand why a four-dimensional problem becomes a two-dimensional one near the horizon. We carry the free real scalar of ϕ^4 theory at

$\lambda = 0$, with the curved-space action of Section 64.5,

$$S = \frac{1}{2}\int \mathrm{d}^4x\,\sqrt{-g}\,g^{\mu\nu}\partial_\mu\phi\,\partial_\nu\phi, \qquad \mathrm{d}s^2 = f(r)\,\mathrm{d}t^2 - \frac{\mathrm{d}r^2}{f(r)} - r^2\,\mathrm{d}\Omega^2, \tag{65.185}$$

with $f(r) = 1 - 2GM/r$ as throughout the chapter and $\sqrt{-g} = r^2\sin\theta$. Expand the field in real spherical harmonics, $\phi(t,r,\theta,\varphi) = \sum_{\ell m}\phi_{\ell m}(t,r)\,Y_{\ell m}(\theta,\varphi)$, and use the orthonormality $\int \mathrm{d}\Omega\,Y_{\ell m}Y_{\ell' m'} = \delta_{\ell\ell'}\delta_{mm'}$ together with $\int \mathrm{d}\Omega\,(\nabla_\Omega Y_{\ell m})^2 = \ell(\ell+1)$ on the unit sphere. The angular integral collapses the action to a sum of decoupled two-dimensional actions, one per mode,

$$S = \frac{1}{2}\sum_{\ell m}\int \mathrm{d}t\,\mathrm{d}r\left[\frac{r^2}{f}\,(\partial_t\phi_{\ell m})^2 - r^2 f\,(\partial_r\phi_{\ell m})^2 - \ell(\ell+1)\,\phi_{\ell m}^2\right]. \tag{65.186}$$

This is precisely a free scalar living on the two-dimensional (t,r) plane with metric

$$\mathrm{d}s^2_{(2)} = f(r)\,\mathrm{d}t^2 - \frac{\mathrm{d}r^2}{f(r)}, \qquad \sqrt{-g_{(2)}} = 1, \quad g^{tt}_{(2)} = \frac{1}{f},\ g^{rr}_{(2)} = -f, \tag{65.187}$$

coupled to a position-dependent *dilaton* $\Phi(r) \equiv r^2$ (the transverse area) and carrying a mass term set by the angular momentum:

$$S = \frac{1}{2}\sum_{\ell m}\int \mathrm{d}^2x\,\sqrt{-g_{(2)}}\;\Phi(r)\left[g^{ab}_{(2)}\partial_a\phi_{\ell m}\partial_b\phi_{\ell m} - \frac{\ell(\ell+1)}{r^2}\,\phi_{\ell m}^2\right]. \tag{65.188}$$

One checks the identification directly: $\Phi g^{tt}_{(2)} = r^2/f$ and $\Phi g^{rr}_{(2)} = -r^2 f$ reproduce the two kinetic terms of Eq. (65.186), and $\Phi\cdot\ell(\ell+1)/r^2 = \ell(\ell+1)$ the mass term. A single higher-dimensional field has become an *infinite tower* of two-dimensional fields indexed by (ℓ, m), each a scalar on the (t,r) plane with a dilaton coupling and an ℓ-dependent potential.

Definition 65.31 (Near-horizon two-dimensional theory)**.** The *near-horizon limit* of Eq. (65.188) is the theory obtained as $r \to r_h = 2GM$, where $f \to 0$. In that limit the dilaton $\Phi \to r_h^2$ is constant, and the effective potential governing the radial wave—read off from Eq. (65.186) in the tortoise coordinate r_* of Eq. (65.75), in which the radial equation becomes $\ddot{\phi}_{\ell m} + (\omega^2 - V_\ell)\phi_{\ell m} = 0$ with $V_\ell = f\left[\ell(\ell+1)/r^2 + f'/r\right]$—vanishes as $V_\ell \propto f \to 0$. Each tower member therefore reduces, in a neighbourhood of the horizon, to a *free, massless, two-dimensional scalar* on Eq. (65.187), with central charge $c = 1$.

The physics of this reduction is the same physics that produced the greybody factors of Section 65.2.1: away from the horizon the potential V_ℓ is a barrier through which a mode must tunnel, and it is exactly this barrier that suppresses the high-ℓ partial waves and shapes the spectrum at infinity. But at the horizon

the barrier is gone—V_ℓ vanishes there because every term carries a factor of f—so the *near-horizon* dynamics of each and every partial wave is that of a free two-dimensional conformal scalar. This is the structural fact the anomaly arguments exploit: whatever the matter content and whatever the angular momentum, the field theory at the horizon is a collection of two-dimensional CFTs, and two dimensions is precisely the dimension in which the trace and gravitational anomalies are simplest and most powerful.

Physical Insight

Dimensional reduction at the horizon is not an approximation we impose for convenience; it is forced by the geometry. The factor $f(r)$ multiplies the angular gradient energy and the potential alike, and $f \to 0$ at the horizon by definition of a horizon. Modes piling up against the horizon are infinitely blueshifted in the (t, r) plane while their transverse structure is frozen, so the only dynamics that survives the limit is two-dimensional and conformal. The horizon manufactures a 2D CFT out of any field thrown at it.

65.6.2 The trace anomaly fixes the flux: the Christensen–Fulling integration

We now compute the outgoing flux of a single near-horizon 2D conformal scalar from its trace anomaly. Pass to null coordinates

$$u = t - r_*, \qquad v = t + r_*, \qquad \frac{\mathrm{d}r_*}{\mathrm{d}r} = \frac{1}{f}, \tag{65.189}$$

in which the two-dimensional metric Eq. (65.187) is conformally flat,

$$\mathrm{d}s^2_{(2)} = f(r)\,\mathrm{d}u\,\mathrm{d}v = e^{2\rho}\,\mathrm{d}u\,\mathrm{d}v, \qquad \rho = \tfrac{1}{2}\ln f(r), \qquad R = f''(r), \tag{65.190}$$

where R is the two-dimensional Ricci scalar in the curvature convention of Appendix A, equivalently $R = -8e^{-2\rho}\partial_u\partial_v\rho$ for a metric of the form $e^{2\rho}\mathrm{d}u\,\mathrm{d}v$. The renormalized stress tensor of the conformal scalar is not traceless: it carries the two-dimensional specialization of the trace anomaly established in general dimension in Eq. (64.199), which with central charge c (Theorem 48.8) reads

$$\langle T^{\mu}{}_{\mu} \rangle = \frac{c}{24\pi}\,R. \tag{65.191}$$

This single anomalous equation, together with covariant conservation $\nabla_\mu T^{\mu}{}_{\nu} = 0$, is enough to determine $\langle T_{\mu\nu} \rangle$ up to two integration functions. We carry out the integration explicitly; this is the Christensen–Fulling computation [123].

Conservation in conformal gauge. For the metric $\mathrm{d}s^2 = e^{2\rho}\mathrm{d}u\,\mathrm{d}v$ the only non-vanishing Christoffel symbols are $\Gamma^u_{uu} = 2\partial_u\rho$ and $\Gamma^v_{vv} = 2\partial_v\rho$, and the inverse metric has the single component $g^{uv} = 2e^{-2\rho}$. Writing out $\nabla_\mu T^\mu{}_u = \partial_\mu T^\mu{}_u + \Gamma^\mu{}_{\mu\lambda}T^\lambda{}_u - \Gamma^\lambda{}_{\mu u}T^\mu{}_\lambda$ and using these data, every term containing $\Gamma^u_{uu}T^u{}_u$ cancels, leaving after multiplication by $\frac{1}{2}e^{2\rho}$ the compact relations

$$\partial_v T_{uu} = -\partial_u T_{uv} + 2(\partial_u\rho)\,T_{uv}, \qquad \partial_u T_{vv} = -\partial_v T_{uv} + 2(\partial_v\rho)\,T_{uv}. \tag{65.192}$$

The trace component is fixed algebraically by the anomaly: from $\langle T^\mu{}_\mu\rangle = g^{\mu\nu}T_{\mu\nu} = 2g^{uv}T_{uv} = 4e^{-2\rho}T_{uv}$ and Eq. (65.191) with $R = -8e^{-2\rho}\partial_u\partial_v\rho$,

$$T_{uv} = -\frac{c}{12\pi}\,\partial_u\partial_v\rho. \tag{65.193}$$

Were the theory conformally invariant at the quantum level we would have $T_{uv} = 0$; the anomaly Eq. (65.191) is exactly the statement that it is not, and this nonzero trace is what sources a nontrivial outgoing component.

Integrating the outgoing component. Substitute Eq. (65.193) into the second relation of Eq. (65.192), the one for T_{vv}; by the obvious $u \leftrightarrow v$ symmetry the same steps applied to the first relation give T_{uu}. Using $-\partial_v T_{uv} = \frac{c}{12\pi}\partial_v\partial_u\partial_v\rho$ and $2(\partial_v\rho)T_{uv} = -\frac{c}{6\pi}(\partial_v\rho)(\partial_u\partial_v\rho) = -\frac{c}{12\pi}\partial_u[(\partial_v\rho)^2]$, the right-hand side collects into a single u-derivative,

$$\partial_u T_{vv} = \frac{c}{12\pi}\,\partial_u[\partial_v^2\rho - (\partial_v\rho)^2], \tag{65.194}$$

which integrates immediately. Doing the same for the outgoing (uu) component,

$$T_{uu} = \frac{c}{12\pi}\left[\partial_u^2\rho - (\partial_u\rho)^2\right] + t_{uu}(u), \qquad T_{vv} = \frac{c}{12\pi}\left[\partial_v^2\rho - (\partial_v\rho)^2\right] + t_{vv}(v), \tag{65.195}$$

where $t_{uu}(u)$ and $t_{vv}(v)$ are integration "constants"—arbitrary functions of a single null coordinate each—left undetermined by the local equations. They encode the choice of quantum state. *All* the dynamical content of the Hawking flux is in fixing them.

Evaluating on Schwarzschild. The conformal factor depends only on $r_* = (v-u)/2$, so with $\mathrm{d}r/\mathrm{d}r_* = f$ and $\mathrm{d}\rho/\mathrm{d}r_* = \frac{1}{2}f'$ we have $\partial_u\rho = -\frac{1}{2}\,\mathrm{d}\rho/\mathrm{d}r_* = -f'/4$ and

$$\partial_u^2\rho = \frac{ff''}{8}, \qquad (\partial_u\rho)^2 = \frac{(f')^2}{16}, \qquad \partial_u^2\rho - (\partial_u\rho)^2 = \frac{ff''}{8} - \frac{(f')^2}{16}. \tag{65.196}$$

This combination has a clean value at both ends of the exterior. At infinity $f \to 1$, $f' \to 0$, $f'' \to 0$, so it vanishes and $T_{uu} \to t_{uu}$: the asymptotic flux is

the integration function alone. At the horizon $f(r_h) = 0$, and with the surface gravity $\kappa = \frac{1}{2}f'(r_h)$ of Section 65.4 so that $f'(r_h) = 2\kappa$,

$$\Big[\partial_u^2\rho - (\partial_u\rho)^2\Big]_{r_h} = -\frac{(f'(r_h))^2}{16} = -\frac{(2\kappa)^2}{16} = -\frac{\kappa^2}{4}, \qquad \Longrightarrow \qquad \frac{c}{12\pi}\Big[\cdots\Big]_{r_h} = -\frac{c\,\kappa^2}{48\pi}. \tag{65.197}$$

The boundary condition and the flux. The integration function is fixed by the demand that the state be regular at the future horizon—the Unruh state appropriate to a black hole formed by collapse and radiating into an initially empty exterior. Regularity in a frame that is smooth at the horizon means the physical (freely-falling) components of $\langle T_{\mu\nu}\rangle$ are finite there. Because the outgoing null coordinate u degenerates at the horizon while the Kruskal coordinate U is regular, and $T_{UU} = (\mathrm{d}u/\mathrm{d}U)^2 T_{uu}$ with $\mathrm{d}u/\mathrm{d}U$ diverging there, finiteness of T_{UU} requires $T_{uu} \to 0$ as $r \to r_h$. Imposing this on Eq. (65.195) with Eq. (65.197),

$$0 = T_{uu}\big|_{r_h} = -\frac{c\,\kappa^2}{48\pi} + t_{uu} \qquad \Longrightarrow \qquad t_{uu} = \frac{c\,\kappa^2}{48\pi}. \tag{65.198}$$

The asymptotic outgoing flux is therefore

$$\boxed{\langle T_{uu}\rangle\big|_{r\to\infty} = t_{uu} = \frac{c\,\kappa^2}{48\pi} = \frac{\pi c}{12}\,T_H^2} \qquad (T_H = \kappa/2\pi), \tag{65.199}$$

using $T_H = \kappa/2\pi$ from Eq. (65.64). For the single conformal scalar, $c = 1$ and the flux is $\kappa^2/48\pi = \pi T_H^2/12$, precisely the value extracted from the mode sum and the renormalized stress tensor in Section 65.2.1.

Theorem 65.32 (Hawking flux from the trace anomaly)**.** *Let a two-dimensional conformal field of central charge c propagate on the near-horizon geometry Eq. (65.187) of a static horizon with surface gravity κ. Covariant conservation of its stress tensor together with the trace anomaly Eq. (65.191), supplemented by the regularity (Unruh) boundary condition $T_{uu} \to 0$ at the future horizon, fixes the outgoing energy flux at infinity uniquely to*

$$\langle T_{uu}\rangle\big|_{\infty} = \frac{c\,\kappa^2}{48\pi} = \frac{\pi c}{12}\,T_H^2. \tag{65.200}$$

The flux depends only on κ (horizon data) and c (matter content); it is independent of the asymptotic region and of the detailed profile of $f(r)$ away from the horizon.

The structure of the argument deserves emphasis. The local equations Eq. (65.195) leave the flux completely free; it is the anomaly coefficient c, multiplying a curvature combination that takes the value $-\kappa^2/4$ at the horizon, that sets the scale, and the horizon regularity condition that converts a free integration constant into the definite number $c\kappa^2/48\pi$. Without the anomaly ($c = 0$) the flux would vanish: a classically conformal field would not radiate. The Hawking flux is an anomaly, full stop.

65.6.3 The same flux from the anomalous (Schwarzian) transformation of T

The integration function t_{uu} is not a tensor. It is the two-dimensional analog of the holomorphic stress tensor $T(z)$ of Chapter 48, and like $T(z)$ it transforms under a conformal change of the null coordinate $u \to \tilde{u}(u)$ with an inhomogeneous Schwarzian term. This gives a second, even shorter derivation of Eq. (65.199), and it makes the central charge's role completely explicit.

Recall from Eq. (48.63) that under a holomorphic map the stress tensor of a 2D CFT picks up the Schwarzian derivative Eq. (48.62); the Lorentzian, null-coordinate version of that statement, applied to the state-dependent piece t_{uu} extracted in Eq. (65.195), is

$$t_{uu}(u) = \left(\frac{\mathrm{d}\tilde{u}}{\mathrm{d}u}\right)^2 t_{\tilde{u}\tilde{u}}(\tilde{u}) - \frac{c}{24\pi}\{\tilde{u}, u\}, \qquad \{\tilde{u}, u\} = \frac{\tilde{u}'''}{\tilde{u}'} - \frac{3}{2}\left(\frac{\tilde{u}''}{\tilde{u}'}\right)^2. \tag{65.201}$$

That this is the correct transformation law follows from the same conservation-plus-anomaly system used above: under $u \to \tilde{u}$ the conformal factor shifts as $\rho \to \rho - \frac{1}{2}\ln(\mathrm{d}\tilde{u}/\mathrm{d}u)$, and feeding this into the geometric piece of Eq. (65.195) produces exactly the Schwarzian inhomogeneity in Eq. (65.201), with the universal coefficient $c/24\pi$ set by the anomaly Eq. (65.191). The cocycle (group) consistency of the Schwarzian, proved in Eq. (48.66), guarantees this law composes correctly.

The strategy is now to identify the one frame in which the state-dependent flux vanishes. The Unruh vacuum is, by construction, the state whose outgoing modes are positive frequency with respect to the Kruskal coordinate U that is regular across the future horizon. In that Kruskal frame the outgoing sector looks like the Minkowski vacuum of an inertial observer, so its normal-ordered stress tensor has no anomalous flux:

$$t_{UU}(U) = 0. \tag{65.202}$$

The exterior retarded coordinate u and the Kruskal coordinate U are related, as established in the ray-tracing analysis of Section 65.2.1, by the exponential map

$$U = -\frac{1}{\kappa}\, e^{-\kappa u}, \tag{65.203}$$

which is the geometric origin of the whole effect: a late-time outgoing wave (large u) is exponentially compressed against the horizon $U \to 0^-$. We need only its Schwarzian. With $U' = e^{-\kappa u}$, $U'' = -\kappa e^{-\kappa u}$, $U''' = \kappa^2 e^{-\kappa u}$,

$$\{U, u\} = \frac{U'''}{U'} - \frac{3}{2}\left(\frac{U''}{U'}\right)^2 = \kappa^2 - \frac{3}{2}\kappa^2 = -\frac{\kappa^2}{2}. \tag{65.204}$$

Setting $\tilde{u} = U$ in Eq. (65.201) and using Eq. (65.202),

$$t_{uu} = (U')^2\, t_{UU} - \frac{c}{24\pi}\{U, u\} = 0 - \frac{c}{24\pi}\left(-\frac{\kappa^2}{2}\right) = \frac{c\,\kappa^2}{48\pi}, \tag{65.205}$$

identical to Eq. (65.199). The two computations are the same computation seen twice: the curvature combination of Christensen–Fulling and the Schwarzian of the Kruskal map are two faces of the one anomaly, and both deliver the flux $c\,\kappa^2/48\pi$. The central charge that fixes the coefficient is the very c defined through the $T(z)T(w)$ operator product in Eq. (48.56); the surface gravity that fixes the scale enters solely through the rate κ of the exponential horizon map Eq. (65.203). Horizon data and central charge, and nothing else.

Worked Example 65.33 (The flux is a two-dimensional Planck spectrum at T_H)**.** The number $c\kappa^2/48\pi$ should be the energy flux of a thermal gas of the near-horizon fields at temperature T_H, since that is what Chapter 64's Bogoliubov analysis says the horizon emits. We check this directly for one bosonic field ($c = 1$). A massless field in two dimensions splits into independent left- and right-moving sectors; the outgoing (right-moving) sector carries an energy flux that, in a thermal state at temperature T_H, is the integral over modes of the energy ω times the Bose occupation $n(\omega) = (e^{\omega/T_H} - 1)^{-1}$, with the one-dimensional density of states $\mathrm{d}\omega/2\pi$,

$$\Phi = \int_0^\infty \frac{\mathrm{d}\omega}{2\pi}\,\frac{\omega}{e^{\omega/T_H}-1} = \frac{T_H^2}{2\pi}\int_0^\infty \frac{x\,\mathrm{d}x}{e^x-1} = \frac{T_H^2}{2\pi}\cdot\frac{\pi^2}{6} = \frac{\pi}{12}\,T_H^2, \tag{65.206}$$

using $\int_0^\infty x\,(e^x-1)^{-1}\mathrm{d}x = \Gamma(2)\zeta(2) = \pi^2/6$ (the standard Bose–Einstein integral of Chapter 64). With $T_H = \kappa/2\pi$ this is $\Phi = \pi T_H^2/12 = \kappa^2/48\pi$, exactly Eq. (65.199) at $c = 1$. The anomaly has reproduced the full Stefan–Boltzmann-type flux of a two-dimensional blackbody at the Hawking temperature, coefficient and all. The $\pi^2/6$ from the thermal integral and the $-\kappa^2/2$ from the Schwarzian are the same physics: $\zeta(2)$ is the Casimir energy of the $c = 1$ theory on a thermal circle, and the Schwarzian term is its anomalous transformation. This is why the central charge controls both.

65.6.4 Robinson–Wilczek: the chiral horizon and the gravitational anomaly

The trace anomaly is one face of the two-dimensional anomaly structure; the other is the gravitational (diffeomorphism) anomaly of a *chiral* field, and it gives a third route to the same flux—the one that makes the role of the horizon as a one-way membrane most vivid. This is the argument of Robinson and Wilczek [418].

The key observation is that, arbitrarily close to the horizon, the ingoing modes are causally irrelevant to the exterior: nothing that crosses inward can come back out. If we restrict attention to a thin shell $r_h \le r \le r_h + \varepsilon$ and ask for the effective theory that governs physics outside, we must integrate out the ingoing modes there, because they have fallen through and decoupled. What remains is a theory of the outgoing modes alone—a *chiral* two-dimensional theory

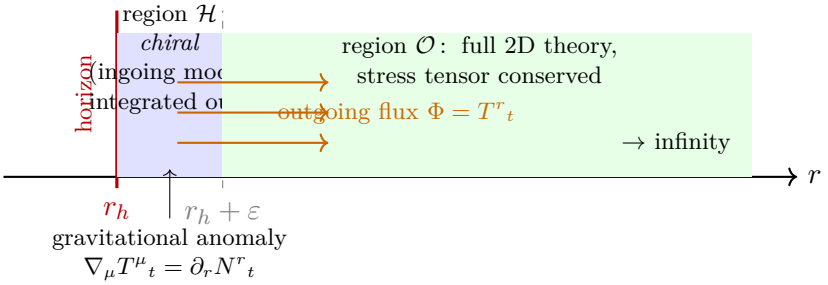


Figure 65.6: The Robinson–Wilczek region split. In the thin near-horizon shell $\mathcal{H} = [r_h, r_h + \varepsilon]$ the ingoing modes are integrated out, leaving a chiral two-dimensional theory whose stress tensor is anomalous, $\nabla_\mu T^\mu{}_t = \partial_r N^r{}_t$. In the exterior $\mathcal{O}$ both chiralities survive and the stress tensor is conserved, so the outgoing energy flux $T^r{}_t$ is constant there. Diffeomorphism invariance of the total effective action forces a cancellation at the boundary $r = r_h + \varepsilon$ that fixes that constant flux to the universal Hawking value.

in the near-horizon region. (In null coordinates the surviving field is a function of u only.) But a two-dimensional chiral field is anomalous under diffeomorphisms: its stress tensor is not conserved, exactly as a chiral fermion's current is not conserved in Theorem 36.4. The gravitational anomaly is the diffeomorphism cousin of the chiral gauge anomaly, and like it, is one-loop exact and fixed by the same Fujikawa measure argument of Section 36.3: under a chiral truncation the path-integral measure is not diffeomorphism invariant, and its Jacobian is a local curvature functional.

The anomalous Ward identity. For the two-dimensional metric Eq. (65.187), the consistent gravitational anomaly of one chiral boson takes the form of a total radial derivative in the energy (time) component of the conservation law,

$$\nabla_\mu T^\mu{}_t = \frac{1}{\sqrt{-g_{(2)}}}\,\partial_r N^r{}_t, \qquad N^r{}_t = \frac{c}{96\pi}\Big(f f'' - \tfrac{1}{2}(f')^2\Big), \tag{65.207}$$

with $c = 1$ per chiral scalar and $\sqrt{-g_{(2)}} = 1$ here. (The structure—an anomaly that is a total derivative of a local curvature polynomial—is the gravitational analog of the chiral-anomaly density $\partial_\mu j^{\mu 5} \propto \partial_\mu K^\mu$ of Eq. (36.50).) In the exterior region $\mathcal{O}$, where both chiralities are present, the theory is anomaly-free, so $\nabla_\mu T^\mu{}_t = 0$ and, the metric being static, $T^r{}_t$ is a constant in r:

$$T^r{}_t\big|_{\mathcal{O}} = -\Phi = \text{const}, \tag{65.208}$$

the constant outgoing energy flux we seek (the sign convention is such that $\Phi > 0$ carries energy outward, $\Phi = -\mathrm{d}M/\mathrm{d}t$). In the near-horizon region $\mathcal{H}$ the chiral theory obeys Eq. (65.207), which integrates to $T^r{}_t|_{\mathcal{H}}(r) = K_{\mathcal{H}} + N^r{}_t(r) - N^r{}_t(r_h)$.

The boundary term and the flux. Write the full stress tensor with a step function separating the two regions, $T^r{}_t = T^r{}_t|_{\mathcal{O}}\,\Theta(r-r_h-\varepsilon) + T^r{}_t|_{\mathcal{H}}\,[1-\Theta(r-r_h-\varepsilon)]$, and demand that the total quantum effective action W be invariant under an infinitesimal diffeomorphism $x^\mu \to x^\mu + \xi^\mu$. The variation is $\delta_\xi W = -\int \mathrm{d}^2x\,\sqrt{-g}\,\xi^\nu \nabla_\mu T^\mu{}_\nu$. Taking $\xi^\nu = \xi^t \delta^\nu_t$ and using the two regional Ward identities, the bulk anomaly term in $\mathcal{H}$ is cancelled by the contribution of the classical ingoing modes that were integrated out (their effective action restores diffeomorphism invariance in the bulk), and what survives is a delta-function supported at the boundary $r = r_h + \varepsilon$,

$$\delta_\xi W = -\int \mathrm{d}^2x\;\xi^t\left[\,T^r{}_t\big|_{\mathcal{O}} - T^r{}_t\big|_{\mathcal{H}} + N^r{}_t\,\right]\delta(r-r_h-\varepsilon) + (\text{bulk, cancelled}). \tag{65.209}$$

Invariance requires the bracket to vanish. As $\varepsilon \to 0$ we impose the covariant boundary condition that fixes the chiral integration constant: the *covariant* energy flux must vanish at the horizon itself, $T^r{}_t|_{\mathcal{H}}(r_h) = 0$, since the horizon is not a source of energy. Then the bracket evaluated at r_h reads $-\Phi - 0 + N^r{}_t(r_h) = 0$, so

$$\Phi = N^r{}_t(r_h) = \frac{c}{96\pi}\Big(\underbrace{f f''}_{0} - \tfrac{1}{2}(f')^2\Big)_{r_h} = -\frac{c}{96\pi}\cdot\frac{1}{2}\,(2\kappa)^2 = -\frac{c\,\kappa^2}{48\pi}, \tag{65.210}$$

where $f(r_h) = 0$ kills the first term and $f'(r_h) = 2\kappa$. Restoring the sign bookkeeping of Eq. (65.208), the magnitude of the outgoing flux is

$$\boxed{\,|\Phi| = \frac{c\,\kappa^2}{48\pi} = \frac{\pi c}{12}\,T_H^2\,} \tag{65.211}$$

the very same number as Eq. (65.199) and Eq. (65.205).

Theorem 65.34 (Hawking flux from the gravitational anomaly)**.** *The condition that the total effective action of a field on the near-horizon geometry Eq. (65.187) be diffeomorphism invariant, given that the field becomes effectively chiral (hence gravitationally anomalous) at the horizon, fixes the outgoing energy flux to* $|\Phi| = c\,\kappa^2/48\pi = \pi c T_H^2/12$. *Equivalently: the gravitational anomaly at the horizon can be cancelled only by an outgoing flux of precisely the Hawking magnitude. Black-hole radiance is the flux required for consistency of the quantum theory in the presence of a horizon.*

65.6.5 Consistent versus covariant anomalies and the horizon boundary term

The Robinson–Wilczek computation, like every anomaly calculation, must navigate the distinction between the *consistent* and *covariant* forms of the anomaly, introduced in the gauge context of Chapter 36. The distinction is not pedantry:

the two anomalies differ by a definite local term, and getting the boundary condition at the horizon to match the anomaly one is using is what makes the coefficient come out right.

The *consistent* anomaly is the one that arises as the variation of a definite effective action, $\mathcal{A}_\nu^{\text{cons}} = \delta W/\delta(\text{diffeo})$; it satisfies the Wess–Zumino consistency conditions (it is a closed cocycle, as the chiral-anomaly consistency conditions of Chapter 36 require) but the associated current/stress tensor does not transform covariantly. The *covariant* anomaly is obtained by adding a local polynomial in the connection—the Bardeen–Zumino term—to restore covariant transformation, at the cost of no longer deriving from a local action. In two dimensions the consistent gravitational anomaly is $N^r{}_t$ as written in Eq. (65.207), while the covariant one is proportional to $\partial_r R$; they differ by exactly the Bardeen–Zumino piece, and the covariant flux at the horizon $\frac{c}{96\pi}(\,2ff''-(f')^2\,)$ differs term-by-term from the consistent $\frac{c}{96\pi}(ff'' - \frac{1}{2}(f')^2)$. At the horizon f vanishes and only the $(f')^2$ pieces survive, but they do *not* coincide: the consistent expression returns $-c\kappa^2/48\pi$ while the covariant one returns $-c\kappa^2/24\pi$, a factor of two larger. The physical fluxes nevertheless agree, because the covariant flux is extracted with a different boundary normalization—the covariant horizon condition $T^r{}_t|_{\text{cov}}(r_h) = 0$ used just below—and not because the two raw horizon values of $N^r{}_t$ are equal.

The role of the boundary term Eq. (65.209) is to enforce that one uses *matching* bookkeeping at the two ends. Robinson and Wilczek used the consistent anomaly and an effective-action boundary term; the cleaner covariant formulation of Banerjee and Kulkarni [44] imposes directly the covariant condition $T^r{}_t|_{\text{cov}}(r_h) = 0$—the statement that a freely-falling observer crossing the horizon measures no net energy flux *there*, the same physical content as the Christensen–Fulling regularity condition Eq. (65.198) that set t_{uu}. The two boundary conditions, $T_{uu} \to 0$ in the trace-anomaly language and $T^r{}_t|_{\text{cov}}(r_h) = 0$ in the gravitational-anomaly language, are the same demand: the Unruh state is regular at the future horizon. With that single physical input, the consistent and covariant routes, and the trace and gravitational anomalies, all return $c\kappa^2/48\pi$.

Caution

It is tempting to read the gravitational-anomaly derivation as saying the radiation "originates" in the thin shell $\mathcal{H}$ or that the anomaly is "produced" at $r_h + \varepsilon$. Neither is right. The shell and its boundary are bookkeeping devices; nothing physical depends on ε, which drops out as $\varepsilon \to 0$. What is physical is that a horizon makes the effective theory chiral, that chirality is anomalous, and that the only flux consistent with diffeomorphism invariance is the Hawking flux. The localization is a feature of the *argument*, not of the radiation, which—as the Bogoliubov computation shows—is emitted into the entire exterior.

65.6.6 Three derivations, one number

We have now computed the Hawking emission three genuinely independent ways, and it is worth stating plainly that they agree, because that agreement is the payoff the whole chapter was built toward. The Bogoliubov/ray-tracing computation of Section 65.2.1 tracked the in-vacuum modes across the collapsing geometry and read off a Planck spectrum at $T_H = \kappa/2\pi$, with luminosity Eq. (65.105). The Euclidean path integral of Section 65.5 found the same T_H as the unique smooth period of imaginary time, with entropy $A/4G$ as the on-shell action's boundary term. And the anomaly arguments of this section fixed the outgoing flux to $c\kappa^2/48\pi = \pi c T_H^2/12$ from horizon data alone—three times over, from the trace anomaly Eq. (65.199), from the Schwarzian transformation of the conformal stress tensor Eq. (65.205), and from the gravitational anomaly of the chiral horizon theory Eq. (65.211), each landing on the identical number that Theorem 65.33 confirmed is the flux of a two-dimensional Planck spectrum at T_H.

These are not three rewordings of one calculation. The Bogoliubov route is canonical quantization on a time-dependent background (Part III's apparatus); the Euclidean route is the gravitational path integral and its saddle points (Part III and Chapter 10's e^{-S_E} pillar); the anomaly route is the one-loop breakdown of conformal and diffeomorphism invariance (Parts X and XIV, the chiral anomaly of Chapter 36 and the conformal stress tensor of Chapters 47 and 48). The canonical, path-integral, and anomaly languages that this book developed in separate parts, for separate purposes, all see the one physical fact: a horizon with surface gravity κ radiates a thermal flux at temperature $\kappa/2\pi$. That a single phenomenon is forced by three unrelated formalisms is the strongest evidence we have that it is a property of the theory and not of any one method of asking.

Physical Insight

The anomaly derivation carries a conceptual sharpening the other two lack. It shows the flux is fixed by *local horizon data*: the surface gravity κ and the central charge c, evaluated in an arbitrarily thin neighbourhood of the horizon. No information about the asymptotic region, the collapse history, or the global structure enters. The radiation is, in this precise sense, inflowing from the anomaly at the horizon. This locality is both reassuring and unsettling: reassuring because it means the result is robust against the details of how the black hole formed, unsettling because it pins the origin of every emitted quantum to the immediate vicinity of the horizon, where, as the next section shows, the modes carrying that energy must have been blueshifted past the Planck scale.

That last point is the bridge to what follows. The anomaly computation tells us the late-time flux is set entirely by horizon-local physics, and the Kruskal

map Eq. (65.203) that supplied the Schwarzian is the same exponential relation $U \propto -e^{-\kappa u}$ that traces a late-time outgoing quantum back to a frequency growing without bound at the horizon. The derivations we have assembled thus all rest, one way or another, on the behaviour of arbitrarily trans-Planckian modes in the near-horizon region. Whether the thermal result genuinely depends on that trans-Planckian input, or is protected against it, is the conceptual worry that Section 65.7 confronts head-on.

65.7 The Trans-Planckian Problem and the Robustness of the Effect

Every derivation of the Hawking flux assembled so far has delivered the same verdict and located it in the same place. The Bogoliubov computation of Section 65.2.1 read the thermal occupation off the modes that peel away from the collapsing surface an instant before the horizon forms; the greybody analysis of Section 65.3 fed those quanta in at the horizon end of the potential barrier; the Euclidean saddle of Section 65.5 was fixed entirely by the geometry of the Euclidean horizon; and the anomaly calculation of the previous section, Section 65.6, made the locality utterly explicit — the flux is determined by the trace and gravitational anomalies evaluated in an arbitrarily thin shell straddling $r = 2GM$, with no reference to the asymptotic region at all. The emission is horizon-local. That is the strength of the result and, read the other way, its embarrassment. If the quantum that reaches a distant telescope today was created at the horizon, and if the horizon redshifts modes without bound, then the quantum was born with a frequency that, traced back far enough, exceeds any scale we are entitled to trust — the Planck scale included. The thermal spectrum appears to be computed by leaning on field modes whose wavelength near the horizon is shorter than the Planck length, deep in a regime where the very framework of quantum fields on a smooth classical metric has no right to hold.

This section confronts that worry, which is the *trans-Planckian problem*, and then dismantles it. We first make the reservoir of super-Planckian frequencies quantitative, turning the logarithmic ray-tracing map of Section 65.2.1 into an explicit exponential blueshift $\omega_{\text{local}} \sim \omega\, e^{\kappa u}$ and showing that essentially all the radiation a real black hole emits traces back to trans-Planckian modes. We then assemble four independent lines of evidence that the Planck spectrum is nonetheless robust: a near-horizon adiabatic argument that pins the flux to the single number κ; explicit modified-dispersion calculations in which the ultraviolet behaviour of the field is deformed by hand and the spectrum survives; Unruh's acoustic "dumb holes," a physical system with a genuine horizon, a *known* short-distance completion, and a measured Hawking-like emission; and finally the Parikh–Wilczek tunneling derivation, a self-contained WKB computation across

the horizon in horizon-regular coordinates that incorporates the back-reaction of the emitted quantum on the geometry. The last of these does more than re-confirm T_H: its emission rate is $\Gamma \sim e^{\Delta S_{\rm BH}}$, an exact exponential in the change of the Bekenstein–Hawking entropy whose leading term is thermal and whose first correction is genuinely non-thermal — the first hint inside the semiclassical calculation itself that the radiation carries correlations, and so the technical doorway to the information problem of Section 65.8.

65.7.1 The trans-Planckian reservoir made quantitative

The origin of the difficulty is the geometric-optics map between the affine parameter on the horizon-generating null ray and the retarded time $u = t - r_*$ in which an asymptotic observer clocks the outgoing radiation. That map was the engine of Section 65.2.1: an outgoing mode that reaches infinity as the clean plane wave $e^{-i\omega u}$ is, when propagated backwards through the collapse and out to where it last sat near the forming horizon, compressed onto a Kruskal-type affine coordinate U by the logarithmic relation

$$U \;=\; -\frac{1}{\kappa}\, e^{-\kappa u}, \qquad u \;=\; -\frac{1}{\kappa}\,\ln(-\kappa U), \tag{65.212}$$

where $\kappa = 1/4GM$ is the surface gravity of Section 65.4. This single relation is the source of *both* the thermal spectrum and the trans-Planckian problem, and it pays to see the two faces together. Substituting Eq. (65.212) into the outgoing phase gives

$$e^{-i\omega u} \;=\; e^{\,(i\omega/\kappa)\ln(-\kappa U)} \;=\; (-\kappa U)^{\,i\omega/\kappa}, \qquad U<0, \tag{65.213}$$

a function whose oscillations accumulate without bound as $U \to 0^-$, i.e. as the ray is traced to the horizon. It is exactly the branch-cut structure of this power — the factor $e^{-\pi\omega/\kappa}$ relating its analytic continuation around $U=0$ from negative to positive U — that produced the Planck factor $(e^{2\pi\omega/\kappa}-1)^{-1} = (e^{\omega/T_H}-1)^{-1}$ in Section 65.2. The thermality is the infinite pile-up of phase near the horizon, made finite by analytic continuation.

But the same pile-up is the reservoir of dangerous frequencies. Define the *local* frequency of the mode Eq. (65.213) as the rate at which its phase advances per unit affine parameter,

$$\omega_U \;\equiv\; \left|\frac{\mathrm{d}}{\mathrm{d}U}\arg\!\Big[(-\kappa U)^{i\omega/\kappa}\Big]\right| \;=\; \frac{\omega}{\kappa}\left|\frac{\mathrm{d}\ln(-\kappa U)}{\mathrm{d}U}\right| \;=\; \frac{\omega}{\kappa\,|U|}. \tag{65.214}$$

The affine parameter U measures proper coordinates for a regular observer crossing the horizon, so ω_U is the frequency such an observer assigns to the wave. Inserting the map Eq. (65.212), $|U| = \kappa^{-1}e^{-\kappa u}$, gives the central estimate of this subsection,

$$\boxed{\;\omega_{\rm local}(u) \;=\; \frac{\omega}{\kappa\,|U|} \;=\; \omega\, e^{\,\kappa u}\;.\;} \tag{65.215}$$

A quantum collected at infinity at retarded time u, with the modest asymptotic frequency $\omega \sim T_H$, was a wave of *local* frequency $\omega\, e^{\kappa u}$ when it last hovered near the horizon. The blueshift is exponential in u with rate κ: each interval $\Delta u = \kappa^{-1} = 4GM$ of late-time emission reaches back to local frequencies larger by a factor e.

How quickly does this run past the Planck scale? Setting $\omega_{\rm local} = M_{\rm Pl}$ in Eq. (65.215) with the representative $\omega \sim T_H$ gives the threshold retarded time

$$\kappa\, u_{\rm Pl} \;=\; \ln\frac{M_{\rm Pl}}{\omega} \;\sim\; \ln\frac{M_{\rm Pl}}{T_H}. \tag{65.216}$$

For a solar-mass hole the Hawking temperature is $T_H \sim 10^{-7}\,\mathrm{K} \sim 10^{-11}\,\mathrm{eV}$ (Section 65.3; recall $1\,\mathrm{K} \sim 10^{-4}\,\mathrm{eV}$), while $M_{\rm Pl} \sim 10^{19}\,\mathrm{GeV} \sim 10^{28}\,\mathrm{eV}$, so $M_{\rm Pl}/T_H \sim 10^{39}$ and

$$\kappa\, u_{\rm Pl} \;\sim\; \ln 10^{39} \;\approx\; 90. \tag{65.217}$$

After only about ninety e-folds of κu — that is, after a retarded time $u_{\rm Pl} \sim 90/\kappa \sim 360\,GM$, a few hundred light-crossing times of the hole, utterly negligible against the evaporation lifetime $\tau \sim G^2M^3 \sim 10^{67}\,\mathrm{yr}$ of Eq. (65.113) — every Hawking quantum arriving at the telescope is traced back to a mode that was trans-Planckian at the horizon. The reservoir is not a tail of the spectrum or a rare event in the deep future; it is the provenance of essentially *all* the radiation a real black hole ever emits. This is the precise content of the trans-Planckian problem (Fig. 65.7(a)), first sharpened by Jacobson and Unruh [280, 479].

Caution: what is and is not in trouble

The blueshift Eq. (65.215) is a statement about a particular mode *decomposition*, not about any locally measurable curvature. A freely falling observer crossing a large black hole's horizon sees nothing singular: the curvature there is $\sim 1/(GM)^2 \ll M_{\rm Pl}^2$, the local vacuum is indistinguishable from Minkowski (the equivalence principle), and no detector registers a Planckian energy density. What is trans-Planckian is the *frequency assigned to an individual outgoing Hawking mode when its global plane-wave form at infinity is referred back to a near-horizon frame.* The worry is therefore not that physics is visibly breaking down at the horizon — it is that the derivation *appears* to require trustworthy field theory for modes of arbitrarily short wavelength. The robustness arguments below show that the answer does not, in fact, depend on that untrustworthy input.

65.7.2 Robustness I: the near-horizon adiabatic argument

The first and most general reason to expect the spectrum to survive is that the ingredients which actually fix it are all infrared. Strip the derivation to

its load-bearing core. The thermal factor came from the analytic structure of Eq. (65.213), which is controlled by exactly one quantity, the surface gravity κ in the exponent of the log map Eq. (65.212). And κ is a property of the classical geometry at the horizon — a first derivative of the metric function, $\kappa = \frac{1}{2}f'(r_h)$ (Section 65.5.1) — evaluated on length scales of order GM, enormously larger than the Planck length for any astrophysical hole. Nothing in the determination of κ knows about Planckian physics.

This is made sharp by the Unruh effect of Theorem 64.20. A static observer hovering at small proper distance ℓ outside the horizon has proper acceleration $a = \kappa/\sqrt{f} \to \infty$ as $\ell \to 0$, but the *locally measured* temperature is set by the local acceleration, and the relation between the near-horizon accelerated frame and the asymptotic frame is precisely the relation between a Rindler wedge and Minkowski space. The near-horizon geometry of any non-extremal horizon is, to leading order in ℓ, the Rindler metric $\mathrm{d}s^2 = \kappa^2\ell^2\,\mathrm{d}t^2 - \mathrm{d}\ell^2 - \dots$ (the Euclidean version of which was the smooth cigar of Fig. 65.5). On that wedge the local vacuum seen by a freely falling observer is the Minkowski vacuum, and a static (uniformly accelerated) detector reads the Unruh temperature $T = a/2\pi$; redshifting that local temperature out to infinity by the Tolman factor $\sqrt{f}$ converts $a = \kappa/\sqrt{f}$ into

$$T_\infty \;=\; \sqrt{f}\,\frac{a}{2\pi} \;=\; \sqrt{f}\,\frac{\kappa/\sqrt{f}}{2\pi} \;=\; \frac{\kappa}{2\pi} \;=\; T_H, \tag{65.218}$$

the Hawking temperature, recovered from the *local, kinematic* Unruh result together with the gravitational redshift. The point for robustness is that Eq. (65.218) is a statement about a freely falling vacuum near a Rindler horizon, and the Unruh effect (Theorem 64.20) holds for any quantum field whose two-point function reduces to the standard form at *short proper-distance separation along the trajectory*. Whatever the true ultraviolet completion of the field — a lattice, a nonlocal smearing, a string — as long as it reproduces ordinary local physics for a freely falling observer at sub-Planckian curvatures (which the equivalence principle demands), it reproduces the Rindler two-point function and hence the temperature $T_H = \kappa/2\pi$. The thermality is an infrared fact protected by the equivalence principle; the trans-Planckian modes appear only when one insists on the global plane-wave labelling, which is a choice, not a physical input. We now verify this expectation in models where the ultraviolet is deformed explicitly.

65.7.3 Robustness II: modified dispersion relations

The cleanest way to test whether the trans-Planckian modes matter is to break the relativistic dispersion relation at high momentum on purpose and ask whether the spectrum changes. Replace the massless wave equation, whose dispersion in a local freely falling frame is $\omega^2 = k^2$, by a deformed relation that bends over at

a fixed momentum scale Λ (which we may think of as $M_{\rm Pl}$),

$$\omega^2 \;=\; k^2 \;\pm\; \frac{k^4}{\Lambda^2} \;+\; \dots, \tag{65.219}$$

the lower sign *subluminal* (group velocity falling below 1 at large k, as for phonons in a Bogoliubov superfluid) and the upper sign *superluminal* (group velocity exceeding 1), plotted in Fig. 65.7(b). Such a term is the leading Lorentz-violating correction one could add; it reduces to the standard theory for $k \ll \Lambda$ and regulates the would-be trans-Planckian oscillations, because a mode can no longer be blueshifted to arbitrary frequency at fixed group structure — its dispersion saturates or turns over near Λ. The decisive question is what Eq. (65.219) does to the late-time flux.

The analysis is a WKB problem in the near-horizon region, exactly the machinery of Section 64.3.2. Write the field in the preferred (free-fall) frame in which the dispersion Eq. (65.219) is local; near the horizon the metric is Rindler, the redshift drives a mode of fixed asymptotic frequency ω to ever-larger local wavenumber k, and the wave equation becomes a higher-order ordinary differential equation in k-space because of the k^4 term. Corley and Jacobson [137], building on Unruh [479] and Brout–Massar–Parentani–Spindel [95], solved this system. The result is the following, which we state as the operative theorem of the subsection.

Theorem 65.35 (Survival of the Planck spectrum under UV deformation)**.** *Let a free field propagate on the collapse background with the modified dispersion relation Eq. (65.219) in the freely-falling frame, with deformation scale Λ. Provided*

(i) *the dispersion is relativistic in the infrared, $\omega^2 \to k^2$ for $k \ll \Lambda$, and*

(ii) *the field is prepared in the state that is the local free-fall vacuum at short distances near the horizon (the adiabatic/Unruh condition),*

then the late-time outgoing flux at infinity is Planckian at the temperature $T_H = \kappa/2\pi$, with relative corrections that vanish as $\Lambda \to \infty$ and are bounded by a positive power of the small ratio T_H/Λ,

$$\frac{\mathrm{d}N}{\mathrm{d}t\,\mathrm{d}\omega} = \frac{1}{2\pi}\,\frac{\Gamma_{\omega\ell}}{e^{\omega/T_H}-1}\Big[1 + O\big((T_H/\Lambda)^p\big)\Big], \qquad p>0. \tag{65.220}$$

Argument. The complete calculation is a connection-formula analysis of the higher-order WKB equation and is carried in the cited works; we give the structure honestly and identify why the correction is suppressed, which is the load-bearing point.

In the near-horizon Rindler region the redshift means that a wavepacket of fixed asymptotic frequency ω is, at proper distance ℓ, composed of local

wavenumbers $k \sim \omega/(\kappa\ell)$, growing without bound as $\ell \to 0$ in the relativistic theory — this *is* the blueshift Eq. (65.215) in position-space form. With the dispersion Eq. (65.219), the WKB phase $\int^{\ell} k(\ell')\,\mathrm{d}\ell'$ governing the mode is modified once k reaches Λ, i.e. once ℓ falls to $\ell_\Lambda \sim \omega/(\kappa\Lambda)$. The created-pair amplitude is the analytic continuation of the WKB solution across the turning structure, and the thermal factor $e^{-\pi\omega/\kappa}$ arises from the *same* contour rotation as in the relativistic case (Section 64.3.2), because in the region $\ell_\Lambda \ll \ell \ll \kappa^{-1}$ the dispersion is still relativistic and the metric is still Rindler; the pile-up of phase that produces the Boltzmann factor occurs entirely in this intermediate window, *above* the deformation scale in length and *below* it in momentum. The deformation acts only at $\ell \lesssim \ell_\Lambda$, where it removes the unphysical infinite-frequency tail and replaces it with a finite, regular mode reservoir (for the subluminal sign, modes "bounce" off the dispersion and never reach $k = \infty$; for the superluminal sign they are emitted from the singularity-free interior region). Either way the leading exponential is set by the IR window and equals $e^{-\pi\omega/\kappa}$; the correction is controlled by how much of the phase integral is contaminated by the deformed region, which is the fraction $\ell_\Lambda/\kappa^{-1} \sim \omega/\Lambda \sim T_H/\Lambda$ raised to a positive power fixed by the order of the dispersion. Hence Eq. (65.220), with p depending on the deformation (for the quartic relation Eq. (65.219) one finds the spectrum thermal to all orders in T_H/Λ for the smooth-passage state, with only nonperturbative $e^{-\Lambda/T_H}$ corrections). □

The lesson of Theorem 65.35 is that the Planck spectrum is manufactured in the infrared window between the deformation scale and the curvature scale, a window that is parametrically large for any $\Lambda \gg T_H$ — and $\Lambda \sim M_{\mathrm{Pl}}$ versus $T_H \sim 10^{-7}\,\mathrm{K}$ is large indeed. The trans-Planckian modes can be excised, replaced, or capped, and the only trace they leave is a correction smaller than any power of T_H/Λ. The effect does not depend on the ultraviolet physics it appeared to invoke. There is a price — the calculation now assumes a preferred free-fall frame and a specific near-horizon "adiabatic" choice of vacuum, which is the modern statement of where the physical input really lives — but the robustness is genuine.

65.7.4 Robustness III: analog horizons and Unruh's dumb holes

The modified-dispersion analysis answers the worry within field theory, but it leaves a residual unease: we deformed the ultraviolet by hand, choosing the deformation and the vacuum. Is there a physical system with a *genuine* horizon, a *known* short-distance completion that we did not get to choose, and a Hawking-like emission we can compute — and ideally measure — from first principles? Unruh found one in 1981 [478]: a moving fluid.

The observation is that sound in a barotropic, irrotational, inviscid fluid does not propagate on the laboratory metric; it propagates on an *acoustic metric* built

from the flow. Linearize the Euler and continuity equations about a background flow with density ρ, velocity $\mathbf{v}$, and local sound speed c_s; the velocity-potential perturbation ϕ_1 (with $\mathbf{v}_1 = \nabla\phi_1$) obeys a wave equation that can be written in exactly the covariant Klein–Gordon form of Eq. (65.72),

$$\frac{1}{\sqrt{-g}}\,\partial_\mu\!\left(\sqrt{-g}\,g^{\mu\nu}\partial_\nu\phi_1\right) = 0, \qquad g_{\mu\nu} = \frac{\rho}{c_s}\begin{pmatrix} -(c_s^2 - v^2) & -\mathbf{v}^{\mathsf{T}} \\ -\mathbf{v} & \mathbf{1}_{3\times 3} \end{pmatrix}, \tag{65.221}$$

the *acoustic metric*. (We have written Eq. (65.221) in the mostly-plus convention standard in the analog-gravity literature for transparency; the physics is convention-independent and we flip to mostly-minus when we quote the temperature.) Phonons are the quanta of ϕ_1, and they live on the effective geometry Eq. (65.221) exactly as our scalar lives on Schwarzschild. The crucial feature is the component $g_{tt} \propto -(c_s^2 - v^2)$: wherever the flow speed $v = |\mathbf{v}|$ exceeds the local sound speed c_s, this changes sign. The surface where $v = c_s$, separating a subsonic exterior from a supersonic interior, is an *acoustic horizon*: sound generated inside cannot swim upstream against a flow faster than itself, just as light cannot escape a black hole. Unruh named these *dumb holes* — dumb in the sense of mute, since no sound emerges.

Repeating the surface-gravity computation on Eq. (65.221), the acoustic surface gravity is the gradient of the flow's normal velocity through the sonic point,

$$\kappa_{\mathrm{ac}} = \frac{1}{2}\,\frac{\mathrm{d}}{\mathrm{d}n}(c_s^2 - v^2)\Big|_{v=c_s} \xrightarrow[c_s \text{ const}]{} c_s\,\frac{\mathrm{d}v_\perp}{\mathrm{d}n}\Big|_{\mathrm{horizon}}, \tag{65.222}$$

and the analog Hawking temperature, restoring $\hbar$ and k_B because this is a laboratory estimate, is

$$\boxed{k_B\,T_{\mathrm{ac}} = \frac{\hbar\,\kappa_{\mathrm{ac}}}{2\pi} = \frac{\hbar}{2\pi}\,\frac{\mathrm{d}v_\perp}{\mathrm{d}n}\Big|_{\mathrm{horizon}}}, \tag{65.223}$$

the identical $\kappa/2\pi$ law, now for phonons streaming out of the subsonic region. The analog system makes vivid everything the robustness arguments claimed. Its "Lorentz invariance" is only emergent: the linear phonon dispersion $\omega = c_s k$ is the long-wavelength limit of a microscopic dispersion that, for a dilute Bose–Einstein condensate, is the Bogoliubov form

$$\omega^2 = c_s^2 k^2\left(1 + \xi^2 k^2\right), \qquad \xi = \frac{\hbar}{2mc_s}, \tag{65.224}$$

with ξ the healing length — precisely the *superluminal* deformation Eq. (65.219) with the known scale $\Lambda = 1/\xi$ set by the atomic physics, not chosen by us. Here there is no trans-Planckian mystery at all: the would-be infinitely blueshifted modes simply run into the atomic granularity of the condensate at $k \sim 1/\xi$, the theory is manifestly finite and complete below that scale, and one can ask without ambiguity whether the thermal phonon flux survives. It does. Numerical

and analytic treatments of phonon emission across a condensate sonic horizon reproduce the temperature Eq. (65.223) with corrections suppressed by powers of $T_{\rm ac}\xi/c_s$, the analog of T_H/Λ in Eq. (65.220) — a direct, controlled confirmation of Theorem 65.35 in a system whose ultraviolet is known atom by atom [46].

Physical Insight: the horizon does the work, not the ultraviolet

The analog black hole isolates which part of Hawking's argument is physics and which is artefact. The acoustic horizon is real: it is a definite surface in a real fluid, defined with no reference to gravity or to Planckian physics. The short-distance theory is real and known: it is the Schrödinger equation for cold atoms, finite and unitary. And the thermal phonon flux is real — it has been measured. What the analog system *lacks* is any dynamical gravity, any Einstein equation, any back-reaction of the phonons on the spacetime. The persistence of the temperature $\kappa/2\pi$ in a system stripped of all gravitational content shows that the Hawking spectrum is a kinematic consequence of quantum fields in the presence of a horizon, robust against the ultraviolet, and not a delicate feature of quantum gravity. Gravity supplies the horizon; the rest is quantum field theory on it.

This is no longer a thought experiment. In a series of experiments culminating in 2016, Steinhauer realized a sonic horizon in a trapped Bose–Einstein condensate, detected the spontaneous emission of phonon pairs across it, and measured their density–density correlations, finding the Hawking partners to be entangled [455]; later runs reconstructed an emission spectrum consistent with the thermal form Eq. (65.223). As of the mid-2020s the analog Hawking effect, including the entanglement of the emitted pairs, is an established laboratory phenomenon. It does not test Hawking radiation from a *gravitational* horizon — nothing can, at $T_H \sim 10^{-7}\,\mathrm{K}$ below the cosmic microwave background — but it tests the field-theoretic mechanism on which the gravitational prediction rests, and the mechanism passes.

65.7.5 Robustness IV: Hawking radiation as tunneling with back-reaction

The arguments so far establish that the spectrum is insensitive to the ultraviolet. The final derivation establishes something complementary: that the emission can be computed as a self-contained semiclassical tunneling process, across the horizon, in coordinates that are perfectly regular there — so that no trans-Planckian mode and no asymptotic mode-matching is invoked at all — and that when one is careful enough to conserve energy, building the back-reaction of the emitted quantum into the geometry, the result is a sharp correction to the thermal spectrum. This is the tunneling method of Parikh and Wilczek [377].

Painlevé–Gullstrand coordinates. The Schwarzschild coordinates of Eq. (65.1) are singular at the horizon (the $\mathrm{d}r^2$ term blows up), which is precisely why the naive mode picture there required arbitrarily blueshifted modes. The cure is to pass to coordinates that are regular across the horizon. Define a new time

$$t_p = t + \int^r \frac{\sqrt{2GM/r'}}{f(r')}\,\mathrm{d}r', \qquad f(r) = 1 - \frac{2GM}{r}, \tag{65.225}$$

the proper time of an observer who falls in radially from rest at infinity. Differentiating, $\mathrm{d}t = \mathrm{d}t_p - \sqrt{2GM/r}\, f^{-1}\mathrm{d}r$, and substituting into Eq. (65.1) the cross terms conspire to remove the coordinate singularity. A short computation gives the Painlevé–Gullstrand form

$$\mathrm{d}s^2 = \Big(1 - \frac{2GM}{r}\Big)\mathrm{d}t_p^2 - 2\sqrt{\frac{2GM}{r}}\,\mathrm{d}t_p\,\mathrm{d}r - \mathrm{d}r^2 - r^2\,\mathrm{d}\Omega^2, \tag{65.226}$$

in the mostly-minus signature. Every metric component is finite and smooth at $r = 2GM$; the determinant is $\sqrt{-g} = r^2\sin\theta$ as in flat space; constant-t_p slices are flat Euclidean space. There is no pathology at the horizon to require trans-Planckian modes.

Radial null rays. A radial light ray has $\mathrm{d}\Omega = 0$ and $\mathrm{d}s^2 = 0$. Dividing Eq. (65.226) by $\mathrm{d}t_p^2$ and writing $\dot r = \mathrm{d}r/\mathrm{d}t_p$,

$$\Big(1 - \frac{2GM}{r}\Big) - 2\sqrt{\frac{2GM}{r}}\,\dot r - \dot r^2 = 0, \tag{65.227}$$

a quadratic for $\dot r$ with solutions

$$\dot r = -\sqrt{\frac{2GM}{r}} \pm 1. \tag{65.228}$$

The upper sign is the outgoing ray, $\dot r = 1 - \sqrt{2GM/r}$, which vanishes at $r = 2GM$ (light marches in place at the horizon) and is positive outside; this is the trajectory along which a Hawking quantum must escape.

The WKB tunneling amplitude. We treat the emitted quantum as a massless shell of energy ω following the outgoing null ray Eq. (65.228) and compute, by the semiclassical method of Section 64.3.2, the probability that it materializes just inside the horizon and tunnels out. In WKB the emission amplitude is e^{iS} with the classical action $S = \int p_r\,\mathrm{d}r$ evaluated along the (here complex) trajectory, and the emission *probability* is

$$\Gamma \;\sim\; \left|e^{iS}\right|^2 \;=\; e^{-2\,\mathrm{Im}\,S}, \qquad \mathrm{Im}\,S = \mathrm{Im}\int_{r_{\mathrm{in}}}^{r_{\mathrm{out}}} p_r\,\mathrm{d}r. \tag{65.229}$$

The tunneling is forbidden classically precisely because the would-be trajectory must cross the horizon, where $\dot r = 0$ for the outgoing ray; the action picks up an imaginary part from the resulting singularity, exactly as a one-dimensional barrier produces an imaginary momentum (Section 64.3.2). The decisive refinement, and the reason this derivation says something new, is to enforce energy conservation. The total ADM mass of the spacetime is fixed; when the shell carries off energy ω', the mass interior to it is no longer M but $M-\omega'$, and the geometry the shell traverses is the Painlevé–Gullstrand metric Eq. (65.226) with $M \to M-\omega'$. The shell moves in the field of the *shrinking* hole; this is the self-gravitation, or back-reaction, that the fixed-background derivations omitted.

Theorem 65.36 (Parikh–Wilczek emission rate)**.** *A massless shell of energy ω emitted from a Schwarzschild black hole of mass M, treated as WKB tunneling across the horizon in the self-gravitating Painlevé–Gullstrand geometry, has emission probability*

$$\boxed{\Gamma \;\sim\; \exp\!\Big[-8\pi G M\,\omega\Big(1-\frac{\omega}{2M}\Big)\Big] \;=\; \exp\!\big(\Delta S_{\mathrm{BH}}\big),} \tag{65.230}$$

where $\Delta S_{\mathrm{BH}} = S_{\mathrm{BH}}(M-\omega) - S_{\mathrm{BH}}(M) < 0$ is the change in the Bekenstein–Hawking entropy Eq. (65.179) of the hole.

Worked Example 65.37 (Imaginary part of the action across the horizon)**.** We compute $\operatorname{Im} S$ of Eq. (65.229) in full. Write the action as the integral of the radial momentum, then trade the momentum integral for an energy integral using Hamilton's equation $\dot r = \partial H/\partial p_r$ at fixed r:

$$\operatorname{Im} S = \operatorname{Im}\int_{r_{\mathrm{in}}}^{r_{\mathrm{out}}} p_r\,\mathrm{d}r = \operatorname{Im}\int_{r_{\mathrm{in}}}^{r_{\mathrm{out}}}\int_0^{p_r} \mathrm{d}p_r'\,\mathrm{d}r = \operatorname{Im}\int_{r_{\mathrm{in}}}^{r_{\mathrm{out}}}\int \frac{\mathrm{d}H}{\dot r}\,\mathrm{d}r. \tag{65.231}$$

As the shell builds up its momentum from 0 to p_r, the Hamiltonian (the energy of the hole-plus-shell system that remains behind the shell) decreases from M to $M-\omega$: with the shell energy ω' running from 0 to ω, the residual mass is $M-\omega'$ and $\mathrm{d}H = -\,\mathrm{d}\omega'$. Along the outgoing ray the radial velocity is Eq. (65.228) evaluated in the geometry of the residual mass,

$$\dot r \;=\; 1-\sqrt{\frac{2G(M-\omega')}{r}}. \tag{65.232}$$

Substituting $\mathrm{d}H = -\mathrm{d}\omega'$ and exchanging the order of integration,

$$\operatorname{Im} S = \operatorname{Im}\int_0^{\omega}(-\mathrm{d}\omega')\int_{r_{\mathrm{in}}}^{r_{\mathrm{out}}} \frac{\mathrm{d}r}{1-\sqrt{2G(M-\omega')/r}}. \tag{65.233}$$

The radial contour integral. Fix ω' and set $a \equiv 2G(M-\omega')$, the horizon radius of the residual hole. The integrand of the inner integral has a simple pole

where the outgoing ray stalls, $r = a$, i.e. exactly at the horizon the shell must cross. Expand near it: with $r = a + x$,

$$1 - \sqrt{\frac{a}{r}} = 1 - \Big(1 + \frac{x}{a}\Big)^{-1/2} = 1 - \Big(1 - \frac{x}{2a} + O(x^2)\Big) = \frac{x}{2a} + O(x^2), \quad (65.234)$$

so near the pole

$$\frac{1}{1 - \sqrt{a/r}} \;\simeq\; \frac{2a}{r - a}, \qquad \mathrm{Res}_{r=a}\, \frac{1}{1 - \sqrt{a/r}} = 2a = 4G(M - \omega'). \quad (65.235)$$

The pole sits on the path of integration, and the correct prescription comes from the Feynman $i\epsilon$ of Section 5.3: the emitted energy carries a small negative imaginary part ($\omega' \to \omega' - i\epsilon$, the retarded/outgoing choice), which displaces the pole off the real r-axis so that the contour passes below it. The integral then equals its principal value (real) plus a clockwise half-residue, contributing the imaginary part

$$\mathrm{Im} \int_{r_{\mathrm{in}}}^{r_{\mathrm{out}}} \frac{\mathrm{d}r}{1 - \sqrt{a/r}} = -\,\pi\, \mathrm{Res}_{r=a}\, \frac{1}{1 - \sqrt{a/r}} = -\,\pi\,(2a) = -\,4\pi G(M - \omega'). \quad (65.236)$$

(The clockwise sense, hence the overall minus sign, is fixed by requiring $\mathrm{Im}\, S > 0$ so that $\Gamma = e^{-2\,\mathrm{Im}\, S} < 1$: emission is suppressed, not enhanced without bound. The same sign follows directly from the $\omega' - i\epsilon$ displacement.)

The energy integral. Insert Eq. (65.236) into Eq. (65.233). The two minus signs — the $(-\mathrm{d}\omega')$ and the $-4\pi G(M - \omega')$ — combine to a plus:

$$\begin{aligned} \mathrm{Im}\, S &= \int_0^{\omega} (-\mathrm{d}\omega')\,[-4\pi G(M - \omega')] = 4\pi G \int_0^{\omega} (M - \omega')\,\mathrm{d}\omega' \\ &= 4\pi G\Big[M\omega - \tfrac{1}{2}\omega^2\Big] = 4\pi G M\,\omega\Big(1 - \frac{\omega}{2M}\Big). \end{aligned} \quad (65.237)$$

Therefore, by Eq. (65.229),

$$\Gamma \sim e^{-2\,\mathrm{Im}\, S} = \exp\Big[-8\pi G M\,\omega\Big(1 - \frac{\omega}{2M}\Big)\Big], \quad (65.238)$$

which is Eq. (65.230). It remains to recognise the exponent as the entropy change. The Bekenstein–Hawking entropy Eq. (65.179) is $S_{\mathrm{BH}}(M) = A/4G = 4\pi(2GM)^2/4G = 4\pi G M^2$, so

$$\begin{aligned} \Delta S_{\mathrm{BH}} &= S_{\mathrm{BH}}(M - \omega) - S_{\mathrm{BH}}(M) = 4\pi G\big[(M - \omega)^2 - M^2\big] \\ &= 4\pi G\big[-2M\omega + \omega^2\big] = -8\pi G M\,\omega\Big(1 - \frac{\omega}{2M}\Big), \end{aligned} \quad (65.239)$$

exactly the exponent of Eq. (65.238). Hence $\Gamma \sim e^{\Delta S_{\mathrm{BH}}}$, completing the proof of Theorem 65.36.

Two features of the computation deserve emphasis because they are the reasons it is trustworthy. First, the entire calculation took place in the Painlevé–Gullstrand chart, regular across the horizon; at no point did a mode have to be matched between a near-horizon and an asymptotic region, and at no point did an arbitrarily blueshifted frequency appear. The tunneling exponent came from a *pole*, a sharply localized contour feature at the horizon, not from an infinite reservoir of short-wavelength modes. This is the sense in which the tunneling derivation sidesteps the trans-Planckian problem rather than confronting it. Second, the use of the horizon-regular chart is not optional: a naive application of the same method in the singular Schwarzschild coordinates Eq. (65.1) produces a temperature too large by a factor of two, because those coordinates carry a spurious discontinuity in t across the horizon (the $\sqrt{2GM/r}\, f^{-1}\mathrm{d}r$ term of Eq. (65.225) that the PG chart absorbs). The temporal part of the invariant action must be accounted for; the virtue of the PG chart is that it is continuous across the horizon, so the temporal contribution vanishes and the spatial integral Eq. (65.233) gives the correct answer outright.

65.7.6 The corrected spectrum: thermal limit, energy conservation, and correlations

The result Eq. (65.230) is richer than T_H alone, and unpacking it furnishes the bridge to the next section.

The thermal limit. For a soft quantum, $\omega \ll M$, the correction term in the exponent is negligible and

$$\Gamma \xrightarrow[\omega \ll M]{} e^{-8\pi GM\omega} = e^{-\omega/T_H}, \tag{65.240}$$

using $T_H = 1/8\pi GM$ (Eq. (65.64)). The leading-order emission probability is the Boltzmann factor at the Hawking temperature: the tunneling method reproduces the thermal spectrum found four other ways in this chapter, now with no appeal to ultraviolet modes. This is the fourth independent confirmation of $T_H = \kappa/2\pi$ promised at the outset and is the leftmost, linear regime of Fig. 65.7(c).

Energy conservation fixes the correction. The exact exponent is not $-\omega/T_H$ but $-\omega/T_H\,(1-\omega/2M)$, and the deviation is precisely what conservation of energy demands. Because the hole loses mass to the quantum it emits, its temperature *rises* during the emission — recall $T_H \propto 1/M$ and the negative heat capacity of Theorem 65.30. A fixed-background calculation, which holds M and hence T_H frozen, cannot see this; it can only ever yield the strict Boltzmann factor Eq. (65.240). The back-reaction term $+\omega^2/2M$ in Eq. (65.237) is the integrated effect of the temperature climbing as the mass falls, and it makes energetic quanta *more* likely to be emitted than a fixed-temperature thermal body

would allow (the exponent is less negative; the shaded region of Fig. 65.7(c)). The cleanest statement of this is the entropy form $\Gamma \sim e^{\Delta S_{\rm BH}}$: in a microcanonical reading, the probability of a transition that lowers the mass by ω is the ratio of the number of final to initial microstates, $e^{S_{\rm BH}(M-\omega)}/e^{S_{\rm BH}(M)} = e^{\Delta S_{\rm BH}}$. Energy conservation plus the area–entropy law Eq. (65.179) *is* the corrected spectrum; nothing further need be assumed.

Correlations, and the doorway to information. A strictly thermal spectrum is structureless: successive quanta are emitted independently, and the radiation carries no information beyond its temperature. The corrected rate is not structureless. Consider emitting two quanta, of energies ω_1 and ω_2. If they were independent, the joint probability would factorize, $\Gamma(\omega_1)\,\Gamma(\omega_2)$. Instead, energy conservation ties them: emitting ω_1 first leaves a hole of mass $M-\omega_1$, so the second emission is governed by $\Delta S_{\rm BH}$ evaluated for that smaller hole, and

$$\Gamma(\omega_1,\omega_2) \sim e^{\Delta S_{\rm BH}(M\to M-\omega_1-\omega_2)} = \exp\!\big[\Delta S_{\rm BH}(\omega_1\,|\,M) + \Delta S_{\rm BH}(\omega_2\,|\,M-\omega_1)\big], \tag{65.241}$$

which does *not* equal $\Gamma(\omega_1)\,\Gamma(\omega_2)$ computed with both referred to the original mass M. The difference is a genuine correlation between the emitted quanta, with mutual information set by the same ω^2 term. The total exponent for emitting a collection of quanta summing to energy E is $\Delta S_{\rm BH}(M \to M-E)$, the full change in horizon entropy, independent of the order or partition — a statement that the radiation, taken as a whole, knows about the total entropy lost by the hole. The single-quantum spectrum still *looks* thermal to leading order Eq. (65.240), which is why the thermal description is so accurate; but the exact rate Eq. (65.230) carries correlations of order ω/M per quantum, hidden beneath the thermal envelope.

Whether these correlations are sufficient to carry off the full information content of the collapsed matter — whether they encode it, or merely demonstrate that the strict thermality is an approximation that must eventually break — is exactly the question that Eq. (65.230) cannot by itself answer, because it is a leading-saddle result that knows about energy conservation but not about the detailed quantum state. That question, quantified by the entanglement entropy of the radiation and the Page-curve requirement that it must eventually turn over if evolution is unitary, is the subject of the final section. The Parikh–Wilczek calculation has shown that the radiation is not exactly thermal and does carry correlations; the information problem asks whether those correlations are the right ones.

With the spectrum shown to be robust against the ultraviolet — protected by the infrared kinematics of the horizon, confirmed under deformed dispersion, realized and measured in analog systems, and re-derived by horizon-regular tunneling — and with that same tunneling calculation revealing a small but genuine non-thermal correlation between the emitted quanta, we have the two

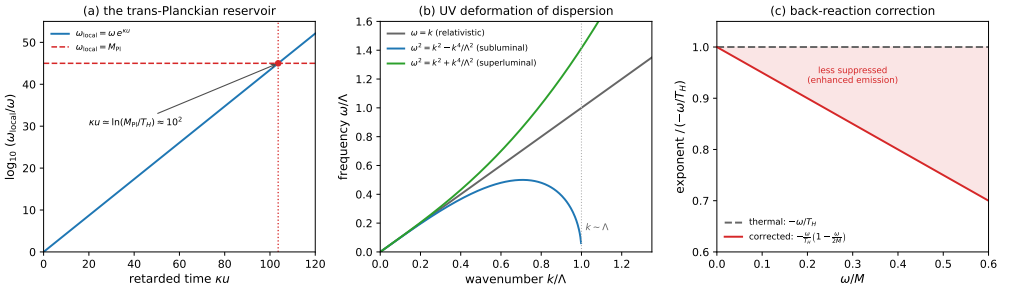

Figure 65.7: The trans-Planckian reservoir and the robustness of the Hawking effect. **(a)** The exponential blueshift Eq. (65.215), $\omega_{\text{local}} = \omega\, e^{\kappa u}$: a quantum received at infinity at $\omega \sim T_H$ is traced back to super-Planckian local frequency after $\kappa u \sim \ln(M_{\text{Pl}}/T_H) \approx 10^2$ e-folds (dashed line, solar-mass hole), so essentially all the radiation originates in the trans-Planckian reservoir. **(b)** Ultraviolet deformations of the dispersion relation Eq. (65.219) that regulate the reservoir — subluminal ($\omega^2 = k^2 - k^4/\Lambda^2$) and superluminal ($+k^4/\Lambda^2$) — both reducing to $\omega = k$ for $k \ll \Lambda$; the Planck spectrum survives either (Theorem 65.35). **(c)** The Parikh–Wilczek exponent Eq. (65.230) relative to the naive thermal exponent $-\omega/T_H$: the back-reaction factor $(1 - \omega/2M)$ makes energetic quanta less suppressed (shaded), the non-thermal correction demanded by energy conservation.

ingredients the final section needs: confidence that the semiclassical prediction is real, and the first evidence that it is not the whole story. The next section turns the correlations into a sharp paradox, quantifies the tension through the entanglement entropy and the Page curve, and confronts the question the corrected spectrum has opened — whether a pure state collapsing into a black hole can return to a pure state in the Hawking radiation.

65.8 The Information Problem and the Frontier

The previous section met the trans-Planckian worry head-on and emerged with the thermal spectrum intact: whatever short-distance physics dresses the horizon, the late-time radiation a distant detector registers is Planckian at $T_H = \kappa/2\pi$ (Section 65.7), and the only correlations the semiclassical calculation supplies are the ones between each outgoing quantum and the partner it left behind. That last clause is where the comfort ends. The corrected, back-reacted spectrum is still, mode by mode, exactly thermal, and a thermal ensemble is a *mixed* state. We assembled, over the course of this chapter, a black hole that is a bona fide thermodynamic body: it has a temperature (Eq. (65.64)), a luminosity and a finite lifetime (Section 65.3, Eq. (65.113)), an entropy $S_{\text{BH}} = A/4G$ that ceilings how much it can hold (Section 65.4, Eq. (65.142)), and a sparse stream of quanta dribbling out one at a time (Section 65.3.7). Put these facts together and a sharp

paradox falls out. A black hole forms from a definite quantum state, a collapsing star described by some pure $|\Psi\rangle$, and over a time $\tau \sim G^2 M_0^3$ it converts itself entirely into outgoing radiation. If that radiation is exactly thermal, then a pure state has evolved into a mixed one — and no unitary evolution can do that. Either the radiation is not exactly thermal and the semiclassical computation is quietly wrong about its fine-grained structure, or quantum mechanics itself fails across a horizon. This section states that dilemma precisely, makes it quantitative with the entanglement entropy and the Page curve, surveys the candidate escapes honestly and dated, and shows how the islands/quantum-extremal-surface program of Chapter 57 — read through the holographic dictionary of Chapter 53 and the Ryu–Takayanagi formula of Chapter 56 — has, by the mid-2020s, reproduced the unitary answer in controlled models. In doing so it closes the book's long arc, the one that began with a single free scalar field.

65.8.1 The paradox stated precisely

Ordinary quantum mechanics evolves states by a unitary operator. In a scattering setting the asymptotic past and future Hilbert spaces are connected by the S-matrix $\mathbf{S}$, and unitarity $\mathbf{S}^\dagger\mathbf{S} = \mathbf{1}$ guarantees that a pure in-state maps to a pure out-state: $|\text{out}\rangle = \mathbf{S}\,|\text{in}\rangle$, and a density matrix evolves as $\rho_{\text{out}} = \mathbf{S}\,\rho_{\text{in}}\,\mathbf{S}^\dagger$, which preserves $\operatorname{Tr}\rho^2$ and hence purity. Unitarity is not a convenience; it is the statement that probability is conserved and that the present determines the past as well as the future. It is the backbone of every calculation in this book.

Hawking's 1976 analysis [256] confronted this backbone with the collapse geometry. The matter that forms the hole is prepared in a pure state on some early Cauchy slice. After the hole has fully evaporated, the only data left in the spacetime is the outgoing radiation, and the chapter's central computation says that radiation is thermal. To state the conclusion as an operator statement, suppose evaporation maps the initial density matrix to a final one by some linear map. Because the output is thermal and *independent of the details of the infalling pure state* — the spectrum Eq. (65.88) depends only on M and the field content, not on what fell in — this map cannot be of the unitary form $\rho \mapsto \mathbf{S}\rho\mathbf{S}^\dagger$. Hawking proposed to replace the S-matrix by a more general linear "superscattering" operator \$ acting on density matrices,

$$\rho_{\text{out}} = \$\,\rho_{\text{in}}, \qquad \$ \text{ not of the form } \mathbf{S}(\cdot)\mathbf{S}^\dagger, \tag{65.242}$$

a map that takes pure states to mixed states and therefore destroys the information about which pure state collapsed. This is the "loss of predictability": from the final radiation one cannot reconstruct the initial state, even in principle. We can state the clash as a list of mutually contradictory propositions, each of which is individually well motivated.

Theorem 65.38 (The information paradox as a clash of premises)**.** *The following four statements cannot all be true:*

(U) Unitarity. *Black-hole formation and evaporation is a unitary process in a single quantum theory: a pure initial state evolves to a pure final state.*

(E) Effective field theory near the horizon. *Physics in the neighbourhood of a large, smooth horizon is well described by quantum field theory on a curved background, so the local computation of Section 65.2 is reliable there: the outgoing quanta are produced in the thermal, partner-entangled state it predicts.*

(C) Completeness of the exterior. *After evaporation, the outgoing radiation is the entire final state; there is no large hidden reservoir (no stable remnant, no baby universe) carrying off the missing correlations.*

(S) Subexponential entropy. *A region of area A holds at most $S_{\rm BH} = A/4G$ bits, the bound established in Section 65.4; the hole's Hilbert space is finite-dimensional with* $\log\dim\mathcal{H} \approx A/4G$.

Proof. We show the four are inconsistent. By (E) the radiation emitted up to any time is, mode by mode, in the thermal state Eq. (65.88), each outgoing quantum maximally correlated with an interior partner. By (S) the interior can encode at most $S_{\rm BH}(t) = A(t)/4G$ bits, a number that *decreases* as the hole shrinks. We will compute in Section 65.8.2 that the fine-grained (von Neumann) entropy of the radiation produced under (E) grows monotonically, and in Section 65.8.3 that for a system whose two parts are the radiation and the hole, the radiation's entropy cannot exceed the smaller subsystem's capacity, here $S_{\rm BH}(t)$ once the hole is the smaller factor. After the Page time the monotone entropy of (E) exceeds the decreasing ceiling of (S): the two are in quantitative contradiction. The only way to keep (E) and (S) is to abandon (U) — to accept the \$-matrix Eq. (65.242) and the loss of purity — unless (C) fails and the missing correlations sit in a reservoir the exterior computation cannot see. Conversely, keeping (U), (C), and (S) forces (E) to break down somewhere a naive estimate says it should hold. No assignment of truth values satisfies all four. □

The value of Theorem 65.38 is that it converts a vague unease into a finite menu: every serious proposal in Section 65.8.5 is, at bottom, a choice of which premise to surrender. Before surveying that menu we must make the two quantitative claims in the proof — the monotone growth and the ceiling — precise. Both are computations the carried free scalar lets us do in full.

65.8.2 The entanglement structure of the Hawking pairs

We continue ϕ^4 theory in its free ($\lambda = 0$) sector, the real scalar quantized in Chapter 9, now in the collapse background. The Bogoliubov analysis of Section 65.2 did more than produce occupation numbers: it expressed the in-vacuum, the state with no incoming particles, as a definite, correlated state in

the out/interior basis. The structure is identical to the two-mode squeezing already met for the Unruh effect in Chapter 64: for each asymptotic out mode of frequency ω (we suppress the angular labels ℓm, which ride along untouched) there is an interior partner mode, and the in-vacuum is a two-mode squeezed state pairing them.

Proposition 65.39 (The in-vacuum as partner-entangled pairs)**.** *Let b_ω annihilate the late-time outgoing quanta at infinity and $\tilde{b}_\omega$ annihilate their interior partner modes (the modes supported behind the horizon, conjugate under the Bogoliubov transformation). The collapse in-vacuum factorizes over frequencies as a product of two-mode squeezed states,*

$$|0\rangle_{\text{in}} = \prod_{\omega} \frac{1}{\cosh r_\omega} \sum_{n=0}^{\infty} (\tanh r_\omega)^n \; |n\rangle_\omega^{\text{out}} \otimes |n\rangle_\omega^{\text{int}}, \qquad \tanh r_\omega = e^{-\pi\omega/\kappa} = e^{-\omega/2T_H}, \tag{65.243}$$

where $|n\rangle_\omega^{\text{out}}, |n\rangle_\omega^{\text{int}}$ are the n-quantum number states of the out and interior oscillators and $\kappa = 2\pi T_H$ is the surface gravity.

Proof. The Bogoliubov transformation relating in and out modes mixes creation and annihilation operators with coefficients whose ratio $|\beta_\omega/\alpha_\omega| = e^{-\pi\omega/\kappa}$ was the engine of the thermal spectrum in Section 65.2. A transformation that is linear in $b, b^\dagger$ and pairs each out mode with one partner is generated by a two-mode squeeze operator $S_\omega = \exp[r_\omega(b_\omega \tilde{b}_\omega - b_\omega^\dagger \tilde{b}_\omega^\dagger)]$, and the in-vacuum is S_ω acting on the out/interior Fock vacuum. Expanding the squeeze operator on the vacuum gives the standard identity $S_\omega |0,0\rangle = (\cosh r_\omega)^{-1} \sum_n (\tanh r_\omega)^n |n,n\rangle$, with the squeezing parameter fixed by $\tanh r_\omega = |\beta_\omega/\alpha_\omega| = e^{-\pi\omega/\kappa}$. Using $\kappa = 2\pi T_H$ rewrites the exponent as $\pi\omega/\kappa = \omega/2T_H$, which is Eq. (65.243). The normalization is automatic: $\cosh^{-2} r \sum_n \tanh^{2n} r = \cosh^{-2} r \, (1 - \tanh^2 r)^{-1} = 1$ since $1 - \tanh^2 r = \cosh^{-2} r$. □

The state Eq. (65.243) is pure — it is the global vacuum, a definite vector. The thermality is not a property of the global state but of what an observer who can access *only the exterior* sees, and seeing only the exterior means tracing out the interior partners. That partial trace is the whole content of the paradox, and it is a one-line computation worth doing in full.

Worked Example 65.40 (The reduced state of one mode is exactly thermal)**.** Fix a single frequency ω and write $r \equiv r_\omega$, $t \equiv \tanh r = e^{-\omega/2T_H}$. From Eq. (65.243) the out/interior pair is in the pure state $|\psi\rangle = \cosh^{-1} r \sum_n t^n \, |n\rangle^{\text{out}} \, |n\rangle^{\text{int}}$, whose density matrix is $\rho = |\psi\rangle\langle\psi|$. The exterior observer's state is the partial trace over the interior,

$$\rho_\omega^{\text{out}} = \text{Tr}_{\text{int}} \; |\psi\rangle\langle\psi| = \frac{1}{\cosh^2 r} \sum_{n,m} t^n t^m \, |n\rangle^{\text{out}} \langle m|^{\text{out}} \underbrace{\langle m|n\rangle^{\text{int}}}_{=\delta_{mn}} = \frac{1}{\cosh^2 r} \sum_n t^{2n} \; |n\rangle^{\text{out}} \langle n|^{\text{out}}. \tag{65.244}$$

The interior number states being orthonormal, the trace collapses the double sum to a diagonal one: *all off-diagonal coherence between number states is gone*. The exterior sees a classical mixture with weights $p_n = \cosh^{-2} r \; t^{2n} = (1-t^2)\, t^{2n}$, using $\cosh^{-2} r = 1 - \tanh^2 r = 1 - t^2$. Now substitute $t^2 = \tanh^2 r = e^{-\omega/T_H}$:

$$p_n = \left(1 - e^{-\omega/T_H}\right) e^{-n\omega/T_H}, \tag{65.245}$$

which is precisely the Boltzmann distribution of a single bosonic oscillator of energy ω at temperature T_H. Hence

$$\rho_\omega^{\text{out}} = \left(1 - e^{-\omega/T_H}\right) e^{-\omega\,\hat{n}/T_H} = \frac{e^{-\hat{H}_\omega/T_H}}{\operatorname{Tr}\, e^{-\hat{H}_\omega/T_H}}, \qquad \hat{H}_\omega = \omega\,\hat{n}, \tag{65.246}$$

a thermal density matrix in the canonical Gibbs form. The mean occupation is the Planck value,

$$\bar{n}_\omega = \sum_n n\, p_n = \frac{e^{-\omega/T_H}}{1 - e^{-\omega/T_H}} = \frac{1}{e^{\omega/T_H} - 1} = \sinh^2 r, \tag{65.247}$$

recovering the spectrum Eq. (65.88) (with greybody factor unity, the horizon value) and confirming $\bar{n} = \sinh^2 r$ from Eq. (65.243). The point is sharper than the spectrum, though: the reduced state is not merely thermal in its occupation numbers but is the *maximally mixed* state compatible with that mean energy. The exterior has no access to the phase information stored in the cross-correlations with the interior.

The von Neumann entropy of this reduced state quantifies exactly how much the exterior observer has lost. It is the entanglement entropy of the out mode with its partner, in the sense defined in Chapter 55 (Theorem 55.4).

Worked Example 65.41 (Entanglement entropy per mode and its sum)**.** From Eq. (65.245), $\log p_n = \log(1 - e^{-\omega/T_H}) - n\,\omega/T_H$, so the single-mode von Neumann entropy is

$$\begin{aligned} s(\omega) &= -\operatorname{Tr}\!\left(\rho_\omega^{\text{out}} \log \rho_\omega^{\text{out}}\right) = -\sum_n p_n \log p_n \\ &= -\log\!\left(1 - e^{-\omega/T_H}\right) + \frac{\omega}{T_H}\,\bar{n}_\omega. \end{aligned} \tag{65.248}$$

To put this in a form that exposes its meaning, use $e^{-\omega/T_H} = \bar{n}/(1+\bar{n})$, equivalently $1 - e^{-\omega/T_H} = 1/(1+\bar{n})$ and $\omega/T_H = \log[(1+\bar{n})/\bar{n}]$, both read off Eq. (65.247). Substituting,

$$\boxed{s(\omega) = (1+\bar{n}_\omega)\log(1+\bar{n}_\omega) - \bar{n}_\omega \log \bar{n}_\omega\,,} \tag{65.249}$$

the entropy of a single thermally occupied bosonic mode. It is positive for all $\bar{n} > 0$, vanishes as $\bar{n} \to 0$ (an empty mode is unentangled), and grows like

$\log \bar{n} + 1$ for $\bar{n} \gg 1$. Each emitted quantum thus arrives carrying a definite, irreducible quantum of entanglement with the hole's interior.

The total entanglement entropy of the radiation field at retarded time u is the sum of Eq. (65.249) over all modes that have been emitted by then. Writing the emission as a steady flux, the entropy collected per unit time is the mode density times $s(\omega)$, weighted by the greybody transmission $\Gamma_{\omega\ell}$ that governs which modes actually escape (Eq. (65.88)):

$$\frac{\mathrm{d}S_{\mathrm{ent}}}{\mathrm{d}t} = \sum_{\ell} (2\ell + 1) \int_0^\infty \frac{\mathrm{d}\omega}{2\pi}\, \Gamma_{\omega\ell} \left[(1 + \bar{n}_\omega) \log(1 + \bar{n}_\omega) - \bar{n}_\omega \log \bar{n}_\omega \right]. \tag{65.250}$$

Every factor in the integrand is positive, so $\mathrm{d}S_{\mathrm{ent}}/\mathrm{d}t > 0$: in the strict semiclassical calculation the entanglement entropy of the radiation *increases monotonically* for as long as the hole keeps emitting. This is the first quantitative claim used in the proof of Theorem 65.38. The integral has exactly the structure of the luminosity Eq. (65.107) with the energy weight ω replaced by the entropy weight $s(\omega)/\omega$; on dimensional grounds it scales as $\mathrm{d}S_{\mathrm{ent}}/\mathrm{d}t \sim 1/GM$, the same inverse mass that set the number-emission rate Eq. (65.114). Integrating from formation to evaporation, and using $\mathrm{d}M/\mathrm{d}t$ from Eq. (65.107), the radiation's coarse-grained entropy at the end is of order the initial horizon entropy $S_0 = A_0/4G$, indeed somewhat larger: because evaporation is irreversible (the negative heat capacity of Theorem 65.30 forbids reversible emission), the emitted entropy exceeds the lost horizon entropy by a fixed factor of order unity — $S_{\mathrm{rad}}^{\mathrm{fin}} \approx 1.6\, S_0$ for a massless thermal field. The precise factor is unimportant; what matters is that the monotone curve climbs to a value *of order* S_0 *or greater* and stays there. Hawking's prediction for the fine-grained entropy of the radiation is this monotone curve.

Physical Insight: thermality is ignorance of the partner

The radiation is thermal for a reason with no thermodynamic content at all. There is no reservoir, no ensemble, no coarse-graining over microstates in Eq. (65.246). The global state Eq. (65.243) is pure and known exactly. The thermal density matrix arises purely from the partial trace in Eq. (65.244): discarding the interior partner of each Hawking quantum turns a pure, maximally correlated pair into a maximally mixed marginal. This is *entanglement entropy masquerading as thermal entropy*, the same phenomenon that made the Rindler wedge thermal in Chapter 64. The paradox is the question of what happens to that entanglement when the partner, trapped behind the horizon, has nowhere left to be: the hole that held the partners has evaporated.

65.8.3 The entropy ceiling and the sharpened contradiction

The second ingredient of Theorem 65.38 is the ceiling. Consider the global state at time t as living on the bipartite Hilbert space $\mathcal{H}_{\rm rad} \otimes \mathcal{H}_{\rm BH}$, the already-emitted radiation times the degrees of freedom still inside the hole. For *any* pure global state the two reduced density matrices share the same nonzero spectrum (Schmidt decomposition), so their von Neumann entropies are equal, $S_{\rm rad} = S_{\rm BH}^{\rm fine}$, and each is bounded by the logarithm of the smaller Hilbert-space dimension:

$$S_{\rm rad} = S_{\rm BH}^{\rm fine} \le \min\bigl(\log \dim \mathcal{H}_{\rm rad},\, \log \dim \mathcal{H}_{\rm BH}\bigr). \tag{65.251}$$

By premise (S) of Theorem 65.38 — the subexponential, area-law bound $\log \dim \mathcal{H}_{\rm BH} \approx S_{\rm BH}(t) = A(t)/4G$ proved in Section 65.4 — the second argument of the minimum is the decreasing horizon entropy. Early on, when little has been emitted, $\mathcal{H}_{\rm rad}$ is the smaller factor and the bound Eq. (65.251) is generous; the entanglement entropy is free to rise, and the monotone curve Eq. (65.250) respects it. But as the hole shrinks, $S_{\rm BH}(t)$ falls, and at the moment the two capacities cross — the *Page time* — the horizon becomes the smaller factor and the ceiling begins to descend. Beyond that point the bound Eq. (65.251) *requires* $S_{\rm rad} \le S_{\rm BH}(t)$, a quantity heading to zero. Hawking's monotone curve does the opposite: it keeps rising. The contradiction of Theorem 65.38 is now explicit and quantitative,

$$S_{\rm ent}^{\rm Hawking}(t) \xrightarrow{\,t>t_{\rm Page}\,} \text{rising}, \qquad \text{but} \qquad S_{\rm rad}^{\rm unitary}(t) \le S_{\rm BH}(t) \xrightarrow{\,t\to\tau\,} 0. \tag{65.252}$$

A pure state cannot have a subsystem whose entanglement entropy exceeds the remaining subsystem's capacity. Something in the semiclassical computation must fail after the Page time, or unitarity is lost. This is the information paradox in its modern, entropic form, due to Page [374].

65.8.4 Page's theorem and the Page curve

What *should* the curve do if evaporation is unitary? Page's answer rests on a single, robust observation: a black hole is, to spectacular accuracy, a scrambler. The interior dynamics is so strongly chaotic that the global pure state, restricted to any modest subsystem, is statistically indistinguishable from the restriction of a Haar-random pure state on the same Hilbert space. For such random states the entanglement entropy of a subsystem is not free to be anything: it is, with overwhelming probability, almost maximal. This is the content of Page's theorem, proved in full in Chapter 57 (Theorem 57.14); we import the result and read off its consequence here rather than reprove it.

Theorem 65.42 (Page's average subsystem entropy; imported)**.** *For a Haar-random pure state on $\mathcal{H}_A \otimes \mathcal{H}_B$ with $d_A = \dim \mathcal{H}_A \le d_B = \dim \mathcal{H}_B$, the expected*

von Neumann entropy of the smaller factor is, by Theorem 57.14,

$$\langle S_A\rangle = \sum_{k=d_B+1}^{d_A d_B} \frac{1}{k} - \frac{d_A-1}{2d_B} \;\simeq\; \log d_A - \frac{d_A}{2d_B} \qquad (1 \ll d_A \le d_B). \tag{65.253}$$

Thus $\langle S_A\rangle$ is within $O(d_A/d_B)$ of its maximum $\log d_A$: a small subsystem of a random pure state is very nearly maximally mixed.

The reading of Eq. (65.253) for the black hole is immediate and is the whole point. Identify A with whichever of {radiation, interior} is smaller. Before the Page time the radiation is the small factor, $d_{\rm rad} \le d_{\rm BH}$, and Eq. (65.253) gives $S_{\rm rad} \simeq \log d_{\rm rad} = S^{\rm th}_{\rm rad}$: the entanglement entropy tracks the (rising) thermal entropy of the emitted radiation, in agreement with Hawking's curve. *This is why the two predictions coincide early*: when the radiation is small, near-maximal entanglement and thermality say the same thing. After the Page time the interior is the small factor, $d_{\rm BH} \le d_{\rm rad}$, and the same formula gives $S_{\rm rad} = S^{\rm fine}_{\rm BH} \simeq \log d_{\rm BH} = S_{\rm BH}(t)$: the fine-grained entropy now tracks the (falling) horizon entropy. The unitary prediction is therefore the lower envelope of the two coarse-grained entropies,

$$\boxed{S_{\rm rad}(t) = \min\bigl(S^{\rm th}_{\rm rad}(t),\, S_{\rm BH}(t)\bigr),} \tag{65.254}$$

the *Page curve*: it rises with the thermal radiation until the two are equal, turns over at the Page time, and descends to zero with the shrinking horizon when the hole has fully evaporated and the radiation is pure again. The naive Hawking curve and the Page curve agree exactly up to $t_{\rm Page}$ and diverge thereafter; the entire information problem lives in the after-Page-time regime. The two predictions are drawn against the chapter's own evaporation law in Fig. 65.8.

Worked Example 65.43 (The Page time for the Schwarzschild cube law)**.** The Page time is fixed by $S^{\rm th}_{\rm rad}(t_{\rm Page}) = S_{\rm BH}(t_{\rm Page})$, the crossing of the two coarse-grained entropies. Using the conservative idealization $S^{\rm th}_{\rm rad} = S_0 - S_{\rm BH}$ (total coarse-grained entropy shared between hole and radiation), the crossing is $S_{\rm BH} = S_0/2$: the Page time is when *half the initial Bekenstein–Hawking entropy has been radiated*. With $S_{\rm BH} = 4\pi G M^2$ this means $M^2_{\rm Page} = M_0^2/2$, i.e.

$$M_{\rm Page} = \frac{M_0}{\sqrt{2}} \approx 0.71\, M_0. \tag{65.255}$$

Translating to time through the cube law Eq. (65.112), $M^3 = M_0^3(1 - t/\tau)$, the Page time is

$$\frac{t_{\rm Page}}{\tau} = 1 - \Bigl(\frac{M_{\rm Page}}{M_0}\Bigr)^3 = 1 - 2^{-3/2} \approx 0.65. \tag{65.256}$$

So although the Page time is "half the entropy gone," it is nearly two-thirds of the way through the hole's *life*, because the entropy $\propto M^2$ is lost faster early on

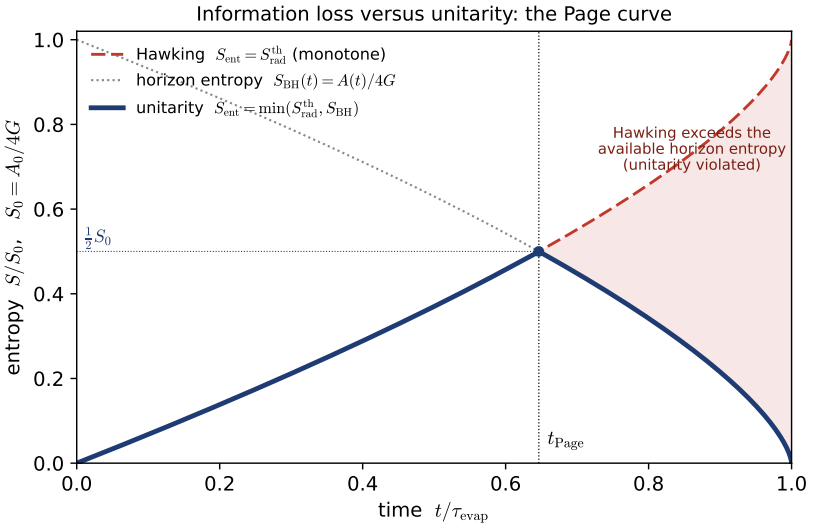

Figure 65.8: The information problem made quantitative, framed by this chapter's evaporation law $M^3(t) = M_0^3(1-t/\tau)$ (Eq. (65.112)), so that the horizon entropy is $S_{\rm BH}(t)/S_0 = (1-t/\tau)^{2/3}$ with $S_0 = A_0/4G$. Hawking's strict semiclassical calculation (dashed red) gives a fine-grained radiation entropy equal to the thermal entropy $S_{\rm rad}^{\rm th} = S_0 - S_{\rm BH}$, rising monotonically: the final radiation is mixed. Unitarity (solid blue) gives the Page curve Eq. (65.254), $S_{\rm rad} = \min(S_{\rm rad}^{\rm th}, S_{\rm BH})$, which turns over at the Page time and returns to zero. Past $t_{\rm Page}$ the Hawking curve exceeds the available horizon entropy (shaded), violating the Schmidt bound Eq. (65.251).

than the mass $\propto M$. By the Page time the hole has shed only about 29% of its mass $(1-2^{-1/2})$ but has passed the point of no return for information: from then on, unitarity demands that every further quantum carry out net information, the radiation's entanglement entropy decreasing by roughly one unit per quantum emitted. The radiation emitted after $t_{\rm Page}$ must be correlated not only with the interior but with the radiation emitted *before* $t_{\rm Page}$ — the hidden correlations that the strictly thermal spectrum of Eq. (65.88) does not contain. Where those correlations come from is the content of every proposed resolution.

65.8.5 The menu of proposals

Theorem 65.38 showed that resolving the paradox means surrendering one of its premises. We survey the principal candidates, each labelled by the premise it sacrifices, with its claim, its cost, and an honest date. None is established as the mechanism operating in our universe; what has changed by the mid-2020s is that one circle of ideas — islands and replica wormholes, Section 65.8.6 — has

been shown to reproduce the unitary Page curve in controlled models, which the others have not.

Remnants (deny C). The earliest escape: perhaps evaporation does not run to completion but halts at a Planck-mass object, a *remnant*, that retains the purifying correlations with the early radiation. The information is not lost; it is locked in a residue the semiclassical calculation cannot follow. The cost is severe. A remnant must store an unbounded amount of information — up to $S_0 = A_0/4G$ bits for an arbitrarily large parent hole — within a Planck-sized region of bounded energy. Such an "infinite internal degeneracy" for a fixed-mass object wreaks havoc with effective field theory: remnants would be pair-produced copiously in any process with enough energy, since the production rate is enhanced by their enormous multiplicity, and the species would gravitate the vacuum unstable. The remnant proposal trades information loss for an infinite tower of nearly degenerate states, a cure most workers find worse than the disease. Dated to the 1980s–1990s; generally disfavoured, though never strictly excluded.

Black-hole complementarity (reinterpret E). Proposed by Susskind, Thorlacius, and Uglum [460], complementarity argues that no single observer ever sees the contradiction, so there is none. An observer who stays outside sees the information returned in the radiation, smeared on a hot "stretched horizon" just above $r = 2GM$; an observer who falls in sees the information pass smoothly through a featureless horizon. The two descriptions are not both valid in one frame — no observer can compare the infalling copy with the outgoing copy, because doing so would require measurements separated by more than the evaporation time or energies above the Planck scale (the Hayden–Preskill bound on information retrieval [260] makes this quantitative: information dumped into an old hole comes back in the radiation after only a scrambling time $\sim GM\log(GM)$, but never fast enough to be cloned). Complementarity preserves (U) and a smooth horizon at the price of giving up a single global description of the quantum state: it is a statement about the limits of operational meaning. The cost is that it must forbid quantum cloning by a conspiracy of bounds, and this is exactly what the firewall argument later challenged. Dated to the early 1990s; influential, and partly vindicated and partly superseded by the island story.

Firewalls (deny E, the smooth horizon). Almheiri, Marolf, Polchinski, and Sully (AMPS) [15] sharpened the tension into a near-theorem. A late Hawking quantum, emitted after the Page time, must (by unitarity and Page's argument) be nearly maximally entangled with the *early* radiation. But a smooth horizon requires, by the local vacuum structure of Chapter 64, that the *same* quantum be nearly maximally entangled with its interior partner. Monogamy of entanglement — a system cannot be maximally entangled with two others at once — forbids both.

AMPS concluded that one assumption must break, and identified the smooth horizon as the weakest: the partner entanglement is severed, which by the same vacuum-structure argument deposits a divergent stress at the horizon, a *firewall* of high-energy quanta that incinerates the infalling observer. The cost is the loss of the equivalence principle at the horizon of an old black hole — "nothing special happens" fails exactly where general relativity insists it holds. Dated 2012–2013; the paradox's modern detonator, and the problem the island construction is widely read as defusing (the entanglement is reshuffled, not severed, so no firewall is needed).

Fuzzballs (deny E, the interior). The fuzzball program, developed by Mathur and collaborators within string theory [341, 342], denies that there is an empty interior at all. In this picture the classical black-hole solution is only a coarse-grained average; each microstate is a horizonless, "fuzzy" string-theoretic geometry that differs from the others at the horizon scale and caps off the interior before any trapped region forms. The $e^{S_{\mathrm{BH}}}$ microstates are genuinely distinct configurations, and radiation leaves from a structured surface rather than a true horizon, so it can carry information out like light from any hot body. Mathur's "small corrections theorem" makes the logical core precise: order-one corrections to the Hawking process at the horizon, not merely Planck-suppressed ones, are required to restore purity — the information cannot leak out in tiny corrections to an otherwise thermal spectrum. The cost is that the semiclassical horizon is an illusion: structure must appear at the horizon scale, far outside where Planckian physics was expected. Dated mid-2000s onward; the most concrete microstate construction, established in detail for special (supersymmetric, near-extremal) holes, with the generic case open.

Soft hair (reconsider C/E). Hawking, Perry, and Strominger [259] revived the question of whether black holes are truly "bald." The classical no-hair theorems leave the horizon characterized by mass, charge, and spin alone, which is why the radiation seemed information-free. But the asymptotic symmetry group of gravity (and of gauge theory) is infinite-dimensional — the BMS supertranslations — and their conserved charges endow the horizon with an infinity of "soft hairs," zero-energy excitations that can in principle record which state collapsed. The claim is that this soft data provides the missing label distinguishing microstates. The cost, and the open question, is whether the soft charges carry *enough* information, and of the right kind, to purify the radiation: most analyses find the soft hair necessary bookkeeping but not by itself sufficient to resolve the paradox. Dated 2016 onward; a suggestive reframing tying the problem to asymptotic symmetries, with its sufficiency unsettled.

Table 65.1: The principal proposals, the premise of Theorem 65.38 each surrenders, and an honest status as of the mid-2020s.

Proposal	Premise denied	Core claim	Status
Remnants	(C) completeness	Planckian residue keeps info	disfavoured
Complementarity	(E) reinterpreted	no observer sees the clash	superseded/a
Firewalls (AMPS)	(E) smooth horizon	horizon is not vacuum	sharpens the
Fuzzballs	(E) empty interior	microstates are horizonless	special cases
Soft hair	(C)/(E) no-hair	asymptotic charges label states	necessity yes,
Islands/QES	none (recomputes E)	gravity path integral is unitary	reproduces P

65.8.6 Islands, replica wormholes, and the semiclassical path integral

The decisive development of the last several years is that the entanglement entropy of the radiation, computed honestly within the same semiclassical gravity that produced Hawking's monotone curve, in fact follows the *Page* curve — once the gravitational path integral is asked the question correctly. The key is that the von Neumann entropy of the radiation is itself a gravitational observable, computed by the replica trick of Chapter 55 (Theorem 55.17) applied to gravity, and the gravitational path integral of Section 65.5 has *more saddles* than the naive one. The full statement, derivation, and the controlled models in which it is established are the business of Chapter 57; we summarize the structure and its significance, and cross-reference rather than reprove.

The replica computation evaluates $\operatorname{Tr}\rho_{\mathrm{rad}}^{n}$ by a path integral over n copies of the system glued cyclically. In gravity one must sum over all geometries with the prescribed replica boundary conditions, and beyond the trivial n-fold cover there exist *replica wormhole* saddles in which the n copies are connected through the bulk [391, 392]. These additional geometries are negligible early but come to dominate after the Page time, and their contribution bends the computed entropy back down. The upshot is packaged in the *island formula* for the radiation entropy (Section 57.4, Eq. (57.84)),

$$S_{\mathrm{rad}} = \min_{\mathcal{I}} \operatorname*{ext}_{\partial\mathcal{I}} \left[\frac{\mathrm{Area}(\partial\mathcal{I})}{4G} + S_{\mathrm{bulk}}\big(\mathrm{rad}\cup\mathcal{I}\big) \right], \tag{65.257}$$

where $\mathcal{I}$ is an *island*, a region of the interior whose boundary is a quantum extremal surface (Eq. (57.99)). The instruction is to extremize the generalized entropy — horizon-area term plus bulk entanglement entropy — over candidate surfaces and take the minimum. Before the Page time the winning configuration has no island ($\mathcal{I} = \varnothing$) and Eq. (65.257) reduces to the bulk entropy of the radiation, the rising Hawking curve. After the Page time an island just inside the horizon wins: the interior partners are then counted as *part of the radiation's*

entropy summary, the area term tracks the shrinking horizon, and the entropy follows $S_{\rm BH}(t)$ down. The crossover between the two extremal surfaces is exactly the turnover of the Page curve, and it occurs at the Page time Eq. (65.256).

Physical Insight: the path integral already knew

The remarkable feature is that nothing was added to the theory. The same semiclassical gravity — the Euclidean path integral of Section 65.5, with its $A/4G$ from the on-shell action Eq. (65.173) — when used to compute an entropy rather than a free energy, produces a unitary Page curve. The information about unitarity was hiding in the subdominant replica-wormhole saddles, geometries that connect the interior of one replica to another. In this precise sense the gravitational path integral "knows" that evaporation is unitary, even though no single semiclassical geometry displays the returning information. The same area-as-entropy that was holography's first whisper in Section 65.5 reappears here as the mechanism that caps the entanglement entropy — which is why the cleanest setting for the whole argument is holography itself.

65.8.7 The bridge to holography

The island formula Eq. (65.257) is the quantum-corrected Ryu–Takayanagi prescription of Chapter 56 (Theorem 56.3): the area term is the RT minimal surface and the bulk term is its quantum correction, the two combining into the quantum extremal surface. Holography is the setting in which the resolution is sharpest because it makes premise (U) manifest. In AdS/CFT (Chapter 53, Section 53.5) a black hole in the bulk is dual to a thermal state in a boundary conformal field theory, and the boundary theory is an ordinary unitary quantum system with a finite density of states. Its evolution is unitary by construction, so the radiation *must* purify; holography therefore guarantees the Page curve as a theorem about the boundary, and the island/replica-wormhole computation is the bulk's way of reproducing what the boundary already knew. The area-law entropy $S_{\rm BH} = A/4G$ that ceilings the hole is, on the boundary, simply the logarithm of the number of accessible states of a finite quantum system — the subexponential bound (S) of Theorem 65.38 is automatic. In this light the entire information problem is the question of how a manifestly unitary boundary theory is encoded in a bulk whose local effective field theory naively seems to lose information, and the island formula is the dictionary entry that resolves it. This is the deepest reason Part XV of this book exists: the holographic principle, first glimpsed as the area-scaling of black-hole entropy, is what reconciles gravity with quantum mechanics at the horizon.

65.8.8 Synthesis: the convergence of the threads and the languages

It is fitting that the book's forward development ends here, because this frontier is where everything built earlier converges. The convergence is literal, on two axes.

First, the three *languages* of the book all see the same physics. The Hawking temperature $T_H = \kappa/2\pi$ was derived three independent ways in this chapter: by canonical quantization and Bogoliubov coefficients (Section 65.2), the heir to the operator methods of Part III; by the Euclidean gravitational path integral and the smoothness of a saddle (Section 65.5), the heir to the path-integral methods of Part IX; and by the quantum anomaly of fields near the horizon (Section 65.6), the heir to the anomaly methods of Part XIV. That the canonical, path-integral, and anomaly formulations of quantum field theory — developed in different parts of the book for different purposes — all deliver the identical $\kappa/2\pi$ is the payoff of insisting throughout that they are one subject in three dialects. The resolution of the information problem then lives in the same path-integral language: it is a statement about which saddles dominate the gravitational functional integral, the very object introduced for the free scalar in Chapter 10 and promoted to a sum over geometries in Section 65.5.

Second, the three carried *threads* arrive together. ϕ^4 theory, the free real scalar we have followed since Chapter 9, is the matter field whose modes we traced across the collapsing horizon: its two-mode squeezed in-vacuum Eq. (65.243), its thermal reduced state Eq. (65.246), and its monotone entanglement entropy Eq. (65.250) are the carried computation, brought to its conclusion in the bipartite entanglement that is the heart of the paradox. The same free-field entanglement, computed in flat space in Part XV, became the area law and the Ryu–Takayanagi formula that Section 65.8.6 now uses to cap that entropy. QED and Yang–Mills theory enter through the soft-hair and asymptotic-symmetry reframing of Section 65.8.5: the infinite-dimensional asymptotic symmetries that might label black-hole microstates are the gravitational cousins of the large gauge transformations and BMS structure that the gauge threads exposed, and the double-copy relation of Chapter 61 that builds gravity from gauge theory is the amplitudes-level statement of the same kinship. The free scalar, the gauge field, and gravity — the three things this book taught how to quantize — meet at the horizon.

Physical Insight: the arc closed

The book opened with the quietest object in physics: a single free scalar field, $\frac{1}{2}(\partial\phi)^2 - \frac{1}{2}m^2\phi^2$, quantized into harmonic oscillators. It ends with that same field, placed on a collapsing star, forcing the deepest open question in theoretical physics — whether quantum mechanics survives a

horizon. Nothing was added but gravity as a background and then, at the very end, gravity as a fluctuating geometry. The entire apparatus between — renormalization, the renormalization group, gauge invariance, anomalies, the conformal bootstrap, holography, scattering amplitudes — was the machinery needed to ask this question sharply and to begin to answer it.

We close with the honesty the frontier demands, dated to the mid-2020s. What is *proven*: in controlled models — two-dimensional dilaton (JT) gravity, and holographic setups where a unitary boundary dual is available — the island formula Eq. (65.257), derived from the semiclassical gravitational path integral including replica-wormhole saddles, reproduces the Page curve Eq. (65.254), turning the entanglement entropy over at the Page time and returning it to zero (Section 57.6.1). In these models the semiclassical gravity path integral is unitary, the firewall is averted because the late radiation's entanglement is reshuffled into the island rather than severed, and the area-as-entropy of black-hole thermodynamics is the agent of the cap. What remains *open* (Section 57.6.5): the microscopic mechanism in our four-dimensional universe, where no boundary dual is in hand; the physical fate of the interior and of an observer who falls in, on which the island story is suggestive but not yet decisive; and the interpretation of the replica wormholes themselves — whether the gravitational path integral computes the entropy of a single black hole or an ensemble average over theories, a question raised acutely by the appearance of these connected geometries [18, 392]. The information paradox is, by the mid-2020s, no longer a paradox of principle — unitary evaporation is realized in honest models — but it is not yet a solved problem of mechanism. It is the live edge of the subject, and the right place for a book that set out to carry the reader from free fields to the frontier to lay down its pen.

The forward development of the book ends here. What follows is the Conclusion, which steps back from the calculations to take stock of the whole: the unity of the subject we have assembled, from the harmonic oscillators of Chapter 9 to the fluctuating geometries of this section, and the open frontier — this information problem foremost among its questions — that the next generation of the theory must settle.

Further reading

The foundational papers remain the clearest entry points: Hawking's derivation of particle creation by black holes [255], Bekenstein's argument that the entropy is proportional to area [54], and the four laws of black-hole mechanics of Bardeen, Carter and Hawking [47]. The Euclidean path-integral approach to the gravitational partition function and the entropy as an on-shell action is Gibbons and Hawking [220], with the requisite boundary term in York [530] and the negative

mode in Gross, Perry and Yaffe [239]; the anti–de Sitter completion and its phase transition is Hawking and Page [258]. The greybody factors and precise emission rates are computed by Page [373]. For the stress-tensor and anomaly viewpoints see Christensen and Fulling [123] and the gravitational-anomaly derivation of Robinson and Wilczek [418] in the covariant form of Banerjee and Kulkarni [44]. The trans-Planckian problem and its resolution are treated by Jacobson [280], Unruh [479], Corley and Jacobson [137], and Brout et al. [95]; the analog-gravity program originates with Unruh [478], is reviewed in [46], and was realized experimentally by Steinhauer [455]. The tunneling derivation is Parikh and Wilczek [377]. On the information problem, the original statement is Hawking [256] and the entropic sharpening is Page [374]; complementarity [460], the Hayden–Preskill bound [260], firewalls [15], fuzzballs [341, 342], and soft hair [259] are the principal proposals, while the island/replica-wormhole resolution is [18, 391, 392]. The standard textbook synthesis of quantum field theory in curved spacetime and black-hole thermodynamics is Wald [488], with the field-theoretic background in Birrell and Davies [76].

Part XVIII

Appendices

Appendix A

Conventions and Notation

A book that promises every number can be reproduced from its own pages owes the reader a single, unambiguous account of the conventions those numbers are written in. Conventions in quantum field theory are not unique, and the freedom is genuine: the metric may be mostly-minus or mostly-plus, the Fourier kernel may carry $e^{-ip\cdot x}$ or $e^{+ip\cdot x}$, the covariant derivative may attach the coupling with either sign, γ^5 may be defined with or without a factor of i, and each choice ripples through every formula downstream. Two correct calculations performed in two convention systems will disagree sign-by-sign at intermediate stages and yet agree on every observable. The cost of that freedom is borne entirely at the transitions between topics, and those transitions are where errors hide. This appendix is the arbiter that closes them: it fixes one convention system, derives its internal consequences, and makes every other chapter answerable to a single page.

The appendix does not introduce physics; it fixes the language in which the physics of the rest of the book is written, and it does so by derivation rather than decree wherever a derivation exists. From the single principle that the action is dimensionless in natural units, Section A.1 extracts the mass dimension of every field and coupling and the renormalizability criterion that organizes Part VI. Section A.2 fixes the mostly-minus metric $\eta_{\mu\nu} = \mathrm{diag}(+,-,-,-)$, the index gymnastics, and the Levi-Civita sign. Section A.3 settles the Fourier kernel, the (2π) bookkeeping, the state normalization, and derives the Lorentz-invariant phase-space measure that Chapter 16 consumes. Section A.4 fixes the Feynman $i\epsilon$, records the three momentum-space propagators, and pins down the Wick rotation and the $e^{iS} \to e^{-S_E}$ Euclidean sign. Section A.5 fixes the action sign and the $+J\phi$ source, the generating functionals Z, W, Γ and their Legendre relations, and the normalization of the amplitude $\mathcal{M}$ and the cross-section and decay-rate formulae. Section A.6 fixes the covariant-derivative sign $D_\mu = \partial_\mu - igA^a_\mu T^a$, the field-strength normalization, and the Hermitian-generator algebra. Section A.7 fixes dimensional regularization with $d = 4 - 2\varepsilon$ and the precise $\overline{\mathrm{MS}}$ definition.

Section A.8 closes with a conversion dictionary to the standard texts and a master symbol glossary.

What this appendix establishes it imports from the chapters where the underlying machinery was built, and it is scrupulous about that division of labor. The group and representation theory behind the generators is Chapter 2; the Lorentz and Poincaré structure that the metric and the spinor indices encode is Chapter 3; the functional calculus, Legendre transform, and Gaussian functional integrals that the generating functionals rest on are Chapter 4; the theory of tempered distributions and the contour technology behind the $i\epsilon$ and the analytic continuations are Chapter 5; the action principle is Chapter 6; the classical $U(1)$ gauge principle is Chapter 8; the path-integral generating functional is Chapter 10; and the non-abelian connection and curvature are Chapter 25. Nothing in those developments is reproved here; this appendix records the conventions in which they are expressed and the consequences that follow purely from convention.

What it does *not* do is equally important to state. The explicit master loop integrals and the Feynman/Schwinger-parameter technology live in Chapter D; the Casimir and Dynkin numerics and the ϵ-tensor contraction identities live in Chapter B; the γ-matrix trace identities and the resolution of γ^5 in dimensional regularization live in Chapter C; and the functional-determinant and ζ-function regularization of the path-integral measure live in Chapter E. This appendix fixes the *normalizations* of the propagators; the operator and path-integral *derivations* of those propagators as physics are Chapter 9 and Chapter 10. And it is honest that a single global arbiter cannot absorb every local convention: the spinor-helicity reality and little-group signs are restated where they are used in Chapter 58, and several bootstrap normalizations are restated in Part XIV, because the literature there is fragmented enough that a frozen central table would mislead more than it would help.

With those imports declared and those deferrals flagged, the appendix is the self-contained reference the rest of the book reaches for whenever a sign, a factor of 2π, or a normalization is in doubt.

A.1 Units, Dimensions, and the Counting of Mass Dimension

A book that asks the reader to reproduce every number it quotes must first fix, once and visibly, the yardsticks against which those numbers are measured. The choice of units is not a cosmetic preliminary: it determines what a symbol like λ or e even *means* dimensionally, and every later statement about which interactions are allowed, which are forbidden, and which loop integrals diverge rests on a count of dimensions that is only well posed once the units are settled. This appendix is the single arbiter of such conventions for the whole book, and this first section establishes the most basic of them. We adopt natural units, show

that they collapse the three independent mechanical dimensions into a single one, and then extract from the one principle that the action is dimensionless a complete table of the dimensions of every field and every coupling we will meet. That table is not bookkeeping for its own sake: it is the seed of the entire theory of renormalization, because the sign of a coupling's dimension decides whether the interaction it multiplies can be consistently quantized to arbitrarily high energies. Every choice made here has a traceable consequence later, and we will trace several of them explicitly.

A.1.1 Natural units and the collapse to a single dimension

In ordinary mechanics three base dimensions suffice to express every quantity: length L, time T, and mass M (or, equivalently, energy $E = ML^2T^{-2}$). Two fundamental constants of nature relate these to one another. The speed of light c has dimensions LT^{-1} and so converts times into lengths; the reduced Planck constant $\hbar$ has dimensions of action, ML^2T^{-1}, and so relates energies to inverse times through $E = \hbar\omega$. The defining move of natural units is to declare both equal to unity,

$$\hbar = c = 1. \tag{A.1}$$

This is not a claim that $\hbar$ and c are numerically one in any laboratory system; it is the decision to measure speed in units of c and action in units of $\hbar$, so that these constants become pure conversion factors equal to one and drop out of every equation. Their dimensional content does not vanish, however, and it is exactly that content which we exploit.

Setting $c = 1$ identifies L and T: a second and a metre are now the same kind of quantity, since c no longer stands between them. Setting $\hbar = 1$ then identifies E with T^{-1}, and hence with L^{-1}. The three base dimensions L, T, M have collapsed to one. We take that one to be *mass* (equivalently energy), and we will express the dimension of every quantity as a single integer or half-integer power of mass. The relations are

$$[\text{mass}] = [\text{energy}] = [\text{time}]^{-1} = [\text{length}]^{-1}, \tag{A.2}$$

where, throughout this appendix and the whole book, the bracket $[\,X\,]$ denotes the mass dimension of X: the unique real number n such that X scales as $(\text{mass})^n$.

Definition A.1 (Mass dimension)**.** For any physical quantity X expressed in natural units (A.1), its *mass dimension* $[\,X\,] \in \mathbb{R}$ is the power n for which X has the units of $(\text{mass})^n$. A quantity with $[\,X\,] = 0$ is *dimensionless* (a pure number, identical in every system of units); a quantity with $[\,X\,] \neq 0$ is said to have "dimension n" or, loosely, "be of order $(\text{mass})^n$." Mass dimension is additive under multiplication, $[\,XY\,] = [\,X\,] + [\,Y\,]$, and homogeneous under powers, $[\,X^k\,] = k\,[\,X\,]$.

The additivity in Theorem A.1 is the only algebraic fact we ever need about the bracket, and it follows immediately from the definition of units as multiplicative scales. It is what makes the dimension of a complicated Lagrangian term computable term by factor. We record at once the dimensions of the objects that appear universally. A spacetime coordinate is a length, so $[\,x^\mu\,] = -1$; consequently a partial derivative, which carries an inverse length, has

$$[\,\partial_\mu\,] = +1, \tag{A.3}$$

and a d-dimensional spacetime volume element has $[\,\mathrm{d}^d x\,] = -d$. A four-momentum is an energy, so $[\,p^\mu\,] = +1$, in keeping with the Fourier duality $p \sim \partial$; a momentum-space measure carries $[\,\mathrm{d}^d p\,] = +d$. These two facts—that coordinate integration lowers the dimension by d and momentum integration raises it by d—are the engine of the divergence counting in Part VI, and we have just derived them from (A.1) alone.

A.1.2 Restoring physical units: the conversion factors

Because $\hbar$ and c have been set to one, a result computed in natural units emerges as a pure power of mass, and to compare it with a laboratory measurement we must reinstate whatever powers of $\hbar$ and c restore the wanted dimensions of length, time, or area. The procedure is mechanical: a natural-units answer of mass dimension n is multiplied by the unique monomial $\hbar^a c^b$ that converts $(\text{mass})^n$ into the desired physical dimension. Since there is only one such monomial for each target, the restoration is unambiguous. The single number that does almost all of this work is the product

$$\hbar c \;=\; 197.327\ \text{MeV fm} \;=\; 0.197327\ \text{GeV fm}, \tag{A.4}$$

which has dimensions of energy×length and therefore equals one in natural units. Equation (A.4) states that an inverse energy is a length: $1\ \text{GeV}^{-1} = 0.197327$ fm. Table A.1 collects the conversions used repeatedly in the book; each is a power of (A.4) together with the elementary $\hbar$ and c.

The entry that recurs most in scattering calculations is the squared product

$$(\hbar c)^2 \;=\; 0.389379\ \text{GeV}^2\,\text{mb}, \qquad \text{so} \qquad 1\ \text{GeV}^{-2} = 0.389379\ \text{mb}, \tag{A.5}$$

because a cross section computed in natural units comes out as an inverse squared mass and must be turned into an area. We exercise (A.5) in Theorem A.7.

A.1.3 The action is dimensionless

Every dimension we are about to assign descends from a single principle: the action is a pure number. The reasoning is quantum-mechanical and admits no

Table A.1: Conversion factors for restoring physical units. Each entry equals one in natural units; multiplying a natural-units result by the appropriate power restores conventional units. Here 1 fm $= 10^{-15}$ m and 1 barn $= 10^{-28}$ m^2 $=$ 100 fm^2, so 1 mb $= 10^{-31}$ m^2.

Quantity	Natural-units value $= 1$	Practical form
Action / angular momentum	$\hbar = 6.582 \times 10^{-22}$ MeV s	$E\,t \to E\,t/\hbar$
Speed	$c = 2.998 \times 10^{8}$ m s^{-1}	$v \to v/c$
Energy$\times$length	$\hbar c = 197.327$ MeV fm	1 GeV$^{-1} = 0.1973$ fm
(Energy$\times$length)^2	$(\hbar c)^2 = 0.3894$ GeV^2 mb	1 GeV$^{-2} = 0.3894$ mb
Time from energy	$\hbar = 6.582 \times 10^{-25}$ GeV s	1 GeV$^{-1} = 6.582 \times 10^{-25}$ s
Mass–energy	c^2	1 GeV$/c^2 = 1.783 \times 10^{-24}$ g

freedom. In the path-integral and operator formulations alike the action enters physics only through the phase $e^{iS/\hbar}$, the weight that each history contributes to a transition amplitude (the action principle and the Euler–Lagrange equations from which S is built are developed in Chapter 6). The argument of an exponential must be dimensionless—there is no meaning to $e^{(\text{metres})}$—so $S/\hbar$ is dimensionless, whence $[\,S\,] = [\,\hbar\,]$. In natural units $\hbar = 1$ is dimensionless, and therefore

$$[\,S\,] = 0. \tag{A.6}$$

This is the master constraint. It is worth stressing that (A.6) is a statement about natural units specifically: with $\hbar$ restored, S has the dimension of $\hbar$, namely action; setting $\hbar = 1$ is precisely what makes the numerical value of S a dimensionless count of phase in units of the quantum of action.

A field theory's action is the spacetime integral of a Lagrangian density,

$$S \;=\; \int \mathrm{d}^d x\, \mathcal{L}, \tag{A.7}$$

in d spacetime dimensions, where we keep d general because the renormalization machinery of Part VI works in $d = 4 - 2\varepsilon$ and the classification below depends on d. Since $[\,\mathrm{d}^d x\,] = -d$ and $[\,S\,] = 0$, additivity (Theorem A.1) forces the Lagrangian density to carry the full dimension of the volume it is integrated over:

$$[\,\mathcal{L}\,] = d. \tag{A.8}$$

Equation (A.8) is the working form of the master constraint: every term in any Lagrangian density, kinetic or interacting, must have mass dimension exactly d. Reading this requirement against the known kinetic terms fixes the dimension of each field; reading it against the interaction terms then fixes the dimension of each coupling. We do both in turn.

A.1.4 Dimensions of the fields

Proposition A.2 (Mass dimensions of the canonical fields)**.** *In d spacetime dimensions, a real or complex scalar field ϕ, a Dirac (or Weyl) spinor field ψ, and a gauge potential A_μ, each with a canonically normalized kinetic term, have mass dimensions*

$$[\,\phi\,] = \frac{d-2}{2}, \qquad [\,\psi\,] = \frac{d-1}{2}, \qquad [\,A_\mu\,] = \frac{d-2}{2}. \tag{A.9}$$

In the physical case $d = 4$ these are $[\,\phi\,] = 1$, $[\,\psi\,] = \frac{3}{2}$, and $[\,A_\mu\,] = 1$.

Proof. The dimension of a dynamical field is set by demanding that its kinetic term, which defines the free propagation and is present in every theory of that field, obey (A.8). We treat the three cases by the same algorithm: write the kinetic term, equate its mass dimension to d using additivity and $[\,\partial_\mu\,] = 1$ from (A.3), and solve.

Scalar. The canonical kinetic term is $\frac{1}{2}(\partial_\mu\phi)(\partial^\mu\phi)$. The numerical $\frac{1}{2}$ is dimensionless, and each factor $\partial_\mu\phi$ has dimension $1 + [\,\phi\,]$, so the term has dimension $2(1 + [\,\phi\,])$. Setting this equal to d,

$$2(1 + [\,\phi\,]) = d \quad\Longrightarrow\quad [\,\phi\,] = \frac{d-2}{2}. \tag{A.10}$$

A mass term $\frac{1}{2}m^2\phi^2$ provides an immediate cross-check: its dimension is $2[\,m\,] + 2[\,\phi\,] = 2[\,m\,] + (d-2)$, which equals d precisely when $[\,m\,] = 1$, as a mass must have. Thus the scalar mass parameter carries mass dimension one in every d, consistent with the name.

Spinor. The canonical Dirac kinetic term is $\bar\psi\, i\partial\!\!\!/\,\psi = \bar\psi\, i\gamma^\mu\partial_\mu\psi$. The gamma matrices are constant numerical arrays (Chapter C) and so are dimensionless; $\bar\psi = \psi^\dagger\gamma^0$ has the same dimension as ψ. Hence the term has dimension $[\,\psi\,] + 1 + [\,\psi\,] = 2[\,\psi\,] + 1$. Setting this equal to d,

$$2[\,\psi\,] + 1 = d \quad\Longrightarrow\quad [\,\psi\,] = \frac{d-1}{2}. \tag{A.11}$$

The Dirac mass term $m\,\bar\psi\psi$ checks this: its dimension is $[\,m\,]+2[\,\psi\,] = [\,m\,]+(d-1)$, equal to d exactly when $[\,m\,] = 1$. The fermionic kinetic term carries a single derivative rather than two, which is why the spinor dimension exceeds the scalar dimension by $\frac{1}{2}$ in every d; this half-integer offset is the dimensional signature of first-order (Dirac) versus second-order (Klein–Gordon) dynamics.

Gauge field. The canonical kinetic term is $-\frac{1}{4}F_{\mu\nu}F^{\mu\nu}$ with $F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu$ (the abelian form; the nonabelian addition $g f^{abc} A^b_\mu A^c_\nu$ does not alter the counting, as we verify in Section A.1.8). The field strength has dimension $[\,F_{\mu\nu}\,] = 1 + [\,A_\mu\,]$, so the kinetic term has dimension $2(1 + [\,A_\mu\,])$, exactly the scalar combination. Hence

$$2(1 + [\,A_\mu\,]) = d \quad\Longrightarrow\quad [\,A_\mu\,] = \frac{d-2}{2}. \tag{A.12}$$

That a gauge potential shares the scalar dimension is no coincidence: both have two-derivative kinetic terms, and mass dimension is blind to the Lorentz indices A_μ carries. It also makes the dimensional content of the covariant derivative $D_\mu = \partial_\mu - igA^a_\mu T^a$ consistent only when the coupling g supplies the missing dimension, a point we return to immediately below. □

The recurring case $d = 4$ deserves to be isolated, since it governs nearly every explicit computation in the book. There a scalar and a gauge field each have dimension one, a fermion has dimension $\frac{3}{2}$, a mass has dimension one, and a derivative has dimension one. Table A.2 records these together with the coupling dimensions derived next.

A.1.5 Dimensions of the couplings, and the general rule

With the field dimensions fixed, the dimension of any coupling is read directly off (A.8). The statement is general and clean.

Proposition A.3 (Coupling of an operator of dimension Δ)**.** *Let $\mathcal{O}$ be a local operator built from fields and their derivatives, with mass dimension $[\,\mathcal{O}\,] = \Delta$, and let g be the coupling constant multiplying it in the Lagrangian density, so that $\mathcal{L} \supset g\,\mathcal{O}$. Then in d spacetime dimensions*

$$[\,g\,] = d - \Delta. \tag{A.13}$$

Proof. By (A.8) the term $g\mathcal{O}$ has dimension d. By additivity (Theorem A.1), $[\,g\mathcal{O}\,] = [\,g\,] + [\,\mathcal{O}\,] = [\,g\,] + \Delta$. Equating, $[\,g\,] + \Delta = d$, which is (A.13). □

Despite its one-line proof, Theorem A.3 is the most consequential statement in this section: it converts a question about an operator's field content into a single number, $d - \Delta$, whose sign will decide the fate of the interaction. We apply it to the three interactions carried through the book; the results appear again, with their full theories, in Section A.1.8.

The quartic scalar coupling. For the interaction $\frac{\lambda}{4!}\phi^4$, the operator is $\mathcal{O} = \phi^4$ with dimension $\Delta = 4[\,\phi\,] = 4 \cdot \frac{d-2}{2} = 2(d-2) = 2d - 4$. Hence

$$[\,\lambda\,] = d - \Delta = d - (2d - 4) = 4 - d. \tag{A.14}$$

In $d = 4$ this is $[\,\lambda\,] = 0$: the quartic coupling is dimensionless. The combinatorial factor $1/4!$ is dimensionless and plays no role in the count; it is fixed by the symmetry-factor conventions of Chapter 15, not by dimensions.

The gauge couplings. A gauge interaction enters through the covariant derivative, and its prototype is the fermion–photon vertex $\bar\psi\,(g\gamma^\mu A_\mu)\,\psi$ obtained by expanding $\bar\psi\, i\not{D}\,\psi$. The operator multiplying the coupling is $\mathcal{O} = \bar\psi\gamma^\mu\psi A_\mu$, of dimension

$$\Delta = 2[\,\psi\,] + [\,A_\mu\,] = (d-1) + \frac{d-2}{2} = \frac{3d-4}{2}, \tag{A.15}$$

so by (A.13)

$$[\,e\,] = [\,g\,] = d - \frac{3d-4}{2} = \frac{4-d}{2}. \tag{A.16}$$

In $d = 4$ both the QED coupling e and the Yang–Mills coupling g are dimensionless. The identical value of $[\,e\,]$ and $[\,g\,]$ is forced by the common structure of minimal coupling: any coupling introduced through a covariant derivative $D_\mu = \partial_\mu - ig(\cdots)$ must, by dimensional consistency of D_μ with ∂_μ, carry exactly the dimension that compensates $[\,A_\mu\,] = \frac{d-2}{2}$, namely $1 - \frac{d-2}{2} = \frac{4-d}{2}$. The same number therefore governs the nonabelian cubic and quartic gluon self-interactions, as we confirm below.

Table A.2: Mass dimensions in d spacetime dimensions and in the physical case $d = 4$. Field dimensions are from Theorem A.2; coupling dimensions from Theorem A.3. All four-dimensional gauge and quartic couplings are dimensionless, the dimensional fingerprint of renormalizability discussed in Section A.1.6.

Object	Mass dimension (general d)	Value at $d = 4$
coordinate x^μ	-1	-1
derivative ∂_μ, momentum p^μ	$+1$	$+1$
action S	0	0
Lagrangian density $\mathcal{L}$	d	4
scalar ϕ	$(d-2)/2$	1
gauge field A_μ	$(d-2)/2$	1
Dirac spinor ψ	$(d-1)/2$	$3/2$
mass m	1	1
quartic coupling λ (ϕ^4)	$4-d$	0
gauge couplings e, g	$(4-d)/2$	0

A.1.6 Relevant, marginal, irrelevant: the renormalizability classification

The dimension of a coupling is not merely a label; it predicts how the importance of the interaction it multiplies changes with the energy at which the theory is probed, and through that, whether the theory makes sense as a fundamental description valid to arbitrarily short distances. We first state the classification, then prove the energy-scaling behaviour that justifies its names, and finally connect it to the power counting of ultraviolet divergences that Part VI develops in full.

Definition A.4 (Relevant, marginal, irrelevant operators)**.** Let $\mathcal{O}$ be a local operator of mass dimension $\Delta = [\,\mathcal{O}\,]$ appearing in a d-dimensional Lagrangian density with coupling g, so $[\,g\,] = d - \Delta$ by Theorem A.3. The operator (equivalently, the interaction it generates) is called

- *relevant* if $\Delta < d$, equivalently $[\,g\,] > 0$;
- *marginal* if $\Delta = d$, equivalently $[\,g\,] = 0$;
- *irrelevant* if $\Delta > d$, equivalently $[\,g\,] < 0$.

The names are dictated by behaviour under change of scale, which we now derive. The terminology is a frequent source of sign confusion, so we pin down at the outset the precise quantity it refers to. The decisive object is the dimensionless ratio that measures the strength of the interaction $g\mathcal{O}$ *relative to the kinetic (free) part of the action* at a probing energy E, not the coupling g in isolation. To isolate it, rescale all coordinates and fields to dimensionless variables measured in units of E: under $x \to x/E$ and a compensating rescaling of each field by the appropriate power of E fixed by Theorem A.2, the kinetic terms become E-independent (they are scale covariant), while the term $g\mathcal{O}$ is left multiplied by a definite power of E. Tracking that power, the dimensionless measure of the interaction's importance at scale E is

$$\lambda_{\mathcal{O}}(E) \;\equiv\; g\,E^{\,\Delta-d} \;=\; g\,E^{-[\,g\,]}. \tag{A.17}$$

Equivalently and more quickly: $\lambda_{\mathcal{O}}(E)$ is the unique dimensionless combination of g and E, since $[\,g\,] = d - \Delta$ must be cancelled by $E^{\Delta-d}$. Its E-dependence is fixed entirely by the sign of $[\,g\,]$, and reading off the three cases proves the assertions implicit in Theorem A.4. The Wilsonian derivation in Chapter 23 carries out this rescaling explicitly, tracking how $\lambda_{\mathcal{O}}(E)$ flows as the cutoff is lowered; here we need only its dimensional skeleton, which (A.17) records.

Proposition A.5 (Infrared/ultraviolet fate of an interaction)**.** *Let $\lambda_{\mathcal{O}}(E) = g\,E^{\,\Delta-d}$ be the dimensionless importance of the interaction $g\mathcal{O}$ at scale E,* (A.17)*. Then:*

1. Relevant *($\Delta < d$, $[\,g\,] > 0$): $\lambda_{\mathcal{O}}(E) \to \infty$ as $E \to 0$ and $\to 0$ as $E \to \infty$. The interaction dominates the infrared and is negligible in the deep ultraviolet—hence "relevant" at low energies.*
2. Marginal *($\Delta = d$, $[\,g\,] = 0$): $\lambda_{\mathcal{O}}(E) = g$, scale independent at this (classical) level. The interaction is equally important at all scales; quantum corrections (the running of Chapter 24) break the tie and decide its true fate.*
3. Irrelevant *($\Delta > d$, $[\,g\,] < 0$): $\lambda_{\mathcal{O}}(E) \to 0$ as $E \to 0$ and $\to \infty$ as $E \to \infty$. The interaction is unimportant at low energies but grows without bound toward the ultraviolet—hence "irrelevant" to long-distance physics, yet the obstruction to a fundamental description.*

Proof. The exponent in $\lambda_{\mathcal{O}}(E) = g\,E^{\,\Delta-d}$ is $\Delta - d = -[\,g\,]$. In the relevant case $\Delta - d < 0$, so $E^{\,\Delta-d}$ diverges as $E \to 0$ and vanishes as $E \to \infty$; in the irrelevant

case $\Delta - d > 0$, so the limits are exchanged; in the marginal case the exponent vanishes and $\lambda_{\mathcal{O}}$ is constant. Each limit is the elementary behaviour of a real power, and the verbal descriptions follow by interpreting $\lambda_{\mathcal{O}} \gg 1$ as "interaction strong" and $\lambda_{\mathcal{O}} \ll 1$ as "interaction weak." □

Theorem A.5 explains the names, but the deepest consequence of the classification is its control over ultraviolet divergences, which is the reason the dimension count is the gateway to renormalization. We can already extract the heart of the power-counting theorem from dimensional analysis alone, deferring only the diagrammatic bookkeeping to Chapter 21.

Proposition A.6 (Dimensional core of power-counting renormalizability)**.** *Consider a theory whose interactions have couplings g_i multiplying operators $\mathcal{O}_i$ of dimensions Δ_i, so $[\,g_i\,] = d - \Delta_i$. The superficial degree of divergence D of a Feynman diagram—the net mass dimension of its loop integrals, defined and computed in Chapter 21—takes the form*

$$D \;=\; (\textit{a fixed number determined by } d \textit{ and the external legs}) \;-\; \sum_i n_i\,[\,g_i\,], \tag{A.18}$$

where n_i is the number of insertions of the vertex from g_i. Consequently: if every $[\,g_i\,] \geq 0$, then D is bounded above independently of the number of vertices, so only finitely many types of amplitude can diverge and finitely many counterterms remove every divergence—the theory is renormalizable*. If some $[\,g_i\,] < 0$, then D grows without bound as n_i increases, so infinitely many amplitude types diverge, each demanding its own counterterm—the theory is* nonrenormalizable *and requires an ultraviolet cutoff to be defined.*

Proof. We establish the structural form (A.18) by dimensional analysis; the explicit evaluation of the leg-dependent constant in terms of the number of internal and external lines is the combinatorial computation carried out in full in Chapter 21, and we do not duplicate it. Consider an amplitude (amputated Green's function) Γ of fixed external content, hence fixed total mass dimension $[\,\Gamma\,]$ determined by d and the dimensions of its external fields. At a given order in perturbation theory Γ is a sum of loop integrals, each accompanied by a product of couplings $\prod_i g_i^{n_i}$, of total dimension $\sum_i n_i[\,g_i\,]$. Since the full amplitude has the fixed dimension $[\,\Gamma\,]$ regardless of order, the loop integral accompanying $\prod_i g_i^{n_i}$ must carry mass dimension

$$[\,\Gamma\,] - \sum_i n_i\,[\,g_i\,]. \tag{A.19}$$

The superficial degree of divergence D is exactly the mass dimension of that loop integral when the divergence is power-like, because a loop integral that diverges as Λ^D (or, in dimensional regularization, exhibits a pole accompanied by external

momenta to the power D) necessarily has mass dimension D supplied by the loop momenta. Hence $D = [\,\Gamma\,] - \sum_i n_i [\,g_i\,]$, which is (A.18) with the leg-dependent constant identified as $[\,\Gamma\,]$. The two conclusions are now arithmetic. If all $[\,g_i\,] \geq 0$, then $-\sum_i n_i [\,g_i\,] \leq 0$, so $D \leq [\,\Gamma\,]$ for every diagram of every order: the degree of divergence cannot be raised by adding more vertices. Only those finitely many external configurations with $[\,\Gamma\,] \geq 0$ can ever produce a divergence, and each is a polynomial in external momenta of bounded degree, removable by adjusting the finitely many parameters (a counterterm for each such configuration). If instead some $[\,g_j\,] < 0$, then increasing n_j increases D without bound: for any external configuration, sufficiently many insertions of $\mathcal{O}_j$ make $D \geq 0$, so infinitely many amplitude types diverge and no finite set of counterterms suffices. The diagrammatic proof that these counterterms can in fact be organized order by order without spoiling lower orders—the Bogoliubov–Parasiuk–Hepp–Zimmermann program—is the content of Chapter 22; what dimensional analysis establishes, and all it needs to establish here, is the dichotomy on the *number* of required counterterms. □

Theorem A.6 is why the dimension count of this section is the foundation of Part VI. Renormalizable theories in $d = 4$ are exactly those whose couplings all have $[\,g_i\,] \geq 0$, that is, those built only from relevant and marginal operators. Reading Table A.2, the scalar mass term ($[\,m^2\,] = 2 > 0$, relevant), the ϕ^4 coupling, the gauge couplings, and the Yukawa coupling (whose operator $\bar{\psi}\psi\phi$ has dimension $2[\,\psi\,] + [\,\phi\,] = (d-1) + \frac{d-2}{2} = \frac{3d-4}{2}$, equal to 4 at $d = 4$, so its coupling has dimension $(4-d)/2$, dimensionless and marginal) exhaust the renormalizable interactions of fields of spin ≤ 1 in four dimensions. Every other local interaction—a ϕ^6 term, a four-fermion contact term $(\bar{\psi}\psi)^2$ of dimension 6, a Pauli moment $\bar{\psi}\sigma^{\mu\nu}\psi F_{\mu\nu}$ of dimension 5—has a coupling of negative mass dimension and is irrelevant, hence nonrenormalizable, hence admissible only within an effective field theory carrying an explicit cutoff. That the Standard Model contains *only* relevant and marginal operators is not an accident but the statement that it is, by construction, a renormalizable theory; the modern reinterpretation of nonrenormalizable terms as the leading windows onto physics above the cutoff is the subject of the effective-field-theory chapters.

A.1.7 Restoring units in practice: two worked computations

The dimensional machinery is only useful if one can move fluently between the natural-units answer a calculation produces and the laboratory number it predicts. We carry out two restorations in full: a cross section, where powers of $\hbar c$ must be reinstated, and the electron anomalous magnetic moment, where the lesson is that a genuinely dimensionless prediction needs no restoration at all—a fact that is itself a sharp consistency check.

Worked Example A.7 (Restoring units in the $e^+e^- \to \mu^+\mu^-$ cross section)**.** The total cross section for $e^+e^- \to \mu^+\mu^-$ at centre-of-mass energy $\sqrt{s}$ well above the muon mass is computed in natural units in Chapter 17; the result is

$$\sigma \;=\; \frac{4\pi\alpha^2}{3s}, \qquad \alpha = \frac{e^2}{4\pi} \approx \frac{1}{137.036}, \tag{A.20}$$

with α the fine-structure constant in Heaviside–Lorentz units (the convention fixed in Chapter 8 and used throughout QED). We restore physical units and evaluate at $\sqrt{s} = 10$ GeV.

Dimensional check. The coupling $\alpha = e^2/4\pi$ is dimensionless ($[\,e\,] = 0$ in $d = 4$ by (A.16)), and s is a squared energy, $[\,s\,] = 2$. Hence $[\,\sigma\,] = -2$: in natural units the cross section is an inverse squared mass. A cross section must have the dimension of an area, $[\,\text{length}\,]^2 = [\,\text{mass}\,]^{-2}$ in natural units, so the count is consistent and the unique restoring factor is $(\hbar c)^2$, which carries $[\,\hbar c\,]^2 = 0$ in natural units but reintroduces $\text{GeV}^2\cdot\text{mb}$ in practical units.

Restoration. Multiplying (A.20) by $(\hbar c)^2 = 0.389379\ \text{GeV}^2\,\text{mb}$ from (A.5),

$$\sigma \;=\; \frac{4\pi\alpha^2}{3s}\,(\hbar c)^2 \;=\; \frac{4\pi}{3}\,\alpha^2\,\frac{0.389379\ \text{GeV}^2\,\text{mb}}{s}. \tag{A.21}$$

Collecting the numerical prefactor with $\alpha = 1/137.036$,

$$\frac{4\pi}{3}\,\alpha^2\,(\hbar c)^2 = \frac{4\pi}{3}\,\frac{1}{(137.036)^2}\,(0.389379)\ \text{GeV}^2\,\text{mb} = 8.68\times10^{-5}\ \text{GeV}^2\,\text{mb}, \tag{A.22}$$

where we used $4\pi/3 = 4.18879$, $(137.036)^{-2} = 5.325\times10^{-5}$, and the product $4.18879\times5.325\times10^{-5}\times0.389379 = 8.68\times10^{-5}$. Since $1\ \text{mb} = 10^6\ \text{nb}$, the coefficient is $86.8\ \text{nb}\cdot\text{GeV}^2$, and the cross section takes the memorable form

$$\sigma \;=\; \frac{86.8\ \text{nb}}{s/\text{GeV}^2}. \tag{A.23}$$

At $\sqrt{s} = 10$ GeV, so $s = 100\ \text{GeV}^2$, this gives $\sigma = 0.868$ nb. The natural-units expression (A.20) carried no $\hbar$ or c and yet, through the single factor $(\hbar c)^2$, produced a number in nanobarns that an experiment can be held to. This is the entire content of unit restoration: identify the mass dimension of the answer, supply the unique power of $\hbar c$ that lands on the desired physical dimension, and read off the conversion from Table A.1.

Worked Example A.8 (The electron anomalous moment is dimensionless)**.** The magnetic moment of the electron is $\boldsymbol{\mu} = -g_e\,\dfrac{e}{2m_e}\,\mathbf{S}$, where g_e is the Landé g-factor and $\mathbf{S}$ the spin. The Dirac equation predicts $g_e = 2$; the deviation is encoded in the *anomalous magnetic moment*

$$a_e \;\equiv\; \frac{g_e - 2}{2}, \tag{A.24}$$

whose leading contribution Schwinger computed (carried out in full in Chapter 20) to be

$$a_e \;=\; \frac{\alpha}{2\pi} \;+\; O(\alpha^2) \;\approx\; \frac{1/137.036}{2\pi} \;\approx\; 1.161 \times 10^{-3}. \tag{A.25}$$

We ask what powers of $\hbar$ and c must be restored in (A.25), and the answer is the point of the example: *none*. The quantity a_e is defined in (A.24) as a ratio of g-factors, and a g-factor is by construction the dimensionless number relating a magnetic moment to the combination $e\hbar/2mc$ (the Bohr magneton, with $\hbar$ and c shown). Thus $[\,a_e\,] = 0$, and Theorem A.3 confirms it: a_e is a function of $\alpha = e^2/4\pi$ alone, and $[\,\alpha\,] = 2[\,e\,] = 0$ in $d = 4$. A dimensionless quantity has the same numerical value in every system of units, so $a_e \approx 1.161 \times 10^{-3}$ stands without any conversion factor whatsoever.

The contrast with the magnetic moment $\boldsymbol{\mu}$ itself is the instructive part. The moment is *not* dimensionless: restoring units, the Bohr magneton is

$$\mu_B \;=\; \frac{e\hbar}{2m_e c} \;=\; 5.788 \times 10^{-11}\ \text{MeV}\,\text{T}^{-1}, \tag{A.26}$$

carrying explicit $\hbar$ and c because a magnetic moment has the dimension of energy per magnetic field. The dimensionful content of $\boldsymbol{\mu}$ lives entirely in μ_B; the quantum field theory of Chapter 20 contributes only the pure number $g_e/2 = 1 + a_e$ multiplying it. This factorization—a dimensionful classical prefactor times a dimensionless loop expansion—is generic: dimensional analysis quarantines all the unit dependence into a known prefactor, leaving the dynamics to predict pure numbers like a_e that are the same whether one works in GeV, ergs, or electronvolts. That a measured a_e agrees with $\alpha/2\pi + \cdots$ to twelve significant figures is therefore a test of the *dynamics*, untainted by any choice of units.

A.1.8 The benchmark couplings, counted

We close by recording the mass dimensions of the three couplings carried through the book, each on its standard Lagrangian and each with a pointer to the chapter that develops the theory. These are applications of Theorem A.3 and contain nothing new; their purpose is to show the single counting principle acting uniformly across the scalar, abelian-gauge, and nonabelian-gauge cases, and to fix the dimensional starting point each thread's renormalization chapter will assume.

ϕ^4 theory. The standard Lagrangian $\mathcal{L} = \tfrac{1}{2}(\partial_\mu\phi)(\partial^\mu\phi) - \tfrac{1}{2}m^2\phi^2 - \tfrac{\lambda}{4!}\phi^4$, introduced classically in Chapter 6, has its quartic coupling counted in (A.14): $[\,\lambda\,] = 4 - d$, dimensionless in $d = 4$ and of dimension $+2\varepsilon$ when continued to $d = 4 - 2\varepsilon$. The small positive dimension that λ acquires below four dimensions is exactly what makes ϕ^4 weakly relevant in $d = 4 - \epsilon$ and underlies the Wilson–Fisher fixed point of Chapter 52; the dimensional bookkeeping here is the first appearance of that mechanism.

QED. The standard Lagrangian $\mathcal{L}_{\text{QED}} = \bar{\psi}(i\not{D} - m)\psi - \frac{1}{4}F_{\mu\nu}F^{\mu\nu}$ with $D_\mu = \partial_\mu + ieA_\mu$, introduced classically in Chapter 8, has its coupling counted in (A.16): $[\,e\,] = (4-d)/2$, dimensionless in $d = 4$. The dimensionlessness of e is the precondition for QED's renormalizability and for the existence of a scale-independent fine-structure constant whose slow logarithmic running (rather than power-law running) is computed in Chapter 24.

Yang–Mills theory. The standard Lagrangian $\mathcal{L}_{\text{YM}} = -\frac{1}{4}F^a_{\mu\nu}F^{a\,\mu\nu} + \bar{\psi}_i(i\not{D} - m)\psi_i$, with $F^a_{\mu\nu} = \partial_\mu A^a_\nu - \partial_\nu A^a_\mu + g f^{abc} A^b_\mu A^c_\nu$ and $D_\mu = \partial_\mu - igA^a_\mu T^a$, introduced classically in Chapter 25, has the same coupling dimension as QED: $[\,g\,] = (4-d)/2$. It is worth verifying that the nonabelian self-interactions, absent in QED, give the same answer, since this confirms the remark after Theorem A.2 that the extra term in $F^a_{\mu\nu}$ does not change the counting. The cubic gluon term arising from $-\frac{1}{4}F^a_{\mu\nu}F^{a\,\mu\nu}$ is of the schematic form $g f^{abc}(\partial_\mu A^a_\nu)A^{b\,\mu}A^{c\,\nu}$; its operator $\mathcal{O} = (\partial A)AA$ has dimension $\Delta = (1+[\,A_\mu\,])+2[\,A_\mu\,] = 1+3\cdot\frac{d-2}{2} = \frac{3d-4}{2}$, identical to (A.15), so Theorem A.3 returns $[\,g\,] = d - \frac{3d-4}{2} = (4-d)/2$ once more. The quartic gluon term $g^2 f^{abe} f^{cde} AAAA$ likewise checks: its operator has dimension $4[\,A_\mu\,] = 2(d-2)$, requiring its coefficient to have dimension $d - 2(d-2) = 4 - d = 2[\,g\,]$, consistent with the coefficient being g^2. That a single coupling g is forced to appear, with these correlated powers, in the cubic and quartic vertices is the dimensional shadow of the gauge invariance that relates them, and it is the starting point for the asymptotic-freedom computation of Chapter 27.

With every field and coupling now assigned a definite mass dimension, the action is a dimensionless object whose every term we can audit at a glance, and momentum integrals carry the definite mass dimensions recorded in Table A.2. This is the settled dimensional footing the next section needs: having fixed *how much* each quantity weighs in powers of mass, we turn to fixing the spacetime arena itself—the signature of the metric, the raising and lowering of indices, and the integration measure—on which all these dimensionful objects live.

A.2 Spacetime, the Metric, and Index Conventions

The previous section weighed every field and coupling in powers of mass and declared the action dimensionless. What it did not yet fix is the arena those dimensionful objects live in: the geometry of the index that turns a ∂_μ into a ∂^μ, the rule that pairs a position with a momentum, and the handful of signs that ride on those choices and propagate, unforgivingly, into every propagator, every dispersion relation, and every Feynman amplitude in the book. A misplaced sign here is not a cosmetic blemish—it flips the sign of an energy, sends a pole to the wrong half-plane, or turns a healthy mode into a tachyon. This section therefore makes the spacetime conventions explicit and, wherever a sign is at stake, shows that it is *forced* by physics rather than chosen by taste. We

fix the signature, the component conventions for four-vectors, the raising and lowering rules, the derivative and d'Alembertian conventions, and the orientation of the Levi-Civita tensor; and we verify, by direct computation, that the mostly-minus metric is exactly what makes the scalar kinetic energy positive and the mass term nontachyonic. The transformation law that gives these objects their tensor character under boosts and rotations belongs to the Lorentz group and is established in Chapter 3; here we presuppose it and fix the numerical conventions it acts on.

A.2.1 The signature and the metric tensor

We use throughout the *mostly-minus* (also called *west-coast* or *particle-physics*) signature, in which the metric tensor is

$$\eta_{\mu\nu} = \mathrm{diag}(+1, -1, -1, -1), \qquad \mu, \nu \in \{0, 1, 2, 3\}, \tag{A.27}$$

with the time index labelled 0 and the three space indices $1, 2, 3$. This is the Peskin–Schroeder and Schwartz convention; it is the opposite of the mostly-plus signature $\mathrm{diag}(-, +, +, +)$ common in the general-relativity and string-theory literature. The single most important consequence of (A.27) is recorded in the next paragraph and is the reason we adopt it: the relativistic invariant p^2 of a physical particle equals $+m^2$, a positive number, so the on-shell condition reads $p^2 = m^2$ with no trailing minus sign. Every later chapter that writes a propagator $i/(p^2 - m^2 + i\varepsilon)$ is relying on (A.27).

Notation Watch

A large fraction of the field-theory literature, and essentially all of general relativity, uses the opposite signature $\eta_{\mu\nu} = \mathrm{diag}(-, +, +, +)$. Under that choice the on-shell condition becomes $p^2 = -m^2$, the scalar kinetic term carries an overall minus sign, and the Levi-Civita relations below flip. When importing a formula from a mostly-plus source, the safe procedure is to send $\eta \to -\eta$ everywhere, which changes the sign of every contracted pair of indices: $p^2 \to -p^2$, $p \cdot x \to -p \cdot x$, and so on. We never mix the two within this book.

A.2.2 Four-vectors and the position–momentum pairing

A contravariant four-vector carries an upper index and is written with its components in the order (time, space). For the position and the four-momentum,

$$x^\mu = (x^0, \mathbf{x}) = (t, \mathbf{x}), \qquad p^\mu = (p^0, \mathbf{p}) = (E, \mathbf{p}), \tag{A.28}$$

where boldface denotes the ordinary spatial three-vector and, in natural units, $x^0 = t$ and $p^0 = E$. Lowering the index with the metric (A.27) flips the sign of

the spatial components and leaves the time component alone,

$$x_\mu = \eta_{\mu\nu} x^\nu = (t, -\mathbf{x}), \qquad p_\mu = \eta_{\mu\nu} p^\nu = (E, -\mathbf{p}), \tag{A.29}$$

since $\eta_{00} = +1$ acts on the time slot and $\eta_{ii} = -1$ (no sum) on each spatial slot. The covariant momentum component therefore reads $p_\mu = (E, -\mathbf{p})$, a fact worth committing to memory because the minus sign on $\mathbf{p}$ is the seed of the pairing we are about to compute.

The Lorentz-invariant pairing of two four-vectors is the contraction of one upper with one lower index. For position and momentum,

$$p \cdot x \equiv p_\mu x^\mu = \eta_{\mu\nu} p^\mu x^\nu = p^0 x^0 - \mathbf{p} \cdot \mathbf{x} = E\,t - \mathbf{p} \cdot \mathbf{x}. \tag{A.30}$$

The middle step is the explicit sum: the $\mu = \nu = 0$ term contributes $\eta_{00} p^0 x^0 = +Et$, while the three spatial terms contribute $\sum_i \eta_{ii} p^i x^i = -\sum_i p^i x^i = -\mathbf{p} \cdot \mathbf{x}$, the ordinary Euclidean dot product of the two three-vectors entering with a minus sign. Note that $p \cdot x = p_\mu x^\mu = p^\mu x_\mu$ gives the same number either way, since $\eta_{\mu\nu} p^\mu x^\nu = \eta_{\mu\nu} p^\nu x^\mu$ by the symmetry of the metric.

The square of a four-vector is the special case $x = p$ of this pairing. For the momentum,

$$p^2 \equiv p \cdot p = p_\mu p^\mu = (p^0)^2 - \mathbf{p} \cdot \mathbf{p} = E^2 - |\mathbf{p}|^2 . \tag{A.31}$$

A timelike vector has $p^2 > 0$, a spacelike vector $p^2 < 0$, and a null (lightlike) vector $p^2 = 0$. For a physical particle of mass m the relativistic energy–momentum relation $E^2 = |\mathbf{p}|^2 + m^2$ rearranges, using (A.31), into the *on-shell condition*

$$p^2 = m^2. \tag{A.32}$$

This is the payoff of the mostly-minus choice advertised above: in this signature a massive particle sits at $p^2 = +m^2$, and the photon, with $m = 0$, at $p^2 = 0$. We will rederive (A.32) from the scalar equation of motion in Theorem A.10 below, confirming that the dispersion relation is a *consequence* of the conventions and the dynamics, not an independent input.

A.2.3 Raising, lowering, and contraction

The inverse metric $\eta^{\mu\nu}$ is defined by $\eta^{\mu\rho}\eta_{\rho\nu} = \delta^\mu{}_\nu$, where $\delta^\mu{}_\nu$ is the Kronecker delta (unity when $\mu = \nu$, zero otherwise). Because (A.27) is diagonal with entries ± 1, it is its own inverse numerically:

$$\eta^{\mu\nu} = \mathrm{diag}(+1, -1, -1, -1), \qquad \eta^{\mu\rho}\eta_{\rho\nu} = \delta^\mu{}_\nu. \tag{A.33}$$

One checks the defining relation componentwise: for $\mu = \nu = 0$, $\eta^{0\rho}\eta_{\rho 0} = \eta^{00}\eta_{00} = (+1)(+1) = 1$; for $\mu = \nu = i$ (spatial, no sum), $\eta^{i\rho}\eta_{\rho i} = \eta^{ii}\eta_{ii} = (-1)(-1) = 1$; and off-diagonal entries vanish because η is diagonal. The trace of the mixed

metric is the spacetime dimension, $\eta^{\mu\nu}\eta_{\mu\nu} = \delta^{\mu}{}_{\mu} = 4$ in $d = 4$, a number that becomes d in dimensional regularization and is the origin of several factors of d in loop integrals.

Indices are raised and lowered by contraction with the metric and its inverse:

$$V_\mu = \eta_{\mu\nu} V^\nu, \qquad V^\mu = \eta^{\mu\nu} V_\nu, \tag{A.34}$$

and the two operations are mutually inverse precisely because of (A.33): $\eta^{\mu\nu}(\eta_{\nu\rho}V^\rho) = \delta^{\mu}{}_{\rho}V^\rho = V^\mu$. The contraction (the "dot product") of two four-vectors can be written in four equivalent ways,

$$V \cdot W = \eta_{\mu\nu} V^\mu W^\nu = V_\mu W^\mu = V^\mu W_\mu = \eta^{\mu\nu} V_\mu W_\nu, \tag{A.35}$$

all yielding the same scalar. The summation convention is in force throughout: *a repeated index, once up and once down, is summed over its four values*, and an index that is not so paired is free and must match on both sides of any equation. An expression with a repeated pair both up or both down (such as $V^\mu W^\mu$ with no metric) is not Lorentz covariant and, in this book, is always an error unless an explicit metric is written.

A.2.4 Derivative and d'Alembertian conventions

The partial derivative with respect to the contravariant coordinate x^μ carries a *lower* index, a placement fixed by the chain rule and not a matter of choice: under a Lorentz transformation $\partial/\partial x^\mu$ transforms with the inverse Jacobian, exactly as a covariant vector does (Chapter 3). We write

$$\partial_\mu \equiv \frac{\partial}{\partial x^\mu} = \left(\frac{\partial}{\partial t}, \nabla\right) = (\partial_t, \nabla), \tag{A.36}$$

so that ∂_μ has time component ∂_t and spatial components $+\nabla = (\partial_x, \partial_y, \partial_z)$ with the ordinary (positive) sign. Raising the index with (A.34) flips the spatial part,

$$\partial^\mu = \eta^{\mu\nu}\partial_\nu = (\partial_t, -\nabla). \tag{A.37}$$

That the lower-index derivative carries $+\nabla$ while the upper-index one carries $-\nabla$ is the mirror image of the four-momentum rule $p^\mu = (E, \mathbf{p})$, $p_\mu = (E, -\mathbf{p})$, and the two are linked: acting on a plane wave $e^{-ip\cdot x}$,

$$\partial_\mu\, e^{-ip\cdot x} = -i\, p_\mu\, e^{-ip\cdot x}, \tag{A.38}$$

since $p \cdot x = p_\nu x^\nu$ and $\partial_\mu x^\nu = \delta_\mu{}^\nu$ give $\partial_\mu(p_\nu x^\nu) = p_\mu$. The replacement $\partial_\mu \to -ip_\mu$ in momentum space is used in every chapter; (A.38) is its derivation and pins down the sign of the exponent against the Fourier convention of the next section.

Contracting two derivatives gives the d'Alembertian, the Lorentz-invariant wave operator,

$$\Box \equiv \partial_\mu \partial^\mu = \eta^{\mu\nu}\partial_\mu\partial_\nu = \partial_t^2 - \nabla^2, \tag{A.39}$$

where $\nabla^2 = \partial_x^2 + \partial_y^2 + \partial_z^2$ is the spatial Laplacian. The relative sign between the time and space second derivatives is the hyperbolic character of the wave equation; it is what allows propagating solutions and, on a plane wave, reproduces the mass shell:

$$\Box\, e^{-ip\cdot x} = (-ip_\mu)(-ip^\mu)\, e^{-ip\cdot x} = -p^2\, e^{-ip\cdot x}, \tag{A.40}$$

using (A.38) twice. We adopt the symbol $\Box$ for $+\partial_t^2 - \nabla^2$; some references reserve $\Box$ for the opposite-signature operator $\nabla^2 - \partial_t^2$, so the sign in (A.39) is part of our convention and is used consistently.

A.2.5 The Levi-Civita tensor and its orientation

The four-dimensional Levi-Civita symbol is the totally antisymmetric object that is fixed by a single value together with antisymmetry. We define it with an *upper*-index normalization,

$$\epsilon^{0123} = +1, \qquad \epsilon^{\mu\nu\rho\sigma} \text{ totally antisymmetric}, \tag{A.41}$$

so that $\epsilon^{\mu\nu\rho\sigma} = +1$ for an even permutation of $(0,1,2,3)$, -1 for an odd permutation, and 0 whenever any two indices coincide. This is the orientation that makes $\epsilon^{0123} = +1$ a right-handed convention with time first; it is the choice in Peskin–Schroeder and is the one that enters the definition $\gamma^5 = i\gamma^0\gamma^1\gamma^2\gamma^3$ and the dual field strength $\tilde{F}^{\mu\nu} = \frac{1}{2}\epsilon^{\mu\nu\rho\sigma}F_{\rho\sigma}$.

Unlike a true tensor, the symbol (A.41) has the *same* numerical entries in every Lorentz frame by fiat; what makes the combination $\epsilon^{\mu\nu\rho\sigma}$ transform as a tensor (up to the sign of the determinant of the transformation) is the interplay of this fixed symbol with the metric, treated in Chapter 3. For index gymnastics what matters is that, once the upper-index value is fixed, the lower-index value is *not* free: it is computed by lowering all four indices with the metric, and the result carries a crucial minus sign that we now derive in full.

Proposition A.9 (Lowered Levi-Civita orientation)**.** *With the convention* $\epsilon^{0123} = +1$ *of* (A.41) *and the mostly-minus metric* (A.27)*, the fully lowered Levi-Civita tensor satisfies*

$$\epsilon_{0123} = -1, \qquad \textit{equivalently} \qquad \epsilon_{\mu\nu\rho\sigma} = \det(\eta)\,\epsilon^{\mu\nu\rho\sigma} = -\,\epsilon^{\mu\nu\rho\sigma}. \tag{A.42}$$

Proof. Lowering all four indices means contracting with one factor of the metric per index,

$$\epsilon_{\mu\nu\rho\sigma} = \eta_{\mu\alpha}\,\eta_{\nu\beta}\,\eta_{\rho\gamma}\,\eta_{\sigma\delta}\,\epsilon^{\alpha\beta\gamma\delta}, \tag{A.43}$$

with the four pairs $(\alpha, \beta, \gamma, \delta)$ summed. Evaluate the particular component ϵ_{0123}. Because the metric (A.27) is diagonal, $\eta_{\mu\alpha}$ is nonzero only when $\alpha = \mu$; hence on the right-hand side of (A.43) the only surviving term has $\alpha = 0$, $\beta = 1$, $\gamma = 2$, $\delta = 3$, and the four sums collapse to a single product:

$$\epsilon_{0123} = \eta_{00}\,\eta_{11}\,\eta_{22}\,\eta_{33}\,\epsilon^{0123} = (+1)(-1)(-1)(-1)\,(+1) = -1. \tag{A.44}$$

The product of the four diagonal entries $(+1)(-1)(-1)(-1) = -1$ is exactly the determinant of the metric, $\det(\eta) = -1$. The same collapse occurs for any ordering of the four distinct indices, since the diagonal metric forces the summed indices to equal the free ones one-for-one and pulls out the identical factor $\det(\eta)$; the antisymmetric structure is carried unchanged by the single surviving $\epsilon^{\alpha\beta\gamma\delta}$. Therefore $\epsilon_{\mu\nu\rho\sigma} = \det(\eta)\,\epsilon^{\mu\nu\rho\sigma} = -\,\epsilon^{\mu\nu\rho\sigma}$, which is the stated result. In particular the lowered symbol takes the value -1 on the reference ordering $(0, 1, 2, 3)$, exactly opposite to the upper-index symbol. □

The minus sign in (A.42) is the four-dimensional reflection of the single timelike direction: lowering picks up one factor of $\eta_{00} = +1$ and three of $\eta_{ii} = -1$, and $(-1)^3 = -1$. In a Euclidean space, where the metric is the identity with $\det = +1$, no such sign appears and $\epsilon_{1234} = \epsilon^{1234} = +1$; the Lorentzian sign is therefore a genuine consequence of the signature and must be carried whenever a parity-odd quantity (an anomaly coefficient, a θ-term, a γ^5 trace) is evaluated.

Caution

The contraction identities for products of two Levi-Civita tensors—for example $\epsilon^{\mu\nu\rho\sigma}\epsilon_{\mu\nu\rho\sigma}$ and the determinant of Kronecker deltas that appears when fewer indices are contracted—inherit an overall minus sign in Lorentzian signature precisely because of (A.42): one finds $\epsilon^{\mu\nu\rho\sigma}\epsilon_{\mu\nu\rho\sigma} = -4! = -24$, not $+24$. The full list of these identities, with the signature signs tracked, is assembled in Chapter B; we use them there and do not reproduce them here, but the reader should remember that every such identity in this book carries the Lorentzian sign and not the naive Euclidean one.

A.2.6 The action, the kinetic sign, and why the signs are forced

We can now close the loop with the scalar field and show that the conventions adopted above are not aesthetic preferences but are dictated by the requirement that energy be bounded below. The Minkowski action is the spacetime integral of the Lagrangian density,

$$S = \int \mathrm{d}^4x\,\mathcal{L}, \qquad \mathrm{d}^4x = \mathrm{d}t\,\mathrm{d}^3\mathbf{x}, \tag{A.45}$$

with the Lagrangian density of the real scalar field (the frozen ϕ^4 theory model, Chapter 6) written in the standard form

$$\mathcal{L} = \tfrac{1}{2}(\partial_\mu\phi)(\partial^\mu\phi) - \tfrac{1}{2}m^2\phi^2 - \frac{\lambda}{4!}\phi^4. \tag{A.46}$$

The overall normalization $+\frac{1}{2}$ on the kinetic term and the relative minus sign on the mass term are the two conventions at stake. We prove that both are forced.

Proposition A.10 (Positive energy and the forced relative sign)**.** *With the mostly-minus metric* (A.27)*, the Lagrangian* (A.46) *has a Hamiltonian density that is a sum of manifestly non-negative terms, and its free Euler–Lagrange equation is the Klein–Gordon equation* $(\Box + m^2)\phi = 0$ *with the mass-squared entering with a positive sign. Reversing either the overall sign of the kinetic term or the relative sign of the mass term spoils one of these two properties; the conventions in* (A.46) *are therefore the unique choice consistent with positive energy and a nontachyonic spectrum.*

Proof. Expand the kinetic contraction using the ingredient of (A.39), $\partial_\mu\phi\,\partial^\mu\phi = \eta^{\mu\nu}\partial_\mu\phi\,\partial_\nu\phi = (\partial_t\phi)^2 - (\nabla\phi)^2$, so that the Lagrangian density reads, in explicit space and time pieces,

$$\mathcal{L} = \tfrac{1}{2}(\partial_t\phi)^2 - \tfrac{1}{2}(\nabla\phi)^2 - \tfrac{1}{2}m^2\phi^2 - \frac{\lambda}{4!}\phi^4. \tag{A.47}$$

The canonical momentum conjugate to ϕ is

$$\pi \equiv \frac{\partial\mathcal{L}}{\partial(\partial_t\phi)} = \partial_t\phi, \tag{A.48}$$

and the Hamiltonian density is the Legendre transform $\mathcal{H} = \pi\,\partial_t\phi - \mathcal{L}$. Substituting (A.47) and (A.48),

$$\begin{aligned}\mathcal{H} &= (\partial_t\phi)^2 - \left[\tfrac{1}{2}(\partial_t\phi)^2 - \tfrac{1}{2}(\nabla\phi)^2 - \tfrac{1}{2}m^2\phi^2 - \frac{\lambda}{4!}\phi^4\right] \\ &= \tfrac{1}{2}(\partial_t\phi)^2 + \tfrac{1}{2}(\nabla\phi)^2 + \tfrac{1}{2}m^2\phi^2 + \frac{\lambda}{4!}\phi^4.\end{aligned} \tag{A.49}$$

Every term in (A.49) is manifestly non-negative for real ϕ, $m^2 \geq 0$, and $\lambda \geq 0$: the first is the kinetic energy of the field's time variation, the second the gradient (shear) energy, the third the mass (rest) energy, the fourth the self-interaction energy. The Hamiltonian $H = \int \mathrm{d}^3\mathbf{x}\,\mathcal{H}$ is therefore bounded below by zero, with the minimum at $\phi = \text{const} = 0$. Had we chosen the opposite overall sign for the kinetic term, $\mathcal{L} \to -\tfrac{1}{2}(\partial_\mu\phi)(\partial^\mu\phi) + \dots$, the Legendre transform would produce $\mathcal{H} = -\tfrac{1}{2}(\partial_t\phi)^2 - \dots$, unbounded below: the field could lower its energy without limit by oscillating faster, and no stable vacuum would exist. The $+\frac{1}{2}$

kinetic normalization with the mostly-minus metric is thus the unique sign giving positive kinetic energy.

For the relative sign of the mass term, vary the free action ($\lambda = 0$). The Euler–Lagrange equation is

$$\partial_\mu \left(\frac{\partial \mathcal{L}}{\partial(\partial_\mu \phi)} \right) - \frac{\partial \mathcal{L}}{\partial \phi} = 0. \tag{A.50}$$

From (A.46) with $\lambda = 0$, the canonical structure gives $\partial\mathcal{L}/\partial(\partial_\mu\phi) = \partial^\mu\phi$ and $\partial\mathcal{L}/\partial\phi = -m^2\phi$, so (A.50) becomes

$$\partial_\mu \partial^\mu \phi + m^2 \phi = (\Box + m^2)\phi = 0, \tag{A.51}$$

the Klein–Gordon equation, in which the mass-squared appears with a *plus* sign relative to the d'Alembertian. Inserting a plane wave $\phi \propto e^{-ip\cdot x}$ and using (A.40), $\Box\, e^{-ip\cdot x} = -p^2 e^{-ip\cdot x}$, turns (A.51) into $(-p^2 + m^2)\phi = 0$, i.e.

$$p^2 = m^2, \qquad E^2 = |\mathbf{p}|^2 + m^2, \tag{A.52}$$

the on-shell condition (A.32) and the standard relativistic dispersion with real, positive energies for every mode. Had the mass term entered (A.46) with the *same* sign as the kinetic term, $\mathcal{L} = \frac{1}{2}(\partial\phi)^2 + \frac{1}{2}m^2\phi^2$, the Euler–Lagrange equation would read $(\Box - m^2)\phi = 0$, giving $p^2 = -m^2$ and $E^2 = |\mathbf{p}|^2 - m^2$: modes with $|\mathbf{p}| < m$ would have imaginary frequency and grow exponentially in time. That is the tachyonic instability, the hallmark of an inverted potential. The relative minus sign between the kinetic and mass terms in (A.46) is therefore the unique choice giving a stable, nontachyonic spectrum. Both signs in (A.46) are forced. □

Physical Insight

The two sign choices have a single physical content: the Lagrangian is (kinetic energy) minus (potential energy), $\mathcal{L} = T - V$, and the mostly-minus metric is exactly what assembles the relativistic kinetic term $\frac{1}{2}(\partial_t\phi)^2 - \frac{1}{2}(\nabla\phi)^2$ so that its *time*-derivative part enters with the same positive sign as a nonrelativistic $\frac{1}{2}m\dot{q}^2$. The potential $V = \frac{1}{2}(\nabla\phi)^2 + \frac{1}{2}m^2\phi^2 + \frac{\lambda}{4!}\phi^4$ then collects every term that costs energy: spatial variation, mass, and self-interaction. Reading the relative signs this way makes them memorable rather than arbitrary, and it is why a positive m^2 is a true mass while a negative m^2 signals an unstable vacuum and triggers spontaneous symmetry breaking (the mechanism developed later in the book).

A.2.7 The benchmark Lagrangians in fixed signature

To anchor every later sign to the conventions just fixed, we rewrite each of the three carried-thread Lagrangians in the mostly-minus signature, exhibiting the

component form where the signs are explicit. No thread is advanced here; the purpose is purely to display the benchmark models against the metric so that no later chapter need rederive their sign structure.

Worked Example A.11 (The three benchmark Lagrangians against the metric)**.** *ϕ^4 theory.* The model is (A.46), already expanded in (A.47). With (A.27) the kinetic contraction is $(\partial_\mu\phi)(\partial^\mu\phi) = (\partial_t\phi)^2 - (\nabla\phi)^2$, the mass term is the negative $-\frac{1}{2}m^2\phi^2$, and the equation of motion is the interacting Klein–Gordon equation obtained by restoring λ in (A.50): $\partial\mathcal{L}/\partial\phi = -m^2\phi - \frac{\lambda}{3!}\phi^3$, hence

$$(\Box + m^2)\phi = -\frac{\lambda}{3!}\phi^3, \tag{A.53}$$

the frozen ϕ^4 equation of motion of Chapter 6, with the on-shell condition $p^2 = m^2$ of (A.52) for the free field.

QED. The standard Lagrangian $\mathcal{L}_{\text{QED}} = \bar\psi(i\not{D} - m)\psi - \frac{1}{4}F_{\mu\nu}F^{\mu\nu}$, with $D_\mu = \partial_\mu + ieA_\mu$ (electron charge $-e$, $e > 0$) and $F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu$, depends on the signature in two places. First, the Dirac kinetic operator $\not{D} = \gamma^\mu D_\mu$ contracts the gamma matrices against D_μ using $\{\gamma^\mu, \gamma^\nu\} = 2\eta^{\mu\nu}$, the Clifford relation built on (A.27) and collected in Chapter C. That the gamma normalization is consistent with the scalar on-shell condition follows by squaring the free Dirac operator: using the Clifford relation,

$$\not{\partial}\not{\partial} = \gamma^\mu\gamma^\nu\partial_\mu\partial_\nu = \tfrac{1}{2}\{\gamma^\mu, \gamma^\nu\}\partial_\mu\partial_\nu = \eta^{\mu\nu}\partial_\mu\partial_\nu = \Box, \tag{A.54}$$

where the symmetric part of $\partial_\mu\partial_\nu$ projects the gamma product onto its anticommutator. Hence $(i\not{\partial} - m)(i\not{\partial} + m) = -\not{\partial}\not{\partial} - m^2 = -(\Box + m^2)$, so any solution of the free Dirac equation also solves $(\Box + m^2)\psi = 0$ and obeys the same on-shell condition $p^2 = m^2$ as the scalar—a check that the Clifford relation and the metric (A.27) are mutually consistent. Second, the Maxwell term in the mostly-minus signature is

$$-\tfrac{1}{4}F_{\mu\nu}F^{\mu\nu} = \tfrac{1}{2}\left(\mathbf{E}^2 - \mathbf{B}^2\right), \tag{A.55}$$

where $\mathbf{E}$ and $\mathbf{B}$ are the electric and magnetic fields packaged in $F_{\mu\nu}$; the overall $-\frac{1}{4}$ is exactly the normalization that makes the electric (time-derivative) part $\frac{1}{2}\mathbf{E}^2$ enter the energy with a positive sign, the photon analogue of the scalar kinetic term whose sign was forced in Theorem A.10.

Yang–Mills theory. The frozen non-abelian Lagrangian

$$\mathcal{L}_{\text{YM}} = -\tfrac{1}{4}F^a_{\mu\nu}F^{a\,\mu\nu} + \bar\psi_i(i\not{D} - m)\psi_i, \tag{A.56}$$

with $F^a_{\mu\nu} = \partial_\mu A^a_\nu - \partial_\nu A^a_\mu + g f^{abc} A^b_\mu A^c_\nu$ and $D_\mu = \partial_\mu - igA^a_\mu T^a$, contracts the colour-vector field strength $F^a_{\mu\nu}$ with the same metric, the colour index a summed with a Euclidean (Kronecker) sum and the Lorentz indices $\mu\nu$ raised by (A.27). The kinetic part of (A.56), obtained by dropping the $g f^{abc}$ term in $F^a_{\mu\nu}$, is a sum

of dim G copies of the Maxwell term (A.55), one per generator, and so carries the same positive-energy sign; the cubic and quartic gluon self-interactions hidden in the $gf^{abc}A^b_\mu A^c_\nu$ piece are the only structural difference from QED, and their Lorentz contractions again use only (A.27). The matter term repeats the QED Dirac analysis (A.54) verbatim, now with D_μ carrying the colour generator. Every sign in (A.56) is thereby fixed by the metric and the Clifford relation already established.

With the signature, the component conventions (A.28) and (A.29), the raising/lowering rules (A.34), the derivative conventions (A.36)–(A.39), and the Levi-Civita orientation (A.41)–(A.42) all fixed, and with the position–momentum pairing (A.30) verified against the plane-wave derivative (A.38), the spacetime arena is fully specified. The next section takes exactly these objects—the metric that defines $p \cdot x = Et - \mathbf{p} \cdot \mathbf{x}$ and the sign of the exponent in $e^{-ip\cdot x}$—and uses them to fix the Fourier-transform convention, the attendant bookkeeping of factors of 2π, and the Lorentz-invariant phase-space measure that weights momentum integrals in every amplitude to come.

A.3 Fourier Conventions, Distributions, and Invariant Measures

The previous section fixed the metric $\eta_{\mu\nu} = \mathrm{diag}(+,-,-,-)$, the on-shell condition $p^2 = m^2$, and the spacetime pairing $p \cdot x = p^0 x^0 - \mathbf{p} \cdot \mathbf{x}$. Those choices are static: they tell us how to read an index. The moment a field is expanded in plane waves, however, a second layer of convention switches on, and it is the one that generates more arithmetic slips than any other in the subject—the placement of factors of 2π. Every momentum integral in a Feynman amplitude carries a $(2\pi)^{-4}$; every momentum-conserving delta function pulls back a $(2\pi)^{+4}$; the relativistic normalization of a one-particle state hides a factor of $2E_{\mathbf{p}}$ that must be there for the inner product to be Lorentz invariant, and that same factor reappears, inverted, in the phase-space measure that weights final states in a cross section. These factors are not free: they are forced, each by the next, once the Fourier convention is fixed. The purpose of this section is to fix that convention, prove the few distributional identities the bookkeeping rests on (importing the analysis from Chapter 5 rather than rebuilding it), and from them *derive*—not postulate—the Lorentz-invariant phase-space measure and the relativistic state normalization that every scattering computation in the book, and every benchmark amplitude, will quote.

A.3.1 The Fourier transform and the (2π) bookkeeping

We use the asymmetric particle-physics convention, in which all the 2π's live on the momentum-integration side and the forward transform carries the sign $e^{+ip\cdot x}$.

Definition A.12 (Fourier transform pair)**.** For a (Schwartz, or more generally tempered) function f on Minkowski space and its transform $\tilde{f}$, the inverse and forward transforms are

$$f(x) = \int \frac{d^4p}{(2\pi)^4}\, e^{-ip\cdot x}\, \tilde{f}(p), \tag{A.57}$$

$$\tilde{f}(p) = \int d^4x\, e^{+ip\cdot x}\, f(x), \tag{A.58}$$

with $p\cdot x = p^0x^0 - \mathbf{p}\cdot\mathbf{x}$ the metric pairing of Section A.2. The operational rule is: *each $\int d^4p$ carries a $(2\pi)^{-4}$, and each four-dimensional delta function produced by an $\int d^4x$ carries a $(2\pi)^{+4}$.* The same convention is used in any number of dimensions n, with $4 \to n$ throughout; Chapter 5 develops the transform abstractly on $\mathbb{R}^n$ in this exact normalization (Eq. (5.37)).

Notation Watch

The forward transform carries $e^{+ip\cdot x}$ and the inverse carries $e^{-ip\cdot x}$. This is the opposite sign convention from much of the mathematics literature (where the forward transform usually carries $e^{-ip\cdot x}$), and the reason is physical: a positive-energy plane wave of a quantum field is $e^{-ip\cdot x} = e^{-iE_{\mathbf{p}}t + i\mathbf{p}\cdot\mathbf{x}}$, so writing the *field* (the position-space object) as the inverse transform Eq. (A.57) makes its mode expansion read with the standard e^{-iEt} time dependence. Fixing the sign here, once, removes the most common source of a stray overall sign in the exponent of every propagator and vertex.

The entire bookkeeping rests on one distributional identity, the spacetime statement that the Fourier transform of the constant function 1 is a delta function. We state it as the controlling identity and then verify the convention is self-consistent.

Proposition A.13 (The distributional delta representation)**.** *As an identity of tempered distributions on momentum space,*

$$\int d^4x\, e^{\,ip\cdot x} = (2\pi)^4\, \delta^{(4)}(p), \tag{A.59}$$

and equivalently, with the pairing read the other way, $\int \frac{d^4p}{(2\pi)^4}\, e^{-ip\cdot x} = \delta^{(4)}(x)$. Here $\delta^{(4)}(p) = \delta(p^0)\,\delta^{(3)}(\mathbf{p})$ is the four-dimensional Dirac delta of Theorem 5.5.

Proof. This is the spacetime instance of the constant-transform identity proved in Chapter 5 as $\widehat{1} = (2\pi)^n\delta$ (Theorem 5.19); we make the metric signature explicit so the reader sees that the indefinite pairing changes nothing. The integrand factorizes over the four coordinates because the exponent does: $e^{ip\cdot x} =$

$e^{ip^0x^0}\,e^{-i\mathbf{p}\cdot\mathbf{x}}$. Carrying out the time integral and the three spatial integrals separately, each is a one-dimensional constant-transform,

$$\int_{-\infty}^{\infty} dx^0\, e^{\,ip^0x^0} = 2\pi\,\delta(p^0), \tag{A.60}$$

$$\int_{-\infty}^{\infty} dx^j\, e^{-ip_jx^j} = 2\pi\,\delta(p_j), \qquad j=1,2,3, \tag{A.61}$$

each understood as the $n=1$ case of Theorem 5.19, in which a Gaussian regulator $e^{-a|x|^2/2}$ is inserted, the resulting convergent Gaussian integral is evaluated, and the limit $a\to 0^+$ is taken inside the distributional pairing (continuity of $\mathcal{F}$ on $\mathcal{S}'$). The relative minus sign on the spatial exponents is invisible to the result, because the delta function is even, $\delta(-p_j)=\delta(p_j)$. Multiplying Eqs. (A.60) and (A.61) gives $(2\pi)^4\,\delta(p^0)\,\delta(p_1)\delta(p_2)\delta(p_3) = (2\pi)^4\,\delta^{(4)}(p)$, which is Eq. (A.59). Dividing by $(2\pi)^4$ and relabelling $p\leftrightarrow x$ gives the inverse-side statement. □

Physical Insight

Equation (A.59) is the bookkeeping in a single line. Read left to right it says: an x-integral over a pure phase delivers a delta function *and* a $(2\pi)^4$. In a Feynman diagram each interaction vertex is an $\int d^4x$ of a product of plane waves, so each vertex produces exactly one such factor—the $(2\pi)^4\delta^{(4)}(\sum p)$ that enforces energy–momentum conservation at the vertex. Read right to left it says: every momentum integral $\int d^4p$ that is eventually killed by such a delta must come with a $(2\pi)^{-4}$ for the two factors to cancel and leave a clean number. The convention is engineered so that they always do.

That engineering is a claim, and we now check it: composing the forward and inverse transforms must return the original function, with every 2π accounted for. This is the consistency proof the spec of this section calls for.

Worked Example A.14 (Forward ∘ inverse closes back to $\delta^{(4)}$)**.** Take a Schwartz function f, transform it forward by Eq. (A.58), and substitute the result into the inverse transform Eq. (A.57); the claim is that we recover f, which forces the (2π) factors to be exactly those in Theorem A.12. Insert Eq. (A.58) into Eq. (A.57), writing the inner integration variable as y to keep it distinct from x:

$$\int \frac{d^4p}{(2\pi)^4}\, e^{-ip\cdot x}\,\tilde f(p) = \int \frac{d^4p}{(2\pi)^4}\, e^{-ip\cdot x}\int d^4y\, e^{\,ip\cdot y}\, f(y). \tag{A.62}$$

The integrand is absolutely integrable in (p,y) jointly once f is Schwartz and a Gaussian regulator is restored, so Fubini's theorem permits exchanging the order of integration. Doing the p-integral first and collecting the two exponentials into

$e^{\,ip\cdot(y-x)}$,

$$= \int d^4y\; f(y) \left[\int \frac{d^4p}{(2\pi)^4}\, e^{\,ip\cdot(y-x)} \right] = \int d^4y\; f(y)\, \delta^{(4)}(y-x) = f(x), \qquad \text{(A.63)}$$

where the bracket is the inverse-side form of Eq. (A.59) (a single $(2\pi)^{-4}$ accompanies the $\int d^4p$, and no leftover 2π survives), and the final step is the defining sifting property of the delta, Theorem 5.5. The chain $f \mapsto \tilde{f} \mapsto f$ closes *exactly*: the $(2\pi)^{-4}$ on the momentum integral is precisely what the delta-representation $(2\pi)^{+4}$ needs to cancel. Had we distributed the 2π's symmetrically (a $(2\pi)^{-2}$ on each transform), the same computation would still close, but then a vertex would emit a $(2\pi)^2\delta^{(4)}$ and the rules would be cluttered with half-integer powers of 2π. The asymmetric convention is chosen so that all factors of 2π are carried by momentum measures and momentum deltas, never by the fields.

Theorem 5.25 packages the residue-by-half-plane rule for the energy integrals these transforms produce; we will not repeat it here, but it is the engine behind every propagator contour in Section A.4.

A.3.2 The delta composed with a function

Deriving the on-shell measure requires one further distributional identity: the rule for a delta function whose argument is itself a function. We state and prove it in one dimension, which is all the measure derivation needs, building on the delta as the distribution defined in Theorem 5.5.

Lemma A.15 (Composition of the delta with a function)**.** *Let $g\colon \mathbb{R} \to \mathbb{R}$ be continuously differentiable with simple zeros $\{x_i\}$ (so $g(x_i) = 0$ and $g'(x_i) \neq 0$) and no zeros at infinity. Then, as a distribution,*

$$\delta(g(x)) = \sum_i \frac{\delta(x - x_i)}{|g'(x_i)|}. \qquad \text{(A.64)}$$

Proof. A distribution is determined by its action on test functions, so we evaluate $\int dx\, \delta(g(x))\, \varphi(x)$ for an arbitrary test function φ. Because $\delta(g(x))$ is supported on the zero set $\{x_i\}$, partition the real line into intervals each containing a single simple zero; the integral is the sum of the contributions, so it suffices to treat one zero x_0 and sum at the end. On a small interval I around x_0, g is strictly monotone (since $g'(x_0) \neq 0$ and g' is continuous), hence invertible there; change variables to $u = g(x)$, so that $du = g'(x)\, dx$ and $x = g^{-1}(u)$. Monotonicity gives $dx = du/g'(x)$ with g' of one fixed sign on I; writing the measure with its absolute value to keep the orientation of integration correct,

$$\int_I dx\; \delta(g(x))\, \varphi(x) = \int_{g(I)} \frac{du}{|g'(g^{-1}(u))|}\, \delta(u)\, \varphi(g^{-1}(u)). \qquad \text{(A.65)}$$

The interval $g(I)$ contains $u = 0$ (the image of x_0), so the sifting property of $\delta(u)$ evaluates the rest of the integrand at $u = 0$, i.e. at $x = g^{-1}(0) = x_0$:

$$= \frac{\varphi(x_0)}{|g'(x_0)|}. \tag{A.66}$$

This is exactly $\int dx\, \dfrac{\delta(x - x_0)}{|g'(x_0)|}\, \varphi(x)$. Summing over all simple zeros x_i reproduces Eq. (A.64), and since φ was arbitrary the two distributions agree. □

Caution

The factor is $|g'(x_i)|$, the *absolute value* of the derivative, not $g'(x_i)$ itself. The absolute value is what makes Eq. (A.64) a positive measure, as it must be: $\delta(g(x))$ is a limit of nonnegative bump functions. Dropping the modulus is a frequent error that flips the sign of a phase space whenever a root has $g' < 0$—and in the measure derivation below the relevant root has $g'(p^0) = 2p^0$, which is positive only because we restrict to the positive-energy sheet.

A.3.3 Relativistic normalization of states

Before deriving the measure we fix the normalization of momentum eigenstates, because the two are two faces of one Lorentz-invariance requirement. In nonrelativistic quantum mechanics one writes $\langle \mathbf{p}|\mathbf{q}\rangle = (2\pi)^3 \delta^{(3)}(\mathbf{p} - \mathbf{q})$, the conventional continuum normalization. The trouble is that $\delta^{(3)}(\mathbf{p} - \mathbf{q})$ is *not* a Lorentz scalar: under a boost the three-momenta and their measure transform, and a bare three-dimensional delta does not hold its form. A relativistic theory must normalize its one-particle states so that the inner product is frame-independent, and the unique minimal fix is to multiply by $2E_{\mathbf{p}}$.

Definition A.16 (Relativistic one-particle normalization)**.** On-shell momentum eigenstates of a particle of mass m, with $E_{\mathbf{p}} = \sqrt{\mathbf{p}^2 + m^2} > 0$, are normalized covariantly by

$$\langle p|q\rangle = (2\pi)^3\, 2E_{\mathbf{p}}\, \delta^{(3)}(\mathbf{p} - \mathbf{q}), \tag{A.67}$$

where $|p\rangle$ denotes the state of four-momentum $p^\mu = (E_{\mathbf{p}}, \mathbf{p})$. This is the convention used by every amplitude in the book, including every benchmark theory (Chapter 14 for ϕ^4 theory, Chapter 17 for QED). The relation to a unit-normalized state $|\mathbf{p}\rangle_{\mathrm{NR}}$ with ${}_{\mathrm{NR}}\langle \mathbf{p}|\mathbf{q}\rangle_{\mathrm{NR}} = (2\pi)^3 \delta^{(3)}(\mathbf{p} - \mathbf{q})$ is $|p\rangle = \sqrt{2E_{\mathbf{p}}}\, |\mathbf{p}\rangle_{\mathrm{NR}}$.

The claim that Eq. (A.67) is Lorentz invariant is the same claim, restated, as the invariance of the measure we are about to derive. We prove that invariance once, for the object $2E_{\mathbf{p}}\, \delta^{(3)}(\mathbf{p} - \mathbf{q})$, in Theorem A.19 below, after the measure is in hand; the two facts are inverse to each other, in the precise sense that $\delta^{(3)}/(2E)$ and $2E\, \delta^{(3)}$ transform with reciprocal Jacobians and so pair to an invariant.

A.3.4 The Lorentz-invariant phase-space measure

We can now reach the central object of the section. A scattering computation sums over final states; that sum is an integral over on-shell momenta, and for the result to be a Lorentz scalar the integration measure must be one too. The naive measure d^3p is not invariant. The correct, invariant measure is $d^3p/((2\pi)^3 2E_{\mathbf{p}})$, and it has a manifestly covariant origin: it is the four-dimensional measure restricted to the positive-energy mass shell by an on-shell delta. We derive it that way, which proves invariance for free, and then verify invariance a second time by an explicit boost.

Theorem A.17 (Lorentz-invariant phase-space measure)**.** *Define the one-particle invariant measure*

$$d\Pi \;\equiv\; \frac{d^3p}{(2\pi)^3\,2E_{\mathbf{p}}}, \qquad E_{\mathbf{p}} = \sqrt{\mathbf{p}^2 + m^2}. \tag{A.68}$$

Then $d\Pi$ is the restriction to the forward mass shell of the manifestly invariant four-dimensional object,

$$d\Pi = \int_{-\infty}^{\infty} \frac{dp^0}{2\pi}\,(2\pi)\,\delta(p^2{-}m^2)\,\theta(p^0)\,\frac{d^3p}{(2\pi)^3} = \frac{d^4p}{(2\pi)^4}\,(2\pi)\,\delta(p^2{-}m^2)\,\theta(p^0), \tag{A.69}$$

and is invariant under the proper orthochronous Lorentz group.

Proof. Step 1: perform the energy integral. Hold $\mathbf{p}$ fixed and integrate Eq. (A.69) over p^0. The argument of the delta is, with the mostly-minus metric,

$$g(p^0) := p^2 - m^2 = (p^0)^2 - \mathbf{p}^2 - m^2 = (p^0)^2 - E_{\mathbf{p}}^2, \tag{A.70}$$

a function of p^0 alone (at fixed $\mathbf{p}$) with two simple zeros at $p^0 = \pm E_{\mathbf{p}}$. Its derivative is $g'(p^0) = 2p^0$, so $|g'(\pm E_{\mathbf{p}})| = 2E_{\mathbf{p}}$ at each root. By the composition rule Theorem A.15,

$$\delta(p^2 - m^2) = \frac{\delta(p^0 - E_{\mathbf{p}})}{2E_{\mathbf{p}}} + \frac{\delta(p^0 + E_{\mathbf{p}})}{2E_{\mathbf{p}}}. \tag{A.71}$$

The step function $\theta(p^0)$ annihilates the second term (which is supported at $p^0 = -E_{\mathbf{p}} < 0$) and leaves the first untouched (its support is at $p^0 = +E_{\mathbf{p}} > 0$, where $\theta = 1$). Hence

$$\theta(p^0)\,\delta(p^2 - m^2) = \frac{1}{2E_{\mathbf{p}}}\,\delta(p^0 - E_{\mathbf{p}}). \tag{A.72}$$

Now integrate over p^0, with the (2π)'s of Eq. (A.69):

$$\int_{-\infty}^{\infty} \frac{dp^0}{2\pi}\,(2\pi)\,\theta(p^0)\,\delta(p^2 - m^2) = \int_{-\infty}^{\infty} dp^0\,\frac{1}{2E_{\mathbf{p}}}\,\delta(p^0 - E_{\mathbf{p}}) = \frac{1}{2E_{\mathbf{p}}}. \tag{A.73}$$

The explicit (2π) in Eq. (A.69) cancels the $(2\pi)^{-1}$ of the energy measure, so no stray 2π is generated by going on shell. Multiplying by the remaining spatial measure $d^3p/(2\pi)^3$ gives precisely $d\Pi = d^3p/((2\pi)^3 2E_{\mathbf{p}})$, which is Eq. (A.68). This establishes the equality Eq. (A.69).

Step 2: invariance from the covariant form. The four pieces of the right-hand expression in Eq. (A.69) are each Lorentz invariant under the proper orthochronous group, so their product is. (i) The four-volume measure d^4p is invariant because a Lorentz transformation Λ acts on p linearly with $\det\Lambda = +1$ for $\Lambda \in \mathrm{SO}(1,3)^+$, so the Jacobian of $p \mapsto \Lambda p$ is $|\det\Lambda| = 1$ and $d^4p' = d^4p$; the constant $(2\pi)^{-4}$ rides along untouched. (ii) The delta $\delta(p^2 - m^2)$ is invariant because its argument p^2 is the Lorentz scalar built in Section A.2, and a delta of a scalar is a scalar. (iii) The step $\theta(p^0)$ is invariant on the support of the delta: there p is timelike ($p^2 = m^2 > 0$), and proper *orthochronous* transformations preserve the sign of the time component of a timelike vector—the orthochronicity condition ${\Lambda^0}_0 \geq 1$ established for the Lorentz group in Chapter 3—so $\theta(p^0) = \theta(p'^0)$ on the mass shell. (iv) The factor (2π) is a constant. Therefore $d\Pi$, being equal to a product of invariants, is itself invariant. The restriction $m = 0$ is included: the forward mass shell degenerates to the forward light cone, and the same argument applies with $\theta(p^0)$ still preserved on the cone by orthochronicity. □

Physical Insight

The cleanest way to remember Eq. (A.68) is to remember Eq. (A.69): *the invariant measure is "d^4p over $(2\pi)^4$, on shell, positive energy."* Everything non-invariant in $d^3p/2E_{\mathbf{p}}$ is an artifact of having already done the p^0 integral and broken manifest covariance. This is the same pattern that recurs throughout the book—a manifestly covariant object (here the four-dimensional integrand) is reduced to a non-covariant but explicit one (the three-dimensional measure) by integrating out a constrained variable, and the covariance, though hidden, is never lost.

The invariance argument above is complete, but it is worth seeing the cancellation happen in the three-dimensional language directly, because that is the form one actually integrates and because the spec asks specifically for the boost that scales the energy component. We carry it out as a worked example.

Worked Example A.18 (Invariance of $d^3p/E_{\mathbf{p}}$ under a boost)**.** Take a boost of rapidity η along the 3-axis (the z-direction), with $\gamma = \cosh\eta$ and $\beta = \tanh\eta$, acting on the on-shell four-momentum $(E_{\mathbf{p}}, \mathbf{p})$. The transverse components are inert and the longitudinal pair mixes:

$$p'^1 = p^1, \qquad p'^2 = p^2, \qquad p'^3 = \gamma\,(p^3 + \beta\,E_{\mathbf{p}}), \tag{A.74}$$

$$E'_{\mathbf{p}} = p'^0 = \gamma\,(E_{\mathbf{p}} + \beta\,p^3). \tag{A.75}$$

We must compare $d^3p'/E'_{\mathbf{p}}$ with $d^3p/E_{\mathbf{p}}$. Since $dp'^1\,dp'^2 = dp^1\,dp^2$, only the longitudinal Jacobian $\partial p'^3/\partial p^3$ is at stake, evaluated *on shell*, where $E_{\mathbf{p}}$ is the dependent function $E_{\mathbf{p}} = \sqrt{(p^3)^2 + p_\perp^2 + m^2}$ and hence

$$\frac{\partial E_{\mathbf{p}}}{\partial p^3} = \frac{p^3}{E_{\mathbf{p}}}. \tag{A.76}$$

Differentiating Eq. (A.74) at fixed p^1, p^2 and using Eq. (A.76),

$$\frac{\partial p'^3}{\partial p^3} = \gamma\left(1 + \beta\,\frac{\partial E_{\mathbf{p}}}{\partial p^3}\right) = \gamma\left(1 + \beta\,\frac{p^3}{E_{\mathbf{p}}}\right) = \frac{\gamma\,(E_{\mathbf{p}} + \beta\,p^3)}{E_{\mathbf{p}}} = \frac{E'_{\mathbf{p}}}{E_{\mathbf{p}}}, \tag{A.77}$$

where the last equality is exactly Eq. (A.75). Therefore

$$d^3p' = \frac{\partial p'^3}{\partial p^3}\,d^3p = \frac{E'_{\mathbf{p}}}{E_{\mathbf{p}}}\,d^3p \qquad \Longrightarrow \qquad \frac{d^3p'}{E'_{\mathbf{p}}} = \frac{d^3p}{E_{\mathbf{p}}}. \tag{A.78}$$

The energy stretches the longitudinal momentum element by precisely the same factor $E'_{\mathbf{p}}/E_{\mathbf{p}}$ by which the energy itself grows, so the ratio $d^3p/E_{\mathbf{p}}$ is held fixed. Dividing by the boost-inert constant $(2\pi)^3 \cdot 2$ gives $d\Pi' = d\Pi$. Rotations are trivially included (they preserve $|\mathbf{p}|$, hence $E_{\mathbf{p}}$, and have unit Jacobian), and a general proper orthochronous transformation is a product of rotations and such boosts, so the result holds for the whole group—reproducing Theorem A.17 from the three-dimensional side.

With the measure proven invariant we can close the loop on the state normalization, showing that Eq. (A.67) is the unique companion convention that makes the completeness relation invariant.

Worked Example A.19 (Invariance of $2E_{\mathbf{p}}\,\delta^{(3)}(\mathbf{p}-\mathbf{q})$ and the resolution of the identity)**.** Consider the one-particle completeness (resolution of the identity on the single-particle subspace),

$$\mathbf{1}_{\text{1-pt}} = \int d\Pi\;|p\rangle\,\langle p| = \int \frac{d^3p}{(2\pi)^3\,2E_{\mathbf{p}}}\;|p\rangle\,\langle p|\,. \tag{A.79}$$

The left-hand side is a frame-independent operator (the projector onto one-particle states), and $d\Pi$ is invariant by Theorem A.17; for the equation to be consistent the integrand combination $|p\rangle\,\langle p|$ together with the normalization must be invariant too. Apply Eq. (A.79) to a state $|q\rangle$ and use the normalization Eq. (A.67):

$$|q\rangle = \int \frac{d^3p}{(2\pi)^3\,2E_{\mathbf{p}}}\;|p\rangle\,\langle p|q\rangle = \int \frac{d^3p}{(2\pi)^3\,2E_{\mathbf{p}}}\;|p\rangle\;(2\pi)^3\,2E_{\mathbf{p}}\,\delta^{(3)}(\mathbf{p}-\mathbf{q}) = \int d^3p\;|p\rangle\;\delta^{(3)}(\mathbf{p}-\mathbf{q}) = |q \tag{A.80}$$

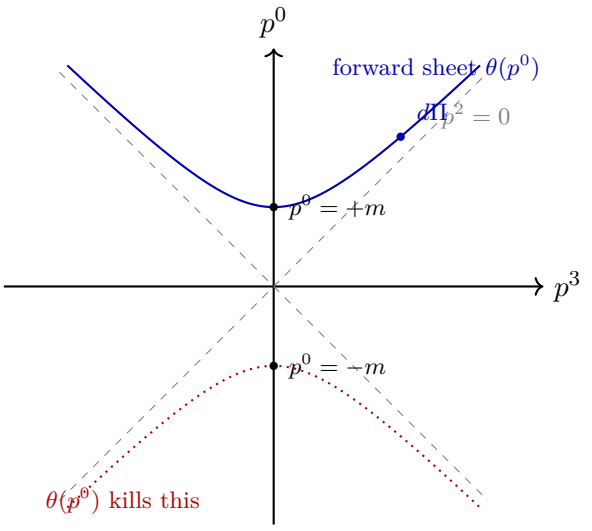

Figure A.1: The two-sheeted mass shell $p^2 = m^2$ in the (p^3, p^0) plane (transverse momenta suppressed), with the light cone $p^2 = 0$ as dashed asymptotes. The on-shell delta $\delta(p^2 - m^2)$ is supported on both hyperbolae; the factor $\theta(p^0)$ in Eq. (A.69) selects the upper, positive-energy sheet (solid blue) and discards the lower one (dotted red). The Lorentz-invariant measure $d\Pi$ of Eq. (A.68) is the induced measure on the forward sheet: a boost slides a point along the hyperbola, and Theorem A.18 shows the induced area element is preserved exactly.

The $2E_{\mathbf{p}}$ in the normalization is exactly what cancels the $1/(2E_{\mathbf{p}})$ in the measure, leaving the bare $\delta^{(3)}$ that sifts to $|q\rangle$. This is the structural reason the relativistic normalization carries the factor $2E_{\mathbf{p}}$: it is the reciprocal of the factor in the invariant measure, so that measure-times-normalization is the plain $d^3p\,\delta^{(3)}$, which is manifestly an invariant statement (the identity operator). Equivalently, since $d^3p/(2E_{\mathbf{p}})$ is invariant by Eq. (A.78), its distributional reciprocal $2E_{\mathbf{p}}\,\delta^{(3)}(\mathbf{p}-\mathbf{q})$—the object that integrates against it to the invariant unit—must transform oppositely and is therefore itself a Lorentz scalar. This is the invariance of Eq. (A.67) promised in Section A.3.3.

Figure A.1 renders the geometry: the on-shell delta lives on the two-sheeted hyperboloid $p^2 = m^2$, the $\theta(p^0)$ keeps the forward sheet, and a boost merely slides points along that sheet while preserving the induced measure.

Physical Insight

The combination that appears in physical formulas is always the invariant pair, never its two factors separately. In a decay rate or cross section the final-state sum is $\prod_f \int d\Pi_f$, with one $d\Pi$ per outgoing particle, and

an overall $(2\pi)^4\delta^{(4)}(\sum p)$ from the single leftover spacetime integral—one energy–momentum-conserving delta for the whole process, each $d\Pi$ carrying its own $(2\pi)^{-3}$ and $1/2E$. The $2E$'s in the relativistic normalization of the incoming states then cancel against the $1/2E$'s in the flux factor, and the entire apparatus collapses to a manifestly invariant number. The bookkeeping of this section is precisely the bookkeeping that makes that collapse exact, with no orphaned factor of 2π or $2E$ anywhere.

We have now fixed the Fourier convention Theorem A.12, proved the delta-representation Eq. (A.59) that powers the (2π) bookkeeping, established the relativistic state normalization Eq. (A.67), and derived the Lorentz-invariant measure $d\Pi$ Eq. (A.68) both from the covariant on-shell delta and by explicit boost. These are the exact conventions the next section needs: to write the momentum-space propagator it will Fourier-transform with the pair Eqs. (A.57) and (A.58), the poles of that propagator sit at the positive-energy roots $p^0 = +E_{\mathbf{p}}$ singled out by the $\theta(p^0)$ above, and choosing which way to route the contour around them is exactly the $i\epsilon$ prescription. With the measure and the delta conventions in hand, we turn to the analytic conventions—the $i\epsilon$ contour, the propagators, and the Wick rotation—that make the momentum-space theory well defined.

A.4 Analytic Conventions: the i-epsilon Prescription, Propagators, and Wick Rotation

The previous section fixed the Fourier transform, the (2π) bookkeeping that accompanies every momentum integral and every momentum-conserving delta function, the normalization of one-particle states, and the Lorentz-invariant phase-space measure $\mathrm{d}\Pi = \mathrm{d}^3p/[(2\pi)^3\,2E_{\mathbf{p}}]$ (Eq. (A.68)). Those conventions are purely kinematical: they tell us how to count momenta and how to weight on-shell states, but they say nothing about what happens when a denominator vanishes. The moment we write a propagator we meet exactly that situation. The free two-point function in momentum space is a ratio whose denominator is $p^2 - m^2$, and this vanishes precisely on the mass shell — the set of physical momenta we just learned to integrate over. A bare $1/(p^2 - m^2)$ is therefore not a function but an ill-defined expression with a pole sitting on the real axis of the energy integration. The content of this section is the single rule that resolves the ambiguity, the *Feynman $i\epsilon$ prescription*, together with everything that follows from it: the precise location of the displaced poles, the way the displacement enforces time ordering, the momentum-space propagators of the three fields the book carries, and the analytic continuation — the Wick rotation — that turns the oscillatory weight e^{iS} into the convergent Euclidean weight e^{-S_E}.

Throughout we use the mostly-minus metric $\eta_{\mu\nu} = \mathrm{diag}(+,-,-,-)$ and the Fourier convention of the previous section; the complex-analytic machinery — contour integration, residues, analytic continuation, and the reading of $i\epsilon$ as a distributional boundary value — is the one developed in Chapter 5 and is used here without reproof.

A.4.1 The Feynman prescription and the displaced poles

We begin with the real scalar field, the cleanest place to see the mechanism. The free Feynman propagator is defined in position space as the time-ordered vacuum two-point function; its operator origin and the proof that it equals the expression below are the business of Chapter 9, and are not assumed here. What this appendix fixes is the analytic form and the sign of the infinitesimal that makes it well defined.

Definition A.20 (Feynman scalar propagator)**.** The momentum-space Feynman propagator of a real scalar of mass m is

$$\widetilde{D_F}(p) \;=\; \frac{i}{p^2 - m^2 + i\epsilon}, \qquad p^2 = (p^0)^2 - \mathbf{p}^2, \tag{A.81}$$

where $\epsilon \to 0^+$ is a positive infinitesimal taken to zero *after* all integrations. The position-space propagator is its Fourier transform,

$$D_F(x) \;=\; \int \frac{\mathrm{d}^4p}{(2\pi)^4}\, \frac{i\, e^{-ip\cdot x}}{p^2 - m^2 + i\epsilon}. \tag{A.82}$$

The symbol $+i\epsilon$ is not decoration. Its entire job is to move the poles of the integrand off the real p^0 axis, and the sign of the displacement is what selects the Feynman (time-ordered) Green function rather than the retarded, advanced, or any other Green function of the same operator $\Box + m^2$. We make the displacement explicit. Writing $E_{\mathbf{p}} \equiv +\sqrt{\mathbf{p}^2 + m^2} > 0$ for the positive on-shell energy, the denominator factorizes in p^0 as

$$p^2 - m^2 + i\epsilon = (p^0)^2 - E_{\mathbf{p}}^2 + i\epsilon. \tag{A.83}$$

Its zeros are the two roots of $(p^0)^2 = E_{\mathbf{p}}^2 - i\epsilon$. Taking the square root and expanding to first order in the infinitesimal,

$$p^0 = \pm\sqrt{E_{\mathbf{p}}^2 - i\epsilon} = \pm E_{\mathbf{p}}\sqrt{1 - \frac{i\epsilon}{E_{\mathbf{p}}^2}} = \pm E_{\mathbf{p}}\Big(1 - \frac{i\epsilon}{2E_{\mathbf{p}}^2} + \cdots\Big) = \pm\Big(E_{\mathbf{p}} - i\epsilon'\Big), \tag{A.84}$$

where $\epsilon' \equiv \epsilon/(2E_{\mathbf{p}}) > 0$ is again a positive infinitesimal; since only its sign matters we will continue to call it ϵ without ambiguity. The two poles therefore sit at

$$p^0_{(+)} = +E_{\mathbf{p}} - i\epsilon \quad \text{(fourth quadrant)}, \qquad p^0_{(-)} = -E_{\mathbf{p}} + i\epsilon \quad \text{(second quadrant)}. \tag{A.85}$$

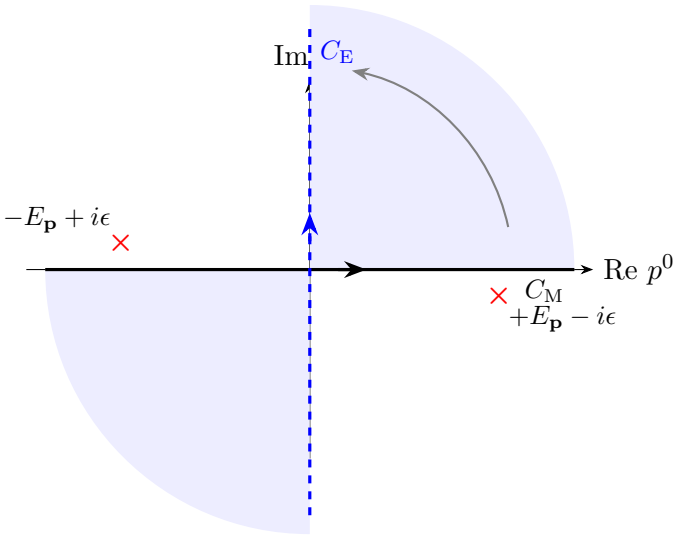

Figure A.2: The complex p^0 plane. The Feynman prescription Eq. (A.81) places the positive-energy pole at $+E_{\mathbf{p}} - i\epsilon$ (fourth quadrant) and the negative-energy pole at $-E_{\mathbf{p}} + i\epsilon$ (second quadrant). The Minkowski contour C_{M} runs along the real axis. Rotating it counterclockwise to the imaginary axis C_{E} (the Wick rotation, Section A.4.3) sweeps the shaded first and third quadrants, which contain no poles; the rotation is therefore legal precisely because of the $i\epsilon$ displacement.

The positive-energy pole is pushed *below* the real axis and the negative-energy pole *above* it. This is the geometric content of the Feynman prescription, drawn in Fig. A.2, and it is the only thing about $i\epsilon$ one ever needs to remember: *$+i\epsilon$ in the denominator means the positive-energy pole drops down and the negative-energy pole lifts up.*

The reason this particular displacement is the right one is that it makes Eq. (A.82) compute the *time-ordered* product. We show this by doing the p^0 integral with the residue theorem; this is the calculation that ties the analytic convention to physics, so we carry every step.

Worked Example A.21 (The Feynman contour enforces time ordering)**.** We evaluate Eq. (A.82) by closing the p^0 contour. Separate the spatial and temporal pieces of $p \cdot x = p^0 x^0 - \mathbf{p} \cdot \mathbf{x}$:

$$D_F(x) = \int \frac{\mathrm{d}^3 p}{(2\pi)^4}\, e^{i\mathbf{p}\cdot\mathbf{x}} \int_{-\infty}^{\infty} \mathrm{d}p^0\, \frac{i\, e^{-ip^0 x^0}}{(p^0 - E_{\mathbf{p}} + i\epsilon)(p^0 + E_{\mathbf{p}} - i\epsilon)}, \tag{A.86}$$

where we have used the factorization implied by Eq. (A.85). The exponential $e^{-ip^0 x^0}$ controls which half-plane we may close in: writing $p^0 = \mathrm{Re}\, p^0 + i\, \mathrm{Im}\, p^0$, the modulus is $e^{(\mathrm{Im}\, p^0) x^0}$, which is bounded on a large semicircle only if $(\mathrm{Im}\, p^0)\, x^0 \le 0$ there.

Case $x^0 > 0$. We must close in the lower half-plane, $\mathrm{Im}\, p^0 < 0$, where the arc contribution vanishes by Jordan's lemma (Chapter 5). The contour is then clockwise and encircles only the positive-energy pole $p^0 = E_{\mathbf{p}} - i\epsilon$. By the residue theorem,

$$\int_{-\infty}^{\infty} \mathrm{d}p^0 (\cdots) = -2\pi i \, \mathrm{Res}_{p^0 = E_{\mathbf{p}}} \frac{i\, e^{-ip^0 x^0}}{(p^0 - E_{\mathbf{p}})(p^0 + E_{\mathbf{p}})} = -2\pi i \cdot \frac{i\, e^{-iE_{\mathbf{p}} x^0}}{2E_{\mathbf{p}}} = \frac{\pi}{E_{\mathbf{p}}}\, e^{-iE_{\mathbf{p}} x^0}, \tag{A.87}$$

the leading $-$ sign coming from the clockwise orientation. Inserting this into Eq. (A.86) collapses the $(2\pi)^4$ to $(2\pi)^3$ and produces the invariant measure of the previous section,

$$D_F(x)\big|_{x^0>0} = \int \frac{\mathrm{d}^3 p}{(2\pi)^3\, 2E_{\mathbf{p}}}\, e^{-iE_{\mathbf{p}} x^0 + i\mathbf{p}\cdot\mathbf{x}} = \int \mathrm{d}\Pi\; e^{-ip\cdot x}\Big|_{p^0 = E_{\mathbf{p}}}. \tag{A.88}$$

This is the positive-frequency Wightman function, the amplitude for a disturbance created at the origin to propagate *forward* to x.

Case $x^0 < 0$. Now we close in the upper half-plane, counterclockwise, and pick up only the negative-energy pole $p^0 = -E_{\mathbf{p}} + i\epsilon$. The orientation is now $+2\pi i$, and the residue at $p^0 = -E_{\mathbf{p}}$ gives $i\, e^{+iE_{\mathbf{p}} x^0}/(-2E_{\mathbf{p}})$, so

$$D_F(x)\big|_{x^0<0} = \int \frac{\mathrm{d}^3 p}{(2\pi)^3\, 2E_{\mathbf{p}}}\, e^{+iE_{\mathbf{p}} x^0 + i\mathbf{p}\cdot\mathbf{x}} = \int \mathrm{d}\Pi\; e^{+ip\cdot x}\Big|_{p^0 = E_{\mathbf{p}}}, \tag{A.89}$$

where in the last step we relabeled $\mathbf{p} \to -\mathbf{p}$ in the measure (which is even). This is the positive-frequency function propagating in the opposite time sense. Combining the two cases with step functions,

$$D_F(x) = \theta(x^0) \int \mathrm{d}\Pi\, e^{-ip\cdot x} + \theta(-x^0) \int \mathrm{d}\Pi\, e^{+ip\cdot x} \quad (p^0 = E_{\mathbf{p}}), \tag{A.90}$$

which is exactly the time-ordered structure: the field created earlier stands to the right. The identification of Eq. (A.90) with $\langle 0|\, \mathcal{T}\phi(x)\phi(0)\, |0\rangle$ at the operator level is carried out in Chapter 9; here we have shown the purely analytic fact that *the sign of* $i\epsilon$ *in Eq. (A.81) is what assigns the two poles to the two half-planes so that the contour reconstructs the time ordering.* Had we chosen $p^2 - m^2 - i\epsilon$ instead, both poles would have moved the other way and the construction would have produced the anti-time-ordered (Dyson) propagator; pushing both poles below the axis gives the retarded function, both above the advanced one.

It is worth recording the distributional face of the same prescription, because it is the form that appears whenever one takes an imaginary part or a discontinuity. The Sokhotski–Plemelj identity established in Chapter 5,

$$\frac{1}{x \pm i\epsilon} = \mathrm{PV}\,\frac{1}{x} \mp i\pi\, \delta(x), \tag{A.91}$$

exhibits $i\epsilon$ as a boundary value of an analytic function from the upper or lower half-plane. Applied to Eq. (A.81) with $x = p^2 - m^2$,

$$\frac{i}{p^2 - m^2 + i\epsilon} = i\ \mathrm{PV}\,\frac{1}{p^2 - m^2} + \pi\,\delta(p^2 - m^2), \tag{A.92}$$

so the on-shell, delta-function part of the propagator is real and supported exactly on the mass shell. This is the bridge back to the invariant measure fixed in the previous section, as the next worked example makes precise.

Worked Example A.22 (The on-shell delta and the invariant measure)**.** The positive-energy mass-shell delta of Eq. (A.92) is the covariant repackaging of the measure $\mathrm{d}\Pi$. By the delta-composition rule Theorem A.15, applied to $f(p^0) = (p^0)^2 - E_{\mathbf{p}}^2$ exactly as in the measure derivation of the previous section, recall (Eq. (A.71))

$$\delta(p^2 - m^2) = \frac{1}{2E_{\mathbf{p}}}\Big[\delta(p^0 - E_{\mathbf{p}}) + \delta(p^0 + E_{\mathbf{p}})\Big]. \tag{A.93}$$

The factor $\theta(p^0)$ keeps only the first term, so integrating over p^0,

$$\int \frac{\mathrm{d}^4p}{(2\pi)^4}\,(2\pi)\,\delta(p^2 - m^2)\,\theta(p^0)\,g(p) = \int \frac{\mathrm{d}^3p}{(2\pi)^3\,2E_{\mathbf{p}}}\,g(p)\Big|_{p^0 = E_{\mathbf{p}}} = \int \mathrm{d}\Pi\; g(p), \tag{A.94}$$

which reproduces, term by term with its (2π) factors, the Lorentz-invariant phase-space measure of the previous section. The same $i\epsilon$ that orders time in Theorem A.21 thus also carries, in its imaginary part, the on-shell measure that weights external states; the two halves of the analytic convention are one object.

A.4.2 The propagators of the carried fields

With the scalar settled, the propagators of the Dirac and gauge fields follow the same prescription: the same $+i\epsilon$, the same pole displacement, with a numerator dictated by the field's tensor or spinor structure. We state them in the analytic conventions of this appendix; their derivation from the free field operators or the Gaussian path integral is owed by Chapters 9 and 10, and for the photon by Chapter 13.

The Dirac propagator. For a Dirac field of mass m the momentum-space propagator is

$$\widetilde{S_F}(p) = \frac{i(\not{p} + m)}{p^2 - m^2 + i\epsilon} = \frac{i}{\not{p} - m + i\epsilon}, \tag{A.95}$$

with $\not{p} \equiv \gamma^\mu p_\mu$ and the gamma matrices of Chapter C. The two forms are equal: rationalizing the second by multiplying numerator and denominator by $(\not{p} + m)$ and using

$$\not{p}\not{p} = p_\mu p_\nu\,\gamma^\mu\gamma^\nu = p_\mu p_\nu\,\tfrac{1}{2}\{\gamma^\mu, \gamma^\nu\} = p_\mu p_\nu\,\eta^{\mu\nu} = p^2, \tag{A.96}$$

where the second equality keeps only the symmetric part of $p_\mu p_\nu$ and the third invokes the Clifford relation $\{\gamma^\mu, \gamma^\nu\} = 2\eta^{\mu\nu}$ of Chapter C, gives $(\not{p}-m)(\not{p}+m) = \not{p}\not{p} - m^2 = p^2 - m^2$. The denominator is therefore the *same* scalar denominator $p^2 - m^2 + i\epsilon$, so the pole positions Eq. (A.85) and the contour analysis of Theorem A.21 carry over verbatim; only the numerator $i(\not{p} + m)$, which projects onto the spin content, is new. The $i\epsilon$ rides on the scalar denominator exactly as before.

The photon propagator. The photon is massless and gauge fields require a gauge-fixing choice before they have a propagator at all; the R_ξ family of covariant gauges, derived in Chapter 13, is parametrized by a real number ξ. In that family the momentum-space photon propagator is

$$\widetilde{D}_{\mu\nu}(k) = \frac{-i}{k^2 + i\epsilon}\left[\eta_{\mu\nu} - (1-\xi)\,\frac{k_\mu k_\nu}{k^2 + i\epsilon}\right]. \tag{A.97}$$

The massless pole sits at $k^2 = 0$, displaced to $k^2 = -i\epsilon$ by the same prescription, so that in the energy plane the poles are at $k^0 = \pm(|\mathbf{k}| - i\epsilon)$ — the $m \to 0$ limit of Eq. (A.85). The default for explicit computation in this book is *Feynman gauge*, $\xi = 1$, in which the longitudinal $k_\mu k_\nu$ term drops and the propagator collapses to the diagonal form

$$\widetilde{D}_{\mu\nu}(k)\big|_{\xi=1} = \frac{-i\,\eta_{\mu\nu}}{k^2 + i\epsilon}. \tag{A.98}$$

Landau gauge is $\xi = 0$, where the bracket becomes the transverse projector $\eta_{\mu\nu} - k_\mu k_\nu / k^2$. Physical (gauge-invariant) quantities are independent of ξ; the propagator itself is not, which is why the gauge must be stated whenever an off-shell Green function is written.

The gluon propagator. For the non-abelian gauge field the gauge-fixing procedure (Faddeev–Popov, Chapter 26) produces the same Lorentz structure carrying in addition an adjoint color delta,

$$\widetilde{D}^{ab}_{\mu\nu}(k) = \frac{-i\,\delta^{ab}}{k^2 + i\epsilon}\left[\eta_{\mu\nu} - (1-\xi)\,\frac{k_\mu k_\nu}{k^2 + i\epsilon}\right], \tag{A.99}$$

accompanied by a ghost propagator $i\delta^{ab}/(k^2 + i\epsilon)$ of its own. These are stated here only to fix the analytic conventions and the gauge default; the machinery that produces them, and the ghosts that accompany Eq. (A.99), is built in Chapter 26.

Notation Watch

The propagators Eqs. (A.81), (A.95), (A.98) and (A.99) are the momentum-space propagators of ϕ^4 theory, QED, and Yang–Mills theory. They are the exact expressions used without restatement in the amplitude computations of Chapter 14 (ϕ^4), Chapter 17 (QED tree level), and Chapter 19 (one-loop QED and the gauge propagators). No layer is added here; this section only certifies the signs and the $i\epsilon$ they all share.

A.4.3 Wick rotation and the Euclidean conventions

The $i\epsilon$ prescription does more than make individual propagators well defined: it makes the entire perturbative expansion analytically continuable to imaginary time, where the oscillatory Minkowski weight e^{iS} becomes a convergent Euclidean weight e^{-S_E}. This continuation, the *Wick rotation*, is the analytic foundation of the path-integral evaluations of Chapter 10 and of every master integral in Chapter D, which are computed in Euclidean space and continued back. We fix it here once.

Definition A.23 (Wick rotation)**.** The Wick rotation continues the real time coordinate into the lower-half complex plane,

$$t = x^0 = -i\tau, \qquad \tau \in \mathbb{R} \text{ (Euclidean time)}, \tag{A.100}$$

and correspondingly rotates the energy onto the imaginary axis,

$$p^0 = i\, p^0_E, \qquad p^0_E \in \mathbb{R}, \tag{A.101}$$

the spatial coordinates and momenta being unchanged. The Euclidean four-vectors $x_E = (\tau, \mathbf{x})$ and $p_E = (p^0_E, \mathbf{p})$ carry the all-plus metric $\delta_{\mu\nu}$, with $p_E^2 = (p^0_E)^2 + \mathbf{p}^2$ and $x_E^2 = \tau^2 + \mathbf{x}^2$.

The choices in Eqs. (A.100) and (A.101) are mutually consistent: the Minkowski phase factor continues to a real Euclidean one,

$$p^0 x^0 = (ip^0_E)(-i\tau) = p^0_E\, \tau, \tag{A.102}$$

and the Minkowski square continues to minus the Euclidean square,

$$p^2 = (p^0)^2 - \mathbf{p}^2 = (ip^0_E)^2 - \mathbf{p}^2 = -(p^0_E)^2 - \mathbf{p}^2 = -p_E^2. \tag{A.103}$$

Geometrically, Eq. (A.101) is the counterclockwise rotation of the p^0 integration contour from the real axis to the imaginary axis drawn in Fig. A.2. The rotation sweeps the first and third quadrants of the p^0 plane. By Eq. (A.85) the poles live in the *second and fourth* quadrants, so the rotating contour never crosses a

pole, and provided the arcs at infinity vanish (which they do for the convergent integrands of a regularized theory, Chapter 5) Cauchy's theorem guarantees the value of the integral is unchanged. *This is the deep reason the Feynman $i\epsilon$ is the right prescription for analytic continuation:* its specific sign is exactly what clears the rotation path of singularities. The retarded or advanced prescriptions, with both poles in the same half-plane, would obstruct the rotation in one of the two swept quadrants.

We now carry out the sign bookkeeping that the rotation induces in the action, term by term, for the carried scalar; the same arithmetic applies verbatim to any local Lagrangian.

Worked Example A.24 ($iS \to -S_E$ by explicit substitution)**.** Take the ϕ^4 Lagrangian density (the model of Chapter 6) in the mostly-minus metric,

$$\mathcal{L} = \tfrac{1}{2}(\partial_0\phi)^2 - \tfrac{1}{2}(\nabla\phi)^2 - \tfrac{1}{2}m^2\phi^2 - V(\phi), \qquad V(\phi) = \frac{\lambda}{4!}\phi^4, \tag{A.104}$$

so that $S = \int \mathrm{d}t\, \mathrm{d}^3x\, \mathcal{L}$. We substitute Eq. (A.100). The time differential and the time derivative continue as

$$\mathrm{d}t = -i\, \mathrm{d}\tau, \qquad \partial_0 = \frac{\partial}{\partial t} = \frac{1}{-i}\frac{\partial}{\partial \tau} = i\, \partial_\tau, \tag{A.105}$$

so the kinetic time term flips sign, $(\partial_0\phi)^2 = (i\partial_\tau\phi)^2 = -(\partial_\tau\phi)^2$, while the spatial gradient, the mass term, and the potential are untouched. Therefore

$$\begin{aligned} iS &= i\int(-i\,\mathrm{d}\tau)\,\mathrm{d}^3x\left[-\tfrac{1}{2}(\partial_\tau\phi)^2 - \tfrac{1}{2}(\nabla\phi)^2 - \tfrac{1}{2}m^2\phi^2 - V(\phi)\right] \\ &= \int \mathrm{d}\tau\,\mathrm{d}^3x\left[-\tfrac{1}{2}(\partial_\tau\phi)^2 - \tfrac{1}{2}(\nabla\phi)^2 - \tfrac{1}{2}m^2\phi^2 - V(\phi)\right] \\ &= -\int \mathrm{d}^4x_E\left[\tfrac{1}{2}(\partial_\tau\phi)^2 + \tfrac{1}{2}(\nabla\phi)^2 + \tfrac{1}{2}m^2\phi^2 + V(\phi)\right] \;\equiv\; -S_E, \end{aligned} \tag{A.106}$$

where the prefactor $i\cdot(-i) = 1$ in the first line, and $\mathrm{d}^4x_E = \mathrm{d}\tau\,\mathrm{d}^3x$. Every term in the brackets is now *added* with a $+$ sign: the kinetic term that was $+\tfrac{1}{2}(\partial_0\phi)^2$ and the gradient that was $-\tfrac{1}{2}(\nabla\phi)^2$ have both become $+\tfrac{1}{2}(\partial^E_\mu\phi)^2$, and the potential, which sat in $\mathcal{L}$ with a relative minus, now sits in S_E with a plus. The Euclidean action is the all-plus quadratic form

$$\boxed{S_E[\phi] = \int \mathrm{d}^4x_E\left[\tfrac{1}{2}\,(\partial^E_\mu\phi)(\partial^E_\mu\phi) + \tfrac{1}{2}m^2\phi^2 + V(\phi)\right], \qquad e^{iS} \longrightarrow e^{-S_E}.} \tag{A.107}$$

Because the gradient and mass pieces are manifestly nonnegative and V is bounded below, $S_E \geq 0$ up to an additive constant, so e^{-S_E} is a genuine, decaying statistical weight rather than a pure phase. This is precisely the property that makes the Euclidean path integral convergent and the Minkowski

one only conditionally defined; it is also why lattice and constructive treatments work in Euclidean signature. (Repeated Euclidean indices in Eq. (A.107) are summed with $\delta_{\mu\nu}$, so up/down placement no longer carries meaning.)

The same continuation acts on the propagator, and turning the analytic crank on Eq. (A.81) delivers the Euclidean propagator without any new input.

Worked Example A.25 (The Euclidean propagator from the Minkowski one)**.** Start from the position-space Minkowski propagator Eq. (A.82) and substitute the rotation Eqs. (A.100) and (A.101). The measure rotates as

$$\int \frac{\mathrm{d}^4 p}{(2\pi)^4} = \int \frac{\mathrm{d}p^0\, \mathrm{d}^3 p}{(2\pi)^4} \;\longrightarrow\; \int \frac{i\,\mathrm{d}p^0_E\, \mathrm{d}^3 p}{(2\pi)^4} = i \int \frac{\mathrm{d}^4 p_E}{(2\pi)^4}, \tag{A.108}$$

using $\mathrm{d}p^0 = i\,\mathrm{d}p^0_E$ from Eq. (A.101). The denominator rotates by Eq. (A.103), and crucially the $+i\epsilon$ is no longer needed once we are on the imaginary axis: the rotated denominator

$$p^2 - m^2 + i\epsilon \;\longrightarrow\; -p_E^2 - m^2 = -(p_E^2 + m^2) \tag{A.109}$$

never vanishes for real Euclidean momentum, since $p_E^2 + m^2 \geq m^2 > 0$ for $m \neq 0$ (and for $m = 0$ only at the single point $p_E = 0$, a set of measure zero). The infinitesimal has done its job — it kept the contour off the poles *during* the rotation — and may be dropped *after* it. Assembling the pieces, the overall i from Eq. (A.81), the i from the measure Eq. (A.108), and the -1 from the denominator Eq. (A.109) combine to

$$i \cdot i \cdot \frac{1}{-(p_E^2 + m^2)} = \frac{i^2 \cdot (-1)}{p_E^2 + m^2} = \frac{1}{p_E^2 + m^2}, \tag{A.110}$$

so that the propagator continues to the manifestly positive, real Euclidean kernel

$$D_F(x) = \int \frac{\mathrm{d}^4 p_E}{(2\pi)^4} \frac{e^{ip_E \cdot x_E}}{p_E^2 + m^2}, \qquad \boxed{\widetilde{D}_E(p_E) = \frac{1}{p_E^2 + m^2}\,,} \tag{A.111}$$

with $p_E \cdot x_E = p^0_E \tau + \mathbf{p} \cdot \mathbf{x}$ the Euclidean dot product. The result is the inverse of the Euclidean quadratic operator $-\partial_E^2 + m^2$ read off from Eq. (A.107), as it must be: the Gaussian weight e^{-S_E} has covariance $(-\partial_E^2 + m^2)^{-1}$, whose Fourier transform is exactly Eq. (A.111). The Dirac and gauge propagators continue the same way — numerators rotate by the same rules and the scalar denominator becomes $1/(p_E^2 + m^2)$ (or $1/p_E^2$ for the gauge field) — so the whole propagator catalogue of Section A.4.2 has a Euclidean image obtained by this single substitution.

The Euclidean propagator Eq. (A.111) is the convergent object on which dimensional regularization operates: in Chapter D every master loop integral is

evaluated against these denominators in $d = 4 - 2\varepsilon$ Euclidean dimensions, after the Wick rotation legitimized here, and continued back to Minkowski signature at the end. The boundary value $i\epsilon$ of Eq. (A.81) and the all-plus weight e^{-S_E} of Eq. (A.107) are thus two presentations of one analytic structure, related by the rotation of Fig. A.2.

These are the analytic conventions the rest of the book runs on. The propagator normalizations fixed here — the overall factor of i, the sign of the $i\epsilon$, and the gauge default $\xi = 1$ — together with the sign rule $e^{iS} \to e^{-S_E}$ for the path-integral weight, are exactly what the next section assumes when it builds the generating functionals $Z[J]$, $W[J]$, and $\Gamma[\phi]$: there the source-coupled integrand is weighted by precisely this e^{iS} (or e^{-S_E} in Euclidean signature), and the propagators above are the free two-point functions it generates by functional differentiation.

A.5 The Action, Generating Functionals, and Amplitude Normalization

The previous section fixed the analytic spine of the theory: the Feynman $i\epsilon$, the momentum-space propagator $i/(p^2 - m^2 + i\epsilon)$, and the Wick rotation that turns the Minkowski weight e^{iS} into the Euclidean weight e^{-S_E} (Section A.4). Those choices are not independent of how we couple sources to fields, how we package correlators into generating functionals, and how we strip an invariant amplitude out of an S-matrix element. A single sign placed inconsistently here propagates into every Feynman rule, every Legendre transform, and every cross section in the book. This section therefore freezes, once and for all, the sign of the source coupling, the definitions of the three generating functionals $Z[J]$, $W[J]$, and $\Gamma[\varphi_{\mathrm{cl}}]$ together with their Legendre relations, the split $\mathbf{S} = 1 + iT$ with its invariant amplitude $\mathcal{M}$, and the master formulae for cross sections and decay rates. Everything is fixed so that the $-i\lambda$ scalar vertex and the $i/(p^2 - m^2 + i\epsilon)$ propagator are mutually consistent, and so that the relativistic state normalization fixed in the Fourier section feeds straight into the phase-space measure.

We import three classes of results rather than reprove them. The functional calculus—functional derivatives, Gaussian functional integrals, and the Legendre transform as an operation on functionals—is developed in Chapter 4. The *physics* of generating functionals, in particular the linked-cluster theorem that $\ln Z$ generates connected correlators and the statement that Γ generates one-particle-irreducible (1PI) vertices, is developed in Chapter 10. The physics of the S-matrix, LSZ reduction, and the cross-section formula is developed in Chapters 14 and 16; here we fix only the normalization conventions those chapters then use. What this section does that no other does is nail the *signs and factors*

of i into a single mutually consistent set, with every intermediate step shown.

A.5.1 The source coupling and the partition functional

Let $S[\phi] = \int \mathrm{d}^4x\, \mathcal{L}(\phi, \partial_\mu \phi)$ be the (real) classical action of a generic field, which we take to be a single real scalar ϕ for definiteness; the bookkeeping is identical for fermions and gauge fields once the appropriate Grassmann or index structure is carried along. We couple an external classical source $J(x)$ to the field with the sign

$$S[\phi] \;\longmapsto\; S[\phi] + \int \mathrm{d}^4x\, J(x)\,\phi(x), \tag{A.112}$$

that is, with a $+J\phi$ in the action. This is a genuine convention, and it is the one this book uses everywhere; the opposite sign is equally consistent internally but would flip the sign in the Legendre relation derived below. We record it explicitly because the next section must place the sign of the covariant derivative consistently with it.

Definition A.26 (Generating functional of correlators)**.** The *generating functional* (or partition functional) of the theory in the presence of the source J is the Minkowski path integral

$$Z[J] \;\equiv\; \int \mathcal{D}\phi\; \exp\Big(i\, S[\phi] + i \int \mathrm{d}^4x\, J(x)\,\phi(x) \Big), \tag{A.113}$$

with the measure $\mathcal{D}\phi$ and its normalization fixed in Chapters 4 and 10. We adopt the normalization

$$Z[0] \;=\; \langle 0 | 0 \rangle \;=\; 1, \tag{A.114}$$

so that vacuum bubbles divide out and $Z[J]/Z[0]$ and $Z[J]$ coincide. Where it matters we write $Z[J]/Z[0]$ to make the cancellation manifest.

The exponent in Eq. (A.113) carries the same i that multiplies S in the Minkowski weight e^{iS}; the source term is inside the same i. This is what makes a single functional derivative bring down a clean factor of $i\phi$. Indeed, varying Eq. (A.113) with respect to J,

$$\frac{\delta}{\delta J(x)}\, Z[J] \;=\; \int \mathcal{D}\phi\; \big(i\,\phi(x)\big)\, \exp\Big(iS + i \int J\phi \Big), \tag{A.115}$$

so that the operator that extracts a bare field insertion is $-i\,\delta/\delta J$. Iterating and setting $J = 0$,

$$\langle 0 |\, \mathcal{T}\, \phi(x_1) \cdots \phi(x_n)\, | 0 \rangle \;=\; \frac{1}{Z[0]} \prod_{k=1}^{n} \Big(-\, i\, \frac{\delta}{\delta J(x_k)} \Big)\, Z[J] \,\Big|_{J=0}, \tag{A.116}$$

the time ordering $\mathcal{T}$ being automatic in the path-integral representation. Equation (A.116) is the operational content of $Z[J]$: it is the generating functional of the full (connected and disconnected) time-ordered correlators, with each insertion carrying one factor of $-i$.

Notation Watch

The $+J\phi$ sign in Eq. (A.112) and the placement of the source *inside* the i in Eq. (A.113) together force the $-i\,\delta/\delta J$ extraction rule (A.116) and, below, the relation $\delta\Gamma/\delta\varphi_{\rm cl} = -J$. A book that put $e^{iS}e^{\int J\phi}$ (source outside the i) would instead extract insertions with a bare $\delta/\delta J$ and would land on $\delta\Gamma/\delta\varphi_{\rm cl} = +iJ$. We never use that variant.

For completeness we record the Euclidean counterpart, since the analytic section ended on the $e^{iS} \to e^{-S_E}$ rotation. After the Wick rotation of Section A.4, the source convention that matches Eqs. (A.112) to (A.113) is

$$Z_E[J] \;=\; \int \mathcal{D}\phi\; \exp\Big(-S_E[\phi] + \int \mathrm{d}^4x_E\, J(x)\,\phi(x)\Big), \qquad W_E[J] \;=\; \ln Z_E[J], \tag{A.117}$$

with no factor of i anywhere: the Euclidean weight is a genuine (positive) probability weight and $W_E = \ln Z_E$ is the free energy. The factor of $-i$ in the Minkowski generator below is precisely the residue of the analytic continuation that takes $\ln Z_E \to -i \ln Z$.

A.5.2 The connected generator $W[J] = -i \ln Z[J]$

The full correlators (A.116) contain disconnected pieces—products of lower correlators in which clusters of points do not communicate. For scattering and for the loop expansion one wants the *connected* correlators, in which every insertion is linked to every other. The linked-cluster theorem (Chapter 10) states that these are generated by the logarithm of Z. With our factors of i the correctly normalized generator is

Definition A.27 (Connected generating functional)**.**

$$W[J] \;\equiv\; -\,i\,\ln Z[J], \qquad \text{equivalently} \qquad Z[J] \;=\; e^{\,i\,W[J]}. \tag{A.118}$$

The $-i$ is fixed, not free, once Eqs. (A.113) and (A.116) are fixed. We prove this by computing the first two derivatives explicitly; the sign of the second is the load-bearing check, because it is the one that must reproduce the i in the Feynman propagator.

Introduce the normalized expectation value in the presence of the source,

$$\langle\,\mathcal{O}\,\rangle_J \;\equiv\; \frac{1}{Z[J]}\int \mathcal{D}\phi\;\mathcal{O}\,\exp\Big(iS + i\int J\phi\Big), \tag{A.119}$$

which reduces to the vacuum correlator at $J = 0$. From Eq. (A.115),

$$\frac{\delta W}{\delta J(x)} \;=\; -i\,\frac{\delta}{\delta J(x)}\ln Z[J] \;=\; -\,i\,\frac{1}{Z[J]}\frac{\delta Z}{\delta J(x)} \;=\; -\,i\,\big(i\,\langle\phi(x)\rangle_J\big) \;=\; \langle\phi(x)\rangle_J \;\equiv\; \varphi_{\rm cl}(x). \tag{A.120}$$

The first derivative of W is therefore the *mean field* $\varphi_{\mathrm{cl}}(x)$—the expectation value of ϕ in the state dragged around by the source. The two factors of i have cancelled cleanly, which is the whole reason for the $-i$ in Eq. (A.118); this is the connected one-point function and it vanishes at $J = 0$ in a theory with no tadpole.

For the second derivative, differentiate Eq. (A.120) once more. Writing $\delta Z/\delta J(x) = i\,Z\,\langle\phi(x)\rangle_J$ from Eq. (A.115), and $\delta^2 Z/\delta J(x)\delta J(y) = -\,Z\,\langle\mathcal{T}\phi(x)\phi(y)\rangle_J$ (two derivatives each bringing an $i\phi$, giving $i^2 = -1$),

$$\begin{aligned}
\frac{\delta^2 W}{\delta J(x)\,\delta J(y)} &= -\,i\,\frac{\delta}{\delta J(y)}\left(\frac{1}{Z}\frac{\delta Z}{\delta J(x)}\right) \\
&= -\,i\left[\frac{1}{Z}\,\frac{\delta^2 Z}{\delta J(x)\,\delta J(y)} - \frac{1}{Z^2}\,\frac{\delta Z}{\delta J(x)}\,\frac{\delta Z}{\delta J(y)}\right] \\
&= -\,i\Big[-\langle\mathcal{T}\phi(x)\phi(y)\rangle_J - \big(i\langle\phi(x)\rangle_J\big)\big(i\langle\phi(y)\rangle_J\big)\Big] \\
&= -\,i\Big[-\langle\mathcal{T}\phi(x)\phi(y)\rangle_J + \langle\phi(x)\rangle_J\langle\phi(y)\rangle_J\Big] \\
&= i\left[\langle\mathcal{T}\phi(x)\phi(y)\rangle_J - \langle\phi(x)\rangle_J\langle\phi(y)\rangle_J\right] \;=\; i\,\langle\mathcal{T}\phi(x)\phi(y)\rangle_{J,\,c}.
\end{aligned} \tag{A.121}$$

The bracket is exactly the connected two-point function. At $J = 0$ this reads $\delta^2 W/\delta J(x)\delta J(y)\big|_0 = i\,G_c(x,y)$, with G_c the connected propagator; in momentum space the free-theory value is $i\cdot$ (the connected propagator), which is the $i/(p^2 - m^2 + i\epsilon)$ of the analytic section. Had we chosen $W = +i\ln Z$ or $W = \ln Z$, the sign or the factor of i here would be wrong, and the propagator extracted from W'' would not match the Feynman propagator. This is the proof that the constant in Eq. (A.118) must be $-i$.

The general statement follows by the same combinatorics. The linked-cluster theorem (Chapter 10) guarantees that $\ln Z$ generates only the connected correlators; tracking the factors of i exactly as above gives

$$\langle\,\mathcal{T}\,\phi(x_1)\cdots\phi(x_n)\,\rangle_c \;=\; i\,(-i)^{\,n}\,\frac{\delta^n W}{\delta J(x_1)\cdots\delta J(x_n)}\bigg|_{J=0}. \tag{A.122}$$

One checks the prefactor against the two cases just computed: for $n = 1$, $i(-i)^1 = 1$, reproducing Eq. (A.120); for $n = 2$, $i(-i)^2 = -i$, so that $\delta^2 W/\delta J\delta J = i\,G_c$, reproducing Eq. (A.121). Equation (A.122) is the connected analogue of Eq. (A.116).

A.5.3 The effective action and the Legendre relations

The third generating functional is the effective action Γ, the Legendre transform of W with respect to its conjugate pair $(J, \varphi_{\mathrm{cl}})$. Its derivatives are the 1PI vertex

functions (Chapter 10); for the purposes of this appendix the point is to fix the Legendre conventions and prove the sign of the quantum equation of motion.

The relation $\varphi_{\mathrm{cl}}(x) = \delta W/\delta J(x)$ of Eq. (A.120) associates to each source profile J a mean field φ_{cl}. Assume this map is invertible (it is, order by order in the loop expansion, with the tree-level inverse being the classical equation of motion), so that one may regard $J = J[\varphi_{\mathrm{cl}}]$ as a functional of the mean field.

Definition A.28 (Effective action)**.**

$$\Gamma[\varphi_{\mathrm{cl}}] \;\equiv\; W[J] - \int \mathrm{d}^4x\, J(x)\,\varphi_{\mathrm{cl}}(x), \qquad \varphi_{\mathrm{cl}}(x) = \frac{\delta W}{\delta J(x)}, \tag{A.123}$$

where on the right J is understood as the source $J[\varphi_{\mathrm{cl}}]$ that produces the given mean field.

Proposition A.29 (Legendre relations)**.** *With the conventions Eqs. (A.112), (A.118) and (A.123),*

$$\frac{\delta W}{\delta J(x)} \;=\; \varphi_{\mathrm{cl}}(x), \qquad \frac{\delta \Gamma}{\delta \varphi_{\mathrm{cl}}(x)} \;=\; -\,J(x). \tag{A.124}$$

In particular, in the absence of sources the mean field obeys the quantum equation of motion $\delta\Gamma/\delta\varphi_{\mathrm{cl}} = 0$*.*

Proof. The first relation is Eq. (A.120). For the second, differentiate Eq. (A.123) with respect to $\varphi_{\mathrm{cl}}(y)$, treating $J = J[\varphi_{\mathrm{cl}}]$ as a functional of the mean field and applying the chain rule for functionals (Chapter 4):

$$\frac{\delta \Gamma}{\delta \varphi_{\mathrm{cl}}(y)} = \int \mathrm{d}^4x\, \frac{\delta W}{\delta J(x)}\,\frac{\delta J(x)}{\delta \varphi_{\mathrm{cl}}(y)} \;-\; J(y) \;-\; \int \mathrm{d}^4x\, \frac{\delta J(x)}{\delta \varphi_{\mathrm{cl}}(y)}\,\varphi_{\mathrm{cl}}(x). \tag{A.125}$$

The explicit $-J(y)$ comes from differentiating the integrand's explicit dependence on $\varphi_{\mathrm{cl}}(y)$ in the term $-\int J\varphi_{\mathrm{cl}}$. Now substitute $\delta W/\delta J(x) = \varphi_{\mathrm{cl}}(x)$ in the first integral. The first and third integrals are then identical except for sign and cancel:

$$\int \mathrm{d}^4x\; \varphi_{\mathrm{cl}}(x)\,\frac{\delta J(x)}{\delta \varphi_{\mathrm{cl}}(y)} - \int \mathrm{d}^4x\, \frac{\delta J(x)}{\delta \varphi_{\mathrm{cl}}(y)}\,\varphi_{\mathrm{cl}}(x) \;=\; 0, \tag{A.126}$$

leaving $\delta\Gamma/\delta\varphi_{\mathrm{cl}}(y) = -J(y)$, which is the second relation in Eq. (A.124). Setting $J = 0$ gives the stationarity condition $\delta\Gamma/\delta\varphi_{\mathrm{cl}} = 0$. □

The minus sign in $\delta\Gamma/\delta\varphi_{\mathrm{cl}} = -J$ is the direct consequence of the $+J\phi$ source convention (A.112): the Legendre transform conjugates J to φ_{cl} with the sign that the chosen source coupling dictates. Differentiating the two relations in Eq. (A.124) once more establishes that the second derivatives of W and Γ are

mutually (negative) inverse kernels. Using $\varphi_{\rm cl}(x) = \delta W/\delta J(x)$ and $J(y) = -\delta\Gamma/\delta\varphi_{\rm cl}(y)$,

$$\begin{aligned}\delta^{(4)}(x-y) = \frac{\delta\varphi_{\rm cl}(x)}{\delta\varphi_{\rm cl}(y)} &= \int \mathrm{d}^4 z\, \frac{\delta\varphi_{\rm cl}(x)}{\delta J(z)}\,\frac{\delta J(z)}{\delta\varphi_{\rm cl}(y)} \\ &= \int \mathrm{d}^4 z\, \frac{\delta^2 W}{\delta J(x)\,\delta J(z)}\left(-\frac{\delta^2\Gamma}{\delta\varphi_{\rm cl}(z)\,\delta\varphi_{\rm cl}(y)}\right). \end{aligned} \tag{A.127}$$

Thus $W^{(2)}$ and $\Gamma^{(2)}$ satisfy $W^{(2)}\,\Gamma^{(2)} = -\mathbf{1}$ as integral kernels. Since $W^{(2)} = iG_c$ by Eq. (A.121), this gives $\Gamma^{(2)} = -\,(iG_c)^{-1} = i\,G_c^{-1}$: the second derivative of the effective action is i times the inverse connected propagator, i.e. the full 1PI two-point function whose tree-level value is $\delta^2 S/\delta\phi^2$, equal in momentum space to $p^2 - m^2$ for the free scalar. That Γ generates the higher 1PI vertices is proved in Chapter 10; Eq. (A.127) is the $n = 2$ instance and the one that fixes the sign.

Physical Insight

$W[J]$ and $\Gamma[\varphi_{\rm cl}]$ are two encodings of the same information related by a Legendre transform, exactly as the Hamiltonian is the Legendre transform of the Lagrangian. W is organized by the source J and counts connected diagrams; Γ is organized by the mean field $\varphi_{\rm cl}$ and counts 1PI diagrams, with the tree diagrams of Γ resumming the loops of W. The stationarity $\delta\Gamma/\delta\varphi_{\rm cl} = 0$ is the full quantum equation of motion: the classical action S is replaced by Γ, which includes all quantum corrections.

A.5.4 The S-matrix, the invariant amplitude, and the $-i\lambda$ vertex

We now turn from correlators to scattering. The physics of LSZ reduction—how a residue on the mass shell of the correlator (A.116) extracts a scattering amplitude—is the content of Chapters 14 and 16; here we fix only the normalization of the in/out states, the split of the S-matrix, and the definition of the invariant amplitude $\mathcal{M}$.

Recall from the Fourier section the relativistically invariant single-particle state normalization

$$\langle\,\mathbf{p}\,|\,\mathbf{q}\,\rangle \;=\; (2\pi)^3\,2E_{\mathbf{p}}\,\delta^{(3)}(\mathbf{p}-\mathbf{q}), \qquad E_{\mathbf{p}} = \sqrt{\mathbf{p}^2 + m^2}, \tag{A.128}$$

and the associated Lorentz-invariant momentum measure

$$\widetilde{\mathrm{d}p} \;\equiv\; \frac{\mathrm{d}^3 p}{(2\pi)^3\,2E_{\mathbf{p}}}, \tag{A.129}$$

both fixed in Sections A.3.3 and A.3.4. With this normalization the resolution of the identity on the one-particle subspace is $\mathbf{1} = \int \widetilde{\mathrm{d}p}\,|\mathbf{p}\rangle\langle\mathbf{p}|$, and Eqs. (A.128) and (A.129) are consistent, as $\int \widetilde{\mathrm{d}q}\,(2\pi)^3 2E_{\mathbf{q}}\delta^{(3)}(\mathbf{p}-\mathbf{q}) = 1$ acting correctly on $|\mathbf{p}\rangle$.

Definition A.30 (S-matrix and invariant amplitude)**.** The scattering operator $\mathbf{S}$ maps in-states to out-states. Because forward propagation with no interaction is the identity, we split off the trivial part:

$$\mathbf{S} \;=\; 1 \;+\; iT. \tag{A.130}$$

For a process $i \to f$ with incoming total momentum $\sum_i p_i$ and outgoing total momentum $\sum_f p_f$, the nontrivial matrix element factors a momentum-conserving delta function and defines the *invariant amplitude* $\mathcal{M}$ (also written $\mathcal{M}_{fi}$):

$$\langle f|\, iT \,|i\rangle \;=\; (2\pi)^4\, \delta^{(4)}\Big(\textstyle\sum_f p_f - \sum_i p_i\Big)\; i\,\mathcal{M}(i \to f). \tag{A.131}$$

The amplitude $\mathcal{M}$ defined by Eq. (A.131) is Lorentz invariant (the noninvariant normalization of the states having been absorbed into Eq. (A.128) and the measures of the master formulae below), and it is the quantity computed directly by the Feynman rules: $i\mathcal{M}$ is the sum of amputated, connected, momentum-space diagrams with external legs put on shell. The factor of i in front of T in Eq. (A.130) and the factor of i in front of $\mathcal{M}$ in Eq. (A.131) are conventional but fixed here; together with the $-i$ extraction rule (A.116) they make the tree-level $\mathcal{M}$ come out as in the next paragraph.

The vertex normalization of ϕ^4 theory follows directly. With the interaction Lagrangian $\mathcal{L}_{\text{int}} = -\frac{\lambda}{4!}\phi^4$ (Chapter 15), the perturbative weight in Eq. (A.113) expands the interaction as $\exp(iS_{\text{int}})$, so the elementary four-point vertex carries the factor $i \times (-\lambda/4!)$ from the action together with the 4! ways of attaching four distinct lines to the four identical fields. The 4! cancels the 1/4!, leaving the Feynman rule

$$\text{four-point vertex} \;=\; -\,i\,\lambda, \tag{A.132}$$

and hence, at leading order, $i\mathcal{M} = -i\lambda$, i.e. $\mathcal{M} = -\lambda$ for $\phi\phi \to \phi\phi$. This is the carried number of ϕ^4 theory; it is fixed here and used unchanged from Chapters 14 and 15 onward. We hand the *sign* of this vertex—the $-i$, traceable to the $+iS_{\text{int}}$ in Eq. (A.113)—to the gauge section, which must put the sign in the covariant derivative $D_\mu = \partial_\mu - igA^a_\mu T^a$ so that the gauge vertices are consistent with it.

Caution

Two distinct factors of i live in Eq. (A.132) and must not be conflated. One is the i multiplying the whole action in e^{iS} (it becomes the i in front of $\mathcal{M}$, and the i in the propagator). The other is the explicit factor of i in $\mathbf{S} = 1 + iT$. The clean statement is: the Feynman rules build $i\mathcal{M}$ directly—propagators are $i/(p^2 - m^2 + i\epsilon)$ and vertices are $i \times$ (coupling structure)—and the cross-section formulae below depend only on $|\mathcal{M}|^2$, in which all these i's have cancelled.

Worked Example A.31 (The $-i\lambda$ vertex from the path integral)**.** We verify Eq. (A.132) from the source formalism, to show the combinatorial 4! explicitly. The order-λ contribution to the connected four-point function $\langle \mathcal{T}\phi_1\phi_2\phi_3\phi_4\rangle_c$ comes from bringing down one power of $iS_{\text{int}} = -i\frac{\lambda}{4!}\int \mathrm{d}^4 z\, \phi(z)^4$ from the exponential in Eq. (A.113) and contracting its four fields with the four external points. By Wick's theorem (Chapter 10) the number of ways to contract the four *distinct* external fields $\phi(x_1), \ldots, \phi(x_4)$ with the four *identical* fields $\phi(z)^4$ is $4! = 24$: the first external field can pair with any of the four $\phi(z)$, the second with any of the remaining three, and so on. Each contraction is a free propagator, and the amputation in LSZ removes the four external propagators, leaving the value at the vertex

$$i\mathcal{M} \;=\; \Big(-i\,\frac{\lambda}{4!}\Big)\times 4! \;=\; -i\,\lambda, \tag{A.133}$$

so $\mathcal{M} = -\lambda$. The $1/4!$ in the Lagrangian is there precisely so that the connected, fully amputated four-point vertex is the clean $-i\lambda$; symmetry factors of *loop* diagrams, where some of the 4! pairings coincide, are treated carefully in Chapter 15.

A.5.5 Cross sections, decay rates, and the invariant phase space

We finally assemble the master formulae. The strategy is the standard finite-volume regularization: put the system in a spatial box of volume V over a time T, normalize states by Eq. (A.128), count transition probabilities, and take $V, T \to \infty$ at the end so that the continuum measure (A.129) reappears. The physics of why this gives the observable rate is in Chapter 16; here we carry the algebra so that the prefactors are pinned down.

From matrix element to probability. In the box, the continuum delta functions become volumes. The squared spacetime delta function in $|\langle f|iT|i\rangle|^2$ is regulated as

$$\big[(2\pi)^4\delta^{(4)}(0)\big] \;=\; V\,T, \tag{A.134}$$

since one $(2\pi)^4\delta^{(4)}$ remains after the other is used to enforce overall momentum conservation, and the leftover evaluated at zero argument counts the available spacetime volume. Likewise the state norm (A.128) becomes $\langle \mathbf{p}|\mathbf{p}\rangle = 2E_{\mathbf{p}}(2\pi)^3\delta^{(3)}(0) = 2E_{\mathbf{p}}V$, and the number of momentum modes in a cell d^3p is $V\,\mathrm{d}^3p/(2\pi)^3$.

Squaring Eq. (A.131) and using Eq. (A.134), the modulus-squared transition matrix element for a fixed final configuration is

$$\big|\langle f|iT|i\rangle\big|^2 \;=\; |\mathcal{M}|^2\,(2\pi)^4\delta^{(4)}\Big(\textstyle\sum_f p_f - \sum_i p_i\Big)\,V\,T. \tag{A.135}$$

To convert this to a genuine probability we divide by the norms $\langle i|i\rangle$ and $\langle f|f\rangle$ of the in- and out-states (the states (A.128) are not unit-normalized), and we

sum over the available final modes with the density $V\mathrm{d}^3p_f/(2\pi)^3$. Collecting the factors,

$$\mathrm{d}P \;=\; \frac{|\langle f|iT|i\rangle|^2}{\big(\prod_{\text{in}} 2E_i V\big)\big(\prod_{\text{out}} 2E_f V\big)} \prod_{\text{out}} \frac{V\,\mathrm{d}^3p_f}{(2\pi)^3}. \tag{A.136}$$

The factors of V from the mode counting cancel the V in each out-state norm, $\prod_{\text{out}}[V\mathrm{d}^3p_f/(2\pi)^3]/[2E_fV] = \prod_{\text{out}} \widetilde{\mathrm{d}p_f}$, exactly reproducing the invariant measure (A.129). Defining the *n-body Lorentz-invariant phase space*

$$\mathrm{d}\Pi_n \;\equiv\; (2\pi)^4\,\delta^{(4)}\Big(P - \textstyle\sum_{f=1}^{n} p_f\Big)\;\prod_{f=1}^{n} \frac{\mathrm{d}^3p_f}{(2\pi)^3\,2E_f}, \qquad P = \textstyle\sum_{\text{in}} p_i, \tag{A.137}$$

and substituting Eq. (A.135) into Eq. (A.136), every surviving V and T collects into a single overall VT from Eq. (A.134) divided by the $\prod_{\text{in}} V$:

$$\mathrm{d}P \;=\; |\mathcal{M}|^2\;\frac{V\,T}{\prod_{\text{in}} 2E_i\,V}\;\mathrm{d}\Pi_n. \tag{A.138}$$

Decay rate. For the decay of a single particle of mass M, there is one incoming line, so $\prod_{\text{in}} 2E_iV = 2MV$ in the rest frame. One factor of V cancels against the V in *Eq.* (A.138), and the rate is the probability per unit time, $\mathrm{d}\Gamma = \mathrm{d}P/T$:

$$\boxed{\mathrm{d}\Gamma \;=\; \frac{1}{2M}\,|\mathcal{M}|^2\,\mathrm{d}\Pi_n} \tag{A.139}$$

in the rest frame. The V and T have both cancelled, as they must for a physical observable; in a general frame $2M$ is replaced by $2E_M$, accounting for relativistic time dilation of the decay.

Cross section. For $2 \to n$ scattering there are two incoming lines, so $\prod_{\text{in}} 2E_iV = 4E_1E_2V^2$. Then Eq. (A.138) gives the transition rate $R = \mathrm{d}P/T = |\mathcal{M}|^2\,\mathrm{d}\Pi_n/(4E_1E_2V)$. The cross section is the rate divided by the incident flux $\mathcal{F}$. With our box normalization there is one particle of each species in the volume V, so each beam has number density $1/V$ and the flux of one beam on the other is $\mathcal{F} = |\mathbf{v}_1 - \mathbf{v}_2|/V$, with $\mathbf{v}_a = \mathbf{p}_a/E_a$ the velocities. The factor of $1/V$ in R cancels the $1/V$ in $\mathcal{F}$, leaving

$$\mathrm{d}\sigma \;=\; \frac{R}{\mathcal{F}} \;=\; \frac{1}{4E_1E_2\,|\mathbf{v}_1 - \mathbf{v}_2|}\,|\mathcal{M}|^2\,\mathrm{d}\Pi_n. \tag{A.140}$$

The kinematic prefactor is made manifestly Lorentz invariant by the identity (proved in Theorem A.32)

$$4E_1E_2\,|\mathbf{v}_1 - \mathbf{v}_2| \;=\; 4\sqrt{(p_1\!\cdot\!p_2)^2 - m_1^2m_2^2} \;\equiv\; F, \tag{A.141}$$

valid for collinear beams (the only configuration relevant to a flux), giving the master formula

$$\boxed{\mathrm{d}\sigma \;=\; \frac{1}{F}\,|\mathcal{M}|^2\,\mathrm{d}\Pi_n\,, \qquad F = 4\sqrt{(p_1\!\cdot\!p_2)^2 - m_1^2m_2^2}} \tag{A.142}$$

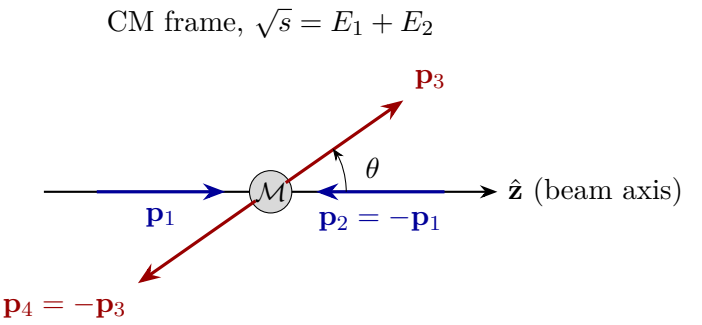

Figure A.3: Center-of-momentum kinematics for a $2 \to 2$ process. The incoming momenta are equal and opposite along the beam axis with magnitude p_i; the outgoing momenta are equal and opposite with magnitude p_f, at scattering angle θ. The invariant amplitude $\mathcal{M}$ sits at the vertex; the flux factor $F = 4p_i\sqrt{s}$ and the two-body phase space $\mathrm{d}\Pi_2 = (p_f/16\pi^2\sqrt{s})\,\mathrm{d}\Omega$ combine into Eq. (A.149).

with the invariant phase space (A.137). Equations (A.139) and (A.142), built on the relativistic normalization (A.128) and the invariant measure (A.129), are the formulae used unchanged throughout the book; the only model-dependent input is $|\mathcal{M}|^2$.

Worked Example A.32 (The invariant flux factor)**.** We prove the identity (A.141). Work in the center-of-momentum (CM) frame, where $\mathbf{p}_1 = -\mathbf{p}_2$; choose the common axis to be $\hat{\mathbf{z}}$ and write $|\mathbf{p}_1| = |\mathbf{p}_2| = p$, $p_1 = (E_1, 0, 0, p)$, $p_2 = (E_2, 0, 0, -p)$. Then $p_1 \cdot p_2 = E_1E_2 + p^2$ (the spatial parts are antiparallel, contributing $-(p)(-p) = +p^2$ in the mostly-minus metric), and using $E_a^2 = p^2 + m_a^2$,

$$\begin{aligned}(p_1\cdot p_2)^2 - m_1^2m_2^2 &= (E_1E_2 + p^2)^2 - (E_1^2 - p^2)(E_2^2 - p^2)\\ &= E_1^2E_2^2 + 2E_1E_2p^2 + p^4 - [E_1^2E_2^2 - (E_1^2 + E_2^2)p^2 + p^4]\\ &= 2E_1E_2\,p^2 + (E_1^2 + E_2^2)\,p^2 \;=\; p^2\,(E_1 + E_2)^2. \qquad \text{(A.143)}\end{aligned}$$

Hence $\sqrt{(p_1\cdot p_2)^2 - m_1^2m_2^2} = p\,(E_1 + E_2)$. On the other side, the beams are collinear and opposite, so the relative speed is $|\mathbf{v}_1 - \mathbf{v}_2| = p/E_1 + p/E_2 = p(E_1 + E_2)/(E_1E_2)$, and

$$4E_1E_2\,|\mathbf{v}_1 - \mathbf{v}_2| \;=\; 4E_1E_2\cdot\frac{p(E_1 + E_2)}{E_1E_2} \;=\; 4p\,(E_1 + E_2) \;=\; 4\sqrt{(p_1\cdot p_2)^2 - m_1^2m_2^2}, \qquad \text{(A.144)}$$

which is Eq. (A.141). Both sides are Lorentz scalars built from the invariants of the two incoming momenta, so the equality, established in the CM frame, holds in any frame related to it by a boost along the beam axis.

Worked Example A.33 (Two-body phase space and the $2 \to 2$ master formula)**.** The most-used special case is $2 \to 2$ scattering, the kinematic skeleton of QED's $e^+e^- \to \mu^+\mu^-$ (Chapter 17). We reduce Eq. (A.137) for $n = 2$ in the CM frame, with total energy $\sqrt{s} = E_1 + E_2$ and final momenta p_3, p_4 of magnitude p_f (Fig. A.3).

Start from

$$\mathrm{d}\Pi_2 \;=\; (2\pi)^4\,\delta^{(4)}(P - p_3 - p_4)\,\frac{\mathrm{d}^3p_3}{(2\pi)^3 2E_3}\,\frac{\mathrm{d}^3p_4}{(2\pi)^3 2E_4}, \qquad P = (\sqrt{s}, \mathbf{0}). \tag{A.145}$$

The spatial part of the delta function does the $\mathbf{p}_4$ integral, setting $\mathbf{p}_4 = -\mathbf{p}_3$ so that $p_f \equiv |\mathbf{p}_3| = |\mathbf{p}_4|$, and leaves

$$\mathrm{d}\Pi_2 \;=\; \frac{1}{(2\pi)^2}\,\delta(\sqrt{s} - E_3 - E_4)\,\frac{\mathrm{d}^3p_3}{4E_3E_4}. \tag{A.146}$$

Write $\mathrm{d}^3p_3 = p_f^2\,\mathrm{d}p_f\,\mathrm{d}\Omega$, with $E_3 = \sqrt{p_f^2 + m_3^2}$, $E_4 = \sqrt{p_f^2 + m_4^2}$. The remaining delta function fixes p_f through the total energy; since

$$\frac{\mathrm{d}(E_3 + E_4)}{\mathrm{d}p_f} \;=\; \frac{p_f}{E_3} + \frac{p_f}{E_4} \;=\; \frac{p_f(E_3 + E_4)}{E_3E_4} \;=\; \frac{p_f\sqrt{s}}{E_3E_4}, \tag{A.147}$$

integrating over p_f against $\delta(\sqrt{s} - E_3 - E_4)$ supplies the Jacobian $E_3E_4/(p_f\sqrt{s})$:

$$\mathrm{d}\Pi_2 \;=\; \frac{1}{(2\pi)^2}\,\frac{p_f^2}{4E_3E_4}\,\frac{E_3E_4}{p_f\sqrt{s}}\,\mathrm{d}\Omega \;=\; \frac{1}{16\pi^2}\,\frac{p_f}{\sqrt{s}}\,\mathrm{d}\Omega. \tag{A.148}$$

For the flux, Eq. (A.141) in the CM frame gives $F = 4\sqrt{(p_1\cdot p_2)^2 - m_1^2m_2^2} = 4p_i(E_1 + E_2) = 4p_i\sqrt{s}$, with p_i the magnitude of the incoming CM momentum. Combining with Eq. (A.142),

$$\frac{\mathrm{d}\sigma}{\mathrm{d}\Omega} \;=\; \frac{1}{F}\,|\mathcal{M}|^2\,\frac{\mathrm{d}\Pi_2}{\mathrm{d}\Omega} \;=\; \frac{1}{4p_i\sqrt{s}}\,|\mathcal{M}|^2\,\frac{1}{16\pi^2}\,\frac{p_f}{\sqrt{s}} \;=\; \frac{|\mathcal{M}|^2}{64\pi^2 s}\,\frac{p_f}{p_i}. \tag{A.149}$$

When all masses are negligible compared to $\sqrt{s}$, $p_f = p_i$ and this collapses to the compact $\mathrm{d}\sigma/\mathrm{d}\Omega = |\mathcal{M}|^2/(64\pi^2 s)$. This is the normalization against which QED reports $e^+e^- \to \mu^+\mu^-$ in Chapter 17; the present section fixes the prefactor, and that chapter supplies $|\mathcal{M}|^2$ from the spin-summed traces.

With the source sign $+J\phi$, the generating functionals Z, $W = -i\ln Z$, Γ with $\delta\Gamma/\delta\varphi_{\mathrm{cl}} = -J$, the split $\mathbf{S} = 1 + iT$ with the $-i\lambda$ vertex, and the cross-section and decay master formulae now all fixed and mutually consistent, the remaining error-prone conventions are those of internal symmetry. The next section takes the coupling- and vertex-sign conventions fixed here—in particular the $-i$ that the $+iS_{\mathrm{int}}$ in Eq. (A.113) forces onto every vertex—and places the matching sign in the covariant derivative $D_\mu = \partial_\mu - igA_\mu^a T^a$, fixing the charge convention, the field-strength normalization, and the generator and structure-constant conventions so that the gauge vertices inherit the signs established here.

A.6 Internal Symmetry and Gauge Conventions

The previous section closed the analytic and combinatorial conventions by tracing every Feynman-rule sign back to a single source: the factor i that multiplies the action in the path-integral weight e^{iS} of Eq. (A.113), which forces the $-i$ on the scalar vertex (A.132) and, through the $+J\phi$ source coupling (A.112), the sign in the Legendre relation $\delta\Gamma/\delta\varphi_{\rm cl} = -J$. Internal-symmetry conventions are the next, and historically the most error-prone, place where a single misplaced sign metastasizes. The covariant-derivative sign, the charge convention, the field-strength normalization, the Hermiticity and trace normalization of the generators, and the reality and antisymmetry of the structure constants are not independent choices: once the coupling enters the action through a covariant derivative, the sign in that derivative is fixed against the $+iS_{\rm int}$ of the previous section, and everything else—the field strength, the Yang–Mills kinetic normalization, the gauge transformation law, the vertices—follows by algebra. This section makes that chain explicit. It is the single home of the gauge-sign conventions of QED and Yang–Mills theory; the physics that motivates them is built in Chapter 8 (the classical $U(1)$ gauge principle) and Chapter 25 (the Yang–Mills connection and its curvature), and the group-theoretic numerics—the Casimirs C_A, C_F, the index T_F, and the explicit structure-constant tables—are deferred to Chapter B. What is owned here is the precise placement of every sign and factor, derived rather than asserted.

A.6.1 Generators, the Lie algebra, and the structure constants

A gauge theory is built on a compact Lie group G—the *gauge group*—acting on the matter fields through a chosen unitary representation. Throughout the book the matter of the benchmark theories sits in the fundamental representation: the electron in the (one-dimensional) charge-carrying representation of $U(1)$, the quarks in the fundamental $\mathbf{N}$ of $\mathrm{SU}(N)$. The infinitesimal action is generated by a basis of the Lie algebra, and the conventions for that basis are the root of all the sign questions that follow.

Definition A.34 (Generators, structure constants, and normalization)**.** Let G be a compact Lie group of dimension $\dim G$ with Lie algebra $\mathfrak{g}$. We choose a basis $\{T^a\}_{a=1}^{\dim G}$ of Hermitian generators in the representation under consideration,

$$(T^a)^\dagger \;=\; T^a, \tag{A.150}$$

satisfying the Lie-algebra commutation relations with real structure constants f^{abc},

$$\Big[T^a, T^b\Big] \;=\; i\, f^{abc}\, T^c, \tag{A.151}$$

and normalized in the fundamental representation by

$$\mathrm{tr}\big(T^a T^b\big) \;=\; \tfrac{1}{2}\,\delta^{ab}. \tag{A.152}$$

A group element connected to the identity is the exponential $U = \exp(i\,\alpha^a T^a)$ with real parameters α^a; the factor of i in the exponent, combined with (A.150), makes U unitary, $U^\dagger = U^{-1}$.

Three conventional choices are buried in Theorem A.34, and each is made for a definite reason. The Hermiticity (A.150) is the choice that keeps the conserved charges $Q^a = \int \mathrm{d}^3x\, J^{0a}$ Hermitian observables; it is the physicist's convention, distinct from the mathematician's anti-Hermitian generators (for which the i in (A.151) would be absent). The factor of i in (A.151) is then forced: the commutator of two Hermitian matrices is anti-Hermitian, so it must equal i times a Hermitian combination, and (A.151) is the statement that this combination is again a real combination of generators. The normalization (A.152) fixes the overall scale of the T^a—without it the structure constants could be rescaled at will—and the particular value $\frac{1}{2}$ is the one that makes the canonical gauge kinetic term carry the coefficient $-\frac{1}{4}$, as we prove in Section A.6.4. These are exactly the conventions stated globally in the style canon and developed group-theoretically in Chapter B; here we record them and extract their immediate consequences, which are themselves frequently misquoted.

Proposition A.35 (Reality and total antisymmetry of f^{abc})**.** *With the conventions* (A.150)–(A.152)*, the structure constants are real and totally antisymmetric in their three indices, and admit the closed form*

$$f^{abc} \;=\; -\,2\,i\,\mathrm{tr}\big(\,\big[T^a, T^b\big]\,T^c\big). \tag{A.153}$$

Worked Example A.36 (Proof of Theorem A.35)**.** Each claim follows from a one-line manipulation of (A.151), (A.152), and the cyclicity of the trace; we carry all three out.

The closed form. Multiply (A.151) on the right by T^c and take the trace,

$$\mathrm{tr}\big(\,\big[T^a, T^b\big]\,T^c\big) \;=\; i\,f^{abd}\,\mathrm{tr}(T^d T^c) \;=\; i\,f^{abd}\,\tfrac{1}{2}\,\delta^{dc} \;=\; \tfrac{i}{2}\,f^{abc}, \tag{A.154}$$

using (A.152) in the second step. Solving for f^{abc} gives (A.153).

Reality. The commutator of two Hermitian matrices is anti-Hermitian: from (A.150),

$$\big[T^a, T^b\big]^\dagger \;=\; (T^aT^b - T^bT^a)^\dagger \;=\; T^bT^a - T^aT^b \;=\; -\big[T^a, T^b\big]. \tag{A.155}$$

Substituting (A.151) into both sides, $(i f^{abc}T^c)^\dagger = -i\,(f^{abc})^*\,T^c$ on the left (the T^c being Hermitian) and $-\,i f^{abc}T^c$ on the right; equating coefficients of the linearly independent T^c gives $(f^{abc})^* = f^{abc}$, so $f^{abc} \in \mathbb{R}$.

Total antisymmetry. Antisymmetry in the first two indices is immediate from the antisymmetry of the commutator, $f^{abc} = -f^{bac}$. For the remaining swaps it is cleanest to work with the manifestly trace-defined object

$$G^{abc} \;\equiv\; \mathrm{tr}(T^a\,\big[T^b, T^c\big]\,) \;=\; \tfrac{i}{2}\,f^{abc}, \tag{A.156}$$

the last equality being (A.154) read with the generators cyclically permuted, $\mathrm{tr}(T^a\,[T^b,T^c]) = \mathrm{tr}([T^b,T^c]\,T^a) = \frac{i}{2}f^{bca} = \frac{i}{2}f^{abc}$, where $f^{bca} = f^{abc}$ is the cyclicity that already follows from antisymmetry in the first two slots once total antisymmetry is established; we use it only to fix the proportionality constant. The object G^{abc} is antisymmetric in $b \leftrightarrow c$ because the commutator is, while it is invariant under the cyclic permutation $(a,b,c) \to (b,c,a)$ because the trace is:

$$\begin{aligned} G^{bca} &= \mathrm{tr}(T^bT^cT^a - T^bT^aT^c) \;=\; \mathrm{tr}(T^aT^bT^c) - \mathrm{tr}(T^aT^cT^b) \\ &= \mathrm{tr}(T^a\,[T^b,T^c]\,) \;=\; G^{abc}, \end{aligned} \tag{A.157}$$

where the middle step used cyclicity of the trace to bring T^a to the front of each term. An object antisymmetric in one adjacent pair and invariant under cyclic rotation is totally antisymmetric: the cyclic rotation carries the antisymmetric pair through every adjacent position, so the sign flips under every transposition of indices. Hence $f^{abc} \propto G^{abc}$ is totally antisymmetric, as claimed.

Total antisymmetry is the property that makes the adjoint representation $(\mathrm{ad}\,T^a)^{bc} = -if^{abc}$ itself Hermitian and the Yang–Mills self-interactions manifestly real; the Jacobi identity satisfied by the f^{abc}, the existence of the quadratic Casimirs, and the explicit numerics $f^{acd}f^{bcd} = C_A\,\delta^{ab}$, $\mathrm{tr}(T^aT^b) = T_F\,\delta^{ab}$ with $T_F = \frac{1}{2}$ in the fundamental, and the like are the business of Chapter B (Eqs. (B.2) and (B.61)) and are imported, not reproved, wherever the book needs a numerical color factor.

A.6.2 The covariant derivative and the matter transformation law

The gauge field enters physics through the covariant derivative, and the sign in front of the coupling there is *the* most frequently mis-set convention in the subject. We fix it, and then *derive*—we do not posit—the transformation law of the gauge field that this choice forces.

It is convenient to package the gauge field into a single Lie-algebra-valued (matrix) object,

$$A_\mu \;\equiv\; A_\mu^a\,T^a, \tag{A.158}$$

which is Hermitian because the components A_μ^a are real and the T^a are Hermitian. The matter field ψ transforms in the representation carried by the T^a.

Definition A.37 (Covariant derivative and the matter law)**.** The covariant derivative acting on a matter field ψ in the chosen representation is

$$D_\mu\psi \;=\; (\partial_\mu - i\,g\,A_\mu)\psi \;=\; (\partial_\mu - i\,g\,A_\mu^aT^a)\psi, \tag{A.159}$$

with g the gauge coupling. Under a gauge transformation parametrized by $U(x) = \exp(i\alpha^a(x)T^a) \in G$, the matter field transforms homogeneously,

$$\psi(x) \;\longmapsto\; \psi'(x) \;=\; U(x)\,\psi(x). \tag{A.160}$$

The sign in (A.159) is $-ig$, and it is fixed against the e^{iS} weight: with this sign the interaction extracted from the matter kinetic term is $+iS_{\text{int}}$ at a vertex carrying a single explicit $+g$, matching the $+iS_{\text{int}}$ convention that produced the $-i\lambda$ scalar vertex of Section A.5.4, as we verify in Theorem A.44. We now require that $D_\mu\psi$ transform the same way as ψ itself—this is the entire point of the construction, that $\bar\psi\, i\not{D}\,\psi$ be gauge invariant—and read off what the gauge field must do.

Proposition A.38 (Gauge transformation of the connection)**.** *The covariant derivative* (A.159) *transforms covariantly, $D_\mu\psi \mapsto U\,(D_\mu\psi)$, if and only if the matrix connection transforms by the affine (inhomogeneous) law*

$$A_\mu \;\longmapsto\; A'_\mu \;=\; U\,A_\mu\,U^{-1} \;-\; \frac{i}{g}\,(\partial_\mu U)\,U^{-1}. \tag{A.161}$$

Infinitesimally, with $U = 1 + i\alpha^a T^a + O(\alpha^2)$,

$$\delta A^a_\mu \;=\; \frac{1}{g}\,\partial_\mu\alpha^a + f^{abc}A^b_\mu\,\alpha^c \;=\; \frac{1}{g}(\partial_\mu\alpha^a + g\,f^{abc}A^b_\mu\alpha^c) \;=\; \frac{1}{g}\,(D_\mu\alpha)^a, \tag{A.162}$$

where $(D_\mu\alpha)^a = \partial_\mu\alpha^a + gf^{abc}A^b_\mu\alpha^c$ is the covariant derivative in the adjoint representation.

Proof. Demand $D'_\mu\psi' = U(D_\mu\psi)$ with $\psi' = U\psi$ and $D'_\mu = \partial_\mu - igA'_\mu$. The left-hand side is

$$D'_\mu(U\psi) \;=\; (\partial_\mu U)\,\psi + U\,\partial_\mu\psi - ig\,A'_\mu\,U\,\psi, \tag{A.163}$$

where the product rule has acted on $U\psi$. The right-hand side is

$$U\,(D_\mu\psi) \;=\; U\,\partial_\mu\psi - ig\,U\,A_\mu\,\psi. \tag{A.164}$$

The terms $U\,\partial_\mu\psi$ cancel between the two sides. Equality for arbitrary ψ then requires the operator identity

$$(\partial_\mu U) - ig\,A'_\mu\,U \;=\; -\,ig\,U\,A_\mu. \tag{A.165}$$

Solve for A'_μ by isolating the term containing it and right-multiplying by U^{-1}:

$$ig\,A'_\mu\,U \;=\; ig\,U\,A_\mu + (\partial_\mu U) \quad\Longrightarrow\quad A'_\mu \;=\; U\,A_\mu\,U^{-1} + \frac{1}{ig}\,(\partial_\mu U)\,U^{-1}, \tag{A.166}$$

and $1/(ig) = -i/g$ gives exactly (A.161). For the infinitesimal form, expand $U = 1 + i\alpha + O(\alpha^2)$ with $\alpha \equiv \alpha^a T^a$ and $U^{-1} = 1 - i\alpha + O(\alpha^2)$:

$$A'_\mu = (1 + i\alpha)\,A_\mu\,(1 - i\alpha) - \frac{i}{g}\,(i\,\partial_\mu\alpha)\,(1 - i\alpha) + O(\alpha^2)$$

$$= A_\mu + i\,[\alpha, A_\mu] + \frac{1}{g}\,\partial_\mu\alpha + O(\alpha^2), \tag{A.167}$$

so that $\delta A_\mu = \frac{1}{g}\partial_\mu\alpha + i\,[\alpha, A_\mu]$. Projecting onto the basis with $A_\mu = A_\mu^c T^c$, $\alpha = \alpha^b T^b$, the commutator is $i\,[\alpha, A_\mu] = i\,\alpha^b A_\mu^c \left[T^b, T^c\right] = i\,\alpha^b A_\mu^c\,(i f^{bcd} T^d) = -f^{bcd}\alpha^b A_\mu^c\,T^d$. Renaming $d \to a$ and using the total antisymmetry of f (Theorem A.35), $-f^{bca} = -f^{abc}\cdot(-1)\cdot(-1) = \ldots$; concretely $-f^{bca}\alpha^b A_\mu^c = f^{abc}A_\mu^b\alpha^c$ after relabeling the dummy pair $b \leftrightarrow c$ and using $f^{acb} = -f^{abc}$. The component thus reads $\delta A_\mu^a = \frac{1}{g}\partial_\mu\alpha^a + f^{abc}A_\mu^b\alpha^c$, which is (A.162). □

The structure of (A.161) is worth naming: the homogeneous piece $UA_\mu U^{-1}$ rotates the connection like an adjoint-valued field, while the inhomogeneous piece $-\frac{i}{g}(\partial_\mu U)U^{-1}$ is the affine shift characteristic of a connection. It is the inhomogeneous piece that allows the gauge field to absorb the $\partial_\mu U$ generated when the derivative hits the matter rotation, and the factor $1/g$ there is precisely what is needed for the cancellation in the proof. One consistency check is immediate and worth recording, because it is the kind of thing a sign error breaks.

Worked Example A.39 (The transformed connection stays Hermitian)**.** The matrix A_μ is Hermitian, and gauge invariance of the theory requires the transformed A'_μ to be Hermitian as well; otherwise the components A'^a_μ would not be real and the gauge field would not be a genuine vector boson field. We verify this from (A.161). The homogeneous term is manifestly Hermitian, $(UA_\mu U^{-1})^\dagger = U^{-1\dagger}A_\mu^\dagger U^\dagger = UA_\mu U^{-1}$, using $A_\mu^\dagger = A_\mu$ and $U^\dagger = U^{-1}$. For the inhomogeneous term, differentiate $UU^{-1} = 1$ to obtain the identity $(\partial_\mu U)U^{-1} = -U(\partial_\mu U^{-1})$, and compute

$$\Big[-\frac{i}{g}(\partial_\mu U)U^{-1}\Big]^\dagger = \frac{i}{g}\,(U^{-1})^\dagger(\partial_\mu U)^\dagger = \frac{i}{g}\,U\,(\partial_\mu U^{-1}) = -\frac{i}{g}\,(\partial_\mu U)U^{-1}, \tag{A.168}$$

where $U^{-1\dagger} = U$, $(\partial_\mu U)^\dagger = \partial_\mu U^\dagger = \partial_\mu U^{-1}$, and the last step used the differentiated identity. The inhomogeneous term is therefore Hermitian as well, so $A'^\dagger_\mu = A'_\mu$ and the transformed components remain real. The factor of i in $-\frac{i}{g}(\partial_\mu U)U^{-1}$ is exactly what is required for this: a real coefficient there would have produced an anti-Hermitian shift.

A.6.3 The field strength as the curvature of the connection

The field strength is the curvature of the gauge connection: it measures the failure of two covariant derivatives to commute. Defining it this way—rather than writing down $\partial_\mu A_\nu - \partial_\nu A_\mu + \cdots$ by hand—makes its gauge covariance automatic and fixes every sign in it at once.

Definition A.40 (Field strength)**.** The field-strength matrix is the commutator of two covariant derivatives, normalized to strip the coupling:

$$F_{\mu\nu} \;\equiv\; \frac{i}{g}\,[D_\mu, D_\nu] \;=\; F^a_{\mu\nu}\,T^a. \tag{A.169}$$

Proposition A.41 (Component form of the field strength)**.** *The definition* (A.169) *evaluates to*

$$F_{\mu\nu} \;=\; \partial_\mu A_\nu - \partial_\nu A_\mu - ig\,[A_\mu, A_\nu]\,, \tag{A.170}$$

which in components is exactly the Yang–Mills field strength of Eq. (A.56)*,*

$$F^a_{\mu\nu} \;=\; \partial_\mu A^a_\nu - \partial_\nu A^a_\mu + g\,f^{abc} A^b_\mu A^c_\nu. \tag{A.171}$$

Proof. The commutator $[D_\mu, D_\nu]$ is a differential operator; we evaluate it acting on an arbitrary ψ and read off the multiplication operator that results. With $D_\mu = \partial_\mu - igA_\mu$,

$$D_\mu D_\nu \psi \;=\; \partial_\mu\partial_\nu\psi - ig\,(\partial_\mu A_\nu)\psi - ig\,A_\nu\,\partial_\mu\psi - ig\,A_\mu\,\partial_\nu\psi - g^2\,A_\mu A_\nu\,\psi, \tag{A.172}$$

where the term $-ig\,\partial_\mu(A_\nu\psi)$ has been expanded by the product rule into $-ig(\partial_\mu A_\nu)\psi - igA_\nu\partial_\mu\psi$. Antisymmetrizing in $\mu \leftrightarrow \nu$, the symmetric pieces drop out: $\partial_\mu\partial_\nu\psi$ cancels, and the two cross terms $-igA_\nu\partial_\mu\psi - igA_\mu\partial_\nu\psi$ are symmetric under the swap and cancel as well. What survives is

$$[D_\mu, D_\nu]\,\psi \;=\; -ig\,(\partial_\mu A_\nu - \partial_\nu A_\mu)\psi - g^2\,[A_\mu, A_\nu]\,\psi. \tag{A.173}$$

Since this holds for all ψ, the operator identity is

$$[D_\mu, D_\nu] = -ig(\partial_\mu A_\nu - \partial_\nu A_\mu) - g^2\,[A_\mu, A_\nu] = -ig\big(\partial_\mu A_\nu - \partial_\nu A_\mu - ig\,[A_\mu, A_\nu]\,\big). \tag{A.174}$$

Multiplying by i/g as in (A.169),

$$F_{\mu\nu} = \frac{i}{g}\,(-ig)\big(\partial_\mu A_\nu - \partial_\nu A_\mu - ig\,[A_\mu, A_\nu]\,\big) = \partial_\mu A_\nu - \partial_\nu A_\mu - ig\,[A_\mu, A_\nu]\,, \tag{A.175}$$

which is (A.170); the prefactor $\frac{i}{g}\cdot(-ig) = 1$ is the reason for the particular normalization chosen in the definition. Finally project onto the basis. The commutator term is $-ig\,[A_\mu, A_\nu] = -ig\,A^b_\mu A^c_\nu\,\big[T^b, T^c\big] = -ig\,A^b_\mu A^c_\nu (if^{bcd}T^d) = g\,f^{bcd}A^b_\mu A^c_\nu\,T^d$, so with $A_\nu = A^a_\nu T^a$ in the linear terms and renaming $d \to a$,

$$F^a_{\mu\nu} = \partial_\mu A^a_\nu - \partial_\nu A^a_\mu + g\,f^{abc} A^b_\mu A^c_\nu, \tag{A.176}$$

which is (A.171). The sign of the gf^{abc} term is positive, matching Eq. (A.56) and Yang–Mills theory of Chapter 25. □

The payoff of defining $F_{\mu\nu}$ as a curvature is that its gauge transformation is now forced and homogeneous.

Proposition A.42 (Adjoint covariance of the field strength)**.** *Under a gauge transformation* (A.161)*, the field strength transforms in the adjoint representation,*

$$F_{\mu\nu} \longmapsto F'_{\mu\nu} = U\,F_{\mu\nu}\,U^{-1}. \tag{A.177}$$

Proof. Theorem A.38 established that $D_\mu\psi \mapsto U(D_\mu\psi)$ for every ψ, i.e. the covariant derivative transforms by conjugation as an operator, $D'_\mu = U\,D_\mu\,U^{-1}$. A commutator of conjugated operators is the conjugate of the commutator, $[UD_\mu U^{-1}, UD_\nu U^{-1}] = U\,[D_\mu, D_\nu]\,U^{-1}$, the inner $U^{-1}U$ telescoping. Hence

$$F'_{\mu\nu} = \frac{i}{g}\left[D'_\mu, D'_\nu\right] = \frac{i}{g}\,U\,[D_\mu, D_\nu]\,U^{-1} = U\,F_{\mu\nu}\,U^{-1}. \tag{A.178}$$

□

Because $F_{\mu\nu}$ is adjoint-covariant rather than invariant, it cannot itself be a Lagrangian; the invariant is its trace square, which is the subject of the next subsection and the place where the normalization (A.152) earns its value.

A.6.4 The Yang–Mills Lagrangian and the canonical $-\frac{1}{4}$ normalization

The gauge-invariant kinetic term is built from $F_{\mu\nu}$ by taking the unique (up to normalization) Lorentz scalar that is also gauge invariant, namely the trace of $F_{\mu\nu}F^{\mu\nu}$. Gauge invariance is immediate from Theorem A.42 and the cyclicity of the trace,

$$\operatorname{tr}(F'_{\mu\nu}F'^{\mu\nu}) = \operatorname{tr}(UF_{\mu\nu}U^{-1}UF^{\mu\nu}U^{-1}) = \operatorname{tr}(F_{\mu\nu}F^{\mu\nu}), \tag{A.179}$$

the inner $U^{-1}U$ telescoping and the outer U, U^{-1} cancelling under the trace. The question is the overall coefficient, and here the normalization (A.152) is decisive.

Proposition A.43 (The trace normalization fixes the $-\frac{1}{4}$)**.** *With the fundamental normalization* $\operatorname{tr}(T^aT^b) = \frac{1}{2}\delta^{ab}$*, the gauge-invariant kinetic term*

$$\mathcal{L}_{\text{gauge}} = -\tfrac{1}{2}\operatorname{tr}(F_{\mu\nu}F^{\mu\nu}) \tag{A.180}$$

equals the canonically normalized component form

$$\mathcal{L}_{\text{gauge}} = -\tfrac{1}{4}\,F^a_{\mu\nu}F^{a\,\mu\nu}, \tag{A.181}$$

in which each gauge field A^a_μ has the same kinetic normalization as the abelian Maxwell field.

Proof. Expand the matrix trace in the basis using $F_{\mu\nu} = F^a_{\mu\nu} T^a$:

$$\operatorname{tr}(F_{\mu\nu} F^{\mu\nu}) = F^a_{\mu\nu} F^{b\,\mu\nu}\, \operatorname{tr}(T^a T^b) = F^a_{\mu\nu} F^{b\,\mu\nu}\, \tfrac{1}{2}\delta^{ab} = \tfrac{1}{2}\, F^a_{\mu\nu} F^{a\,\mu\nu}, \tag{A.182}$$

where the second equality is exactly (A.152). Multiplying by $-\frac{1}{2}$ gives $-\frac{1}{2}\operatorname{tr}(FF) = -\frac{1}{4} F^a_{\mu\nu} F^{a\,\mu\nu}$, which is (A.181). The coefficient $-\frac{1}{4}$ is therefore not an independent convention: it is the product of two prior choices, the $-\frac{1}{2}$ in front of the trace (fixed by demanding the abelian limit reproduce Maxwell, below) and the $\frac{1}{2}$ in $\operatorname{tr}(T^a T^b)$. Had the generators been normalized to $\operatorname{tr}(T^a T^b) = \delta^{ab}$ instead, (A.182) would have produced $F^a F^a$ with no $\frac{1}{2}$, and the same $-\frac{1}{2}\operatorname{tr}(FF)$ would have read $-\frac{1}{2} F^a F^a$, which is *not* the canonical $-\frac{1}{4}$; one would then be forced to rescale either the trace coefficient or the gauge field to recover a properly normalized propagator. The pairing of $\operatorname{tr}(T^a T^b) = \frac{1}{2}\delta^{ab}$ with $-\frac{1}{2}\operatorname{tr}(FF)$ is what makes the component coefficient come out at the canonical $-\frac{1}{4}$. □

The sign of (A.181)—the minus—is the gauge-field counterpart of the scalar's $+\frac{1}{2}(\partial\phi)^2$ and is fixed for the same reason given in Section A.2.6 and Theorem A.10: in mostly-minus signature, $-\frac{1}{4} F^a_{\mu\nu} F^{a\,\mu\nu} = \frac{1}{2}(\mathbf{E}^a \cdot \mathbf{E}^a - \mathbf{B}^a \cdot \mathbf{B}^a)$, so the electric energy density is positive and the Hamiltonian is bounded below. With the kinetic term fixed, the coupling sign of Eq. (A.159) can be checked against the vertex-sign convention handed over from the previous section.

Worked Example A.44 (The gauge vertices and consistency with the $+iS_{\text{int}}$ convention)**.** The previous section fixed every vertex to be $i\times$(coupling structure from $\mathcal{L}_{\text{int}}$), the explicit i being the $+iS_{\text{int}}$ in the weight e^{iS} of Eq. (A.113); this is what made the ϕ^4 vertex $-i\lambda$. We check that the sign $-ig$ in (A.159) delivers gauge vertices consistent with that rule.

Expand the matter kinetic term using $\not{D} = \gamma^\mu D_\mu = \gamma^\mu(\partial_\mu - igA^a_\mu T^a)$:

$$\bar\psi\, i\not{D}\,\psi = \bar\psi\, i\not{\partial}\,\psi + g\,\bar\psi\,\gamma^\mu T^a \psi\, A^a_\mu, \tag{A.183}$$

the second term being the interaction $\mathcal{L}_{\text{int}} = g\,\bar\psi\gamma^\mu T^a \psi\, A^a_\mu$, with the $+g$ produced by $i\cdot(-ig) = +g$ when the i of $i\not{D}$ meets the $-ig$ of the covariant derivative. The Feynman rule for the quark–gluon vertex is then $i\times$(coefficient of the three fields), namely

$$\text{quark–gluon vertex} \;=\; i\,g\,\gamma^\mu T^a, \tag{A.184}$$

with a single explicit power of $+g$, exactly as the $+iS_{\text{int}}$ rule requires (Fig. A.4). For the abelian thread the same expansion with $D_\mu = \partial_\mu + ieA_\mu$ gives $\mathcal{L}_{\text{int}} = -e\,\bar\psi\gamma^\mu\psi\, A_\mu$ (the relative sign because the electron charge is $-e$; see Section A.6.5), and the QED vertex

$$\text{QED electron–photon vertex} \;=\; -\,i\,e\,\gamma^\mu. \tag{A.185}$$

Both vertices carry the single factor of i from e^{iS}, and the sign in each—the $+g$ of (A.184) and the $-e$ of (A.185)—is dictated by the covariant-derivative sign together with the charge of the matter field, not chosen independently.

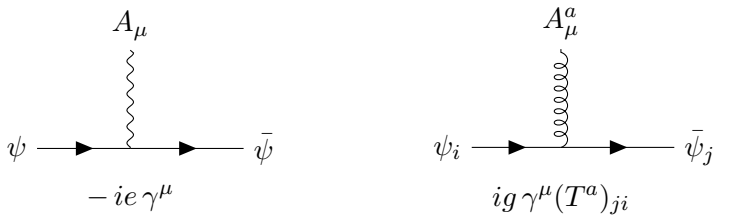

Figure A.4: The two minimal-coupling vertices in the book's conventions. Left: the QED electron–photon vertex $-ie\gamma^\mu$ from $\mathcal{L}_{\text{int}} = -e\bar{\psi}\gamma^\mu\psi A_\mu$, with the minus sign tracing to the electron charge $-e$. Right: the quark–gluon vertex $ig\gamma^\mu(T^a)_{ji}$ from $\mathcal{L}_{\text{int}} = g\bar{\psi}\gamma^\mu T^a\psi A^a_\mu$, with the $+g$ tracing to the $-ig$ in the covariant derivative (A.159). Both carry one factor of i from the e^{iS} weight. The full nonabelian Feynman rules, including the triple- and quartic-gluon vertices from $-\frac{1}{4}F^a_{\mu\nu}F^{a\,\mu\nu}$, are derived in Chapter 26.

A.6.5 The abelian reduction and the charge convention

The abelian case is not a separate convention but the $U(1)$ specialization of everything above, and seeing it as such resolves the single most common confusion in the subject: why the electron's covariant derivative carries $+ie$ while the nonabelian one carries $-ig$. The two are the same rule.

For $G = U(1)$ the algebra is one-dimensional; the single "generator" acting on a field is just its charge, the real number q by which the field is rotated. The structure constants vanish identically, so $f^{abc} = 0$ and the commutator term in the field strength drops out. The covariant derivative (A.159) becomes, for a field of charge q,

$$D_\mu\psi \;=\; (\partial_\mu - i\,q\,A_\mu)\psi, \tag{A.186}$$

with the *same* $-i$ as the nonabelian master formula—the charge q here plays the role of $g\,T^a$. The electron is the charge-$(-e)$ field with $e > 0$ the elementary charge, so substituting $q = -e$,

$$D_\mu\psi \;=\; (\partial_\mu - i(-e)A_\mu)\psi \;=\; (\partial_\mu + i\,e\,A_\mu)\psi. \tag{A.187}$$

The $+ie$ on the electron is therefore not a sign flip relative to the nonabelian $-ig$: it is the universal $-i\,q\,A_\mu$ evaluated at the electron's negative charge $q = -e$. This is the reconciliation of Eqs. (A.159) and (A.187), and it is the frozen QED convention used from Chapter 8 onward, matching the QED Lagrangian fixed in Theorem A.11 of the metric section.

The field strength reduces, with $f^{abc} = 0$, to the abelian Maxwell tensor

$$F_{\mu\nu} = \frac{i}{q}\,[D_\mu, D_\nu] = \partial_\mu A_\nu - \partial_\nu A_\mu, \tag{A.188}$$

gauge invariant on its own (no conjugation, since $U(1)$ is abelian and $UFU^{-1} = F$), and the kinetic term $-\frac{1}{4}F_{\mu\nu}F^{\mu\nu}$ is the Maxwell action whose normalization Theorem A.43 was built to reproduce in the nonabelian case. The gauge transformation of Theorem A.38 reduces, for a field of charge q transforming as $\psi \mapsto e^{iq\lambda(x)}\psi$, to the inhomogeneous shift

$$A_\mu \;\longmapsto\; A_\mu + \partial_\mu \lambda, \tag{A.189}$$

the $-\frac{i}{q}(\partial_\mu U)U^{-1}$ term of (A.161) collapsing to $-\frac{i}{q}(iq\,\partial_\mu\lambda) = \partial_\mu\lambda$ for $U = e^{iq\lambda}$. (This is the same transformation written in Chapter 8 with gauge parameter $\alpha = -\lambda$; the relative sign of the parameter is immaterial, the physical content being $D_\mu\psi \mapsto e^{iq\lambda}D_\mu\psi$.) The electron's electromagnetic current and the verification that minimal coupling is *derived*, not imposed, by promoting the rigid phase symmetry $\psi \to e^{iq\lambda}\psi$ to a local one are the content of Chapter 8 (the gauge principle); here we have only fixed the signs that chapter then uses.

Finally we record the fine-structure normalization, used everywhere QED reports a number. The dimensionless coupling that organizes the perturbation series is

$$\alpha \;\equiv\; \frac{e^2}{4\pi} \;\approx\; \frac{1}{137.036} \qquad \text{(at low energy)}, \tag{A.190}$$

with the 4π the rationalized Heaviside–Lorentz convention consistent with the $-\frac{1}{4}F^2$ normalization and the natural units of this book; the nonabelian counterpart is $\alpha_s \equiv g^2/4\pi$. The running of α with scale, and Schwinger's $a_e = \alpha/2\pi$, are carried numbers of Chapter 24 and the $g-2$ chapter, computed in the scheme fixed next.

Notation Watch

The apparent clash between the nonabelian $D_\mu = \partial_\mu - igA^a_\mu T^a$ and the QED $D_\mu = \partial_\mu + ieA_\mu$ is illusory: both are the single rule $D_\mu = \partial_\mu - i(\text{charge})A_\mu$, with the QED $+ie$ arising solely because the electron's charge $q = -e$ is negative. A book that wrote $D_\mu = \partial_\mu + igA^a_\mu T^a$ for the nonabelian case (the opposite sign, used by some references) would flip the sign of every structure-constant term in $F^a_{\mu\nu}$ and of every gauge vertex; we never use that variant.

With the covariant-derivative sign $-ig$, the charge convention $q = -e$ for the electron, the field strength $F^a_{\mu\nu} = \partial_\mu A^a_\nu - \partial_\nu A^a_\mu + g f^{abc}A^b_\mu A^c_\nu$ as the curvature (A.169), the Hermitian generators with $\left[T^a, T^b\right] = if^{abc}T^c$ and $\mathrm{tr}(T^aT^b) = \frac{1}{2}\delta^{ab}$, the finite gauge law (A.161), and the canonical $-\frac{1}{4}F^a_{\mu\nu}F^{a\,\mu\nu}$ all fixed and mutually consistent, the dimensionful object handed forward is the coupling itself. The gauge couplings e and g are dimensionless in $d = 4$, as counted in Section A.1.8; the next section takes that dimensionlessness and shows what happens to it the moment one leaves four dimensions, promoting $g \to g\,\mu^\varepsilon$ and $e \to e\,\mu^\varepsilon$ so that the dimensionless expansion parameter survives dimensional regularization.

A.7 Regularization and Renormalization-Scheme Conventions

The previous section settled the gauge couplings and found, for both the abelian e and the nonabelian g, the mass dimension $[\,e\,] = [\,g\,] = (4-d)/2$ recorded in (A.16); the quartic scalar coupling came out as $[\,\lambda\,] = 4-d$ in (A.14). In the physical dimension $d = 4$ all three vanish, which is precisely the dimensionlessness that Theorem A.6 identified with renormalizability. But the renormalization machinery of Part VI never works at $d = 4$ exactly: it works in a neighbourhood of four dimensions, where the loop integrals that diverge at $d = 4$ are instead finite and the divergence reappears as a pole in the small parameter that measures the departure from four dimensions. The moment one leaves $d = 4$, those three couplings cease to be dimensionless, and a single new scale must be introduced to absorb the dimension they acquire. This section fixes, once for the whole book, exactly how that continuation and that scale are defined: the convention $d = 4 - 2\varepsilon$ with poles in $1/\varepsilon$, the promotion of every coupling by the unique power of a mass μ that restores its dimensionlessness, and the precise definition of the modified minimal-subtraction scheme $\overline{\text{MS}}$ that Part VI and everything downstream of it uses by default. The integrals these conventions act on, and the analytic continuation that defines them, are the business of Chapter D; here we fix the conventions, not the integrals, deriving each from the dimension count already in hand.

A.7.1 Dimensional continuation: $d = 4 - 2\varepsilon$

The regulator of choice throughout the book is dimensional regularization: the spacetime dimension d is treated as a continuous complex variable, loop integrals are defined by analytic continuation in d from the region where they converge, and the ultraviolet divergences of $d = 4$ surface as poles at $d = 4$. We fix the parametrization of the continuation.

Definition A.45 (Dimensional-regularization parameter)**.** The spacetime dimension is continued away from four by writing

$$d \;=\; 4 - 2\varepsilon, \tag{A.191}$$

with ε a small parameter. The physical theory is recovered in the limit $\varepsilon \to 0$. Ultraviolet divergences of four-dimensional loop integrals appear, in this parametrization, as poles in ε at $\varepsilon = 0$: a logarithmically divergent one-loop integral produces a simple pole $1/\varepsilon$, an L-loop integral whose subdivergences have been arranged appropriately produces poles up to $1/\varepsilon^{L}$. The convention is that $\varepsilon > 0$ regulates ultraviolet divergences (so $d < 4$); infrared divergences, when they are regulated dimensionally, require $\varepsilon < 0$ ($d > 4$), and the two regions are connected by the analytic continuation that defines the integral.

Two features of (A.191) are conventional choices, and both are made to keep later formulas as clean as possible. The first is the *factor of two*. A logarithmically divergent one-loop integral behaves, near four dimensions, like $\int^{\Lambda} \mathrm{d}^d k \,/k^4 \sim \Lambda^{d-4}$, so its dimensionally continued value carries the structure $\Gamma\!\left(2 - \frac{d}{2}\right)$, the Euler gamma function having a simple pole whenever its argument is a nonpositive integer. With $d = 4 - 2\varepsilon$ the argument is $2 - \frac{d}{2} = \varepsilon$, and $\Gamma(\varepsilon) = 1/\varepsilon - \gamma_{\mathrm{E}} + O(\varepsilon)$ delivers a pole of residue exactly one in ε. Had we written $d = 4 - \varepsilon$ instead, the same integral would have given $\Gamma(\varepsilon/2)$ and a pole $2/\varepsilon$, sprinkling factors of two through every anomalous dimension and beta function in the book. The choice $d = 4 - 2\varepsilon$ is the one for which $1/\varepsilon$ is the residue, not $2/\varepsilon$, and it is universal in the modern literature; we adopt it without exception. The second choice is the *sign*: $d = 4 - 2\varepsilon$ with $\varepsilon > 0$ for the ultraviolet means that increasing ε moves to lower dimension, where integrals converge better, which is the direction in which the regulator does its work.

It bears emphasis that (A.191) is a statement about the analytic structure of integrals, not a claim that spacetime literally has $4 - 2\varepsilon$ dimensions. The objects being continued are the values of momentum integrals, which are functions of d that happen to be meromorphic; dimensional regularization defines a divergent four-dimensional integral as the $\varepsilon \to 0$ limit of the meromorphic function obtained by computing in d where it converges and continuing. The explicit construction—Feynman and Schwinger parametrization, the Wick rotation to a Euclidean integral, and the resulting closed forms for the master integrals—is carried out in Chapter D, and dimensional regularization makes its first physical appearance in the QED one-loop programme of Chapter 19. What we need here is only the bookkeeping convention (A.191) and its consequence for the dimensions of couplings, to which we turn.

A.7.2 Promotion of the couplings and the scale μ

Once $d \neq 4$, the couplings λ, e, and g are no longer dimensionless. This is not optional: it is forced by the same counting that gave (A.14) and (A.16), now read at $d = 4 - 2\varepsilon$ rather than at $d = 4$. Substituting (A.191) into those results,

$$[\,\lambda\,] \;=\; 4 - d \;=\; 2\varepsilon, \qquad [\,e\,] \;=\; [\,g\,] \;=\; \frac{4-d}{2} \;=\; \varepsilon. \tag{A.192}$$

Each bare coupling in the Lagrangian therefore carries a small positive mass dimension proportional to ε. Perturbation theory, however, is an expansion in *dimensionless* couplings: a Feynman amplitude is a pure number (times the kinematic structure carrying its external dimension), and one cannot expand sensibly in a quantity that itself carries dimension. The resolution is to factor out the dimension into a fixed power of an arbitrary mass scale, leaving a dimensionless coupling to expand in.

Definition A.46 (Renormalization scale and coupling promotion)**.** Introduce a mass parameter μ, the *renormalization scale*, with $[\,\mu\,] = 1$. The dimensionful Lagrangian couplings in $d = 4 - 2\varepsilon$ are written as μ raised to the power dictated by (A.192) times a dimensionless coupling that retains the original name:

$$\lambda \;\longrightarrow\; \lambda\,\mu^{2\varepsilon}, \tag{A.193}$$

$$e \;\longrightarrow\; e\,\mu^{\varepsilon}, \qquad g \;\longrightarrow\; g\,\mu^{\varepsilon}. \tag{A.194}$$

After the promotion, λ, e, and g on the right-hand sides are dimensionless for all ε, and μ alone carries the dimension demanded by (A.192). The scale μ is arbitrary; no physical quantity can depend on it, and the requirement that it does not is the renormalization group, derived in Chapter 24.

The power of μ in (A.193)–(A.194) is not free: it is the unique exponent that makes the count work, and we derive it rather than assert it.

Proposition A.47 (The exact μ-power each coupling must carry)**.** *Let $g_{\mathcal{O}}$ be the coupling of a local operator $\mathcal{O}$ of four-dimensional mass dimension Δ_4, so that at $d = 4$ the coupling has dimension $[\,g_{\mathcal{O}}\,]_{d=4} = 4 - \Delta_4$. If $g_{\mathcal{O}}$ is dimensionless at $d = 4$ (a marginal coupling, $\Delta_4 = 4$), then continued to $d = 4 - 2\varepsilon$ it acquires dimension $[\,g_{\mathcal{O}}\,] = (4 - d) \cdot \left(\frac{\partial \Delta}{\partial d}\right)$ evaluated through the field content; concretely, writing the operator's dimension as a function of d as in Section A.1.4, the coupling carries*

$$[\,g_{\mathcal{O}}\,] \;=\; d - \Delta(d), \tag{A.195}$$

and the promotion $g_{\mathcal{O}} \to g_{\mathcal{O}}\,\mu^{\,\Delta(d)-d}\big|_{\text{restored}} = g_{\mathcal{O}}\,\mu^{\,d-\Delta(d)}$ with the dimensionless coupling on the right requires the exponent

$$\rho_{\mathcal{O}} \;=\; d - \Delta(d) \;=\; [\,g_{\mathcal{O}}\,]. \tag{A.196}$$

For the ϕ^4 coupling $\rho_\lambda = 2\varepsilon$; for the gauge couplings $\rho_e = \rho_g = \varepsilon$.

Proof. The exponent is fixed by a single requirement: after promotion the renamed coupling must be dimensionless, while the Lagrangian term it sits in must continue to carry the full dimension $[\,\mathcal{L}\,] = d$ demanded by (A.8). Write the Lagrangian term as $g_{\mathcal{O}}^{(\dim)}\,\mathcal{O}$ with the dimensionful coupling $g_{\mathcal{O}}^{(\dim)} = \mu^{\rho_{\mathcal{O}}}\,g_{\mathcal{O}}$, the factored coupling $g_{\mathcal{O}}$ dimensionless. Taking mass dimensions and using additivity (Theorem A.1),

$$d \;=\; [\,g_{\mathcal{O}}^{(\dim)}\,\mathcal{O}\,] \;=\; \rho_{\mathcal{O}}[\,\mu\,] + [\,g_{\mathcal{O}}\,] + [\,\mathcal{O}\,] \;=\; \rho_{\mathcal{O}} + 0 + \Delta(d), \tag{A.197}$$

where $[\,\mu\,] = 1$ and $[\,g_{\mathcal{O}}\,] = 0$ by construction, and $\Delta(d) = [\,\mathcal{O}\,]$ is the operator's dimension at the continued d, computed from the field dimensions of Theorem A.2. Solving (A.197) for $\rho_{\mathcal{O}}$ gives $\rho_{\mathcal{O}} = d - \Delta(d)$, which is (A.196) and equals the dimension $[\,g_{\mathcal{O}}^{(\dim)}\,]$ the unfactored coupling had by Theorem A.3. The two

named cases are immediate from (A.192): for $\mathcal{O} = \phi^4$, $\Delta(d) = 2(d-2)$ and $\rho_\lambda = d - 2(d-2) = 4 - d = 2\varepsilon$; for the minimal-coupling operator $\bar{\psi}\gamma^\mu\psi A_\mu$, $\Delta(d) = (3d-4)/2$ and $\rho = d - (3d-4)/2 = (4-d)/2 = \varepsilon$. The cubic and quartic gluon vertices, whose operators were shown in Section A.1.8 to have the same dimensions, inherit the same μ-powers ε and 2ε respectively, consistent with their coefficients being $g\mu^\varepsilon$ and $(g\mu^\varepsilon)^2$. □

The factor $\mu^{2\varepsilon}$ on λ and μ^ε on e, g is therefore not a device chosen for convenience but the only assignment that preserves both the dimensionlessness of the expansion parameter and the dimensional integrity of the action. The practical effect is that every loop integral, which after continuation carries a residual dimension $(\text{mass})^{-2\varepsilon}$ per loop from the unbalanced momentum measure, is multiplied by exactly the compensating $\mu^{2\varepsilon}$ from the vertices, so that the dimensionless combination that finally appears is a ratio of μ^2 to the physical scales of the integral. That combination is the seat of the logarithm of μ whose slope is the beta function. We see the mechanism explicitly in the next subsection.

A.7.3 The generic one-loop structure and its ε-expansion

Every one-loop calculation in dimensional regularization, after Feynman parametrization and Wick rotation, reduces to a single scalar integral whose closed form is derived in Chapter D. We import it; we do not reprove it. With a Euclidean denominator power n and a Feynman-combined mass-squared $\Delta > 0$, the master one-loop integral is

$$\int \frac{\mathrm{d}^d\ell}{(2\pi)^d}\,\frac{1}{(\ell^2 - \Delta + i\epsilon)^n} \;=\; \frac{(-1)^n\, i}{(4\pi)^{d/2}}\,\frac{\Gamma\!\left(n - \frac{d}{2}\right)}{\Gamma(n)}\,\frac{1}{\Delta^{\,n-d/2}}, \tag{A.198}$$

established as the master scalar integral of Chapter D (Theorem D.22, Eq. (D.77)), with the Wick rotation $\ell^0 = i\ell^0_E$ defined there. The entire scheme dependence of the book is contained in how one expands the right-hand side of (A.198) near $d = 4$, so we carry that expansion out in complete detail for the case that produces a logarithmic divergence, $n = 2$, which is the workhorse of marginal-coupling renormalization.

Set $n = 2$ and $d = 4 - 2\varepsilon$, so that $d/2 = 2 - \varepsilon$ and $n - d/2 = \varepsilon$. Then (A.198) becomes

$$\int \frac{\mathrm{d}^d\ell}{(2\pi)^d}\,\frac{1}{(\ell^2 - \Delta + i\epsilon)^2} \;=\; \frac{i}{(4\pi)^{2-\varepsilon}}\,\Gamma(\varepsilon)\,\Delta^{-\varepsilon} \;=\; \frac{i}{(4\pi)^2}\,(4\pi)^{\varepsilon}\,\Gamma(\varepsilon)\,\Delta^{-\varepsilon}, \tag{A.199}$$

using $\Gamma(2) = 1$. Restoring the compensating scale factor from the coupling promotion, Theorem A.46, supplies a $\mu^{2\varepsilon}$ per loop, and the combination that actually enters a dimensionless amplitude is

$$\mu^{2\varepsilon}\,(4\pi)^{\varepsilon}\,\Gamma(\varepsilon)\,\Delta^{-\varepsilon} \;=\; \Gamma(\varepsilon)\,\left(\frac{4\pi\mu^2}{\Delta}\right)^{\varepsilon}. \tag{A.200}$$

This single expression is the generic skeleton of every one-loop logarithmic divergence in the book, and the $\overline{\text{MS}}$ scheme is nothing more than a convention for reading its ε-expansion. We expand each factor. The Laurent expansion of the gamma function about its pole is

$$\Gamma(\varepsilon) \;=\; \frac{1}{\varepsilon} - \gamma_{\text{E}} + O(\varepsilon), \tag{A.201}$$

where $\gamma_{\text{E}} = 0.5772\ldots$ is the Euler–Mascheroni constant; this is the standard expansion $\Gamma(1+\varepsilon) = 1 - \gamma_{\text{E}}\varepsilon + O(\varepsilon^2)$ divided by $\Gamma(\varepsilon) = \Gamma(1+\varepsilon)/\varepsilon$. The power of the dimensionless ratio expands as

$$\left(\frac{4\pi\mu^2}{\Delta}\right)^{\varepsilon} = \exp\left[\varepsilon \ln \frac{4\pi\mu^2}{\Delta}\right] = 1 + \varepsilon \ln \frac{4\pi\mu^2}{\Delta} + O(\varepsilon^2). \tag{A.202}$$

Multiplying (A.201) and (A.202), the order-ε term of one factor meets the $1/\varepsilon$ pole of the other, and the constant $-\gamma_{\text{E}}$ survives:

$$\begin{aligned} \Gamma(\varepsilon)\left(\frac{4\pi\mu^2}{\Delta}\right)^{\varepsilon} &= \left(\frac{1}{\varepsilon} - \gamma_{\text{E}}\right)\left(1 + \varepsilon \ln \frac{4\pi\mu^2}{\Delta}\right) + O(\varepsilon) \\ &= \frac{1}{\varepsilon} - \gamma_{\text{E}} + \ln \frac{4\pi\mu^2}{\Delta} + O(\varepsilon) \\ &= \frac{1}{\varepsilon} - \gamma_{\text{E}} + \ln 4\pi + \ln \frac{\mu^2}{\Delta} + O(\varepsilon). \end{aligned} \tag{A.203}$$

Equation (A.203) is the central computation of this section. It shows that the pole $1/\varepsilon$ never travels alone: it is invariably accompanied by the same two finite constants, $-\gamma_{\text{E}}$ and $\ln 4\pi$, which arise from the gamma function and from the $(4\pi)^{d/2}$ in the loop measure and have nothing to do with the physics of the diagram. They appear in this fixed combination at every order and in every theory. A scheme that subtracts only the $1/\varepsilon$ leaves these universal constants littering every finite result; the modified scheme that subtracts them along with the pole is the one the book uses, and we now define both precisely.

A.7.4 MS versus $\overline{\text{MS}}$

A renormalization scheme is a rule that says which part of a divergent amplitude is removed by counterterms. Minimal subtraction and its modification are the two simplest such rules, distinguished only by whether the universal constants of (A.203) are swept into the counterterm along with the pole.

Definition A.48 (Minimal subtraction, MS)**.** In the *minimal-subtraction* scheme the counterterms are chosen to cancel exactly the pole terms in ε and nothing else: a counterterm is a pure Laurent polynomial in $1/\varepsilon$ with no finite part. At one loop this means subtracting only the $1/\varepsilon$ in (A.203), leaving the finite remainder $-\gamma_{\text{E}} + \ln 4\pi + \ln(\mu^2/\Delta)$ in every renormalized amplitude.

Definition A.49 (Modified minimal subtraction, $\overline{\text{MS}}$)**.** In the *modified minimal-subtraction* scheme, $\overline{\text{MS}}$, the counterterms cancel the pole together with the universal constants $-\gamma_{\text{E}} + \ln 4\pi$ that accompany it in (A.203). Equivalently, $\overline{\text{MS}}$ subtracts multiples of the combination

$$\frac{1}{\bar{\varepsilon}} \;\equiv\; \frac{1}{\varepsilon} - \gamma_{\text{E}} + \ln 4\pi, \tag{A.204}$$

in place of the bare pole $1/\varepsilon$. This is the default scheme of the book.

The two formulations of $\overline{\text{MS}}$—"subtract $1/\bar{\varepsilon}$" and "absorb $-\gamma_{\text{E}} + \ln 4\pi$ into the scale"—are identical, and the bridge between them is a redefinition of the renormalization scale that is worth making explicit, because it is the form in which $\overline{\text{MS}}$ is most often stated.

Proposition A.50 (The $\overline{\text{MS}}$ scale and the equivalence of the two formulations)**.** *Define the modified scale $\bar{\mu}$ by*

$$\bar{\mu}^2 \;\equiv\; 4\pi\,\mu^2\, e^{-\gamma_{\text{E}}}. \tag{A.205}$$

Then the one-loop combination (A.203) *can be written in either of the equivalent forms*

$$\Gamma(\varepsilon)\left(\frac{4\pi\mu^2}{\Delta}\right)^{\varepsilon} \;=\; \frac{1}{\bar{\varepsilon}} + \ln\frac{\mu^2}{\Delta} + O(\varepsilon) \;=\; \frac{1}{\varepsilon} + \ln\frac{\bar{\mu}^2}{\Delta} + O(\varepsilon). \tag{A.206}$$

Subtracting $1/\bar{\varepsilon}$ in the μ variable (the first form) leaves the finite logarithm $\ln(\mu^2/\Delta)$; subtracting the bare pole $1/\varepsilon$ in the $\bar{\mu}$ variable (the second form) leaves the finite logarithm $\ln(\bar{\mu}^2/\Delta)$. The two prescriptions are the same renormalization, and in the second form one conventionally renames $\bar{\mu} \to \mu$ and calls it "the $\overline{MS}$ scale," so that $\overline{MS}$ results carry logarithms $\ln(\mu^2/\Delta)$ with μ understood as $\bar{\mu}$.

Proof. The first equality of (A.206) is a regrouping of (A.203): collect the pole and the two universal constants into the single symbol $1/\bar{\varepsilon}$ of (A.204), leaving $\ln(\mu^2/\Delta)$ as the only Δ-dependent finite piece. For the second equality, take the logarithm of (A.205),

$$\ln\bar{\mu}^2 = \ln 4\pi - \gamma_{\text{E}} + \ln\mu^2, \tag{A.207}$$

and substitute into (A.203):

$$\begin{aligned}\frac{1}{\varepsilon} - \gamma_{\text{E}} + \ln 4\pi + \ln\frac{\mu^2}{\Delta} &= \frac{1}{\varepsilon} + \left(\ln 4\pi - \gamma_{\text{E}} + \ln\mu^2\right) - \ln\Delta \\ &= \frac{1}{\varepsilon} + \ln\bar{\mu}^2 - \ln\Delta = \frac{1}{\varepsilon} + \ln\frac{\bar{\mu}^2}{\Delta}.\end{aligned} \tag{A.208}$$

The two forms in (A.206) are thus algebraically identical expressions for the same quantity (A.203), differing only in whether the universal constants are displayed

as part of the subtracted constant ($1/\bar{\varepsilon}$) or hidden inside the redefined scale ($\bar{\mu}$). Removing $1/\bar{\varepsilon}$ from the first form and removing $1/\varepsilon$ from the second therefore yield finite remainders that differ only by $\ln(\bar{\mu}^2/\mu^2) = \ln 4\pi - \gamma_{\mathrm{E}}$, i.e. by the very constant absorbed into the scale; after the conventional renaming $\bar{\mu} \to \mu$ they coincide. This is the precise sense in which "$\overline{\mathrm{MS}}$ is MS with 4π and γ_{E} absorbed into μ." □

The content of (A.204) and (A.205) is worth stating in words, because it is the single most useful operational fact about the scheme: to convert any minimal-subtraction result into the modified scheme, one replaces every $1/\varepsilon$ by $1/\bar{\varepsilon} = 1/\varepsilon - \gamma_{\mathrm{E}} + \ln 4\pi$, or equivalently trades the scale μ^2 for $\bar{\mu}^2 = 4\pi\mu^2 e^{-\gamma_{\mathrm{E}}}$. Because γ_{E} and $\ln 4\pi$ are pure numbers attached to the regulator and not to any physical scale, the difference between MS and $\overline{\mathrm{MS}}$ is a finite, scheme-dependent shift of the renormalized couplings and has no effect on any physical observable; it does, however, shift the numerical value of the renormalization scale at which a given coupling takes a given value, which is why quoting a coupling such as $\alpha_s(M_Z)$ is meaningless without naming the scheme. The book quotes couplings and runs them in $\overline{\mathrm{MS}}$ throughout.

Remark A.51 (What $\overline{\mathrm{MS}}$ does *not* fix). Modified minimal subtraction fixes the finite part of the counterterms but says nothing about two further conventions that the loop chapters must still pin down, and which live elsewhere in these appendices. The first is the treatment of γ^5 and the Levi-Civita tensor in $d \neq 4$, which cannot be continued while preserving all their four-dimensional properties; the inconsistency, the 't Hooft–Veltman–Breitenlohner–Maison repair, and the pragmatic alternatives are proved and catalogued in Sections C.7 and C.7.5 and are not repeated here. The second is the explicit evaluation of the master integrals, their Feynman/Schwinger parametrizations, and the Wick rotation, all of which are Chapter D. The present section fixes only $d = 4 - 2\varepsilon$, the promotion μ-powers, and the subtraction constant $1/\bar{\varepsilon}$; those are the conventions, and they are scheme-defining, but they are not the whole computational toolkit.

A.7.5 A worked one-loop subtraction in $\overline{\mathrm{MS}}$

The conventions just fixed are best seen in action on the simplest nontrivial loop in the book, the one-loop correction to the four-point coupling in the ϕ^4 thread. The computation that follows is illustrative: it demonstrates how the $\mu^{2\varepsilon}$ promotion, the master integral (A.198), and the $\overline{\mathrm{MS}}$ subtraction (A.204) interlock to produce a finite, scale-dependent renormalized vertex. The extraction of the beta function from this divergence is the work of Chapter 24, and we do not anticipate it; we stop at the counterterm.

Worked Example A.52 (The ϕ^4 one-loop vertex and its $\overline{\mathrm{MS}}$ counterterm)**.** We continue ϕ^4 theory, whose standard Lagrangian and dimensionless coupling λ

were counted in Section A.1.8. At one loop the $2 \to 2$ amplitude receives, beyond the tree value $-i\lambda\mu^{2\varepsilon}$, a contribution from the three one-loop bubbles in the s, t, and u channels. Consider the s-channel bubble, with external momenta combining to p. Its two quartic vertices each contribute a factor $-i\lambda\mu^{2\varepsilon}$, and the diagram carries the symmetry factor $\tfrac{1}{2}$:

$$i\mathcal{M}_s \;=\; \frac{1}{2}\,\big(-i\lambda\mu^{2\varepsilon}\big)^2 \int \frac{\mathrm{d}^d k}{(2\pi)^d}\,\frac{i}{k^2 - m^2 + i\epsilon}\,\frac{i}{(k+p)^2 - m^2 + i\epsilon}. \tag{A.209}$$

The two propagator numerators give $i \cdot i = -1$ and the vertex factors give $(-i\lambda\mu^{2\varepsilon})^2 = -\lambda^2\mu^{4\varepsilon}$, so

$$i\mathcal{M}_s = \frac{\lambda^2\mu^{4\varepsilon}}{2}\int \frac{\mathrm{d}^d k}{(2\pi)^d}\,\frac{1}{(k^2 - m^2)\big((k+p)^2 - m^2\big)}, \tag{A.210}$$

with the $i\epsilon$ implicit. Feynman-combining the two denominators with a parameter $x \in [0,1]$ (the identity is established in Chapter D) and shifting $\ell = k + xp$ produces a single quadratic denominator $(\ell^2 - \Delta)^2$ with

$$\Delta \;=\; m^2 - x(1-x)\,p^2, \tag{A.211}$$

so that

$$i\mathcal{M}_s = \frac{\lambda^2\mu^{4\varepsilon}}{2}\int_0^1 \mathrm{d}x \int \frac{\mathrm{d}^d \ell}{(2\pi)^d}\,\frac{1}{(\ell^2 - \Delta + i\epsilon)^2}. \tag{A.212}$$

The inner integral is exactly the $n = 2$ master integral (A.199). Inserting it,

$$i\mathcal{M}_s = \frac{\lambda^2\mu^{4\varepsilon}}{2}\,\frac{i}{(4\pi)^2}\,(4\pi)^{\varepsilon}\,\Gamma(\varepsilon)\int_0^1 \mathrm{d}x\,\Delta^{-\varepsilon} = \frac{i\lambda^2\mu^{2\varepsilon}}{32\pi^2}\int_0^1 \mathrm{d}x\,\Gamma(\varepsilon)\left(\frac{4\pi\mu^2}{\Delta}\right)^{\varepsilon}, \tag{A.213}$$

where in the last step one factor of $\mu^{2\varepsilon}$ has been kept outside to match the dimension of the tree vertex and the remaining $\mu^{2\varepsilon}$ has been combined with $(4\pi)^{\varepsilon}\Delta^{-\varepsilon}$ into the dimensionless ratio $(4\pi\mu^2/\Delta)^{\varepsilon}$, precisely the combination (A.200) whose expansion we computed. Using (A.203) in the form (A.206),

$$i\mathcal{M}_s = \frac{i\lambda^2\mu^{2\varepsilon}}{32\pi^2}\int_0^1 \mathrm{d}x\left[\frac{1}{\bar{\varepsilon}} + \ln\frac{\mu^2}{\Delta}\right] + O(\varepsilon) = \frac{i\lambda^2\mu^{2\varepsilon}}{32\pi^2}\left[\frac{1}{\bar{\varepsilon}} + \int_0^1 \mathrm{d}x\,\ln\frac{\mu^2}{m^2 - x(1-x)p^2}\right]. \tag{A.214}$$

The t- and u-channel bubbles have the identical structure with p^2 replaced by the appropriate Mandelstam invariant; their divergent parts are the same, so the total one-loop divergence of the four-point amplitude is three times the pole of (A.214):

$$i\mathcal{M}^{\text{1-loop}}\Big|_{\text{pole}} = 3 \times \frac{i\lambda^2\mu^{2\varepsilon}}{32\pi^2}\,\frac{1}{\bar{\varepsilon}} = \frac{3i\lambda^2\mu^{2\varepsilon}}{32\pi^2}\,\frac{1}{\bar{\varepsilon}}. \tag{A.215}$$

Renormalization cancels this with a counterterm vertex $-i\,\delta_\lambda\,\mu^{2\varepsilon}$, the one-loop piece of the rescaling $\lambda_0 = \mu^{2\varepsilon}(\lambda + \delta_\lambda)$ that relates the bare coupling λ_0 to the

renormalized one. In $\overline{\text{MS}}$ the counterterm removes exactly the $1/\bar{\varepsilon}$ combination, so

$$\delta_\lambda^{\overline{\text{MS}}} = \frac{3\lambda^2}{32\pi^2}\,\frac{1}{\bar{\varepsilon}} = \frac{3\lambda^2}{16\pi^2}\,\frac{1}{2\bar{\varepsilon}}, \tag{A.216}$$

chosen so that $i\mathcal{M}^{\text{1-loop}} - i\delta_\lambda \mu^{2\varepsilon}$ is finite as $\varepsilon \to 0$. The renormalized one-loop vertex that survives is the finite, μ-dependent expression

$$i\mathcal{M}^{\text{ren}} = -i\lambda\mu^{2\varepsilon} + \frac{i\lambda^2\mu^{2\varepsilon}}{32\pi^2}\sum_{\sigma=s,t,u}\int_0^1 \mathrm{d}x\,\ln\frac{\mu^2}{m^2 - x(1-x)\sigma} + O(\lambda^3), \tag{A.217}$$

in which every γ_{E} and $\ln 4\pi$ has been absorbed by the choice of $\bar{\varepsilon}$, leaving only the physical logarithms of μ^2 against the kinematic scales. The reappearance of μ inside these logarithms is exactly what the renormalization-group equation of Chapter 24 exploits: demanding that the physical amplitude be independent of the arbitrary μ converts the residue of the $1/\bar{\varepsilon}$ pole in (A.216) into the one-loop beta function $\beta_\lambda = 3\lambda^2/16\pi^2$. We carry the computation no further here; the conventions are what this section owns, and they are now exhibited acting on a complete one-loop diagram from start to finite answer.

The frozen carried numbers of the three benchmark theories—the scalar $\beta_\lambda = 3\lambda^2/16\pi^2$, the QED $\beta_e = e^3/12\pi^2$, and the Yang–Mills coefficient $b_0 = \frac{11}{3}C_A - \frac{4}{3}T_F n_f$—are all computed in precisely the $\overline{\text{MS}}$ scheme defined here, in Chapter 24 (scalar and QED) and Chapter 27 (Yang–Mills). They are quoted, not recomputed, in this appendix; the worked example above shows only the divergence and its subtraction, which is the part the conventions govern. With the regularization parameter $d = 4 - 2\varepsilon$, the coupling-promotion powers $\mu^{2\varepsilon}$ and μ^{ε}, and the modified minimal-subtraction constant $1/\bar{\varepsilon} = 1/\varepsilon - \gamma_{\text{E}} + \ln 4\pi$ now fixed, the book's computational convention set is complete: every loop integral, every counterterm, and every running coupling in Part VI and beyond is defined by the choices made in this section together with the master integrals of Chapter D and the γ^5 rules of Chapter C. What remains is to make these conventions usable alongside the standard literature, whose every reference differs from ours in at least one sign or factor. The next section provides the translation dictionary that maps the canon assembled across this appendix onto the conventions of the major texts, and closes with the master glossary of symbols.

A.8 A Translation Dictionary and the Master Glossary

The seven preceding sections have assembled a single, internally consistent convention set: the units and mass-dimension count of Section A.1, the mostly-minus metric and index gymnastics of Section A.2, the Fourier conventions

and invariant measures of Section A.3, the analytic $i\epsilon$, propagator, and Wick-rotation conventions of Section A.4, the action and amplitude normalizations of Section A.5, the spinor and gamma-matrix conventions collected in Chapter C, the gauge and charge conventions and group-theory normalizations of Section A.6, and the dimensional-regularization and $\overline{\text{MS}}$ conventions of Section A.7. Within these covers that set is the law, and every chapter that follows is written in it. But the reader does not live inside these covers alone: the standard literature of the field—Peskin and Schroeder, Srednicki, Weinberg, Schwartz, Zee—is written in conventions that differ from ours and from one another, most consequentially in the sign of the metric. A formula copied from one of those books into a calculation framed in ours will, if the conventions are not reconciled, be wrong by signs and factors of i that no amount of algebra will repair. This closing section gives the reader the means to reconcile them. It does so in two complementary ways. First, and most importantly, it isolates the *single* transformation—a relabelling of the metric—from which almost every cross-text discrepancy descends, and proves exactly how that transformation acts on an action, on an on-shell condition, and on an $i\epsilon$ prescription, so that the reader can convert *any* formula in *any* of these texts from first principles rather than trusting a table. Second, it records the explicit conversion tables for quick reference, with honest warnings about the few entries that are genuinely fragile across editions. It then states plainly which local conventions this book deliberately does not globalize, and closes the appendix with the master symbol glossary, each entry keyed both to the chapter where the symbol first appears and to the section here that fixes its meaning.

A.8.1 The one principle: a relabelling of the metric

There are two ways to live with the convention diversity of the literature. One is to memorize, for each external source, a table of its choices and a list of substitution rules; this is fragile, edition-dependent, and silent about why the rules take the form they do. The other is to recognize that the dominant source of disagreement—the metric signature—enters every Lorentz-covariant expression through exactly one operation, the contraction of indices, and to learn once and for all how that operation responds to a change of signature. We take the second route. Everything in this subsection is derived, not quoted, and the result is a procedure that converts a formula written in the opposite signature with no appeal to any text's idiosyncrasies.

Definition A.53 (The two signatures)**.** Write $\eta^{(-)}_{\mu\nu} = \mathrm{diag}(+,-,-,-)$ for this book's *mostly-minus* metric (Section A.2) and $\eta^{(+)}_{\mu\nu} = \mathrm{diag}(-,+,+,+)$ for the *mostly-plus* metric of Srednicki [454] and Weinberg [500]. The two are related by an overall sign,

$$\eta^{(+)}_{\mu\nu} \;=\; -\,\eta^{(-)}_{\mu\nu}, \qquad \eta^{(+)\,\mu\nu} \;=\; -\,\eta^{(-)\,\mu\nu}, \tag{A.218}$$

the second equality following because the matrix inverse of $-M$ is $-M^{-1}$. Contravariant components a^μ of any vector (the physical components, such as energy and three-momentum in $p^\mu = (E, \mathbf{p})$) are the *same* numbers in both conventions; only the rule for lowering an index, and hence every contraction, changes sign.

The entire conversion rests on a single elementary observation about contractions.

Lemma A.54 (Scalar products flip sign)**.** *For any two four-vectors with fixed contravariant components a^μ, b^μ, the Lorentz scalar product computed in the two conventions differs by an overall sign:*

$$(a \cdot b)_+ \;=\; -\,(a \cdot b)_-, \tag{A.219}$$

where $(a \cdot b)_\pm \equiv \eta^{(\pm)}_{\mu\nu} a^\mu b^\nu$. In particular $(p^2)_+ = -(p^2)_-$ for any momentum p^μ.

Proof. Direct from (A.218): $(a\cdot b)_+ = \eta^{(+)}_{\mu\nu} a^\mu b^\nu = -\eta^{(-)}_{\mu\nu} a^\mu b^\nu = -(a\cdot b)_-$. Setting $b = a$ gives the statement for p^2. □

From Theorem A.54 one already reads off the most frequently needed conversion. The mostly-minus on-shell condition $p^2 = m^2$, with m the rest mass (a Lorentz scalar parameter, hence the same number in both conventions), becomes, on substituting $(p^2)_- = -(p^2)_+$,

$$(p^2)_- = m^2 \quad\Longleftrightarrow\quad -(p^2)_+ = m^2 \quad\Longleftrightarrow\quad (p^2)_+ = -m^2, \tag{A.220}$$

which is exactly the form $p^2 = -m^2$ that a reader of Srednicki or Weinberg will recognize. The mass-shell has not moved; only the number assigned to p^2 on it has changed sign. The same arithmetic governs whole Lagrangians, once we account for the fact that different terms carry different numbers of contractions.

Theorem A.55 (Master sign rule for signature change)**.** *Let a Lorentz-scalar Lagrangian density be written in the mostly-minus convention as a sum of monomials,*

$$\mathcal{L}_- \;=\; \sum_i c_i\, T_i, \tag{A.221}$$

where each T_i is a Lorentz scalar built from fields and derivatives and c_i is a numerical (signature-independent) coefficient. Let k_i be the number of metric contractions in T_i, that is, the number of factors of $\eta_{\mu\nu}$ or $\eta^{\mu\nu}$ needed to write T_i with all field and derivative indices in their natural (contravariant for ∂^μ via raising, etc.) positions. Then the same physical theory *—the same action, hence the same e^{iS} and the same equations of motion—is described in the mostly-plus convention by*

$$\mathcal{L}_+ \;=\; \sum_i c_i\,(-1)^{k_i}\, T_i, \tag{A.222}$$

each T_i now evaluated with $\eta^{(+)}$.

Proof. A single metric contraction is, by Theorem A.54, an operation whose numerical value flips sign under $\eta^{(-)} \to \eta^{(+)}$; a scalar with k_i independent contractions therefore satisfies

$$(T_i)_+ \;=\; (-1)^{k_i}\,(T_i)_-, \tag{A.223}$$

since each contraction contributes one factor of η (or η^{-1}) and each such factor flips sign by (A.218), the signs multiplying because distinct contractions involve distinct metric factors. Now demand that the action be the same physical object in both descriptions, $S_+ = S_-$, term by term: the i-th contribution must satisfy $c_i(-1)^{k_i}(T_i)_+ = c_i(T_i)_-$. Using (A.223) the left side is $c_i(-1)^{k_i}(-1)^{k_i}(T_i)_- = c_i(T_i)_-$, which equals the right side identically. Hence the coefficients $c_i(-1)^{k_i}$ in (A.222) are exactly those that preserve the numerical value of every term, and (A.222) describes the same action. Because the action is unchanged, so are the Euler–Lagrange equations and every observable. □

Theorem A.55 is the engine of all signature conversion: a term flips sign once for every contracted index pair it contains, and not otherwise. A mass or potential term, which contracts no indices, never changes sign; a two-derivative kinetic term, with one contraction, always does; a term like $F_{\mu\nu}F^{\mu\nu}$, with two contractions, changes sign twice and so is invariant. We exhibit the rule on the scalar of ϕ^4 theory.

Worked Example A.56 (Translating the scalar Lagrangian and propagator to mostly-plus)**.** The frozen ϕ^4 Lagrangian (Chapter 6) in this book's convention is

$$\mathcal{L}_- \;=\; \tfrac{1}{2}\,(\partial_\mu\phi)(\partial^\mu\phi) - \tfrac{1}{2}\,m^2\phi^2 - \frac{\lambda}{4!}\,\phi^4. \tag{A.224}$$

Classify the three terms by their contraction count: the kinetic term $\tfrac{1}{2}\partial_\mu\phi\,\partial^\mu\phi = \tfrac{1}{2}\eta^{\mu\nu}\partial_\mu\phi\,\partial_\nu\phi$ has $k=1$; the mass term and the quartic term contract nothing, so $k=0$. By Theorem A.55 only the kinetic term flips:

$$\mathcal{L}_+ \;=\; -\tfrac{1}{2}\,(\partial_\mu\phi)(\partial^\mu\phi) - \tfrac{1}{2}\,m^2\phi^2 - \frac{\lambda}{4!}\,\phi^4, \tag{A.225}$$

with $\partial^\mu\phi$ now raised by $\eta^{(+)}$. This is precisely the mostly-plus scalar Lagrangian of Srednicki [454]: the leading minus sign on the kinetic term, which to a first-time reader looks like a different theory, is nothing but the single sign demanded by the one contraction in the kinetic term. As a check, evaluate the kinetic term in components in each convention with $\eta^{(\pm)}$. Mostly-minus, $\tfrac{1}{2}\partial_\mu\phi\,\partial^\mu\phi = \tfrac{1}{2}\big[(\partial_t\phi)^2 - (\nabla\phi)^2\big]$; mostly-plus, $-\tfrac{1}{2}\partial_\mu\phi\,\partial^\mu\phi = -\tfrac{1}{2}\big[-(\partial_t\phi)^2 + (\nabla\phi)^2\big] = \tfrac{1}{2}\big[(\partial_t\phi)^2 - (\nabla\phi)^2\big]$. The two are numerically identical, as Theorem A.55 guarantees: the physical Lagrangian—positive time-kinetic energy, negative gradient energy—is the same object written twice.

The Feynman propagator translates with no more than Theorem A.54 and a careful tracking of the $i\epsilon$. The book's momentum-space propagator (Section A.4) is the time-ordered two-point function

$$\langle 0|\,\mathcal{T}\,\phi(x)\phi(y)\,|0\rangle \;=\; \int \frac{\mathrm{d}^4p}{(2\pi)^4}\;\frac{i}{p^2-m^2+i\epsilon}\;e^{-ip\cdot(x-y)}, \tag{A.226}$$

with $p^2=(p^2)_-$. We convert the integrand by substituting $(p^2)_-=-(p^2)_+$ from Theorem A.54, taking care to factor the sign cleanly through the $i\epsilon$:

$$\frac{i}{(p^2)_- - m^2+i\epsilon} \;=\; \frac{i}{-(p^2)_+ - m^2+i\epsilon} \;=\; \frac{i}{-\big[(p^2)_+ + m^2 - i\epsilon\big]} \;=\; \frac{-i}{(p^2)_+ + m^2 - i\epsilon}. \tag{A.227}$$

Two things flipped together. The denominator p^2-m^2 became $-\big[(p^2)_+ + m^2\big]$, exposing the mostly-plus mass-shell $(p^2)_+=-m^2$ of (A.220) as the location of the pole; and the prescription $+i\epsilon$ became $-i\epsilon$, because pulling the overall -1 out of the bracket carries the infinitesimal with it. The result,

$$\langle 0|\,\mathcal{T}\,\phi(x)\phi(y)\,|0\rangle \;=\; \int \frac{\mathrm{d}^4p}{(2\pi)^4}\;\frac{-i}{p^2+m^2-i\epsilon}\;e^{+ip\cdot(x-y)}, \tag{A.228}$$

is the mostly-plus Feynman propagator. (The plane-wave phase has likewise become $e^{+ip\cdot(x-y)}$, since $p\cdot(x-y)$ itself flipped sign; this is the origin of the "Fourier sign" row in the tables below.) Comparison with Srednicki is exact: his free propagator is $\widetilde{\Delta}(p)=1/(p^2+m^2-i\epsilon)$ together with the convention $\langle 0|\mathcal{T}\phi\phi|0\rangle=(1/i)\Delta$, so that $\langle 0|\mathcal{T}\phi\phi|0\rangle=-i/(p^2+m^2-i\epsilon)$, identical to (A.228). The physical correlator is one object; the book and Srednicki write it in opposite signatures, and the master rule maps one writing onto the other with no residue.

The one extra wrinkle: gamma matrices. Scalars and gauge fields convert by Theorem A.55 alone, because their Lagrangian terms are built only from fields, derivatives, and explicit metric factors. Spinors carry one more piece of metric data: the Clifford algebra $\{\gamma^\mu,\gamma^\nu\}=2\eta^{\mu\nu}$ (Chapter C) ties the gamma matrices themselves to the signature, so a change of η forces a redefinition of the gammas before the master rule can be applied. The redefinition is fixed by demanding that the new gammas obey the new algebra. Take

$$\gamma^\mu_+ \;\equiv\; i\,\gamma^\mu_-, \tag{A.229}$$

where γ^μ_- are the book's matrices with $\{\gamma^\mu_-,\gamma^\nu_-\}=2\eta^{(-)\,\mu\nu}$. Then

$$\{\gamma^\mu_+,\gamma^\nu_+\} \;=\; i^2\,\{\gamma^\mu_-,\gamma^\nu_-\} \;=\; -\,2\,\eta^{(-)\,\mu\nu} \;=\; 2\,\eta^{(+)\,\mu\nu}, \tag{A.230}$$

using (A.218) in the last step, so (A.229) indeed produces a set of matrices satisfying the mostly-plus algebra. Hermiticity tracks correctly too: in mostly-minus γ^0_- is Hermitian and γ^i_- anti-Hermitian, so by (A.229) γ^0_+ is anti-Hermitian

(as required by $(\gamma_+^0)^2 = \eta^{(+)\,00} = -1$) and γ_+^i Hermitian. Applying (A.229) to the book's free Dirac Lagrangian $\mathcal{L}_- = \bar{\psi}(i\not{\partial}_- - m)\psi$ with $\not{\partial}_- = \gamma_-^\mu \partial_\mu$ gives $i\not{\partial}_- = i\gamma_-^\mu \partial_\mu = i(-i\gamma_+^\mu)\partial_\mu = \gamma_+^\mu \partial_\mu = \not{\partial}_+$, and one checks that the Dirac adjoint is unchanged ($\bar{\psi} = \psi^\dagger \gamma_-^0 = \psi^\dagger(-i\gamma_+^0)$ is the correct mostly-plus adjoint $\psi^\dagger \beta_+$ with the Hermitian $\beta_+ = -i\gamma_+^0$), so

$$\mathcal{L}_+ \;=\; \bar{\psi}(\not{\partial}_+ - m)\psi, \qquad \not{\partial}_+ = \gamma_+^\mu \partial_\mu. \tag{A.231}$$

The explicit factor of i that sits in front of the kinetic term in mostly-minus has been absorbed into the redefinition (A.229); whether one sees that i depends on which normalization of the mostly-plus gammas a given text adopts. We isolate this lesson, because it is the single most common trap in cross-text spinor algebra.

Caution

Not everything that differs between texts is fixed by the metric. The signature determines the scalar-product sign, the on-shell condition $p^2 = \pm m^2$, and the propagator denominator and $i\epsilon$ (Theorems A.54 and A.56) unambiguously. But the placement of the factor i in the Dirac kinetic term, the overall sign of γ^5, the Hermiticity assignment of γ^0, and the sign in the spinor propagator numerator depend on the gamma and Dirac-adjoint normalization a text chooses *in addition* to its signature. Convert the metric-determined data with Theorem A.55; for the gamma normalization, read the target text's explicit definitions (or this book's, in Chapter C) directly. As a concrete anchor, the metric-determined content of the Dirac propagator is its denominator: the book's $\langle \mathcal{T}\psi\bar{\psi}\rangle \propto i/(p^2 - m^2 + i\epsilon)$ has the mostly-plus denominator $p^2 + m^2 - i\epsilon$, matching Srednicki's $\widetilde{S}(p) = (-\not{p} + m)/(p^2 + m^2 - i\epsilon)$; the numerator's $\not{p}$ sign and the location of the overall i follow his gamma and adjoint conventions, not the signature alone.

A.8.2 The conversion tables

We now record, for quick reference, the conventions of the five most widely used graduate texts against this book's. Table A.3 collects the choices that descend from the metric signature—the items that Theorem A.55 and Theorem A.54 convert mechanically—and Table A.4 collects the remaining discrete choices (the γ^5 sign, the orientation ϵ^{0123}, the gauge and charge conventions, and the coupling normalization α). The reader is urged to treat the tables as an index into the derivations above, not as a substitute for them: the few fragile rows, flagged below, are exactly the ones where consulting the source text's own statement is safer than trusting a remembered entry.

Table A.3: Signature-linked conventions. Every entry in this table is converted mechanically by the master sign rule Theorem A.55 and the scalar-flip lemma Theorem A.54. "$+\frac{1}{2}(\partial\phi)^2$" abbreviates the sign of the scalar kinetic term in $\mathcal{L}$; the positive-energy plane wave is the sign in the exponent $e^{\mp ip\cdot x}$; the on-shell relation is the value of p^2 for a particle of mass m. All five texts and this book use the Minkowski path-integral weight e^{+iS}.

	Metric $\eta_{\mu\nu}$	Kinetic sign	Pos.-energy wave	On-shell
This book	$(+,-,-,-)$	$+\frac{1}{2}(\partial\phi)^2$	$e^{-ip\cdot x}$	$p^2 = m^2$
Peskin–Schroeder	$(+,-,-,-)$	$+\frac{1}{2}(\partial\phi)^2$	$e^{-ip\cdot x}$	$p^2 = m^2$
Schwartz	$(+,-,-,-)$	$+\frac{1}{2}(\partial\phi)^2$	$e^{-ip\cdot x}$	$p^2 = m^2$
Zee	$(+,-,-,-)$	$+\frac{1}{2}(\partial\phi)^2$	$e^{-ip\cdot x}$	$p^2 = m^2$
Srednicki	$(-,+,+,+)$	$-\frac{1}{2}(\partial\phi)^2$	$e^{+ip\cdot x}$	$p^2 = -m^2$
Weinberg	$(-,+,+,+)$	$-\frac{1}{2}(\partial\phi)^2$	$e^{+ip\cdot x}$	$p^2 = -m^2$

Table A.4: Discrete and coupling conventions not fixed by the metric alone. The γ^5 and ϵ^{0123} rows give each text's stated definition with $\epsilon^{0123} = -\epsilon_{0123}$ in either signature (since $\det\eta = -1$ in both, see Section A.2). The electron-charge column records whether the symbol e denotes the positive elementary charge ($e > 0$) or the signed electron charge ($e < 0$). The last two rows are the fragile ones discussed in Section A.8.2.

	This book	Peskin–Schr.	Srednicki	Weinberg	Schwartz / Zee
γ^5	$i\gamma^0\gamma^1\gamma^2\gamma^3$	$i\gamma^0\gamma^1\gamma^2\gamma^3$	$i\gamma^0\gamma^1\gamma^2\gamma^3$	$-i\gamma^0\gamma^1\gamma^2\gamma^3$	$i\gamma^0\gamma^1\gamma^2\gamma^3$
ϵ^{0123}	$+1$	$+1$	$+1$	-1	$+1$
α	$e^2/4\pi$	$e^2/4\pi$	$e^2/4\pi$	$e^2/4\pi$	$e^2/4\pi$
electron e	$e > 0$	$e < 0$	$e > 0$	$e > 0$	$e > 0$
D_μ (electron)	$\partial_\mu + ieA_\mu$	$\partial_\mu + ieA_\mu$	$\partial_\mu - ieA_\mu$	$\partial_\mu - ieA_\mu$	$\partial_\mu + ieA_\mu$

The reassuring rows are the first and third of Table A.4: every text in standard use, and this book, writes $\gamma^5 = i\gamma^0\gamma^1\gamma^2\gamma^3$ (Weinberg [500] alone carries the opposite overall sign, which exchanges the left- and right-handed projectors $P_{L,R} = \frac{1}{2}(1 \mp \gamma^5)$), and every one of them uses rationalized Heaviside–Lorentz units in which $\alpha = e^2/4\pi \approx 1/137$ rather than the Gaussian $\alpha = e^2$. The fine-structure constant is therefore the same symbol with the same value across all six conventions, which is why numerical cross sections quoted in any of these books can be compared directly once the signature-linked factors have been reconciled.

Caution

The charge and covariant-derivative rows are convention-fragile. The last two rows of Table A.4 are the entries most likely to be misremembered, because they encode *two* independent choices—the sign in the covariant derivative, $D_\mu = \partial_\mu \mp ieA_\mu$, and the meaning of the symbol e (positive elementary charge versus signed electron charge)—and different texts split these differently. Peskin and Schroeder [396] are the notorious case: they write $D_\mu = \partial_\mu + ieA_\mu$ with e *negative*, equal to the signed electron charge, so their photon–electron vertex carries a sign opposite to what a reader expecting $e > 0$ would assume. This book, like Schwartz [432] and Zee [532], takes $e > 0$ and assigns the electron charge $-e$, writing $D_\mu = \partial_\mu + ieA_\mu$ on the electron field (equivalently $D_\mu = \partial_\mu - iqA_\mu$ for a field of physical charge q, matching the nonabelian $D_\mu = \partial_\mu - igA^a_\mu T^a$ of Section A.6). The crucial point is that none of these choices is physical on its own: the simultaneous replacement

$$e \;\to\; -e, \qquad A_\mu \;\to\; -A_\mu \tag{A.232}$$

is a field redefinition (a relabelling of the photon field's sign) that leaves D_μ, the field strength $F_{\mu\nu}$, the Lagrangian, and every observable invariant. In particular $\alpha = e^2/4\pi$ is invariant under (A.232), so a cross section copied from Peskin needs *no* charge-sign correction; only an amplitude in which a *single* power of e appears alongside an external photon polarization—an interference term linear in the charge—is sensitive to the convention, and there one simply uses (A.232) to align the sign of e with the sign of A_μ. When in doubt, verify the source's covariant derivative and its statement of the electron charge directly rather than trusting the table; this is the one place where a remembered entry is genuinely dangerous.

A.8.3 The translation procedure, step by step

Collecting the results above into a recipe: to import a Lorentz-covariant formula from an external text into this book's conventions (or to export one), proceed as follows.

1. *Identify the source signature* from Table A.3. If it agrees with ours (Peskin, Schwartz, Zee), no metric conversion is needed and one proceeds to step 4. If it is mostly-plus (Srednicki, Weinberg), continue.

2. *Convert every scalar product* by $(a \cdot b) \to -(a \cdot b)$ (Theorem A.54). In particular replace each $p^2 + m^2$ by $-(p^2 - m^2)$ and each $p^2 - m^2$-type denominator's $i\epsilon$ by its opposite sign, as in (A.227).

3. *Convert Lagrangian terms* by the master rule Theorem A.55: flip the sign of each term once per contracted index pair. Two-derivative kinetic terms flip; mass and potential terms do not; $F_{\mu\nu}F^{\mu\nu}$ does not.

4. *Reconcile the gamma normalization* by hand (Section A.8.1): match the source's γ^5 sign and Dirac-adjoint convention against Chapter C, using Table A.4.

5. *Reconcile the charge convention* with (A.232) if the source uses a different sign of e (Section A.8.2); recall that α and unsigned observables are unaffected.

Worked Example A.57 (Exporting the QED Dirac Lagrangian to Srednicki's conventions)**.** Take the QED Lagrangian (Chapter 8) in this book's mostly-minus form,

$$\mathcal{L}^{-}_{\text{QED}} \;=\; \bar\psi(i\not{D} - m)\psi - \tfrac{1}{4}\,F_{\mu\nu}F^{\mu\nu}, \qquad D_\mu = \partial_\mu + ieA_\mu, \tag{A.233}$$

and convert it to Srednicki's mostly-plus conventions. We run the recipe. The source signature is mostly-plus, so steps 2–4 apply. The gauge kinetic term $-\frac{1}{4}F_{\mu\nu}F^{\mu\nu} = -\frac{1}{4}\eta^{\mu\alpha}\eta^{\nu\beta}F_{\mu\nu}F_{\alpha\beta}$ has $k = 2$ contractions, hence by Theorem A.55 flips sign twice and is *unchanged*: $-\frac{1}{4}F_{\mu\nu}F^{\mu\nu}$ in both conventions. The fermion mass term $-m\bar\psi\psi$ has $k = 0$ and is unchanged. The covariant kinetic term $i\bar\psi\not{D}\psi = i\bar\psi\gamma^\mu_-(\partial_\mu + ieA_\mu)\psi$ contains the spinor wrinkle; applying the gamma redefinition (A.229), $i\gamma^\mu_- = \gamma^\mu_+$, exactly as for the free Dirac term (A.231), so $i\bar\psi\not{D}_-\psi = \bar\psi\,\gamma^\mu_+(\partial_\mu + ieA_\mu)\psi = \bar\psi\not{D}_+\psi$ with $\not{D}_+ = \gamma^\mu_+ D_\mu$. Assembling,

$$\mathcal{L}^{+}_{\text{QED}} \;=\; \bar\psi(\not{D}_+ - m)\psi - \tfrac{1}{4}\,F_{\mu\nu}F^{\mu\nu}, \qquad D_\mu = \partial_\mu + ieA_\mu. \tag{A.234}$$

The gauge sector and the covariant-derivative form are identical to the mostly-minus expression (A.233)—the photon kinetic term because its two contractions cancel, the covariant derivative because the gauge field's mass dimension and the coupling structure are signature-blind (Section A.1)—while the Dirac kinetic term has shed its explicit i into the redefined gammas. This matches Srednicki's QED up to his particular gamma normalization (Section A.8.1) and his opposite photon-sign convention, reconciled below; should one wish instead to land on his stated form $i\bar\psi\gamma^\mu D_\mu\psi$ with a manifest i, one simply chooses the mostly-plus gammas to be γ^μ_- themselves (which satisfy $\{\gamma_-,\gamma_-\} = 2\eta^{(-)} = -2\eta^{(+)}$, the opposite-sign Clifford convention some mostly-plus texts adopt) rather than $i\gamma^\mu_-$, whereupon the i reappears unchanged. Either way, the physical content—the Dirac equation squaring to the Klein–Gordon operator with $p^2 = -m^2$, the vertex $\propto e$, the cross sections of Chapter 17—is identical, as it must be. Finally, although Srednicki takes $e > 0$ as we do, his stated electron covariant derivative is $D_\mu = \partial_\mu - ieA_\mu$ (Table A.4), the opposite photon sign to our $\partial_\mu + ieA_\mu$; landing on his form therefore requires the photon relabeling $A_\mu \to -A_\mu$—the A-half

of (A.232), with e left untouched since both conventions take it positive. Were one translating instead from Peskin, who writes the same $D_\mu = \partial_\mu + ieA_\mu$ as we do but with $e < 0$, the required step would instead be the charge relabeling $e \to -e$. Either piece is half of the unphysical field redefinition (A.232), so every observable is unchanged.

A.8.4 Conventions deliberately kept local

A notation arbiter must say not only what it fixes globally but also what it declines to fix, lest a reader assume a global convention where none exists. As of this writing (mid-2020s), the book makes two deliberate exceptions to global standardization, in both cases because the local community's conventions are so entrenched and so finely tuned to their subject that importing them into a single global standard would do more harm than good.

Spinor-helicity variables. The angle and square brackets $\langle ij \rangle$ and $[ij]$ of the modern amplitudes program, together with the little-group and reality conventions that fix their relative signs, are *not* globalized. They are defined at their point of use in Chapter 58 and restated at the top of every amplitudes chapter, precisely because the sign conventions for these brackets differ between the major references and even between papers by the same authors, and because the spinor-helicity formalism is most naturally phrased with its own metric and reality conditions that interact with the choices of Chapter C in ways best handled in situ rather than by a global decree. A reader who needs the bracket conventions should look to Chapter 58, not to this appendix.

Conformal and bootstrap normalizations. The conformal field theory and conformal-bootstrap chapters carry their own normalizations for operator dimensions, two- and three-point function coefficients, OPE coefficients, and the conformal blocks, fixed locally in Chapter 48 and used throughout Part XIV. These are likewise *not* promoted to global conventions: the bootstrap literature has settled on particular normalizations (unit-normalized two-point functions, specific conventions for the cross-ratios and for the sign of the OPE coefficients) whose value lies in matching the numerical bootstrap output exactly, and re-expressing them in a foreign global convention would sever that connection without benefit. Where a quantity defined in those chapters is used elsewhere, it is imported by Chapter 48 and Part XIV with its local normalization stated, not silently absorbed here.

Notation Watch

The two exceptions above are the *only* places in the book where a quantity load-bearing in its own part is governed by a convention not fixed in this appendix. Everywhere else—every metric contraction, every propagator, every gamma trace, every covariant derivative, every coupling

normalization—the conventions of Sections A.1 to A.7 are in force without exception. When a chapter restates the spinor-helicity or bootstrap conventions, it does so because they are local by this deliberate design, not because the global conventions have lapsed.

A.8.5 The master glossary

We close the appendix with the master symbol glossary. Each entry lists a symbol, its meaning, the section of this appendix (or the appendix) that fixes its convention, and the chapter in which it first appears in the main text. The glossary is the single index a reader should consult when an unfamiliar symbol is encountered: it points simultaneously to where the symbol is *defined* (its first-use chapter) and to where its *convention* is pinned down (the relevant section here). Table A.5 covers the kinematic and field-theoretic core; Table A.6 covers the gauge, spinor, group, and renormalization symbols; Table A.7 covers the symbols proper to the three benchmark theories and the deliberately local conventions of Section A.8.4.

Table A.5: Master glossary, part I: kinematics, measures, and the field-theory core.

Symbol	Meaning	Convention fixed in	First used
$\hbar = c = 1$	natural units	Section A.1	Chapter 1
$[\,X\,]$	mass dimension of X	Theorem A.1	Chapter 6
$\eta_{\mu\nu}$	metric $\mathrm{diag}(+,-,-,-)$	Section A.2	Chapter 5
x^μ, p^μ	coordinates, four-momentum	Section A.2	Chapter 6
∂_μ, $\Box$	derivative, d'Alembertian $\partial_\mu\partial^\mu$	Section A.2	Chapter 6
$\epsilon^{\mu\nu\rho\sigma}$	Levi-Civita, $\epsilon^{0123} = +1$	Section A.2	Chapter 11
S	action $\int \mathrm{d}^d x\, \mathcal{L}$, $[\,S\,] = 0$	Eq. (A.6)	Chapter 6
$\mathcal{L}$	Lagrangian density, $[\,\mathcal{L}\,] = d$	Eq. (A.8)	Chapter 6
$\displaystyle\int \frac{\mathrm{d}^4 p}{(2\pi)^4}$	momentum measure	Section A.3	Chapter 9
$\delta^{(4)}(p)$	delta function, $(2\pi)^4$ per x-integral	Section A.3	Chapter 9
$e^{-ip\cdot x}$	positive-energy plane wave	Section A.3	Chapter 9
D_F, S_F	scalar, fermion Feynman propagator	Section A.4	Chapter 10
$i\epsilon$	Feynman prescription $i/(p^2 - m^2 + i\epsilon)$	Section A.4	Chapter 10
$Z[J]$, $W[J]$, Γ	generating functionals	Section A.5	Chapter 10
$\lvert 0\rangle$, $\langle\,\cdot\,\rangle$	vacuum, time-ordered correlator	Section A.4	Chapter 9

With the glossary in place, the appendix closes. The reader now holds two instruments. The first is a single, internally consistent convention set, fixed across Sections A.1 to A.7 and indexed by the glossary of Section A.8.5, which serves as the sole arbiter for every notational question the main text can raise. The second is the translation machinery of Section A.8.1—the metric-flip lemma,

Table A.6: Master glossary, part II: spinors, gauge fields, group theory, and renormalization.

Symbol	Meaning	Convention fixed in	First used
γ^μ	Dirac matrices, $\{\gamma^\mu,\gamma^\nu\}=2\eta^{\mu\nu}$	Chapter C	Chapter 11
γ^5	$i\gamma^0\gamma^1\gamma^2\gamma^3$	Chapter C	Chapter 11
ψ, $\bar\psi$	Dirac field, $\bar\psi=\psi^\dagger\gamma^0$	Chapter C	Chapter 11
$\sigma^{\mu\nu}$	$\frac{i}{2}[\gamma^\mu,\gamma^\nu]$	Chapter C	Chapter 11
$\not{p}$	$\gamma^\mu p_\mu$	Chapter C	Chapter 11
A_μ, A^a_μ	gauge potential	Section A.6	Chapter 8
$F_{\mu\nu}$, $F^a_{\mu\nu}$	field strength	Section A.6	Chapter 8
D_μ	$\partial_\mu - igA^a_\mu T^a$	Section A.6	Chapter 8
e	elementary charge $e>0$, electron charge $-e$	Section A.6	Chapter 8
α	$e^2/4\pi$ (Heaviside–Lorentz)	Section A.6	Chapter 8
ξ	gauge-fixing parameter, R_ξ gauges	Section A.6	Chapter 13
T^a, f^{abc}	generators, structure constants	Section A.6	Chapter 25
$\mathrm{tr}(T^aT^b)=\frac{1}{2}\delta^{ab}$	fundamental normalization	Section A.6	Chapter 25
C_A, C_F, T_F	Casimirs and Dynkin index	Chapter B	Chapter 27
$d=4-2\varepsilon$	dimensional regularization	Section A.7	Chapter 21
μ	renormalization scale	Section A.7	Chapter 22
$\overline{\mathrm{MS}}$	modified minimal subtraction	Section A.7	Chapter 22

the master sign rule, and the step-by-step procedure—which lets any formula from any of the standard texts be carried into this book's conventions, or out of them, without convention drift. Equipped with both, the reader can move freely between this book and the wider literature, confident that every sign and every factor of i has a derivation behind it rather than a convention to be taken on faith.

Further reading

The conventions fixed here are, with minor exceptions, those of Peskin and Schroeder [396] and Schwartz [432], and a reader cross-checking a sign or a normalization against those texts will find the dictionary of Section A.8 the fastest route. Srednicki [454] uses the opposite, mostly-plus metric and a distinct γ-matrix and $\overline{\mathrm{MS}}$ bookkeeping, and is the most instructive contrast precisely because so much differs; Weinberg [500] develops the foundations from the particle-state viewpoint with its own careful conventions, and Zee [532] offers a complementary, more heuristic register. For the particle-data and numerical conventions used when our formulae are confronted with experiment, the current edition of the Review of Particle Physics [382] is the standing reference. The definitive treatment of renormalization conventions, the precise content of $\overline{\mathrm{MS}}$, and the scheme dependence that the regularization section only fixes is Collins

Table A.7: Master glossary, part III: the benchmark theories and the deliberately local conventions of Section A.8.4.

Symbol	Meaning	Convention fixed in	First used
ϕ, m, λ	ϕ^4 theory: scalar, mass, quartic coupling	Section A.1.8	Chapter 6
ψ, m, e	QED: electron, mass, charge	Section A.1.8	Chapter 8
A^a_μ, g, α_s	Yang–Mills theory: gluon, coupling, $\alpha_s = g^2/4\pi$	Section A.1.8	Chapter 25
n_f, b_0	flavor number, beta-function coefficient	Section A.6	Chapter 27
$\langle ij\rangle$, $[ij]$	spinor-helicity brackets (*local*)	Chapter 58	Chapter 58
Δ, c_{ijk}	CFT dimension, OPE coefficient (*local*)	Chapter 48	Chapter 48

[134]; it is where to go beyond the conventions recorded here.

Appendix B

Group Theory Data

Every gauge theory in this book runs on a small, fixed bundle of numbers: the index $T(R)$ and quadratic Casimir $C_2(R)$ of a representation, the structure constants f^{abc} and the symmetric invariants d^{abc}, the completeness relation that collapses a string of generators, and the handful of SU(N) color factors C_F, C_A, T_F that decorate every loop in a non-abelian amplitude. These quantities are not deep once the representation theory behind them is in hand, but they are needed so often, and with such unforgiving sign and normalization conventions, that collecting them in one place pays for itself many times over. That is the role of this appendix: it is the gauge-theory *data* appendix, the lookup table the computational chapters reach for, kept disjoint from the conceptual development of Lie theory itself.

The division of labor with Chapter 2 is deliberate and worth stating plainly. Chapter 2 is where the ideas live — what a Lie group and its algebra are, the exponential map, Schur's lemma, irreducibility, the adjoint representation, the classification of root systems and the Weyl and Freudenthal formulas that generate dimensions and indices. None of that is reproved here. This appendix imports those results by reference and puts them to work: it converts the abstract machinery into the explicit matrices, traces, and tables a working calculation consumes. Where a derivation here is short and illuminating — the master relation $\dim(R)\,C_2(R) = \dim(G)\,T(R)$, the total antisymmetry of f^{abc}, the fundamental completeness relation — it is carried out in full, because seeing it once fixes the conventions for good. Where a derivation belongs to Chapter 2 — the Weyl dimension formula, the Freudenthal recursion — it is quoted as a tool and its outputs are tabulated.

The appendix is built from the ground up. We begin in Section B.1 with the two invariants every representation carries, the index and the quadratic Casimir, and prove the relation that ties them to each other and to the adjoint. Section B.2 makes everything concrete with the Pauli and Gell-Mann matrices and the full $\mathfrak{su}(2)$ and $\mathfrak{su}(3)$ algebra. Section B.3 establishes the fundamental

completeness (color-Fierz) relation for SU(N) and the trace-reduction algorithm it powers. Section B.4 assembles the standard SU(N) Casimirs and color factors, including the $f^{acd}f^{bcd} = C_A\,\delta^{ab}$ identity that feeds the Yang–Mills beta function. Section B.5 introduces the cubic symmetric invariant d^{abc} and the anomaly coefficient $A(R)$. Section B.6 closes with a book-wide master table of $\dim(R)$, $T(R)$, $C_2(R)$, and $A(R)$ for the classical families SU(N), SO(N), Sp(N) and for the grand-unified representations of SU(5) and SO(10).

The data collected here is consumed throughout the gauge-theory chapters: the color factors of Chapter 27 and Chapter 28, the anomaly bookkeeping of Chapters 36 and 37, and the model-building of Chapter 35 all draw on these tables. We also lean on the global normalization fixed in Chapter A — the fundamental normalization $\mathrm{tr}(T^aT^b) = \frac{1}{2}\delta^{ab}$ in particular — and on the Lorentz-representation context of Chapter 3 and Chapter C, which determines which spinor multiplets carry the gauge charges tabulated here. With those imports declared, the appendix is otherwise self-contained.

B.1 Invariants of a Representation: The Index and the Quadratic Casimir

The chapter introduction framed this appendix as the place where the abstract representation theory built in Chapter 2 is turned into the concrete numbers that gauge-theory computations consume. Where Chapter 2 asked *which* representations a compact Lie algebra has and *how* they decompose, this appendix asks a narrower and more arithmetical question: given a representation, what scalar data does it carry, and how is that data assembled into the coefficients of a beta function, a color factor, an anomalous dimension? Every such number, it turns out, is built from just two invariants attached to each representation — the Dynkin index $T(R)$ and the quadratic Casimir $C_2(R)$ — together with the structure constants of the algebra. This opening section defines those two invariants, proves the single master identity that ties them together, and fixes the one normalization freedom that any conventions document must pin down. Everything in the rest of the appendix — the Pauli and Gell-Mann matrices, the SU(N) identities, the explicit tables — is the evaluation of these abstract objects in a chosen basis. We therefore prove the general statements here, once, and never reprove them.

B.1.1 Setup: the algebra, its generators, and a representation

We import the framework of Chapter 2 wholesale and recall only what we use. Let $\mathfrak{g}$ be a compact simple Lie algebra of dimension $\dim G$ — the number of independent generators, equivalently the number of gauge fields a gauge theory based on $\mathfrak{g}$ carries. In a fixed basis the generators obey the bracket fixed in

Eq. (2.70),

$$\left[T^a, T^b\right] = i f^{abc}\, T^c, \qquad a, b, c = 1, \ldots, \dim G, \tag{B.1}$$

with real structure constants f^{abc} (their reality is reproved below, in Theorem B.7, from the conventions we now adopt). Throughout this appendix the generators are taken *Hermitian*; this is always possible for a compact algebra and is the convention of Chapter A, where the global normalization is fixed by demanding that in the defining (fundamental) representation of $\mathrm{SU}(N)$,

$$\mathrm{tr}\big(T^a T^b\big) = \tfrac{1}{2}\,\delta^{ab} \qquad \text{(fundamental representation)}. \tag{B.2}$$

The choice of the number $\frac{1}{2}$ on the right is the normalization freedom; making it explicit and tracing its consequences is one of the tasks of this section.

A *representation* R assigns to each generator a Hermitian matrix T^a_R of size $\dim R \times \dim R$, preserving the bracket, $\left[T^a_R, T^b_R\right] = i f^{abc} T^c_R$. Two representations recur so often that they deserve standing names and symbols. The *fundamental* (defining) representation, denoted F, is the one normalized by Eq. (B.2). The *adjoint* representation, denoted adj, is the action of the algebra on itself by the bracket; in the basis of Eq. (B.1) its matrices are read off from the structure constants,

$$\left(T^a_{\mathrm{adj}}\right)_{bc} = -i f^{abc}. \tag{B.3}$$

That these matrices satisfy the bracket Eq. (B.1) is precisely the Jacobi identity, as established in Chapter 2; their dimension is the dimension of the algebra itself,

$$\dim(\mathrm{adj}) = \dim G. \tag{B.4}$$

Because f^{abc} is real and (as we show) totally antisymmetric, the matrix $T^a_{\mathrm{adj}} = -i f^{a\,\cdot\,\cdot}$ is i times a real antisymmetric matrix, hence Hermitian, consistent with our standing convention.

One fact from Chapter 2 will be used repeatedly and is worth isolating: for a *simple* algebra the adjoint representation is irreducible, and the generators in *any* representation are traceless,

$$\mathrm{tr}\, T^a_R = 0. \tag{B.5}$$

The tracelessness is immediate from Eq. (B.1): a simple algebra satisfies $\mathfrak{g} = [\mathfrak{g}, \mathfrak{g}]$, so every generator is a linear combination of commutators $\left[T^b_R, T^c_R\right]$, and the trace of a commutator vanishes by cyclicity. We will lean on irreducibility through Schur's lemma (Theorem 2.21) and on Eq. (B.5) when computing indices of tensor products.

B.1.2 Two scalars attached to a representation

There are exactly two natural scalars one can build by contracting two generators of a representation: trace them against each other over the representation space, or sum them against each other over the algebra index. These give the index and the Casimir respectively. We treat each in turn, in each case first establishing that the construction yields a single number rather than a tensor.

The Dynkin index. Consider the matrix-valued, symmetric, two-index object $\mathrm{tr}(T_R^a T_R^b)$. The claim is that it is proportional to δ^{ab}, with a proportionality constant that depends only on R. The key input is that this object is an *invariant* symmetric tensor on the algebra, and that on a simple algebra such tensors are unique up to scale. We prove the uniqueness statement as a lemma, since the same lemma also fixes the Killing form and thereby the normalization conventions.

Lemma B.1 (Uniqueness of the invariant symmetric form)**.** *Let $\mathfrak{g}$ be simple. A symmetric tensor $B^{ab} = B^{ba}$ is called* invariant *if*

$$f^{cad}\, B^{db} + f^{cbd}\, B^{ad} = 0 \qquad \text{for all } a, b, c. \tag{B.6}$$

The space of invariant symmetric tensors is one-dimensional: any two are proportional. In particular, in the basis fixed by Eq. (B.2) the Kronecker tensor δ^{ab} is invariant, and every invariant symmetric tensor is a multiple of δ^{ab}.

Proof. First, Eq. (B.6) is the infinitesimal statement that B is preserved by the adjoint action: it is the component form of $B([Z,X],Y) + B(X,[Z,Y]) = 0$, the requirement that the bilinear form B be ad-invariant. We verify that δ^{ab} satisfies it once f^{abc} is totally antisymmetric (proved independently in Theorem B.7): substituting $B^{ab} = \delta^{ab}$ gives $f^{cab} + f^{cba} = 0$, true by antisymmetry in the last two indices. Thus at least one invariant symmetric tensor, namely δ^{ab}, exists in our basis.

Now let B^{ab} be any invariant symmetric tensor and define a linear operator A on the algebra by its matrix elements $A_{ab} := B^{ab}$ (we use δ to identify upper and lower indices, which is legitimate precisely because δ is invariant). We show A commutes with every adjoint generator. Using Eq. (B.3),

$$\begin{aligned} \left(T^c_{\mathrm{adj}} A\right)_{ab} - \left(A\, T^c_{\mathrm{adj}}\right)_{ab} &= \left(T^c_{\mathrm{adj}}\right)_{ad} A_{db} - A_{ad} \left(T^c_{\mathrm{adj}}\right)_{db} \\ &= -i f^{cad} B^{db} - B^{ad}\left(-i f^{cdb}\right) \\ &= -i\left(f^{cad} B^{db} + f^{cbd} B^{ad}\right) = 0, \end{aligned} \tag{B.7}$$

where in the last line we used $f^{cdb} = -f^{cbd}$ and then Eq. (B.6). Hence A intertwines the adjoint representation with itself. Since $\mathfrak{g}$ is simple, the adjoint representation is irreducible (Chapter 2), so by Schur's lemma (Theorem 2.21) $A = c\,\mathbf{1}$ for a single scalar c, that is $B^{ab} = c\,\delta^{ab}$. Any two invariant symmetric tensors are therefore each proportional to δ^{ab}, hence to one another. □

The trace form $\mathrm{tr}(T_R^a T_R^b)$ is symmetric by cyclicity and invariant because

$$\mathrm{tr}([T_R^c, T_R^a]\, T_R^b) + \mathrm{tr}(T_R^a \left[T_R^c, T_R^b\right]) = \mathrm{tr}\left[T_R^c, T_R^a T_R^b\right] = 0, \tag{B.8}$$

which in components, using Eq. (B.1), is exactly Eq. (B.6) with $B^{ab} = \mathrm{tr}(T_R^a T_R^b)$. By Theorem B.1 it is a multiple of δ^{ab}. That multiple is the index.

Definition B.2 (Dynkin index)**.** The *Dynkin index* (or simply the *index*) $T(R)$ of a representation R is the proportionality constant in

$$\boxed{\mathrm{tr}(T_R^a T_R^b) = T(R)\,\delta^{ab}} \tag{B.9}$$

(no sum on the right). Equivalently, setting $a = b$ and summing, $T(R) = \dfrac{1}{\dim G}\sum_a \mathrm{tr}(T_R^a T_R^a)$.

The index is real and nonnegative: for each fixed a, Hermiticity gives $T(R) = \mathrm{tr}(T_R^a (T_R^a)^\dagger) = \sum_{ij} |(T_R^a)_{ij}|^2 \geq 0$, and it is strictly positive for any faithful representation. Comparison with the normalization Eq. (B.2) gives the standing value of the fundamental index that the threads use,

$$T(F) \equiv T_F = \tfrac{1}{2}. \tag{B.10}$$

This single number is the entire content of the normalization choice: had we set $\mathrm{tr}(T^a T^b) = \delta^{ab}$ in the fundamental we would have $T_F = 1$ instead, and every index and Casimir in the appendix would rescale accordingly. The physics — ratios of color factors, the structure of beta functions — is independent of the choice; only the bookkeeping changes. Section B.1.4 records the clash with conventions that make the other choice.

The quadratic Casimir. The complementary contraction sums the two generators over the algebra index rather than tracing over the representation space:

$$C_R := \sum_a T_R^a\, T_R^a. \tag{B.11}$$

This is a matrix on the representation space, not a number; but it is a very special matrix.

Proposition B.3 (The quadratic Casimir is a c-number on an irreducible representation)**.** *The operator C_R of Eq. (B.11) commutes with every generator, $\left[C_R, T_R^b\right] = 0$. If R is irreducible, then $C_R = C_2(R)\,\mathbf{1}$ for a single scalar $C_2(R)$, the* quadratic Casimir *of R.*

Proof. Using the Leibniz rule for the commutator, $\left[T_R^a T_R^a, T_R^b\right] = T_R^a \left[T_R^a, T_R^b\right] + \left[T_R^a, T_R^b\right] T_R^a$, and the bracket Eq. (B.1),

$$\left[C_R, T_R^b\right] = \sum_a \left(T_R^a \, i f^{abc} T_R^c + i f^{abc} T_R^c \, T_R^a\right) = i f^{abc} (T_R^a T_R^c + T_R^c T_R^a). \tag{B.12}$$

The bracket $\{T_R^a, T_R^c\}$ is symmetric in $a \leftrightarrow c$, while f^{abc} is antisymmetric in $a \leftrightarrow c$ (Theorem B.7); the contraction of a symmetric with an antisymmetric tensor vanishes, so $\left[C_R, T_R^b\right] = 0$. Thus C_R commutes with every element of the representation. If R is irreducible, Schur's lemma (Theorem 2.21) forces C_R to be a multiple of the identity, $C_R = C_2(R)\,\mathbf{1}$. □

Definition B.4 (Quadratic Casimir)**.** For an irreducible representation R, the *quadratic Casimir* $C_2(R)$ is the scalar defined by

$$\boxed{\sum_a T_R^a T_R^a = C_2(R)\,\mathbf{1}} \tag{B.13}$$

The Casimir of the fundamental is denoted $C_F := C_2(F)$ and that of the adjoint $C_A := C_2(\mathrm{adj})$.

Caution

The Casimir is a c-number only on an *irreducible* representation. On a reducible $R = \bigoplus_i R_i$ the operator C_R is block-diagonal, equal to $C_2(R_i)\mathbf{1}$ on the i-th block, and is a genuine multiple of the identity only when all the $C_2(R_i)$ coincide. The index $T(R)$, by contrast, is defined and additive for any R (Theorem B.9). This asymmetry is why the master relation below is stated for irreducible R but its trace form survives for reducible R.

B.1.3 The master relation

The index and the Casimir are not independent: they are two ways of contracting the same object $\sum_a T_R^a T_R^a$, and equating the two evaluations of its trace binds them. This is the structural backbone of the whole appendix.

Theorem B.5 (Index–Casimir master relation)**.** *For any irreducible representation R of a compact simple Lie algebra,*

$$\boxed{\dim(R)\, C_2(R) = \dim(G)\, T(R)} \tag{B.14}$$

where $\dim(R)$ *is the dimension of the representation space and* $\dim(G)$ *the dimension of the algebra.*

Proof. Compute the number $\sum_a \operatorname{tr}(T_R^a T_R^a)$ in two ways. On the one hand, the trace acts on the representation space; using Eq. (B.13),

$$\sum_a \operatorname{tr}(T_R^a T_R^a) = \operatorname{tr}\Big(\sum_a T_R^a T_R^a\Big) = \operatorname{tr}\big(C_2(R)\,\mathbf{1}\big) = C_2(R)\,\dim(R). \tag{B.15}$$

On the other hand, take the trace first and use the index Eq. (B.9) with $a = b$:

$$\sum_a \operatorname{tr}(T_R^a T_R^a) = \sum_a T(R)\,\delta^{aa} = T(R)\sum_a 1 = T(R)\,\dim(G), \tag{B.16}$$

since the index a runs over the $\dim(G)$ generators. Equating Eq. (B.15) and Eq. (B.16) gives Eq. (B.14). □

The relation is a rigid constraint: given the dimensions $\dim(R)$ and $\dim(G)$ and either invariant, the other is fixed. Two consequences fix terminology for the rest of the book.

First, applied to the fundamental of SU(N), where $\dim(G) = N^2 - 1$, $\dim(F) = N$, and $T_F = \frac{1}{2}$ from Eq. (B.10), it gives

$$C_F = \frac{\dim(G)}{\dim(F)}\,T_F = \frac{N^2-1}{N}\cdot\frac{1}{2} = \frac{N^2-1}{2N}, \tag{B.17}$$

the standing value used throughout Yang–Mills theory. (The explicit verification that the SU(N) fundamental indeed has $T_F = \frac{1}{2}$, from the Pauli and Gell-Mann matrices, is the business of the next section; here we only show that *given* T_F, the Casimir is forced.)

Second, applied to the adjoint, where $\dim(\text{adj}) = \dim(G)$ by Eq. (B.4), the master relation collapses to an identity of the two adjoint invariants.

Corollary B.6 (The adjoint index equals the adjoint Casimir)**.** *For the adjoint representation,* $\dim(\text{adj}) = \dim(G)$*, so Eq.* (B.14) *reads* $\dim(G)\,C_2(\text{adj}) = \dim(G)\,T(\text{adj})$*, i.e.*

$$T(\text{adj}) = C_2(\text{adj}) \;\equiv\; C_A. \tag{B.18}$$

The common value C_A is the single number carried by the adjoint representation.

That the adjoint's index and Casimir coincide is the reason a non-abelian gauge field contributes to its own beta function through the one symbol C_A: the gluon loop is governed by the adjoint index, the gluon self-energy by the adjoint Casimir, and they are equal. We make the value $C_A = N$ for SU(N) explicit once the structure constants are in hand; the equality Eq. (B.18) is prior to any such evaluation.

Physical Insight

The two invariants are exactly the two ways a representation enters a one-loop diagram. A matter loop — a closed loop of fields in representation R inserted in a gauge-boson propagator — produces a trace over R of two generators, and so is proportional to the *index* $T(R)$; this is the origin of the $-\frac{4}{3}T_F n_f$ matter contribution to the Yang–Mills beta function in Chapter 27. A gauge boson attached at both ends to a single matter line — the rainbow self-energy of that line — produces a sum over the algebra index of two generators, $\sum_a T_R^a T_R^a$, and so is proportional to the *Casimir* $C_2(R)$; this is the origin of the C_F in the fermion field renormalization and of C_A in the gluon's. The master relation is then the bookkeeping fact that ensures the two computations are consistent. This is the sense in which the present section "supplies" Yang–Mills theory without yet advancing it: the symbols C_A, T_F, C_F are defined and related here, to be consumed in Chapters 27 and 28.

B.1.4 Structure constants: total antisymmetry, reality, and the Killing form

We owe two facts used above: that f^{abc} is totally antisymmetric and real, and that the Killing form is proportional to δ^{ab}. Both follow from the trace normalization once we express f^{abc} as a trace.

Multiply the bracket Eq. (B.1), written in representation R, by T_R^d and trace, using Eq. (B.9):

$$\operatorname{tr}\!\left(\left[T_R^a, T_R^b\right] T_R^d\right) = i f^{abc}\, \operatorname{tr}\!\left(T_R^c T_R^d\right) = i f^{abc}\, T(R)\, \delta^{cd} = i\, T(R)\, f^{abd}. \tag{B.19}$$

Solving for the structure constant exhibits it as a trace,

$$f^{abc} = -\frac{i}{T(R)}\, \operatorname{tr}\!\left(\left[T_R^a, T_R^b\right] T_R^c\right), \tag{B.20}$$

valid in any faithful representation (so that $T(R) \neq 0$); the right-hand side is manifestly independent of R because the left-hand side is.

Proposition B.7 (f^{abc} is totally antisymmetric and real)**.** *The structure constants in the Hermitian, trace-orthonormal basis are completely antisymmetric under permutation of a, b, c and are real.*

Proof. Write $h^{abc} := \operatorname{tr}\!\left(\left[T_R^a, T_R^b\right] T_R^c\right)$, so that $f^{abc} = -i\, h^{abc}/T(R)$ by Eq. (B.20). We establish the symmetries of h.

Antisymmetry in $a \leftrightarrow b$. Immediate, since $\left[T_R^a, T_R^b\right] = -\left[T_R^b, T_R^a\right]$, hence $h^{abc} = -h^{bac}$.

Cyclicity. Expand $h^{abc} = \mathrm{tr}(T_R^a T_R^b T_R^c) - \mathrm{tr}(T_R^b T_R^a T_R^c)$ and use the cyclicity of the trace, $\mathrm{tr}(XYZ) = \mathrm{tr}(YZX)$, on each term: $\mathrm{tr}(T_R^a T_R^b T_R^c) = \mathrm{tr}(T_R^b T_R^c T_R^a)$ and $\mathrm{tr}(T_R^b T_R^a T_R^c) = \mathrm{tr}(T_R^a T_R^c T_R^b) = \mathrm{tr}(T_R^c T_R^b T_R^a)$. Therefore

$$h^{abc} = \mathrm{tr}(T_R^b T_R^c T_R^a) - \mathrm{tr}(T_R^c T_R^b T_R^a) = \mathrm{tr}\Big(\Big[T_R^b, T_R^c\Big] T_R^a\Big) = h^{bca}. \tag{B.21}$$

A function of three indices that is cyclic and antisymmetric under one transposition is antisymmetric under all of them: combining $h^{abc} = h^{bca}$ with $h^{abc} = -h^{bac}$ gives $h^{acb} = h^{cba} = h^{bac} = -h^{abc}$ and likewise for the remaining odd permutations, so every transposition flips the sign. Thus h^{abc}, and with it f^{abc}, is totally antisymmetric.

Reality. For any matrix M, $(\mathrm{tr}\, M)^* = \mathrm{tr}(M^\dagger)$. Take $M = \Big[T_R^a, T_R^b\Big] T_R^c$; using Hermiticity $T_R^{a\dagger} = T_R^a$,

$$M^\dagger = T_R^c \Big[T_R^a, T_R^b\Big]^\dagger = T_R^c (T_R^b T_R^a - T_R^a T_R^b) = -\, T_R^c \Big[T_R^a, T_R^b\Big], \tag{B.22}$$

so that, by cyclicity again, $(h^{abc})^* = \mathrm{tr}(M^\dagger) = -\,\mathrm{tr}(T_R^c \Big[T_R^a, T_R^b\Big]) = -\,\mathrm{tr}(\Big[T_R^a, T_R^b\Big] T_R^c) = -h^{abc}$. Hence h^{abc} is purely imaginary. Since $T(R)$ is real and positive (Theorem B.2), $f^{abc} = -i\, h^{abc}/T(R)$ obeys $(f^{abc})^* = +i\,(h^{abc})^*/T(R) = +i\,(-h^{abc})/T(R) = -i\, h^{abc}/T(R) = f^{abc}$, i.e. f^{abc} is real. □

With f^{abc} real and totally antisymmetric, the adjoint generators Eq. (B.3) are Hermitian as promised, and the consistency check on δ^{ab} in Theorem B.1 is justified. The final piece is the Killing form, the invariant form built directly from the structure constants.

Proposition B.8 (The Killing form fixes the normalization)**.** *Define the Killing form $K^{ab} := f^{acd} f^{bcd}$ (summed over c, d). Then*

$$K^{ab} = \mathrm{tr}(T_{\mathrm{adj}}^a T_{\mathrm{adj}}^b) = T(\mathrm{adj})\, \delta^{ab} = C_A\, \delta^{ab}. \tag{B.23}$$

In particular the Killing form is proportional to δ^{ab}, and for a compact algebra (with our Hermitian generators) it is positive-definite, with the single positive eigenvalue C_A. This proportionality is the statement that the algebra is simple: it leaves exactly one overall scale free, the scale fixed by Eq. (B.2).

Proof. Insert the adjoint matrices Eq. (B.3) into the trace:

$$\mathrm{tr}(T_{\mathrm{adj}}^a T_{\mathrm{adj}}^b) = (T_{\mathrm{adj}}^a)_{cd} (T_{\mathrm{adj}}^b)_{dc} = (-i f^{acd})(-i f^{bdc}) = -f^{acd} f^{bdc}. \tag{B.24}$$

By the total antisymmetry of Theorem B.7, $f^{bdc} = -f^{bcd}$, so $-f^{acd} f^{bdc} = f^{acd} f^{bcd} = K^{ab}$, which is the first equality in Eq. (B.23). But $\mathrm{tr}(T_{\mathrm{adj}}^a T_{\mathrm{adj}}^b)$ is the trace form of the adjoint representation, equal to $T(\mathrm{adj})\, \delta^{ab}$ by the index definition Eq. (B.9); with $T(\mathrm{adj}) = C_A$ from Theorem B.6 this gives the remaining

equalities. Positive-definiteness is the ≥ 0 argument of Theorem B.2 applied to the (Hermitian, faithful) adjoint representation: $K^{aa} = \sum_{c,d} |f^{acd}|^2 > 0$ for each a, since a nonzero generator has at least one nonvanishing structure constant in a simple algebra. Finally, that K^{ab} is forced to be a *single* multiple of δ^{ab} — rather than, say, a different multiple in each invariant subspace — is the content of Theorem B.1: the Killing form is an invariant symmetric tensor, and on a simple algebra there is only one such up to scale. A non-simple (e.g. semisimple) algebra would have one free scale per simple factor; simplicity is precisely what reduces this to a single overall normalization. □

Notation Watch

The one convention to keep straight across references is the value of T_F. This book and the bulk of the particle-physics literature (Peskin–Schroeder, Schwartz) set $\mathrm{tr}(T_F^a T_F^b) = \frac{1}{2}\delta^{ab}$, hence $T_F = \frac{1}{2}$, $C_A = N$, $C_F = \frac{N^2-1}{2N}$ for SU(N). Some mathematical and older texts normalize the adjoint instead, taking the Killing form itself as the metric ($C_A = 1$), which rescales every index and Casimir. The dimensionless ratios that enter physical predictions — for instance C_A/T_F and C_F/C_A in the beta function — are invariant under the choice; only the absolute values move. When importing a number from outside this book, check which T_F it assumes before using it.

B.1.5 Worked examples

The two invariants behave simply under the two ways of building new representations from old — direct sums and tensor products — and these behaviors are exactly what is needed to handle a theory with several matter multiplets. We work them out here, staying entirely within the abstract setting; the explicit low-rank evaluations are deferred to the next section.

Worked Example B.9 (The index is additive; the Casimir is per-irreducible–component)**.** Let $R = R_1 \oplus R_2$ be a direct sum, so that on the block-diagonal representation space the generators are $T_R^a = T_{R_1}^a \oplus T_{R_2}^a = \begin{pmatrix} T_{R_1}^a & 0 \\ 0 & T_{R_2}^a \end{pmatrix}$. The trace of a block-diagonal product is the sum of the block traces, so

$$\mathrm{tr}(T_R^a T_R^b) = \mathrm{tr}(T_{R_1}^a T_{R_1}^b) + \mathrm{tr}(T_{R_2}^a T_{R_2}^b) = (T(R_1) + T(R_2))\delta^{ab}, \tag{B.25}$$

whence the index is additive over direct sums,

$$T(R_1 \oplus R_2) = T(R_1) + T(R_2). \tag{B.26}$$

This is why a gauge theory with n_f Dirac fermions in the fundamental contributes a matter index $n_f\, T_F$ to the beta function: the n_f flavors furnish the direct

sum $F^{\oplus n_f}$, of index $n_f T_F$, which is the origin of the $-\frac{4}{3}T_F n_f$ term carried in Yang–Mills theory (Chapter 27).

The Casimir does not combine so simply, and the contrast is instructive. The Casimir operator on the sum is block-diagonal,

$$C_R = \sum_a T_R^a T_R^a = \big(C_2(R_1)\mathbf{1}_{R_1}\big) \oplus \big(C_2(R_2)\mathbf{1}_{R_2}\big), \tag{B.27}$$

which is a single multiple of the identity only if $C_2(R_1) = C_2(R_2)$. There is no scalar "$C_2(R_1 \oplus R_2)$" in general; the Casimir is an invariant of an *irreducible* representation. What *does* survive for the reducible sum is the trace form of the master relation: taking the trace of C_R,

$$\sum_i C_2(R_i)\,\dim(R_i) = \dim(G)\,T(R), \tag{B.28}$$

the dimension-weighted sum of the component Casimirs equals $\dim(G)$ times the total index, the natural generalization of Eq. (B.14) to a reducible R.

Worked Example B.10 (The index of a tensor product)**.** Let $R_1 \otimes R_2$ be a tensor product. On the product space the generators act by the Leibniz (co-product) rule established in Chapter 2,

$$T^a_{R_1\otimes R_2} = T^a_{R_1} \otimes \mathbf{1}_{R_2} + \mathbf{1}_{R_1} \otimes T^a_{R_2}. \tag{B.29}$$

We compute the index from Eq. (B.9). Using $\mathrm{tr}(X \otimes Y) = \mathrm{tr}\,X\ \mathrm{tr}\,Y$ and expanding the product of two co-products,

$$\begin{aligned}\mathrm{tr}\big(T^a_{R_1\otimes R_2} T^b_{R_1\otimes R_2}\big) = {}& \mathrm{tr}\big(T^a_{R_1}T^b_{R_1}\big)\ \mathrm{tr}\big(\mathbf{1}_{R_2}\big) + \mathrm{tr}\big(\mathbf{1}_{R_1}\big)\ \mathrm{tr}\big(T^a_{R_2}T^b_{R_2}\big) \\ & + \mathrm{tr}\big(T^a_{R_1}\big)\,\mathrm{tr}\big(T^b_{R_2}\big) + \mathrm{tr}\big(T^b_{R_1}\big)\,\mathrm{tr}\big(T^a_{R_2}\big).\end{aligned} \tag{B.30}$$

The two cross terms in the second line vanish because the generators of a simple algebra are traceless, Eq. (B.5). The surviving terms give, with $\mathrm{tr}\,\mathbf{1}_{R_i} = \dim(R_i)$,

$$\mathrm{tr}\big(T^a_{R_1\otimes R_2} T^b_{R_1\otimes R_2}\big) = \big(T(R_1)\dim(R_2) + \dim(R_1)\,T(R_2)\big)\delta^{ab}, \tag{B.31}$$

so the index of a tensor product is

$$T(R_1 \otimes R_2) = T(R_1)\dim(R_2) + \dim(R_1)\,T(R_2). \tag{B.32}$$

It is worth seeing how the Casimir, by contrast, is well-behaved on a tensor product precisely *because* of the cross term that dropped out above. Squaring the co-product Eq. (B.29) and summing over a,

$$\sum_a T^a_{R_1\otimes R_2} T^a_{R_1\otimes R_2} = C_2(R_1)\,\mathbf{1}\otimes\mathbf{1} + \mathbf{1}\otimes\mathbf{1}\,C_2(R_2) + 2\sum_a T^a_{R_1}\otimes T^a_{R_2}. \tag{B.33}$$

The mixed term $2\sum_a T^a_{R_1}\otimes T^a_{R_2}$ is *not* a multiple of the identity — the product $R_1 \otimes R_2$ is in general reducible, and this operator is what distinguishes its

irreducible summands. Indeed, restricting Eq. (B.33) to an irreducible component $R \subseteq R_1 \otimes R_2$ (on which the left side is $C_2(R)\mathbf{1}$ by Theorem B.3) solves for the mixed term and yields the "addition of Casimirs" rule

$$\sum_a T^a_{R_1} \otimes T^a_{R_2}\Big|_R = \tfrac{1}{2}\big(C_2(R) - C_2(R_1) - C_2(R_2)\big)\mathbf{1}, \tag{B.34}$$

the group-theoretic analogue of $\mathbf{S}_1\cdot\mathbf{S}_2 = \frac{1}{2}(\mathbf{S}^2 - \mathbf{S}_1^2 - \mathbf{S}_2^2)$ from the addition of angular momenta. Equation (B.34) is the color algebra behind every quark–antiquark or quark–gluon interaction: it converts a contracted pair of generators on two distinct lines into the difference of Casimirs of the total and the individual representations.

We now have the abstract pair $\big(T(R), C_2(R)\big)$ for every representation, the master relation $\dim(R)\,C_2(R) = \dim(G)\,T(R)$ that binds them, the identification $T(\text{adj}) = C_2(\text{adj}) = C_A$, and the additive and tensor-product rules that handle composite matter content — all proved from the single normalization Eq. (B.2). What remains is to turn these abstractions into numbers. The next section does exactly that, writing the Pauli and Gell-Mann matrices explicitly, extracting the $\mathfrak{su}(3)$ structure constants and symmetric symbols, and verifying the master relation in its first two concrete instances: the $\mathfrak{su}(2)$ spin-j representations and the $\mathfrak{su}(3)$ fundamental.

B.2 The Low-Rank Algebras: Pauli and Gell-Mann Matrices

The previous section attached to every representation R of a compact simple Lie algebra two scalars—the Dynkin index $T(R)$ of Theorem B.2 and the quadratic Casimir $C_2(R)$ of Theorem B.4—and proved that they are not independent but bound by the master identity $\dim(R)\,C_2(R) = \dim(G)\,T(R)$ of Theorem B.5. That development was deliberately abstract: it used only the defining trace normalization and Schur's lemma, never a single explicit generator. The price of that generality is that the reader has, so far, no concrete object to hold. This section pays the abstraction back. We write down the generators of the two algebras that the rest of the book actually uses—$\mathfrak{su}(2)$, the algebra of weak isospin and of ordinary spin, and $\mathfrak{su}(3)$, the algebra of color—in the only two forms a physicist ever needs them: the Pauli matrices σ^i and the Gell-Mann matrices λ^a. From these explicit matrices we prove the multiplication laws that downstream chapters quote in passing, extract the full set of $\mathfrak{su}(3)$ structure constants f^{abc} and the symmetric symbols d^{abc} by direct trace computation, and then close the loop with Section 1 by evaluating $T(R)$ and $C_2(R)$ in their first two nontrivial instances and watching the master identity come out right to the digit. A secondary purpose is bookkeeping across appendices: the Pauli algebra

proved here is exactly the input that Chapter C imports without proof when it builds the four-dimensional Dirac technology, and the $\mathfrak{su}(3)$ data primes the color-factor machinery that Yang–Mills theory leans on.

Throughout we use the global generator convention of Chapter A: generators T^a are Hermitian, the structure constants are real and defined by $\left[T^a, T^b\right] = if^{abc}T^c$, and the fundamental representation is normalized by $\mathrm{tr}(T^aT^b) = \frac{1}{2}\delta^{ab}$. Fixing this normalization is what makes $T(\mathrm{fund}) = \frac{1}{2}$ a definition rather than a derived number; everything else in the section is then forced.

B.2.1 The Pauli matrices and the algebra $\mathfrak{su}(2)$

Definition B.11 (Pauli matrices)**.** The three *Pauli matrices* are the Hermitian, traceless 2×2 matrices

$$\sigma^1 = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}, \qquad \sigma^2 = \begin{pmatrix} 0 & -i \\ i & 0 \end{pmatrix}, \qquad \sigma^3 = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}. \tag{B.35}$$

The generators of $\mathfrak{su}(2)$ in the fundamental (spin-$\frac{1}{2}$) representation are $T^i = \frac{1}{2}\sigma^i$.

Everything about $\mathfrak{su}(2)$ at the matrix level follows from a single product law, and that law is read off by multiplying the explicit matrices. There is nothing to assume: we compute the nine products $\sigma^i\sigma^j$ once and recognize the pattern.

Proposition B.12 (Pauli product law)**.** *The Pauli matrices satisfy*

$$\sigma^i\sigma^j = \delta^{ij}\,\mathbf{1} + i\,\epsilon^{ijk}\sigma^k, \tag{B.36}$$

with $\mathbf{1}$ *the* 2×2 *identity and* ϵ^{ijk} *the totally antisymmetric symbol normalized by* $\epsilon^{123} = 1$*. Equivalently, separating the symmetric and antisymmetric parts in* $i \leftrightarrow j$*,*

$$\left\{\sigma^i, \sigma^j\right\} = 2\,\delta^{ij}\,\mathbf{1}, \tag{B.37}$$

$$\left[\sigma^i, \sigma^j\right] = 2i\,\epsilon^{ijk}\sigma^k. \tag{B.38}$$

Proof. The diagonal products are immediate from Eq. (B.35): each Pauli matrix squares to the identity,

$$(\sigma^1)^2 = (\sigma^2)^2 = (\sigma^3)^2 = \mathbf{1}, \tag{B.39}$$

as one checks by squaring each 2×2 matrix—for instance $(\sigma^2)^2 = \left(\begin{smallmatrix} 0 & -i \\ i & 0 \end{smallmatrix}\right)\left(\begin{smallmatrix} 0 & -i \\ i & 0 \end{smallmatrix}\right) = \left(\begin{smallmatrix} 1 & 0 \\ 0 & 1 \end{smallmatrix}\right)$. The three independent off-diagonal products are

$$\sigma^1\sigma^2 = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}\begin{pmatrix} 0 & -i \\ i & 0 \end{pmatrix} = \begin{pmatrix} i & 0 \\ 0 & -i \end{pmatrix} = i\,\sigma^3, \tag{B.40}$$

$$\sigma^2\sigma^3 = \begin{pmatrix} 0 & -i \\ i & 0 \end{pmatrix}\begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix} = \begin{pmatrix} 0 & i \\ i & 0 \end{pmatrix} = i\,\sigma^1, \tag{B.41}$$

$$\sigma^3\sigma^1 = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}\begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix} = \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix} = i\,\sigma^2. \tag{B.42}$$

The reversed orderings follow by taking the Hermitian conjugate of these three lines (each σ^i is Hermitian, and $(AB)^\dagger = B^\dagger A^\dagger$), which flips the sign of the imaginary right-hand sides: $\sigma^2\sigma^1 = -i\sigma^3$, and cyclically. Collecting the diagonal results into $\sigma^i\sigma^i = \mathbf{1}$ (no sum) and the off-diagonal results into $\sigma^i\sigma^j = i\epsilon^{ijk}\sigma^k$ for $i \neq j$ is precisely the single statement Eq. (B.36): the δ^{ij} term supplies the diagonal case and the $i\epsilon^{ijk}\sigma^k$ term supplies the off-diagonal case, and the two never overlap. Adding Eq. (B.36) to itself with i, j swapped, and using $\epsilon^{ijk} = -\epsilon^{jik}$, gives Eq. (B.37); subtracting gives Eq. (B.38). □

Three consequences are worth recording because the book uses them by name. First, Eq. (B.38) divided by 2 in each factor reads $[T^i, T^j] = i\epsilon^{ijk}T^k$, so the $\mathfrak{su}(2)$ structure constants in the convention $\left[T^a, T^b\right] = if^{abc}T^c$ are simply

$$f^{ijk} = \epsilon^{ijk}. \tag{B.43}$$

Second, the anticommutator Eq. (B.37) fixes the fundamental trace normalization:

$$\operatorname{tr}(T^iT^j) = \tfrac{1}{4}\operatorname{tr}(\sigma^i\sigma^j) = \tfrac{1}{4}\operatorname{tr}\Big(\tfrac{1}{2}\left\{\sigma^i, \sigma^j\right\}\Big) = \tfrac{1}{4}\,\delta^{ij}\operatorname{tr}\mathbf{1}\cdot\tfrac{1}{2}\cdot 2 = \tfrac{1}{2}\,\delta^{ij}, \tag{B.44}$$

where we used $\operatorname{tr}(\sigma^i\sigma^j) = \frac{1}{2}\operatorname{tr}\{\sigma^i, \sigma^j\}$ because the trace of the antisymmetric commutator part vanishes, then $\operatorname{tr}\mathbf{1} = 2$. This confirms $T(\text{fund}) = \frac{1}{2}$ for $\mathfrak{su}(2)$ and is the $\mathfrak{su}(2)$ instance of the canonical normalization. Third, and most useful downstream, is the completeness statement that the four matrices $\{\mathbf{1}, \sigma^1, \sigma^2, \sigma^3\}$ span the space of all 2×2 matrices.

Proposition B.13 (Pauli completeness relation)**.** *With Latin indices $a, b, c, d \in \{1, 2\}$ labelling matrix entries,*

$$\sum_{i=1}^{3}(\sigma^i)_{ab}\,(\sigma^i)_{cd} = 2\,\delta_{ad}\,\delta_{bc} - \delta_{ab}\,\delta_{cd}. \tag{B.45}$$

Proof. Adjoin the identity to the Pauli matrices and write the four-element set $\tau^\mu = (\mathbf{1}, \sigma^1, \sigma^2, \sigma^3)$, $\mu = 0, 1, 2, 3$. These four matrices are orthonormal under the inner product $\langle A, B\rangle = \frac{1}{2}\operatorname{tr}(A^\dagger B)$ on the four-dimensional complex vector space of 2×2 matrices: indeed $\frac{1}{2}\operatorname{tr}(\mathbf{1}\,\mathbf{1}) = 1$, $\frac{1}{2}\operatorname{tr}(\mathbf{1}\,\sigma^i) = 0$ by tracelessness, and $\frac{1}{2}\operatorname{tr}(\sigma^i\sigma^j) = \delta^{ij}$ by Eq. (B.44) scaled up by four. Four orthonormal vectors in a four-dimensional space form a complete basis. Completeness of an orthonormal basis $\{B_\mu = \tau^\mu/\sqrt{2}\}$ under the unnormalized trace pairing $\operatorname{tr}(A^\dagger B)$ means that

every matrix M obeys $M = \sum_\mu \operatorname{tr}(B_\mu^\dagger M)\, B_\mu$; reading off the (a,b) entry for arbitrary M and stripping M gives the resolution of the identity on matrix space,

$$\sum_\mu (B_\mu)_{ab}\,(B_\mu)^*_{dc} = \delta_{ad}\,\delta_{bc}. \tag{B.46}$$

The τ^μ are Hermitian, so $(B_\mu)^*_{dc} = (B_\mu)_{cd}$, and with $B_\mu = \tau^\mu/\sqrt{2}$ this is

$$\tfrac{1}{2}\sum_{\mu=0}^{3} (\tau^\mu)_{ab}\,(\tau^\mu)_{cd} = \delta_{ad}\,\delta_{bc}. \tag{B.47}$$

Separating the $\mu = 0$ term $(\tau^0)_{ab}(\tau^0)_{cd} = \delta_{ab}\delta_{cd}$ from the three Pauli terms and solving for the latter yields Eq. (B.45). □

Equation (B.45) is the $\mathfrak{su}(2)$ ancestor of the SU(N) color-Fierz identity that Section B.3.1 builds in general; in the two-component spinor calculus of Chapter C it is the relation that collapses products of σ-matrices and underlies the Fierz rearrangement of Pauli bilinears. We have now discharged, with full proofs, every Pauli identity that Chapter C imports: the product law Eq. (B.36), the anticommutator Eq. (B.37), and the completeness relation Eq. (B.45).

B.2.2 The representation invariants of $\mathfrak{su}(2)$

To evaluate C_2 and T for the general spin-j representation we import the representation theory itself, not rebuild it: Theorem 2.53 constructs, for each $j \in \{0, \tfrac{1}{2}, 1, \tfrac{3}{2}, \dots\}$, an irreducible representation on a $(2j+1)$-dimensional space with orthonormal basis $|j,m\rangle$, $m = -j, -j+1, \dots, j$, on which the Hermitian generators J_i (the spin-j image of the abstract T^i, so that $[J_i, J_j] = i\epsilon^{ijk}J_k$) act by

$$J_3\,|j,m\rangle = m\,|j,m\rangle\,, \qquad J_\pm\,|j,m\rangle = \sqrt{j(j+1) - m(m\pm 1)}\;\,|j,m\pm 1\rangle\,, \tag{B.48}$$

with $J_\pm = J_1 \pm i J_2$. We take Eq. (B.48) as given and compute the two invariants from it.

Proposition B.14 ($\mathfrak{su}(2)$ Casimir and index)**.** *For the spin-j representation of $\mathfrak{su}(2)$,*

$$C_2(j) = j(j+1), \tag{B.49}$$

$$T(j) = \tfrac{1}{3}\, j(j+1)(2j+1). \tag{B.50}$$

Proof. The Casimir. By Theorem B.4 the quadratic Casimir is the operator $J^2 \equiv \sum_i J_i J_i = C_2(j)\,\mathbf{1}$, a multiple of the identity because it commutes with every J_i and the representation is irreducible (Schur's lemma). To find the constant, evaluate J^2 on a single convenient state. Write

$$J^2 = J_3^2 + \tfrac{1}{2}(J_+J_- + J_-J_+), \tag{B.51}$$

which follows from $J_\pm = J_1 \pm iJ_2$ since $J_+J_- + J_-J_+ = 2(J_1^2 + J_2^2)$. Act on the highest-weight state $|j,j\rangle$. From Eq. (B.48), $J_+ |j,j\rangle = 0$ because the square root $\sqrt{j(j+1) - j(j+1)}$ vanishes, so $J_-J_+ |j,j\rangle = 0$. The remaining term is $J_+J_- |j,j\rangle$: lowering then raising,

$$J_+J_- |j,j\rangle = \big[j(j+1) - j(j-1)\big] |j,j\rangle = 2j \ |j,j\rangle \,, \tag{B.52}$$

using Eq. (B.48) twice (the two square-root factors multiply to the bracket). Hence

$$J^2 |j,j\rangle = \Big(j^2 + \tfrac{1}{2}\cdot 2j\Big) |j,j\rangle = j(j+1) |j,j\rangle \,, \tag{B.53}$$

and since J^2 is the constant $C_2(j)$ times the identity, $C_2(j) = j(j+1)$, which is Eq. (B.49).

The index. By Theorem B.2, $T(j)$ is defined by $\mathrm{tr}(J_aJ_b) = T(j)\delta_{ab}$; setting $a = b = 3$ (no sum) gives $T(j) = \mathrm{tr}(J_3^2)$. The trace is over the orthonormal basis $|j,m\rangle$, on which J_3 is diagonal with eigenvalues m, so

$$T(j) = \sum_{m=-j}^{j} m^2 . \tag{B.54}$$

It remains to evaluate this finite sum and show it equals $\frac{1}{3}j(j+1)(2j+1)$ for both integer and half-integer j. For *integer* j the sum is symmetric about zero, so

$$\sum_{m=-j}^{j} m^2 = 2\sum_{m=1}^{j} m^2 = 2\cdot\frac{j(j+1)(2j+1)}{6} = \frac{j(j+1)(2j+1)}{3}, \tag{B.55}$$

using the elementary closed form $\sum_{m=1}^{n} m^2 = \frac{1}{6}n(n+1)(2n+1)$. For *half-integer* j write $j = p - \frac{1}{2}$ with p a positive integer; the allowed m are $\pm\frac{1}{2}, \pm\frac{3}{2}, \ldots, \pm(p-\frac{1}{2})$, and

$$\begin{aligned}\sum_{m=-j}^{j} m^2 &= 2\sum_{k=1}^{p}\Big(k-\tfrac{1}{2}\Big)^2 = 2\sum_{k=1}^{p}\Big(k^2 - k + \tfrac{1}{4}\Big) \\ &= 2\left[\frac{p(p+1)(2p+1)}{6} - \frac{p(p+1)}{2} + \frac{p}{4}\right] = \frac{2p^3+3p^2+p}{3} - p^2 - p + \frac{p}{2} \\ &= \frac{2p^3}{3} - \frac{p}{6}. \end{aligned} \tag{B.56}$$

On the other hand, substituting $j = p - \frac{1}{2}$ into $\frac{1}{3}j(j+1)(2j+1)$ and using $2j+1 = 2p$, $j(j+1) = (p-\frac{1}{2})(p+\frac{1}{2}) = p^2 - \frac{1}{4}$, gives $\frac{1}{3}(p^2-\frac{1}{4})(2p) = \frac{2p^3}{3} - \frac{p}{6}$, the same value. Thus Eq. (B.54) equals $\frac{1}{3}j(j+1)(2j+1)$ for every allowed j, establishing Eq. (B.50). □

Worked Example B.15 (The master identity for $\mathfrak{su}(2)$ spin-j)**.** Theorem B.5 asserts $\dim(R)\,C_2(R) = \dim(G)\,T(R)$ for every representation, with $\dim(G)$ the dimension of the algebra. For $\mathfrak{su}(2)$ the algebra is three-dimensional ($\dim G = 3$, the three generators), and the spin-j representation has $\dim R = 2j+1$. The left-hand side, using Eq. (B.49), is

$$\dim(R)\,C_2(R) = (2j+1)\,j(j+1). \tag{B.57}$$

The right-hand side, using Eq. (B.50), is

$$\dim(G)\,T(R) = 3\cdot\tfrac{1}{3}\,j(j+1)(2j+1) = (2j+1)\,j(j+1). \tag{B.58}$$

The two agree identically in j—the factor of three in $\dim(G)$ exactly cancels the $\frac{1}{3}$ in $T(j)$, which is no coincidence but the content of the master identity, since both sides are $\sum_a \mathrm{tr}(J_a J_a) = \mathrm{tr}(J^2)$ computed two ways. As a numerical sanity check, take the three smallest cases. The fundamental $j=\frac{1}{2}$ gives $\dim R = 2$, $C_2 = \frac{3}{4}$, $T = \frac{1}{2}$, and indeed $2\cdot\frac{3}{4} = \frac{3}{2} = 3\cdot\frac{1}{2}$. The adjoint $j=1$ gives $\dim R = 3$, $C_2 = 2$, $T = 2$, and $3\cdot 2 = 6 = 3\cdot 2$; note $C_2(\text{adjoint}) = 2$ reproduces $C_A = N = 2$ for SU(2), as it must. The case $j=\frac{3}{2}$ gives $\dim R = 4$, $C_2 = \frac{15}{4}$, $T = 5$, and $4\cdot\frac{15}{4} = 15 = 3\cdot 5$. Every instance closes.

B.2.3 The Gell-Mann matrices and the algebra $\mathfrak{su}(3)$

The step from $\mathfrak{su}(2)$ to $\mathfrak{su}(3)$ is the step from spin to color, and it is where the structure becomes rich enough to need both an antisymmetric and a symmetric invariant tensor. The fundamental representation of $\mathfrak{su}(3)$ acts on $\mathbb{C}^3$, so its generators are eight independent Hermitian traceless 3×3 matrices (the dimension of $\mathfrak{su}(N)$ is N^2-1, here $9-1=8$). The standard choice generalizes the Pauli matrices block by block.

Definition B.16 (Gell-Mann matrices)**.** The eight *Gell-Mann matrices* are

$$\lambda^1 = \begin{pmatrix} 0 & 1 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix}, \quad \lambda^2 = \begin{pmatrix} 0 & -i & 0 \\ i & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix}, \quad \lambda^3 = \begin{pmatrix} 1 & 0 & 0 \\ 0 & -1 & 0 \\ 0 & 0 & 0 \end{pmatrix},$$

$$\lambda^4 = \begin{pmatrix} 0 & 0 & 1 \\ 0 & 0 & 0 \\ 1 & 0 & 0 \end{pmatrix}, \quad \lambda^5 = \begin{pmatrix} 0 & 0 & -i \\ 0 & 0 & 0 \\ i & 0 & 0 \end{pmatrix}, \quad \lambda^6 = \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & 1 \\ 0 & 1 & 0 \end{pmatrix},$$

$$\lambda^7 = \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & -i \\ 0 & i & 0 \end{pmatrix}, \qquad \lambda^8 = \frac{1}{\sqrt{3}}\begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & -2 \end{pmatrix}. \tag{B.59}$$

The $\mathfrak{su}(3)$ generators in the fundamental are $T^a = \frac{1}{2}\lambda^a$, $a = 1,\dots,8$.

The organizing logic is transparent from the explicit forms. The triple $(\lambda^1, \lambda^2, \lambda^3)$ is the Pauli set embedded in the upper-left 2×2 block—this is the isospin $\mathfrak{su}(2)$ inside $\mathfrak{su}(3)$. The pairs (λ^4, λ^5) and (λ^6, λ^7) are the off-diagonal real/imaginary partners coupling the 1–3 and 2–3 subspaces, the two other $\mathfrak{su}(2)$ subalgebras ("U-spin" and "V-spin"). The eighth matrix λ^8 is the second diagonal (Cartan) generator, made traceless and orthogonal to λ^3, with the $1/\sqrt{3}$ fixed precisely by the normalization we now verify.

Proposition B.17 (Gell-Mann normalization)**.** *The Gell-Mann matrices are Hermitian and traceless, and satisfy*

$$\operatorname{tr}(\lambda^a \lambda^b) = 2\,\delta^{ab}, \qquad \textit{equivalently} \qquad \operatorname{tr}(T^a T^b) = \tfrac{1}{2}\,\delta^{ab}. \tag{B.60}$$

Proof. Hermiticity is visible matrix by matrix: the real symmetric ones equal their transpose, and the imaginary ones (with a $-i$ above the diagonal and $+i$ below) equal their conjugate transpose. Tracelessness is immediate for $\lambda^{1,\dots,7}$, which have zero diagonal, and for λ^8 because $1 + 1 - 2 = 0$. For the orthogonality Eq. (B.60) we must check $\operatorname{tr}(\lambda^a \lambda^b) = 2\delta^{ab}$ for all pairs. The diagonal entries $a = b$: for each of $\lambda^{1,\dots,7}$ the square has two unit entries on its diagonal—e.g. $(\lambda^1)^2 = \operatorname{diag}(1, 1, 0)$ and $(\lambda^5)^2 = \operatorname{diag}(1, 0, 1)$—so $\operatorname{tr}(\lambda^a)^2 = 2$; for λ^8, $\operatorname{tr}(\lambda^8)^2 = \frac{1}{3}(1+1+4) = 2$, which is exactly what the $1/\sqrt{3}$ prefactor was chosen to arrange. The off-diagonal entries $a \neq b$ vanish: two matrices supported on different off-diagonal positions have a product with zero diagonal; a real and an imaginary matrix on the *same* positions, such as λ^1 and λ^2, give $\operatorname{tr}(\lambda^1 \lambda^2) = \operatorname{tr}\left(i\,\operatorname{diag}(1, -1, 0)\right) = 0$; and the diagonal λ^3, λ^8 are mutually orthogonal because $\operatorname{tr}(\lambda^3 \lambda^8) = \frac{1}{\sqrt{3}}(1 \cdot 1 + (-1) \cdot 1 + 0) = 0$. Dividing by four gives the generator form, $\operatorname{tr}(T^a T^b) = \frac{1}{2}\delta^{ab}$, so $T(\text{fund}) = \frac{1}{2}$ for $\mathfrak{su}(3)$ as well. □

B.2.4 Structure constants and symmetric symbols of $\mathfrak{su}(3)$

The product of two $\mathfrak{su}(3)$ generators is not closed inside the generators alone—unlike $\mathfrak{su}(2)$, where $\sigma^i \sigma^j$ landed back in $\{\mathbf{1}, \sigma^k\}$ by Eq. (B.36). The commutator does close (that is the Lie algebra), but the anticommutator produces a genuinely new symmetric tensor. Both are captured by expanding products in the complete set $\{\mathbf{1}, T^c\}$ of nine Hermitian 3×3 matrices.

Definition B.18 (f and d symbols)**.** The *structure constants* f^{abc} and *symmetric symbols* d^{abc} of $\mathfrak{su}(3)$ are defined by

$$\left[T^a, T^b\right] = i\, f^{abc}\, T^c, \tag{B.61}$$

$$\left\{T^a, T^b\right\} = \tfrac{1}{3}\,\delta^{ab}\,\mathbf{1} + d^{abc}\, T^c. \tag{B.62}$$

We must justify that Eq. (B.62) has exactly this form and then give closed expressions for the coefficients. Both products $\left[T^a, T^b\right]$ and $\left\{T^a, T^b\right\}$ are linear

combinations of the nine matrices $\{\mathbf{1}, T^c\}$, since those span all 3×3 matrices and the products are themselves 3×3 matrices. The commutator is traceless and anti-Hermitian-times-i, hence has no $\mathbf{1}$ component and lies purely in the span of the T^c; that the coefficient is if^{abc} with f real is the content of Chapter A's convention, and antisymmetry $f^{abc} = -f^{bac}$ is manifest. The anticommutator is Hermitian and generally has a trace, so it acquires an $\mathbf{1}$ piece. Taking the trace of Eq. (B.62) and using $\operatorname{tr} T^c = 0$, $\operatorname{tr} \mathbf{1} = 3$, $\operatorname{tr}\left\{T^a, T^b\right\} = 2\operatorname{tr}(T^a T^b) = \delta^{ab}$ fixes the $\mathbf{1}$ coefficient: $\delta^{ab} = 3 \cdot \frac{1}{3}\delta^{ab}$, consistent, so the coefficient is exactly $\frac{1}{3}$. The remaining traceless Hermitian part is some combination $d^{abc}T^c$ with real, symmetric (in $a \leftrightarrow b$) coefficients. Closed forms follow by multiplying each relation by T^c and tracing with Eq. (B.60):

$$f^{abc} = -2i\ \operatorname{tr}\left(\left[T^a, T^b\right] T^c\right) = \frac{1}{4i}\ \operatorname{tr}\left(\left[\lambda^a, \lambda^b\right] \lambda^c\right), \tag{B.63}$$

$$d^{abc} = 2\ \operatorname{tr}\left(\left\{T^a, T^b\right\} T^c\right) = \frac{1}{4}\ \operatorname{tr}\left(\left\{\lambda^a, \lambda^b\right\} \lambda^c\right). \tag{B.64}$$

To get Eq. (B.63), multiply Eq. (B.61) by T^c, trace, and use $\operatorname{tr}(T^e T^c) = \frac{1}{2}\delta^{ec}$ to obtain $\operatorname{tr}\left(\left[T^a, T^b\right] T^c\right) = \frac{i}{2} f^{abc}$; solving and inserting $T = \lambda/2$ gives the λ-form. The same step with the anticommutator, noting that the $\frac{1}{3}\delta^{ab}\mathbf{1}$ term contributes $\frac{1}{3}\delta^{ab}\operatorname{tr} T^c = 0$, gives Eq. (B.64).

These trace formulas have three structural consequences, each provable in one line from the cyclicity of the trace and the (anti)symmetry of the (anti)commutator. *f^{abc} is totally antisymmetric:* antisymmetry in $a \leftrightarrow b$ is built in, and cyclicity of the trace in $\operatorname{tr}\left(\left[T^a, T^b\right] T^c\right) = \operatorname{tr}(T^a T^b T^c) - \operatorname{tr}(T^b T^a T^c)$ rearranges into $\operatorname{tr}\left(\left[T^b, T^c\right] T^a\right)$, giving antisymmetry under $a \leftrightarrow c$ as well; the two transpositions generate the full antisymmetric group. *d^{abc} is totally symmetric:* the same cyclicity applied to the anticommutator form makes it invariant under any interchange. *Both are real:* f^{abc} is real because the structure constants of a compact algebra in a Hermitian basis are real, and d^{abc} is real because $\left\{\lambda^a, \lambda^b\right\} \lambda^c$ has real trace (its Hermitian conjugate is $\lambda^c \left\{\lambda^a, \lambda^b\right\}$, with the same trace).

We now compute representative entries directly from Eqs. (B.63) and (B.64), using matrix-unit notation E_{ij} for the 3×3 matrix with a single 1 in row i, column j, so that $E_{ij}E_{kl} = \delta_{jk}E_{il}$. Every value in the full tables below is obtained by the identical procedure; we carry four cases in complete detail and tabulate the rest.

Worked Example B.19 (Representative f^{abc} and d^{abc} by direct trace)**.** $f^{123} = 1$. Since $(\lambda^1, \lambda^2, \lambda^3)$ are the Pauli matrices in the upper 2×2 block, $[\lambda^1, \lambda^2] = 2i\lambda^3$ by Eq. (B.38). Hence

$$f^{123} = \frac{1}{4i}\operatorname{tr}(2i\,\lambda^3\lambda^3) = \frac{2i}{4i}\ \operatorname{tr}(\lambda^3)^2 = \tfrac{1}{2} \cdot 2 = 1. \tag{B.65}$$

$f^{147} = \frac{1}{2}$. Write $\lambda^1 = E_{12} + E_{21}$ and $\lambda^4 = E_{13} + E_{31}$. Using $E_{ij}E_{kl} = \delta_{jk}E_{il}$,

$$\lambda^1\lambda^4 = (E_{12}+E_{21})(E_{13}+E_{31}) = E_{23}, \qquad \lambda^4\lambda^1 = (E_{13}+E_{31})(E_{12}+E_{21}) = E_{32}, \tag{B.66}$$

because only the terms with a matched inner index survive ($E_{21}E_{13} = E_{23}$ and $E_{31}E_{12} = E_{32}$, all others vanish). Therefore $[\lambda^1, \lambda^4] = E_{23} - E_{32}$. Comparing with $\lambda^7 = -i(E_{23} - E_{32})$ gives $E_{23} - E_{32} = i\lambda^7$, so $[\lambda^1, \lambda^4] = i\lambda^7$ and

$$f^{147} = \frac{1}{4i}\operatorname{tr}(i\,\lambda^7\lambda^7) = \frac{i}{4i}\operatorname{tr}(\lambda^7)^2 = \tfrac{1}{2}\cdot 2 = \tfrac{1}{2}. \tag{B.67}$$

$d^{118} = \frac{1}{\sqrt{3}}$. Here $\{\lambda^1, \lambda^1\} = 2(\lambda^1)^2 = 2\ \mathrm{diag}(1,1,0)$. Then

$$d^{118} = \frac{1}{4}\operatorname{tr}\Big(2\ \mathrm{diag}(1,1,0)\cdot\tfrac{1}{\sqrt{3}}\,\mathrm{diag}(1,1,-2)\Big) = \frac{1}{2\sqrt{3}}\operatorname{tr}\mathrm{diag}(1,1,0) = \frac{1}{2\sqrt{3}}\cdot 2 = \frac{1}{\sqrt{3}}. \tag{B.68}$$

$d^{146} = \frac{1}{2}$. From the matrix-unit products above, $\{\lambda^1, \lambda^4\} = \lambda^1\lambda^4 + \lambda^4\lambda^1 = E_{23} + E_{32} = \lambda^6$. Hence

$$d^{146} = \frac{1}{4}\operatorname{tr}(\lambda^6\lambda^6) = \frac{1}{4}\cdot 2 = \frac{1}{2}. \tag{B.69}$$

Each computation uses only the explicit matrices of Eq. (B.59), the matrix-unit algebra, and the normalization Eq. (B.60); nothing is quoted.

Carrying out the identical procedure for every index triple—a finite computation, mechanized here but reproducible by hand exactly as in Theorem B.19—yields the complete tables. By total antisymmetry of f and total symmetry of d, it suffices to list one ordering of each nonzero independent triple; all others follow by permutation (with a sign for f).

Table B.1: The nonzero independent structure constants f^{abc} of $\mathfrak{su}(3)$ (totally antisymmetric; permutations of indices give the same value up to the sign of the permutation). All unlisted independent triples vanish.

abc	123	147	156	246	257	345	367	458	678
f^{abc}	1	$\frac{1}{2}$	$-\frac{1}{2}$	$\frac{1}{2}$	$\frac{1}{2}$	$\frac{1}{2}$	$-\frac{1}{2}$	$\frac{\sqrt{3}}{2}$	

The reader should note the internal checks built into these tables. The f entries $f^{123} = 1$, $f^{147} = f^{246} = f^{257} = f^{345} = \frac{1}{2}$, $f^{156} = f^{367} = -\frac{1}{2}$ record the three embedded $\mathfrak{su}(2)$ subalgebras and their interlocking; the pair $f^{458} = f^{678} = \frac{\sqrt{3}}{2}$ involves the second Cartan direction λ^8. The d entries involving λ^8 must satisfy a consistency relation that follows from contracting Eq. (B.62): since $\{\lambda^8, \lambda^8\} = 2(\lambda^8)^2 = \frac{2}{3}\,\mathrm{diag}(1,1,4)$, one reads $d^{888} = -\frac{1}{\sqrt{3}}$ and the four equal entries $d^{aa8} = -\frac{1}{2\sqrt{3}}$ for $a \in \{4,5,6,7\}$ off the diagonal of $(\lambda^8)^2$, consistent with the table.

Table B.2: The nonzero independent symmetric symbols d^{abc} of $\mathfrak{su}(3)$ (totally symmetric; all index permutations give the same value). All unlisted independent triples vanish.

value $+\frac{1}{2}$	value $-\frac{1}{2}$	involving λ^8
$d^{146} = d^{157} = \frac{1}{2}$	$d^{247} = -\frac{1}{2}$	$d^{118} = d^{228} = d^{338} = \frac{1}{\sqrt{3}}$
$d^{256} = d^{344} = d^{355} = \frac{1}{2}$	$d^{366} = d^{377} = -\frac{1}{2}$	$d^{448} = d^{558} = d^{668} = d^{778} = -\frac{1}{2\sqrt{3}}$
		$d^{888} = -\frac{1}{\sqrt{3}}$

Physical Insight

The appearance of *two* invariant tensors, f^{abc} and d^{abc}, is not an $\mathfrak{su}(3)$ accident but the first sign of a structural fact: for $\mathfrak{su}(N)$ with $N \geq 3$ the symmetric cubic invariant d^{abc} is nonzero, whereas for $\mathfrak{su}(2)$ it vanishes identically (there is no symmetric traceless cubic in the Pauli matrices). Physically the two tensors play different roles. The antisymmetric f^{abc} is the structure constant: it sits in the gauge-boson self-interactions and is what makes Yang–Mills nonabelian. The symmetric d^{abc} measures the anomaly content of the representation—the triangle-diagram anomaly coefficient of a fermion in representation R is proportional to a trace $\mathrm{tr}(\{T^a, T^b\} T^c) \propto d^{abc} A(R)$—which is why $\mathfrak{su}(2)$, having $d^{abc} = 0$, is automatically anomaly-free while $\mathfrak{su}(3)$ and the electroweak hypercharge sector are not. The cancellation of these d-weighted traces generation by generation is exactly the arithmetic carried out in Chapter F.

B.2.5 The representation invariants of the $\mathfrak{su}(3)$ fundamental

With explicit generators in hand we evaluate the two invariants for the fundamental representation and confirm the master identity in its second instance. The index is already fixed: $\mathrm{tr}(T^a T^b) = \frac{1}{2}\delta^{ab}$ from Eq. (B.60) is precisely the statement $T(\mathrm{fund}) = \frac{1}{2}$. The Casimir requires a short computation, which we do by the Schur-plus-trace argument—the same logic that gave C_2 for $\mathfrak{su}(2)$, now applied without needing a highest-weight state.

Proposition B.20 (Fundamental Casimir of $\mathfrak{su}(3)$)**.** *For the fundamental representation of* $\mathfrak{su}(3)$*,*

$$C_2(\mathit{fund}) = \left.\frac{N^2 - 1}{2N}\right|_{N=3} = \frac{4}{3}. \tag{B.70}$$

Proof. By Theorem B.4 the Casimir is $\sum_a T^a T^a = C_2(\mathrm{fund})\, \mathbf{1}_{3\times 3}$, a multiple of the identity because it commutes with all T^b and the fundamental is irreducible

(Schur). Take the trace of both sides. On the right, $\operatorname{tr}\mathbf{1}_{3\times3} = 3$, so the right-hand side is $3\,C_2(\text{fund})$. On the left, exchanging trace and sum and using Eq. (B.60) with $a = b$,

$$\operatorname{tr}\Big(\sum_{a=1}^{8} T^a T^a\Big) = \sum_{a=1}^{8} \operatorname{tr}\left(T^a T^a\right) = \sum_{a=1}^{8} \tfrac{1}{2} = 8 \cdot \tfrac{1}{2} = 4. \tag{B.71}$$

Equating, $3\,C_2(\text{fund}) = 4$, hence $C_2(\text{fund}) = \frac{4}{3}$. Equivalently, in terms of the matrices, $\sum_a (\lambda^a)^2 = 4\sum_a T^a T^a = \frac{16}{3}\mathbf{1}$. The result is the $N = 3$ value of the general fundamental Casimir $C_F = (N^2-1)/2N$ of Chapter A, which Section B.3.1 proves for all N from the completeness relation. □

Worked Example B.21 (The master identity for the $\mathfrak{su}(3)$ fundamental)**.** The algebra $\mathfrak{su}(3)$ is eight-dimensional, so $\dim(G) = 8$, and the fundamental has $\dim(R) = 3$. The left-hand side of Theorem B.5, using Eq. (B.70), is

$$\dim(R)\,C_2(R) = 3 \cdot \tfrac{4}{3} = 4. \tag{B.72}$$

The right-hand side, using $T(\text{fund}) = \frac{1}{2}$, is

$$\dim(G)\,T(R) = 8 \cdot \tfrac{1}{2} = 4. \tag{B.73}$$

They agree: $4 = 4$. The identity is satisfied, and the agreement is again the trace $\operatorname{tr}(\sum_a T^a T^a)$ read in two directions—once as $\dim(R)\,C_2(R)$ by collapsing the Casimir, once as $\sum_a \operatorname{tr}(T^a T^a) = \dim(G)\,T(R)$ by collapsing the index. Combined with Theorem B.15, we have now verified the master identity of Section 1 in both of the cases the rest of the book uses most: the spin-j tower of $\mathfrak{su}(2)$ and the color triplet of $\mathfrak{su}(3)$.

It is worth seeing the fundamental of $\mathfrak{su}(3)$ once as a picture, because the weight diagram makes the role of the two Cartan generators T^3, T^8 concrete and is the object the quark model and Yang–Mills theory both draw on. The three basis states of $\mathbb{C}^3$ are simultaneous eigenstates of the commuting pair (T^3, T^8); reading the diagonals of λ^3 and λ^8 in Eq. (B.59) gives their eigenvalues, and in the physically conventional coordinates $(t_3, y) = (\frac{1}{2}\lambda^3, \frac{1}{\sqrt{3}}\lambda^8)$ the three weights form an equilateral triangle.

Two features of Fig. B.1 encode invariants computed above. The centroid of the triangle is the origin because each Cartan generator is traceless, $\sum_{\text{states}} t_3 = \sum_{\text{states}} y = 0$. And the common squared distance of the three weights from the origin is tied to the Casimir, provided one measures it with the canonically normalized Cartan generators $T^3 = \frac{1}{2}\lambda^3$ and $T^8 = \frac{1}{2}\lambda^8$ rather than the hypercharge-rescaled $Y = \frac{1}{\sqrt{3}}\lambda^8$ used as the plot's vertical axis. The eigenvalues of T^8 on the three states are $\frac{1}{2\sqrt{3}}, \frac{1}{2\sqrt{3}}, -\frac{1}{\sqrt{3}}$, so summing $t_3^2 + (T^8\text{-eigenvalue})^2$ over the three vertices gives $(\frac{1}{4} + \frac{1}{12}) + (\frac{1}{4} + \frac{1}{12}) + (0 + \frac{1}{3}) = \frac{1}{2} + \frac{1}{2} = 1$, which

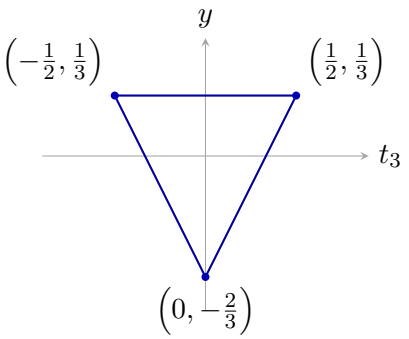

Figure B.1: Weight diagram of the $\mathfrak{su}(3)$ fundamental representation **3** in the Cartan plane (t_3, y), with t_3 the eigenvalue of $T^3 = \frac{1}{2}\lambda^3$ and y the eigenvalue of $Y = \frac{1}{\sqrt{3}}\lambda^8$. The three color states sit at the vertices of an equilateral triangle; the conjugate $\overline{\mathbf{3}}$ is the same triangle inverted. The centroid is at the origin, reflecting tracelessness $\operatorname{tr} T^3 = \operatorname{tr} Y = 0$.

is $\operatorname{tr}\big((T^3)^2 + (T^8)^2\big)$; this is the contribution of the two Cartan directions to $\operatorname{tr}(\sum_a T^a T^a) = 4$, the remaining 3 coming in equal shares of $\frac{1}{2}$ from the six off-diagonal (root) generators. The decomposition is a small but honest check that the same number, $\dim(R)\, C_2(R) = 4$, is what the geometry is drawing.

We have now made the abstract index–Casimir pair of Section 1 fully explicit for the two smallest simple algebras: explicit generators, their multiplication laws, and the complete f/d symbol structure of $\mathfrak{su}(3)$, all proved from the matrices themselves and all consistent with the master identity. The next section takes the single most important of these structures—the completeness of the fundamental generators, of which the Pauli relation Eq. (B.45) is the $N = 2$ shadow—and promotes it to the general $\mathrm{SU}(N)$ color-Fierz identity, the computational engine on which every color-factor reduction in the gauge-theory chapters runs.

B.3 The Fundamental Completeness Relation and Color Fierz Identities

The previous section put explicit matrices in our hands: the Pauli generators of $\mathfrak{su}(2)$ and the Gell-Mann generators of $\mathfrak{su}(3)$, together with the structure constants f^{abc} and the symmetric symbols d^{abc} that organize their products (Section B.2). Explicit matrices are indispensable for fixing conventions, but they are the wrong tool for computation. No one evaluates a QCD color factor by multiplying 3×3 Gell-Mann matrices entry by entry; the diagrams of a single one-loop process would generate dozens of such products and the arithmetic would be hopeless and unilluminating. What one wants instead is an algebra of *identities* that lets a string of fundamental generators be collapsed to numbers

and Kronecker deltas without ever touching a matrix entry, and that works for general N so that the SU(N) dependence is exposed rather than buried. The single identity from which this entire calculus flows is the *completeness relation* for the fundamental generators. This section proves it from the one structural fact that distinguishes $\mathfrak{su}(N)$ from $\mathfrak{u}(N)$ — the tracelessness of the generators — and then turns it into the two workhorses of color algebra: the color-Fierz rearrangement of fermion bilinears, and the trace-reduction algorithm that the Yang–Mills and QCD chapters reduce every color factor to.

Throughout, T^a ($a = 1, \dots, N^2-1$) are the Hermitian fundamental generators of $\mathfrak{su}(N)$, normalized as fixed in Section B.1,

$$(T^a)^\dagger = T^a, \qquad \operatorname{tr} T^a = 0, \qquad \operatorname{tr}(T^a T^b) = \tfrac{1}{2}\,\delta^{ab}, \tag{B.74}$$

acting on the N-dimensional fundamental (color) space with indices $i, j, k, l = 1, \dots, N$. Repeated adjoint indices a are summed from 1 to $N^2 - 1$ and repeated color indices from 1 to N. The symbol $\mathbf{1}$ denotes the $N \times N$ identity on color space.

B.3.1 The fundamental completeness relation

The starting point is a counting fact dressed as a geometric one. The complex $N \times N$ matrices form a vector space of complex dimension N^2; the Hermitian ones form a *real* vector space of the same dimension N^2, since a Hermitian matrix has N real diagonal entries and $\binom{N}{2}$ complex off-diagonal entries above the diagonal, for $N + 2 \cdot \frac{N(N-1)}{2} = N^2$ real parameters. On this space the natural inner product is the Hilbert–Schmidt (trace) pairing

$$\langle A, B \rangle \equiv \operatorname{tr}(A^\dagger B), \tag{B.75}$$

which for Hermitian A, B reduces to $\operatorname{tr}(AB)$ and is real, symmetric, and positive definite ($\langle A, A \rangle = \operatorname{tr}(A^\dagger A) = \sum_{ij} |A_{ij}|^2 \geq 0$, vanishing only for $A = 0$). The $N^2 - 1$ generators T^a are Hermitian, traceless, and mutually orthogonal under (B.75) by the normalization (B.74). They are one short of a basis. The missing direction is the trace direction, supplied by the identity matrix.

Lemma B.22 (Orthonormal basis of Hermitian matrices)**.** *The N^2 matrices*

$$T^0 \equiv \frac{1}{\sqrt{N}}\,\mathbf{1}, \qquad \widehat{T}^a \equiv \sqrt{2}\,T^a \quad (a = 1, \dots, N^2 - 1), \tag{B.76}$$

form an orthonormal basis of the space of $N \times N$ Hermitian matrices with respect to (B.75)*.*

Proof. We check orthonormality of the N^2 matrices in (B.76); since they are N^2 mutually orthogonal nonzero vectors in an N^2-dimensional space, they are

automatically a basis. First,

$$\langle T^0, T^0\rangle = \operatorname{tr}\Big(\tfrac{1}{N}\mathbf{1}\Big) = \frac{1}{N}\cdot N = 1.$$

Next, the cross terms vanish by tracelessness of the generators,

$$\langle T^0, \widehat{T}^a\rangle = \frac{\sqrt{2}}{\sqrt{N}}\,\operatorname{tr} T^a = 0,$$

and this is the one place the defining property $\operatorname{tr} T^a = 0$ enters: it is what makes the identity direction orthogonal to every generator. Finally the generator block is orthonormal because

$$\langle \widehat{T}^a, \widehat{T}^b\rangle = 2\,\operatorname{tr}(T^a T^b) = 2\cdot\tfrac{1}{2}\,\delta^{ab} = \delta^{ab},$$

using (B.74). That an orthonormal set of N^2 vectors spans the N^2-dimensional real space of Hermitian matrices is the elementary completeness of orthonormal systems in finite dimension, established in Chapter 2. □

An orthonormal basis resolves any vector into its components. For a general $N\times N$ matrix M — not necessarily Hermitian, since the basis (B.76) spans the complex matrices once complex coefficients are allowed — the expansion reads

$$M = \langle T^0, M\rangle\, T^0 + \sum_a \langle \widehat{T}^a, M\rangle\, \widehat{T}^a = \frac{1}{N}\,(\operatorname{tr} M)\,\mathbf{1} + 2\sum_a \operatorname{tr}(T^a M)\,T^a. \tag{B.77}$$

This is already a useful statement: it says that any matrix splits into its trace part, proportional to the identity, and its traceless part, expanded on the generators with coefficients $2\operatorname{tr}(T^a M)$. The completeness relation is what (B.77) becomes when we feed it the most elementary matrices of all.

Theorem B.23 (Fundamental completeness relation)**.** *The fundamental generators of* $\mathfrak{su}(N)$ *satisfy*

$$\boxed{\sum_{a=1}^{N^2-1} (T^a)_{ij}\,(T^a)_{kl} = \tfrac{1}{2}\Big(\delta_{il}\,\delta_{jk} - \tfrac{1}{N}\,\delta_{ij}\,\delta_{kl}\Big).} \tag{B.78}$$

Proof. Apply the expansion (B.77) to the elementary matrix E_{jk}, defined by $(E_{jk})_{pq} = \delta_{pj}\,\delta_{qk}$ (a single 1 in row j, column k). Its trace is $\operatorname{tr} E_{jk} = \sum_p (E_{jk})_{pp} = \delta_{jk}$, and its generator components are

$$\operatorname{tr}(T^a E_{jk}) = \sum_{p,q} (T^a)_{pq}\,(E_{jk})_{qp} = \sum_{p,q} (T^a)_{pq}\,\delta_{qj}\,\delta_{pk} = (T^a)_{kj}.$$

Substituting into (B.77) and reading off the (i,l) matrix element, with $(E_{jk})_{il} = \delta_{ij}\delta_{lk}$ and $(\mathbf{1})_{il} = \delta_{il}$,

$$\delta_{ij}\,\delta_{lk} = \frac{1}{N}\,\delta_{jk}\,\delta_{il} + 2\sum_a (T^a)_{il}\,(T^a)_{kj}. \tag{B.79}$$

Solving for the generator sum,

$$\sum_a (T^a)_{il}\,(T^a)_{kj} = \tfrac{1}{2}\Big(\delta_{ij}\,\delta_{lk} - \tfrac{1}{N}\,\delta_{il}\,\delta_{jk}\Big).$$

Relabel the dummy index names by the swap $j \leftrightarrow l$ (a mere renaming of the four free labels) so the first factor reads $(T^a)_{ij}$ and the second $(T^a)_{kl}$; the right-hand side becomes $\frac{1}{2}(\delta_{il}\delta_{jk} - \frac{1}{N}\delta_{ij}\delta_{kl})$, which is (B.78). □

Equation (B.78) is the central computational engine of $\mathfrak{su}(N)$ color algebra; everything below is a corollary. Two consistency checks confirm the coefficients before we trust them. Contracting $j = i$ (and summing) collapses the left side to $\sum_a (T^a)_{ii}(T^a)_{kl} = \sum_a (\operatorname{tr} T^a)(T^a)_{kl} = 0$ by tracelessness, while the right side gives $\frac{1}{2}(\delta_{il}\delta_{ik} - \frac{1}{N}N\delta_{kl}) = \frac{1}{2}(\delta_{kl} - \delta_{kl}) = 0$: consistent, and again it is the $-1/N$ piece, weighted by $\delta_{ii} = N$, that cancels the would-be trace. Contracting instead $j = k$ gives $\sum_a (T^a T^a)_{il} = \frac{1}{2}(\delta_{il}\delta_{jj} - \frac{1}{N}\delta_{ij}\delta_{jl}) = \frac{1}{2}(N - \frac{1}{N})\delta_{il} = \frac{N^2-1}{2N}\delta_{il}$, the quadratic Casimir in the fundamental, to which we return in Section B.4.

Physical Insight

The completeness relation has a transparent diagrammatic meaning in 't Hooft's double-line notation, drawn in Fig. B.2. A gluon, carrying an adjoint index a, is a quark line and an antiquark line glued together: it transports color from one fundamental index to another. The first term $\frac{1}{2}\delta_{il}\delta_{jk}$ is the "swap" in which the color simply flows through, $i \to l$ and $k \to j$; the second term $-\frac{1}{2N}\delta_{ij}\delta_{kl}$ subtracts the trace, i.e. the would-be $\mathfrak{u}(1)$ photon that an honest SU(N) gluon must not contain. In the large-N limit the subtraction is suppressed by $1/N$, which is the diagrammatic origin of the planar expansion.

The $-1/N$ term is not a convention; it is forced, and it is exactly what separates SU(N) from U(N). To see this, restore the trace generator. The Lie algebra $\mathfrak{u}(N)$ is spanned by the N^2 Hermitian generators $\{T^A\} = \{T^0, T^a\}$ with $T^0 = \mathbf{1}/\sqrt{2N}$, normalized so that $\operatorname{tr}(T^0T^0) = \frac{1}{2N}\operatorname{tr}\mathbf{1} = \frac{1}{2}$ matches (B.74). For $\mathfrak{u}(N)$ the completeness sum runs over all N^2 generators, and the extra term is

$$(T^0)_{ij}\,(T^0)_{kl} = \frac{1}{2N}\,\delta_{ij}\,\delta_{kl}. \tag{B.80}$$

Adding this to the SU(N) result (B.78),

$$\sum_{A=0}^{N^2-1} (T^A)_{ij}\,(T^A)_{kl} = \tfrac{1}{2}\Big(\delta_{il}\,\delta_{jk} - \tfrac{1}{N}\,\delta_{ij}\,\delta_{kl}\Big) + \frac{1}{2N}\,\delta_{ij}\,\delta_{kl} = \tfrac{1}{2}\,\delta_{il}\,\delta_{jk}, \tag{B.81}$$

the clean "swap" with no trace subtraction. This is the cleaner relation precisely because U(N) contains the full set of Hermitian matrices, with no constraint to enforce; the $-1/N$ in (B.78) is the algebraic price of removing the trace direction to descend from U(N) to SU(N).

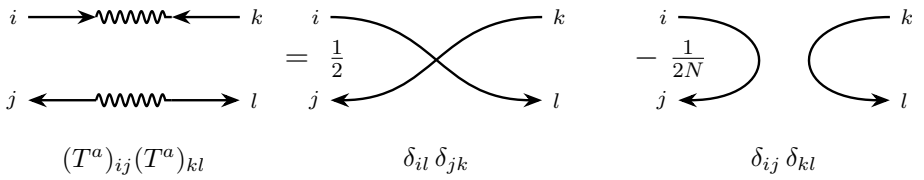

Figure B.2: The completeness relation (B.78) in 't Hooft double-line notation. A gluon (coiled, carrying adjoint index a) is resolved into a quark line and an antiquark line. The first term lets color flow straight through ($i\to l$, $k\to j$); the second subtracts the trace ($i\to j$, $k\to l$) with weight $1/N$, removing the $\mathfrak{u}(1)$ direction absent from SU(N). For U(N) the second term is absent and the gluon is a bare quark–antiquark pair, (B.81).

B.3.2 The color-Fierz identity

The first deployment of completeness is the rearrangement of a product of two color-octet currents into color-singlet combinations. This is the *color* Fierz identity — distinct from, and acting on different indices than, the spinor Fierz identity of Section C.8, which rearranges the Dirac structure. The color Fierz acts only on the fundamental color indices and leaves the spinor structure Γ of each bilinear untouched.

Consider two quark bilinears coupled through a generator, with the color indices written out explicitly and the (arbitrary) Dirac matrices Γ, Γ' carried as spectators:

$$(\bar q\,\Gamma\,T^a q)(\bar q'\,\Gamma'\,T^a q') = \bar q_i\,\Gamma\,q_j\;\bar q'_k\,\Gamma'\,q'_l\;\sum_a (T^a)_{ij}\,(T^a)_{kl}. \tag{B.82}$$

This is exactly the structure produced by single-gluon exchange between two quark currents, the gluon's adjoint index a being summed. Inserting the completeness relation (B.78),

$$\begin{aligned}(\bar q\,\Gamma\,T^a q)(\bar q'\,\Gamma'\,T^a q') &= \tfrac12\,\bar q_i\,\Gamma\,q_j\;\bar q'_k\,\Gamma'\,q'_l\,\Big(\delta_{il}\,\delta_{jk} - \tfrac{1}{N}\,\delta_{ij}\,\delta_{kl}\Big)\\ &= \tfrac12\,(\bar q_i\,\Gamma\,q_j)(\bar q'_j\,\Gamma'\,q'_i) - \tfrac{1}{2N}\,(\bar q_i\,\Gamma\,q_i)(\bar q'_k\,\Gamma'\,q'_k)\\ &= \tfrac12\,(\bar q\,\Gamma\,q')(\bar q'\,\Gamma'\,q) - \tfrac{1}{2N}\,(\bar q\,\Gamma\,q)(\bar q'\,\Gamma'\,q').\end{aligned} \tag{B.83}$$

In the last line the color indices have been contracted into singlets: in the first term the constraint $i=l$, $j=k$ pairs $\bar q$ with q' and $\bar q'$ with q, while in the second term $i=j$, $k=l$ leaves each bilinear color-diagonal. No fermion fields were moved past one another — only color contractions were relabeled — so no statistics sign is generated; any sign from reordering the spinors belongs to the separate spinor Fierz step. The identity (B.83) is the color-space content of one-gluon exchange: an octet × octet current is precisely a color-singlet exchange (coefficient $\frac12$) minus $\frac{1}{2N}$ of the disconnected singlet product. This is the algebraic

seed of the attractive quark–antiquark singlet channel and of the $1/N$ counting that organizes large-N QCD; the explicit channel color factors are assembled in Section B.4 and used in Chapter 28.

B.3.3 The trace-reduction algorithm

We now extract from completeness the single rule that reduces *any* string of fundamental generators with a contracted (summed) adjoint index. Suppose two equal generators T^a sandwich an arbitrary $N \times N$ matrix X — itself any product of generators and identities, with the index a summed. Then completeness collapses the pair.

Proposition B.24 (The fundamental reduction rule)**.** *For any $N \times N$ matrix X,*

$$\boxed{\sum_{a=1}^{N^2-1} T^a\, X\, T^a = \tfrac{1}{2}\Big(\operatorname{tr}(X)\,\mathbf{1} - \tfrac{1}{N}\,X\Big).} \tag{B.84}$$

Proof. Take the (i,l) matrix element and insert completeness (B.78):

$$\begin{aligned}\big(T^a X T^a\big)_{il} &= (T^a)_{ij}\,X_{jk}\,(T^a)_{kl} = X_{jk}\sum_a (T^a)_{ij}\,(T^a)_{kl} \\ &= X_{jk}\cdot\tfrac{1}{2}\Big(\delta_{il}\,\delta_{jk} - \tfrac{1}{N}\,\delta_{ij}\,\delta_{kl}\Big) = \tfrac{1}{2}\Big(\delta_{il}\,X_{jj} - \tfrac{1}{N}\,X_{il}\Big) = \tfrac{1}{2}\Big(\operatorname{tr}(X)\,\delta_{il} - \tfrac{1}{N}\,X_{il}\Big),\end{aligned}$$

which is (B.84) read as a matrix identity. □

Equation (B.84) is the whole algorithm in one line: it "eats" a contracted gluon, converting the sandwiched string X into its trace (a shorter, simpler object) plus a multiple of X itself. Every standard reduction is a special case.

Setting $X = \mathbf{1}$ recovers the quadratic Casimir already glimpsed above,

$$T^a T^a = \tfrac{1}{2}\Big(\operatorname{tr}(\mathbf{1})\,\mathbf{1} - \tfrac{1}{N}\,\mathbf{1}\Big) = \frac{N^2-1}{2N}\,\mathbf{1} \equiv C_F\,\mathbf{1}, \tag{B.85}$$

defining the fundamental Casimir $C_F = (N^2-1)/2N$ whose evaluation and role are taken up in Section B.4. Setting $X = T^b$ and using $\operatorname{tr} T^b = 0$ gives the first of the named trace reductions,

$$T^a T^b T^a = \tfrac{1}{2}\Big(\operatorname{tr}(T^b)\,\mathbf{1} - \tfrac{1}{N}\,T^b\Big) = -\frac{1}{2N}\,T^b, \tag{B.86}$$

the coefficient $-1/(2N)$ emerging directly: the trace term dies because the generators are traceless, leaving only the $-X/N$ piece. Taking the trace of (B.86),

$$\operatorname{tr}\big(T^a T^b T^a\big) = -\frac{1}{2N}\,\operatorname{tr}(T^b) = 0, \tag{B.87}$$

which vanishes, as every trace of an odd number of generators must once each contracted pair is removed. The relation (B.86) can equivalently be written $T^aT^bT^a = (C_F - \frac{1}{2}C_A)T^b$ with $C_A = N$; that this equals $-1/(2N)$ is the consistency of $C_F - \frac{1}{2}C_A = \frac{N^2-1}{2N} - \frac{N}{2} = -\frac{1}{2N}$, derived independently in Section B.4 via the structure constants.

The next reduction in the standard list is the four-generator trace with one contracted pair, which the rule disposes of in a single step.

Worked Example B.25 (The trace $\mathrm{tr}(T^aT^bT^aT^c)$)**.** We reduce $\mathrm{tr}(T^aT^bT^aT^c)$, summed over a. The two T^a sandwich $X = T^b$, so by (B.86) the inner triple collapses before the trace is taken:

$$\mathrm{tr}\big(T^aT^bT^aT^c\big) = \mathrm{tr}\big[(T^aT^bT^a)\,T^c\big] = \mathrm{tr}\Big[-\tfrac{1}{2N}\,T^b\,T^c\Big] = -\frac{1}{2N}\;\mathrm{tr}(T^bT^c) = -\frac{1}{2N}\cdot\tfrac{1}{2}\,\delta^{bc} = -\frac{1}{4N}$$

using $\mathrm{tr}(T^bT^c) = \frac{1}{2}\delta^{bc}$ from (B.74) at the end. The whole computation is one application of the reduction rule followed by the normalization; no matrix entries appear, and the answer is exact for every N.

The general algorithm for collapsing an arbitrary string $T^{a_1}T^{a_2}\cdots T^{a_n}$ in which some adjoint indices are repeated (summed) now follows mechanically. The procedure is:

1. **Locate a contracted pair.** Pick any adjoint index, say a, that appears twice in the string. The two occurrences sandwich some sub-string X (a product of the intervening generators, possibly empty so that $X = \mathbf{1}$).

2. **Eat it.** Replace T^aXT^a by $\frac{1}{2}\big(\mathrm{tr}(X)\,\mathbf{1} - \frac{1}{N}X\big)$ via (B.84). This lowers the number of generators in the string by two and spawns, in the trace term, a shorter trace $\mathrm{tr}(X)$ to be reduced separately.

3. **Recurse.** The trace $\mathrm{tr}(X)$ and the remaining string each contain fewer contracted pairs; reapply steps 1–2 until no repeated adjoint index remains.

4. **Finish.** What survives is a string (or trace) of distinct generators. Reduce traces of two generators by $\mathrm{tr}(T^aT^b) = \frac{1}{2}\delta^{ab}$, traces of three by $\mathrm{tr}(T^aT^bT^c) = \frac{1}{4}(d^{abc} + if^{abc})$ (Section B.2), and convert any commutators that arise from reordering via $\big[T^a, T^b\big] = if^{abc}T^c$.

When the two equal indices are not nested but interleaved with other contractions, one first uses $\big[T^a, T^b\big] = if^{abc}T^c$ to bring them adjacent or to expose a sandwich, then applies the rule; the structure constants generated are reduced by the adjoint identities of Sections B.2 and B.4. The point is that the loop terminates: each application of (B.84) strictly reduces the length, so any string of generators reduces in finitely many steps to numbers, Kronecker deltas, f^{abc}, and d^{abc}. The following worked example exercises the recursion twice.

Worked Example B.26 (Reducing longer strings)**.** *(a) The standard one-loop string* $\operatorname{tr}(T^aT^bT^aT^b)$. The two T^a sandwich $X = T^b$, so (B.86) gives $T^aT^bT^a = -\frac{1}{2N}T^b$ and

$$\operatorname{tr}(T^aT^bT^aT^b) = \operatorname{tr}\big[(T^aT^bT^a)T^b\big] = -\frac{1}{2N}\,\operatorname{tr}(T^bT^b) = -\frac{1}{2N}\cdot\frac{N^2-1}{2} = -\frac{N^2-1}{4N},$$

where $\operatorname{tr}(T^bT^b) = \sum_b \frac{1}{2} = \frac{N^2-1}{2}$ counts the N^2-1 generators. For $N=3$ this is $-\frac{8}{12} = -\frac{2}{3}$. This combination measures the difference between the abelian-like and genuinely non-abelian parts of a gluon self-energy insertion.

(b) A nested six-generator trace $\operatorname{tr}(T^aT^bT^cT^aT^bT^c)$. Apply the rule to the outermost contracted pair, the two T^a, which sandwich $X = T^bT^c$. By (B.84) with $\operatorname{tr}(T^bT^c) = \frac{1}{2}\delta^{bc}$,

$$T^a\,(T^bT^c)\,T^a = \tfrac{1}{2}\Big(\tfrac{1}{2}\delta^{bc}\,\mathbf{1} - \tfrac{1}{N}\,T^bT^c\Big) = \tfrac{1}{4}\delta^{bc}\,\mathbf{1} - \tfrac{1}{2N}\,T^bT^c.$$

Insert this into the string and multiply by the trailing T^bT^c:

$$T^aT^bT^cT^aT^bT^c = \Big(\tfrac{1}{4}\delta^{bc}\,\mathbf{1} - \tfrac{1}{2N}\,T^bT^c\Big)T^bT^c = \tfrac{1}{4}\,\delta^{bc}T^bT^c - \tfrac{1}{2N}\,T^bT^cT^bT^c.$$

The first term is $\frac{1}{4}T^bT^b = \frac{1}{4}C_F\,\mathbf{1}$ by (B.85). For the second, eat the pair of T^b, which sandwich $X = T^c$: by (B.86), $T^bT^cT^b = -\frac{1}{2N}T^c$, so $T^bT^cT^bT^c = -\frac{1}{2N}T^cT^c = -\frac{1}{2N}C_F\,\mathbf{1}$. Hence

$$T^aT^bT^cT^aT^bT^c = \tfrac{1}{4}C_F\,\mathbf{1} - \tfrac{1}{2N}\Big(-\tfrac{1}{2N}C_F\Big)\mathbf{1} = \frac{C_F}{4}\Big(1+\frac{1}{N^2}\Big)\mathbf{1}.$$

Taking the trace multiplies by $\operatorname{tr}\mathbf{1} = N$ and, with $C_F = (N^2-1)/2N$,

$$\operatorname{tr}(T^aT^bT^cT^aT^bT^c) = \frac{C_FN}{4}\Big(1+\frac{1}{N^2}\Big) = \frac{N^2-1}{8}\cdot\frac{N^2+1}{N^2} = \frac{N^4-1}{8N^2},$$

which for $N=3$ equals $\frac{80}{72} = \frac{10}{9}$. Two applications of the single rule (B.84), with no matrix multiplication, deliver the closed-form N-dependence.

The reduction rule also subsumes the color content of the simplest physical color sums, the ones Chapter 28 needs for the R-ratio and for color-averaged cross sections. When a colorless probe (a photon or a color-singlet current) couples diagonally, $\propto \delta_{ij}$, the final-state color sum is the bare trace $\operatorname{tr}\mathbf{1} = N$, the famous factor of $N_c = 3$ that multiplies $\sum_f Q_f^2$ in $R = \sigma(e^+e^- \to \text{hadrons})/\sigma(e^+e^- \to \mu^+\mu^-)$. When instead a gluon is exchanged, the color factor is one of the combinations (B.83), (B.85), or (B.86), reduced by the algorithm above. Either way, every color factor in the perturbative expansion of QCD is a finite sequence of applications of Theorem B.23 and Theorem B.24.

With the completeness relation (B.78) and the reduction rule (B.84) in hand, the canonical SU(N) invariants are now within immediate reach: the contraction $T^aT^a = C_F\mathbf{1}$ of (B.85) already exhibits the fundamental Casimir, and the adjoint Casimir C_A and Dynkin index T_F follow from the same machinery applied to the structure constants. The next section evaluates all three, specializes them to the SU(3) values of QCD, and assembles the color factors that feed the one-loop Yang–Mills beta coefficient.

B.4 Casimirs and Color Factors of SU(N)

The completeness relation and the trace-reduction algorithm assembled in Section B.3.1 were built for a purpose: to evaluate, once and cleanly, the handful of pure numbers on which every gauge-theory loop computation depends. Those numbers are the quadratic Casimir invariants and Dynkin indices of SU(N), defined in the abstract in Section B.1 and now to be reduced to explicit N-dependent expressions. The strategy is the one the engine was designed for. Contracting a pair of fundamental generators with the completeness relation delivers the fundamental Casimir C_F in a single line; feeding the same identity into a product of two structure constants delivers the adjoint Casimir C_A after a short but completely explicit trace computation; and the normalization fixed in Section B.1 already fixes the fundamental index T_F outright. We then specialize to SU(3) to read off the values the QCD literature carries, verify the general results against the master relation of Theorem B.5 across a range of N as an independent check, and finally assemble the color factors that the one-loop Yang–Mills beta function consumes in Chapter 27. This last step advances Yang–Mills theory at the level of group-theory data: it produces the carried coefficient $b_0 = \frac{11}{3}C_A - \frac{4}{3}T_F n_f$ in its SU(3) form.

B.4.1 The three named invariants

We recall from Section B.1 the two scalars attached to any representation R of a compact simple Lie algebra. The *quadratic Casimir* $C_2(R)$ is the (Schur-forced) eigenvalue of the Casimir operator,

$$\sum_a T_R^a\, T_R^a \;=\; C_2(R)\,\mathbf{1}_{\dim R}, \tag{B.88}$$

a multiple of the identity because $\sum_a T_R^a T_R^a$ commutes with every generator (Theorem B.3). The *Dynkin index* $T(R)$ is fixed by the trace of two generators,

$$\operatorname{tr}\!\left(T_R^a\, T_R^b\right) \;=\; T(R)\,\delta^{ab}, \tag{B.89}$$

which is proportional to δ^{ab} because the trace form is the unique (up to scale) invariant symmetric tensor on a simple algebra (Theorem B.1). The two are tied

by the master relation of Theorem B.5,

$$\dim(R)\, C_2(R) \;=\; \dim(G)\, T(R), \tag{B.90}$$

with $\dim(G) = N^2 - 1$ the dimension of $\mathfrak{su}(N)$. The three invariants that QCD needs carry standard names. Writing $\square$ for the fundamental (N-dimensional) representation and adj for the adjoint ((N^2-1)-dimensional) representation,

$$C_F \;\equiv\; C_2(\square), \qquad C_A \;\equiv\; C_2(\mathrm{adj}), \qquad T_F \;\equiv\; T(\square). \tag{B.91}$$

Our task in this section is to evaluate all three as functions of N.

The normalization is already settled and supplies the one numerical input. The convention $\mathrm{tr}(T^a T^b) = \frac{1}{2}\delta^{ab}$ for the fundamental generators, fixed in Eq. (B.2) and used throughout the book, is by (B.89) precisely the statement

$$T_F \;=\; \tfrac{1}{2}. \tag{B.92}$$

This is a choice, not a theorem (Section B.1.4); every other index and Casimir in the appendix is measured against it. It is the input that turns the abstract relation (B.90) into numbers.

B.4.2 The fundamental Casimir C_F

The master relation already determines C_F without further work: with $\dim(\square) = N$, $\dim(G) = N^2 - 1$, and $T_F = \frac{1}{2}$, equation (B.90) reads $N\, C_F = (N^2-1)\cdot\frac{1}{2}$, hence $C_F = (N^2-1)/2N$ (this is Eq. (B.17)). It is nonetheless worth re-deriving the same number directly from the completeness relation, both because that route makes no appeal to the abstract uniqueness arguments and because it is the warm-up whose structure the C_A computation repeats. Recall the fundamental completeness relation (B.78) of Theorem B.23,

$$\sum_a (T^a)_{ij}\,(T^a)_{kl} \;=\; \tfrac{1}{2}\Big(\delta_{il}\,\delta_{jk} - \tfrac{1}{N}\,\delta_{ij}\,\delta_{kl}\Big), \tag{B.93}$$

the sum on the adjoint index a running over all $N^2 - 1$ generators.

Proposition B.27 (Fundamental Casimir of SU(N))**.** *The quadratic Casimir of the fundamental representation of* SU(N) *is*

$$C_F \;=\; \frac{N^2-1}{2N}. \tag{B.94}$$

Proof. By (B.88), C_F is read off the matrix $(T^a T^a)_{il} = \sum_a (T^a)_{ij}(T^a)_{jl}$, in which the fundamental color index j is summed. This is the left-hand side of (B.93) with the relabeling $k \to j$ and the index j contracted. Performing that contraction,

$$(T^a T^a)_{il} \;=\; \sum_a (T^a)_{ij}(T^a)_{jl} \;=\; \tfrac{1}{2}\Big(\delta_{il}\,\delta_{jj} - \tfrac{1}{N}\,\delta_{ij}\,\delta_{jl}\Big)$$

$$= \tfrac{1}{2}\Big(N\,\delta_{il} - \tfrac{1}{N}\,\delta_{il}\Big) = \tfrac{1}{2}\,\frac{N^2-1}{N}\,\delta_{il}, \tag{B.95}$$

using $\delta_{jj} = N$ (the trace of the $N \times N$ identity) and $\delta_{ij}\delta_{jl} = \delta_{il}$. Comparison with $T^aT^a = C_F\,\mathbf{1}$ gives (B.94). □

This is the same value Eq. (B.85) of Section B.3.3 obtained as a special case of the reduction rule, and the same value the master relation forces; the threefold agreement is the first entry of the consistency check of Section B.4.5. The number is small but carries real physics: $C_F = (N^2-1)/2N$ is the squared color charge of a single quark, the coefficient that multiplies the quark self-energy and the SU(N) analogue of the Coulomb potential.

B.4.3 The structure-constant contraction and C_A

The adjoint Casimir is the eigenvalue of $\sum_a T^a_{\rm adj}T^a_{\rm adj}$, and the adjoint generators are the structure constants themselves. In the adjoint representation a generator acts on the algebra by the bracket, $(\mathrm{ad}\,T^a)\,T^b = \big[T^a, T^b\big] = if^{abc}T^c$, so in the basis $\{T^b\}$ its matrix elements are those fixed in Eq. (B.3),

$$(T^a_{\rm adj})_{bc} = (\mathrm{ad}\,T^a)_{bc} = -\,i\,f^{abc}. \tag{B.96}$$

That these matrices furnish a genuine representation is the content of the Jacobi identity: written out in structure constants, $\big[T^a, \big[T^b, T^c\big]\big] + (\text{cyclic}) = 0$ becomes

$$f^{ade}f^{bcd} + f^{bde}f^{cad} + f^{cde}f^{abd} = 0, \tag{B.97}$$

which is precisely $\big[\mathrm{ad}\,T^a, \mathrm{ad}\,T^b\big] = if^{abc}\,\mathrm{ad}\,T^c$. The adjoint Casimir operator $\sum_c T^c_{\rm adj}T^c_{\rm adj}$ therefore commutes with every generator and, since the adjoint of a simple algebra is irreducible, Schur's lemma forces it to be a multiple of the identity on the (N^2-1)-dimensional adjoint space. Its (a,b) matrix element follows from (B.96),

$$(T^c_{\rm adj}T^c_{\rm adj})_{ab} = (\mathrm{ad}\,T^c)_{ad}(\mathrm{ad}\,T^c)_{db} = (-if^{cad})(-if^{cdb}) = -\,f^{cad}f^{cdb} = f^{acd}f^{bcd}, \tag{B.98}$$

where the final equality uses the total antisymmetry of f proved in Theorem B.7: $f^{cad} = -f^{acd}$ and $f^{cdb} = f^{bcd}$ (cycling the second factor's indices, $cdb \to dbc \to bcd$, an even permutation), and the two introduced signs multiply to $+1$ against the leading minus to give $f^{acd}f^{bcd}$. Thus the adjoint Casimir *is* the standard contraction of two structure constants,

$$f^{acd}f^{bcd} = C_A\,\delta^{ab}, \tag{B.99}$$

proportional to δ^{ab} by the Jacobi-guaranteed irreducibility and identified with $C_2(\mathrm{adj}) = C_A$. This is also the Killing form K^{ab} of Theorem B.8, computed

there from the abstract uniqueness of the invariant form; here we instead pin the constant by an explicit descent to the fundamental.

For that descent we need the two consequences of completeness already established as the reduction rule of Section B.3.3, which we recall rather than reprove. From Theorem B.24, for any $N \times N$ matrix X,

$$\sum_a T^a\, X\, T^a \;=\; \tfrac{1}{2}\Big(\operatorname{tr}(X)\,\mathbf{1} - \tfrac{1}{N}\,X\Big), \tag{B.100}$$

which specializes (Eqs. (B.85) and (B.86)) to the two instances we use repeatedly,

$$\sum_a T^a\, T^a \;=\; C_F\,\mathbf{1} \;=\; \frac{N^2-1}{2N}\,\mathbf{1}, \qquad\qquad \sum_a T^a\, T^b\, T^a \;=\; -\,\frac{1}{2N}\,T^b, \tag{B.101}$$

the first by $X = \mathbf{1}$, the second by $X = T^b$ with $\operatorname{tr} T^b = 0$. With these in hand the adjoint Casimir is a four-term trace.

Theorem B.28 (Adjoint Casimir of $\mathrm{SU}(N)$)**.** *The structure constants of* $\mathrm{SU}(N)$ *satisfy*

$$f^{acd} f^{bcd} \;=\; N\,\delta^{ab}, \qquad \textit{so that} \qquad C_A \;=\; N. \tag{B.102}$$

Proof. Express the structure constants through fundamental generators. Contracting the bracket $[T^a, T^c] = i f^{acd} T^d$ against T^e and tracing with $\operatorname{tr}(T^d T^e) = \tfrac{1}{2}\delta^{de}$ inverts to the resolvent

$$f^{acd}\, T^d \;=\; -\,i\,[T^a, T^c]\,. \tag{B.103}$$

Now project (B.99) onto a trace by contracting two copies. Using (B.103) for both factors and $\operatorname{tr}(T^d T^e) = \tfrac{1}{2}\delta^{de}$,

$$\begin{aligned} \tfrac{1}{2}\, f^{acd} f^{bcd} \;&=\; f^{acd} f^{bce}\, \operatorname{tr}(T^d T^e) \;=\; \operatorname{tr}\big[(f^{acd} T^d)(f^{bce} T^e)\big] \\ &=\; \operatorname{tr}\big[(-i\,[T^a, T^c])(-i\,\big[T^b, T^c\big])\big] \;=\; -\operatorname{tr}\big(\,[T^a, T^c]\,\big[T^b, T^c\big]\,\big), \end{aligned} \tag{B.104}$$

with the fundamental color index c summed. Hence

$$f^{acd} f^{bcd} \;=\; -\,2\,\operatorname{tr}\big(\,[T^a, T^c]\,\big[T^b, T^c\big]\,\big). \tag{B.105}$$

Expanding the two commutators gives four traces, each summed over c,

$$[T^a, T^c]\,\big[T^b, T^c\big] = \underbrace{T^a T^c T^b T^c}_{\text{(I)}}\; \underbrace{-\,T^a T^c T^c T^b}_{\text{(II)}}\; \underbrace{-\,T^c T^a T^b T^c}_{\text{(III)}}\; \underbrace{+\,T^c T^a T^c T^b}_{\text{(IV)}}. \tag{B.106}$$

We evaluate each with the insertion identities (B.100)–(B.101), using $\operatorname{tr} T^a = 0$, $\operatorname{tr}(T^a T^b) = \tfrac{1}{2}\delta^{ab}$, and $\operatorname{tr}\mathbf{1} = N$ at the end.

Term (I). The inner sum is $\sum_c T^c T^b T^c = -\frac{1}{2N} T^b$ by the second relation in (B.101), so

$$\mathrm{tr}(\mathrm{I}) = \mathrm{tr}\Big(T^a\big(-\tfrac{1}{2N}T^b\big)\Big) = -\tfrac{1}{2N}\cdot\tfrac{1}{2}\,\delta^{ab} = -\tfrac{1}{4N}\,\delta^{ab}. \tag{B.107}$$

Term (II). Here $\sum_c T^c T^c = C_F \mathbf{1}$ by the first relation in (B.101), so

$$\mathrm{tr}(\mathrm{II}) = -\,\mathrm{tr}\big(T^a\, C_F \mathbf{1}\, T^b\big) = -\,C_F\,\mathrm{tr}(T^a T^b) = -\tfrac{1}{2}\,C_F\,\delta^{ab}. \tag{B.108}$$

Term (III). Now $\sum_c T^c (T^a T^b) T^c = \frac{1}{2}\big(\mathrm{tr}(T^a T^b)\mathbf{1} - \frac{1}{N} T^a T^b\big)$ from (B.100) with $X = T^a T^b$, whose trace is

$$\mathrm{tr}(\mathrm{III}) = -\tfrac{1}{2}\Big(\mathrm{tr}(T^a T^b)\,N - \tfrac{1}{N}\,\mathrm{tr}(T^a T^b)\Big) = -\tfrac{1}{2}\cdot\tfrac{1}{2}\delta^{ab}\Big(N - \tfrac{1}{N}\Big) = -\tfrac{1}{4}\,\frac{N^2-1}{N}\,\delta^{ab} = -\tfrac{1}{2}\,C_F\,\delta^{ab} \tag{B.109}$$

Term (IV). Again $\sum_c T^c T^a T^c = -\frac{1}{2N} T^a$, so

$$\mathrm{tr}(\mathrm{IV}) = \mathrm{tr}\Big(\big(-\tfrac{1}{2N}T^a\big)T^b\Big) = -\tfrac{1}{4N}\,\delta^{ab}. \tag{B.110}$$

Adding the four contributions,

$$\mathrm{tr}\big([T^a, T^c]\,\big[T^b, T^c\big]\big) = \Big(-\tfrac{1}{4N} - \tfrac{1}{2}C_F - \tfrac{1}{2}C_F - \tfrac{1}{4N}\Big)\delta^{ab} = -\Big(C_F + \tfrac{1}{2N}\Big)\delta^{ab}. \tag{B.111}$$

With $C_F = (N^2-1)/2N$ the bracket telescopes to an integer,

$$C_F + \tfrac{1}{2N} = \frac{N^2-1}{2N} + \frac{1}{2N} = \frac{N^2}{2N} = \frac{N}{2}, \tag{B.112}$$

so $\mathrm{tr}([T^a, T^c]\,[T^b, T^c]) = -\frac{N}{2}\,\delta^{ab}$. Substituting into (B.105),

$$f^{acd} f^{bcd} = -2\cdot\Big(-\tfrac{N}{2}\,\delta^{ab}\Big) = N\,\delta^{ab}, \tag{B.113}$$

which is (B.102); comparison with (B.99) identifies $C_A = N$. □

It is worth pausing on why the answer comes out an integer. The two "$1/N$" subtractions buried in the completeness relation — the tracelessness corrections that distinguish $\mathfrak{su}(N)$ from $\mathfrak{u}(N)$ — enter through the pairs (I)+(IV) and (II)+(III), and combine with the -1 inside $C_F = (N^2-1)/2N$ so that the $1/N$ pieces cancel exactly, leaving the bare N. The same cancellation is the reason C_A is an integer for every N while C_F is not. The identification $f^{acd} f^{bcd} = C_A \delta^{ab}$ with $C_A = N$ is the structure-constant identity announced in the section goal; it is what makes the gluon and ghost loops of Chapter 27 collapse to a single color symbol.

Physical Insight

The contrast between C_F and C_A is the contrast between a charge carried by a probe and a charge carried by the force itself. $C_F = (N^2-1)/2N$ measures how strongly a single fundamental quark couples to the gluon field — it grows only logarithmically with N, $C_F \to N/2$ at large N. $C_A = N$ measures how strongly the gluon couples to *itself*, through the non-abelian self-interaction encoded in f^{abc}. That a gauge boson carries the adjoint charge $C_A = N$, with no abelian analogue (for U(1), $f^{abc} = 0$ and $C_A = 0$), is the algebraic root of asymptotic freedom: the gluon's self-charge antiscreens the coupling, an effect simply absent in QED.

B.4.4 The SU(3) values for QCD

Specializing (B.94), (B.102), and (B.92) to $N = 3$ — the color group of QCD, whose explicit Gell-Mann generators were tabulated in Section B.2.3 and whose fundamental Casimir was checked directly in Section B.2.5 — gives the numbers the entire QCD literature carries:

$$\boxed{C_F = \frac{3^2-1}{2\cdot 3} = \frac{8}{6} = \frac{4}{3}, \qquad C_A = 3, \qquad T_F = \frac{1}{2}.} \tag{B.114}$$

The first, $C_F = \frac{4}{3}$, is the color charge a single quark presents; it sets the size of the quark self-energy and of the static quark–antiquark potential. The second, $C_A = 3$, is the gluon's self-coupling charge and the source of the antiscreening that makes QCD asymptotically free. The third, $T_F = \frac{1}{2}$, weights each quark flavor in a gluon vacuum-polarization loop. These three numbers, together with the active-flavor count n_f, are the complete group-theory input to the one-loop running of α_s.

B.4.5 An independent numerical check: the master relation

The derivations of C_F in Theorem B.27 (via completeness) and of C_A in Theorem B.28 (via the structure-constant contraction) made no use of the master relation (B.90); reinserting the results into it is therefore a genuine consistency test, not a tautology. For the fundamental, $\dim(\square) = N$ and $C_F = (N^2-1)/2N$ give

$$\dim(\square)\, C_F = N \cdot \frac{N^2-1}{2N} = \frac{N^2-1}{2}, \tag{B.115}$$

which must equal $\dim(G)\, T_F = (N^2-1)\cdot\frac{1}{2}$; the two agree for every N. For the adjoint, $\dim(\text{adj}) = \dim(G) = N^2-1$ and $C_A = N$ give $\dim(\text{adj})\, C_A = N(N^2-1)$, which must equal $\dim(G)\, T(\text{adj})$; since $\dim(\text{adj}) = \dim(G)$ the relation collapses to $T(\text{adj}) = C_A = N$, the statement of Theorem B.6 that

for the adjoint the index and the Casimir coincide. Table B.3 carries this out arithmetically for $N = 2, \dots, 5$, listing both representations and confirming $\dim(R)\, C_2(R) = \dim(G)\, T(R)$ in every row.

Table B.3: Numerical verification of the master relation $\dim(R)\, C_2(R) = \dim(G)\, T(R)$ for the fundamental and adjoint of SU(N), $N = 2, \dots, 5$. Here $\dim(G) = N^2 - 1$, $T_F = \frac{1}{2}$, $C_F = (N^2 - 1)/2N$, $C_A = N$, and $T(\text{adj}) = N$. The last two columns agree in every row, the independent check that the completeness-derived C_F and the structure-constant-derived C_A are mutually consistent.

Group	$\dim(G)$	R	$\dim(R)$	$C_2(R)$	$T(R)$	$\dim(R)\, C_2(R)$	$\dim(G)\, T(R)$
SU(2)	3	$\square$	2	3/4	1/2	3/2	3/2
		adj	3	2	2	6	6
SU(3)	8	$\square$	3	4/3	1/2	4	4
		adj	8	3	3	24	24
SU(4)	15	$\square$	4	15/8	1/2	15/2	15/2
		adj	15	4	4	60	60
SU(5)	24	$\square$	5	12/5	1/2	12	12
		adj	24	5	5	120	120

The SU(2) row doubles as a check against angular-momentum theory. There the fundamental is the spin-$\frac{1}{2}$ doublet with $C_F = \frac{3}{4} = j(j+1)\big|_{j=1/2}$ in the normalization $T^a = \frac{1}{2}\sigma^a$, and the adjoint is the spin-1 triplet with $C_A = 2 = j(j+1)\big|_{j=1}$, exactly the values found from the Pauli completeness relation in Theorem B.14. The Casimirs we computed group-theoretically are nothing but the total-angular-momentum eigenvalues, recovered here from the completeness relation rather than from ladder operators.

B.4.6 Assembling the Yang–Mills color factors

We now collect the data in the form the one-loop Yang–Mills beta function needs, advancing Yang–Mills theory at the data layer. The one-loop coefficient b_0 in $\beta_g = -\dfrac{g^3}{16\pi^2}\, b_0$ is built from exactly three group-theory inputs: the gluon and ghost loops contribute through C_A, and each quark flavor contributes through T_F. The full diagrammatic computation — the loop integrals, the gauge-fixing machinery, the Ward–identity cancellations — is carried out in Chapter 27; the role of this appendix is to supply, ready-evaluated, the color factors that multiply each contribution, and to compute the carried number for QCD.

Worked Example B.29 (The SU(3) color factors entering b_0)**.** The one-loop Yang–Mills beta-function coefficient with n_f Dirac fermions in the fundamental,

in the standing normalization of Yang–Mills theory, is

$$b_0 \;=\; \tfrac{11}{3}\,C_A \;-\; \tfrac{4}{3}\,T_F\,n_f. \tag{B.116}$$

We trace the group-theory origin of each term and then specialize to SU(3).

The gauge sector, $\frac{11}{3}C_A$. The gluon self-energy at one loop receives a gluon loop and a Faddeev–Popov ghost loop, each carrying a contraction of two structure constants at its pair of trilinear vertices. By Theorem B.28 every such contraction reduces to $f^{acd}f^{bcd} = C_A\,\delta^{ab} = N\delta^{ab}$, so the entire color content of the gauge sector is the single symbol C_A. The transverse kinematic coefficients — which combine the gluon-loop and ghost-loop pieces into the gauge-invariant $\frac{11}{3}$ — are computed in Chapter 27; what the group theory fixes here is that the color structure is purely C_A, traceable directly to the adjoint Casimir we have just evaluated.

The matter sector, $-\frac{4}{3}T_F\,n_f$. Each fermion flavor runs in one vacuum-polarization loop with two gluon insertions, contributing the color trace $\mathrm{tr}(T^aT^b) = T_F\,\delta^{ab}$ over the fundamental indices. The n_f flavors form the direct sum $\square^{\oplus n_f}$, and by the additivity of the index (Theorem B.9) their combined color factor is $n_f\,T_F$. This is exactly the $-\frac{4}{3}T_Fn_f$ term, with the kinematic $\frac{4}{3}$ supplied by Chapter 27.

The role of C_F. The fundamental Casimir C_F does appear in the intermediate, gauge-dependent pieces of the calculation — in the quark field-strength renormalization Z_2 and the quark–gluon vertex renormalization Z_1 — but the Slavnov–Taylor (non-abelian Ward) identity ties these together so that C_F drops out of the gauge-invariant combination defining the coupling renormalization. This is why (B.116) carries only C_A and T_Fn_f; the cancellation is exhibited explicitly in Chapter 27.

The QCD number. Inserting the SU(3) values (B.114), $C_A = 3$ and $T_F = \frac{1}{2}$,

$$b_0 \;=\; \tfrac{11}{3}\cdot 3 \;-\; \tfrac{4}{3}\cdot\tfrac{1}{2}\,n_f \;=\; 11 \;-\; \tfrac{2}{3}\,n_f. \tag{B.117}$$

For every $n_f \le 16$ this is positive, so $\beta_g < 0$ and the coupling decreases toward high energy: asymptotic freedom. With the six known quark flavors, $n_f = 6$, one finds $b_0 = 11 - 4 = 7 > 0$; even at $n_f = 16$, $b_0 = 11 - \frac{32}{3} = \frac{1}{3} > 0$, while $n_f = 17$ would tip b_0 negative and destroy asymptotic freedom. The carried number $b_0 = 11 - \frac{2}{3}n_f$ is precisely the input Chapter 27 converts into the running of α_s and the dynamically generated scale Λ_{QCD}.

With $C_F = (N^2-1)/2N$, $C_A = N$, and $T_F = \frac{1}{2}$ in hand, the quadratic invariants of SU(N) are complete, and the SU(3) color factors that feed the one-loop Yang–Mills beta coefficient are assembled and evaluated. The remaining gauge-theory data are the *cubic* symmetric invariants — the totally symmetric tensor d^{abc} and the anomaly coefficient $A(R)$ it defines — which measure not the strength of a representation but its chirality-sensitive asymmetry. Those are

what the next section constructs, enriching the quadratic Casimir set built here with the symmetric invariants the anomaly-cancellation chapters consume.

B.5 Symmetric Invariants and the Anomaly Coefficient

The previous section closed the file on the *quadratic* invariants of $\mathfrak{su}(N)$: the Dynkin index $T(R)$, the quadratic Casimirs $C_2(R)$, and the canonical color factors $C_F = (N^2-1)/2N$, $C_A = N$, $T_F = \frac{1}{2}$ that feed the one-loop Yang–Mills β-coefficient (Section B.4). Those numbers all descend from a single symmetric invariant tensor of rank two, $\mathrm{tr}(T^a T^b) \propto \delta^{ab}$, and from the structure-constant contraction $f^{acd} f^{bcd} = C_A\, \delta^{ab}$. There is exactly one quadratic invariant, and after specifying its normalization there is nothing more to say at that order.

The next invariant up the ladder is *cubic*, and it is not a mere refinement of the quadratic data: it is the precise group-theoretic object that decides whether a chiral gauge theory is consistent. A theory of chiral (Weyl) fermions is only well defined if the gauge current remains conserved at one loop; the obstruction is the triangle diagram with three external gauge bosons and a chiral fermion circulating in the loop (Fig. B.3). The diagram's group-theory factor is the symmetrized trace $\mathrm{tr}_R(\{T^a, T^b\}T^c)$ over the fermion representation, and its kinematic part is the same for every fermion. Consistency therefore requires that a single number built from this trace—the *anomaly coefficient* $A(R)$, summed over all left-handed fermions—vanish. This section isolates that number, computes it for the representations the book uses, and proves the three structural facts that make anomaly cancellation tractable: $A(\bar{R}) = -A(R)$, $A(\mathrm{adj}) = 0$, and the vanishing of the cubic invariant for every simple algebra except $\mathfrak{su}(N)$ with $N \geq 3$. The dynamical derivation of the triangle anomaly itself lives in Chapter 36, and its application to the Standard Model and to grand unification in Chapter 37; here we supply only the data those chapters consume.

B.5.1 The symmetrized trace and the cubic invariant

Fix a compact simple Lie algebra with Hermitian generators T^a in a representation R, normalized in the fundamental by $\mathrm{tr}(T^a T^b) = \frac{1}{2}\delta^{ab}$ (Section B.4). The object the triangle produces is the totally symmetrized trace of three generators. We begin by isolating it from the ordinary product trace.

Write the trace of three fundamental generators as the sum of its symmetric and antisymmetric parts in the index pair. Using $\left\{T^a, T^b\right\}$ and $\left[T^a, T^b\right] = i f^{abc} T^c$,

$$\mathrm{tr}(T^a T^b T^c) = \tfrac{1}{2}\,\mathrm{tr}\left(\left\{T^a, T^b\right\} T^c\right) + \tfrac{1}{2}\,\mathrm{tr}\left(\left[T^a, T^b\right] T^c\right) = \tfrac{1}{4}\, d^{abc} + \tfrac{i}{4}\, f^{abc}, \tag{B.118}$$

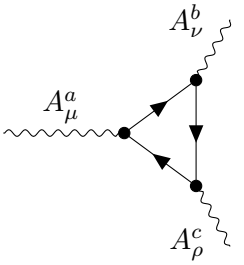

Figure B.3: The triangle (AVV) diagram whose group-theory factor is the symmetrized trace $\mathrm{tr}_R(\{T^a,T^b\}T^c) = \frac{1}{2}A(R)\,d^{abc}$. Summed over the closed fermion loop together with the crossed diagram (legs $b \leftrightarrow c$ exchanged), the antisymmetric f^{abc} part cancels and only the totally symmetric d^{abc} piece survives, weighted by $A(R)$. The kinematic factor is representation-independent; the entire dependence on the matter content is $\sum_i A(R_i)$. The amplitude is computed in Chapter 36.

where the first equality is the trivial split into anticommutator and commutator, and the second uses $\mathrm{tr}(\left[T^a,T^b\right]T^c) = if^{abd}\,\mathrm{tr}(T^dT^c) = \frac{i}{2}f^{abc}$ together with the definition of d^{abc} below. The antisymmetric piece reproduces the structure constants; the symmetric piece defines a new, totally symmetric invariant tensor.

Definition B.30 (Cubic symmetric invariant)**.** The *cubic symmetric tensor* d^{abc} of $\mathfrak{su}(N)$ is

$$d^{abc} \;\equiv\; 2\,\mathrm{tr}\big(\left\{T^a,T^b\right\}T^c\big)\Big|_{\text{fundamental}}\,, \tag{B.119}$$

equivalently the coefficient in the fundamental anticommutator

$$\left\{T^a,T^b\right\} \;=\; \frac{1}{N}\,\delta^{ab}\,\mathbf{1} \;+\; d^{abc}\,T^c. \tag{B.120}$$

For $\mathfrak{su}(3)$ in the Gell-Mann basis $T^a = \lambda^a/2$ this is the totally symmetric symbol with the nonzero independent entries $d^{118} = d^{228} = d^{338} = 1/\sqrt{3}$, $d^{888} = -1/\sqrt{3}$, etc., tabulated in Table B.2 of Section B.2.4.

That Eqs. (B.119) and (B.120) agree, and that they are consistent with the $\frac{1}{4}$ in Eq. (B.118), is a one-line check: tracing Eq. (B.120) against T^e and using $\mathrm{tr}(T^cT^e) = \frac{1}{2}\delta^{ce}$ and $\mathrm{tr}\,T^e = 0$ gives $\mathrm{tr}(\left\{T^a,T^b\right\}T^e) = \frac{1}{2}d^{abe}$, which is Eq. (B.119). The constant $1/N$ multiplying the identity is fixed by tracing Eq. (B.120) over $a = b$ (no sum on the matrix, sum on the index): $\mathrm{tr}\left\{T^a,T^b\right\} = 2\,\mathrm{tr}(T^aT^b) = \delta^{ab}$, while the right side gives $\frac{1}{N}\delta^{ab}\,N = \delta^{ab}$, consistent for the $N \times N$ fundamental. The completeness relation that makes Eq. (B.120) an identity on the full matrix algebra is recorded in Section B.3.1; we take it as given.

With the symbol in hand we promote the symmetrized trace to a representation-dependent number.

Definition B.31 (Anomaly coefficient)**.** The *anomaly coefficient* $A(R)$ of a representation R is defined by

$$\mathrm{tr}_R\big(\{T_R^a, T_R^b\}\, T_R^c\big) \;=\; \tfrac{1}{2}\, A(R)\, d^{abc}, \tag{B.121}$$

with d^{abc} the fundamental-normalized tensor of Theorem B.30. By Eq. (B.119) the normalization is $A(\mathrm{fund}) = 1$.

For Eq. (B.121) to define a single number rather than an overdetermined system of constraints, the left-hand side must be *proportional* to d^{abc} for every R. This is the central structural fact, and it has two ingredients: the trace is a totally symmetric invariant tensor, and the space of such tensors is at most one-dimensional. We prove the first now and treat the second in Section B.5.4.

Proposition B.32 (Total symmetry and invariance)**.** *For any representation R, the symmetrized trace $D^{abc}(R) \equiv \mathrm{tr}_R(\{T_R^a, T_R^b\}\, T_R^c)$ is totally symmetric in (a, b, c) and is an invariant tensor of the algebra,*

$$f^{ade} D^{ebc} + f^{bde} D^{aec} + f^{cde} D^{abe} = 0. \tag{B.122}$$

Proof. Symmetry in $a \leftrightarrow b$ is manifest from $\{T^a, T^b\} = \{T^b, T^a\}$. For the remaining transposition, expand and use cyclicity of the trace:

$$D^{abc} = \mathrm{tr}(T^a T^b T^c) + \mathrm{tr}(T^b T^a T^c) = \mathrm{tr}(T^a T^b T^c) + \mathrm{tr}(T^a T^c T^b) = \mathrm{tr}\big(T^a \{T^b, T^c\}\big), \tag{B.123}$$

where the middle equality moves T^b from the front of the second trace to the back by cyclicity, $\mathrm{tr}(T^b T^a T^c) = \mathrm{tr}(T^a T^c T^b)$. The result $D^{abc} = \mathrm{tr}(T^a \{T^b, T^c\})$ is manifestly symmetric in $b \leftrightarrow c$. Since the transpositions $(a\,b)$ and $(b\,c)$ generate the full symmetric group S_3, D^{abc} is totally symmetric.

For invariance, vary the generators by an infinitesimal algebra rotation $\delta T^a = i\,\theta^d \big[T^d, T^a\big] = -\theta^d f^{dae} T^e$. The trace of a product of generators is invariant under a simultaneous similarity transformation $T^a \to U T^a U^{-1}$ of all factors, so the sum of the three variations of D^{abc} vanishes:

$$0 = \delta D^{abc} = -\theta^d \big(f^{dae} D^{ebc} + f^{dbe} D^{aec} + f^{dce} D^{abe}\big). \tag{B.124}$$

As θ^d is arbitrary, Eq. (B.122) follows. □

Theorem B.32 guarantees that $D^{abc}(R)$ lives in the space of totally symmetric invariant rank-three tensors. Once Section B.5.4 establishes that this space is at most one-dimensional, Eq. (B.121) is well posed and $A(R)$ is a genuine invariant of the representation.

B.5.2 Conjugation reverses the sign

The single most useful property of $A(R)$ for model building is that it changes sign under complex conjugation of the representation. This is what allows a vector-like pair $R \oplus \bar{R}$ to be automatically anomaly-free, and it is the engine behind every chiral cancellation in Chapter 37.

Theorem B.33 (Sign reversal under conjugation)**.** *For every representation R,*

$$A(\bar{R}) = -A(R). \tag{B.125}$$

Consequently every real or pseudoreal representation, for which $R \cong \bar{R}$, has $A(R) = 0$.

Proof. The conjugate representation acts by $T^a_{\bar{R}} = -(T^a_R)^{\mathsf{T}}$; this is the unique sign choice making the $T^a_{\bar{R}}$ Hermitian and satisfying the same commutators (transposition reverses the order in a product, and the extra minus restores $\left[T^a_{\bar{R}}, T^b_{\bar{R}}\right] = i f^{abc} T^c_{\bar{R}}$). Insert this into the symmetrized trace. For two matrices the transpose of an anticommutator is the anticommutator of the transposes, $\left\{M^{\mathsf{T}}, N^{\mathsf{T}}\right\} = (NM)^{\mathsf{T}} + (MN)^{\mathsf{T}} = \left(\{M, N\}\right)^{\mathsf{T}}$, so with $M = T^a_R$, $N = T^b_R$,

$$\begin{aligned} D^{abc}(\bar{R}) &= \operatorname{tr}\Big(\left\{-(T^a_R)^{\mathsf{T}}, -(T^b_R)^{\mathsf{T}}\right\} \left(-(T^c_R)^{\mathsf{T}}\right)\Big) = -\operatorname{tr}\Big(\left(\left\{T^a_R, T^b_R\right\}\right)^{\mathsf{T}} (T^c_R)^{\mathsf{T}}\Big) \\ &= -\operatorname{tr}\Big(\left(T^c_R \left\{T^a_R, T^b_R\right\}\right)^{\mathsf{T}}\Big) = -\operatorname{tr}\left(T^c_R \left\{T^a_R, T^b_R\right\}\right) = -D^{abc}(R), \end{aligned} \tag{B.126}$$

using $(XY)^{\mathsf{T}} = Y^{\mathsf{T}} X^{\mathsf{T}}$ in the third step and the trace's invariance under transposition in the fourth. Comparing with Eq. (B.121) gives $A(\bar{R}) = -A(R)$.

If R is real or pseudoreal then $R \cong \bar{R}$: there exists an invertible S with $T^a_{\bar{R}} = S\, T^a_R\, S^{-1}$, and the trace is unchanged by this similarity, so $A(\bar{R}) = A(R)$. Together with Eq. (B.125) this forces $2A(R) = 0$, hence $A(R) = 0$. □

In particular the fundamental and antifundamental of $\mathfrak{su}(N)$ carry opposite anomalies, $A(\bar{N}) = -A(N) = -1$. A Dirac fermion—a left-handed N together with a right-handed N, which is a left-handed $\bar{N}$—is automatically anomaly-free, $A(N) + A(\bar{N}) = 0$, as it must be: vector-like matter never generates a gauge anomaly.

B.5.3 The adjoint is anomaly-free

The adjoint representation is real (the structure constants are real and the generators $(T^a_{\text{adj}})_{bc} = -i f^{abc}$ are Hermitian and purely imaginary, hence equivalent to their conjugate), so Theorem B.33 already gives $A(\text{adj}) = 0$. It is worth seeing

the same result fall out directly from the antisymmetry of f, because the computation exhibits why the *symmetric* invariant must vanish on a representation built from f itself.

Proposition B.34 (Vanishing adjoint anomaly)**.** $A(\mathrm{adj}) = 0$ *for every simple Lie algebra.*

Proof. Write M^a for the adjoint generator regarded as a matrix, $(M^a)_{de} = -if^{ade}$. Because $f^{ade} = -f^{aed}$, each M^a is an antisymmetric matrix, $(M^a)^{\mathsf{T}} = -M^a$. Set $G^{abc} \equiv \mathrm{tr}(M^a M^b M^c)$. Transposing inside the trace and using antisymmetry of every factor,

$$G^{abc} = \mathrm{tr}\big((M^a M^b M^c)^{\mathsf{T}}\big) = \mathrm{tr}\big((M^c)^{\mathsf{T}}(M^b)^{\mathsf{T}}(M^a)^{\mathsf{T}}\big) = (-1)^3\,\mathrm{tr}(M^c M^b M^a) = -\,G^{cba}. \tag{B.127}$$

Thus G^{abc} is antisymmetric under the reversal $(a,b,c) \to (c,b,a)$; combined with the cyclicity $G^{abc} = G^{bca} = G^{cab}$, reversal is the same as the transposition $(a\,c)$ followed by a cycle, and one finds G^{abc} is *totally antisymmetric* in its three indices. Now

$$D^{abc}(\mathrm{adj}) = \mathrm{tr}(M^a M^b M^c) + \mathrm{tr}(M^b M^a M^c) = G^{abc} + G^{bac} = G^{abc} - G^{abc} = 0, \tag{B.128}$$

since exchanging $a \leftrightarrow b$ flips the sign of the totally antisymmetric G. Hence $A(\mathrm{adj}) = 0$. □

The computation also confirms the content of Eq. (B.118) in the adjoint: the product trace $\mathrm{tr}_{\mathrm{adj}}(T^a T^b T^c) = iG^{abc}$ is purely antisymmetric, proportional to f^{abc} alone, with no d^{abc} component. The adjoint "sees" only the antisymmetric invariant.

B.5.4 Which algebras carry a cubic invariant

We can now settle when $A(R)$ is even a meaningful quantity. The definition Eq. (B.121) presumes a nonzero symmetric tensor d^{abc} to be proportional to; if no totally symmetric invariant of rank three exists, then $D^{abc}(R)$ vanishes identically for every R and the theory is anomaly-free for any matter content whatsoever.

Theorem B.35 (Anomaly-free algebras)**.** *Among the compact simple Lie algebras, a nonzero totally symmetric invariant tensor d^{abc} exists* only *for $\mathfrak{su}(N)$ with $N \geq 3$. For every other simple algebra—$\mathfrak{su}(2)$, all $\mathfrak{so}(N)$, all $\mathrm{Sp}(N)$, and the exceptional algebras G_2, F_4, E_6, E_7, E_8—the cubic symmetric invariant vanishes, so $A(R) = 0$ for every representation and no perturbative gauge anomaly can arise.*

Proof for $\mathfrak{su}(2)$. The decisive case for physics is $\mathfrak{su}(2)$, where the vanishing is immediate. With $T^a = \sigma^a/2$ and the Pauli identity $\{\sigma^a, \sigma^b\} = 2\delta^{ab}\mathbf{1}$,

$$\{T^a, T^b\} = \tfrac{1}{2}\delta^{ab}\mathbf{1} \implies \operatorname{tr}_{\mathbf{2}}(\{T^a, T^b\} T^c) = \tfrac{1}{2}\delta^{ab} \operatorname{tr} T^c = 0. \tag{B.129}$$

The anticommutator is pure identity—there is no $d^{abc}T^c$ term, equivalently $d^{abc} \equiv 0$ for $\mathfrak{su}(2)$ (this is the $N = 2$ specialization of Eq. (B.120), where the symmetric symbol has no independent components). Since the cubic invariant vanishes in the defining representation it vanishes in all of them: every $\mathfrak{su}(2)$ representation is real or pseudoreal, so $A(R) = 0$ also follows from Theorem B.33. Either way, $\mathfrak{su}(2)$ gauge theory is automatically free of the cubic anomaly. □

Structural argument for the remaining algebras. The general statement is a fact about the ring of invariant polynomials. A rank-r compact simple Lie algebra has exactly r algebraically independent (primitive) Casimir invariants, of fixed degrees $m_1+1, \ldots, m_r+1$ where the m_i are the exponents of the algebra. Every symmetric invariant tensor is built, via the symmetrized trace, from these primitives; a totally symmetric invariant of rank three exists iff one of the primitive degrees equals 3. The degrees are: for $A_{N-1} = \mathfrak{su}(N)$, $\{2, 3, 4, \ldots, N\}$; for $B_r = \mathfrak{so}(2r+1)$ and $C_r = \mathrm{Sp}(2r)$, $\{2, 4, 6, \ldots, 2r\}$; for $D_r = \mathfrak{so}(2r)$, $\{2, 4, \ldots, 2r-2\}$ together with r; and for the exceptionals the degree sets begin $G_2 : \{2, 6\}$, $F_4 : \{2, 6, 8, 12\}$, $E_6 : \{2, 5, 6, 8, 9, 12\}$, $E_7 : \{2, 6, 8, 10, 12, 14, 18\}$, $E_8 : \{2, 8, 12, 14, 18, 20, 24, 30\}$. A primitive of degree 3 appears in exactly one family: the A series, and only from $A_2 = \mathfrak{su}(3)$ onward (the $A_1 = \mathfrak{su}(2)$ degree set is $\{2\}$, with no cubic). Every other algebra has its first invariant beyond the quadratic at degree 4 or higher, so its symmetric rank-three invariant tensor is identically zero, $d^{abc} = 0$, and Eq. (B.121) forces $A(R) = 0$ for all R. Reality of the relevant representations of $\mathfrak{so}(N)$ and $\mathrm{Sp}(2r)$ provides an independent confirmation through Theorem B.33. □

Physical Insight

The list in Theorem B.35 is exactly why the Standard Model gauge group is so forgiving. Of its three factors, $\mathfrak{su}(2)_L$ and $\mathrm{U}(1)_Y$-mixed-with-$\mathfrak{su}(2)$ pieces involving the $\mathfrak{su}(2)$ cubic vanish automatically, and the strong group $\mathfrak{su}(3)_c$ couples vector-like (left and right quarks in the same color $\mathbf{3}$), so its cubic anomaly cancels representation by representation. The only cubic anomalies that must be arranged to cancel nontrivially are the $\mathrm{U}(1)_Y^3$ and mixed $\mathfrak{su}(2)_L^2\,\mathrm{U}(1)_Y$, $\mathfrak{su}(3)_c^2\,\mathrm{U}(1)_Y$, and gravitational $\mathrm{U}(1)_Y$ conditions—the celebrated hypercharge sum rules of Chapter 37. Every $\mathfrak{su}(N)$ with $N \geq 3$, by contrast, can support a genuine chiral anomaly, which is why $\mathfrak{su}(5)$ grand unification must be checked explicitly (Theorem B.38).

B.5.5 Computing $A(\mathbf{fund})$ and the additive structure

The normalization $A(\mathrm{fund}) = 1$ was built into Theorem B.31 by choosing d^{abc} to be the fundamental symbol. It is reassuring to see it emerge from the explicit $\mathfrak{su}(3)$ data. With $T^a = \lambda^a/2$ and the Gell-Mann anticommutator $\{\lambda^a, \lambda^b\} = \frac{4}{3}\delta^{ab}\mathbf{1} + 2d^{abc}\lambda^c$ (Section B.2.4),

$$\mathrm{tr}_{\mathbf{3}}\big(\{T^a, T^b\}\, T^c\big) = \tfrac{1}{4}\,\mathrm{tr}\big(\{\lambda^a, \lambda^b\}\,\tfrac{\lambda^c}{2}\big) = \tfrac{1}{4}\Big(\tfrac{4}{3}\delta^{ab}\underbrace{\mathrm{tr}\,\tfrac{\lambda^c}{2}}_{0} + 2d^{abe}\underbrace{\mathrm{tr}\,\tfrac{\lambda^e\lambda^c}{2}}_{\delta^{ec}}\Big) = \tfrac{1}{2}d^{abc}, \tag{B.130}$$

so $A(\mathbf{3}) = 1$ by Eq. (B.121), and $A(\bar{\mathbf{3}}) = -1$ by Theorem B.33. For general $\mathfrak{su}(N)$ the same computation using Eq. (B.120) gives $\mathrm{tr}_{\mathrm{fund}}(\{T^a, T^b\}\, T^c) = \frac{1}{2}d^{abc}$ identically, confirming $A(\mathrm{fund}) = 1$ for every $N \geq 3$.

To use $A(R)$ on composite representations we need its behavior under direct sums and tensor products.

Proposition B.36 (Additivity)**.** *For representations R_1, R_2,*

$$A(R_1 \oplus R_2) = A(R_1) + A(R_2), \tag{B.131}$$

$$A(R_1 \otimes R_2) = \dim(R_2)\, A(R_1) + \dim(R_1)\, A(R_2). \tag{B.132}$$

Proof. The direct-sum rule is immediate: in $R_1 \oplus R_2$ the generators are block-diagonal, $T^a = T^a_{R_1} \oplus T^a_{R_2}$, and the trace of any product splits as a sum over blocks, so $D^{abc}(R_1 \oplus R_2) = D^{abc}(R_1) + D^{abc}(R_2)$, giving Eq. (B.131). The tensor-product rule is the worked computation Theorem B.37. □

Worked Example B.37 (The tensor-product anomaly rule)**.** On $V_1 \otimes V_2$ the generators act as $T^a = A^a \otimes \mathbf{1} + \mathbf{1} \otimes B^a$, with A^a the generators on V_1 (dimension d_1, anomaly A_1) and B^a those on V_2 (dimension d_2, anomaly A_2). Expanding the product,

$$T^a T^b = A^a A^b \otimes \mathbf{1} + A^a \otimes B^b + A^b \otimes B^a + \mathbf{1} \otimes B^a B^b, \tag{B.133}$$

so the anticommutator is

$$\{T^a, T^b\} = \{A^a, A^b\} \otimes \mathbf{1} + \mathbf{1} \otimes \{B^a, B^b\} + 2(A^a \otimes B^b + A^b \otimes B^a). \tag{B.134}$$

Multiply by $T^c = A^c \otimes \mathbf{1} + \mathbf{1} \otimes B^c$ and take the trace, using $\mathrm{tr}_{V_1 \otimes V_2}(X \otimes Y) = \mathrm{tr}\, X\ \mathrm{tr}\, Y$ and the tracelessness $\mathrm{tr}\, A^a = \mathrm{tr}\, B^a = 0$. Every term in the cross piece $2(A^a \otimes B^b + A^b \otimes B^a)\, T^c$ produces a single-generator trace and vanishes, as does the cross term from the identity blocks ($\mathrm{tr}\,\{A^a, A^b\}\ \mathrm{tr}\, B^c \propto \delta^{ab}\,\mathrm{tr}\, B^c = 0$). The survivors are

$$\mathrm{tr}\big(\{T^a, T^b\}\, T^c\big) = \mathrm{tr}_{V_1}\big(\{A^a, A^b\}\, A^c\big)\ \mathrm{tr}_{V_2}\,\mathbf{1} + \mathrm{tr}_{V_1}\,\mathbf{1}\ \mathrm{tr}_{V_2}\big(\{B^a, B^b\}\, B^c\big)$$

$$= d_2 \cdot \tfrac{1}{2} A_1\, d^{abc} + d_1 \cdot \tfrac{1}{2} A_2\, d^{abc} = \tfrac{1}{2}(d_2 A_1 + d_1 A_2) d^{abc}, \quad \text{(B.135)}$$

which is Eq. (B.132). The structure is intuitive: each factor contributes its own anomaly weighted by the number of "spectator" states dim of the other factor.

The sum and product rules let us read off the anomaly of any representation appearing in a tensor power of the fundamental. The two-index tensors are the immediate application, and they decide the consistency of the simplest grand unified theory.

Worked Example B.38 (Anomalies of the $\mathfrak{su}(N)$ two-index tensors and $\mathfrak{su}(5)$ unification)**.** The product of two fundamentals decomposes as $N \otimes N = \mathrm{Sym}^2 \oplus \Lambda^2$, the symmetric and antisymmetric two-index representations of dimensions $\frac{N(N+1)}{2}$ and $\frac{N(N-1)}{2}$. By Eq. (B.132) with $R_1 = R_2 = \text{fund}$,

$$A(\mathrm{Sym}^2) + A(\Lambda^2) = A(N \otimes N) = N \cdot 1 + N \cdot 1 = 2N. \quad \text{(B.136)}$$

A second relation comes from the swap operator P on $V \otimes V$, which is $+1$ on Sym^2 and -1 on Λ^2, so that $A(\mathrm{Sym}^2) - A(\Lambda^2) = \frac{2}{d^{abc}} \operatorname{tr}\big(P \left\{T^a, T^b\right\} T^c\big)$. The trace of P against a tensor-product operator collapses to a single-factor trace, $\operatorname{tr}_{V\otimes V}\big(P\,(X \otimes Y)\big) = \operatorname{tr}(XY)$, which follows from $P_{ij,kl} = \delta_{il}\delta_{jk}$:

$$\operatorname{tr}_{V\otimes V}\big(P\,(X\otimes Y)\big) = \sum_{ij} \big[P(X\otimes Y)\big]_{ij,ij} = \sum_{ijkl} \delta_{il}\delta_{jk} X_{ki} Y_{lj} = \sum_{ij} X_{ji} Y_{ij} = \operatorname{tr}(XY). \quad \text{(B.137)}$$

Applying this term by term to $\left\{T^a, T^b\right\} T^c$ (now in terms of the single-factor generators A^a of the N) and using $\operatorname{tr}(A^a \left\{A^b, A^c\right\}) = \frac{1}{2} d^{abc}$ throughout, the identity-block pieces each give $\frac{1}{2}d^{abc} + \frac{1}{2}d^{abc}$, while the cross piece $2(A^a \otimes A^b + A^b \otimes A^a)T^c$ now *survives* the swap and contributes $4 \cdot \frac{1}{2} d^{abc} = 2d^{abc}$. Summing, $\operatorname{tr}(P \left\{T^a, T^b\right\} T^c) = (1 + 1 + 2) d^{abc} = 4 d^{abc}$, hence

$$A(\mathrm{Sym}^2) - A(\Lambda^2) = 8. \quad \text{(B.138)}$$

Solving the two relations,

$$A(\mathrm{Sym}^2) = N + 4, \qquad A(\Lambda^2) = N - 4. \quad \text{(B.139)}$$

For $\mathfrak{su}(5)$ the antisymmetric $\Lambda^2 = \mathbf{10}$ therefore has $A(\mathbf{10}) = 5 - 4 = 1$, while $A(\overline{\mathbf{5}}) = -A(\mathbf{5}) = -1$. One generation of the Georgi–Glashow model places its left-handed fermions in $\overline{\mathbf{5}} \oplus \mathbf{10}$, with total anomaly

$$A(\overline{\mathbf{5}}) + A(\mathbf{10}) = -1 + 1 = 0. \quad \text{(B.140)}$$

The cancellation is exact, generation by generation: $\mathfrak{su}(5)$ unification is anomaly-free precisely because the cubic anomaly of the antisymmetric $\mathbf{10}$ is the negative of that of the $\overline{\mathbf{5}}$. This is the group-theory content imported wholesale by Chapter 37.

B.5.6 Higher invariants and where the ladder stops

The quadratic index $T(R)$ and the cubic coefficient $A(R)$ are the first two rungs of an infinite ladder of symmetrized-trace invariants

$$d^{(n)\,a_1\cdots a_n}(R) \;=\; \mathrm{Str}_R\big(T^{a_1}\cdots T^{a_n}\big) \;\equiv\; \frac{1}{n!}\sum_{\sigma\in S_n}\mathrm{tr}_R\big(T^{a_{\sigma(1)}}\cdots T^{a_{\sigma(n)}}\big), \quad \text{(B.141)}$$

with $d^{(2)} \propto T(R)\,\delta^{ab}$ and $d^{(3)} \propto A(R)\,d^{abc}$. Two facts govern how far this is useful. First, only the primitive degrees of the algebra (Theorem B.35) carry *new* information; symmetrized traces at composite degrees reduce, by Newton's identities and the Cayley–Hamilton theorem, to polynomials in the primitive ones. For $\mathfrak{su}(N)$ the primitives sit at degrees $2, 3, \ldots, N$, so an independent quartic invariant first appears at $\mathfrak{su}(4)$, an independent quintic at $\mathfrak{su}(5)$, and the tower of *algebraically independent* symmetric invariants terminates at degree N; everything higher is expressible through the lower ones. Second, in four-dimensional gauge theory only $T(R)$ and $A(R)$ enter the renormalization and consistency conditions: the quadratic index controls the one-loop β-function (Section B.4), and the cubic coefficient controls the chiral anomaly (Chapter 36). The quartic Casimir—encoded in a fourth-rank symmetric tensor $d^{(4)abcd}$ and an associated quartic index—becomes load-bearing only beyond this setting: for the box (square) anomaly in six dimensions, for certain global anomalies, and as the distinguishing invariant of $\mathfrak{so}(N)$ and the exceptional groups, which possess no cubic at all. The data this book needs from the cubic rung is now complete: the symbol d^{abc}, the coefficient $A(R)$, its sign reversal, and the table of values $A(\text{fund}) = 1$, $A(\text{adj}) = 0$, $A(\Lambda^2) = N - 4$, $A(\text{Sym}^2) = N + 4$.

With the three low-order invariants $T(R)$, $C_2(R)$, and $A(R)$ now all in hand and computed in representative cases, what remains is to assemble them into a single reference. The next section fixes the Cartan–Weyl language—roots, weights, and Dynkin labels—needed to compute these entries for an *arbitrary* representation of any compact simple algebra, and gathers the results into the book-wide master table of $\dim(R)$, $T(R)$, $C_2(R)$, and $A(R)$ that the gauge-theory chapters cite.

B.6 Roots, Weights, and a Master Table of Group-Theory Data

The previous sections of this appendix built, one invariant at a time, the complete set of numbers a gauge-theory computation actually consumes: the Dynkin index $T(R)$ that controls every coupling renormalization, the quadratic Casimir $C_2(R)$ that sets the size of self-energy and Sudakov logarithms, and the cubic anomaly coefficient $A(R)$ that decides whether a chiral theory is consistent at all. For the unitary groups these were obtained in closed form; for the representations that

recur throughout the book they were tabulated as they arose. What remains is to do two things at once. First, to record the *Cartan–Weyl* bookkeeping—roots, weights, Dynkin labels, the A–G classification—in enough depth that a reader can locate *any* compact simple algebra in the standard list and read off the structural data that the index and Casimir formulas need, even for a group this book never uses explicitly. Second, to demonstrate that the table is not a list of memorized constants but a computable object: we take the imported classification of Theorem 2.75 together with the Weyl and Freudenthal machinery of Theorem 2.74, apply it by hand to the smallest nontrivial case, $\mathfrak{su}(3)$, and watch it reproduce the very values $T_F = \frac{1}{2}$, $C_2(F) = \frac{4}{3}$, $C_A = 3$ that Sections 2 and 4 obtained by direct trace. With that confidence established we assemble the master table that the gauge, anomaly, and grand-unification chapters cite by label: dim, T, C_2, and A for SU(N), SO(N), Sp($2n$), and the grand-unified representations of SU(5) and SO(10), every entry carrying a self-contained derivation.

This section is the appendix's closing service. It owns no new physics; it owns the *reference* object. The conceptual content—what a root system is, why the classification is what it is, the Weyl dimension formula—was established in Chapter 2 and is imported here as a tool, not reproved. The invariant definitions and the SU(N) results are imported from Sections 1–5 of this appendix. The new work here is the consolidation, the worked computability check, and the table.

B.6.1 The Cartan–Weyl picture, at reference depth

We recall, in compressed form, the language fixed in Section 2.6; the reader who wants the constructions and proofs should consult that section, while the reader who wants only to use the table needs the vocabulary collected here.

Let $\mathfrak{g}$ be a compact simple Lie algebra of dimension $\dim \mathfrak{g}$, which we always take with Hermitian generators T^a obeying $\left[T^a, T^b\right] = i f^{abc} T^c$. A *Cartan subalgebra* $\mathfrak{h} \subset \mathfrak{g}$ is a maximal set of mutually commuting generators; its dimension is the *rank* r of $\mathfrak{g}$ and is an invariant of the algebra. Diagonalizing the adjoint action of $\mathfrak{h}$ decomposes the complexified algebra as

$$\mathfrak{g}_{\mathbb{C}} = \mathfrak{h}_{\mathbb{C}} \oplus \bigoplus_{\alpha \in \Delta} \mathfrak{g}_\alpha, \qquad [H, E_\alpha] = \alpha(H)\, E_\alpha \quad \text{for } H \in \mathfrak{h}, \tag{B.142}$$

where each *root space* $\mathfrak{g}_\alpha$ is one-dimensional and the nonzero linear functionals $\alpha \in \mathfrak{h}^*$ are the *roots*. The set Δ of roots is the *root system*. The Killing form, restricted to $\mathfrak{h}^*$, gives a positive-definite inner product $\langle \cdot, \cdot \rangle$ in which roots have definite lengths; we write $\alpha^\vee \equiv 2\alpha/\langle \alpha, \alpha \rangle$ for the *coroot*.

Choosing a hyperplane that misses every root splits Δ into positive and negative roots, $\Delta = \Delta_+ \cup (-\Delta_+)$. The positive roots that cannot be written as a

sum of two positive roots are the r *simple roots* $\alpha_1, \dots, \alpha_r$; they form a basis of $\mathfrak{h}^*$, and every root is an integer combination of them with coefficients all of one sign. The entire root system—hence, by the classification theorem, the algebra itself—is encoded in the *Cartan matrix*

$$A_{ij} = \langle \alpha_i, \alpha_j^\vee \rangle = \frac{2\langle \alpha_i, \alpha_j \rangle}{\langle \alpha_j, \alpha_j \rangle}, \tag{B.143}$$

whose diagonal entries are 2 and whose off-diagonal entries are non-positive integers with $A_{ij}A_{ji} \in \{0, 1, 2, 3\}$. The Cartan matrix is drawn as a *Dynkin diagram*: one node per simple root, with $A_{ij}A_{ji}$ bonds between nodes i and j (so $0, 1, 2, 3$ bonds mean orthogonal, 120°, 135°, 150° between the roots), and an arrow pointing from the long root to the short one when the two have different lengths. A simple algebra has a *connected* Dynkin diagram; a direct sum of simple algebras has a disconnected one. The possible connected diagrams are exactly the content of the next subsection.

B.6.2 The Cartan classification and its physics dictionary

The classification theorem (Theorem 2.75) states that every compact simple Lie algebra is, up to isomorphism, one of four infinite families A_n, B_n, C_n, D_n or one of five exceptional algebras G_2, F_4, E_6, E_7, E_8. The subscript is the rank. Figure B.4 draws the nine connected Dynkin diagrams; Table B.4 gives the dictionary to the matrix groups physics uses and records the dimension, which is what the master relation $T \dim \mathfrak{g} = C_2 \dim R$ of Section B.6.3 needs.

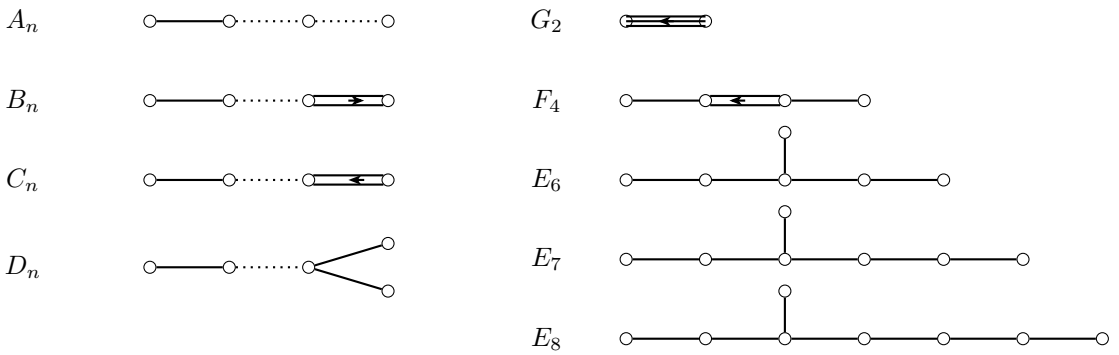

Figure B.4: The connected Dynkin diagrams: the four infinite families and the five exceptional algebras. A single bond is a 120° angle between simple roots, a double bond 135°, a triple bond 150°; the arrow points from the long root to the short one. Dotted segments indicate the omitted middle of a chain of n nodes. The branch node of D_n and the E series is what makes those algebras admit (for D_n, chiral; for E_6, complex) spinorial representations.

Table B.4: The Cartan classification and its physics dictionary. "Group" is the compact connected group whose Lie algebra is the listed algebra; Spin denotes the simply connected double cover of SO(), and $\mathrm{USp}(2n) = \mathrm{Sp}(2n)$ the compact symplectic group of rank n. Dimensions are $\dim \mathfrak{g} = r + |\Delta|$.

Type	Rank	Algebra	Group	$\dim \mathfrak{g}$
A_n	n	$\mathfrak{su}(n+1)$	$\mathrm{SU}(n+1)$	$n(n+2)$
B_n	n	$\mathfrak{so}(2n+1)$	$\mathrm{Spin}(2n+1)$	$n(2n+1)$
C_n	n	$\mathfrak{sp}(2n)$	$\mathrm{Sp}(2n) = \mathrm{USp}(2n)$	$n(2n+1)$
D_n	n	$\mathfrak{so}(2n)$	$\mathrm{Spin}(2n)$	$n(2n-1)$
G_2	2	$\mathfrak{g}_2$	G_2	14
F_4	4	$\mathfrak{f}_4$	F_4	52
E_6	6	$\mathfrak{e}_6$	E_6	78
E_7	7	$\mathfrak{e}_7$	E_7	133
E_8	8	$\mathfrak{e}_8$	E_8	248

The infinite families exhaust the classical matrix groups: A_n is the special unitary algebra, B_n and D_n the orthogonal algebras in odd and even dimension, and C_n the symplectic algebra. The exceptional algebras have no such elementary matrix description; G_2 is the automorphism algebra of the octonions and F_4, E_6, E_7, E_8 are built on the exceptional Jordan algebra, but for our purposes they enter only as candidate grand-unified groups, E_6 being the one of direct phenomenological interest because it admits complex representations.

Two cautions about small rank are worth stating once, because they underlie several isomorphisms physics exploits. The classification is non-redundant only for A_n $(n \geq 1)$, B_n $(n \geq 2)$, C_n $(n \geq 3)$, D_n $(n \geq 4)$; outside that range the diagrams coincide and so do the algebras. The accidental isomorphisms are

$$A_1 \cong B_1 \cong C_1, \quad B_2 \cong C_2, \quad D_2 \cong A_1 \oplus A_1, \quad A_3 \cong D_3, \tag{B.144}$$

i.e. $\mathfrak{su}(2) \cong \mathfrak{so}(3) \cong \mathfrak{sp}(2)$, $\mathfrak{so}(5) \cong \mathfrak{sp}(4)$, $\mathfrak{so}(4) \cong \mathfrak{su}(2) \oplus \mathfrak{su}(2)$, and $\mathfrak{su}(4) \cong \mathfrak{so}(6)$. The last is the Pati–Salam identity used in unification; D_2 being non-simple is why SO(4) splits into two independent SU(2) factors. We will use $\mathfrak{su}(4) \cong \mathfrak{so}(6)$ as an internal consistency check on the master table.

Caution

The notation "Sp()" is overloaded in the literature: some authors write $\mathrm{Sp}(n)$ for the rank-n compact symplectic group (our $\mathrm{Sp}(2n)$), others write $\mathrm{Sp}(2n)$ for the $2n \times 2n$ symplectic group over $\mathbb{R}$ or $\mathbb{C}$, which is *non-compact*. Throughout this book $\mathrm{Sp}(2n)$ denotes the *compact* group $\mathrm{USp}(2n)$ of rank n, with defining representation of dimension $2n$; this is the C_n algebra of Table B.4.

B.6.3 Weights, Dynkin labels, and the invariant formulas

A finite-dimensional irreducible representation R of $\mathfrak{g}$ is fixed by its weights—the simultaneous eigenvalues of the Cartan generators on the basis states—and in particular by its unique *highest weight* λ, the one not raised by any E_α with $\alpha \in \Delta_+$. The fundamental weights $\omega_1, \dots, \omega_r$ are the basis of $\mathfrak{h}^*$ dual to the coroots,

$$\langle \omega_i, \alpha_j^\vee \rangle = \delta_{ij}, \tag{B.145}$$

and every dominant highest weight is a non-negative integer combination $\lambda = \sum_i a_i\, \omega_i$. The integers $a_i \geq 0$ are the *Dynkin labels*, written $[a_1, \dots, a_r]$; they are the universal address of a representation, independent of any matrix realization. The defining representation of $\mathrm{SU}(N)$ is $[1, 0, \dots, 0]$; its conjugate is $[0, \dots, 0, 1]$; the adjoint of $\mathrm{SU}(N \geq 3)$ is $[1, 0, \dots, 0, 1]$. A representation is real, pseudoreal, or complex according to whether the diagram symmetry that conjugates it acts trivially or not, which is exactly the structure that decides the sign behaviour of $A(R)$ recorded in Section 5.

The half-sum of the positive roots,

$$\rho \equiv \tfrac{1}{2} \sum_{\alpha \in \Delta_+} \alpha = \sum_{i=1}^{r} \omega_i, \tag{B.146}$$

the *Weyl vector*, has all Dynkin labels equal to one and organizes both formulas we now import. The first is the *Weyl dimension formula* for the representation of highest weight λ,

$$\dim R_\lambda = \prod_{\alpha \in \Delta_+} \frac{\langle \lambda + \rho, \alpha \rangle}{\langle \rho, \alpha \rangle}, \tag{B.147}$$

stated and used in Theorem 2.74 and imported here as a tool. The second is the eigenvalue of the quadratic Casimir, which on R_λ acts as a multiple of the identity (Schur), with multiple

$$C_2(\lambda) = \langle \lambda, \lambda + 2\rho \rangle. \tag{B.148}$$

Equation (B.148) is stated in the *Cartan normalization*, in which the long roots have $\langle \alpha, \alpha \rangle = 2$. The physical normalization of this book is the one fixed in Sections 2 and 4, $\mathrm{tr}_F(T^a T^b) = \frac{1}{2}\delta^{ab}$ in the defining representation; the two differ by an overall positive constant $\kappa_{\mathfrak{g}}$ that depends only on the algebra, so that $C_2^{\mathrm{phys}}(\lambda) = \kappa_{\mathfrak{g}}\, \langle \lambda, \lambda + 2\rho \rangle$. For $\mathfrak{su}(N)$ this constant is $\kappa = \frac{1}{2}$, as the worked computation below makes explicit; quoting C_2 in the physical normalization is what makes the master table directly usable in a Feynman-diagram calculation.

These two imported formulas are tied to the Section 2–5 invariants by a single identity, the *index–Casimir relation*, which we restate with its one-line proof because every table entry below is generated from it. Taking the trace of the defining relation $T^a T^a = C_2(R)\, \mathbf{1}_R$ gives $\mathrm{tr}_R(T^a T^a) = C_2(R) \dim R$, while the

definition $\mathrm{tr}_R(T^aT^b) = T(R)\delta^{ab}$ gives the same trace as $T(R)\,\delta^{aa} = T(R)\dim\mathfrak{g}$. Equating,

$$T(R)\ \dim\mathfrak{g}\ =\ C_2(R)\ \dim R. \tag{B.149}$$

Thus any one of T and C_2 determines the other once $\dim R$ and $\dim\mathfrak{g}$ are known. There is, finally, a direct route to $T(R)$ from the weights alone that we will use as the algebraic engine of the table. Choose an orthonormal basis $\{H_i\}_{i=1}^{r}$ of the Cartan subalgebra in the physical normalization, $\mathrm{tr}_F(H_iH_j) = \frac{1}{2}\delta_{ij}$. The eigenvalue of H_i on a weight state $|\mu\rangle$ is the i-th component μ_i, so $\mathrm{tr}_R(H_iH_j) = \sum_{\mu\in R}\mu_i\mu_j = T(R)\delta_{ij}$, where the sum runs over all weights with multiplicity. Taking the trace over $i = j$,

$$T(R) = \frac{1}{r}\sum_{\mu\in R}|\mu|^2, \tag{B.150}$$

with $|\mu|^2$ the squared length of the weight in the orthonormal (physical) basis. Equation (B.150) reduces the index of any representation to a finite sum over its weight diagram, and it is normalization-honest: because the same H_i that define the defining-representation normalization are used in R, the result comes out directly in the convention $T_F = \frac{1}{2}$.

B.6.4 Worked case: $\mathfrak{su}(3)$ from its weights

We now carry out, in full, the computation that the rest of the table only summarizes: starting from the explicit roots and weights of $\mathfrak{su}(3)$, we recover T_F, $C_2(F)$, T_A, and C_A and check them against Eq. (B.147), Eq. (B.148), and the SU(N) formulas of Section 4. This is the demonstration of computability promised in the section goal.

Worked Example B.39 (Index and Casimir of the $\mathfrak{su}(3)$ fundamental and adjoint from the weights)**.** The algebra $\mathfrak{su}(3)$ (A_2) has rank $r = 2$ and Cartan matrix $A = \left(\begin{smallmatrix} 2 & -1 \\ -1 & 2 \end{smallmatrix}\right)$; all roots have the same length, so it is simply laced and $\alpha_i^\vee = \alpha_i$ in the Cartan normalization $\langle\alpha_i,\alpha_i\rangle = 2$.

Explicit physical realization. Use the two diagonal Gell-Mann generators of Section 5,

$$H_1 = T^3 = \tfrac{1}{2}\,\mathrm{diag}(1,-1,0), \qquad H_2 = T^8 = \tfrac{1}{2\sqrt{3}}\,\mathrm{diag}(1,1,-2), \tag{B.151}$$

which satisfy $\mathrm{tr}_F(H_iH_j) = \frac{1}{2}\delta_{ij}$: indeed $\mathrm{tr}_F\,H_1^2 = \frac{1}{4}(1+1) = \frac{1}{2}$, $\mathrm{tr}_F\,H_2^2 = \frac{1}{12}(1+1+4) = \frac{1}{2}$, and $\mathrm{tr}_F(H_1H_2) \propto \mathrm{tr}\,\mathrm{diag}(1,-1,0) = 0$. This is the orthonormal physical basis demanded by Eq. (B.150).

Weights of the fundamental $\mathbf{3}$. Reading the diagonal entries of Eq. (B.151) as the pairs $(\mu_1,\mu_2) = ((H_1)_{kk},(H_2)_{kk})$, the three weights are

$$\mu^{(1)} = \left(\tfrac{1}{2},\tfrac{1}{2\sqrt{3}}\right), \quad \mu^{(2)} = \left(-\tfrac{1}{2},\tfrac{1}{2\sqrt{3}}\right), \quad \mu^{(3)} = \left(0,-\tfrac{1}{\sqrt{3}}\right). \tag{B.152}$$

Each has the same length squared, $|\mu^{(1)}|^2 = \frac{1}{4} + \frac{1}{12} = \frac{1}{3}$, and likewise $|\mu^{(2)}|^2 = |\mu^{(3)}|^2 = \frac{1}{3}$, so $\sum_\mu |\mu|^2 = 3 \cdot \frac{1}{3} = 1$. Equation (B.150) gives immediately

$$T(F) = \frac{1}{r} \sum_{\mu} |\mu|^2 = \frac{1}{2} \cdot 1 = \frac{1}{2}, \tag{B.153}$$

and then Eq. (B.149) with $\dim \mathfrak{g} = 8$, $\dim F = 3$ gives

$$C_2(F) = T(F) \, \frac{\dim \mathfrak{g}}{\dim F} = \frac{1}{2} \cdot \frac{8}{3} = \frac{4}{3}. \tag{B.154}$$

These are exactly the Section 4 values $T_F = \frac{1}{2}$ and $C_F = (N^2-1)/(2N) = 8/6 = \frac{4}{3}$ at $N = 3$.

Weights of the adjoint **8**. The weights of the adjoint are the six roots together with the two zero weights of the Cartan subalgebra. The roots are the differences $\mu^{(i)} - \mu^{(j)}$ of fundamental weights:

$$\pm(1,0), \quad \pm\Big(\tfrac{1}{2}, \tfrac{\sqrt{3}}{2}\Big), \quad \pm\Big(\tfrac{1}{2}, -\tfrac{\sqrt{3}}{2}\Big), \tag{B.155}$$

each of length squared $|\alpha|^2 = 1$, plus the two zero weights. Hence $\sum_\mu |\mu|^2 = 6 \cdot 1 + 2 \cdot 0 = 6$ and

$$T(A) = \frac{1}{2} \cdot 6 = 3, \qquad C_2(A) = T(A) \, \frac{\dim \mathfrak{g}}{\dim A} = 3 \cdot \frac{8}{8} = 3, \tag{B.156}$$

matching $C_A = N = 3$ and $T_A = N = 3$ from Section 4.

Cross-check against the imported formulas. In the Cartan normalization the fundamental and adjoint of A_2 have highest weights $\lambda_F = \omega_1 = [1,0]$ and $\lambda_A = \omega_1 + \omega_2 = \rho = [1,1]$. From the inverse Cartan matrix $A^{-1} = \frac{1}{3}\left(\begin{smallmatrix} 2 & 1 \\ 1 & 2 \end{smallmatrix}\right)$ one reads $\langle \omega_i, \omega_j \rangle = (A^{-1})_{ij}$, so $\langle \omega_1, \omega_1 \rangle = \frac{2}{3}$, $\langle \omega_1, \omega_2 \rangle = \frac{1}{3}$, and $\langle \rho, \rho \rangle = \frac{2}{3} + \frac{2}{3} + \frac{2}{3} = 2$. The Weyl dimension formula (B.147) over the positive roots $\alpha_1, \alpha_2, \alpha_1 + \alpha_2$, using $\langle \omega_i, \alpha_j \rangle = \delta_{ij}$ and $\langle \rho, \alpha \rangle = 1, 1, 2$, gives for the fundamental $\dim = \frac{2 \cdot 1 \cdot 3}{1 \cdot 1 \cdot 2} = 3$ and for the adjoint $\dim = \frac{2 \cdot 2 \cdot 4}{1 \cdot 1 \cdot 2} = 8$, as required. The Casimir formula (B.148) gives, in Cartan normalization,

$$C_2^{\mathrm{Cartan}}(F) = \langle \omega_1, \omega_1 + 2\rho \rangle = \tfrac{2}{3} + 2 \cdot 1 = \tfrac{8}{3}, \qquad C_2^{\mathrm{Cartan}}(A) = \langle \rho, 3\rho \rangle = 3\langle \rho, \rho \rangle = 6. \tag{B.157}$$

These exceed the physical values (B.154) and (B.156) by exactly the factor $\kappa_{\mathfrak{su}(N)} = \frac{1}{2}$ anticipated below Eq. (B.148): physically the roots have $|\alpha|^2 = 1$, half the Cartan value 2, and C_2 scales with the metric. The independent routes agree, which is the point of the exercise: the imported Weyl/Freudenthal apparatus and the trace definitions describe one and the same numbers.

Figure B.5 draws the data of Theorem B.39: the hexagon of roots that is the nonzero part of the adjoint weight diagram, and the inner triangle of fundamental weights.

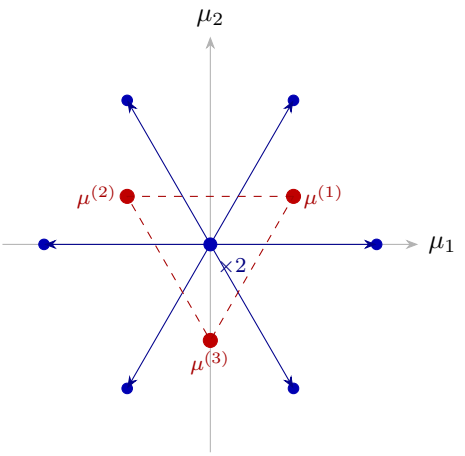

Figure B.5: The $\mathfrak{su}(3)$ weight data underlying Theorem B.39. Blue: the six roots (length 1 in the physical normalization) plus the doubled zero weight, which together are the eight weights of the adjoint **8**. Red: the three weights $\mu^{(1,2,3)}$ of the fundamental **3**, an inner triangle. The index formula (B.150) is the sum of squared lengths of these dots, divided by the rank.

B.6.5 The two-index tensors of SU(N) from a single generator

Before assembling the table we need the two-index symmetric and antisymmetric representations of SU(N), since the grand-unified **10** of SU(5) is the antisymmetric one. Their indices follow from one clean computation that uses only a diagonal generator and the decomposition of the tensor square, so no value is imported on faith.

Let $H = \mathrm{diag}(h_1, \ldots, h_N)$ be a traceless diagonal generator of $\mathfrak{su}(N)$, acting on the defining representation V with $\mathrm{tr}_V\, H^2 = \sum_i h_i^2$ and, because $\mathfrak{su}(N)$ has no diagonal trace, $\sum_i h_i = 0$. On the tensor square $V \otimes V$ the generator acts as $H_\otimes = H \otimes \mathbf{1} + \mathbf{1} \otimes H$ with eigenvalue $h_i + h_j$ on the basis state $|ij\rangle$. Squaring and tracing, and using $\mathrm{tr}\, H = 0$,

$$\mathrm{tr}_{V\otimes V}\, H_\otimes^2 = \mathrm{tr}(H^2 \otimes \mathbf{1}) + 2\ \mathrm{tr}\, H\ \mathrm{tr}\, H + \mathrm{tr}(\mathbf{1} \otimes H^2) = 2N\ \mathrm{tr}_V\, H^2. \tag{B.158}$$

The tensor square splits as $V \otimes V = \mathrm{Sym}^2 \oplus \Lambda^2$, so $\mathrm{tr}_{\mathrm{Sym}^2}\, H_\otimes^2 + \mathrm{tr}_{\Lambda^2}\, H_\otimes^2 = 2N\ \mathrm{tr}_V\, H^2$. Their difference is the contribution of the diagonal states $|ii\rangle$, which live in Sym^2 only and carry eigenvalue $2h_i$:

$$\mathrm{tr}_{\mathrm{Sym}^2}\, H_\otimes^2 - \mathrm{tr}_{\Lambda^2}\, H_\otimes^2 = \sum_i (2h_i)^2 = 4\ \mathrm{tr}_V\, H^2. \tag{B.159}$$

Solving Eqs. (B.158) and (B.159) and dividing by the defining-rep value ($\mathrm{tr}_V\, H^2 = T_F = \frac{1}{2}$ for the single Cartan generator H, i.e. the index is the trace ratio times

$T_F = \frac{1}{2}$),

$$T(\mathrm{Sym}^2) = \frac{N+2}{2}, \qquad T(\Lambda^2) = \frac{N-2}{2}. \tag{B.160}$$

Equation (B.149) with $\dim \mathrm{Sym}^2 = \frac{N(N+1)}{2}$, $\dim \Lambda^2 = \frac{N(N-1)}{2}$, and $\dim \mathfrak{g} = N^2 - 1$ then yields

$$C_2(\mathrm{Sym}^2) = \frac{(N+2)(N-1)}{N}, \qquad C_2(\Lambda^2) = \frac{(N-2)(N+1)}{N}. \tag{B.161}$$

The same diagonal-generator method delivers the anomaly coefficients of Section 5. The cubic invariant in a Cartan direction is $\propto \mathrm{tr}_R\, H^3$, so the cubic charge adds across a tensor product exactly as the quadratic one did: from $(H\otimes\mathbf{1}+\mathbf{1}\otimes H)^3$ and $\mathrm{tr}\, H = 0$, $\mathrm{tr}_{V\otimes V}\, H^3_{\otimes} = 2N\ \mathrm{tr}_V\, H^3$, hence $A(\mathrm{Sym}^2) + A(\Lambda^2) = 2N\, A(F) = 2N$, while the diagonal states give $\mathrm{tr}_{\mathrm{Sym}^2}\, H^3_{\otimes} - \mathrm{tr}_{\Lambda^2}\, H^3_{\otimes} = \sum_i (2h_i)^3 = 8\ \mathrm{tr}_V\, H^3$, i.e. $A(\mathrm{Sym}^2) - A(\Lambda^2) = 8\, A(F) = 8$. With the Section 5 normalization $A(F) = 1$,

$$A(\mathrm{Sym}^2) = N + 4, \qquad A(\Lambda^2) = N - 4. \tag{B.162}$$

The antisymmetric value $A(\Lambda^2) = N-4$ vanishes at $N = 4$, the precise reason the **6** of SU(4) $\cong$ SO(6) is anomaly-free—the $\mathfrak{so}(N)$ side of the coincidence (B.144) has no cubic invariant at all—and the combination $A(\bar{\mathbf{5}}) + A(\mathbf{10}) = -1+1 = 0$ at $N = 5$ is the cancellation that makes one SU(5) generation consistent, anticipated for Chapter 35.

B.6.6 The master table

We can now assemble the reference object. Table B.5 records the general formulas for the classical families, each entry traceable to a complete computation: the SU(N) fundamental and adjoint to Section 4 and to Theorem B.39; the SU(N) two-index tensors to Eqs. (B.160) to (B.162); and the SO(N) and Sp($2n$) entries to the explicit generator traces below. Table B.6 specializes to the grand-unified representations cited by Chapter 35 and consolidates the SU(3) colour data used throughout Yang–Mills theory.

A word on normalizations, because they differ by family and the table is useless without them stated. For SU(N) and Sp($2n$) we use $T(\text{defining}) = \frac{1}{2}$, matching the book-wide $\mathrm{tr}_F(T^a T^b) = \frac{1}{2}\delta^{ab}$. For SO($N$) we use the natural orthogonal normalization $T(\text{vector}) = 2$, in which the generators are $(T^{ab})_{cd} = -i(\delta^a_c\delta^b_d - \delta^a_d\delta^b_c)$; the value $T(\text{vector}) = 2$ is read off directly from $\mathrm{tr}_{\text{vec}}\,[(T^{ab})^2] = 2(\delta^{aa}\delta^{bb} - \delta^{ab}\delta^{ba}) = 2$ for a fixed pair $a < b$. Ratios of invariants within a single group are normalization-independent and provide the cross-checks; only the overall scale carries the convention.

For the orthogonal family the vector and adjoint entries follow from Eq. (B.149):

with $\dim \mathfrak{g} = \frac{N(N-1)}{2}$ and $\dim(\text{vector}) = N$,

$$C_2(\text{vector}) = T(\text{vector})\frac{N(N-1)/2}{N} = N-1, \qquad C_2(\text{adj}) = N-2 \text{ (scaled: } 2(N-2)), \tag{B.163}$$

where the adjoint Casimir $C_2(\text{adj}) = 2(N-2)$ in the $T(\text{vector}) = 2$ normalization is the dual Coxeter number $h^\vee(\mathfrak{so}(N)) = N-2$ times the scale factor. The spinor of SO(N) has dimension $2^{\lfloor N/2 \rfloor}$ (Dirac) and, from the gamma-matrix generators $\Sigma^{ab} = \frac{i}{2}\Gamma^a\Gamma^b$ ($a \neq b$) with $(\Sigma^{ab})^2 = \frac{1}{4}$, index $T(\text{spinor}) = 2^{\lfloor N/2 \rfloor}/4$, giving by Eq. (B.149)

$$C_2(\text{spinor}) = \frac{N(N-1)}{8}. \tag{B.164}$$

For the symplectic family, the defining $2n$ and its adjoint (the symmetric square, of dimension $n(2n+1)$) give in the $T(\text{fund}) = \frac{1}{2}$ normalization $C_2(\text{fund}) = \frac{2n+1}{4}$ and $C_2(\text{adj}) = n+1 = h^\vee(\mathfrak{sp}(2n))$; the value $\frac{2n+1}{4}$ reduces to $\frac{3}{4}$ at $n=1$, the correct SU(2) fundamental Casimir, since $\mathrm{Sp}(2) \cong \mathrm{SU}(2)$.

Table B.5: Master group-theory data for the classical families. $\dim \mathfrak{g}$ is the algebra dimension from Table B.4. Normalizations: $T(\text{defining}) = \frac{1}{2}$ for $\mathrm{SU}(N), \mathrm{Sp}(2n)$; $T(\text{vector}) = 2$ for $\mathrm{SO}(N)$. Each C_2 follows from the index by the index–Casimir relation (B.149). Anomaly coefficients A are normalized to $A(\text{fund}) = 1$; entries marked 0 are for algebras with no cubic Casimir ($\mathrm{SO}(N \neq 6)$, $\mathrm{Sp}(2n)$) or for (pseudo)real representations.

Group	Representation	$\dim R$	$T(R)$	$C_2(R)$	$A(R)$
SU(N)	fundamental $\mathbf{N}$	N	$\frac{1}{2}$	$\frac{N^2-1}{2N}$	1
SU(N)	conjugate $\overline{\mathbf{N}}$	N	$\frac{1}{2}$	$\frac{N^2-1}{2N}$	-1
SU(N)	adjoint	N^2-1	N	N	0
SU(N)	antisym. Λ^2	$\frac{N(N-1)}{2}$	$\frac{N-2}{2}$	$\frac{(N-2)(N+1)}{N}$	$N-4$
SU(N)	sym. Sym^2	$\frac{N(N+1)}{2}$	$\frac{N+2}{2}$	$\frac{(N+2)(N-1)}{N}$	$N+4$
SO(N)	vector	N	2	$N-1$	0
SO(N)	adjoint	$\frac{N(N-1)}{2}$	$2(N-2)$	$2(N-2)$	0
SO(N)	spinor (Dirac)	$2^{\lfloor N/2 \rfloor}$	$2^{\lfloor N/2 \rfloor}/4$	$\frac{N(N-1)}{8}$	0
Sp($2n$)	fundamental	$2n$	$\frac{1}{2}$	$\frac{2n+1}{4}$	0
Sp($2n$)	adjoint	$n(2n+1)$	$n+1$	$n+1$	0

Table B.6: Master data for the grand-unified representations of SU(5) and SO(10), and the SU(3) colour representations of Yang–Mills theory. The SU(5) entries specialize Table B.5 at $N = 5$; the SO(10) entries use $N = 10$ with the **16** the chiral (Weyl) half-spinor, $\dim = 2^{5-1} = 16$, sharing the Dirac Casimir. The combination $\overline{\mathbf{5}} \oplus \mathbf{10}$ of SU(5) has total anomaly $-1 + 1 = 0$; SO(10) has no cubic Casimir, so its representations are automatically anomaly-free.

Group	Rep	$\dim R$	$T(R)$	$C_2(R)$	$A(R)$
SU(5)	$\mathbf{5}$	5	$\frac{1}{2}$	$\frac{12}{5}$	1
SU(5)	$\overline{\mathbf{5}}$	5	$\frac{1}{2}$	$\frac{12}{5}$	-1
SU(5)	$\mathbf{10}$	10	$\frac{3}{2}$	$\frac{18}{5}$	1
SU(5)	$\mathbf{24}$ (adj)	24	5	5	0
SO(10)	$\mathbf{10}$ (vector)	10	2	9	0
SO(10)	$\mathbf{16}$ (spinor)	16	4	$\frac{45}{4}$	0
SO(10)	$\mathbf{45}$ (adj)	45	16	16	0
SU(3)	$\mathbf{3}$	3	$\frac{1}{2}$	$\frac{4}{3}$	1
SU(3)	$\mathbf{8}$ (adj)	8	3	3	0
SU(3)	$\mathbf{6}$ (sym)	6	$\frac{5}{2}$	$\frac{10}{3}$	7

Every number in Table B.6 has a one-line origin in Table B.5. The SU(5) $\mathbf{10} = \Lambda^2$ has $T = (5-2)/2 = \frac{3}{2}$, $C_2 = (3)(6)/5 = \frac{18}{5}$, $A = 5 - 4 = 1$; the $\mathbf{5}$ has $C_2 = (25-1)/10 = \frac{12}{5}$; the adjoint $\mathbf{24}$ has $C_2 = C_A = 5$. For SO(10) the vector has $C_2 = N - 1 = 9$, the adjoint $\mathbf{45}$ has $C_2 = 2(N-2) = 16$, and the Weyl spinor $\mathbf{16}$ shares the Dirac Casimir $C_2 = N(N-1)/8 = \frac{45}{4}$ with $T(\mathbf{16}) = C_2 \dim R/\dim \mathfrak{g} = \frac{45}{4} \cdot 16/45 = 4$. The SU(3) block reproduces the worked Theorem B.39 and adds the colour-sextet via $N = 3$ in Eqs. (B.160) to (B.162). As an external consistency check, the coincidence $\mathfrak{su}(4) \cong \mathfrak{so}(6)$ requires the SU(4) data to match the SO(6) data after fixing the relative normalization: the $\mathbf{6}$ of SU(4) (Λ^2, with $T = 1$, $C_2 = \frac{(2)(5)}{4} = \frac{5}{2}$) is the vector of SO(6) ($T = 2$, $C_2 = 5$), and indeed the two Casimirs stand in the ratio $1 : 2$ set by the two normalization conventions, while $A(\mathbf{6}_{\mathrm{SU}(4)}) = N - 4 = 0$ correctly reflects that SO(6) has no cubic invariant.

B.6.7 Embedding indices and the role in unification

The master table fixes data inside a single group; coupling unification needs one further number that compares a group to a subgroup. Given an embedding $\iota : \mathfrak{h} \hookrightarrow \mathfrak{g}$ of one simple algebra in another, a representation R of $\mathfrak{g}$ restricts to a (generally reducible) representation of $\mathfrak{h}$, and the ratio

$$j_\iota = \frac{T_{\mathfrak{h}}(R|_{\mathfrak{h}})}{T_{\mathfrak{g}}(R)} \tag{B.165}$$

is independent of which R is used; it is the *embedding index* (or Dynkin index of the embedding). It is a positive integer for the maximal embeddings of physical interest and measures how the normalization of generators changes on passing to the subgroup. The same statement for an abelian factor $\mathfrak{u}(1) \subset \mathfrak{g}$ becomes the normalization of the U(1) generator relative to the trace convention of $\mathfrak{g}$, and this is exactly the input grand unification turns on: when the Standard Model group is embedded in a simple group such as SU(5), the properly normalized hypercharge generator differs from the conventionally normalized Y by the factor that produces $g_1^2 = \frac{5}{3}\, g_Y^2$, the celebrated $5/3$ that makes the three gauge couplings meet. We state the embedding index here only at the level of its definition and its role; its computation for the Standard Model chain and the resulting prediction for $\sin^2\theta_W$ at unification are carried out in Chapter 35, which consumes the SU(5) and SO(10) rows of Table B.6 together with Eq. (B.165).

With the Cartan–Weyl vocabulary fixed, the computability of the entries demonstrated on $\mathfrak{su}(3)$, and the master tables B.5 and B.6 assembled, this appendix has discharged its service role: every dim, T, C_2, and A that the gauge, anomaly, and grand-unification chapters quote is now a single labelled object with a complete derivation behind it. The grand-unified rows feed directly into Chapter 35, and the SU(N) rows close the loop with the colour factors of Yang–Mills theory established in Chapters 27 and 28.

Further reading

The cleanest physicist's route into the representation theory used here is Georgi [218], whose treatment of SU(N), weights, and tensor methods parallels this appendix closely; Ramond [413] covers the same ground with more attention to the exceptional groups and grand unification. For the mathematical foundations — the full classification, character theory, and the Weyl and Freudenthal formulas quoted here — Fulton and Harris [206] is the standard reference. The diagrammatic "birdtrack" technology that evaluates the higher invariants we only mention is developed exhaustively in Cvitanović [142]. The encyclopedic tables of branching rules, indices, and anomaly coefficients for model building, far beyond what we tabulate, are Slansky [445]. Finally, the group-theory appendices of the standard field-theory texts — Peskin and Schroeder [396], Schwartz [432], and Weinberg [501, Vol. II] — give complementary conventions and worked color algebra for the reader cross-checking signs and normalizations against other sources.

Appendix C

Gamma Matrices and Spinor Technology

This appendix is the complete computational arsenal for everything spinorial in the book. Every gamma-matrix identity, every trace, every Fierz coefficient, every spin sum that a chapter quotes in passing is established here in full, with all intermediate algebra on the page. It is meant to be used as a reference, but it is a proof-carrying reference: nothing in it is merely tabulated. A reader who wants to reconstruct any trace identity, the value of any contraction, the sign of any charge-conjugation relation, or the precise statement of the γ^5 problem in dimensional regularization should be able to do so from this appendix alone, without reaching for an external table or trusting an unjustified formula. The discipline of the rest of the book—carry the algebra, prove what you use—applies here with no exception, and applies especially because these are precisely the results other chapters lean on most heavily and check least often.

The narrative thread arrives here from two earlier places. Chapter 3 classified the relativistic fields as representations of the Lorentz group: it identified the Weyl and Dirac spinors abstractly through the (j_-, j_+) labelling and the $\mathfrak{su}(2) \oplus \mathfrak{su}(2)$ structure of the complexified Lorentz algebra, answering the question of *what* a spinor is and why it must exist. Chapter 11 then put that abstraction to work, introducing the Dirac field proper, its plane-wave solutions u and v, and the discrete symmetries C, P, T as operators acting on it. Those chapters fixed the physical content. This appendix supplies the algebra that content lives in and the manipulation rules that turn a spinorial Lagrangian or matrix element into a number. The division of labor is deliberate: physical interpretation—what $u_s(p)$ means, why C exchanges particle and antiparticle, what a bilinear measures—belongs to Chapters 3 and 11; the identities and their proofs belong here; and downstream chapters import a result by cross-reference to its label in this appendix rather than re-deriving it in place.

The conventions are those of the rest of the book, collected in Chapter A:

the mostly-minus metric $\eta_{\mu\nu} = \mathrm{diag}(+,-,-,-)$, the defining Clifford relation $\{\gamma^\mu, \gamma^\nu\} = 2\eta^{\mu\nu}$, the chirality matrix $\gamma^5 = i\gamma^0\gamma^1\gamma^2\gamma^3$, and the Dirac adjoint $\bar\psi = \psi^\dagger\gamma^0$. Two import boundaries should be kept in mind throughout. First, the Pauli matrices and all $\mathfrak{su}(2)$ representation data are taken from Chapter 2 and Chapter B, not rebuilt here; we use them as known. Second, there are two distinct families of rearrangement identity that share the name "Fierz" and must not be confused: the *color* or group-theoretic Fierz identities, which act on the internal-symmetry indices and follow from completeness of the generators, live in Chapter B, whereas the *spinor* Fierz identities, which rearrange the order of Dirac bilinears, are derived in this appendix from the completeness of the sixteen covariants.

The appendix is built as a single developing argument rather than a catalogue, and reading it in order is the intended path. We begin with the abstract Clifford algebra $\mathrm{Cl}(1,3)$ and its Lorentz content, showing how the antisymmetrized products $\sigma^{\mu\nu}$ furnish a representation of the Lorentz algebra. We then prove that this algebra has, up to similarity, a unique irreducible representation of dimension $2^{d/2}$—Pauli's fundamental theorem, with its full proof—which is what licenses every later "choose a representation" move. From there we descend to the explicit four-dimensional representations (Dirac, chiral, Majorana) and the Hermiticity relation $\gamma^{\mu\dagger} = \gamma^0\gamma^\mu\gamma^0$; classify the intertwining matrices γ^0, C, and the parity and time-reversal matrices; assemble the sixteen bilinear covariants into a complete trace-orthogonal basis; and extract from that basis the trace and contraction technology in four dimensions, including the γ^5–ϵ trace. We then continue everything to $d = 4 - 2\varepsilon$ for dimensional regularization and confront the γ^5 problem honestly rather than papering over it. The final two sections deliver the spinor Fierz rearrangement together with the external-state spin sums and projectors, and the two-component van der Waerden calculus that the amplitudes part builds on. Downstream, Chapters 17 and 19 draw on the four-dimensional and d-dimensional traces, Chapter 36 on the dimensionally-continued γ^5 for the chiral anomaly, and Chapter 58 on the two-component calculus as the substrate for spinor-helicity.

C.1 The Clifford Algebra and Its Lorentz Content

Chapter 3 classified the relativistic fields by representations of the Lorentz group. Among the irreducible building blocks it identified the two inequivalent two-dimensional spinor representations, $(\frac{1}{2},0)$ and $(0,\frac{1}{2})$, and their reducible Dirac sum $(\frac{1}{2},0)\oplus(0,\frac{1}{2})$; the language of Lie algebras and their representations in which that classification was carried out is the one set up in Chapter 2. That analysis was abstract: it told us *which* representation a Dirac field carries and *why*, but it did not hand us a concrete object on which the Lorentz generators act by explicit matrices we can multiply, trace, and contract. The purpose of this section is

to manufacture exactly such an object, and to do it in a way that makes the appearance of the Lorentz group automatic rather than imposed. The route is a single algebraic relation. We will demand a set of four quantities γ^μ that square, in the appropriate sense, to the metric; show that the associative algebra they generate is finite-dimensional and has a canonical basis; and discover that this algebra already *contains* a copy of the Lorentz algebra $\mathfrak{so}(1,3)$, built from the γ^μ by a fixed formula. The upshot, made precise below, is that "gamma matrices" and "the spin representation of $\mathfrak{so}(1,3)$" are not two facts to be reconciled but one object seen from two sides.

C.1.1 The Clifford algebra defined by anticommutation

We work throughout with the mostly-minus Minkowski metric $\eta_{\mu\nu} = \mathrm{diag}(+,-,-,-)$ fixed in Chapter A, indices running over $\mu,\nu \in \{0,1,2,3\}$. The starting point is purely algebraic and makes no reference to matrices, dimensions, or a vector space to act on.

Definition C.1 (The Clifford algebra $\mathrm{Cl}(1,3)$)**.** Let $\mathcal{A}$ be the associative, unital algebra over $\mathbb{C}$ generated by four symbols $\gamma^0,\gamma^1,\gamma^2,\gamma^3$ subject only to the relation

$$\{\gamma^\mu,\gamma^\nu\} \;=\; \gamma^\mu\gamma^\nu+\gamma^\nu\gamma^\mu \;=\; 2\,\eta^{\mu\nu}\,\mathbf{1}, \tag{C.1}$$

where $\mathbf{1}$ is the algebra unit. Concretely, $\mathcal{A}$ is the free associative algebra on the four symbols modulo the two-sided ideal generated by $\gamma^\mu\gamma^\nu+\gamma^\nu\gamma^\mu-2\eta^{\mu\nu}\mathbf{1}$. This algebra is the (complexified) *Clifford algebra* $\mathrm{Cl}(1,3)$ of Minkowski space.

Three immediate consequences of Eq. (C.1) fix the arithmetic we will use constantly. Setting $\mu=\nu$ gives the squares of the generators,

$$(\gamma^0)^2=\mathbf{1}, \qquad (\gamma^1)^2=(\gamma^2)^2=(\gamma^3)^2=-\mathbf{1}, \tag{C.2}$$

so γ^0 is its own inverse while each spatial γ^i has inverse $-\gamma^i$. For $\mu\neq\nu$ the right-hand side of Eq. (C.1) vanishes, so distinct generators anticommute,

$$\gamma^\mu\gamma^\nu=-\gamma^\nu\gamma^\mu \qquad (\mu\neq\nu). \tag{C.3}$$

Every generator is therefore invertible, and consequently so is every product of generators; the algebra has no need of an enveloping construction beyond the words in the γ^μ. We have not yet asserted that $\mathcal{A}$ is anything but possibly trivial or infinite-dimensional. The first structural theorem settles its size.

C.1.2 The antisymmetrized basis and the dimension count

Relation Eq. (C.3) lets us reorder any product of generators at the cost of signs, and Eq. (C.2) lets us delete repeated factors. It is natural to organize the resulting

normal forms by which generators they involve. Write $d = 4$ for the spacetime dimension. For an ordered subset $A = \{a_1 < a_2 < \cdots < a_k\} \subseteq \{0, 1, 2, 3\}$ define the monomial

$$\Gamma_A \;=\; \gamma^{a_1}\gamma^{a_2}\cdots\gamma^{a_k}, \qquad \Gamma_\emptyset := \mathbf{1}, \tag{C.4}$$

the factors written in increasing index order. Because the generators with distinct indices anticommute, Γ_A is (up to sign) the antisymmetrized product $\gamma^{[a_1}\cdots\gamma^{a_k]}$, which is why these objects are called the *antisymmetrized products*; in $d = 4$ they are

$$\underbrace{\mathbf{1}}_{1},\quad \underbrace{\gamma^\mu}_{4},\quad \underbrace{\gamma^\mu\gamma^\nu\ (\mu<\nu)}_{6},\quad \underbrace{\gamma^\mu\gamma^\nu\gamma^\rho\ (\mu<\nu<\rho)}_{4},\quad \underbrace{\gamma^0\gamma^1\gamma^2\gamma^3}_{1}. \tag{C.5}$$

Theorem C.2 (Dimension of the Clifford algebra)**.** *The 2^d monomials $\{\Gamma_A\}_{A\subseteq\{0,\ldots,d-1\}}$ form a basis of $\mathcal{A} = \mathrm{Cl}(1,3)$ as a complex vector space. Hence*

$$\dim_{\mathbb{C}} \mathcal{A} \;=\; \sum_{k=0}^{d} \binom{d}{k} \;=\; 2^d, \tag{C.6}$$

which is $2^4 = 16$ in $d = 4$.

The proof has two halves: spanning (the monomials generate, so $\dim \mathcal{A} \le 2^d$) and linear independence (no nontrivial relation among them, so $\dim \mathcal{A} \ge 2^d$). Spanning is a direct reduction argument. Independence is more delicate, because at this point we have *not* constructed any matrices on which to evaluate a trace; that construction is the business of Section C.2. We therefore give a proof of independence that is purely internal to the abstract algebra, using only Eq. (C.1). It rests on the following lemma.

Lemma C.3 (Anticommuting partner)**.** *For every nonempty $A \subseteq \{0, \ldots, d-1\}$ in $d = 4$ there exists a generator γ^μ that anticommutes with Γ_A: $\gamma^\mu\Gamma_A = -\Gamma_A\gamma^\mu$.*

Proof. Let $|A| = k \ge 1$. Moving a single generator γ^μ through $\Gamma_A = \gamma^{a_1}\cdots\gamma^{a_k}$ produces one sign (-1) for each factor γ^{a_i} with $a_i \ne \mu$ (by Eq. (C.3)) and no sign for a factor with $a_i = \mu$. Hence

$$\gamma^\mu\,\Gamma_A = (-1)^{\,k-[\mu\in A]}\,\Gamma_A\,\gamma^\mu, \tag{C.7}$$

where $[\mu \in A]$ is 1 if $\mu \in A$ and 0 otherwise. We need an index making the exponent odd. If k is odd, choose any $\mu \notin A$ (such an index exists whenever $k < d$, and for $k = d$ the count k is even, so this case does not arise here): the exponent is k, which is odd. If k is even, choose any $\mu \in A$ (which is nonempty): the exponent is $k - 1$, again odd. In either case $\gamma^\mu\Gamma_A = -\Gamma_A\gamma^\mu$, as claimed. (For $A = \{0, 1, 2, 3\}$, where $k = d = 4$ is even, the second case applies and any $\mu \in A$ works; this is the statement, used later, that $\gamma^0\gamma^1\gamma^2\gamma^3$ anticommutes with every γ^μ.) □

Proof of Theorem C.2. Spanning. Any element of $\mathcal{A}$ is a finite linear combination of words $\gamma^{\mu_1}\cdots\gamma^{\mu_n}$. Take any such word. Using Eq. (C.3) repeatedly we may sort the factors into nondecreasing index order, each transposition contributing a factor (-1). Whenever two equal indices become adjacent, Eq. (C.2) replaces $\gamma^\mu\gamma^\mu$ by the scalar $\eta^{\mu\mu}\mathbf{1} = \pm\mathbf{1}$, shortening the word. Iterating, every word reduces to a scalar multiple of some Γ_A with A a set of *distinct* indices in increasing order. Thus the Γ_A span $\mathcal{A}$, and there are at most 2^d of them, giving $\dim\mathcal{A} \le 2^d$.

Independence. Suppose

$$\sum_A c_A\,\Gamma_A = 0, \qquad c_A \in \mathbb{C}. \tag{C.8}$$

We show every $c_A = 0$. The key is a projector built entirely from conjugations inside $\mathcal{A}$. For ordered subsets A, S, the monomials Γ_A and Γ_S are products of distinct generators, so by Eq. (C.3) they either commute or anticommute: $\Gamma_S\Gamma_A = \chi_A(S)\,\Gamma_A\Gamma_S$ with $\chi_A(S) \in \{+1,-1\}$. Since each Γ_S is invertible, conjugation gives the pure sign

$$\Gamma_S\,\Gamma_A\,\Gamma_S^{-1} = \chi_A(S)\,\Gamma_A. \tag{C.9}$$

The map $S \mapsto \chi_A(S)$ is a homomorphism from the set of subsets under symmetric difference into $\{\pm1\}$: conjugating successively by Γ_S and $\Gamma_{S'}$ multiplies the signs, while $\Gamma_{S'}\Gamma_S$ and $\Gamma_{S\triangle S'}$ differ only by an overall scalar that cancels in a conjugation, so $\chi_A(S\triangle S') = \chi_A(S)\,\chi_A(S')$. For $A = \emptyset$ we have $\Gamma_\emptyset = \mathbf{1}$ and $\chi_\emptyset \equiv 1$, the trivial character. For $A \neq \emptyset$, Theorem C.3 supplies a generator γ^μ with $\chi_A(\{\mu\}) = -1$, so χ_A is a *nontrivial* character.

Now average Eq. (C.8) over all 2^d conjugations:

$$0 = \frac{1}{2^d}\sum_S \Gamma_S\Big(\sum_A c_A\Gamma_A\Big)\Gamma_S^{-1} = \sum_A c_A\,\Gamma_A\left[\frac{1}{2^d}\sum_S \chi_A(S)\right]. \tag{C.10}$$

A nontrivial character of a finite abelian group sums to zero over the group; the trivial one sums to the group order. Hence the bracket equals 1 for $A = \emptyset$ and 0 for $A \neq \emptyset$, and Eq. (C.10) collapses to $c_\emptyset\,\mathbf{1} = 0$, i.e. $c_\emptyset = 0$. To reach an arbitrary B, multiply Eq. (C.8) on the right by Γ_B^{-1}; since $\Gamma_A\Gamma_B^{-1}$ is a scalar multiple of $\Gamma_{A\triangle B}$ and equals a nonzero scalar times $\mathbf{1}$ precisely when $A = B$, the same averaging applied to $\sum_A c_A\Gamma_A\Gamma_B^{-1} = 0$ extracts the coefficient of $\mathbf{1}$, which is a nonzero multiple of c_B. Therefore $c_B = 0$ for every B. The Γ_A are linearly independent, $\dim\mathcal{A} \ge 2^d$, and with the spanning bound $\dim\mathcal{A} = 2^d$. □

The argument used nothing but Eq. (C.1): the Clifford algebra is genuinely 16-dimensional as an abstract object, before any matrix representation is in hand. This is the precise sense in which the algebra is "waiting" for the representation that Section C.2 will build.

Physical Insight

The basis Eq. (C.5) is the skeleton of every spinor bilinear in the book. Read against Eq. (C.6), the five rows are the rank-0, 1, 2, 3, 4 antisymmetric tensors on spacetime, with $\binom{4}{0}+\binom{4}{1}+\binom{4}{2}+\binom{4}{3}+\binom{4}{4}=16$ components in all. Once $\bar\psi=\psi^\dagger\gamma^0$ is available one contracts these against ψ to get the scalar, vector, tensor, axial-vector, and pseudoscalar currents; the rank-2 row is, up to the factor fixed next, exactly the spin generator $\sigma^{\mu\nu}$. The bilinear catalogue and its 16 trace-orthogonality relations are assembled in Section C.5.

C.1.3 The Lorentz content: $\sigma^{\mu\nu}$ as a representation of $\mathfrak{so}(1,3)$

We now extract the Lorentz algebra from the rank-2 row of Eq. (C.5). Define

$$\sigma^{\mu\nu} \;:=\; \frac{i}{4}\,[\gamma^\mu,\gamma^\nu] \;=\; \frac{i}{2}(\gamma^\mu\gamma^\nu-\eta^{\mu\nu}\mathbf{1}), \tag{C.11}$$

the second equality following from $\gamma^\mu\gamma^\nu=\frac12\{\gamma^\mu,\gamma^\nu\}+\frac12[\gamma^\mu,\gamma^\nu]=\eta^{\mu\nu}\mathbf{1}+\frac12[\gamma^\mu,\gamma^\nu]$ together with Eq. (C.1). By construction $\sigma^{\mu\nu}=-\sigma^{\nu\mu}$; for $\mu\neq\nu$ it reduces to $\sigma^{\mu\nu}=\frac{i}{2}\gamma^\mu\gamma^\nu$. Inverting Eq. (C.11) records the product of two generators in the form we will reuse repeatedly,

$$\gamma^\mu\gamma^\nu=\eta^{\mu\nu}\mathbf{1}-2i\,\sigma^{\mu\nu}. \tag{C.12}$$

The first computation is the action of $\sigma^{\mu\nu}$ on a single generator; it is the technical heart of everything that follows.

Proposition C.4 (γ^ρ is a vector under $\sigma^{\mu\nu}$)**.** *In* $\mathrm{Cl}(1,3)$,

$$[\gamma^\rho,\sigma^{\mu\nu}] \;=\; i(\eta^{\rho\mu}\gamma^\nu-\eta^{\rho\nu}\gamma^\mu). \tag{C.13}$$

Proof. The scalar term in Eq. (C.11) drops out of the commutator, so $[\gamma^\rho,\sigma^{\mu\nu}]=\frac{i}{2}[\gamma^\rho,\gamma^\mu\gamma^\nu]$. Expand using $\gamma^\rho\gamma^\mu=2\eta^{\rho\mu}\mathbf{1}-\gamma^\mu\gamma^\rho$ from Eq. (C.1):

$$\begin{aligned}[\gamma^\rho,\gamma^\mu\gamma^\nu]&=\gamma^\rho\gamma^\mu\gamma^\nu-\gamma^\mu\gamma^\nu\gamma^\rho\\&=(2\eta^{\rho\mu}-\gamma^\mu\gamma^\rho)\gamma^\nu-\gamma^\mu\gamma^\nu\gamma^\rho\\&=2\eta^{\rho\mu}\gamma^\nu-\gamma^\mu(2\eta^{\rho\nu}-\gamma^\nu\gamma^\rho)-\gamma^\mu\gamma^\nu\gamma^\rho\\&=2\eta^{\rho\mu}\gamma^\nu-2\eta^{\rho\nu}\gamma^\mu,\end{aligned} \tag{C.14}$$

the two triple products cancelling in the last line. Multiplying by $\frac{i}{2}$ gives Eq. (C.13). □

The right-hand side of Eq. (C.13) is exactly the action of an $\mathfrak{so}(1,3)$ generator labelled $(\mu\nu)$ on a vector index ρ: $\sigma^{\mu\nu}$ rotates γ^ρ into a combination of γ^μ and γ^ν with the metric-dictated coefficients. That the $\sigma^{\mu\nu}$ close among themselves into the Lorentz algebra is now a short computation.

Theorem C.5 ($\sigma^{\mu\nu}$ represents $\mathfrak{so}(1,3)$)**.** *The matrices $\sigma^{\mu\nu}$ satisfy*

$$[\sigma^{\mu\nu},\sigma^{\rho\sigma}] = i\big(\eta^{\nu\rho}\sigma^{\mu\sigma} - \eta^{\mu\rho}\sigma^{\nu\sigma} - \eta^{\nu\sigma}\sigma^{\mu\rho} + \eta^{\mu\sigma}\sigma^{\nu\rho}\big), \tag{C.15}$$

which is precisely the Lie bracket of the Lorentz algebra $\mathfrak{so}(1,3)$ established in Chapter 3. Hence $M^{\mu\nu} \mapsto \sigma^{\mu\nu}$ is a representation of $\mathfrak{so}(1,3)$ inside $\mathrm{Cl}(1,3)$.

Proof. Write $\sigma^{\rho\sigma} = \frac{i}{2}(\gamma^\rho\gamma^\sigma - \eta^{\rho\sigma}\mathbf{1})$; the scalar drops from the commutator, leaving $[\sigma^{\mu\nu},\sigma^{\rho\sigma}] = \frac{i}{2}\,[\sigma^{\mu\nu},\gamma^\rho\gamma^\sigma]$. Apply the Leibniz rule and Eq. (C.13) (using $[\sigma^{\mu\nu},\gamma^\rho] = -\,[\gamma^\rho,\sigma^{\mu\nu}] = -i(\eta^{\rho\mu}\gamma^\nu - \eta^{\rho\nu}\gamma^\mu)$):

$$\begin{aligned}[\sigma^{\mu\nu},\gamma^\rho\gamma^\sigma] &= [\sigma^{\mu\nu},\gamma^\rho]\,\gamma^\sigma + \gamma^\rho\,[\sigma^{\mu\nu},\gamma^\sigma] \\ &= -i(\eta^{\rho\mu}\gamma^\nu - \eta^{\rho\nu}\gamma^\mu)\gamma^\sigma - i\,\gamma^\rho(\eta^{\sigma\mu}\gamma^\nu - \eta^{\sigma\nu}\gamma^\mu).\end{aligned} \tag{C.16}$$

Therefore

$$[\sigma^{\mu\nu},\sigma^{\rho\sigma}] = \frac{i}{2}\,(-i)\Big[\eta^{\rho\mu}\gamma^\nu\gamma^\sigma - \eta^{\rho\nu}\gamma^\mu\gamma^\sigma + \eta^{\sigma\mu}\gamma^\rho\gamma^\nu - \eta^{\sigma\nu}\gamma^\rho\gamma^\mu\Big]. \tag{C.17}$$

Now replace each product of generators by Eq. (C.12), e.g. $\gamma^\nu\gamma^\sigma = \eta^{\nu\sigma}\mathbf{1} - 2i\sigma^{\nu\sigma}$. The purely scalar (metric×metric) part is

$$\eta^{\rho\mu}\eta^{\nu\sigma} - \eta^{\rho\nu}\eta^{\mu\sigma} + \eta^{\sigma\mu}\eta^{\rho\nu} - \eta^{\sigma\nu}\eta^{\rho\mu} = 0, \tag{C.18}$$

which vanishes term by term because η is symmetric (the first and last cancel, as do the middle two). Only the σ pieces survive, each carrying a factor $-2i$:

$$\begin{aligned}[\sigma^{\mu\nu},\sigma^{\rho\sigma}] &= \frac{i}{2}\,(-i)\,(-2i)\Big[\eta^{\rho\mu}\sigma^{\nu\sigma} - \eta^{\rho\nu}\sigma^{\mu\sigma} + \eta^{\sigma\mu}\sigma^{\rho\nu} - \eta^{\sigma\nu}\sigma^{\rho\mu}\Big] \\ &= -i\Big[\eta^{\mu\rho}\sigma^{\nu\sigma} - \eta^{\nu\rho}\sigma^{\mu\sigma} - \eta^{\mu\sigma}\sigma^{\nu\rho} + \eta^{\nu\sigma}\sigma^{\mu\rho}\Big],\end{aligned} \tag{C.19}$$

where in the last line we used $\sigma^{\rho\nu} = -\sigma^{\nu\rho}$ and $\sigma^{\rho\mu} = -\sigma^{\mu\rho}$ to flip the third and fourth terms. Distributing the overall sign and reordering reproduces Eq. (C.15). The prefactor arithmetic, $\frac{i}{2}\cdot(-i)\cdot(-2i) = -i$, is the source of the clean coefficient i on the right. □

C.1.4 Finite Lorentz transformations of spinors

The infinitesimal statement Eq. (C.15) exponentiates to a finite group action. A Lorentz transformation Λ connected to the identity is $\Lambda = \exp\omega$ with $\omega^\mu{}_\nu$ generating $\mathfrak{so}(1,3)$, i.e. $\omega_{\mu\nu} = \eta_{\mu\rho}\omega^\rho{}_\nu$ antisymmetric (this is the defining condition $\Lambda^{\mathsf{T}}\eta\Lambda = \eta$ at the Lie-algebra level, Chapter 3). To each such ω associate the spinor operator

$$S(\Lambda) = \exp\Big(-\tfrac{i}{2}\,\omega_{\mu\nu}\,\sigma^{\mu\nu}\Big). \tag{C.20}$$

The factor $\frac{1}{2}$ compensates the double sum over the antisymmetric pair (μ,ν).

Theorem C.6 (γ^μ transforms as a four-vector)**.** *With $S(\Lambda)$ as in Eq. (C.20) and $\Lambda = \exp\omega$,*

$$S(\Lambda)^{-1}\,\gamma^\mu\,S(\Lambda) \;=\; \Lambda^\mu{}_\nu\,\gamma^\nu. \tag{C.21}$$

Equivalently $S(\Lambda)\,\gamma^\mu\,S(\Lambda)^{-1} = (\Lambda^{-1})^\mu{}_\nu\,\gamma^\nu$. The Dirac equation $(i\gamma^\mu\partial_\mu - m)\psi = 0$ is Lorentz covariant precisely because of this intertwining relation; that physical consequence is drawn in Chapter 11.

Proof. Introduce the one-parameter family $S(t) = \exp\!\big(-\tfrac{i}{2}t\,\omega_{\rho\sigma}\sigma^{\rho\sigma}\big)$ and

$$\gamma^\mu(t) := S(t)^{-1}\gamma^\mu S(t). \tag{C.22}$$

Differentiate, using $\dot S(t) = -\tfrac{i}{2}\omega_{\rho\sigma}\sigma^{\rho\sigma}S(t)$ and $\dot{S^{-1}} = +\tfrac{i}{2}\omega_{\rho\sigma}\sigma^{\rho\sigma}S(t)^{-1}$:

$$\frac{d}{dt}\gamma^\mu(t) = \frac{i}{2}\omega_{\rho\sigma}\,S^{-1}\,[\sigma^{\rho\sigma},\gamma^\mu]\,S. \tag{C.23}$$

From Eq. (C.13), $[\sigma^{\rho\sigma},\gamma^\mu] = -\,[\gamma^\mu,\sigma^{\rho\sigma}] = -i(\eta^{\mu\rho}\gamma^\sigma - \eta^{\mu\sigma}\gamma^\rho)$, so

$$\begin{aligned}\frac{i}{2}\omega_{\rho\sigma}\,[\sigma^{\rho\sigma},\gamma^\mu] &= \frac{i}{2}\omega_{\rho\sigma}\,(-i)\big(\eta^{\mu\rho}\gamma^\sigma - \eta^{\mu\sigma}\gamma^\rho\big) = \frac{1}{2}\big(\omega^\mu{}_\sigma\gamma^\sigma - \omega_\rho{}^\mu\gamma^\rho\big)\\ &= \frac{1}{2}\big(\omega^\mu{}_\sigma\gamma^\sigma + \omega^\mu{}_\rho\gamma^\rho\big) = \omega^\mu{}_\nu\,\gamma^\nu,\end{aligned} \tag{C.24}$$

where we raised an index with η and used antisymmetry $\omega_\rho{}^\mu = -\omega^\mu{}_\rho$ to combine the two terms. Conjugating by S (which is t-independent in its action on the constant coefficient $\omega^\mu{}_\nu$) turns Eq. (C.23) into the closed linear system

$$\frac{d}{dt}\gamma^\mu(t) = \omega^\mu{}_\nu\,\gamma^\nu(t), \qquad \gamma^\mu(0) = \gamma^\mu. \tag{C.25}$$

Its unique solution is $\gamma^\mu(t) = (e^{t\omega})^\mu{}_\nu\,\gamma^\nu$. Setting $t = 1$ and $\Lambda = e^\omega$ gives Eq. (C.21). □

Caution

The matrix $S(\Lambda)$ is *not* unitary for boosts. The boost generators σ^{0i} are anti-Hermitian in the standard representations (Section C.3.6), so the boost part of $\exp(-\tfrac{i}{2}\omega\sigma)$ is Hermitian and exponentially growing in rapidity, reflecting that the finite-dimensional spinor representation of the noncompact Lorentz group cannot be unitary. This is consistent: the Hilbert-space unitary representations are infinite-dimensional and act on multiparticle states; the finite-dimensional $S(\Lambda)$ acts on the field components. The relation $\gamma^0 S^\dagger \gamma^0 = S^{-1}$ that repairs the would-be unitarity is the γ^0 intertwiner classified in Section C.4.

C.1.5 Identification with the $(\frac{1}{2},0)\oplus(0,\frac{1}{2})$ representation

The representation $\sigma^{\mu\nu}$ acts on a four-dimensional space (once we have the matrices of Section C.2). Chapter 3 predicts that the Dirac representation is reducible, splitting as $(\frac{1}{2},0)\oplus(0,\frac{1}{2})$ over the complexified algebra $\mathfrak{so}(1,3)_{\mathbb{C}} \cong \mathfrak{su}(2)\oplus\mathfrak{su}(2)$. We can already see the splitting abstractly, before choosing matrices, through the chirality element

$$\gamma^5 := i\,\gamma^0\gamma^1\gamma^2\gamma^3 = -\frac{i}{4!}\,\epsilon_{\mu\nu\rho\sigma}\gamma^\mu\gamma^\nu\gamma^\rho\gamma^\sigma, \tag{C.26}$$

the top element of the basis Eq. (C.5) normalized as fixed in Chapter A. Two facts follow from the Clifford relation alone. First, $(\gamma^5)^2 = \mathbf{1}$: writing $\gamma^5 = i\gamma^0\gamma^1\gamma^2\gamma^3$ and squaring, the reordering needed to pair each generator with its partner produces $(i)^2(-1)^6(\gamma^0)^2(\gamma^1)^2(\gamma^2)^2(\gamma^3)^2 = (-1)(+1)(1)(-1)(-1)(-1) = 1$, where $(-1)^6$ counts the six transpositions that sort $\gamma^0\gamma^1\gamma^2\gamma^3\gamma^0\gamma^1\gamma^2\gamma^3$ into paired form. Second, γ^5 anticommutes with every generator: by Theorem C.3 applied to $A = \{0,1,2,3\}$, or directly, moving γ^μ through the four distinct factors of γ^5 yields three sign changes (one factor equals γ^μ, three do not), so

$$\left\{\gamma^5,\gamma^\mu\right\} = 0. \tag{C.27}$$

Because $\sigma^{\mu\nu}$ is a product of *two* generators, Eq. (C.27) gives the crucial commutation

$$\left[\gamma^5,\sigma^{\mu\nu}\right] = 0. \tag{C.28}$$

Indeed $\gamma^5\gamma^\mu\gamma^\nu = (-1)^2\gamma^\mu\gamma^\nu\gamma^5 = \gamma^\mu\gamma^\nu\gamma^5$, and the scalar piece of $\sigma^{\mu\nu}$ commutes trivially.

Proposition C.7 (Chiral decomposition of the spin representation)**.** *The operators $P_\pm = \frac{1}{2}(\mathbf{1}\pm\gamma^5)$ are complementary orthogonal idempotents, $P_+^2 = P_+$, $P_-^2 = P_-$, $P_+P_- = P_-P_+ = 0$, $P_+ + P_- = \mathbf{1}$, and they commute with $S(\Lambda)$ for every Λ. Consequently the spin representation $\Lambda \mapsto S(\Lambda)$ leaves invariant the two subspaces $P_\pm\mathcal{V}$ and decomposes as a direct sum of two subrepresentations. These are the left- and right-handed Weyl representations $(\frac{1}{2},0)$ and $(0,\frac{1}{2})$ of Chapter 3.*

Proof. The idempotent identities are immediate from $(\gamma^5)^2 = \mathbf{1}$: $P_\pm^2 = \frac{1}{4}(\mathbf{1}\pm 2\gamma^5+(\gamma^5)^2) = \frac{1}{4}(2\mathbf{1}\pm 2\gamma^5) = P_\pm$, and $P_+P_- = \frac{1}{4}(\mathbf{1}-(\gamma^5)^2) = 0$. From Eq. (C.28), γ^5 commutes with $\sigma^{\mu\nu}$ and hence with every power series in the $\sigma^{\mu\nu}$, in particular with $S(\Lambda) = \exp(-\frac{i}{2}\omega_{\mu\nu}\sigma^{\mu\nu})$; therefore $P_\pm S(\Lambda) = S(\Lambda)P_\pm$. The projected subspaces are invariant and $S(\Lambda) = S(\Lambda)P_+ + S(\Lambda)P_-$ block-diagonalizes the action. That the two blocks carry the inequivalent two-dimensional representations $(\frac{1}{2},0)$ and $(0,\frac{1}{2})$ — equivalently, that the self-dual and anti-self-dual combinations of $\sigma^{\mu\nu}$ generate the two commuting $\mathfrak{su}(2)$ factors — is the content of the Lorentz classification in Chapter 3; here it is realized concretely as the $\gamma^5 = \pm 1$ eigenspaces. The matrix realization in which $P_\pm$ are the obvious block

projectors is the chiral (Weyl) basis of Section C.3.2, and the eigenvalue ± 1 of γ^5 is the chirality of Chapter 11. □

This is the promised identification. "Gamma matrices" and "the spin representation of $\mathfrak{so}(1,3)$" are the same structure: the four generators encode, through Eq. (C.11), a representation of the Lorentz algebra, and that representation is reducibly the Dirac sum of the two Weyl spinors that Chapter 3 introduced abstractly.

C.1.6 Worked examples

Worked Example C.8 (Rotations, boosts, and the double cover $S(2\pi) = -\mathbf{1}$)**.** We extract the rotation and boost generators from $\sigma^{\mu\nu}$ and exhibit the hallmark of a spinor representation: a 2π rotation acts as $-\mathbf{1}$, not $+\mathbf{1}$. This is the algebraic shadow of the $\mathrm{SL}(2,\mathbb{C}) \to \mathrm{SO}^+(1,3)$ double cover established in Chapter 3.

Consider a rotation by angle θ about the z-axis, generated by the single nonzero pair $\omega_{12} = -\omega_{21} = -\theta$ (all other components zero). The exponent in Eq. (C.20) is

$$-\tfrac{i}{2}\,\omega_{\mu\nu}\sigma^{\mu\nu} = -\tfrac{i}{2}(\omega_{12}\sigma^{12}+\omega_{21}\sigma^{21}) = -\tfrac{i}{2}((-\theta)\sigma^{12}+(\theta)(-\sigma^{12})) = i\theta\,\sigma^{12}, \tag{C.29}$$

so $S(\theta) = \exp(i\theta\,\sigma^{12})$. The square of the generator follows from the Clifford relation:

$$(\sigma^{12})^2 = \left(\tfrac{i}{2}\gamma^1\gamma^2\right)^2 = -\tfrac{1}{4}\,\gamma^1\gamma^2\gamma^1\gamma^2 = -\tfrac{1}{4}\,(-1)\gamma^1\gamma^1\gamma^2\gamma^2 = -\tfrac{1}{4}\,(\eta^{11})(\eta^{22})\mathbf{1} = \tfrac{1}{4}\,\mathbf{1}, \tag{C.30}$$

using $\gamma^2\gamma^1 = -\gamma^1\gamma^2$ and $\eta^{11} = \eta^{22} = -1$. Thus σ^{12} has eigenvalues $\pm\frac{1}{2}$, the spin-$\frac{1}{2}$ values. With $(\sigma^{12})^2 = \frac{1}{4}\mathbf{1}$ the exponential resums to a closed form: separating even and odd powers,

$$S(\theta) = e^{i\theta\sigma^{12}} = \cos\!\left(\tfrac{\theta}{2}\right)\mathbf{1} + 2i\,\sigma^{12}\,\sin\!\left(\tfrac{\theta}{2}\right). \tag{C.31}$$

The half-angle is the spin-$\frac{1}{2}$ fingerprint. At $\theta = 2\pi$, $\cos\pi = -1$ and $\sin\pi = 0$, so

$$S(2\pi) = -\mathbf{1}, \tag{C.32}$$

a full spatial revolution returns the spinor to minus itself. A second revolution, $\theta = 4\pi$, restores $+\mathbf{1}$. The map $\Lambda \mapsto S(\Lambda)$ is therefore two-valued on the rotation group: it is a genuine representation of the double cover, the concrete manifestation of the $\mathrm{SL}(2,\mathbb{C})$ structure of Chapter 3.

For comparison, a boost of rapidity η along x^1 uses $\omega_{01} = -\omega_{10} = \eta$, giving $S = \exp(-i\eta\,\sigma^{01})$ with $(\sigma^{01})^2 = (\frac{i}{2}\gamma^0\gamma^1)^2 = -\frac{1}{4}\gamma^0\gamma^1\gamma^0\gamma^1 = \frac{1}{4}\gamma^0\gamma^0\gamma^1\gamma^1 = \frac{1}{4}(\eta^{00})(\eta^{11})\mathbf{1} = -\frac{1}{4}\mathbf{1}$, where $\gamma^1\gamma^0 = -\gamma^0\gamma^1$ supplies the middle sign and $\eta^{00} = +1$, $\eta^{11} = -1$; this is the opposite sign to Eq. (C.30). The resummation then produces hyperbolic functions $\cosh(\eta/2)$, $\sinh(\eta/2)$ rather than trigonometric ones, confirming the noncompact, non-unitary character of boosts flagged above.

Worked Example C.9 (Direct check of the $\mathfrak{so}(1,3)$ bracket)**.** We verify Eq. (C.15) on a representative pair by computing the commutator straight from the generators, with no appeal to the general formula, and then confirm agreement. Take $(\mu\nu) = (12)$ and $(\rho\sigma) = (23)$, two rotation generators sharing the index 2. Using $\sigma^{12} = \frac{i}{2}\gamma^1\gamma^2$ and $\sigma^{23} = \frac{i}{2}\gamma^2\gamma^3$,

$$\sigma^{12}\sigma^{23} = -\tfrac{1}{4}\,\gamma^1\gamma^2\gamma^2\gamma^3 = -\tfrac{1}{4}\,\eta^{22}\,\gamma^1\gamma^3 = \tfrac{1}{4}\,\gamma^1\gamma^3, \tag{C.33}$$

$$\sigma^{23}\sigma^{12} = -\tfrac{1}{4}\,\gamma^2\gamma^3\gamma^1\gamma^2 = -\tfrac{1}{4}\,\gamma^1\gamma^3, \tag{C.34}$$

where the second line uses $\gamma^2\gamma^3\gamma^1\gamma^2 = \gamma^1\gamma^3$, obtained by the three anticommutations $\gamma^2\gamma^3\gamma^1\gamma^2 = -\gamma^3\gamma^2\gamma^1\gamma^2 = +\gamma^3\gamma^1\gamma^2\gamma^2 = \eta^{22}\gamma^3\gamma^1 = -\gamma^3\gamma^1 = \gamma^1\gamma^3$. Hence

$$\left[\sigma^{12},\sigma^{23}\right] = \tfrac{1}{4}\gamma^1\gamma^3 - (-\tfrac{1}{4}\gamma^1\gamma^3) = \tfrac{1}{2}\,\gamma^1\gamma^3. \tag{C.35}$$

Since $\sigma^{13} = \frac{i}{2}\gamma^1\gamma^3$, i.e. $\gamma^1\gamma^3 = -2i\,\sigma^{13}$, this is

$$\left[\sigma^{12},\sigma^{23}\right] = -i\,\sigma^{13}. \tag{C.36}$$

The general formula Eq. (C.15) with $\mu = 1, \nu = 2, \rho = 2, \sigma = 3$ keeps only the term with $\eta^{\nu\rho} = \eta^{22} = -1$ (the others carry off-diagonal η components that vanish), giving $i\,\eta^{22}\sigma^{13} = -i\,\sigma^{13}$. The two computations agree. The mostly-minus signature shows itself in the sign $\eta^{22} = -1$: it is what turns the three spatial rotation generators $\Sigma^k := \frac{1}{2}\epsilon^{kij}\sigma^{ij}$ into a standard $\mathfrak{su}(2)$ with $\left[\Sigma^i,\Sigma^j\right] = i\epsilon^{ijk}\Sigma^k$, the rotation subalgebra imported from Chapter 2.

We have now built, from one anticommutation relation, a 16-dimensional associative algebra with a canonical basis and shown that it carries the Lorentz algebra through $\sigma^{\mu\nu}$. What is conspicuously absent is any actual matrix: every statement so far is a relation among abstract symbols. The next section confronts the question this raises. A representation of $\mathrm{Cl}(1,3)$ by matrices must exist for the spinor fields of Chapter 11 to be column vectors at all, and the abstract 16-dimensionality forces such a representation to have a definite minimal size. Section C.2 proves that in even dimension the irreducible representation exists, has dimension $2^{d/2} = 4$ in $d = 4$, and is unique up to similarity — Pauli's fundamental theorem — the result on which every intertwining matrix in the rest of this appendix depends.

C.2 Existence and Uniqueness of the Representation

The previous section took the gamma matrices to be *any* objects obeying the Clifford relation $\{\gamma^\mu,\gamma^\nu\} = 2\eta^{\mu\nu}\mathbf{1}$ and built from them the 2^d-dimensional algebra basis $\{\Gamma_A\}$ of ordered products (Section C.1). That was a purely algebraic enterprise: nothing in it guaranteed that matrices satisfying the relation actually

exist, let alone that there is essentially only one way to realize them. Yet every concrete computation in this book—every trace, every spin sum, every Fierz rearrangement—is performed with specific numerical matrices, and the representation-independence of the final answers is taken for granted. Both facts must be earned. This section earns them. We construct, by an explicit Kronecker-product recursion, a $2^{d/2}$-dimensional representation in every even dimension d; we prove it is irreducible and that irreducibility forces precisely this dimension; and we prove Pauli's fundamental theorem, which states that any two solutions of the Clifford relation of this size are conjugate by a matrix S unique up to a scalar. Pauli's theorem is the workhorse of everything that follows: it is the machine that converts the bare statement "$\{\gamma'^{\mu}\}$ obeys the Clifford relation" into "there is a unique-up-to-scale S with $\gamma'^{\mu} = S\,\gamma^{\mu}S^{-1}$," and in Section C.3 and beyond every intertwining matrix—γ^0, the charge-conjugation matrix C, and the parity and time-reversal matrices—is nothing but the S of this theorem applied to a cleverly chosen second solution.

Throughout this section d is even, $d = 2n$, unless we explicitly turn to the odd case; we abbreviate the representation dimension as $N \equiv 2^n = 2^{d/2}$. We work over the complex numbers: the signature of the metric will turn out to be irrelevant to the questions of existence, dimension, and uniqueness, because complexifying the Clifford algebra erases the distinction between timelike and spacelike generators. The Pauli matrices $\sigma^1, \sigma^2, \sigma^3$ and their algebra are imported from Chapters 2 and B; Schur's lemma, in both of the forms we use below, is imported from Chapter 2.

C.2.1 Explicit construction by Kronecker products

It is cleanest to build a Euclidean set first—matrices Γ^a $(a = 1, \ldots, d)$ satisfying

$$\left\{\Gamma^a, \Gamma^b\right\} = 2\delta^{ab}\,\mathbf{1}, \tag{C.37}$$

so that each generator squares to $+\mathbf{1}$ and distinct generators anticommute—and to pass to the physical Lorentzian signature at the very end by inserting factors of i. The single ingredient is the Pauli algebra

$$\left\{\sigma^i, \sigma^j\right\} = 2\delta^{ij}\,\mathbf{1}_2, \qquad (\sigma^i)^2 = \mathbf{1}_2, \qquad \sigma^1\sigma^2 = i\sigma^3 \text{ (cyclic)}, \tag{C.38}$$

each σ^i being Hermitian and 2×2. The two matrices σ^1, σ^2 already furnish the case $d = 2$: they anticommute and square to the identity, so $\Gamma^1 = \sigma^1$, $\Gamma^2 = \sigma^2$ is a 2-dimensional $(N = 2^1)$ solution of Eq. (C.37). The reserved third matrix $\sigma^3 = -i\sigma^1\sigma^2$ is the chirality element in two dimensions; it anticommutes with both Γ^1, Γ^2 and squares to $\mathbf{1}_2$. This last property is exactly what lets us climb the ladder.

Theorem C.10 (Inductive Kronecker construction)**.** *For every even $d = 2n$ there exist d Hermitian matrices Γ^a of size $N \times N$, $N = 2^n$, satisfying the Euclidean Clifford relation Eq. (C.37). They are generated by the recursion*

$$\Gamma^a_{(n+1)} = \Gamma^a_{(n)} \otimes \sigma^3 \quad (a = 1, \dots, 2n), \qquad \Gamma^{2n+1}_{(n+1)} = \mathbf{1}_{2^n} \otimes \sigma^1, \qquad \Gamma^{2n+2}_{(n+1)} = \mathbf{1}_{2^n} \otimes \sigma^2, \tag{C.39}$$

started from $\Gamma^1_{(1)} = \sigma^1$, $\Gamma^2_{(1)} = \sigma^2$.

Proof. We verify that if $\{\Gamma^a_{(n)}\}_{a=1}^{2n}$ obey Eq. (C.37) in dimension 2^n, then the matrices Eq. (C.39) obey it in dimension 2^{n+1}. The Kronecker product multiplies blockwise, $(P \otimes Q)(P' \otimes Q') = PP' \otimes QQ'$, so anticommutators factorize whenever one tensor slot commutes through. We check the three types of pair.

Two old generators. For $a, b \le 2n$,

$$\left\{\Gamma^a_{(n)} \otimes \sigma^3, \Gamma^b_{(n)} \otimes \sigma^3\right\} = \left\{\Gamma^a_{(n)}, \Gamma^b_{(n)}\right\} \otimes (\sigma^3)^2 = 2\delta^{ab} \mathbf{1}_{2^n} \otimes \mathbf{1}_2 = 2\delta^{ab} \mathbf{1}_{2^{n+1}}, \tag{C.40}$$

where we used $(\sigma^3)^2 = \mathbf{1}_2$ and the induction hypothesis.

One old, one new. For $a \le 2n$ and either of the new generators $\mathbf{1} \otimes \sigma^{1,2}$,

$$\left\{\Gamma^a_{(n)} \otimes \sigma^3, \mathbf{1}_{2^n} \otimes \sigma^{1,2}\right\} = \Gamma^a_{(n)} \otimes \left\{\sigma^3, \sigma^{1,2}\right\} = \Gamma^a_{(n)} \otimes 0 = 0, \tag{C.41}$$

because σ^3 anticommutes with σ^1 and with σ^2.

Two new generators. The two new matrices commute through their first slot trivially and anticommute in the second,

$$\left\{\mathbf{1} \otimes \sigma^1, \mathbf{1} \otimes \sigma^2\right\} = \mathbf{1} \otimes \left\{\sigma^1, \sigma^2\right\} = 0, \qquad (\mathbf{1} \otimes \sigma^{1,2})^2 = \mathbf{1} \otimes (\sigma^{1,2})^2 = \mathbf{1}_{2^{n+1}}. \tag{C.42}$$

Thus all $2n + 2$ matrices anticommute pairwise and square to the identity: Eq. (C.37) holds in dimension 2^{n+1}. Hermiticity is preserved because $\sigma^1, \sigma^2, \sigma^3$ and the inductive $\Gamma^a_{(n)}$ are Hermitian and the Kronecker product of Hermitian matrices is Hermitian. The base case $d = 2$ was checked above, so the claim holds for all even d by induction. □

The dimension obeys $N(n) = 2N(n-1)$ with $N(1) = 2$, i.e. $N = 2^n = 2^{d/2}$, doubling with each pair of new dimensions. That this is also the *smallest* possible dimension is the content of Section C.2.2; for now we have established existence.

Worked Example C.11 (The 4×4 matrices in $d = 4$)**.** Running the recursion once, from $n = 1$ to $n = 2$, produces the four Euclidean Dirac matrices of four-dimensional spacetime. With $\Gamma^1_{(1)} = \sigma^1$, $\Gamma^2_{(1)} = \sigma^2$,

$$\Gamma^1 = \sigma^1 \otimes \sigma^3, \qquad \Gamma^2 = \sigma^2 \otimes \sigma^3, \qquad \Gamma^3 = \mathbf{1}_2 \otimes \sigma^1, \qquad \Gamma^4 = \mathbf{1}_2 \otimes \sigma^2, \tag{C.43}$$

four Hermitian 4×4 matrices with $\left\{\Gamma^a, \Gamma^b\right\} = 2\delta^{ab}\mathbf{1}_4$. Written as 2×2 blocks of 2×2 matrices (using $\sigma^3 = \mathrm{diag}(1, -1)$ to expand the first factor),

$$\Gamma^1 = \begin{pmatrix} 0 & \sigma^3 \\ \sigma^3 & 0 \end{pmatrix}, \quad \Gamma^2 = \begin{pmatrix} 0 & -i\sigma^3 \\ i\sigma^3 & 0 \end{pmatrix}, \quad \Gamma^3 = \begin{pmatrix} \sigma^1 & 0 \\ 0 & \sigma^1 \end{pmatrix}, \quad \Gamma^4 = \begin{pmatrix} \sigma^2 & 0 \\ 0 & \sigma^2 \end{pmatrix}. \tag{C.44}$$

To reach the mostly-minus Lorentzian Clifford relation $\{\gamma^\mu, \gamma^\nu\} = 2\eta^{\mu\nu}\mathbf{1}$ with $\eta = \mathrm{diag}(+, -, -, -)$ we need one generator squaring to $+\mathbf{1}$ (timelike) and three squaring to $-\mathbf{1}$ (spacelike). Since every Γ^a here is Hermitian with $(\Gamma^a)^2 = +\mathbf{1}$, set

$$\gamma^0 = \Gamma^4, \qquad \gamma^1 = i\,\Gamma^1, \qquad \gamma^2 = i\,\Gamma^2, \qquad \gamma^3 = i\,\Gamma^3. \tag{C.45}$$

Then $(\gamma^0)^2 = (\Gamma^4)^2 = +\mathbf{1}$, matching $\eta^{00} = +1$, while $(\gamma^j)^2 = i^2(\Gamma^a)^2 = -\mathbf{1}$ for the three spatial slots, matching $\eta^{jj} = -1$; and for $\mu \neq \nu$ the anticommutator inherits the vanishing of the Euclidean one, $\{\gamma^\mu, \gamma^\nu\} = (\pm i)(\pm i)\left\{\Gamma^a, \Gamma^b\right\} = 0$. Hence $\{\gamma^\mu, \gamma^\nu\} = 2\eta^{\mu\nu}\mathbf{1}_4$. We have produced, with our bare hands, an explicit 4×4 representation. We deliberately do *not* call this "the Dirac representation": the assignment Eq. (C.45) is one of infinitely many, and the physically named bases (Dirac, chiral, Majorana) are pinned down in Section C.3. What matters here is only that a 4×4 solution exists.

C.2.2 Tracelessness, completeness, and irreducibility

We now show that the constructed representation cannot be split into smaller pieces, and that no smaller faithful realization is possible. The argument turns on two elementary facts about the product basis $\{\Gamma_A\}$, where A ranges over the 2^d ordered subsets of $\{0, \ldots, d-1\}$ and $\Gamma_\varnothing = \mathbf{1}$. The first is that every nontrivial basis element is traceless; the second is that the basis elements span the entire matrix algebra. Recall from Section C.1 that the Γ_A close under multiplication up to a sign, $\Gamma_A\Gamma_B = \pm\Gamma_C$, that each satisfies $\Gamma_A^2 = \pm\mathbf{1}$ so that $\Gamma_A^{-1} = \pm\Gamma_A$, and that $\Gamma_A\Gamma_B = \pm\mathbf{1}$ precisely when $B = A$ (the product is the identity only when the two index sets coincide).

Lemma C.12 (Tracelessness of nontrivial basis elements)**.** *For even d and any $A \neq \varnothing$, there is a generator γ^ν with $\gamma^\nu\Gamma_A\,(\gamma^\nu)^{-1} = -\Gamma_A$; consequently* $\mathrm{Tr}\,\Gamma_A = 0$.

Proof. Let $\Gamma_A = \gamma^{\mu_1} \cdots \gamma^{\mu_k}$ be a product of $k \geq 1$ distinct generators. Moving a generator γ^ν past Γ_A costs a sign (-1) for each factor it anticommutes with. If $\nu \notin \{\mu_1, \ldots, \mu_k\}$ then γ^ν anticommutes with all k factors, so $\gamma^\nu\Gamma_A = (-1)^k\Gamma_A\gamma^\nu$; if $\nu = \mu_j$ for some j, it anticommutes with the other $k-1$ factors and commutes with γ^{μ_j} only up to its square, giving $\gamma^\nu\Gamma_A = (-1)^{k-1}\Gamma_A\gamma^\nu$. We need a ν producing an overall minus sign.

If k is odd, choose any $\nu \notin \{\mu_i\}$. Such a ν exists because $k < d$: a product of all d distinct generators has $k = d$, which is even, so an odd-length

product never exhausts the index set. Then $\gamma^\nu \Gamma_A = (-1)^k \Gamma_A \gamma^\nu = -\Gamma_A \gamma^\nu$. If k is even, choose $\nu = \mu_1 \in \{\mu_i\}$; then $\gamma^\nu \Gamma_A = (-1)^{k-1} \Gamma_A \gamma^\nu = -\Gamma_A \gamma^\nu$. In either case $\gamma^\nu \Gamma_A (\gamma^\nu)^{-1} = -\Gamma_A$. Taking the trace and using cyclicity, $\operatorname{Tr} \Gamma_A = \operatorname{Tr}\big(\gamma^\nu \Gamma_A (\gamma^\nu)^{-1}\big) = \operatorname{Tr}(-\Gamma_A) = -\operatorname{Tr} \Gamma_A$, hence $\operatorname{Tr} \Gamma_A = 0$. □

The reliance on d even is not cosmetic. When d is odd, the top product $\gamma^0 \cdots \gamma^{d-1}$ has odd length but its index set *is* exhausted, so the construction in the lemma fails for it—and indeed that element is central, not traceless. This is the algebraic root of the two-irreducible-representation phenomenon in odd dimensions, to which we return in Section C.2.4.

Lemma C.13 (Linear independence and completeness)**.** *In the N-dimensional representation of Theorem C.10 the 2^d matrices $\{\Gamma_A\}$ are linearly independent. Since $N^2 = (2^n)^2 = 2^{2n} = 2^d$, they therefore form a basis of the full matrix algebra $M_N(\mathbb{C})$.*

Proof. Suppose $\sum_A c_A \Gamma_A = 0$. Fix any index B, multiply on the right by Γ_B^{-1}, and take the trace:

$$0 = \operatorname{Tr}\Big(\sum_A c_A \, \Gamma_A \Gamma_B^{-1} \Big) = \sum_A c_A \, \operatorname{Tr}(\Gamma_A \Gamma_B^{-1}). \tag{C.46}$$

Now $\Gamma_A \Gamma_B^{-1} = \pm \Gamma_C$ for some C, and $C = \varnothing$ (so $\Gamma_A \Gamma_B^{-1} = \pm \mathbf{1}$) if and only if $A = B$. By Theorem C.12, $\operatorname{Tr} \Gamma_C = 0$ whenever $C \neq \varnothing$, so every term with $A \neq B$ drops out, leaving $c_B \operatorname{Tr}(\pm \mathbf{1}) = \pm c_B N = 0$. Since $N \neq 0$, $c_B = 0$. As B was arbitrary, all coefficients vanish and the Γ_A are independent. They are $2^d = N^2$ independent elements of the N^2-dimensional space $M_N(\mathbb{C})$, hence a basis of it. □

Theorem C.13 is the structural heart of the even-dimensional theory: *the matrices generated by the gamma matrices fill out all of $M_N(\mathbb{C})$*. Equivalently, the map from the abstract 2^d-dimensional Clifford algebra of Section C.1 to $M_N(\mathbb{C})$ sending Γ_A to its constructed image is a surjection between spaces of equal dimension 2^d, hence an isomorphism. The even-dimensional Clifford algebra is therefore a full matrix algebra—in particular it is *simple* (it has no two-sided ideals other than $\{0\}$ and itself, since $M_N(\mathbb{C})$ does not). Both observations feed directly into irreducibility and uniqueness.

Theorem C.14 (Irreducibility and forced dimension)**.** *The representation of Theorem C.10 is irreducible. Moreover, every irreducible representation of the even-d Clifford algebra has dimension exactly $N = 2^{d/2}$.*

Proof. Irreducibility of the constructed representation. By Schur's lemma over $\mathbb{C}$ (Chapter 2), a finite-dimensional complex representation is irreducible if and only if its commutant is trivial, i.e. the only matrices commuting with every

representing matrix are scalar multiples of $\mathbf{1}$. Let M commute with all γ^μ. Then M commutes with every product Γ_A, hence with their entire span, which by Theorem C.13 is all of $M_N(\mathbb{C})$. A matrix commuting with every element of $M_N(\mathbb{C})$ lies in its center, and the center of a full matrix algebra consists exactly of the scalars; thus $M = \lambda\mathbf{1}$. The commutant is trivial, so the representation is irreducible.

Forced dimension. Let ρ be *any* irreducible representation, of some dimension N', of the even-d Clifford algebra. Because that algebra is simple (the paragraph following Theorem C.13), ρ is faithful: its kernel is a two-sided ideal, and a nonzero representation cannot have kernel equal to the whole algebra, so the kernel is $\{0\}$. Faithfulness means the images $\rho(\Gamma_A)$ are again linearly independent—the proof of Theorem C.13 used only the Clifford relations and tracelessness, both of which are preserved by any faithful representation[1]—so $2^d \le (N')^2$. For the reverse inequality we use that ρ is irreducible: by Schur the commutant of ρ is trivial, and an irreducibly-acting algebra of matrices on a finite-dimensional complex space spans the full endomorphism algebra (Burnside's theorem, Chapter 2). The algebra spanned by $\{\rho(\Gamma_A)\}$ is closed under multiplication (products of Γ_A are $\pm\Gamma_C$) and acts irreducibly, so its span is all of $M_{N'}(\mathbb{C})$; but that span has dimension at most 2^d, giving $(N')^2 \le 2^d$. Combining, $(N')^2 = 2^d$ and $N' = 2^{d/2} = N$. □

Thus in even dimension there is a single irreducible size, $2^{d/2}$, and in $d = 4$ this is the familiar 4. We close the subsection by recording the averaging identity that the irreducibility argument secretly contains; it is the same "sum over the group of Γ's" device that powers Pauli's theorem below and the Fierz machinery of Section C.8.

Worked Example C.15 (The completeness average)**.** For any $N \times N$ matrix X define the average $\Phi(X) = \sum_A \Gamma_A X \Gamma_A^{-1}$, the sum running over all 2^d basis elements. We claim

$$\Phi(X) = \sum_A \Gamma_A X \Gamma_A^{-1} = N\,(\operatorname{Tr} X)\,\mathbf{1}. \tag{C.47}$$

First, $\Phi(X)$ commutes with every Γ_B: conjugating term by term,

$$\Gamma_B\,\Phi(X)\,\Gamma_B^{-1} = \sum_A \Gamma_B\Gamma_A\,X\,\Gamma_A^{-1}\Gamma_B^{-1} = \sum_A (\Gamma_B\Gamma_A)\,X\,(\Gamma_B\Gamma_A)^{-1} = \sum_{A'} \Gamma_{A'}\,X\,\Gamma_{A'}^{-1} = \Phi(X), \tag{C.48}$$

because left multiplication by Γ_B permutes the Γ_A up to signs that cancel between $\Gamma_B\Gamma_A$ and its inverse, so $A \mapsto A'$ is a bijection of the index set. Since $\Phi(X)$ commutes with every Γ_B, hence with all of $M_N(\mathbb{C})$ (Theorem C.13), Schur

[1] Tracelessness in ρ follows verbatim from Theorem C.12, whose argument is purely algebraic; the trace there is the trace of $N' \times N'$ matrices and the conclusion $\operatorname{Tr}\rho(\Gamma_A) = 0$ for $A \neq \varnothing$ stands.

gives $\Phi(X) = \phi(X)\,\mathbf{1}$ for a scalar $\phi(X)$. Taking the trace fixes the scalar: $\operatorname{Tr}\Phi(X) = \sum_A \operatorname{Tr}(\Gamma_A X \Gamma_A^{-1}) = \sum_A \operatorname{Tr} X = 2^d \operatorname{Tr} X$, while $\operatorname{Tr}(\phi(X)\mathbf{1}) = N\phi(X)$, so $\phi(X) = 2^d \operatorname{Tr} X/N = N \operatorname{Tr} X$ using $2^d = N^2$. This proves Eq. (C.47). The same identity, written componentwise, is the statement $\sum_A (\Gamma_A)_{ij}(\Gamma_A^{-1})_{kl} = N\,\delta_{il}\delta_{kj}$, the completeness relation for the basis $\{\Gamma_A\}$ that we will reuse repeatedly.

C.2.3 Pauli's fundamental theorem

We can now prove the result on which the rest of the appendix rests. Two physicists who each write down four matrices obeying $\{\gamma^\mu, \gamma^\nu\} = 2\eta^{\mu\nu}\mathbf{1}$ in dimension 4 will in general write down *different* matrices—one in the Dirac basis, one in the chiral basis, one in some basis of their own. Pauli's theorem says these are never genuinely different: they are conjugate, and the conjugating matrix is essentially unique. This is what guarantees that a trace identity proved in one basis holds in all, and it is the abstract template every later intertwiner instantiates.

Theorem C.16 (Pauli's fundamental theorem)**.** *Let $\{\gamma^\mu\}$ and $\{\gamma'^\mu\}$, $\mu = 0, \dots, d-1$ with d even, be two sets of $N \times N$ matrices ($N = 2^{d/2}$) each satisfying $\{\gamma^\mu, \gamma^\nu\} = 2\eta^{\mu\nu}\mathbf{1}$. Then there exists an invertible matrix S with*

$$\gamma'^\mu = S\,\gamma^\mu\,S^{-1}, \qquad \mu = 0, \dots, d-1, \tag{C.49}$$

and S is unique up to a nonzero complex scalar.

Proof. Form the two product bases $\{\Gamma_A\}$ and $\{\Gamma'_A\}$ from the unprimed and primed generators using the *same* ordered index sets A. Because both sets obey identical Clifford relations, the combinatorics of their products is identical: for each generator index μ and each A,

$$\gamma^\mu\,\Gamma_A = \eta_A\,\Gamma_{B(A)} \qquad \Longleftrightarrow \qquad \gamma'^\mu\,\Gamma'_A = \eta_A\,\Gamma'_{B(A)}, \tag{C.50}$$

with the *same* sign $\eta_A \in \{\pm 1\}$ and the *same* reindexing $A \mapsto B(A)$, because the sign and the resulting index depend only on which generators appear in Γ_A and on the anticommutation rule—data shared by both sets. For fixed μ the map $A \mapsto B(A)$ is a bijection of the index set: left multiplication by the invertible γ^μ permutes the basis up to sign, so it has an inverse.

The averaging operator. For an arbitrary $N \times N$ matrix F define

$$S \equiv \sum_A \Gamma'_A\,F\,\Gamma_A^{-1}. \tag{C.51}$$

We claim that for *every* F this S intertwines the two sets: $\gamma'^\mu\,S = S\,\gamma^\mu$ for all μ. Compute, using Eq. (C.50) on the left factor and its consequence $\Gamma_A^{-1} =$

$\eta_A \Gamma^{-1}_{B(A)} \gamma^\mu$ on the right factor (which follows by inverting $\gamma^\mu \Gamma_A = \eta_A \Gamma_{B(A)}$ and using $\eta_A^2 = 1$):

$$\begin{aligned} \gamma'^\mu S &= \sum_A (\gamma'^\mu \Gamma'_A) F \Gamma_A^{-1} = \sum_A \eta_A \Gamma'_{B(A)} F \Gamma_A^{-1} \\ &= \sum_A \eta_A \Gamma'_{B(A)} F (\eta_A \Gamma^{-1}_{B(A)} \gamma^\mu) = \sum_A \eta_A^2 \Gamma'_{B(A)} F \Gamma^{-1}_{B(A)} \gamma^\mu \\ &= \Big(\sum_B \Gamma'_B F \Gamma_B^{-1} \Big) \gamma^\mu = S \gamma^\mu, \end{aligned} \tag{C.52}$$

where in the penultimate step we used that $A \mapsto B(A)$ is a bijection to relabel the sum. Thus Eq. (C.51) produces an intertwiner for any choice of F.

Some choice of F makes $S \neq 0$. View the assignment $F \mapsto S$ as the linear map $\sum_A \Gamma'_A (\cdot) \Gamma_A^{-1}$, whose kernel-or-not is governed by the tensor $\mathcal{T} = \sum_A \Gamma'_A \otimes (\Gamma_A^{-1})^\top \in M_N(\mathbb{C}) \otimes M_N(\mathbb{C})$; indeed $S = 0$ for all F would force $\mathcal{T} = 0$. But $\mathcal{T} \neq 0$. The matrices $\{\Gamma'_A\}$ are linearly independent (Theorem C.13 applied to the primed set), and so are $\{(\Gamma_A^{-1})^\top\} = \{\pm(\Gamma_A)^\top\}$ (transpose and sign preserve independence). For two families with $\{X_A\}$ independent and $\{Y_A\}$ independent, the "diagonal" tensors $\{X_A \otimes Y_A\}$ are themselves linearly independent: if $\sum_A c_A X_A \otimes Y_A = 0$, apply any linear functional ψ to the second factor to get $\sum_A c_A \psi(Y_A) X_A = 0$, whence $c_A \psi(Y_A) = 0$ for every A and every ψ by independence of the X_A; choosing for each A a ψ with $\psi(Y_A) \neq 0$ (possible since $Y_A \neq 0$) forces $c_A = 0$. Hence the 2^d tensors $\Gamma'_A \otimes (\Gamma_A^{-1})^\top$ are independent and their equal-coefficient sum $\mathcal{T}$ is nonzero. Therefore $S \neq 0$ for some F; fix such an F.

S is invertible. Both $\{\gamma^\mu\}$ and $\{\gamma'^\mu\}$ generate irreducible representations of dimension $N = 2^{d/2}$, by Theorem C.14. The relation Eq. (C.52) says S is a nonzero intertwiner between these two irreducible representations. By Schur's lemma (Chapter 2), a nonzero intertwiner between irreducible representations is an isomorphism, so S is invertible. Multiplying Eq. (C.52) on the right by S^{-1} yields Eq. (C.49).

Uniqueness up to scale. Suppose S and $\widetilde{S}$ both satisfy Eq. (C.49). Then $\gamma^\mu = S^{-1}\gamma'^\mu S = \widetilde{S}^{-1}\gamma'^\mu \widetilde{S}$, so $\widetilde{S}S^{-1}$ commutes with every γ'^μ. By the irreducibility of $\{\gamma'^\mu\}$ and Schur's lemma over $\mathbb{C}$, $\widetilde{S}S^{-1} = \lambda \mathbf{1}$ for a scalar λ, necessarily nonzero since $\widetilde{S}$ is invertible. Hence $\widetilde{S} = \lambda S$: the intertwiner is unique up to a nonzero multiplicative constant. □

Corollary C.17 (Reality of the scale and a canonical normalization)**.** *The residual freedom $S \to \lambda S$ in Pauli's theorem is exactly one complex scalar. Whenever a later construction supplements Eq. (C.49) with one further algebraic condition on S that is homogeneous of nonzero degree (for instance $S^\dagger S = \mathbf{1}$, fixing $|\lambda|$, or $S^2 = \pm\mathbf{1}$, or a prescribed value of a single matrix element), the scalar is pinned down up to a finite phase or sign. This is the mechanism by*

which γ^0, the charge-conjugation matrix C, and the discrete-symmetry matrices of Section C.4 acquire definite normalizations: each is the Pauli S for a specific second solution of the Clifford relation, made unique by one supplementary normalization.

Proof. The freedom is one scalar by Theorem C.16. A condition homogeneous of degree $k \neq 0$ in S becomes λ^k (or $\bar{\lambda}^j \lambda^k$ for mixed conjugate-degree conditions) times the corresponding quantity for the reference S; setting it to a fixed value is a polynomial equation in λ (or in λ and $\bar{\lambda}$) with finitely many solutions, leaving at most a finite phase/sign ambiguity. □

Caution

Pauli's theorem is a statement about the *full* set of d matrices satisfying the *same* Clifford relation, in the *irreducible* dimension. If two sets satisfy Clifford relations with opposite overall metric sign (one set with $\{\gamma^\mu, \gamma^\nu\} = 2\eta^{\mu\nu}$, the other with $-2\eta^{\mu\nu}$), they are generally *not* similar in even d, since $\mathrm{Tr}(\gamma^\mu \gamma^\nu) \propto \eta^{\mu\nu}$ is similarity-invariant and would flip sign. Such cases are handled not by similarity but by combining similarity with transposition or complex conjugation—precisely the loophole that defines the charge-conjugation matrix in Section C.4. Likewise, applying the theorem in a reducible dimension is illegitimate: there the intertwiner need not be unique, and the averaging operator can vanish identically.

C.2.4 The odd-dimensional case

For completeness, and to make precise why the physical case $d = 4$ enjoys a single irreducible representation, we record what changes in odd dimension. Let $d = 2n + 1$. Take the $2n$ even-dimensional generators $\gamma^0, \ldots, \gamma^{2n-1}$ of dimension $N = 2^n$ from Theorem C.10 (in the appropriate signature) and adjoin the chirality element

$$\gamma^{2n} \;\propto\; \gamma^0 \gamma^1 \cdots \gamma^{2n-1}, \tag{C.53}$$

normalized so that $(\gamma^{2n})^2 = \pm \mathbf{1}$ matches the required metric sign. As shown in Section C.1, this element anticommutes with each of $\gamma^0, \ldots, \gamma^{2n-1}$ and squares to a scalar, so $\{\gamma^0, \ldots, \gamma^{2n}\}$ obeys the $(2n+1)$-dimensional Clifford relation in dimension $N = 2^n = 2^{(d-1)/2}$. Two features distinguish this from the even case.

The top product is central. In dimension $d = 2n + 1$ the longest product $\gamma^0 \gamma^1 \cdots \gamma^{2n}$ contains *all* generators, an odd number of them. Moving any single γ^ν through it costs $2n$ sign flips (one for each of the other factors), an even number, so γ^ν commutes with the full product. The top product is thus central; by Schur it acts as a scalar in any irreducible representation. That scalar is fixed by the Clifford relations up to a sign—the two roots of $(\gamma^0 \cdots \gamma^{2n})^2 = \mathrm{const} \cdot \mathbf{1}$.

Two inequivalent irreducible representations. The two sign choices in Eq. (C.53)—equivalently, the two values $\pm$ that the central top product may take—give representations that are *not* related by any similarity, because the value of a central element is a similarity invariant. Concretely, $\{\gamma^0, \ldots, \gamma^{2n-1}, +\gamma^{2n}\}$ and $\{\gamma^0, \ldots, \gamma^{2n-1}, -\gamma^{2n}\}$ have central elements of opposite sign and so cannot satisfy $\gamma'^{\mu} = S\gamma^{\mu}S^{-1}$ for all μ simultaneously (the relation would force the central elements, hence their scalar values, to agree). Each of the two is irreducible of dimension $2^{(d-1)/2}$, by the same completeness-and-Schur argument as in the even case applied to the $2n$ traceless generators. Pauli's theorem therefore holds in odd d only *within* each of the two classes; across classes the best one can do is relate $\{\gamma^{\mu}\}$ to $\{-\gamma^{\mu}\}$ or invoke transposition.

This is exactly the structural reason the even case is cleaner. In even d the top product $\gamma^0 \cdots \gamma^{d-1} \propto \gamma^5$ has *even* length and *anticommutes* with every generator (each γ^{ν} flips $d-1$ signs, an odd number); it is therefore *not* central, the algebra is the simple matrix algebra $M_{2^{d/2}}(\mathbb{C})$, and there is a unique irreducible representation. For $d = 4$ this is the single 4-dimensional representation that all of relativistic field theory uses, and $\gamma^5 = i\gamma^0\gamma^1\gamma^2\gamma^3$ is the noncentral chirality operator whose anticommuting character makes the chiral projectors of Section C.3 possible.

With existence settled by the explicit 4×4 construction of Theorem C.11 and uniqueness settled by Pauli's theorem (Theorem C.16), we have the two tools the next section needs. Section C.3 writes down the Dirac, chiral, and Majorana representations as three specific solutions of the same Clifford relation; by Pauli's theorem each is conjugate to the others through a definite S, and the Hermiticity relation $\gamma^{\mu\dagger} = \gamma^0\gamma^{\mu}\gamma^0$ is itself an instance of Eq. (C.49) with $\gamma'^{\mu} = \gamma^{\mu\dagger}$—the first of the intertwining matrices that this theorem exists to deliver.

C.3 The Standard Representations: Dirac, Chiral, and Majorana

The previous section settled the structural question once and for all: in $d = 4$ the Clifford algebra $\{\gamma^{\mu}, \gamma^{\nu}\} = 2\eta^{\mu\nu} I_4$ has, up to similarity, exactly one irreducible representation, and it is four-dimensional (Section C.2). Pauli's fundamental theorem (Theorem C.16) tells us more: any two sets of 4×4 matrices obeying the same anticommutation relations are conjugate by a matrix that is unique up to an overall scale. The practical consequence is liberating. We are free to write down whatever explicit matrices are most convenient for the calculation at hand, secure in the knowledge that they all describe *the same* algebra and that every basis-independent statement—a trace, a chirality assignment, a spin sum—comes out the same in all of them. Different problems reward different choices: nonrelativistic reductions and the Dirac equation's plane-wave solutions

are cleanest in the *standard* (Dirac) basis; the splitting into left- and right-handed pieces, and with it the entire $V-A$ structure of the weak interaction and of QED, is manifest only in the *chiral* (Weyl) basis; the reality of the Dirac equation, and hence the Majorana condition, is laid bare by the *Majorana* basis. This section writes down all three, proves each satisfies the Clifford relation by direct matrix multiplication, exhibits the explicit unitary similarities promised by Pauli's theorem that carry one into another, builds γ^5 and the chirality projectors, fixes the Hermiticity convention $\gamma^{\mu\dagger} = \gamma^0\gamma^\mu\gamma^0$ that every later bilinear computation rests on, and closes the loop with Chapter 3 by showing that in the chiral basis the Lorentz generators split into precisely the $(\tfrac{1}{2},0)$ and $(0,\tfrac{1}{2})$ blocks of the abstract classification.

Throughout, I denotes the 2×2 identity, I_4 the 4×4 identity, and $\mathbf{0}$ a 2×2 block of zeros; all explicit matrices are written in 2×2 block form. The Pauli matrices are imported from Chapters 2 and B in the standard convention

$$\sigma^1 = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}, \quad \sigma^2 = \begin{pmatrix} 0 & -i \\ i & 0 \end{pmatrix}, \quad \sigma^3 = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}, \tag{C.54}$$

with the algebra we shall use repeatedly,

$$\sigma^i\sigma^j = \delta^{ij} I + i\,\epsilon^{ijk}\sigma^k, \qquad \Longrightarrow \qquad \left\{\sigma^i,\sigma^j\right\} = 2\delta^{ij} I, \quad \left[\sigma^i,\sigma^j\right] = 2i\,\epsilon^{ijk}\sigma^k, \tag{C.55}$$

and the Hermiticity $\sigma^{i\dagger} = \sigma^i$ together with $(\sigma^i)^2 = I$. Recall (Chapter A) the metric is $\eta_{\mu\nu} = \mathrm{diag}(+,-,-,-)$, so that the Clifford relation reads, component by component, $(\gamma^0)^2 = I_4$, $(\gamma^i)^2 = -I_4$, and $\{\gamma^\mu,\gamma^\nu\} = 0$ for $\mu \neq \nu$.

C.3.1 The Dirac (standard) representation

The historically first and still most widely used explicit choice is the one in which γ^0 is diagonal; it diagonalizes the rest mass, which is why nonrelativistic expansions are transparent in it.

Definition C.18 (Dirac representation)**.** The *Dirac* or *standard* representation is

$$\gamma^0 = \begin{pmatrix} I & \mathbf{0} \\ \mathbf{0} & -I \end{pmatrix}, \qquad \gamma^i = \begin{pmatrix} \mathbf{0} & \sigma^i \\ -\sigma^i & \mathbf{0} \end{pmatrix}, \qquad i = 1,2,3. \tag{C.56}$$

Proposition C.19. *The matrices* (C.56) *satisfy* $\{\gamma^\mu,\gamma^\nu\} = 2\eta^{\mu\nu} I_4$.

Proof. We compute the three independent cases by block multiplication. First,

$$(\gamma^0)^2 = \begin{pmatrix} I & \mathbf{0} \\ \mathbf{0} & -I \end{pmatrix}^2 = \begin{pmatrix} I & \mathbf{0} \\ \mathbf{0} & I \end{pmatrix} = I_4 = \eta^{00} I_4.$$

Next the mixed time–space anticommutator:

$$\gamma^0\gamma^i = \begin{pmatrix} I & \mathbf{0} \\ \mathbf{0} & -I \end{pmatrix}\begin{pmatrix} \mathbf{0} & \sigma^i \\ -\sigma^i & \mathbf{0} \end{pmatrix} = \begin{pmatrix} \mathbf{0} & \sigma^i \\ \sigma^i & \mathbf{0} \end{pmatrix},$$
$$\gamma^i\gamma^0 = \begin{pmatrix} \mathbf{0} & \sigma^i \\ -\sigma^i & \mathbf{0} \end{pmatrix}\begin{pmatrix} I & \mathbf{0} \\ \mathbf{0} & -I \end{pmatrix} = \begin{pmatrix} \mathbf{0} & -\sigma^i \\ -\sigma^i & \mathbf{0} \end{pmatrix},$$

whose sum is $\{\gamma^0, \gamma^i\} = \mathbf{0} = 2\eta^{0i} I_4$. Finally the spatial–spatial product,

$$\gamma^i\gamma^j = \begin{pmatrix} \mathbf{0} & \sigma^i \\ -\sigma^i & \mathbf{0} \end{pmatrix}\begin{pmatrix} \mathbf{0} & \sigma^j \\ -\sigma^j & \mathbf{0} \end{pmatrix} = \begin{pmatrix} -\sigma^i\sigma^j & \mathbf{0} \\ \mathbf{0} & -\sigma^i\sigma^j \end{pmatrix},$$

so, using $\{\sigma^i, \sigma^j\} = 2\delta^{ij} I$ from (C.55),

$$\left\{\gamma^i, \gamma^j\right\} = \begin{pmatrix} -\{\sigma^i, \sigma^j\} & \mathbf{0} \\ \mathbf{0} & -\{\sigma^i, \sigma^j\} \end{pmatrix} = -2\delta^{ij} I_4 = 2\eta^{ij} I_4,$$

since $\eta^{ij} = -\delta^{ij}$. The three cases together are exactly $\{\gamma^\mu, \gamma^\nu\} = 2\eta^{\mu\nu} I_4$. □

C.3.2 The chiral (Weyl) representation

The chiral basis differs from the Dirac basis only in γ^0 (the γ^i are identical), but that single change is exactly what is needed to make γ^5 diagonal and the handedness of a spinor a property of its upper versus lower components. It is the natural home for massless fermions and for the whole of QED's $V-A$ bookkeeping.

Definition C.20 (Chiral representation)**.** The *chiral* or *Weyl* representation is

$$\gamma^0 = \begin{pmatrix} \mathbf{0} & I \\ I & \mathbf{0} \end{pmatrix}, \qquad \gamma^i = \begin{pmatrix} \mathbf{0} & \sigma^i \\ -\sigma^i & \mathbf{0} \end{pmatrix}. \tag{C.57}$$

It is compactly written by introducing the two-component objects

$$\sigma^\mu \equiv (I,\ \sigma^i), \qquad \bar\sigma^\mu \equiv (I,\ -\sigma^i), \qquad \text{so that} \qquad \gamma^\mu = \begin{pmatrix} \mathbf{0} & \sigma^\mu \\ \bar\sigma^\mu & \mathbf{0} \end{pmatrix}. \tag{C.58}$$

The symbols $\sigma^\mu, \bar\sigma^\mu$ are the seeds of the van der Waerden two-component calculus developed in full in Section C.9; here we use them only as packaging.

Proposition C.21. *The matrices* (C.57) *satisfy* $\{\gamma^\mu, \gamma^\nu\} = 2\eta^{\mu\nu} I_4$.

Proof. With the packaging (C.58), a single block multiplication does all four-by-four cases at once:

$$\gamma^\mu\gamma^\nu = \begin{pmatrix} \mathbf{0} & \sigma^\mu \\ \bar\sigma^\mu & \mathbf{0} \end{pmatrix}\begin{pmatrix} \mathbf{0} & \sigma^\nu \\ \bar\sigma^\nu & \mathbf{0} \end{pmatrix} = \begin{pmatrix} \sigma^\mu\bar\sigma^\nu & \mathbf{0} \\ \mathbf{0} & \bar\sigma^\mu\sigma^\nu \end{pmatrix},$$

so that $\{\gamma^\mu,\gamma^\nu\}$ is block diagonal with upper block $\sigma^\mu\bar\sigma^\nu+\sigma^\nu\bar\sigma^\mu$ and lower block $\bar\sigma^\mu\sigma^\nu+\bar\sigma^\nu\sigma^\mu$. We show both equal $2\eta^{\mu\nu}I$. For $\mu=\nu=0$ both read $2I=2\eta^{00}I$. For $\mu=0,\nu=i$ the upper block is $\sigma^0\bar\sigma^i+\sigma^i\bar\sigma^0=(-\sigma^i)+\sigma^i=\mathbf{0}$, and likewise the lower; this is $2\eta^{0i}I$. For $\mu=i,\nu=j$ the upper block is

$$\sigma^i\bar\sigma^j+\sigma^j\bar\sigma^i=(-\sigma^i\sigma^j)+(-\sigma^j\sigma^i)=-\left\{\sigma^i,\sigma^j\right\}=-2\delta^{ij}I=2\eta^{ij}I,$$

and the lower block $\bar\sigma^i\sigma^j+\bar\sigma^j\sigma^i=-\{\sigma^i,\sigma^j\}=2\eta^{ij}I$ identically. Hence $\{\gamma^\mu,\gamma^\nu\}=2\eta^{\mu\nu}I_4$. □

The block identities just used,

$$\sigma^\mu\bar\sigma^\nu+\sigma^\nu\bar\sigma^\mu=2\eta^{\mu\nu}I,\qquad \bar\sigma^\mu\sigma^\nu+\bar\sigma^\nu\sigma^\mu=2\eta^{\mu\nu}I, \tag{C.59}$$

are the two-component shadow of the Clifford relation and will reappear as the workhorse of Section C.9.

C.3.3 The Majorana representation

The Dirac operator $i\gamma^\mu\partial_\mu-m$ has, generically, complex matrix entries, so its solutions are complex even when no charge is present. There exists, however, a basis in which *every* γ^μ is purely imaginary; then $i\gamma^\mu\partial_\mu-m$ is a real operator, the Dirac equation admits real solutions $\psi^*=\psi$, and a fermion can be its own antiparticle. This is the Majorana basis. Its very existence is a statement about the Clifford algebra in $d=4$, and it is the cleanest setting in which to discuss the reality (Majorana) condition systematically in Section C.4.

Definition C.22 (Majorana representation)**.** The *Majorana* representation is

$$\gamma^0=\begin{pmatrix}\mathbf{0}&\sigma^2\\ \sigma^2&\mathbf{0}\end{pmatrix},\quad \gamma^1=\begin{pmatrix}i\sigma^3&\mathbf{0}\\ \mathbf{0}&i\sigma^3\end{pmatrix},\quad \gamma^2=\begin{pmatrix}\mathbf{0}&-\sigma^2\\ \sigma^2&\mathbf{0}\end{pmatrix},\quad \gamma^3=\begin{pmatrix}-i\sigma^1&\mathbf{0}\\ \mathbf{0}&-i\sigma^1\end{pmatrix}. \tag{C.60}$$

Because σ^2 is purely imaginary while σ^1,σ^3 are real, every entry of every γ^μ in (C.60) is purely imaginary: $\gamma^{\mu*}=-\gamma^\mu$.

That all four are imaginary is the defining feature; that they satisfy the Clifford relation needs the same direct check as before. Because the bookkeeping is slightly heavier, we promote it to a worked example so that not a single anticommutator is taken on faith.

Worked Example C.23 (The Majorana matrices satisfy the Clifford relation)**.** We verify $\{\gamma^\mu,\gamma^\nu\}=2\eta^{\mu\nu}I_4$ for (C.60). Using $(\sigma^a)^2=I$ for the diagonal squares,

$$(\gamma^0)^2=\begin{pmatrix}\mathbf{0}&\sigma^2\\ \sigma^2&\mathbf{0}\end{pmatrix}^2=\begin{pmatrix}(\sigma^2)^2&\mathbf{0}\\ \mathbf{0}&(\sigma^2)^2\end{pmatrix}=I_4=\eta^{00}I_4,$$

$$(\gamma^1)^2 = \begin{pmatrix} (i\sigma^3)^2 & \mathbf{0} \\ \mathbf{0} & (i\sigma^3)^2 \end{pmatrix} = -I_4 = \eta^{11} I_4,$$
$$(\gamma^2)^2 = \begin{pmatrix} -(\sigma^2)^2 & \mathbf{0} \\ \mathbf{0} & -(\sigma^2)^2 \end{pmatrix} = -I_4 = \eta^{22} I_4,$$
$$(\gamma^3)^2 = \begin{pmatrix} (-i\sigma^1)^2 & \mathbf{0} \\ \mathbf{0} & (-i\sigma^1)^2 \end{pmatrix} = -I_4 = \eta^{33} I_4,$$

so the diagonal of the Clifford relation is the metric. For the six off-diagonal anticommutators we use $\left\{\sigma^a, \sigma^b\right\} = 2\delta^{ab} I$, i.e. distinct Pauli matrices anticommute. The pairs that mix an off-diagonal block (γ^0, γ^2) with a diagonal block (γ^1, γ^3) give, e.g.,

$$\gamma^0\gamma^1 = \begin{pmatrix} \mathbf{0} & i\sigma^2\sigma^3 \\ i\sigma^2\sigma^3 & \mathbf{0} \end{pmatrix}, \qquad \gamma^1\gamma^0 = \begin{pmatrix} \mathbf{0} & i\sigma^3\sigma^2 \\ i\sigma^3\sigma^2 & \mathbf{0} \end{pmatrix},$$

whose sum carries $i\{\sigma^2, \sigma^3\} = \mathbf{0}$; identically $\{\gamma^0, \gamma^3\}$ carries $-i\{\sigma^2, \sigma^1\} = \mathbf{0}$, $\{\gamma^2, \gamma^1\}$ carries $i\{\sigma^3, \sigma^2\} = \mathbf{0}$ (with a relative sign between the two off-diagonal blocks that does not affect their vanishing), and $\{\gamma^2, \gamma^3\}$ carries $i\{\sigma^2, \sigma^1\} = \mathbf{0}$. The two pairs within a single block type give

$$\left\{\gamma^0, \gamma^2\right\} = \begin{pmatrix} \sigma^2(-\sigma^2) + (-\sigma^2)\sigma^2 & \mathbf{0} \\ \mathbf{0} & (\sigma^2)^2 - (\sigma^2)^2 \end{pmatrix} = \mathbf{0},$$
$$\left\{\gamma^1, \gamma^3\right\} = \begin{pmatrix} \{i\sigma^3, -i\sigma^1\} & \mathbf{0} \\ \mathbf{0} & \{i\sigma^3, -i\sigma^1\} \end{pmatrix} = \begin{pmatrix} \{\sigma^3, \sigma^1\} & \mathbf{0} \\ \mathbf{0} & \{\sigma^3, \sigma^1\} \end{pmatrix} = \mathbf{0}.$$

All six off-diagonal anticommutators vanish, so $\{\gamma^\mu, \gamma^\nu\} = 2\eta^{\mu\nu} I_4$, and the representation is genuine.

C.3.4 The unitary equivalences

By Theorem C.16 the three representations are similar; because they are all built from Hermitian or anti-Hermitian blocks, the connecting similarities can be chosen unitary, which is what one wants physically (a change of spinor basis should preserve the inner product $\psi^\dagger\psi$). We exhibit the similarities explicitly rather than merely assert them.

Proposition C.24 (Dirac $\leftrightarrow$ chiral)**.** *With the unitary matrix*

$$U = \frac{1}{\sqrt{2}} \begin{pmatrix} I & -I \\ I & I \end{pmatrix}, \qquad U^{-1} = U^\dagger = \frac{1}{\sqrt{2}} \begin{pmatrix} I & I \\ -I & I \end{pmatrix}, \tag{C.61}$$

one has $\gamma^\mu_{\text{chiral}} = U\,\gamma^\mu_{\text{Dirac}}\,U^{-1}$.

Proof. Unitarity is the computation $UU^\dagger = \frac{1}{2}\left(\begin{smallmatrix} I & -I \\ I & I \end{smallmatrix}\right)\left(\begin{smallmatrix} I & I \\ -I & I \end{smallmatrix}\right) = \frac{1}{2}\left(\begin{smallmatrix} 2I & \mathbf{0} \\ \mathbf{0} & 2I \end{smallmatrix}\right) = I_4$. For γ^0,

$$U\gamma^0_{\text{Dirac}}U^{-1} = \frac{1}{2}\begin{pmatrix} I & -I \\ I & I \end{pmatrix}\begin{pmatrix} I & \mathbf{0} \\ \mathbf{0} & -I \end{pmatrix}\begin{pmatrix} I & I \\ -I & I \end{pmatrix} = \frac{1}{2}\begin{pmatrix} I & -I \\ I & I \end{pmatrix}\begin{pmatrix} I & I \\ I & -I \end{pmatrix}$$
$$= \frac{1}{2}\begin{pmatrix} \mathbf{0} & 2I \\ 2I & \mathbf{0} \end{pmatrix} = \begin{pmatrix} \mathbf{0} & I \\ I & \mathbf{0} \end{pmatrix} = \gamma^0_{\text{chiral}}.$$

For the spatial matrices, since $\gamma^i_{\text{Dirac}} = \gamma^i_{\text{chiral}}$ already, we need only check U leaves them fixed:

$$U\gamma^i_{\text{Dirac}}U^{-1} = \frac{1}{2}\begin{pmatrix} I & -I \\ I & I \end{pmatrix}\begin{pmatrix} \mathbf{0} & \sigma^i \\ -\sigma^i & \mathbf{0} \end{pmatrix}\begin{pmatrix} I & I \\ -I & I \end{pmatrix} = \frac{1}{2}\begin{pmatrix} \sigma^i & \sigma^i \\ -\sigma^i & \sigma^i \end{pmatrix}\begin{pmatrix} I & I \\ -I & I \end{pmatrix}$$
$$= \frac{1}{2}\begin{pmatrix} \mathbf{0} & 2\sigma^i \\ -2\sigma^i & \mathbf{0} \end{pmatrix} = \begin{pmatrix} \mathbf{0} & \sigma^i \\ -\sigma^i & \mathbf{0} \end{pmatrix} = \gamma^i_{\text{chiral}}.$$ □

Proposition C.25 (Dirac ↔ Majorana)**.** *With the Hermitian unitary involution*

$$W = \frac{1}{\sqrt{2}}\begin{pmatrix} I & \sigma^2 \\ \sigma^2 & -I \end{pmatrix}, \qquad W^\dagger = W, \qquad W^2 = I_4 \;\Rightarrow\; W^{-1} = W, \tag{C.62}$$

one has $\gamma^\mu_{\text{Majorana}} = W\,\gamma^\mu_{\text{Dirac}}\,W$.

Proof. That $W = W^\dagger$ follows from $\sigma^{2\dagger} = \sigma^2$; that $W^2 = I_4$ is $\frac{1}{2}\left(\begin{smallmatrix} I & \sigma^2 \\ \sigma^2 & -I \end{smallmatrix}\right)^2 = \frac{1}{2}\left(\begin{smallmatrix} I+(\sigma^2)^2 & \mathbf{0} \\ \mathbf{0} & (\sigma^2)^2+I \end{smallmatrix}\right) = I_4$. We verify the conjugation on each $\gamma^\mu_{\text{Dirac}}$ from (C.56), using $(\sigma^2)^2 = I$, $\sigma^2\sigma^1 = -i\sigma^3$, $\sigma^2\sigma^3 = i\sigma^1$, and their reverses:

$$W\gamma^0_{\text{Dirac}}W = \frac{1}{2}\begin{pmatrix} I & \sigma^2 \\ \sigma^2 & -I \end{pmatrix}\begin{pmatrix} I & \mathbf{0} \\ \mathbf{0} & -I \end{pmatrix}\begin{pmatrix} I & \sigma^2 \\ \sigma^2 & -I \end{pmatrix} = \begin{pmatrix} \mathbf{0} & \sigma^2 \\ \sigma^2 & \mathbf{0} \end{pmatrix} = \gamma^0_{\text{Majorana}},$$

$$W\gamma^1_{\text{Dirac}}W = \frac{1}{2}\begin{pmatrix} I & \sigma^2 \\ \sigma^2 & -I \end{pmatrix}\begin{pmatrix} \mathbf{0} & \sigma^1 \\ -\sigma^1 & \mathbf{0} \end{pmatrix}\begin{pmatrix} I & \sigma^2 \\ \sigma^2 & -I \end{pmatrix} = \begin{pmatrix} i\sigma^3 & \mathbf{0} \\ \mathbf{0} & i\sigma^3 \end{pmatrix} = \gamma^1_{\text{Majorana}},$$

$$W\gamma^2_{\text{Dirac}}W = \begin{pmatrix} \mathbf{0} & -\sigma^2 \\ \sigma^2 & \mathbf{0} \end{pmatrix} = \gamma^2_{\text{Majorana}}, \qquad W\gamma^3_{\text{Dirac}}W = \begin{pmatrix} -i\sigma^1 & \mathbf{0} \\ \mathbf{0} & -i\sigma^1 \end{pmatrix} = \gamma^3_{\text{Majorana}},$$

where the last two follow by the identical block arithmetic. (As a check on γ^1: the $(1,1)$ block of $W\gamma^1_{\text{D}}W$ is $\frac{1}{2}[\sigma^2(-\sigma^1) + (-\sigma^1)\cdot 0 \cdot \dots]$; carrying out the two multiplications gives $\frac{1}{2}(\sigma^2\sigma^1\cdot(-1)+\dots)$ which collapses to $i\sigma^3$ once $\sigma^2\sigma^1 = -i\sigma^3$ is used.) All four match (C.60), so $\gamma^\mu_{\text{Majorana}} = W\gamma^\mu_{\text{Dirac}}W$. □

These two propositions make Pauli's abstract theorem concrete: the Dirac, chiral, and Majorana bases are connected by the unitaries U and W (and by WU^{-1} for chiral → Majorana). Any object defined invariantly—the chirality of a state, a trace of gamma matrices, an unpolarized squared amplitude—is therefore the same number in all three, which is precisely why the book is free to compute QED's traces (Chapters 17 and 19) in whatever basis is most convenient.

C.3.5 The chirality matrix γ^5 and its projectors

We now build the single most important derived object of the Clifford algebra, the chirality matrix. Its definition is fixed (Chapter A) as

$$\gamma^5 \equiv i\,\gamma^0\gamma^1\gamma^2\gamma^3 = -\tfrac{i}{4!}\,\epsilon_{\mu\nu\rho\sigma}\gamma^\mu\gamma^\nu\gamma^\rho\gamma^\sigma, \tag{C.63}$$

the second form (with $\epsilon^{0123} = +1$, equivalently $\epsilon_{0123} = -1$) following because the totally antisymmetrized product of all four distinct gammas is $\gamma^0\gamma^1\gamma^2\gamma^3$ times the sign of the permutation. Its defining algebraic properties are representation-independent; we prove them from (C.63) and the Clifford relation alone.

Proposition C.26 (Properties of γ^5)**.** γ^5 *obeys*

$$(\gamma^5)^2 = I_4, \qquad \left\{\gamma^5, \gamma^\mu\right\} = 0 \quad (\mu = 0,1,2,3), \qquad \gamma^{5\dagger} = \gamma^5, \qquad \operatorname{tr}\gamma^5 = 0. \tag{C.64}$$

Proof. Square. Write $A \equiv \gamma^0\gamma^1\gamma^2\gamma^3$, so $\gamma^5 = iA$ and $(\gamma^5)^2 = -A^2$. Evaluate A^2 by sliding each repeated factor leftward and using $\{\gamma^\mu, \gamma^\nu\} = 0$ for $\mu \neq \nu$:

$$\begin{aligned} A^2 = \gamma^0\gamma^1\gamma^2\gamma^3\,\gamma^0\gamma^1\gamma^2\gamma^3 &= (-1)^3(\gamma^0)^2\,\gamma^1\gamma^2\gamma^3\gamma^1\gamma^2\gamma^3 && \text{(move the second } \gamma^0 \text{ left past } \gamma^3\gamma^2\gamma^1\text{)} \\ &= -(\gamma^0)^2(-1)^2(\gamma^1)^2\,\gamma^2\gamma^3\gamma^2\gamma^3 && \text{(move } \gamma^1 \text{ left past } \gamma^3\gamma^2\text{)} \\ &= -(\gamma^0)^2(\gamma^1)^2(-1)(\gamma^2)^2(\gamma^3)^2 && \text{(move } \gamma^2 \text{ left past } \gamma^3\text{)}. \end{aligned}$$

Now insert $(\gamma^0)^2 = +I_4$ and $(\gamma^1)^2 = (\gamma^2)^2 = (\gamma^3)^2 = -I_4$:

$$A^2 = -(+1)(-1)(-1)(-1)(-1)\,I_4 = -\,I_4,$$

so $(\gamma^5)^2 = -A^2 = +I_4$.

Anticommutation with γ^μ. Fix μ. Among the four factors $\gamma^0\gamma^1\gamma^2\gamma^3$ in A, exactly three carry an index different from μ (with which γ^μ anticommutes) and exactly one equals γ^μ (with which it commutes trivially as it is the same matrix). Sliding γ^μ from the right all the way through A to merge with its own copy therefore produces three sign changes,

$$\gamma^\mu A = (-1)^3 A\gamma^\mu = -A\gamma^\mu \quad\Longrightarrow\quad \gamma^\mu\gamma^5 = -\gamma^5\gamma^\mu,$$

i.e. $\{\gamma^5, \gamma^\mu\} = 0$. (Concretely for $\mu = 0$: $\gamma^0 A = \gamma^0\gamma^0\gamma^1\gamma^2\gamma^3$, while $A\gamma^0 = \gamma^0\gamma^1\gamma^2\gamma^3\gamma^0 = (-1)^3\gamma^0\gamma^0\gamma^1\gamma^2\gamma^3$, so $\gamma^0 A = -A\gamma^0$.)

Hermiticity. Using the Hermiticity relation $\gamma^{\mu\dagger} = \gamma^0\gamma^\mu\gamma^0$ proved in Theorem C.30 below,

$$\gamma^{5\dagger} = (i\gamma^0\gamma^1\gamma^2\gamma^3)^\dagger = -i\,\gamma^{3\dagger}\gamma^{2\dagger}\gamma^{1\dagger}\gamma^{0\dagger} = -i\,(\gamma^0\gamma^3\gamma^0)(\gamma^0\gamma^2\gamma^0)(\gamma^0\gamma^1\gamma^0)\,\gamma^0 = -i\,\gamma^0\gamma^3\gamma^2\gamma^1,$$

where the adjacent pairs $\gamma^0\gamma^0 = I$ have cancelled. Reversing the order $\gamma^3\gamma^2\gamma^1$ back to $\gamma^1\gamma^2\gamma^3$ costs the sign $(-1)^3$, so $\gamma^{5\dagger} = +i\,\gamma^0\gamma^1\gamma^2\gamma^3 = \gamma^5$. (Equivalently,

in the chiral basis $\gamma^5 = \mathrm{diag}(-I, I)$ is manifestly Hermitian, and since Hermiticity of a matrix is preserved under the unitary changes of basis of Section C.3.4, $\gamma^{5\dagger} = \gamma^5$ in every one of our representations.)

Tracelessness. Because $(\gamma^0)^2 = I_4$ and γ^5 anticommutes with γ^0,

$$\operatorname{tr}\gamma^5 = \operatorname{tr}(\gamma^5(\gamma^0)^2) = \operatorname{tr}(\gamma^0\gamma^5\gamma^0) = -\operatorname{tr}((\gamma^0)^2\gamma^5) = -\operatorname{tr}\gamma^5,$$

where the second equality is cyclicity of the trace and the third is $\gamma^5\gamma^0 = -\gamma^0\gamma^5$. Hence $2\operatorname{tr}\gamma^5 = 0$, i.e. $\operatorname{tr}\gamma^5 = 0$. □

The anticommutation $\{\gamma^5, \gamma^\mu\} = 0$ is the structural fact that makes γ^5 commute with the Lorentz generators $\sigma^{\mu\nu} \propto [\gamma^\mu, \gamma^\nu]$ (an even product of gammas), so that γ^5 is a Lorentz scalar and its eigenspaces are Lorentz-invariant. Those eigenspaces are the chiralities, isolated by the projectors:

Definition C.27 (Chirality projectors)**.**

$$P_L \equiv \frac{1-\gamma^5}{2}, \qquad P_R \equiv \frac{1+\gamma^5}{2}. \tag{C.65}$$

A spinor with $\gamma^5\psi = -\psi$ (so $P_L\psi = \psi$) is *left-handed*; one with $\gamma^5\psi = +\psi$ (so $P_R\psi = \psi$) is *right-handed*.

Proposition C.28. *The $P_{L,R}$ are a complete set of orthogonal projectors:*

$$P_L + P_R = I_4, \qquad P_L^2 = P_L, \qquad P_R^2 = P_R, \qquad P_L P_R = P_R P_L = \mathbf{0}. \tag{C.66}$$

Moreover they obey the intertwining relation $\gamma^\mu P_L = P_R\gamma^\mu$ and $\gamma^\mu P_R = P_L\gamma^\mu$.

Proof. Completeness is immediate: $P_L + P_R = \frac{1}{2}[(1-\gamma^5) + (1+\gamma^5)] = I_4$. Idempotency uses $(\gamma^5)^2 = I_4$:

$$P_L^2 = \frac{(1-\gamma^5)^2}{4} = \frac{1 - 2\gamma^5 + (\gamma^5)^2}{4} = \frac{2-2\gamma^5}{4} = \frac{1-\gamma^5}{2} = P_L,$$

and likewise $P_R^2 = P_R$. Orthogonality is the difference of squares:

$$P_L P_R = \frac{(1-\gamma^5)(1+\gamma^5)}{4} = \frac{1-(\gamma^5)^2}{4} = \mathbf{0},$$

and $P_R P_L = \mathbf{0}$ identically. Finally, since $\gamma^\mu\gamma^5 = -\gamma^5\gamma^\mu$,

$$\gamma^\mu P_L = \gamma^\mu \frac{1-\gamma^5}{2} = \frac{1+\gamma^5}{2}\gamma^\mu = P_R\gamma^\mu,$$

and similarly $\gamma^\mu P_R = P_L\gamma^\mu$. □

The intertwining $\gamma^\mu P_L = P_R \gamma^\mu$ is the algebraic origin of the chirality flip that a vector current induces: it is why $\bar\psi\gamma^\mu\psi$ couples left to left and right to right, while a mass term $\bar\psi\psi$ couples left to right. This is the backbone of the $V-A$ structure that QED and the electroweak chapters will lean on.

It is worth recording γ^5 and the projectors in each basis, since chapters quote them. From (C.63) by direct multiplication:

$$\gamma^5_{\text{Dirac}} = \begin{pmatrix} \mathbf{0} & I \\ I & \mathbf{0} \end{pmatrix}, \qquad \gamma^5_{\text{chiral}} = \begin{pmatrix} -I & \mathbf{0} \\ \mathbf{0} & I \end{pmatrix}, \qquad \gamma^5_{\text{Majorana}} = \begin{pmatrix} \sigma^2 & \mathbf{0} \\ \mathbf{0} & -\sigma^2 \end{pmatrix}. \tag{C.67}$$

In the chiral basis γ^5 is diagonal, so the projectors are the trivial block projectors

$$P_L = \begin{pmatrix} I & \mathbf{0} \\ \mathbf{0} & \mathbf{0} \end{pmatrix}, \qquad P_R = \begin{pmatrix} \mathbf{0} & \mathbf{0} \\ \mathbf{0} & I \end{pmatrix}, \tag{C.68}$$

which is the whole point of the chiral basis: a Dirac spinor $\psi = (\psi_L, \psi_R)^{\mathsf T}$ wears its handedness on its sleeve, the upper two components being the left-handed Weyl spinor and the lower two the right-handed one. In the Majorana basis, by contrast, γ^5 is purely imaginary, consistent with $\gamma^{\mu *} = -\gamma^\mu$ and $\gamma^5 = i\gamma^0\gamma^1\gamma^2\gamma^3$. Let us confirm the first entry of (C.67).

Worked Example C.29 (γ^5 in the Dirac and chiral bases)**.** In the Dirac basis, $\gamma^1\gamma^2 = \left(\begin{smallmatrix} -\sigma^1\sigma^2 & \mathbf{0} \\ \mathbf{0} & -\sigma^1\sigma^2 \end{smallmatrix}\right) = \left(\begin{smallmatrix} -i\sigma^3 & \mathbf{0} \\ \mathbf{0} & -i\sigma^3 \end{smallmatrix}\right)$ using $\sigma^1\sigma^2 = i\sigma^3$. Then

$$\gamma^1\gamma^2\gamma^3 = \begin{pmatrix} -i\sigma^3 & \mathbf{0} \\ \mathbf{0} & -i\sigma^3 \end{pmatrix} \begin{pmatrix} \mathbf{0} & \sigma^3 \\ -\sigma^3 & \mathbf{0} \end{pmatrix} = \begin{pmatrix} \mathbf{0} & -i(\sigma^3)^2 \\ i(\sigma^3)^2 & \mathbf{0} \end{pmatrix} = \begin{pmatrix} \mathbf{0} & -iI \\ iI & \mathbf{0} \end{pmatrix},$$

and so

$$\gamma^5_{\text{Dirac}} = i\gamma^0\gamma^1\gamma^2\gamma^3 = i \begin{pmatrix} I & \mathbf{0} \\ \mathbf{0} & -I \end{pmatrix} \begin{pmatrix} \mathbf{0} & -iI \\ iI & \mathbf{0} \end{pmatrix} = i \begin{pmatrix} \mathbf{0} & -iI \\ -iI & \mathbf{0} \end{pmatrix} = \begin{pmatrix} \mathbf{0} & I \\ I & \mathbf{0} \end{pmatrix},$$

which is the first matrix in (C.67). Applying the equivalence of Theorem C.24, $\gamma^5_{\text{chiral}} = U\gamma^5_{\text{Dirac}}U^{-1} = \frac{1}{2}\left(\begin{smallmatrix} I & -I \\ I & I \end{smallmatrix}\right)\left(\begin{smallmatrix} \mathbf{0} & I \\ I & \mathbf{0} \end{smallmatrix}\right)\left(\begin{smallmatrix} I & I \\ -I & I \end{smallmatrix}\right) = \left(\begin{smallmatrix} -I & \mathbf{0} \\ \mathbf{0} & I \end{smallmatrix}\right)$, the diagonal form. Thus the same invariant matrix γ^5 is off-diagonal in the Dirac basis and diagonal in the chiral basis—a vivid illustration that "which components are left-handed" is a basis-dependent statement, while "γ^5 has eigenvalues ± 1, each twice" is not.

C.3.6 The Hermiticity convention

To form Lorentz-covariant bilinears one needs $\psi^\dagger\Gamma\psi$ to transform correctly, and this hinges on how $\gamma^{\mu\dagger}$ relates to γ^μ. The relation is uniform across all three of our bases and is the convention adopted throughout the book.

Theorem C.30 (Hermiticity relation)**.** *In the Dirac, chiral, and Majorana representations,*

$$\gamma^{0\dagger} = \gamma^0, \qquad \gamma^{i\dagger} = -\gamma^i, \tag{C.69}$$

which combine into the single covariant statement

$$\boxed{\gamma^{\mu\dagger} = \gamma^0 \gamma^\mu \gamma^0} \tag{C.70}$$

The same relation holds in every representation related to these by a unitary similarity.

Proof. Component relations. In the Dirac basis $\gamma^0 = \mathrm{diag}(I, -I)$ is real symmetric, hence Hermitian: $\gamma^{0\dagger} = \gamma^0$. The spatial $\gamma^i = \left(\begin{smallmatrix} \mathbf{0} & \sigma^i \\ -\sigma^i & \mathbf{0} \end{smallmatrix}\right)$ has Hermitian conjugate $\left(\begin{smallmatrix} \mathbf{0} & -\sigma^{i\dagger} \\ \sigma^{i\dagger} & \mathbf{0} \end{smallmatrix}\right) = \left(\begin{smallmatrix} \mathbf{0} & -\sigma^i \\ \sigma^i & \mathbf{0} \end{smallmatrix}\right) = -\gamma^i$, using $\sigma^{i\dagger} = \sigma^i$. The same two facts hold in the chiral basis ($\gamma^0 = \left(\begin{smallmatrix} \mathbf{0} & I \\ I & \mathbf{0} \end{smallmatrix}\right)$ is Hermitian, the γ^i are identical to the Dirac ones), and in the Majorana basis one checks directly from (C.60): $\gamma^0 = \left(\begin{smallmatrix} \mathbf{0} & \sigma^2 \\ \sigma^2 & \mathbf{0} \end{smallmatrix}\right)$ is Hermitian, while $\gamma^{1\dagger} = \left(\begin{smallmatrix} (i\sigma^3)^\dagger & \mathbf{0} \\ \mathbf{0} & (i\sigma^3)^\dagger \end{smallmatrix}\right) = \left(\begin{smallmatrix} -i\sigma^3 & \mathbf{0} \\ \mathbf{0} & -i\sigma^3 \end{smallmatrix}\right) = -\gamma^1$, and identically $\gamma^{2\dagger} = -\gamma^2$, $\gamma^{3\dagger} = -\gamma^3$ (each spatial Majorana matrix is anti-Hermitian, being i times a Hermitian Pauli block).

Covariant form. We show (C.69) is equivalent to (C.70), using only $(\gamma^0)^2 = I_4$ and the Clifford relation. For the time component, $\gamma^0\gamma^0\gamma^0 = (\gamma^0)^2\gamma^0 = \gamma^0 = \gamma^{0\dagger}$. For a space component, $\gamma^0\gamma^i\gamma^0 = \gamma^0\gamma^i\gamma^0$; since $\{\gamma^0, \gamma^i\} = 0$ we have $\gamma^i\gamma^0 = -\gamma^0\gamma^i$, so

$$\gamma^0\gamma^i\gamma^0 = \gamma^0\,(\gamma^i\gamma^0) = \gamma^0(-\gamma^0\gamma^i) = -(\gamma^0)^2\gamma^i = -\gamma^i = \gamma^{i\dagger}.$$

Thus $\gamma^{\mu\dagger} = \gamma^0\gamma^\mu\gamma^0$ for every μ.

Stability under unitary change of basis. If $\gamma^{\mu\prime} = S\gamma^\mu S^{-1}$ with S unitary ($S^{-1} = S^\dagger$), then

$$\gamma^{\mu\prime\dagger} = (S\gamma^\mu S^{-1})^\dagger = S\,\gamma^{\mu\dagger}\,S^{-1} = S\,(\gamma^0\gamma^\mu\gamma^0)\,S^{-1} = (S\gamma^0 S^{-1})(S\gamma^\mu S^{-1})(S\gamma^0 S^{-1}) = \gamma^{0\prime}\gamma^{\mu\prime}\gamma^{0}$$

so the relation (C.70) is preserved with γ^0 replaced by the transformed $\gamma^{0\prime}$. Since U and W of Section C.3.4 are unitary, all three standard bases obey (C.70). □

Remark C.31 (Representation-independent existence; first sight of an intertwiner). The relation (C.70) is more than a convenient feature of three particular bases. Taking the Hermitian conjugate of $\{\gamma^\mu, \gamma^\nu\} = 2\eta^{\mu\nu} I_4$ gives $\left\{\gamma^{\nu\dagger}, \gamma^{\mu\dagger}\right\} = 2\eta^{\mu\nu} I_4$, i.e. the four matrices $\{\gamma^{\mu\dagger}\}$ satisfy the *same* Clifford relation as $\{\gamma^\mu\}$. By Pauli's fundamental theorem (Theorem C.16) there is therefore a matrix A, unique up to scale, with

$$\gamma^{\mu\dagger} = A\,\gamma^\mu\,A^{-1} \qquad \text{for all } \mu, \tag{C.71}$$

and one shows A may be chosen Hermitian; in our bases the choice is exactly $A = \gamma^0$. This A—the *Dirac conjugation* or Hermitizing matrix—is the first and simplest member of the family of intertwining matrices that the next section classifies. It is the reason the Dirac adjoint is $\bar\psi = \psi^\dagger\gamma^0$ rather than $\psi^\dagger$: only with the γ^0 inserted does $\bar\psi\psi$ transform as a scalar.

The same Hermiticity relation controls the conjugate of the Lorentz generator. Define the antisymmetric tensor of gammas

$$\sigma^{\mu\nu} \equiv \frac{i}{2}\left[\gamma^\mu, \gamma^\nu\right], \tag{C.72}$$

(the same object whose bilinear $\bar\psi\sigma^{\mu\nu}\psi$ is catalogued in Section C.5). Its Hermiticity follows mechanically.

Proposition C.32. $(\sigma^{\mu\nu})^\dagger = \gamma^0\sigma^{\mu\nu}\gamma^0$.

Proof. Conjugating (C.72),

$$(\sigma^{\mu\nu})^\dagger = -\frac{i}{2}\left[\gamma^\mu, \gamma^\nu\right]^\dagger = -\frac{i}{2}(\gamma^{\nu\dagger}\gamma^{\mu\dagger} - \gamma^{\mu\dagger}\gamma^{\nu\dagger}) = \frac{i}{2}\left[\gamma^{\mu\dagger}, \gamma^{\nu\dagger}\right].$$

Insert $\gamma^{\mu\dagger} = \gamma^0\gamma^\mu\gamma^0$ and use $(\gamma^0)^2 = I_4$ to cancel the inner pair:

$$\left[\gamma^0\gamma^\mu\gamma^0, \gamma^0\gamma^\nu\gamma^0\right] = \gamma^0\gamma^\mu\gamma^\nu\gamma^0 - \gamma^0\gamma^\nu\gamma^\mu\gamma^0 = \gamma^0\left[\gamma^\mu, \gamma^\nu\right]\gamma^0,$$

hence $(\sigma^{\mu\nu})^\dagger = \dfrac{i}{2}\gamma^0\left[\gamma^\mu, \gamma^\nu\right]\gamma^0 = \gamma^0\sigma^{\mu\nu}\gamma^0$. □

C.3.7 The chiral basis and the $(\frac{1}{2}, 0) \oplus (0, \frac{1}{2})$ decomposition

We close the section by tying the chiral basis back to the abstract Lorentz representation theory of Chapter 3. There a Dirac spinor was identified as the reducible representation $(\frac{1}{2}, 0) \oplus (0, \frac{1}{2})$ of the Lorentz algebra $\mathfrak{so}(1,3) \cong \mathfrak{su}(2) \oplus \mathfrak{su}(2)$, the two summands being the left- and right-handed Weyl spinors. We now *see* this directly: in the chiral basis the spin-$\frac{1}{2}$ Lorentz generators are block diagonal, and the two blocks act exactly as the two Weyl representations.

Recall (Chapter 3) that on a Dirac field the Lorentz generators are

$$S^{\mu\nu} = \frac{i}{4}\left[\gamma^\mu, \gamma^\nu\right] = \frac{1}{2}\sigma^{\mu\nu}, \qquad \psi \to \exp\Big(-\tfrac{i}{2}\omega_{\mu\nu}S^{\mu\nu}\Big)\psi, \tag{C.73}$$

with rotation generators $J^k = \frac{1}{2}\epsilon^{kij}S^{ij}$ and boost generators $K^i = S^{0i}$. We compute these in the chiral basis.

Worked Example C.33 (Block-diagonalization of the Lorentz generators)**.** *Boosts.* In the chiral basis,

$$\gamma^0\gamma^i = \begin{pmatrix} \mathbf{0} & I \\ I & \mathbf{0} \end{pmatrix}\begin{pmatrix} \mathbf{0} & \sigma^i \\ -\sigma^i & \mathbf{0} \end{pmatrix} = \begin{pmatrix} -\sigma^i & \mathbf{0} \\ \mathbf{0} & \sigma^i \end{pmatrix}, \quad \gamma^i\gamma^0 = \begin{pmatrix} \mathbf{0} & \sigma^i \\ -\sigma^i & \mathbf{0} \end{pmatrix}\begin{pmatrix} \mathbf{0} & I \\ I & \mathbf{0} \end{pmatrix} = \begin{pmatrix} \sigma^i & \mathbf{0} \\ \mathbf{0} & -\sigma^i \end{pmatrix},$$

so $\left[\gamma^0, \gamma^i\right] = \left(\begin{smallmatrix} -2\sigma^i & \mathbf{0} \\ \mathbf{0} & 2\sigma^i \end{smallmatrix}\right)$ and

$$K^i = S^{0i} = \frac{i}{4}\left[\gamma^0, \gamma^i\right] = \begin{pmatrix} -\frac{i}{2}\sigma^i & \mathbf{0} \\ \mathbf{0} & +\frac{i}{2}\sigma^i \end{pmatrix}. \tag{C.74}$$

Rotations. Likewise

$$\gamma^i\gamma^j = \begin{pmatrix} \mathbf{0} & \sigma^i \\ -\sigma^i & \mathbf{0} \end{pmatrix}\begin{pmatrix} \mathbf{0} & \sigma^j \\ -\sigma^j & \mathbf{0} \end{pmatrix} = \begin{pmatrix} -\sigma^i\sigma^j & \mathbf{0} \\ \mathbf{0} & -\sigma^i\sigma^j \end{pmatrix} \Rightarrow \left[\gamma^i, \gamma^j\right] = \begin{pmatrix} -\left[\sigma^i, \sigma^j\right] & \mathbf{0} \\ \mathbf{0} & -\left[\sigma^i, \sigma^j\right] \end{pmatrix}$$

and with $\left[\sigma^i, \sigma^j\right] = 2i\epsilon^{ijk}\sigma^k$,

$$S^{ij} = \frac{i}{4}\left[\gamma^i, \gamma^j\right] = \frac{i}{4}(-2i\epsilon^{ijk})\begin{pmatrix} \sigma^k & \mathbf{0} \\ \mathbf{0} & \sigma^k \end{pmatrix} = \frac{1}{2}\epsilon^{ijk}\begin{pmatrix} \sigma^k & \mathbf{0} \\ \mathbf{0} & \sigma^k \end{pmatrix}, \tag{C.75}$$

so that $J^k = \frac{1}{2}\epsilon^{kij}S^{ij} = \frac{1}{4}\epsilon^{kij}\epsilon^{ijl}\,\mathrm{diag}(\sigma^l, \sigma^l) = \frac{1}{2}\,\mathrm{diag}(\sigma^k, \sigma^k)$, using $\epsilon^{kij}\epsilon^{lij} = 2\delta^{kl}$.

Reading off the two Weyl representations. Both K^i and J^k are block diagonal, so the Lorentz action never mixes the upper two components with the lower two: the chiral Dirac spinor $\psi = (\psi_L, \psi_R)^{\mathsf{T}}$ splits into two invariant two-component pieces. On the upper (left) block,

$$J^k_L = \tfrac{1}{2}\sigma^k, \qquad K^i_L = -\tfrac{i}{2}\sigma^i,$$

while on the lower (right) block $J^k_R = \frac{1}{2}\sigma^k$, $K^i_R = +\frac{i}{2}\sigma^i$. Forming the standard self-dual/anti-self-dual combinations $A^i = \frac{1}{2}(J^i + iK^i)$ and $B^i = \frac{1}{2}(J^i - iK^i)$ that diagonalize $\mathfrak{su}(2) \oplus \mathfrak{su}(2)$ (Chapter 3), the upper block gives

$$A^i_L = \tfrac{1}{2}(\tfrac{1}{2}\sigma^i + i(-\tfrac{i}{2}\sigma^i)) = \tfrac{1}{2}\sigma^i, \qquad B^i_L = \tfrac{1}{2}(\tfrac{1}{2}\sigma^i - i(-\tfrac{i}{2}\sigma^i)) = 0,$$

so the left block carries spin $\frac{1}{2}$ under the first $\mathfrak{su}(2)$ and spin 0 under the second: it is the $(\frac{1}{2}, 0)$ representation. The lower block gives the mirror image,

$$A^i_R = \tfrac{1}{2}(\tfrac{1}{2}\sigma^i + i(+\tfrac{i}{2}\sigma^i)) = 0, \qquad B^i_R = \tfrac{1}{2}(\tfrac{1}{2}\sigma^i - i(+\tfrac{i}{2}\sigma^i)) = \tfrac{1}{2}\sigma^i,$$

the $(0, \frac{1}{2})$ representation. Thus the chiral Dirac spinor is exactly $(\frac{1}{2}, 0) \oplus (0, \frac{1}{2})$, with P_L projecting onto $(\frac{1}{2}, 0)$ and P_R onto $(0, \frac{1}{2})$, in precise agreement with Chapter 3.

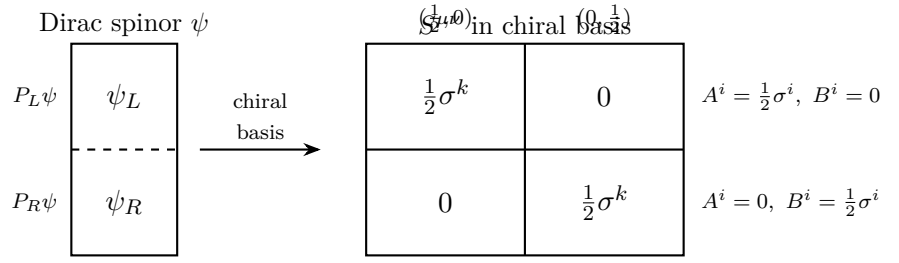

Figure C.1: In the chiral basis $\gamma^5 = \mathrm{diag}(-I, I)$ is diagonal, so the projectors $P_{L,R}$ split a Dirac spinor into its two-component Weyl pieces ψ_L, ψ_R. The Lorentz generators $S^{\mu\nu} = \frac{i}{4}[\gamma^\mu, \gamma^\nu]$ are then block diagonal: the upper block realizes the $(\frac{1}{2}, 0)$ representation ($A^i = \frac{1}{2}\sigma^i$, $B^i = 0$) and the lower block the $(0, \frac{1}{2})$ representation, matching the classification of Chapter 3.

The agreement is not a coincidence of conventions: it is forced. Because $\gamma^5 = \mathrm{diag}(-I, I)$ commutes with every $S^{\mu\nu}$ (an even product of gammas), its ∓ 1 eigenspaces are Lorentz-invariant, and the projectors $P_{L,R}$ of (C.68) are precisely the projectors onto the two irreducible Weyl summands. The boost generators (C.74) are anti-Hermitian-times-i in a way that differs by a sign between the blocks—this is the concrete statement that the finite-dimensional spinor representation of the boosts is *non-unitary* (as it must be, the Lorentz group being noncompact), and that complex conjugation exchanges the two Weyl types, $(\frac{1}{2}, 0) \leftrightarrow (0, \frac{1}{2})$. Fig. C.1 summarizes the block structure.

With three concrete representations in hand, the explicit unitaries relating them, and the Hermiticity relation $\gamma^{\mu\dagger} = \gamma^0\gamma^\mu\gamma^0$, we have met our first intertwining matrix in the guise of γ^0: the matrix that conjugates the set $\{\gamma^\mu\}$ into the set $\{\gamma^{\mu\dagger}\}$, both of which obey the identical Clifford relation. The next section takes this single example and turns it into a system, classifying *all* the matrices that intertwine $\{\gamma^\mu\}$ with $\{-\gamma^{\mu\mathsf{T}}\}$, $\{\gamma^{\mu *}\}$, and $\{\gamma^{\mu\dagger}\}$—the Dirac, charge-conjugation, and parity/time-reversal matrices—and characterizing precisely when a spinor may be its own conjugate, the Majorana condition that the imaginary representation of Section C.3.3 was built to expose.

C.4 Conjugation and Intertwining Matrices: Dirac, Charge, Parity, Time Reversal

The Hermiticity relation $\gamma^{\mu\dagger} = \gamma^0\gamma^\mu\gamma^0$ established with the explicit matrices of Section C.3 is more than a bookkeeping convenience: it is the statement that the matrix γ^0 *intertwines* two different sets of 4×4 matrices, $\{\gamma^\mu\}$ and $\{\gamma^{\mu\dagger}\}$, both of which obey the same Clifford relation $\{\gamma^\mu, \gamma^\nu\} = 2\eta^{\mu\nu}$. This is one instance of a general phenomenon. From a given representation $\{\gamma^\mu\}$ one can manufacture

four sets of matrices by applying the three antilinear/linear operations that preserve the algebra,

$$\{\gamma^\mu\}, \qquad \{-\gamma^{\mu T}\}, \qquad \{\gamma^{\mu *}\}, \qquad \{\gamma^{\mu \dagger}\}, \tag{C.76}$$

each of which, as we verify below, again satisfies the Clifford relation. Pauli's fundamental theorem (Section C.2) then guarantees that in $d = 4$, where the irreducible representation is unique up to similarity, each of these four sets is conjugate to $\{\gamma^\mu\}$ by a matrix that is unique up to an overall scalar. Those intertwiners are precisely the workhorse matrices of every spinorial manipulation in the book: the Dirac (Hermiticity/parity) matrix γ^0, the charge-conjugation matrix C, the reality matrix B, and the time-reversal matrix. This section pins them down, proves their algebraic properties, builds the symmetry table that the next section needs, and characterizes the Majorana reality condition representation-independently.

C.4.1 The four Clifford-equivalent representations

Proposition C.34 (The conjugate sets obey the Clifford relation)**.** *If* $\{\gamma^\mu\}$ *satisfies* $\{\gamma^\mu, \gamma^\nu\} = 2\eta^{\mu\nu}\mathbf{1}$*, then so do each of* $\{\gamma^{\mu\dagger}\}$*,* $\{\gamma^{\mu *}\}$*, and* $\{-\gamma^{\mu T}\}$*.*

Proof. The metric components $\eta^{\mu\nu}$ are real, so taking the Hermitian conjugate of the Clifford relation gives

$$\{\gamma^{\mu\dagger}, \gamma^{\nu\dagger}\} = \left(\{\gamma^\nu, \gamma^\mu\}\right)^\dagger = (2\eta^{\mu\nu}\mathbf{1})^\dagger = 2\eta^{\mu\nu}\mathbf{1}, \tag{C.77}$$

using $(\gamma^\mu\gamma^\nu)^\dagger = \gamma^{\nu\dagger}\gamma^{\mu\dagger}$ and $\eta^{\mu\nu} = \eta^{\nu\mu}$. Identically, complex conjugation gives $\{\gamma^{\mu *}, \gamma^{\nu *}\} = (\{\gamma^\mu, \gamma^\nu\})^* = 2\eta^{\mu\nu}\mathbf{1}$. For the transpose, $(\gamma^\mu\gamma^\nu + \gamma^\nu\gamma^\mu)^T = \gamma^{\nu T}\gamma^{\mu T} + \gamma^{\mu T}\gamma^{\nu T} = \{\gamma^{\mu T}, \gamma^{\nu T}\}$, so

$$\{-\gamma^{\mu T}, -\gamma^{\nu T}\} = \{\gamma^{\mu T}, \gamma^{\nu T}\} = \left(\{\gamma^\mu, \gamma^\nu\}\right)^T = 2\eta^{\mu\nu}\mathbf{1}, \tag{C.78}$$

the two minus signs squaring to a plus. □

Because each set in (C.76) is a four-dimensional representation of the same Clifford algebra, and that algebra has a unique irreducible representation up to similarity in $d = 4$ (Section C.2), there exist nonsingular matrices effecting the conjugations. We name them as follows.

Definition C.35 (Intertwining matrices)**.** The *Dirac (Hermiticity) matrix* A, the *charge-conjugation matrix* C, and the *reality matrix* B are the nonsingular 4×4 matrices, each unique up to a nonzero scalar, defined by

$$A\,\gamma^\mu A^{-1} = \gamma^{\mu\dagger}, \tag{C.79}$$

$$C\,\gamma^\mu C^{-1} = -\gamma^{\mu T}, \tag{C.80}$$

$$B\,\gamma^\mu B^{-1} = \gamma^{\mu *}. \tag{C.81}$$

Their existence and uniqueness-up-to-scale are immediate from Pauli's theorem applied, respectively, to the sets $\{\gamma^{\mu\dagger}\}$, $\{-\gamma^{\mu T}\}$, and $\{\gamma^{\mu *}\}$ of Theorem C.34: each is conjugate to $\{\gamma^\mu\}$, and Schur's lemma fixes the conjugating matrix up to a scalar (any two such conjugators differ by a matrix commuting with the irreducible $\{\gamma^\mu\}$, hence by a multiple of $\mathbf{1}$). The three matrices are not independent. Since $\gamma^{\mu *} = (\gamma^{\mu\dagger})^T$, the reality matrix can be built from A and C; we make this explicit in Section C.4.8. The relationships are summarized in Fig. C.2.

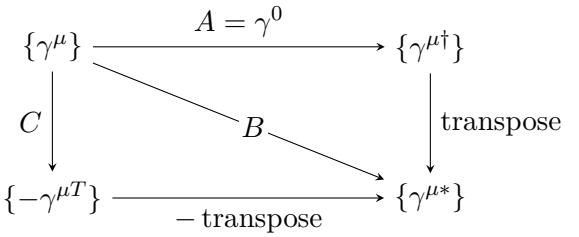

Figure C.2: The four Clifford-equivalent representations of (C.76) and the intertwiners relating them. The Dirac matrix $A = \gamma^0$ produces the Hermitian conjugate, C the negative transpose, and B the complex conjugate. Since $\gamma^{\mu *} = (\gamma^{\mu\dagger})^T = -(\gamma^{\mu T})^\dagger$ the square commutes up to scalars, fixing B in terms of A and C.

C.4.2 The Dirac matrix and the parity matrix

The matrix A of (C.79) is the one already met in Section C.3: the Hermiticity relation proved there says exactly that $\gamma^0\gamma^\mu\gamma^0 = \gamma^{\mu\dagger}$, so in every standard representation

$$A = \gamma^0, \qquad A^\dagger = A, \qquad A^2 = \mathbf{1}. \tag{C.82}$$

This is the matrix that defines the Dirac adjoint $\bar\psi = \psi^\dagger A = \psi^\dagger\gamma^0$ (Chapter 11); its job is to convert $\psi^\dagger$, which transforms in the conjugate of the spinor representation, into an object that pairs with ψ to make Lorentz covariants. We will see in Section C.5 that the existence of A with $A\gamma^\mu A^{-1} = \gamma^{\mu\dagger}$ is precisely what makes $\bar\psi\Gamma_A\psi$ transform cleanly.

The same matrix governs parity. The parity operation reflects the spatial axes, $x = (t, \mathbf{x}) \mapsto (t, -\mathbf{x})$, which on the gamma matrices is the map $\gamma^0 \mapsto \gamma^0$, $\gamma^i \mapsto -\gamma^i$. This is implemented by conjugation with γ^0:

$$\gamma^0\gamma^\mu\gamma^0 = \gamma_\mu = (\gamma^0, -\gamma^i), \tag{C.83}$$

which follows at once from $\{\gamma^0, \gamma^i\} = 0$ and $(\gamma^0)^2 = \mathbf{1}$. Hence the matrix accompanying the parity transformation of the Dirac field, $\psi(t, \mathbf{x}) \mapsto \eta_P\,\gamma^0\psi(t, -\mathbf{x})$, is γ^0 up to the unobservable phase η_P. The physical content of P as an operator on Fock space is developed in Chapter 11; here we record only that the *parity matrix is the Dirac matrix* $A = \gamma^0$, doing double duty.

C.4.3 The charge-conjugation matrix: existence and uniqueness

Theorem C.36 (Existence and uniqueness of C)**.** *In $d = 4$ there exists a nonsingular matrix C, unique up to a nonzero scalar, satisfying $C\gamma^\mu C^{-1} = -\gamma^{\mu T}$.*

Proof. By Theorem C.34 the set $\{-\gamma^{\mu T}\}$ obeys the Clifford relation and is a four-dimensional representation, hence irreducible and equivalent to $\{\gamma^\mu\}$ by Pauli's fundamental theorem (Section C.2). Equivalence is exactly the existence of a nonsingular C with $-\gamma^{\mu T} = C\gamma^\mu C^{-1}$. For uniqueness, suppose C' also satisfies $C'\gamma^\mu C'^{-1} = -\gamma^{\mu T}$. Then $C^{-1}C'$ commutes with every γ^μ:

$$C^{-1}C'\,\gamma^\mu\,(C^{-1}C')^{-1} = C^{-1}(C'\gamma^\mu C'^{-1})C = C^{-1}(-\gamma^{\mu T})C = \gamma^\mu. \tag{C.84}$$

Since $\{\gamma^\mu\}$ acts irreducibly, Schur's lemma forces $C^{-1}C' = \lambda\,\mathbf{1}$, i.e. $C' = \lambda C$. □

Caution

The *sign* chosen in (C.80) is a convention adapted to $d = 4$. In an even dimension both $\{+\gamma^{\mu T}\}$ and $\{-\gamma^{\mu T}\}$ are equivalent to $\{\gamma^\mu\}$ — they are related to each other by conjugation with γ^5, which obeys $\gamma^5\gamma^\mu(\gamma^5)^{-1} = -\gamma^\mu$ — so there are in fact two transpose-intertwiners, C (for $-\gamma^{\mu T}$) and $C' \propto C\gamma^5$ (for $+\gamma^{\mu T}$). In odd dimensions only one of the two signs occurs. The symmetry $C^T = \pm C$ derived next, and the existence of Majorana spinors, depend on d mod 8; we prove the $d = 4$ facts and flag the general pattern where it matters.

C.4.4 Symmetry of C and the bilinear symmetry table

Theorem C.37 (Antisymmetry of C in $d = 4$)**.** *The charge-conjugation matrix of Theorem C.36 satisfies $C^T = -C$.*

Proof. We proceed in two steps: first that $C^T = \lambda C$ with $\lambda = \pm 1$, then that $\lambda = -1$ by counting.

Step 1 — $C^T = \pm C$. Transpose the defining relation $C\gamma^\mu C^{-1} = -\gamma^{\mu T}$. The left side transposes to $(C^{-1})^T\gamma^{\mu T}C^T = (C^T)^{-1}\gamma^{\mu T}C^T$, the right side to $-\gamma^\mu$, so

$$(C^T)^{-1}\gamma^{\mu T}C^T = -\gamma^\mu. \tag{C.85}$$

Now substitute $\gamma^{\mu T} = -C\gamma^\mu C^{-1}$ (the defining relation rearranged):

$$(C^T)^{-1}(-C\gamma^\mu C^{-1})C^T = -\gamma^\mu \implies (C^{-1}C^T)^{-1}\gamma^\mu(C^{-1}C^T) = \gamma^\mu. \tag{C.86}$$

Thus $M \equiv C^{-1}C^T$ commutes with all γ^μ, and Schur's lemma gives $M = \lambda\mathbf{1}$, i.e. $C^T = \lambda C$. Transposing this once more, $C = \lambda C^T = \lambda^2 C$, so $\lambda^2 = 1$ and $\lambda = \pm 1$.

Step 2 — the counting argument fixes $\lambda = -1$. Recall the sixteen matrices

$$\{\Gamma_A\} = \{\mathbf{1},\ \gamma^\mu,\ \sigma^{\mu\nu}\ (\mu<\nu),\ \gamma^\mu\gamma^5,\ \gamma^5\}, \qquad \sigma^{\mu\nu} = \tfrac{i}{2}[\gamma^\mu,\gamma^\nu], \tag{C.87}$$

which are linearly independent and span the full algebra of 4×4 matrices (Section C.5). Since C is invertible, the sixteen products $\{C\Gamma_A\}$ are likewise a basis of the 16-dimensional matrix algebra. Every 4×4 matrix splits uniquely into a symmetric and an antisymmetric part, and the spaces of symmetric and antisymmetric 4×4 matrices have dimensions $\binom{4+1}{2} = 10$ and $\binom{4}{2} = 6$ respectively. A basis of the full algebra in which every element is purely symmetric or purely antisymmetric must therefore contain exactly 10 symmetric and 6 antisymmetric members. We now show that each $C\Gamma_A$ *is* purely symmetric or antisymmetric, compute which, and read off λ from the requirement that the totals come out $(10, 6)$.

For each basis element define the sign $t_A = \pm 1$ by $\Gamma_A^T = t_A\, C\Gamma_A C^{-1}$; this is well defined because conjugation by C maps each Γ_A to a multiple of its own transpose, as we verify. Then

$$(C\Gamma_A)^T = \Gamma_A^T C^T = (t_A\, C\Gamma_A C^{-1})(\lambda C) = \lambda t_A\, C\Gamma_A, \tag{C.88}$$

so $C\Gamma_A$ is symmetric when $\lambda t_A = +1$ and antisymmetric when $\lambda t_A = -1$. The signs t_A follow directly from (C.80):

- $\Gamma = \mathbf{1}$: trivially $\mathbf{1}^T = \mathbf{1} = C\mathbf{1}C^{-1}$, so $t = +1$.
- $\Gamma = \gamma^\mu$: $\gamma^{\mu T} = -C\gamma^\mu C^{-1}$, so $t = -1$.
- $\Gamma = \sigma^{\mu\nu}$: using $[\gamma^\mu,\gamma^\nu]^T = [\gamma^{\nu T},\gamma^{\mu T}] = -[\gamma^{\mu T},\gamma^{\nu T}]$ and $\gamma^{\mu T} = -C\gamma^\mu C^{-1}$,

  $$[\gamma^{\mu T},\gamma^{\nu T}] = [\,-C\gamma^\mu C^{-1}, -C\gamma^\nu C^{-1}] = C[\gamma^\mu,\gamma^\nu]C^{-1}, \tag{C.89}$$

  hence $\sigma^{\mu\nu T} = \frac{i}{2}[\gamma^\mu,\gamma^\nu]^T = -C\,\frac{i}{2}[\gamma^\mu,\gamma^\nu]\,C^{-1} = -C\sigma^{\mu\nu}C^{-1}$, so $t = -1$.
- $\Gamma = \gamma^5$: with $\gamma^5 = i\gamma^0\gamma^1\gamma^2\gamma^3$,

  $$\gamma^{5T} = i\,\gamma^{3T}\gamma^{2T}\gamma^{1T}\gamma^{0T} = i(-1)^4 C\,\gamma^3\gamma^2\gamma^1\gamma^0\,C^{-1} = i\,C\,\gamma^0\gamma^1\gamma^2\gamma^3\,C^{-1} = C\gamma^5 C^{-1}, \tag{C.90}$$

  where reversing the order of four distinct anticommuting factors costs $(-1)^{4\cdot 3/2} = +1$, so $\gamma^3\gamma^2\gamma^1\gamma^0 = \gamma^0\gamma^1\gamma^2\gamma^3$; thus $t = +1$.
- $\Gamma = \gamma^\mu\gamma^5$: $(\gamma^\mu\gamma^5)^T = \gamma^{5T}\gamma^{\mu T} = (C\gamma^5C^{-1})(-C\gamma^\mu C^{-1}) = -C\gamma^5\gamma^\mu C^{-1} = C\gamma^\mu\gamma^5 C^{-1}$, using $\gamma^5\gamma^\mu = -\gamma^\mu\gamma^5$; so $t = +1$.

Collecting the multiplicities, $t_A = +1$ for the six matrices $\{\mathbf{1},\gamma^5,\gamma^\mu\gamma^5\}$ and $t_A = -1$ for the ten matrices $\{\gamma^\mu,\sigma^{\mu\nu}\}$. By (C.88) the number of *antisymmetric* $C\Gamma_A$ is the number with $\lambda t_A = -1$:

$$\lambda = +1: \quad \text{antisymmetric} \Leftrightarrow t_A = -1: \quad \# = 4 + 6 = 10, \tag{C.91}$$

$$\lambda = -1: \quad \text{antisymmetric} \Leftrightarrow t_A = +1: \quad \# = 1 + 1 + 4 = 6. \tag{C.92}$$

Only $\lambda = -1$ yields the required 6 antisymmetric (and correspondingly 10 symmetric) matrices; $\lambda = +1$ would demand 10 antisymmetric 4×4 matrices, which is impossible. Therefore $\lambda = -1$, i.e. $C^T = -C$. □

The same computation hands the next section its central tool. Combining $C^T = -C$ with the signs t_A gives the symmetry of each bilinear-form matrix $C\Gamma_A$, the data that controls Fierz rearrangement and the symmetry of Majorana bilinears.

Table C.1: Symmetry of the matrices $C\Gamma_A$ in $d = 4$, where $(C\Gamma_A)^T = \lambda t_A (C\Gamma_A)$ with $\lambda = -1$. "S" denotes symmetric, "A" antisymmetric. The counts (10 symmetric, 6 antisymmetric) saturate the dimensions of the symmetric and antisymmetric 4×4 matrices.

Γ_A	multiplicity	t_A	$(C\Gamma_A)^T/(C\Gamma_A)$	symmetry
$\mathbf{1}$	1	$+1$	-1	A
γ^μ	4	-1	$+1$	S
$\sigma^{\mu\nu}$	6	-1	$+1$	S
$\gamma^\mu\gamma^5$	4	$+1$	-1	A
γ^5	1	$+1$	-1	A
		totals:	S= 10	A= 6

C.4.5 The explicit form $C = i\gamma^2\gamma^0$

Theorems C.36–C.37 fix C abstractly; in the Dirac and chiral representations of Section C.3 it has a clean closed form. The relevant input is the transpose pattern of the standard matrices. In both the Dirac and chiral bases the spatial matrices are built from the Pauli matrices (Chapter B) as $\gamma^i = \left(\begin{smallmatrix} 0 & \sigma^i \\ -\sigma^i & 0 \end{smallmatrix}\right)$, with σ^1, σ^3 real symmetric and σ^2 imaginary antisymmetric, while γ^0 is symmetric. Consequently

$$\gamma^{0T} = \gamma^0, \quad \gamma^{1T} = -\gamma^1, \quad \gamma^{2T} = \gamma^2, \quad \gamma^{3T} = -\gamma^3, \tag{C.93}$$

so γ^0, γ^2 are symmetric and γ^1, γ^3 antisymmetric; equivalently, γ^2 is the unique imaginary matrix, $\gamma^{\mu *} = \gamma^\mu$ for $\mu \neq 2$ and $\gamma^{2*} = -\gamma^2$.

Lemma C.38 (Explicit charge-conjugation matrix)**.** *In any representation with the transpose pattern* (C.93) *(in particular the Dirac and chiral bases),*

$$C = i\gamma^2\gamma^0, \qquad C^{-1} = -C, \qquad C^2 = -\mathbf{1}, \qquad C^T = -C, \qquad C^\dagger = C^{-1}. \tag{C.94}$$

Proof. We verify the intertwining property and then each algebraic relation, carrying all the algebra. First, the auxiliary relations

$$(\gamma^0)^2 = \mathbf{1}, \qquad (\gamma^2)^2 = \eta^{22}\mathbf{1} = -\mathbf{1}, \qquad \gamma^0\gamma^2 = -\gamma^2\gamma^0. \tag{C.95}$$

From these, $C^{-1} = (i\gamma^2\gamma^0)^{-1} = -i\,(\gamma^0)^{-1}(\gamma^2)^{-1} = -i\,\gamma^0(-\gamma^2) = i\gamma^0\gamma^2 = -i\gamma^2\gamma^0 = -C$. Hence $C^{-1} = -C$, equivalently $C^2 = -\mathbf{1}$.

Next the intertwining. With $C^{-1} = -C = -i\gamma^2\gamma^0$,

$$C\gamma^\mu C^{-1} = (i\gamma^2\gamma^0)\gamma^\mu(-i\gamma^2\gamma^0) = \gamma^2\gamma^0\gamma^\mu\gamma^2\gamma^0. \tag{C.96}$$

Evaluate component by component using only the anticommutation rules and $\gamma^0\gamma^2\gamma^0 = -\gamma^2$:

$$\mu = 0: \quad \gamma^2\gamma^0\gamma^0\gamma^2\gamma^0 = \gamma^2\gamma^2\gamma^0 = (\gamma^2)^2\gamma^0 = -\gamma^0 = -\gamma^{0T}, \tag{C.97}$$

$$\mu = 1: \quad \gamma^2\gamma^0\gamma^1\gamma^2\gamma^0 = -\gamma^2\gamma^1(\gamma^0\gamma^2\gamma^0) = -\gamma^2\gamma^1(-\gamma^2) = \gamma^2\gamma^1\gamma^2 = -(\gamma^2)^2\gamma^1 = \gamma^1 = -\gamma^{1T}, \tag{C.98}$$

$$\mu = 2: \quad \gamma^2\gamma^0\gamma^2\gamma^2\gamma^0 = \gamma^2\gamma^0(-1)\gamma^0 = -\gamma^2 = -\gamma^{2T}, \tag{C.99}$$

$$\mu = 3: \quad \gamma^2\gamma^0\gamma^3\gamma^2\gamma^0 = -\gamma^2\gamma^3(\gamma^0\gamma^2\gamma^0) = -\gamma^2\gamma^3(-\gamma^2) = \gamma^2\gamma^3\gamma^2 = -(\gamma^2)^2\gamma^3 = \gamma^3 = -\gamma^{3T}, \tag{C.100}$$

where in the last column we used the transpose pattern (C.93). Thus $C\gamma^\mu C^{-1} = -\gamma^{\mu T}$ for all μ, confirming (C.80).

Finally the symmetry and unitarity. Using $\gamma^{0T} = \gamma^0$, $\gamma^{2T} = \gamma^2$,

$$C^T = (i\gamma^2\gamma^0)^T = i\,\gamma^{0T}\gamma^{2T} = i\gamma^0\gamma^2 = -i\gamma^2\gamma^0 = -C, \tag{C.101}$$

reproducing $C^T = -C$ from Theorem C.37 in this basis. For the adjoint, the Hermiticity convention $\gamma^{i\dagger} = -\gamma^i$, $\gamma^{0\dagger} = \gamma^0$ gives

$$C^\dagger = (i\gamma^2\gamma^0)^\dagger = -i\,\gamma^{0\dagger}\gamma^{2\dagger} = -i\,\gamma^0(-\gamma^2) = i\gamma^0\gamma^2 = -i\gamma^2\gamma^0 = -C = C^{-1}, \tag{C.102}$$

so C is unitary, $C^\dagger C = \mathbf{1}$. □

The relation $C^\dagger = C^{-1}$ is not forced by Theorems C.36 and C.37 alone — it is a normalization. The scalar freedom $C \to zC$ rescales $C^\dagger C \to |z|^2 C^\dagger C$, and one checks (by the same Schur argument as for uniqueness) that $C^\dagger C$ is a positive multiple of $\mathbf{1}$; choosing $|z|$ to make $C^\dagger C = \mathbf{1}$ is always possible and is the standard convention adopted here. With that and $C^T = -C$ fixed, the only remaining freedom is a phase, fixed by (C.94) to give $C^2 = -\mathbf{1}$.

C.4.6 Intertwining of γ^5 and $\sigma^{\mu\nu}$

The signs t_A computed in the proof of Theorem C.37 are exactly the statements of how C conjugates the higher basis elements, since $\Gamma_A^T = t_A C\Gamma_A C^{-1}$ means $C\Gamma_A C^{-1} = t_A\Gamma_A^T$. Reading them off:

Proposition C.39 (C on γ^5 and $\sigma^{\mu\nu}$)**.** *The charge-conjugation matrix satisfies*

$$C\gamma^5 C^{-1} = \gamma^{5T}, \qquad C\,\sigma^{\mu\nu}C^{-1} = -\sigma^{\mu\nu T}, \qquad C(\gamma^\mu\gamma^5)C^{-1} = (\gamma^\mu\gamma^5)^T = \gamma^{5T}\gamma^{\mu T}. \tag{C.103}$$

These three relations, together with $C\gamma^\mu C^{-1} = -\gamma^{\mu T}$ and $C\mathbf{1}C^{-1} = \mathbf{1}$, complete the action of C on the entire basis. In the chiral and Dirac representations γ^5 is symmetric, $\gamma^{5T} = \gamma^5$, so the first relation reads $C\gamma^5 C^{-1} = \gamma^5$: charge conjugation commutes with chirality up to the transpose, which is the algebraic root of the fact (used in Chapter 11 and in the anomaly analysis of Chapter 36) that charge conjugation maps a left-handed antiparticle to a right-handed particle. The second relation, $C\sigma^{\mu\nu}C^{-1} = -\sigma^{\mu\nu T}$, is what makes the tensor bilinear $\bar\psi\sigma^{\mu\nu}\psi$ odd under C.

C.4.7 Charge conjugation of spinors and the antiparticle solutions

We can now make precise the operation that turns a particle wavefunction into the corresponding antiparticle wavefunction at the level of the Dirac matrices — the algebraic backbone of every v-spinor manipulation in QED (Chapters 17 and 18). The charge-conjugate of a Dirac field is defined (Chapter 11) by

$$\psi^c \equiv C\bar\psi^{\,T}, \qquad \bar\psi = \psi^\dagger\gamma^0. \tag{C.104}$$

Worked Example C.40 (The v-spinors as charge conjugates of the u-spinors)**.** Let $u^s(p)$ be a positive-energy solution of the Dirac equation in momentum space, so that $(\not p - m)u^s(p) = 0$ and, taking the Dirac adjoint, $\bar u^s(p)(\not p - m) = 0$. We show that the charge conjugate of u solves the *negative*-energy equation $(\not p + m)v = 0$, which is the defining equation of the v-spinors, so that $v^s(p) \propto C\bar u^s(p)^T$.

Start from the adjoint equation and transpose it, using $(\not p)^T = p_\mu\gamma^{\mu T}$:

$$\bar u(\not p - m) = 0 \quad \xRightarrow{\text{transpose}} \quad (p_\mu\gamma^{\mu T} - m)\,\bar u^{\,T} = 0. \tag{C.105}$$

Now eliminate the transposed gammas with $\gamma^{\mu T} = -C\gamma^\mu C^{-1}$:

$$(-C\,p_\mu\gamma^\mu C^{-1} - m)\,\bar u^{\,T} = 0. \tag{C.106}$$

Left-multiply by $-C^{-1}$ and use $C^{-1}\bar u^T$ as the new object:

$$(p_\mu\gamma^\mu + m)\,C^{-1}\bar u^{\,T} = 0 \quad \Longleftrightarrow \quad (\not p + m)\,(C^{-1}\bar u^{\,T}) = 0. \tag{C.107}$$

Thus $C^{-1}\bar u^{\,T}$ satisfies exactly the v-spinor equation. Because $C^{-1} = -C$ (Theorem C.38) and (C.107) is homogeneous, $C\bar u^{\,T}$ solves it as well; the overall sign is the conventional phase, and the standard normalization fixes

$$v^s(p) = C\,\bar u^s(p)^{\,T}, \qquad u^s(p) = C\,\bar v^s(p)^{\,T}, \tag{C.108}$$

the second relation following by the same computation with $m \to -m$. This is the identity that lets every spin sum and trace over antiparticle states in Chapters 17 and 18 be rewritten in terms of u-spinors, and it is the reason the completeness relations $\sum_s u\bar{u} = \not{p} + m$ and $\sum_s v\bar{v} = \not{p} - m$ are charge conjugates of one another.

C.4.8 Time reversal and the reality matrix

Time reversal is antiunitary, so its matrix is naturally an intertwiner of $\{\gamma^\mu\}$ with the *complex-conjugate* set $\{\gamma^{\mu *}\}$, with one extra relative sign between the time and space components reflecting $t \mapsto -t$. Demanding that $\psi'(t,\mathbf{x}) = T\psi^*(-t,\mathbf{x})$ again solve the Dirac equation forces (the derivation is the operator content of Chapter 11; here we record the matrix condition)

$$T^{-1}\gamma^0 T = \gamma^{0*}, \qquad T^{-1}\gamma^i T = -\gamma^{i*}, \qquad \text{i.e.} \qquad T^{-1}\gamma^\mu T = \gamma^*_\mu. \tag{C.109}$$

In a representation with the transpose pattern (C.93), where only γ^2 is imaginary, (C.109) requires T to commute with γ^0, γ^2 and anticommute with γ^1, γ^3. The unique solution up to scale is

$$T = \gamma^1\gamma^3 \qquad \text{(up to a phase)}, \tag{C.110}$$

as one checks directly: $\gamma^1\gamma^3$ contains the two matrices it must anticommute with and none of those it must commute with, and using $\{\gamma^\mu, \gamma^\nu\} = 2\eta^{\mu\nu}$, $\gamma^1\gamma^3$ commutes with γ^0 and γ^2 (each crosses two anticommuting factors, $(-1)^2 = +1$) and anticommutes with γ^1 and γ^3 (each crosses one).

The time-reversal matrix is not independent of C. In these representations

$$C\gamma^5 = i\gamma^2\gamma^0 \cdot i\gamma^0\gamma^1\gamma^2\gamma^3 = -\gamma^2\gamma^1\gamma^2\gamma^3 = \gamma^1(\gamma^2)^2\gamma^3 = -\gamma^1\gamma^3 = -T, \tag{C.111}$$

so $T = -C\gamma^5$, displaying the discrete-symmetry matrices as a single algebraic family generated by γ^0, C, and γ^5. The reality matrix B of (C.81) belongs to the same family: from $\gamma^{\mu *} = (\gamma^{\mu\dagger})^T = (\gamma^0\gamma^\mu\gamma^0)^T = \gamma^{0T}\gamma^{\mu T}\gamma^{0T}$ and $\gamma^{\mu T} = -C\gamma^\mu C^{-1}$ one finds, after using $\gamma^{0T} = -C\gamma^0 C^{-1}$,

$$\gamma^{\mu *} = -(C\gamma^0)\,\gamma^\mu\,(C\gamma^0)^{-1}, \tag{C.112}$$

so $C\gamma^0$ intertwines $\{\gamma^\mu\}$ with $\{-\gamma^{\mu *}\}$; the matrix B of (C.81) for $\{+\gamma^{\mu *}\}$ is therefore $B \propto \gamma^5 C\gamma^0$ (prepending the γ^5 conjugation flips the overall sign). The product of the parity, charge-conjugation, and time-reversal matrices is proportional to γ^5, the matrix that accompanies the combined CPT transformation; we return to this in the discussion of CPT and of the chiral anomaly in Chapters 11 and 36.

C.4.9 The Majorana reality condition

A Dirac spinor carries four complex, i.e. eight real, components. The reality (Majorana) condition asks whether one can impose, consistently and Lorentz-covariantly, that a spinor equal its own charge conjugate, halving the count. With $\psi^c = C\bar{\psi}^T$ from (C.104), the condition is

Definition C.41 (Majorana spinor)**.** A Dirac spinor ψ is a *Majorana spinor* if it equals its charge conjugate,

$$\psi = \psi^c = C\bar{\psi}^T. \tag{C.113}$$

The right-hand side is antilinear in ψ, so (C.113) is a reality condition relating ψ to ψ^*, not a linear constraint within the complex vector space. Writing $\bar{\psi}^T = (\psi^\dagger\gamma^0)^T = \gamma^{0T}\psi^*$, it takes the form $\psi = M\psi^*$ with the antilinear-involution matrix

$$M \equiv C\gamma^{0T}. \tag{C.114}$$

For such a condition to be imposable, the map $\psi \mapsto M\psi^*$ must square to the identity, so that (C.113) has a nontrivial solution space rather than only $\psi = 0$.

Theorem C.42 (Consistency and component count of the Majorana condition)**.** *In $d = 4$ the antilinear map $K : \psi \mapsto M\psi^*$ with $M = C\gamma^{0T}$ satisfies $K^2 = \mathbf{1}$, so the Majorana condition* (C.113) *is consistent. Its solution space is a* real *vector space of dimension* 4*: a Majorana spinor has four independent real components, the same count as a single Weyl spinor.*

Proof. Consistency. Applying K twice, $K^2\psi = M\,(M\psi^*)^* = MM^*\psi$, so $K^2 = \mathbf{1}$ iff $MM^* = \mathbf{1}$. Compute MM^* using $\gamma^{0\dagger} = \gamma^0$ (hence $\gamma^{0T*} = \gamma^{0\dagger} = \gamma^0$), $C^* = -C^{-1}$ (from $C^\dagger = C^{-1}$ and $C^T = -C$, since $C^\dagger = (C^T)^* = -C^*$), $\gamma^{0T} = -C\gamma^0C^{-1}$, and $C^2 = -\mathbf{1}$:

$$\begin{aligned} MM^* &= C\gamma^{0T}\,(C\gamma^{0T})^* = C\gamma^{0T}\,C^*\gamma^{0\dagger} = C\big(-C\gamma^0C^{-1}\big)\big(-C^{-1}\big)\gamma^0 \\ &= C^2\,\gamma^0\,C^{-2}\,\gamma^0 = (-\mathbf{1})\gamma^0(-\mathbf{1})\gamma^0 = \gamma^0\gamma^0 = \mathbf{1}. \end{aligned} \tag{C.115}$$

Thus $K^2 = \mathbf{1}$; the condition is an honest involution. (Had $C^2 = +\mathbf{1}$ instead — the situation in dimensions $d \equiv 6 \bmod 8$ — one would find $MM^* = -\mathbf{1}$, $K^2 = -\mathbf{1}$, and no Majorana spinor could exist; the existence of the reality condition is thus tied to d mod 8, and $d = 4$ is one of the dimensions where it succeeds.)

Component count. The solution space is $V_M = \{\psi \in \mathbb{C}^4 : \psi = K\psi\}$, the $+1$ eigenspace of the antilinear involution K. It is closed under real but not complex scalar multiplication, so it is a real vector space; we compute its real dimension. Consider the real-linear map $P : \mathbb{C}^4 \to \mathbb{C}^4$, $P\varphi = \frac{1}{2}(\varphi + K\varphi)$. Because $K^2 = \mathbf{1}$, P is idempotent: $P^2\varphi = \frac{1}{4}(\varphi + K\varphi + K\varphi + K^2\varphi) = \frac{1}{2}(\varphi + K\varphi) = P\varphi$, and $KP\varphi = \frac{1}{2}(K\varphi + \varphi) = P\varphi$, so the image of P lies in V_M; conversely every $\psi \in V_M$

satisfies $P\psi = \psi$, so $\operatorname{im} P = V_M$. Likewise $Q = \frac{1}{2}(\mathbf{1} - K)$ is a complementary real idempotent with $\operatorname{im} Q = \{\psi : K\psi = -\psi\}$, and $P + Q = \mathbf{1}$. As a real vector space $\mathbb{C}^4$ has dimension 8 and splits as $\operatorname{im} P \oplus \operatorname{im} Q$. The two summands are isomorphic as real spaces via multiplication by i, which anticommutes with the antilinear K (i.e. $K(i\psi) = -iK\psi$) and so exchanges the ± 1 eigenspaces; hence $\dim_{\mathbb{R}} \operatorname{im} P = \dim_{\mathbb{R}} \operatorname{im} Q = 4$. Therefore $\dim_{\mathbb{R}} V_M = 4$. □

Worked Example C.43 (Why a Majorana spinor carries the data of one Weyl spinor)**.** We re-derive the count of Theorem C.42 constructively, exhibiting the four real degrees of freedom directly and showing how they organize into a single two-component object — the bridge to the Weyl description of Chapter 11 and the $(\frac{1}{2}, 0)$ representation of Chapter 3. Define, for an arbitrary $\varphi \in \mathbb{C}^4$,

$$\psi(\varphi) = \varphi + M\varphi^*. \tag{C.116}$$

Then $\psi(\varphi)$ is automatically Majorana: using $MM^* = \mathbf{1}$,

$$K\psi(\varphi) = M(\varphi + M\varphi^*)^* = M\varphi^* + MM^*\varphi = M\varphi^* + \varphi = \psi(\varphi). \tag{C.117}$$

The map $\varphi \mapsto \psi(\varphi)$ from $\mathbb{C}^4$ (real dimension 8) onto V_M is real-linear and surjective, since any $\psi \in V_M$ is its own image, $\psi(\psi) = \psi + M\psi^* = \psi + K\psi = 2\psi$, up to the harmless factor 2. Its kernel is $\{\varphi : \varphi = -M\varphi^*\} = \operatorname{im} Q$, of real dimension 4. By rank–nullity for real vector spaces, $\dim_{\mathbb{R}} V_M = 8 - 4 = 4$, confirming the count. In the chiral basis (Section C.3), where $\psi = (\psi_L, \psi_R)^T$ and chirality is block-diagonal, the Majorana condition (C.113) reduces to the single relation $\psi_R = i\sigma^2\psi_L^*$ (with σ^2 from Chapter B): the right-handed component is completely determined by the left-handed one, leaving the two complex — four real — components of ψ_L as the independent data. A Majorana spinor is thus precisely a Weyl spinor together with the reality condition that ties its conjugate to its other chirality, which is why a Majorana mass and a Weyl description carry the same information.

With the charge-conjugation matrix C constructed and its symmetry settled, we have in hand exactly the data the next section needs. The signs t_A and the symmetry table Table C.1 determine which of the sixteen bilinears $\bar{\psi}\Gamma_A\psi$ are symmetric or antisymmetric under interchange of the two spinors — the input for Majorana bilinears, for the relative signs in crossing, and for the Fierz rearrangement built next — while the matrices γ^0 (parity/Dirac), C (charge conjugation), and $\gamma^1\gamma^3$ (time reversal) are the discrete-symmetry intertwiners that Chapters 11 and 36 import as the matrix part of the C, P, T operators. We turn now to assembling the Γ_A into a complete, trace-orthogonal basis and reading off the Lorentz character of each bilinear.

C.5 The Sixteen Bilinear Covariants and Completeness

Sections C.3 and C.4 handed us everything we need to organize the Dirac algebra into a usable basis: the explicit matrices γ^μ, the spin generators $\sigma^{\mu\nu} = \frac{i}{2}[\gamma^\mu, \gamma^\nu]$, the chirality matrix $\gamma^5 = i\gamma^0\gamma^1\gamma^2\gamma^3$, and the Dirac conjugation $\bar\psi = \psi^\dagger\gamma^0$ together with the discrete-symmetry intertwiners C and γ^0 (parity). What remains is to assemble these into a single algebraic statement that powers every spinor computation in the book: the space of 4×4 complex matrices is 16-dimensional, and a particular sixteen-element set built from the gammas is simultaneously (i) a basis, (ii) *trace-orthonormal*, and (iii) sorted by Lorentz character into a scalar, a vector, an antisymmetric tensor, an axial vector, and a pseudoscalar. The trace-orthonormality is the engine that lets us project any matrix onto the basis with a single trace; sorting by Lorentz character tells us, with no further work, how each fermion bilinear $\bar\psi\,\Gamma^A\psi$ behaves under the Lorentz group; and the resolution of the identity that follows — the spinor completeness, or Fierz, relation — is the master rearrangement identity that the amplitude chapters lean on constantly. Everything in this section is proved from the Clifford relation $\{\gamma^\mu, \gamma^\nu\} = 2\eta^{\mu\nu}\mathbf{1}$ and the elementary trace facts it forces.

C.5.1 The sixteen matrices and the index set A

The four gamma matrices anticommute and square to $\pm\mathbf{1}$. Consequently any product of gammas can be reduced, using $\gamma^\mu\gamma^\nu = -\gamma^\nu\gamma^\mu$ for $\mu \neq \nu$ and $(\gamma^\mu)^2 = \eta^{\mu\mu}\mathbf{1}$ (no sum), to a product in which each of the four distinct matrices $\gamma^0, \gamma^1, \gamma^2, \gamma^3$ appears *at most once*, times a numerical factor ± 1 or $\pm i$. The distinct reduced products are labelled by the *subsets* of $\{0,1,2,3\}$: there are $\binom{4}{0} = 1$ empty product, $\binom{4}{1} = 4$ singletons, $\binom{4}{2} = 6$ pairs, $\binom{4}{3} = 4$ triples, and $\binom{4}{4} = 1$ quadruple, for a total of $1+4+6+4+1 = 16$. These sixteen reduced products, normalized as in the table below, are the *bilinear covariants*.

Definition C.44 (The sixteen Γ^A)**.** The basis matrices $\{\Gamma^A\}_{A=1}^{16}$ of the Dirac algebra, grouped by the number of distinct gammas they contain, are

$$\underbrace{\mathbf{1}}_{S}, \qquad \underbrace{\gamma^\mu}_{V}, \qquad \underbrace{\sigma^{\mu\nu}\ (\mu<\nu)}_{T}, \qquad \underbrace{\gamma^\mu\gamma^5}_{A}, \qquad \underbrace{\gamma^5}_{P}, \tag{C.118}$$

where $\sigma^{\mu\nu} = \frac{i}{2}[\gamma^\mu, \gamma^\nu] = i\gamma^\mu\gamma^\nu$ for $\mu \neq \nu$ (cf. Section C.3), and $\gamma^5 = i\gamma^0\gamma^1\gamma^2\gamma^3$. The labels S, V, T, A, P denote scalar, vector, tensor, axial-vector, and pseudoscalar; their multiplicities are $1, 4, 6, 4, 1$. We write the index A as a collective label ranging over these sixteen matrices, and we always sum a repeated A over all sixteen.

The triples are not listed separately because each product of three distinct gammas is, up to a factor, one of the $\gamma^\mu\gamma^5$: with all four indices distinct,

Type	Γ^A	# components	$(\Gamma^A)^2$	bilinear $\bar\psi\,\Gamma^A\psi$
Scalar S	$\mathbf{1}$	1	$+\mathbf{1}$	$\bar\psi\psi$
Vector V	γ^μ	4	$\eta^{\mu\mu}\mathbf{1}$	$\bar\psi\gamma^\mu\psi$
Tensor T	$\sigma^{\mu\nu}$	6	$\eta^{\mu\mu}\eta^{\nu\nu}\mathbf{1}$	$\bar\psi\sigma^{\mu\nu}\psi$
Axial vector A	$\gamma^\mu\gamma^5$	4	$-\eta^{\mu\mu}\mathbf{1}$	$\bar\psi\gamma^\mu\gamma^5\psi$
Pseudoscalar P	γ^5	1	$+\mathbf{1}$	$\bar\psi\gamma^5\psi$

Table C.2: The sixteen bilinear covariants. Repeated indices in the "$(\Gamma^A)^2$" column are *not* summed; each square is $\pm\mathbf{1}$. The Lorentz transformation laws of the bilinears are derived in Section C.5.5.

$\gamma^\nu\gamma^\rho\gamma^\sigma \propto \gamma^\mu\gamma^5$ where μ is the missing index. Thus the "four triples" are exactly the axial set A, and the single "quadruple" is γ^5 itself. The reorganization into Eq. (C.118) is the one adapted to the Lorentz group, as Section C.5.5 makes precise.

Squares and the dual basis. Every Γ^A squares to $\pm\mathbf{1}$, as recorded in Table C.2. The scalar and pseudoscalar are immediate: $\mathbf{1}^2 = \mathbf{1}$ and $(\gamma^5)^2 = \mathbf{1}$ (proved in Section C.3). For the vector, $(\gamma^\mu)^2 = \eta^{\mu\mu}\mathbf{1}$ (no sum) is the diagonal Clifford relation. For the tensor with $\mu \neq \nu$,

$$(\sigma^{\mu\nu})^2 = (i\gamma^\mu\gamma^\nu)^2 = -\gamma^\mu\gamma^\nu\gamma^\mu\gamma^\nu = +\gamma^\mu\gamma^\mu\gamma^\nu\gamma^\nu = \eta^{\mu\mu}\eta^{\nu\nu}\,\mathbf{1} \qquad \text{(no sum)}, \tag{C.119}$$

where we used $\gamma^\nu\gamma^\mu = -\gamma^\mu\gamma^\nu$ once. For the axial vector,

$$(\gamma^\mu\gamma^5)^2 = \gamma^\mu\gamma^5\gamma^\mu\gamma^5 = -\gamma^\mu\gamma^\mu(\gamma^5)^2 = -\eta^{\mu\mu}\,\mathbf{1} \qquad \text{(no sum)}, \tag{C.120}$$

using $\{\gamma^5, \gamma^\mu\} = 0$. Since each $(\Gamma^A)^2 = \eta_A\mathbf{1}$ with $\eta_A \in \{+1, -1\}$, every Γ^A is invertible with

$$\Gamma_A := (\Gamma^A)^{-1} = \eta_A\,\Gamma^A. \tag{C.121}$$

We call Γ_A the *dual* of Γ^A. Concretely, Γ_A is obtained by lowering all Lorentz indices: $\mathbf{1} \mapsto \mathbf{1}$, $\gamma^\mu \mapsto \gamma_\mu$, $\sigma^{\mu\nu} \mapsto \sigma_{\mu\nu}$, $\gamma^5 \mapsto \gamma^5$, while for the axial set the inverse carries an extra sign, $(\gamma^\mu\gamma^5)^{-1} = -\gamma_\mu\gamma^5$ (from Eq. (C.120), since $\eta_A = -\eta^{\mu\mu}$). This dual is exactly what makes the trace pairing in Section C.5.4 come out as a Kronecker delta.

C.5.2 Elementary trace facts

The trace pairing rests on a handful of facts, all consequences of the Clifford relation, of cyclicity of the trace, and of the properties of γ^5 established in

Section C.3. The systematic trace recursion — the full toolkit for traces of arbitrarily many gammas — is the business of Section C.6; here we need only the minimum.

Lemma C.45 (Basic traces)**.** *In the $d = 4$ representation,*

$$\operatorname{tr} \mathbf{1} = 4, \tag{C.122}$$

$$\operatorname{tr}(\gamma^{\mu_1} \cdots \gamma^{\mu_n}) = 0 \quad \text{for } n \text{ odd}, \tag{C.123}$$

$$\operatorname{tr}(\gamma^{\mu}\gamma^{\nu}) = 4\,\eta^{\mu\nu}, \tag{C.124}$$

$$\operatorname{tr} \gamma^5 = 0. \tag{C.125}$$

Proof. Equation (C.122) is the statement that the representation acts on $\mathbb{C}^4$. For Eq. (C.123), insert $\mathbf{1} = (\gamma^5)^2$ and slide one γ^5 through the string. Because $\{\gamma^5, \gamma^\mu\} = 0$, moving a γ^5 past n gammas costs $(-1)^n$:

$$\operatorname{tr}(\gamma^{\mu_1} \cdots \gamma^{\mu_n}) = \operatorname{tr}(\gamma^5 \gamma^5 \gamma^{\mu_1} \cdots \gamma^{\mu_n}) = (-1)^n \operatorname{tr}(\gamma^5 \gamma^{\mu_1} \cdots \gamma^{\mu_n} \gamma^5) = (-1)^n \operatorname{tr}(\gamma^{\mu_1} \cdots \gamma^{\mu_n}), \tag{C.126}$$

where the last equality used cyclicity to bring the trailing γ^5 to the front and $(\gamma^5)^2 = \mathbf{1}$. For n odd the trace equals minus itself, hence vanishes. Equation (C.124) follows by symmetrizing: by cyclicity $\operatorname{tr}(\gamma^\mu\gamma^\nu) = \operatorname{tr}(\gamma^\nu\gamma^\mu)$, so

$$\operatorname{tr}(\gamma^{\mu}\gamma^{\nu}) = \tfrac{1}{2} \operatorname{tr}\big(\{\gamma^\mu, \gamma^\nu\} \big) = \tfrac{1}{2} \operatorname{tr}(2\eta^{\mu\nu}\mathbf{1}) = \eta^{\mu\nu} \operatorname{tr} \mathbf{1} = 4\,\eta^{\mu\nu}. \tag{C.127}$$

Finally, for Eq. (C.125) choose any single index, say 0, and use $(\gamma^0)^2 = \mathbf{1}$:

$$\operatorname{tr} \gamma^5 = \operatorname{tr}(\gamma^5 \gamma^0 \gamma^0) = \operatorname{tr}(\gamma^0 \gamma^5 \gamma^0) = -\operatorname{tr}(\gamma^5 \gamma^0 \gamma^0) = -\operatorname{tr} \gamma^5, \tag{C.128}$$

where the middle step is cyclicity and the next uses $\{\gamma^5, \gamma^0\} = 0$. Hence $\operatorname{tr} \gamma^5 = 0$. □

C.5.3 Each nontrivial Γ^A is traceless, and the set closes under multiplication

The orthogonality theorem needs two structural facts about the sixteen matrices: every one except the identity is traceless, and the product of any two is again one of the sixteen up to a numerical factor. Both follow from a single observation — that for every $\Gamma^A \neq \mathbf{1}$ there is an *anticommuting partner* among the gammas.

Lemma C.46 (Tracelessness)**.** $\operatorname{tr} \Gamma^A = 0$ *for every A except* $\Gamma^A = \mathbf{1}$.

Proof. For each $\Gamma^A \neq \mathbf{1}$ we exhibit an invertible matrix B with $B\Gamma^A B^{-1} = -\Gamma^A$; then cyclicity gives $\operatorname{tr} \Gamma^A = \operatorname{tr}(B\Gamma^A B^{-1}) = -\operatorname{tr} \Gamma^A = 0$.

- $\Gamma^A = \gamma^\mu$: take $B = \gamma^5$. Then $\gamma^5\gamma^\mu(\gamma^5)^{-1} = -\gamma^\mu$ because $\{\gamma^5, \gamma^\mu\} = 0$.

- $\Gamma^A = \sigma^{\mu\nu} = i\gamma^\mu\gamma^\nu$ ($\mu \neq \nu$): take $B = \gamma^\mu$. Since $\gamma^\mu(\gamma^\mu\gamma^\nu) = (\gamma^\mu)^2\gamma^\nu$ while $(\gamma^\mu\gamma^\nu)\gamma^\mu = -(\gamma^\mu)^2\gamma^\nu$, the matrix γ^μ anticommutes with $\gamma^\mu\gamma^\nu$, hence with $\sigma^{\mu\nu}$.

- $\Gamma^A = \gamma^\mu\gamma^5$: take $B = \gamma^\mu$. As in Eq. (C.120), $\gamma^\mu(\gamma^\mu\gamma^5) = (\gamma^\mu)^2\gamma^5$ and $(\gamma^\mu\gamma^5)\gamma^\mu = -(\gamma^\mu)^2\gamma^5$, so they anticommute.

- $\Gamma^A = \gamma^5$: take any $B = \gamma^\rho$, since $\{\gamma^5, \gamma^\rho\} = 0$.

In every case B is one of γ^ρ or γ^5, all invertible by Eq. (C.121). □

Lemma C.47 (Closure)**.** *For any two basis matrices,* $\Gamma^A\Gamma^B = c_{AB}\,\Gamma^C$ *for some* Γ^C *in the set and some scalar* $c_{AB} \in \{\pm 1, \pm i\}$*. Moreover* $\Gamma^C = \mathbf{1}$ *if and only if* $A = B$*.*

Proof. Each Γ^A is, up to the normalizing factor $\pm i$ in Theorem C.44, the ordered product of the distinct gammas indexed by a subset $S_A \subseteq \{0, 1, 2, 3\}$. The product $\Gamma^A\Gamma^B$ is then the ordered product over S_A followed by that over S_B. Anticommuting the two strings into a single ordered product introduces signs only; whenever an index appears in both S_A and S_B the two copies meet and collapse via $(\gamma^\rho)^2 = \eta^{\rho\rho}\mathbf{1}$, again only a sign. What survives is the ordered product over the symmetric difference $S_A \triangle S_B$, times a factor in $\{\pm 1, \pm i\}$. That surviving product is, after restoring the normalization of Theorem C.44, exactly one of the sixteen Γ^C. Finally $\Gamma^A\Gamma^B \propto \mathbf{1}$ demands $S_A \triangle S_B = \varnothing$, i.e. $S_A = S_B$, i.e. $A = B$. □

C.5.4 Trace-orthogonality and the basis property

We can now state the central algebraic fact of the section.

Theorem C.48 (Trace-orthonormality)**.** *With the dual matrices* $\Gamma_A = (\Gamma^A)^{-1}$ *of Eq.* (C.121)*,*

$$\operatorname{tr}(\Gamma^A\,\Gamma_B) = 4\,\delta^A{}_B. \tag{C.129}$$

Proof. If $A = B$ then $\Gamma^A\Gamma_A = \Gamma^A(\Gamma^A)^{-1} = \mathbf{1}$ and the trace is $\operatorname{tr}\mathbf{1} = 4$ by Eq. (C.122). If $A \neq B$ then, writing $\Gamma_B = \eta_B\Gamma^B$ from Eq. (C.121) and applying Theorem C.47, $\Gamma^A\Gamma_B = \eta_B\,c_{AB}\,\Gamma^C$ with $\Gamma^C \neq \mathbf{1}$ (because $A \neq B$). By Theorem C.46 every nontrivial Γ^C is traceless, so the trace vanishes. Together these give Eq. (C.129). □

Trace-orthonormality forces linear independence, and with the dimension count this makes the sixteen matrices a basis.

Theorem C.49 (Basis and projection formula)**.** *The sixteen Γ^A are linearly independent and therefore form a basis of the 16-dimensional complex vector space of 4×4 matrices. Every 4×4 matrix M has the unique expansion*

$$M = \frac{1}{4}\sum_{A} \operatorname{tr}(M\,\Gamma_A)\,\Gamma^A. \tag{C.130}$$

Proof. Suppose $\sum_A c_A\,\Gamma^A = 0$ for scalars c_A. Multiply by Γ_B and take the trace; by Eq. (C.129),

$$0 = \operatorname{tr}\Big(\sum_A c_A\,\Gamma^A\,\Gamma_B\Big) = \sum_A c_A \cdot 4\,\delta^A{}_B = 4\,c_B, \tag{C.131}$$

so every $c_B = 0$ and the set is linearly independent. Sixteen linearly independent vectors in a sixteen-dimensional space form a basis, so we may write $M = \sum_A m_A\,\Gamma^A$ with unique coefficients m_A. Multiplying by Γ_B and tracing, $\operatorname{tr}(M\Gamma_B) = \sum_A m_A \cdot 4\,\delta^A{}_B = 4\,m_B$, which gives $m_A = \frac{1}{4}\operatorname{tr}(M\Gamma_A)$ and hence Eq. (C.130). □

Equation (C.130) is the workhorse: it reduces "what is this matrix?" to sixteen trace computations. The following worked example exercises it on a matrix that recurs in practice, the projector built from a unit timelike vector.

Worked Example C.50 (Expanding a chiral projector and a spin projector)**.** Consider first $M = P_R = \frac{1}{2}(\mathbf{1}+\gamma^5)$, the right-handed chirality projector. We expand it in the Γ^A basis using Eq. (C.130). The only nonzero traces are against the scalar and pseudoscalar duals: $\operatorname{tr}(P_R\,\mathbf{1}) = \frac{1}{2}(\operatorname{tr}\mathbf{1} + \operatorname{tr}\gamma^5) = 2$ and $\operatorname{tr}(P_R\,\gamma^5) = \frac{1}{2}(\operatorname{tr}\gamma^5 + \operatorname{tr}(\gamma^5)^2) = \frac{1}{2}\operatorname{tr}\mathbf{1} = 2$, while every trace against γ_μ, $\sigma_{\mu\nu}$ or $-\gamma_\mu\gamma^5$ vanishes by Theorem C.45 (odd numbers of gammas, or $\operatorname{tr}\gamma^5 = 0$, or $\operatorname{tr}(\gamma^5\gamma^\mu) = 0$ since $\gamma^5\gamma^\mu$ is a product of five gammas). Thus

$$P_R = \frac{1}{4}\big[\,2\cdot\mathbf{1} + 2\cdot\gamma^5\,\big] = \tfrac{1}{2}(\mathbf{1}+\gamma^5), \tag{C.132}$$

reproducing the input — a consistency check that the projection formula is faithful, and a reminder that P_R lives entirely in the $S\oplus P$ sector.

For a less trivial case take $M = \not{a}\not{b}$ with a, b four-vectors, where $\not{a} = a_\mu\gamma^\mu$. Using $\not{a}\not{b} = a_\mu b_\nu\gamma^\mu\gamma^\nu = a_\mu b_\nu(\frac{1}{2}\{\gamma^\mu,\gamma^\nu\} + \frac{1}{2}[\gamma^\mu,\gamma^\nu]) = (a\cdot b)\,\mathbf{1} - i\,a_\mu b_\nu\,\sigma^{\mu\nu}$, the expansion is read off directly: the scalar coefficient is $a\cdot b$ and the tensor coefficient is $-i\,a_\mu b_\nu$, with no vector, axial, or pseudoscalar part. Verifying through Eq. (C.130): $\frac{1}{4}\operatorname{tr}(\not{a}\not{b}) = \frac{1}{4}a_\mu b_\nu\operatorname{tr}(\gamma^\mu\gamma^\nu) = a\cdot b$ by Eq. (C.124), matching the scalar coefficient, and the antisymmetric remainder is carried by $\sigma^{\mu\nu}$. This decomposition of a product of two slashes into a symmetric (scalar) and antisymmetric (tensor) piece is used repeatedly when reducing amplitudes.

C.5.5 Lorentz classification of the bilinears

We now justify the names in Table C.2 by computing how each $\bar\psi\,\Gamma^A\psi$ transforms. Under a proper orthochronous Lorentz transformation Λ, the Dirac field transforms with the spinor representation $S(\Lambda)$ built in Section C.3,

$$\psi(x) \;\longmapsto\; S(\Lambda)\,\psi(\Lambda^{-1}x), \qquad S^{-1}(\Lambda)\,\gamma^\mu\,S(\Lambda) = \Lambda^\mu{}_\nu\,\gamma^\nu. \tag{C.133}$$

The Dirac conjugate transforms contragrediently: from $\bar\psi = \psi^\dagger\gamma^0$ and the property $S^\dagger\gamma^0 = \gamma^0 S^{-1}$ proved in Section C.4, one finds $\bar\psi(x) \mapsto \bar\psi(\Lambda^{-1}x)\,S^{-1}(\Lambda)$. Hence a bilinear transforms by *conjugating* the matrix sandwiched between the spinors,

$$\bar\psi\,\Gamma\,\psi \;\longmapsto\; \bar\psi\,(S^{-1}\Gamma\,S)\,\psi, \tag{C.134}$$

with the field arguments evaluated at $\Lambda^{-1}x$ throughout (we suppress them). Everything now reduces to computing $S^{-1}\Gamma^A S$ for each A.

Scalar. For $\Gamma = \mathbf{1}$, trivially $S^{-1}\mathbf{1}\,S = \mathbf{1}$, so $\bar\psi\psi$ is invariant: a Lorentz *scalar*.

Vector. For $\Gamma = \gamma^\mu$, Eq. (C.133) gives directly

$$\bar\psi\gamma^\mu\psi \;\longmapsto\; \Lambda^\mu{}_\nu\,\bar\psi\gamma^\nu\psi, \tag{C.135}$$

the transformation law of a contravariant *four-vector*.

Tensor. For $\Gamma = \sigma^{\mu\nu} = \frac{i}{2}\,[\gamma^\mu,\gamma^\nu]$, conjugation distributes over the commutator and we apply Eq. (C.133) to each factor:

$$S^{-1}\sigma^{\mu\nu}S = \tfrac{i}{2}\left[S^{-1}\gamma^\mu S, S^{-1}\gamma^\nu S\right] = \Lambda^\mu{}_\alpha\Lambda^\nu{}_\beta\,\tfrac{i}{2}\left[\gamma^\alpha,\gamma^\beta\right] = \Lambda^\mu{}_\alpha\Lambda^\nu{}_\beta\,\sigma^{\alpha\beta}, \tag{C.136}$$

so $\bar\psi\sigma^{\mu\nu}\psi$ transforms as an antisymmetric rank-two *tensor*.

Axial vector and pseudoscalar. These two require the behaviour of γ^5 under conjugation. Write γ^5 in its manifestly covariant form (proved in Section C.3),

$$\gamma^5 = -\frac{i}{4!}\,\epsilon_{\mu\nu\rho\sigma}\,\gamma^\mu\gamma^\nu\gamma^\rho\gamma^\sigma, \qquad \epsilon^{0123} = +1. \tag{C.137}$$

Conjugating each gamma with Eq. (C.133) produces four factors of Λ contracted into ϵ, and the totally antisymmetric symbol satisfies the determinant identity $\epsilon_{\mu\nu\rho\sigma}\Lambda^\mu{}_\alpha\Lambda^\nu{}_\beta\Lambda^\rho{}_\gamma\Lambda^\sigma{}_\delta = (\det\Lambda)\,\epsilon_{\alpha\beta\gamma\delta}$. Hence

$$S^{-1}\gamma^5 S = -\frac{i}{4!}\,(\det\Lambda)\,\epsilon_{\alpha\beta\gamma\delta}\,\gamma^\alpha\gamma^\beta\gamma^\gamma\gamma^\delta = (\det\Lambda)\,\gamma^5. \tag{C.138}$$

For a proper transformation $\det\Lambda = +1$, so $S^{-1}\gamma^5 S = \gamma^5$; equivalently, γ^5 commutes with the spin generators $\sigma^{\mu\nu}$ (it anticommutes with each γ^μ, hence commutes with their products of two), which is the infinitesimal version of the same statement. Combining Eq. (C.138) with the vector and scalar results,

$$\bar\psi\gamma^\mu\gamma^5\psi \;\longmapsto\; (\det\Lambda)\,\Lambda^\mu{}_\nu\,\bar\psi\gamma^\nu\gamma^5\psi, \tag{C.139}$$

$$\bar\psi\gamma^5\psi \;\longmapsto\; (\det\Lambda)\,\bar\psi\gamma^5\psi. \tag{C.140}$$

Under the proper orthochronous subgroup these transform exactly like a vector and a scalar, but they carry the extra factor $\det\Lambda$ under improper transformations: they are an *axial vector* and a *pseudoscalar*.

The factor $\det\Lambda$ is invisible inside the connected Lorentz group and shows itself only under parity. From Section C.4, the parity intertwiner is γ^0, with $\psi(t,\mathbf{x}) \mapsto \gamma^0\psi(t,-\mathbf{x})$, so a bilinear transforms by sandwiching $\gamma^0\Gamma^A\gamma^0$. Using $\gamma^0\gamma^0 = \mathbf{1}$, $\gamma^0\gamma^i\gamma^0 = -\gamma^i$, and $\gamma^0\gamma^5\gamma^0 = -\gamma^5$, one reads off the parity eigenvalues: $\bar\psi\psi$ is even, $\bar\psi\gamma^\mu\psi$ transforms as $(+,-,-,-)$ on $(\mu = 0, i)$ like a polar vector, $\bar\psi\gamma^\mu\gamma^5\psi$ transforms as $(-,+,+,+)$ like an axial vector, and $\bar\psi\gamma^5\psi$ is odd. This is the precise content of $\det\Lambda_P = -1$ in Eqs. (C.139) and (C.140).

Worked Example C.51 (The vector and axial currents of the Dirac field)**.** The two bilinears that the book uses most are the vector current $j^\mu = \bar\psi\gamma^\mu\psi$ and the axial current $j^\mu_5 = \bar\psi\gamma^\mu\gamma^5\psi$. Equation (C.135) states that j^μ is a genuine four-vector: it can therefore be contracted with the photon field A_μ to form the Lorentz scalar $-e\,A_\mu\,\bar\psi\gamma^\mu\psi$ that is the QED interaction, and its conservation $\partial_\mu j^\mu = 0$ (the Noether current of the global $U(1)$ phase symmetry, Chapter 8) is a Lorentz-covariant statement. This is the structure that Chapter 17 feeds into the Feynman rules for $e^+e^- \to \mu^+\mu^-$: each vertex contributes one factor of γ^μ precisely because the conserved current is a vector bilinear.

Equation (C.139) states that j^μ_5 transforms identically under proper rotations and boosts but flips sign relative to j^μ under parity. Classically the massless Dirac Lagrangian has, alongside the vector symmetry, an axial $U(1)$ whose Noether current is j^μ_5; the chirality projectors of Theorem C.50 split a Dirac fermion into the two pieces this current weighs oppositely. That j^μ_5 is an axial vector — not a polar vector — is exactly why its naive conservation law cannot survive quantization in the presence of two vector currents: the would-be conserved $\partial_\mu j^\mu_5$ acquires the parity-odd, ϵ-tensor anomaly computed in Chapter 36. The Lorentz classification proved here is the kinematic input that makes the anomaly's $\epsilon^{\mu\nu\rho\sigma}F_{\mu\nu}F_{\rho\sigma}$ structure the only possibility.

C.5.6 The completeness (Fierz) relation

The projection formula Eq. (C.130) holds for *every* matrix M. Applying it to the elementary matrices — the matrix units E_{ij} with a single 1 in row i, column

j — packages the entire content of the basis into one tensor identity on the spinor indices. This is the spinor completeness relation, the seed of every Fierz rearrangement.

Theorem C.52 (Spinor completeness / Fierz identity)**.** *For all spinor indices* $i, j, k, l \in \{1, 2, 3, 4\}$,

$$\delta_{ij}\,\delta_{kl} = \frac{1}{4}\sum_{A} \left(\Gamma^{A}\right)_{il} \left(\Gamma_{A}\right)_{kj}, \tag{C.141}$$

the sum running over all sixteen basis matrices with their duals $\Gamma_A = (\Gamma^A)^{-1}$.

Proof. Equation (C.130) applied to an arbitrary M and read off in components gives, for every entry (i, l),

$$M_{il} = \frac{1}{4}\sum_{A} \left(\Gamma^{A}\right)_{il} \operatorname{tr}(M\,\Gamma_{A}) = \frac{1}{4}\sum_{A} \left(\Gamma^{A}\right)_{il} \sum_{a,b} M_{ba} \left(\Gamma_{A}\right)_{ab}, \tag{C.142}$$

where we wrote out $\operatorname{tr}(M\Gamma_A) = \sum_{a,b} M_{ba}(\Gamma_A)_{ab}$. Since this holds for an arbitrary matrix M, the coefficient of each independent entry M_{ba} on the two sides must agree. On the left, $M_{il} = \sum_{a,b} M_{ba}\,\delta_{ib}\delta_{la}$. Matching coefficients of M_{ba},

$$\delta_{ib}\,\delta_{la} = \frac{1}{4}\sum_{A} \left(\Gamma^{A}\right)_{il} \left(\Gamma_{A}\right)_{ab}. \tag{C.143}$$

Renaming the dummy indices $b \to j$, $a \to k$ (so that Γ_A carries indices k, j) yields $\delta_{ij}\,\delta_{kl} = \frac{1}{4}\sum_A (\Gamma^A)_{il}(\Gamma_A)_{kj}$, which is Eq. (C.141). □

Spelling out the dual matrices through Eq. (C.121), the relation takes its fully explicit form, with the multiplicities and index placements of Table C.2 made visible:

$$\delta_{ij}\,\delta_{kl} = \frac{1}{4}\Big[\delta_{il}\,\delta_{kj} + (\gamma^{\mu})_{il}(\gamma_{\mu})_{kj} + \tfrac{1}{2}(\sigma^{\mu\nu})_{il}(\sigma_{\mu\nu})_{kj} - (\gamma^{\mu}\gamma^{5})_{il}(\gamma_{\mu}\gamma^{5})_{kj} + (\gamma^{5})_{il}(\gamma^{5})_{kj}\Big]. \tag{C.144}$$

Three features deserve comment, each a direct consequence of the construction. The factor $\frac{1}{2}$ on the tensor term converts the constrained sum over $\mu < \nu$ (the six independent components) into the unconstrained sum over all μ, ν used here, since $\sigma^{\mu\nu}$ is antisymmetric and the unconstrained sum double-counts. The relative minus sign on the axial term is precisely the extra factor $\eta_A = -\eta^{\mu\mu}$ in the dual Eq. (C.121): $(\gamma^\mu\gamma^5)^{-1} = -\gamma_\mu\gamma^5$. And the contraction pattern (i, l) on Γ^A against (k, j) on Γ_A — the "crossed" pairing of Eq. (C.141) — is exactly what lets one trade $(\bar\psi_1\psi_2)(\bar\psi_3\psi_4)$ for sums of $(\bar\psi_1\psi_4)(\bar\psi_3\psi_2)$, which is the Fierz rearrangement.

Two contractions of Eq. (C.141) confirm the normalization. First set $j = i$ and $l = k$ and sum over i, k. The left side is $\sum_{i,k}\delta_{ii}\delta_{kk} = 4 \cdot 4 = 16$, while the right side becomes $\frac{1}{4}\sum_A \sum_{i,k}(\Gamma^A)_{ik}(\Gamma_A)_{ki} = \frac{1}{4}\sum_A \operatorname{tr}(\Gamma^A\Gamma_A) = \frac{1}{4}\cdot 16 \cdot 4 = 16$

by Eq. (C.129) (each of the sixteen terms contributes 4). Second, set $l = i$ and $j = k$ and sum: the left side is $\sum_{i,k} \delta_{ik}\delta_{ki} = 4$, while the right side is $\frac{1}{4}\sum_A \operatorname{tr}(\Gamma^A)\operatorname{tr}(\Gamma_A) = \frac{1}{4}(\operatorname{tr}\mathbf{1})^2 = 4$, since by Theorem C.46 only the scalar term survives. Both checks balance. The systematic exploitation of Eq. (C.141) for rearranging products of bilinears, together with the trace identities that Theorem C.48 makes available, is taken up next: the trace-orthonormality relation is the engine of Section C.6, and the completeness relation Eq. (C.141) is the engine of the Fierz rearrangements assembled there.

C.6 Trace and Contraction Technology in Four Dimensions

The previous section closed by establishing that the sixteen bilinear covariants $\{1, \gamma^\mu, \sigma^{\mu\nu}, \gamma^\mu\gamma^5, \gamma^5\}$ form a trace-orthogonal basis of the 4×4 matrix algebra, and in particular that every one of them except the identity is traceless: $\operatorname{tr}\gamma^\mu = 0$, $\operatorname{tr}\sigma^{\mu\nu} = 0$, $\operatorname{tr}(\gamma^\mu\gamma^5) = 0$, and $\operatorname{tr}\gamma^5 = 0$ (Section C.5). Those vanishing traces are the seeds of everything in this section. Trace orthogonality tells us that the trace of *any* product of gamma matrices is, after expansion in the basis, just 4 times the coefficient of the identity in that product; the entire technology below is the systematic bookkeeping of when and how the identity appears. The payoff is concrete and central to the rest of the book: when an amplitude is squared and summed over spins, the Dirac structure collapses—via the completeness relations of Chapter 11—into traces of strings of gamma matrices, and those traces must be reduced to ordinary Lorentz-covariant functions of the external momenta. This is precisely the machinery that turns the spin-summed $|\mathcal{M}|^2$ for $e^+e^- \to \mu^+\mu^-$ into a function of Mandelstam invariants in Chapter 17, and that evaluates the Dirac numerators of the one-loop QED diagrams in Chapter 19. We assemble the complete $d = 4$ toolkit here, proving each identity from the two structural facts that drive all of them—the cyclicity of the trace and the Clifford relation—and we finish with the trace that detects orientation, the one carrying γ^5 and the Levi-Civita tensor.

Throughout we use the conventions fixed in Chapter A and Section C.1: the mostly-minus metric $\eta_{\mu\nu} = \operatorname{diag}(+,-,-,-)$, the Clifford relation

$$\{\gamma^\mu, \gamma^\nu\} = 2\,\eta^{\mu\nu}\,\mathbf{1}, \tag{C.145}$$

the irreducible representation acting on a four-dimensional spinor space, and $\gamma^5 = i\gamma^0\gamma^1\gamma^2\gamma^3$ with $(\gamma^5)^2 = \mathbf{1}$ and $\{\gamma^5, \gamma^\mu\} = 0$.

C.6.1 The two pillars: cyclicity and the Clifford relation

Every identity in this section rests on exactly two facts. The first is purely algebraic and dimension-independent: the trace of a product is invariant under

cyclic permutation,

$$\operatorname{tr}(AB\cdots Z) = \operatorname{tr}(B\cdots ZA), \tag{C.146}$$

which follows at once from $\operatorname{tr}(AB) = \operatorname{tr}(BA)$ applied to A and the block $B\cdots Z$. The second is the Clifford relation Eq. (C.145), which lets us trade the order of two adjacent gamma matrices for a c-number,

$$\gamma^\mu\gamma^\nu = 2\eta^{\mu\nu}\mathbf{1} - \gamma^\nu\gamma^\mu. \tag{C.147}$$

The strategy that recurs below is always the same: use Eq. (C.147) to march one gamma matrix through a string until it returns to its starting point, picking up metric tensors along the way, then use Eq. (C.146) to close the loop and solve the resulting linear relation for the trace. The only place the number 4—the dimension of the representation—enters is through

$$\operatorname{tr}\mathbf{1} = 4, \tag{C.148}$$

which holds because the irreducible representation of the $d = 4$ Clifford algebra acts on a space of dimension $2^{\lfloor 4/2\rfloor} = 4$ (Section C.1); the identity there is the 4×4 unit matrix. We carry $\operatorname{tr}\mathbf{1} = 4$ as a constant; in Section C.7 it will become a continuation parameter when we move off $d = 4$.

C.6.2 Vanishing of odd traces

Proposition C.53 (Odd traces vanish)**.** *The trace of a product of an odd number of gamma matrices is zero:*

$$\operatorname{tr}(\gamma^{\mu_1}\gamma^{\mu_2}\cdots\gamma^{\mu_n}) = 0 \qquad (n \text{ odd}). \tag{C.149}$$

Proof. Write $M = \gamma^{\mu_1}\cdots\gamma^{\mu_n}$ and insert $\mathbf{1} = (\gamma^5)^2$ at the front:

$$\operatorname{tr} M = \operatorname{tr}(\gamma^5\,\gamma^5\,M). \tag{C.150}$$

By cyclicity Eq. (C.146) move the leftmost γ^5 to the far right, $\operatorname{tr}(\gamma^5\,\gamma^5 M) = \operatorname{tr}(\gamma^5 M\gamma^5)$. Now push the remaining left γ^5 rightward through the n gamma matrices of M; each pass costs a sign because $\{\gamma^5,\gamma^\mu\} = 0$, so $\gamma^5 M = (-1)^n M\gamma^5$. Hence

$$\operatorname{tr} M = \operatorname{tr}(\gamma^5 M\gamma^5) = (-1)^n\,\operatorname{tr}(M\,\gamma^5\,\gamma^5) = (-1)^n\operatorname{tr} M. \tag{C.151}$$

For odd n this reads $\operatorname{tr} M = -\operatorname{tr} M$, so $\operatorname{tr} M = 0$. □

This single argument disposes of $\operatorname{tr}\gamma^\mu = 0$, $\operatorname{tr}(\gamma^\mu\gamma^\nu\gamma^\rho) = 0$, and every higher odd string at once, and it does so using only $(\gamma^5)^2 = \mathbf{1}$ and the anticommutation of γ^5—no explicit representation required. It is the same γ^5-insertion trick that will return below to show that short γ^5-traces vanish.

C.6.3 The even traces and the master recursion

The lowest even trace follows immediately from Eq. (C.147). Symmetrizing,

$$\operatorname{tr}(\gamma^\mu\gamma^\nu) = \tfrac{1}{2}\operatorname{tr}\left(\{\gamma^\mu,\gamma^\nu\}\right) = \tfrac{1}{2}\,(2\eta^{\mu\nu})\,\operatorname{tr}\mathbf{1} = 4\,\eta^{\mu\nu}, \tag{C.152}$$

where the antisymmetric part $\frac{1}{2}[\gamma^\mu,\gamma^\nu] = -i\sigma^{\mu\nu}$ dropped out because $\operatorname{tr}\sigma^{\mu\nu} = 0$ (Section C.5). For four gamma matrices we could symmetrize repeatedly, but it is cleaner—and sets up the general pattern—to establish the recursion that reduces any even trace to a sum of traces two matrices shorter.

Theorem C.54 (Trace recursion)**.** *For even n,*

$$\operatorname{tr}(\gamma^{\mu_1}\gamma^{\mu_2}\cdots\gamma^{\mu_n}) = \sum_{k=2}^{n}(-1)^k\,\eta^{\mu_1\mu_k}\,\operatorname{tr}(\gamma^{\mu_2}\cdots\widehat{\gamma^{\mu_k}}\cdots\gamma^{\mu_n}), \tag{C.153}$$

where the hat denotes omission of the indicated factor.

Proof. Anticommute γ^{μ_1} rightward through the string using Eq. (C.147). Past the first neighbour,

$$\gamma^{\mu_1}\gamma^{\mu_2}\cdots = 2\eta^{\mu_1\mu_2}\gamma^{\mu_3}\cdots\gamma^{\mu_n} - \gamma^{\mu_2}\gamma^{\mu_1}\gamma^{\mu_3}\cdots\gamma^{\mu_n}. \tag{C.154}$$

Past the next, $\gamma^{\mu_1}\gamma^{\mu_3} = 2\eta^{\mu_1\mu_3} - \gamma^{\mu_3}\gamma^{\mu_1}$, generating $-2\eta^{\mu_1\mu_3}$ with the accumulated sign, and so on. After γ^{μ_1} has passed all of $\gamma^{\mu_2},\dots,\gamma^{\mu_n}$,

$$\gamma^{\mu_1}\gamma^{\mu_2}\cdots\gamma^{\mu_n} = 2\sum_{k=2}^{n}(-1)^k\,\eta^{\mu_1\mu_k}\,\gamma^{\mu_2}\cdots\widehat{\gamma^{\mu_k}}\cdots\gamma^{\mu_n} + (-1)^{n-1}\gamma^{\mu_2}\cdots\gamma^{\mu_n}\gamma^{\mu_1}. \tag{C.155}$$

The alternating sign $(-1)^k$ records the parity of transpositions needed to bring γ^{μ_1} adjacent to γ^{μ_k}. Take the trace of Eq. (C.155). In the last term, cyclicity Eq. (C.146) returns $\operatorname{tr}(\gamma^{\mu_2}\cdots\gamma^{\mu_n}\gamma^{\mu_1}) = \operatorname{tr}(\gamma^{\mu_1}\gamma^{\mu_2}\cdots\gamma^{\mu_n})$, and for even n the prefactor is $(-1)^{n-1} = -1$. Thus

$$\operatorname{tr}(\gamma^{\mu_1}\cdots\gamma^{\mu_n}) = 2\sum_{k=2}^{n}(-1)^k\eta^{\mu_1\mu_k}\,\operatorname{tr}(\gamma^{\mu_2}\cdots\widehat{\gamma^{\mu_k}}\cdots\gamma^{\mu_n}) - \operatorname{tr}(\gamma^{\mu_1}\cdots\gamma^{\mu_n}), \tag{C.156}$$

and moving the last term to the left and dividing by two yields Eq. (C.153). □

The recursion is the whole story for γ^5-free even traces: applied repeatedly it terminates at $\operatorname{tr}(\gamma^\mu\gamma^\nu) = 4\eta^{\mu\nu}$ and expresses any $\operatorname{tr}(\gamma^{\mu_1}\cdots\gamma^{\mu_{2m}})$ as 4 times a sum over all $(2m-1)!!$ ways of pairing the $2m$ indices into metric tensors, each pairing weighted by the sign of the permutation that brings the paired indices adjacent. For the four-index trace, Eq. (C.153) with $n = 4$ gives the workhorse identity

$$\operatorname{tr}(\gamma^\mu\gamma^\nu\gamma^\rho\gamma^\sigma) = \eta^{\mu\nu}\operatorname{tr}(\gamma^\rho\gamma^\sigma) - \eta^{\mu\rho}\operatorname{tr}(\gamma^\nu\gamma^\sigma) + \eta^{\mu\sigma}\operatorname{tr}(\gamma^\nu\gamma^\rho)$$

$$= 4(\eta^{\mu\nu}\eta^{\rho\sigma} - \eta^{\mu\rho}\eta^{\nu\sigma} + \eta^{\mu\sigma}\eta^{\nu\rho}). \tag{C.157}$$

The three terms are the three pairings $\{(\mu\nu)(\rho\sigma), (\mu\rho)(\nu\sigma), (\mu\sigma)(\nu\rho)\}$ with the alternating signs; the middle one is negative because separating μ from ρ requires crossing ν.

C.6.4 The reversal identity

A symmetry of traces that saves real labour in amplitude calculations is that a string may be read backwards without changing its trace.

Proposition C.55 (Reversal)**.** *For any number of gamma matrices,*

$$\operatorname{tr}(\gamma^{\mu_1}\gamma^{\mu_2}\cdots\gamma^{\mu_n}) = \operatorname{tr}(\gamma^{\mu_n}\cdots\gamma^{\mu_2}\gamma^{\mu_1}). \tag{C.158}$$

Proof. For odd n both sides vanish by Theorem C.53, so take n even. The charge-conjugation matrix C constructed in Section C.4 satisfies $C\gamma^{\mu}C^{-1} = -(\gamma^{\mu})^{\mathsf{T}}$. Conjugating a product and using $C^{-1}C = \mathbf{1}$ between factors,

$$C\,\gamma^{\mu_1}\cdots\gamma^{\mu_n}\,C^{-1} = (-1)^n(\gamma^{\mu_1})^{\mathsf{T}}\cdots(\gamma^{\mu_n})^{\mathsf{T}} = (-1)^n(\gamma^{\mu_n}\cdots\gamma^{\mu_1})^{\mathsf{T}}, \tag{C.159}$$

where the last step is the reversal of order under transposition of a product. The trace is invariant under similarity transformations and under transposition, so

$$\operatorname{tr}(\gamma^{\mu_1}\cdots\gamma^{\mu_n}) = \operatorname{tr}\Big(C\,\gamma^{\mu_1}\cdots\gamma^{\mu_n}\,C^{-1}\Big) = (-1)^n\,\operatorname{tr}(\gamma^{\mu_n}\cdots\gamma^{\mu_1}), \tag{C.160}$$

and $(-1)^n = 1$ for even n. □

One checks Eq. (C.158) directly on Eq. (C.157): reversing $\mu\nu\rho\sigma \to \sigma\rho\nu\mu$ maps the three pairings to themselves, leaving the result unchanged. In practice the reversal identity is used to recognize that, e.g., $\operatorname{tr}(\not{a}\not{b}\not{c}\not{d}) = \operatorname{tr}(\not{d}\not{c}\not{b}\not{a})$ without re-expanding.

C.6.5 Traces with γ^5 and the Levi-Civita tensor

The remaining traces are those that carry one factor of γ^5. They are what distinguish a theory from its mirror image: a nonzero γ^5-trace is the algebraic fingerprint of parity violation and of the chiral anomaly (Chapter 19 and beyond). We first dispose of the short ones, then compute the single nonvanishing case.

Proposition C.56 (Short γ^5-traces vanish)**.**

$$\operatorname{tr}\gamma^5 = 0, \qquad \operatorname{tr}(\gamma^5\gamma^{\mu}) = 0, \qquad \operatorname{tr}(\gamma^5\gamma^{\mu}\gamma^{\nu}) = 0, \qquad \operatorname{tr}(\gamma^5\gamma^{\mu}\gamma^{\nu}\gamma^{\rho}) = 0. \tag{C.161}$$

Proof. That $\operatorname{tr}\gamma^5 = 0$ was handed to us by Section C.5; it also follows directly from $(\gamma^0)^2 = \eta^{00}\mathbf{1} = \mathbf{1}$ together with $\gamma^0\gamma^5 = -\gamma^5\gamma^0$:

$$\operatorname{tr}\gamma^5 = \operatorname{tr}(\gamma^5(\gamma^0)^2) = \operatorname{tr}(\gamma^0\gamma^5\gamma^0) = -\operatorname{tr}(\gamma^5(\gamma^0)^2) = -\operatorname{tr}\gamma^5, \tag{C.162}$$

using cyclicity in the middle step. The traces $\operatorname{tr}(\gamma^5\gamma^\mu)$ and $\operatorname{tr}(\gamma^5\gamma^\mu\gamma^\nu\gamma^\rho)$ contain an odd number of ordinary gamma matrices; since γ^5 is itself a product of four gammas, each is a trace of an odd total number of gamma matrices and vanishes by Theorem C.53. For $\operatorname{tr}(\gamma^5\gamma^\mu\gamma^\nu)$ with $\mu = \nu$ the string collapses to $\eta^{\mu\mu}\operatorname{tr}\gamma^5 = 0$. For $\mu \neq \nu$, choose an index α distinct from both μ and ν—possible because spacetime is four-dimensional—so that $(\gamma^\alpha)^2 = \eta^{\alpha\alpha}\mathbf{1}$ with $\eta^{\alpha\alpha} = \pm 1 \neq 0$. Insert $\mathbf{1} = (\eta^{\alpha\alpha})^{-1}(\gamma^\alpha)^2$ at the right and cycle one γ^α to the front:

$$\operatorname{tr}(\gamma^5\gamma^\mu\gamma^\nu) = \frac{1}{\eta^{\alpha\alpha}}\operatorname{tr}(\gamma^\alpha\gamma^5\gamma^\mu\gamma^\nu\gamma^\alpha). \tag{C.163}$$

Now move the leading γ^α rightward: it anticommutes with γ^5 (one sign) and with each of γ^μ, γ^ν (two signs, since $\alpha \neq \mu, \nu$), so $\gamma^\alpha\gamma^5\gamma^\mu\gamma^\nu = -\gamma^5\gamma^\mu\gamma^\nu\gamma^\alpha$. Hence the right side equals $(\eta^{\alpha\alpha})^{-1}(-1)\eta^{\alpha\alpha}\operatorname{tr}(\gamma^5\gamma^\mu\gamma^\nu) = -\operatorname{tr}(\gamma^5\gamma^\mu\gamma^\nu)$, forcing it to zero. □

The only γ^5-trace that survives in $d = 4$ is the one with four gamma matrices, and it produces the totally antisymmetric Levi-Civita tensor.

Theorem C.57 (The γ^5 four-trace)**.**

$$\operatorname{tr}(\gamma^5\gamma^\mu\gamma^\nu\gamma^\rho\gamma^\sigma) = -4i\,\epsilon^{\mu\nu\rho\sigma}, \tag{C.164}$$

with the convention $\epsilon^{0123} = +1$.

Proof. First, the left side is totally antisymmetric in $\mu\nu\rho\sigma$. If any two of the indices coincide, the corresponding pair of adjacent (after permutation) gamma matrices can be replaced via the Clifford relation by a metric factor times the identity, leaving a γ^5-trace with at most two gamma matrices, which vanishes by Theorem C.56; antisymmetry under interchange of unequal adjacent indices follows because $\gamma^\rho\gamma^\sigma = -\gamma^\sigma\gamma^\rho$ when $\rho \neq \sigma$. A totally antisymmetric four-index Lorentz tensor in four dimensions is unique up to scale, so

$$\operatorname{tr}(\gamma^5\gamma^\mu\gamma^\nu\gamma^\rho\gamma^\sigma) = K\,\epsilon^{\mu\nu\rho\sigma} \tag{C.165}$$

for some constant K. Fix K by evaluating at $(\mu\nu\rho\sigma) = (0123)$, where $\epsilon^{0123} = +1$. From the definition $\gamma^5 = i\gamma^0\gamma^1\gamma^2\gamma^3$ we have $\gamma^0\gamma^1\gamma^2\gamma^3 = -i\gamma^5$, so

$$\operatorname{tr}(\gamma^5\gamma^0\gamma^1\gamma^2\gamma^3) = \operatorname{tr}(\gamma^5(-i\gamma^5)) = -i\,\operatorname{tr}((\gamma^5)^2) = -i\,\operatorname{tr}\mathbf{1} = -4i. \tag{C.166}$$

Therefore $K \cdot (+1) = -4i$, i.e. $K = -4i$, which is Eq. (C.164). □

Notation Watch

The sign and i in Eq. (C.164) are convention-laden and must be quoted together with the Levi-Civita normalization. We use $\epsilon^{0123} = +1$, which in the mostly-minus metric forces $\epsilon_{0123} = \eta_{0\alpha}\eta_{1\beta}\eta_{2\gamma}\eta_{3\delta}\,\epsilon^{\alpha\beta\gamma\delta} = (+1)(-1)(-1)(-1)\,\epsilon^{0123} = -1$. With $\gamma^5 = i\gamma^0\gamma^1\gamma^2\gamma^3$ and $\operatorname{tr}\mathbf{1} = 4$ this fixes $\operatorname{tr}(\gamma^5\gamma^\mu\gamma^\nu\gamma^\rho\gamma^\sigma) = -4i\,\epsilon^{\mu\nu\rho\sigma}$. This matches the convention recorded in Chapter A; a text using $\epsilon_{0123} = +1$ or the opposite-sign γ^5 would report $+4i\,\epsilon^{\mu\nu\rho\sigma}$. Sign errors here propagate directly into parity-odd observables, so the convention is fixed once and used everywhere.

For amplitudes that square a parity-violating current one also needs the contraction of two Levi-Civita tensors. Because ϵ is totally antisymmetric, $\epsilon^{\mu\nu\rho\sigma}\epsilon_{\alpha\beta\gamma\delta}$ equals the determinant of the 4×4 matrix of Kronecker deltas δ^μ_α, multiplied by the sign $\det\eta = -1$ that arises from the single index raising needed to compare $\epsilon^{0123} = +1$ with $\epsilon_{0123} = -1$. Contracting indices then gives the chain

$$\begin{aligned}
\epsilon^{\mu\nu\rho\sigma}\epsilon_{\mu\nu\rho\sigma} &= -24, \qquad \epsilon^{\mu\nu\rho\sigma}\epsilon_{\mu\nu\rho\delta} = -6\,\delta^\sigma_\delta,\\
\epsilon^{\mu\nu\rho\sigma}\epsilon_{\mu\nu\gamma\delta} &= -2\big(\delta^\rho_\gamma\delta^\sigma_\delta - \delta^\rho_\delta\delta^\sigma_\gamma\big),
\end{aligned} \tag{C.167}$$

each carrying the leading minus sign characteristic of Lorentzian signature; the full determinant form is recorded in Chapter A.

C.6.6 Index-contraction identities

When a gamma string is sandwiched between propagator numerators and one contracts a repeated Lorentz index—as happens whenever a photon or gluon line is summed over polarizations in Feynman gauge—the string shortens according to a second family of identities. Unlike the traces, these are matrix identities (no trace taken); they too follow directly from the Clifford relation, and unlike the traces they depend explicitly on the spacetime dimension through $\gamma^\mu\gamma_\mu = d$. In $d = 4$:

Theorem C.58 (Contraction identities, $d = 4$)**.**

$$\gamma^\mu\gamma_\mu = 4\,\mathbf{1}, \tag{C.168}$$
$$\gamma^\mu\gamma^\nu\gamma_\mu = -2\,\gamma^\nu, \tag{C.169}$$
$$\gamma^\mu\gamma^\nu\gamma^\rho\gamma_\mu = 4\,\eta^{\nu\rho}\mathbf{1}, \tag{C.170}$$
$$\gamma^\mu\gamma^\nu\gamma^\rho\gamma^\sigma\gamma_\mu = -2\,\gamma^\sigma\gamma^\rho\gamma^\nu. \tag{C.171}$$

Proof. For Eq. (C.168), symmetrize the contracted product:

$$\gamma^\mu\gamma_\mu = \eta_{\mu\nu}\gamma^\mu\gamma^\nu = \tfrac{1}{2}\eta_{\mu\nu}\,\{\gamma^\mu,\gamma^\nu\} = \eta_{\mu\nu}\eta^{\mu\nu}\mathbf{1} = \delta^\mu_\mu\mathbf{1} = 4\,\mathbf{1}, \tag{C.172}$$

where $\delta^\mu_\mu = d = 4$. For Eq. (C.169), push γ_μ leftward past γ^ν using $\gamma^\nu\gamma_\mu = 2\delta^\nu_\mu \mathbf{1} - \gamma_\mu\gamma^\nu$:

$$\gamma^\mu\gamma^\nu\gamma_\mu = \gamma^\mu\big(2\delta^\nu_\mu - \gamma_\mu\gamma^\nu\big) = 2\gamma^\nu - (\gamma^\mu\gamma_\mu)\gamma^\nu = 2\gamma^\nu - 4\gamma^\nu = -2\gamma^\nu. \tag{C.173}$$

For Eq. (C.170), move γ_μ leftward one step at a time. Using $\gamma^\rho\gamma_\mu = 2\delta^\rho_\mu - \gamma_\mu\gamma^\rho$,

$$\gamma^\mu\gamma^\nu\gamma^\rho\gamma_\mu = 2\,\gamma^\rho\gamma^\nu - \gamma^\mu\gamma^\nu\gamma_\mu\gamma^\rho = 2\,\gamma^\rho\gamma^\nu - (-2\gamma^\nu)\gamma^\rho = 2\big(\gamma^\rho\gamma^\nu + \gamma^\nu\gamma^\rho\big) = 4\,\eta^{\nu\rho}\mathbf{1}, \tag{C.174}$$

where the first term used $\gamma^\mu\, 2\delta^\rho_\mu = 2\gamma^\rho$ and $\gamma^\mu\gamma^\nu\gamma_\mu = -2\gamma^\nu$ from Eq. (C.169). For Eq. (C.171), the same move on the outermost factor gives

$$\gamma^\mu\gamma^\nu\gamma^\rho\gamma^\sigma\gamma_\mu = 2\,\gamma^\sigma\gamma^\nu\gamma^\rho - \gamma^\mu\gamma^\nu\gamma^\rho\gamma_\mu\gamma^\sigma = 2\,\gamma^\sigma\gamma^\nu\gamma^\rho - 4\eta^{\nu\rho}\gamma^\sigma, \tag{C.175}$$

using Eq. (C.170). Finally rewrite the first term with $\gamma^\nu\gamma^\rho = 2\eta^{\nu\rho}\mathbf{1} - \gamma^\rho\gamma^\nu$:

$$2\gamma^\sigma\gamma^\nu\gamma^\rho = 2\gamma^\sigma\big(2\eta^{\nu\rho} - \gamma^\rho\gamma^\nu\big) = 4\eta^{\nu\rho}\gamma^\sigma - 2\gamma^\sigma\gamma^\rho\gamma^\nu, \tag{C.176}$$

so the two $4\eta^{\nu\rho}\gamma^\sigma$ pieces cancel and $\gamma^\mu\gamma^\nu\gamma^\rho\gamma^\sigma\gamma_\mu = -2\gamma^\sigma\gamma^\rho\gamma^\nu$. □

The pattern is transparent: contracting a pair of identical gamma matrices across a string of r matrices alternately contracts the enclosed indices (even r between them) or reverses the enclosed string (odd r between them), with the sign and the numerical coefficient set by $\gamma^\mu\gamma_\mu = d$. Keeping the dependence on d explicit—$\gamma^\mu\gamma_\mu = d$, $\gamma^\mu\gamma^\nu\gamma_\mu = (2-d)\gamma^\nu$, and so on—is exactly what Section C.7 will require for dimensional regularization; here we have set $d = 4$.

C.6.7 The toolkit in slash notation, and a worked trace

In amplitudes the gamma matrices are almost always contracted with momenta, $\not{p} \equiv \gamma^\mu p_\mu$. Re-expressing the identities above in slash form gives the shapes one actually meets. Contracting Eq. (C.152), Eq. (C.157), and Eq. (C.164) with four arbitrary four-vectors a, b, c, d,

$$\operatorname{tr}(\not{a}\not{b}) = 4\,(a\cdot b), \tag{C.177}$$

$$\operatorname{tr}(\not{a}\not{b}\not{c}\not{d}) = 4\big[(a\cdot b)(c\cdot d) - (a\cdot c)(b\cdot d) + (a\cdot d)(b\cdot c)\big], \tag{C.178}$$

$$\operatorname{tr}(\gamma^5\not{a}\not{b}\not{c}\not{d}) = -4i\,\epsilon_{\mu\nu\rho\sigma}\,a^\mu b^\nu c^\rho d^\sigma, \tag{C.179}$$

while the contraction identities become $\gamma^\mu\not{a}\gamma_\mu = -2\not{a}$ and $\gamma^\mu\not{a}\not{b}\gamma_\mu = 4\,(a\cdot b)\mathbf{1}$ and $\gamma^\mu\not{a}\not{b}\not{c}\gamma_\mu = -2\,\not{c}\not{b}\not{a}$. With Eq. (C.148), Eq. (C.177), Eq. (C.178), Eq. (C.179) and the contraction rules, every Dirac trace arising from a tree- or one-loop QED amplitude can be reduced to scalar invariants. The following worked example carries out the reduction that Chapter 17 needs.

Worked Example C.59 (The muon tensor in $e^+e^- \to \mu^+\mu^-$)**.** In $e^+e^- \to \mu^+\mu^-$ the squared amplitude factorizes, after summing over final muon spins and using the completeness relations $\sum_s u(p)\bar{u}(p) = \not{p} + m$ and $\sum_s v(p)\bar{v}(p) = \not{p} - m$ (Chapter 11), into a product of an electron tensor and a muon tensor. The muon tensor is

$$L^{\mu\nu} = \operatorname{tr}\Big[(\not{p}_3 + m)\,\gamma^\mu\,(\not{p}_4 - m)\,\gamma^\nu\Big], \tag{C.180}$$

where p_3 is the μ^- momentum, p_4 the μ^+ momentum, and $m = m_\mu$. Expand the product:

$$L^{\mu\nu} = \operatorname{tr}(\not{p}_3\gamma^\mu\not{p}_4\gamma^\nu) - m\,\operatorname{tr}(\not{p}_3\gamma^\mu\gamma^\nu) + m\,\operatorname{tr}(\gamma^\mu\not{p}_4\gamma^\nu) - m^2\,\operatorname{tr}(\gamma^\mu\gamma^\nu). \tag{C.181}$$

The two terms linear in m each contain three gamma matrices and vanish by Theorem C.53. The first term, written with explicit momentum indices, uses Eq. (C.157):

$$\begin{aligned}\operatorname{tr}(\not{p}_3\gamma^\mu\not{p}_4\gamma^\nu) &= p_{3\alpha}p_{4\beta}\,\operatorname{tr}(\gamma^\alpha\gamma^\mu\gamma^\beta\gamma^\nu)\\ &= 4\,p_{3\alpha}p_{4\beta}(\eta^{\alpha\mu}\eta^{\beta\nu} - \eta^{\alpha\beta}\eta^{\mu\nu} + \eta^{\alpha\nu}\eta^{\mu\beta})\\ &= 4(p_3^\mu p_4^\nu - (p_3\cdot p_4)\,\eta^{\mu\nu} + p_3^\nu p_4^\mu).\end{aligned} \tag{C.182}$$

The last term is $-m^2\operatorname{tr}(\gamma^\mu\gamma^\nu) = -4m^2\eta^{\mu\nu}$ by Eq. (C.152). Adding,

$$\boxed{L^{\mu\nu} = 4\Big[p_3^\mu p_4^\nu + p_3^\nu p_4^\mu - (p_3\cdot p_4 + m^2)\eta^{\mu\nu}\Big].} \tag{C.183}$$

The structure is exactly what symmetry demands: $L^{\mu\nu}$ is symmetric in $\mu\nu$ and, contracting with the photon momentum $q = p_3 + p_4$, one verifies $q_\mu L^{\mu\nu} = 4[(q\cdot p_3)p_4^\nu + (q\cdot p_4)p_3^\nu - (p_3\cdot p_4 + m^2)q^\nu]$, which on shell ($p_3^2 = p_4^2 = m^2$, so $q\cdot p_3 = m^2 + p_3\cdot p_4 = q\cdot p_4$) reduces to $q_\mu L^{\mu\nu} = 4(q\cdot p_3)(p_3+p_4)^\nu - 4(p_3\cdot p_4 + m^2)q^\nu = 0$, the transversality forced by current conservation. The electron tensor has the same form with $p_3, p_4 \to p_1, p_2$ and $m \to m_e$; contracting $L^{\mu\nu}$ with its electron counterpart and dividing by the four initial spin states yields the unpolarized $|\mathcal{M}|^2$ assembled in Chapter 17. Every gamma matrix has disappeared; what remains is a polynomial in dot products of the external momenta, which is the entire purpose of the trace technology.

The toolkit of this section—Eq. (C.148), the recursion Eq. (C.153) with its descendants Eq. (C.152) and Eq. (C.157), the reversal identity Eq. (C.158), the γ^5-trace Eq. (C.164), and the contraction identities of Theorem C.58—is complete for any spin-summed calculation performed in exactly four dimensions. The moment a loop integral is regulated, however, the gamma algebra must be continued to $d = 4 - 2\varepsilon$ dimensions, and three of the results above develop a dimension dependence that cannot be ignored: $\gamma^\mu\gamma_\mu = d$ rather than 4, the contraction identities acquire d-dependent coefficients, and—most consequentially—the totally antisymmetric four-index object behind Eq. (C.164) ceases to make unambiguous sense, because

γ^5 has no natural anticommuting definition away from integer dimension. The next section takes up precisely this continuation and confronts the γ^5 problem head-on.

C.7 Continuation to $d = 4 - 2\varepsilon$ and the γ^5 Problem

The trace and contraction technology assembled in Section C.6 was built in exactly four spacetime dimensions: the contraction $\eta^\mu{}_\mu = 4$ appeared as a number, the Dirac matrices were 4×4, and $\gamma^5 = i\gamma^0\gamma^1\gamma^2\gamma^3$ was a concrete sixteenth element of the bilinear basis. Dimensional regularization, the workhorse of every loop chapter in this book (the master integrals live in Chapter D; their first use is the QED one-loop programme of Chapter 19), demands that we continue all of this to non-integer dimension $d = 4 - 2\varepsilon$. We must therefore ask, of each identity in turn, whether it survives the continuation, and if so in what d-dependent form. Most of the toolkit passes through cleanly, acquiring only d-dependent prefactors that the loop chapters quote and expand in ε. One element does *not* pass through: the matrix γ^5, which is intrinsically four-dimensional, cannot be continued while keeping all of its four-dimensional algebraic properties. This section gives the surviving d-dimensional rules in full, then confronts the γ^5 obstruction honestly — proving the inconsistency, exhibiting the standard 't Hooft–Veltman–Breitenlohner–Maison repair, and naming its price.

C.7.1 The formal Clifford algebra in d dimensions

There is no honest finite-dimensional representation of the Clifford algebra in non-integer dimension: γ^μ for "$d = 3.99$" is not a matrix. What dimensional regularization actually provides is an *algebra of formal manipulation rules*, fixed once and for all, together with the analytic continuation of the scalar loop integrals those manipulations produce. The rules are chosen so that (i) they reduce to the genuine four-dimensional algebra at $d = 4$, (ii) they are internally consistent enough to define every trace and contraction unambiguously, and (iii) they make the loop integrand a meromorphic function of d whose poles at $d = 4$ carry the ultraviolet divergences. A fully rigorous construction realizes the γ^μ as operators on an infinite-dimensional space with the index μ ranging over a formally d-dimensional metric space; for computation, only the contraction and trace rules below are ever needed.

Definition C.60 (Formal d-dimensional Clifford data)**.** The d-dimensional gamma matrices satisfy the Clifford relation

$$\{\gamma^\mu, \gamma^\nu\} = 2\eta^{\mu\nu}\mathbf{1}, \tag{C.184}$$

where the metric $\eta^{\mu\nu}$ now carries a formally d-dimensional trace,

$$\eta^\mu{}_\mu = \eta^{\mu\nu}\eta_{\mu\nu} = \delta^\mu{}_\mu = d. \tag{C.185}$$

The trace over the (suppressed) Dirac indices of the identity is fixed to

$$\operatorname{tr}\mathbf{1} = 4, \tag{C.186}$$

and the trace is linear and cyclic, $\operatorname{tr}(AB) = \operatorname{tr}(BA)$.

Two conventions inside Theorem C.60 deserve comment. First, Eq. (C.185) is the single structural change that distinguishes the d-dimensional algebra from its four-dimensional parent: every time an index pair is contracted around the loop, the bookkeeping value 4 is replaced by the symbol $d = 4 - 2\varepsilon$. This one substitution generates all the d-dependence in the contraction identities below. Second, the choice Eq. (C.186) retains $\operatorname{tr}\mathbf{1} = 4$ rather than the alternative $\operatorname{tr}\mathbf{1} = 2^{d/2}$ that one would obtain by literally continuing the dimension $2^{\lfloor d/2 \rfloor}$ of an irreducible Dirac representation. The two differ by $2^{d/2} = 4 \cdot 2^{-\varepsilon} = 4\,(1 - \varepsilon \ln 2 + \dots)$, i.e. only at $O(\varepsilon)$. Because an overall constant multiplying every trace is a global normalization that cancels in ratios and is absorbed into the (scheme-dependent) finite parts of counterterms, both choices give identical physics; we follow the universal convention $\operatorname{tr}\mathbf{1} = 4$ so that the four-dimensional trace formulae of Section C.6 continue to hold verbatim in form.

C.7.2 The d-dependent contraction identities

We now run the four-dimensional contraction recursion of Section C.6 with $\eta^{\mu}{}_{\mu} = d$ in place of 4. Every step uses only Eqs. (C.184) and (C.185); the proofs are short and we give all the algebra, since the loop chapters quote the results constantly.

Proposition C.61 (Contraction identities in d dimensions)**.** *With $d = 4 - 2\varepsilon$ understood,*

$$\gamma^{\mu}\gamma_{\mu} = d\,\mathbf{1}, \tag{C.187}$$

$$\gamma^{\mu}\gamma^{\nu}\gamma_{\mu} = (2 - d)\,\gamma^{\nu}, \tag{C.188}$$

$$\gamma^{\mu}\gamma^{\nu}\gamma^{\rho}\gamma_{\mu} = 4\,\eta^{\nu\rho}\mathbf{1} - (4 - d)\,\gamma^{\nu}\gamma^{\rho}, \tag{C.189}$$

$$\gamma^{\mu}\gamma^{\nu}\gamma^{\rho}\gamma^{\sigma}\gamma_{\mu} = -2\,\gamma^{\sigma}\gamma^{\rho}\gamma^{\nu} + (4 - d)\,\gamma^{\nu}\gamma^{\rho}\gamma^{\sigma}. \tag{C.190}$$

Proof. For Eq. (C.187), symmetrize the contracted product with Eq. (C.184): $\gamma^{\mu}\gamma_{\mu} = \frac{1}{2}\{\gamma^{\mu}, \gamma_{\mu}\} = \frac{1}{2} \cdot 2\,\eta^{\mu}{}_{\mu}\mathbf{1} = d\,\mathbf{1}$ by Eq. (C.185).

For Eq. (C.188), anticommute the left factor inward, $\gamma^{\mu}\gamma^{\nu} = 2\eta^{\mu\nu}\mathbf{1} - \gamma^{\nu}\gamma^{\mu}$, and then apply Eq. (C.187):

$$\gamma^{\mu}\gamma^{\nu}\gamma_{\mu} = (2\eta^{\mu\nu} - \gamma^{\nu}\gamma^{\mu})\gamma_{\mu} = 2\gamma^{\nu} - \gamma^{\nu}\,(\gamma^{\mu}\gamma_{\mu}) = 2\gamma^{\nu} - d\,\gamma^{\nu} = (2 - d)\gamma^{\nu}. \tag{C.191}$$

For Eq. (C.189), do the same with the leftmost pair and feed in Eq. (C.188):

$$\gamma^{\mu}\gamma^{\nu}\gamma^{\rho}\gamma_{\mu} = (2\eta^{\mu\nu} - \gamma^{\nu}\gamma^{\mu})\gamma^{\rho}\gamma_{\mu} = 2\gamma^{\rho}\gamma^{\nu} - \gamma^{\nu}\,(\gamma^{\mu}\gamma^{\rho}\gamma_{\mu})$$

$$= 2\gamma^\rho\gamma^\nu - (2-d)\,\gamma^\nu\gamma^\rho. \tag{C.192}$$

Now reduce the first term with $\gamma^\rho\gamma^\nu = 2\eta^{\nu\rho}\mathbf{1} - \gamma^\nu\gamma^\rho$, giving $2\gamma^\rho\gamma^\nu = 4\eta^{\nu\rho}\mathbf{1} - 2\gamma^\nu\gamma^\rho$, so that

$$\gamma^\mu\gamma^\nu\gamma^\rho\gamma_\mu = 4\eta^{\nu\rho}\mathbf{1} - 2\gamma^\nu\gamma^\rho - (2-d)\gamma^\nu\gamma^\rho = 4\eta^{\nu\rho}\mathbf{1} - (4-d)\gamma^\nu\gamma^\rho. \tag{C.193}$$

For Eq. (C.190), anticommute the left factor past γ^ν and apply Eq. (C.189):

$$\begin{aligned}\gamma^\mu\gamma^\nu\gamma^\rho\gamma^\sigma\gamma_\mu &= (2\eta^{\mu\nu} - \gamma^\nu\gamma^\mu)\gamma^\rho\gamma^\sigma\gamma_\mu = 2\gamma^\rho\gamma^\sigma\gamma^\nu - \gamma^\nu\,(\gamma^\mu\gamma^\rho\gamma^\sigma\gamma_\mu)\\ &= 2\gamma^\rho\gamma^\sigma\gamma^\nu - \gamma^\nu\big[4\eta^{\rho\sigma}\mathbf{1} - (4-d)\gamma^\rho\gamma^\sigma\big]\\ &= 2\gamma^\rho\gamma^\sigma\gamma^\nu - 4\eta^{\rho\sigma}\gamma^\nu + (4-d)\gamma^\nu\gamma^\rho\gamma^\sigma.\end{aligned} \tag{C.194}$$

Writing $2\gamma^\rho\gamma^\sigma = 4\eta^{\rho\sigma}\mathbf{1} - 2\gamma^\sigma\gamma^\rho$ collapses the first two terms, $2\gamma^\rho\gamma^\sigma\gamma^\nu - 4\eta^{\rho\sigma}\gamma^\nu = -2\gamma^\sigma\gamma^\rho\gamma^\nu$, and Eq. (C.190) follows. □

The hallmark of these formulae is that the four-dimensional results are recovered by setting $d = 4$, whereupon Eqs. (C.187) to (C.190) read 4, $-2\gamma^\nu$, $4\eta^{\nu\rho}\mathbf{1}$, and $-2\gamma^\sigma\gamma^\rho\gamma^\nu$, exactly as in Section C.6. The corrections $(2-d) = 2(\varepsilon-1)$ and $(4-d) = 2\varepsilon$ are precisely the $O(\varepsilon)$ remnants that, multiplied against a $1/\varepsilon$ pole from a divergent integral, leave a finite contribution; this is why the loop chapters cannot drop them.

We shall need one identity at the next order, the contraction of a pair around a *four*-gamma string, for the γ^5 analysis to follow.

Lemma C.62 (Sandwich of four gammas)**.** *In d dimensions,*

$$\gamma^\alpha\gamma^\mu\gamma^\nu\gamma^\rho\gamma^\sigma\gamma_\alpha = 2\,\gamma^\nu\gamma^\rho\gamma^\sigma\gamma^\mu + 2\,\gamma^\mu\gamma^\sigma\gamma^\rho\gamma^\nu - (4-d)\,\gamma^\mu\gamma^\nu\gamma^\rho\gamma^\sigma. \tag{C.195}$$

Proof. Anticommute the left γ^α past γ^μ, $\gamma^\alpha\gamma^\mu = 2\eta^{\alpha\mu}\mathbf{1} - \gamma^\mu\gamma^\alpha$:

$$\gamma^\alpha\gamma^\mu\gamma^\nu\gamma^\rho\gamma^\sigma\gamma_\alpha = 2\,\gamma^\nu\gamma^\rho\gamma^\sigma\gamma^\mu - \gamma^\mu\,(\gamma^\alpha\gamma^\nu\gamma^\rho\gamma^\sigma\gamma_\alpha). \tag{C.196}$$

The bracketed factor is Eq. (C.190) with indices (ν,ρ,σ), equal to $-2\gamma^\sigma\gamma^\rho\gamma^\nu + (4-d)\gamma^\nu\gamma^\rho\gamma^\sigma$. Substituting and distributing the $-\gamma^\mu$ gives Eq. (C.195). □

C.7.3 Traces in d dimensions

The trace identities *without* γ^5 are unchanged in form. Their derivations in Section C.6 used only the Clifford relation, the cyclicity of the trace, and $\operatorname{tr}\mathbf{1} = 4$ — never the integer value of $\eta^\mu{}_\mu$ inside the trace itself — so they continue verbatim:

$$\operatorname{tr}\mathbf{1} = 4, \qquad \operatorname{tr}(\gamma^{\mu_1}\cdots\gamma^{\mu_n}) = 0 \quad (n \text{ odd}), \tag{C.197}$$

$$\operatorname{tr}(\gamma^\mu\gamma^\nu) = 4\,\eta^{\mu\nu}, \tag{C.198}$$

$$\operatorname{tr}(\gamma^\mu\gamma^\nu\gamma^\rho\gamma^\sigma) = 4(\eta^{\mu\nu}\eta^{\rho\sigma} - \eta^{\mu\rho}\eta^{\nu\sigma} + \eta^{\mu\sigma}\eta^{\nu\rho}). \tag{C.199}$$

The dimension d enters traces only through Eq. (C.185), when an index is contracted *between* matrices inside the trace before the trace is taken. For instance $\mathrm{tr}(\gamma^\mu\gamma^\nu)\eta_{\mu\nu} = 4\,\eta^\mu{}_\mu = 4d$, and the contracted four-gamma trace becomes

$$\mathrm{tr}\big(\gamma^\mu\gamma^\nu\gamma_\mu\gamma_\nu\big) = \mathrm{tr}\big[(2-d)\gamma^\nu\gamma_\nu\big] = (2-d)\,d\;\mathrm{tr}\,\mathbf{1} = 4d(2-d), \tag{C.200}$$

using Eq. (C.188) then Eq. (C.187). Every such contracted factor produces a polynomial in $d = 4-2\varepsilon$ that, in a physical amplitude, multiplies the ε-expansion of a master integral. The loop chapters therefore carry these prefactors symbolically until the very end and only then expand: e.g. $d = 4-2\varepsilon$, $(2-d) = -2+2\varepsilon$, $(4-d) = 2\varepsilon$, $(d-2)/(d-1) = \frac{2}{3}(1+\frac{1}{2}\varepsilon+\dots)$, and so on. The discipline is simple but unforgiving: an $O(\varepsilon)$ slip in a prefactor times a $1/\varepsilon$ pole is a finite error in the answer.

Worked Example C.63 (The QED self-energy numerator)**.** The one-loop electron self-energy of Chapter 19 contains the Dirac structure

$$N(p) \;\equiv\; \gamma^\mu\,(\not{p}+m)\,\gamma_\mu, \tag{C.201}$$

the numerator left after the photon line contracts the two QED vertices. We reduce it in d dimensions. Split into the two pieces and apply Theorem C.61:

$$\gamma^\mu\not{p}\,\gamma_\mu = p_\alpha\,\gamma^\mu\gamma^\alpha\gamma_\mu = (2-d)\,p_\alpha\gamma^\alpha = (2-d)\,\not{p}, \tag{C.202}$$

$$\gamma^\mu\,m\,\gamma_\mu = m\,\gamma^\mu\gamma_\mu = m\,d. \tag{C.203}$$

Hence

$$N(p) = (2-d)\,\not{p} + d\,m. \tag{C.204}$$

Inserting $d = 4-2\varepsilon$,

$$N(p) = (-2+2\varepsilon)\,\not{p} + (4-2\varepsilon)\,m = -2\,(1-\varepsilon)\,\not{p} + 2\,(2-\varepsilon)\,m, \tag{C.205}$$

which at $d = 4$ collapses to the familiar $-2\not{p}+4m$. The retained ε-pieces are exactly what survive against the $1/\varepsilon$ pole of the accompanying scalar integral and feed the residue that fixes the field-strength and mass renormalization constants Z_2, Z_m in Chapter 19. This is the prototype for every numerator algebra in QED's loop computations (Chapters 17, 19 and 20): contract with Theorem C.61, keep d symbolic, expand last.

C.7.4 The γ^5 obstruction

Everything above continued without incident because γ^5 never appeared. The trouble is specific to $\gamma^5 = i\gamma^0\gamma^1\gamma^2\gamma^3$, a product of *exactly four* fixed matrices, an object whose definition presupposes that spacetime has exactly four directions. Three properties of γ^5 are used pervasively in four-dimensional calculations, and one would like to keep all three under continuation:

(P1) total anticommutation, $\{\gamma^5, \gamma^\mu\} = 0$ for *every* $\mu = 0, 1, \ldots, d-1$;

(P2) the nonvanishing chiral trace, $\operatorname{tr}(\gamma^5\,\gamma^\mu\gamma^\nu\gamma^\rho\gamma^\sigma) = -4i\,\varepsilon^{\mu\nu\rho\sigma}$ (the convention and sign fixed in Section C.6, with $\varepsilon^{0123} = +1$ as in Chapter A);

(P3) cyclicity of the trace, together with $\operatorname{tr}\mathbf{1} = 4$.

These three demands are mutually inconsistent for $d \neq 4$. The proof is a single trace evaluated two ways.

Theorem C.64 (Incompatibility of the naive γ^5 rules)**.** *Assume (P1), (P3), and the contraction algebra of Theorem C.61, all taken to hold for general d. Then*

$$(d-4)\,\operatorname{tr}(\gamma^5\,\gamma^\mu\gamma^\nu\gamma^\rho\gamma^\sigma) = 0. \tag{C.206}$$

Consequently, for $d \neq 4$ the chiral trace must vanish, in direct contradiction with (P2). No continuation can keep all of (P1), (P2), (P3) at once.

Proof. Write $T^{\mu\nu\rho\sigma} \equiv \operatorname{tr}(\gamma^5\,\gamma^\mu\gamma^\nu\gamma^\rho\gamma^\sigma)$ and consider the single object

$$Y \;\equiv\; \operatorname{tr}(\gamma^5\,\gamma^\mu\gamma^\nu\gamma^\rho\gamma^\sigma\,\gamma_\alpha\gamma^\alpha). \tag{C.207}$$

First evaluation. Contract the trailing pair immediately with Eq. (C.187), $\gamma_\alpha\gamma^\alpha = d\,\mathbf{1}$:

$$Y = d\,\operatorname{tr}(\gamma^5\,\gamma^\mu\gamma^\nu\gamma^\rho\gamma^\sigma) = d\,T^{\mu\nu\rho\sigma}. \tag{C.208}$$

Second evaluation. Leave the pair uncontracted and instead move the rightmost factor γ^α around the trace. By cyclicity (P3),

$$Y = \operatorname{tr}(\gamma^\alpha\,\gamma^5\,\gamma^\mu\gamma^\nu\gamma^\rho\gamma^\sigma\,\gamma_\alpha). \tag{C.209}$$

By total anticommutation (P1), $\gamma^\alpha\gamma^5 = -\gamma^5\gamma^\alpha$, so

$$Y = -\operatorname{tr}(\gamma^5\,\gamma^\alpha\,\gamma^\mu\gamma^\nu\gamma^\rho\gamma^\sigma\,\gamma_\alpha). \tag{C.210}$$

The remaining string is the four-gamma sandwich Eq. (C.195). Substituting it,

$$\begin{aligned} Y &= -\operatorname{tr}\Big(\gamma^5\big[\,2\gamma^\nu\gamma^\rho\gamma^\sigma\gamma^\mu + 2\gamma^\mu\gamma^\sigma\gamma^\rho\gamma^\nu - (4-d)\gamma^\mu\gamma^\nu\gamma^\rho\gamma^\sigma\big]\Big) \\ &= -2\,T^{\nu\rho\sigma\mu} - 2\,T^{\mu\sigma\rho\nu} + (4-d)\,T^{\mu\nu\rho\sigma}. \end{aligned} \tag{C.211}$$

Now use the total antisymmetry of $T^{\mu\nu\rho\sigma}$ in its four indices, which follows from (P2) but in fact only needs the anticommutator Eq. (C.184) inside the trace together with cyclicity: swapping any two adjacent gammas costs a sign (the symmetric remainder $2\eta\,\operatorname{tr}(\gamma^5\,\gamma\gamma) = 0$ vanishes by Eq. (C.197), as it is a γ^5-trace of two gammas). Thus T is alternating, and

$$T^{\nu\rho\sigma\mu} = -T^{\mu\nu\rho\sigma}, \qquad T^{\mu\sigma\rho\nu} = -T^{\mu\nu\rho\sigma}, \tag{C.212}$$

the first because $(\nu\rho\sigma\mu)$ is a single left-cyclic shift of $(\mu\nu\rho\sigma)$, an odd permutation of four objects, the second because $(\mu\sigma\rho\nu)$ differs from $(\mu\nu\rho\sigma)$ by the transposition $\nu \leftrightarrow \sigma$. Hence Eq. (C.211) becomes

$$Y = -2(-T^{\mu\nu\rho\sigma}) - 2(-T^{\mu\nu\rho\sigma}) + (4-d)T^{\mu\nu\rho\sigma} = (8-d)\,T^{\mu\nu\rho\sigma}. \tag{C.213}$$

Consistency. Equating the two evaluations Eq. (C.208) and Eq. (C.213),

$$d\,T^{\mu\nu\rho\sigma} = (8-d)\,T^{\mu\nu\rho\sigma} \quad\Longrightarrow\quad (2d-8)\,T^{\mu\nu\rho\sigma} = 0 \quad\Longrightarrow\quad 2(d-4)\,T^{\mu\nu\rho\sigma} = 0, \tag{C.214}$$

which is Eq. (C.206). For $d \neq 4$ this forces $T^{\mu\nu\rho\sigma} = 0$, contradicting (P2), where $T^{\mu\nu\rho\sigma} = -4i\,\varepsilon^{\mu\nu\rho\sigma} \neq 0$. □

Physical Insight

The contradiction is not a technical accident; it is the algebraic fingerprint of the chiral anomaly. The single piece of data that is genuinely four-dimensional — the Levi-Civita symbol $\varepsilon^{\mu\nu\rho\sigma}$ carried by the chiral trace — cannot be reconciled with a smooth, fully chirally symmetric continuation to general d. Whatever prescription one adopts, it must *break* something, and the breaking is exactly what surfaces as the nonconservation of the axial current computed in Chapter 36. A regulator that respected chiral symmetry exactly would predict no anomaly, in conflict with experiment ($\pi^0 \to \gamma\gamma$); the γ^5 problem of dimensional regularization is the price of having a regulator at all.

C.7.5 The 't Hooft–Veltman–Breitenlohner–Maison scheme

Theorem C.64 says we must sacrifice one of (P1), (P2), (P3). Cyclicity (P3) and the nonvanishing trace (P2) are too valuable — and too closely tied to the physical anomaly — to give up. The 't Hooft–Veltman prescription, made algebraically rigorous and proved consistent to all orders by Breitenlohner and Maison (the BMHV scheme), therefore sacrifices the *universality* of (P1): γ^5 is kept anticommuting with the four genuinely physical gamma matrices and made *commuting* with the remaining $(d-4)$ evanescent ones.

Definition C.65 (BMHV split)**.** Decompose the formally d-dimensional space into a four-dimensional "physical" subspace and a $(d-4)$-dimensional "evanescent" subspace. The metric and gamma matrices split as

$$\eta^{\mu\nu} = \bar{\eta}^{\mu\nu} + \hat{\eta}^{\mu\nu}, \qquad \bar{\eta}^{\mu}{}_{\mu} = 4, \quad \hat{\eta}^{\mu}{}_{\mu} = d-4 = -2\varepsilon, \tag{C.215}$$

$$\gamma^{\mu} = \bar{\gamma}^{\mu} + \hat{\gamma}^{\mu}, \qquad \bar{\gamma}^{\mu} \equiv \bar{\eta}^{\mu}{}_{\nu}\gamma^{\nu}, \quad \hat{\gamma}^{\mu} \equiv \hat{\eta}^{\mu}{}_{\nu}\gamma^{\nu}, \tag{C.216}$$

where the barred matrices $\bar{\gamma}^{\mu}$ obey the four-dimensional Clifford algebra $\{\bar{\gamma}^{\mu}, \bar{\gamma}^{\nu}\} = 2\bar{\eta}^{\mu\nu}$, the hatted matrices the evanescent one $\{\hat{\gamma}^{\mu}, \hat{\gamma}^{\nu}\} = 2\hat{\eta}^{\mu\nu}$, and the two sectors

anticommute, $\{\bar{\gamma}^\mu, \hat{\gamma}^\nu\} = 0$. The chiral matrix is defined purely in the physical sector,

$$\gamma^5 \equiv i\,\bar{\gamma}^0\bar{\gamma}^1\bar{\gamma}^2\bar{\gamma}^3. \tag{C.217}$$

The defining (an)ticommutators follow at once from Eq. (C.217) and the sector algebra: γ^5 is built from four barred matrices, so it anticommutes with each barred matrix and commutes with each hatted one,

$$\left\{\gamma^5, \bar{\gamma}^\mu\right\} = 0, \qquad \left[\gamma^5, \hat{\gamma}^\mu\right] = 0. \tag{C.218}$$

Recombining via Eq. (C.216),

$$\left\{\gamma^5, \gamma^\mu\right\} = \left\{\gamma^5, \bar{\gamma}^\mu\right\} + \left\{\gamma^5, \hat{\gamma}^\mu\right\} = 2\,\gamma^5\,\hat{\gamma}^\mu, \tag{C.219}$$

the right-hand side being purely evanescent (it is $O(\varepsilon)$ in the sense that it lives entirely in the $(d-4)$-dimensional sector). This is the precise statement that (P1) fails: γ^5 anticommutes with γ^μ only up to the evanescent remainder $2\gamma^5\hat{\gamma}^\mu$.

This single concession dissolves the contradiction of Theorem C.64. Retrace the second evaluation: the step $\gamma^\alpha\gamma^5 = -\gamma^5\gamma^\alpha$ is no longer exact, because $\{\gamma^5, \gamma^\alpha\} = 2\gamma^5\hat{\gamma}^\alpha \neq 0$. The extra evanescent term it generates is exactly what restores agreement with the first evaluation while leaving the genuinely four-dimensional chiral trace

$$\operatorname{tr}(\gamma^5\,\bar{\gamma}^\mu\bar{\gamma}^\nu\bar{\gamma}^\rho\bar{\gamma}^\sigma) = -4i\,\varepsilon^{\mu\nu\rho\sigma} \tag{C.220}$$

nonzero and consistent — the four matrices here are barred, so the obstruction, which required anticommuting an evanescent γ^α through γ^5, never triggers. Cyclicity and $\operatorname{tr}\mathbf{1} = 4$ are kept intact; the chiral trace is kept nonzero; and the algebra is provably consistent and unitary to all loop orders.

The price is stated honestly: because γ^5 no longer anticommutes with the full γ^μ, the scheme *breaks chiral symmetry by hand*. The chiral (and, in chiral gauge theories, the gauge) Ward identities acquire spurious violations of order ε from the evanescent remainder Eq. (C.219); multiplied by the $1/\varepsilon$ poles of divergent subgraphs, these leave *finite*, nonzero, symmetry-breaking residues. The Breitenlohner–Maison consistency theorem guarantees that all such breakings are local and can be cancelled, order by order in perturbation theory, by adding *finite, non-symmetric counterterms* tuned to restore the Ward identities. Where the violation is spurious — an artifact of the regulator — these finite counterterms remove it completely; where it is the genuine anomaly — as in the triangle graph of Chapter 36 — no symmetric counterterm exists, and the surviving finite piece is the physical anomaly coefficient, correctly normalized (the BMHV scheme automatically reproduces the Adler–Bardeen result).

Caution

The restoring counterterms in the BMHV scheme are an obligatory part of the calculation, not an optional polish. Omitting them does not merely shift a scheme convention; it leaves a wrong, gauge-variant answer. In any chiral calculation done with BMHV, one must check the relevant Ward–Takahashi identity (Chapter 19) at each order and add the finite counterterm needed to enforce it before quoting a physical result.

C.7.6 Naive dimensional regularization, Larin's scheme, and evanescent operators

The BMHV scheme is correct but cumbersome: the split into barred and hatted sectors multiplies the bookkeeping, and the restoring counterterms must be computed separately. Two pragmatic alternatives are in common use, each trading rigor for convenience in a controlled domain.

Naive dimensional regularization (NDR) keeps the four-dimensional rules wholesale: it imposes (P1) totally anticommuting γ^5 *and* retains cyclicity and $\operatorname{tr}\mathbf{1} = 4$, simply declining to apply both at the dangerous step. By Theorem C.64 this is inconsistent in general, and the inconsistency is concentrated entirely in traces containing a single γ^5 together with four or more other gamma matrices — precisely the "γ^5-odd" traces that probe the $\varepsilon^{\mu\nu\rho\sigma}$ structure. For amplitudes in which no such trace arises, or in which γ^5's appear in pairs that can be reduced away by $\gamma^5\gamma^5 = \mathbf{1}$ and $\{\gamma^5, \gamma^\mu\} = 0$ before any trace is closed, NDR is unambiguous and agrees with BMHV. It is the default in much of multiloop QCD, where chirality enters through vector and axial vertices in patterns that NDR handles cleanly. Its failure is exactly at the anomaly: an NDR calculation of the triangle graph must be supplemented by an external input (a "reading-point" prescription or the known Adler–Bardeen coefficient) to fix the ambiguity that Theorem C.64 guarantees is present.

Larin's scheme is a systematic prescription within dimensional regularization that sidesteps a free-floating γ^5 altogether by trading it, inside the d-dimensional algebra, for an explicit Levi-Civita tensor: one substitutes

$$\gamma^5\,\gamma^\mu \;\longrightarrow\; \frac{i}{3!}\,\varepsilon^{\mu\nu\rho\sigma}\,\gamma_\nu\gamma_\rho\gamma_\sigma, \qquad \gamma^5 \;\longrightarrow\; \frac{i}{4!}\,\varepsilon^{\mu\nu\rho\sigma}\,\gamma^\mu\gamma^\nu\gamma^\rho\gamma^\sigma, \tag{C.221}$$

treats the ε-tensor as a four-dimensional object contracted only at the end (with two ε's combining into a determinant of metrics carrying the full d-dependence), and then restores the correct Ward identities and the canonical normalization of the axial current by computing finite renormalization constants Z_5 and Z_A^{fin} once and for all. This is the scheme of choice for high-order axial-current and singlet-anomaly calculations in QCD, where its mechanical, manifestly d-dimensional rules make automation tractable.

Common to all three schemes is the notion of an *evanescent operator*: a Lorentz structure that vanishes identically at $d = 4$ but is nonzero at $d = 4 - 2\varepsilon$, such as the hatted bilinears built from $\hat{\gamma}^\mu$ in Eq. (C.216) or the difference between a d-dimensional Dirac string and its four-dimensional Fierz-reduced form. Evanescent operators are harmless at tree level but contribute through their $1/\varepsilon$ poles inside loops, mixing into physical operators with finite, scheme-dependent coefficients. They must be carried explicitly in the operator basis, renormalized like any other operator, and their finite mixing fixed by a stated convention; consistency between schemes is precisely the statement that physical quantities are independent of how the evanescent sector is renormalized once the same Ward identities are enforced. Their systematic treatment belongs to the operator-mixing machinery of Chapters 19 and 36; here we have established the algebra they live in and the reason they are unavoidable.

These rules — the d-dependent contractions Theorem C.61, the form-invariant traces Eqs. (C.198) and (C.199), and an explicitly chosen γ^5 scheme with its restoring counterterms — are the regularization-ready toolkit that QED's one-loop computations import in Chapters 19 and 20 and that the chiral-anomaly calculation of Chapter 36 cannot do without. With the algebra now continued and the γ^5 ambiguity pinned down rather than hidden, we return in the next section to four dimensions to turn the completeness relation into Fierz rearrangement and to assemble the external-state spinor sums that convert matrix elements into squared amplitudes.

C.8 Fierz Identities and External-State Spinor Technology

The completeness relation of Section C.5 is the statement that the sixteen matrices $\Gamma^A = \{\mathbf{1}, \gamma^\mu, \sigma^{\mu\nu}, \gamma^\mu\gamma^5, \gamma^5\}$ form a basis of the algebra of 4×4 matrices. Read forward, that result told us how to decompose any Dirac structure into bilinears. Read *sideways*, it tells us something more powerful: a product of two bilinears in which the four spinors are paired one way can be re-expanded as a sum of products in which they are paired the other way. This is the Fierz rearrangement, and it is the workhorse identity whenever a four-fermion operator must be regrouped — most famously when the charged-current weak interaction, written with the lepton paired to its neutrino, must be rewritten with the lepton paired to the other lepton. We derive the general rearrangement directly from completeness, paying close attention to the signs that the trace metric (Section C.6) and Fermi statistics (Section C.4, where the charge-conjugation data lives) introduce, and we carry the two canonical cases — scalar×scalar and the self-Fierzing $V-A$ current — in full.

We then assemble the second half of the section: the external-state spinor reference. Every cross section computed in this book contracts amplitudes against

the plane-wave solutions $u_s(p)$, $v_s(p)$ of the Dirac equation. We recall those solutions from Chapter 11 (their *existence* and physical meaning belong there; their *algebra* belongs here), establish their normalization and orthogonality, prove the spin-sum completeness relations and the energy projectors $\Lambda_\pm$, and finish with the Gordon decomposition — the identity that splits the electromagnetic current into a convection piece and a magnetic-moment piece, and so seeds the $g-2$ computation of Chapter 20.

C.8.1 The Fierz rearrangement problem

Fix four Dirac spinors and consider the product of two bilinears

$$(\bar\psi_1\,\Gamma^A\,\psi_2)(\bar\psi_3\,\Gamma^B\,\psi_4), \tag{C.222}$$

in which spinor 1 is contracted with 2 and spinor 3 with 4. We want to re-express this as a sum of products in which 1 is contracted with 4 and 3 with 2,

$$\sum_{C,D} F^{AB}{}_{CD}\,(\bar\psi_1\,\Gamma^C\,\psi_4)(\bar\psi_3\,\Gamma^D\,\psi_2). \tag{C.223}$$

The coefficients $F^{AB}{}_{CD}$ are pure numbers — they do not depend on the spinors — because (C.222) and (C.223) are both built from the same four spinors and the rearrangement is an identity at the level of the gamma matrices alone. Writing out the spinor indices (i,j,k,l running over the four Dirac components),

$$(\bar\psi_1)_i\,(\Gamma^A)_{ij}\,(\psi_2)_j\;(\bar\psi_3)_k\,(\Gamma^B)_{kl}\,(\psi_4)_l, \tag{C.224}$$

the entire content of the rearrangement is a statement about the tensor $(\Gamma^A)_{ij}(\Gamma^B)_{kl}$: we must re-expand it on the basis $(\Gamma^C)_{il}(\Gamma^D)_{kj}$, which carries the indices grouped so that i (spinor 1) sits with l (spinor 4) and k (spinor 3) with j (spinor 2).

C.8.2 The master formula and the 16×16 Fierz matrix

Recall from Section C.5 the normalized basis and its dual. With $\Gamma^A\in\{\mathbf{1},\gamma^\mu,\sigma^{\mu\nu},\gamma^\mu\gamma^5,\gamma^5\}$ we have the orthogonality

$$\operatorname{tr}\!\big(\Gamma^A\,\Gamma_B\big)=4\,\delta^A{}_B, \tag{C.225}$$

where the dual basis Γ_A is obtained by lowering with the diagonal Clifford metric g_{AB} defined by $\operatorname{tr}(\Gamma^A\Gamma^B)=4\,g^{AB}$. Explicitly, in the mostly-minus signature,

$$\Gamma_S=\mathbf{1},\qquad \Gamma_V=\gamma_\mu,\qquad \Gamma_T=\sigma_{\mu\nu},\qquad \Gamma_A=-\gamma_\mu\gamma^5,\qquad \Gamma_P=\gamma^5, \tag{C.226}$$

the crucial sign being the -1 on the axial sector, which follows from $\operatorname{tr}(\gamma^\mu\gamma^5\,\gamma^\nu\gamma^5)=-4\eta^{\mu\nu}$ (the two γ^5's and the anticommutation flip the sign relative to the vector sector). Completeness then states that any 4×4 matrix M obeys

$$M=\tfrac{1}{4}\sum_A \operatorname{tr}(\Gamma_A M)\,\Gamma^A. \tag{C.227}$$

Proposition C.66 (Fierz master formula)**.** *For the sixteen-element basis* $\{\Gamma^A\}$*,*

$$(\Gamma^A)_{ij}\,(\Gamma^B)_{kl} \;=\; \sum_{C,D} F^{AB}{}_{CD}\,(\Gamma^C)_{il}\,(\Gamma^D)_{kj}, \qquad F^{AB}{}_{CD} = \frac{1}{16}\,\mathrm{tr}(\Gamma^A\,\Gamma_D\,\Gamma^B\,\Gamma_C). \tag{C.228}$$

The 256 *numbers* $F^{AB}{}_{CD}$ *are the entries of the* 16×16 *Fierz matrix.*

Proof. Because the sixteen matrices Γ^C are a basis, and because for fixed i,l the object $(\Gamma^C)_{il}$ ranges over a basis of one index-pair while $(\Gamma^D)_{kj}$ ranges over a basis of the other, the products $(\Gamma^C)_{il}(\Gamma^D)_{kj}$ are a basis for the space of tensors with the index structure of the left-hand side. Hence an expansion of the form (C.228) exists with *some* coefficients $F^{AB}{}_{CD}$; it remains to extract them. Multiply both sides by $(\Gamma_{C'})_{li}\,(\Gamma_{D'})_{jk}$ and sum over all four indices. On the left,

$$\sum_{ijkl}(\Gamma^A)_{ij}(\Gamma^B)_{kl}(\Gamma_{C'})_{li}(\Gamma_{D'})_{jk} = \sum_{ijkl}(\Gamma^A)_{ij}(\Gamma_{D'})_{jk}(\Gamma^B)_{kl}(\Gamma_{C'})_{li} = \mathrm{tr}\big(\Gamma^A\,\Gamma_{D'}\,\Gamma^B\,\Gamma_{C'}\big), \tag{C.229}$$

where we have simply followed the index chain $i\to j\to k\to l\to i$. On the right,

$$\begin{aligned}\sum_{C,D} F^{AB}{}_{CD}\sum_{ijkl}(\Gamma^C)_{il}(\Gamma_{C'})_{li}\,(\Gamma^D)_{kj}(\Gamma_{D'})_{jk} &= \sum_{C,D} F^{AB}{}_{CD}\;\mathrm{tr}(\Gamma^C\Gamma_{C'})\;\mathrm{tr}(\Gamma^D\Gamma_{D'})\\ &= \sum_{C,D} F^{AB}{}_{CD}\,(4\delta^C{}_{C'})(4\delta^D{}_{D'}) = 16\,F^{AB}{}_{C'D'},\end{aligned} \tag{C.230}$$

using (C.225). Equating the two and renaming $C'D'\to CD$ gives the stated formula. □

Equation (C.228) is exact and completely general; everything below is its evaluation in physically important cases, together with the bookkeeping of Fermi statistics.

The sign from Fermi statistics. The identity (C.228) is a statement about gamma matrices, and it holds verbatim when the ψ's are commuting (c-number) external-state spinors — the situation in a scattering amplitude, where $u_s(p)$ and $v_s(p)$ are ordinary numbers. When instead the four bilinears are built from *anticommuting field operators*, as in an effective four-fermion operator $(\bar\psi_1\Gamma^A\psi_2)(\bar\psi_3\Gamma^B\psi_4)$, regrouping the fields to bring (C.222) into the form (C.223) requires moving ψ_2 past ψ_3 and ψ_4 (equivalently, reordering the four Grassmann factors from 1234 to 1432), which is an *odd* permutation and supplies an overall factor -1. We will state both versions explicitly; the -1 is exactly what makes the $V-A$ interaction self-Fierzing below.

C.8.3 Canonical case I: the scalar×scalar Fierz

Set $\Gamma^A = \Gamma^B = \mathbf{1}$. Then $F^{SS}{}_{CD} = \frac{1}{16}\,\mathrm{tr}(\Gamma_D\Gamma_C) = \frac{1}{16}\cdot 4\,g_{DC} = \frac{1}{4}g_{DC}$, using $\mathrm{tr}(\Gamma_D\Gamma_C) = 4g_{DC}$. Since $\sum_D g_{DC}\,\Gamma^D = \Gamma_C$, the sum over D collapses and

$$(\mathbf{1})_{ij}(\mathbf{1})_{kl} = \tfrac{1}{4}\sum_C (\Gamma^C)_{il}(\Gamma_C)_{kj}. \tag{C.231}$$

Spelling out the five sectors — and using the dual basis (C.226), so that the axial sector enters with a relative minus sign and the tensor sector carries the $\frac{1}{2}$ that compensates the double count of $\sigma_{\mu\nu} = -\sigma_{\nu\mu}$ when μ,ν are summed independently —

$$(\mathbf{1})_{ij}(\mathbf{1})_{kl} = \tfrac{1}{4}\Big[(\mathbf{1})_{il}(\mathbf{1})_{kj} + (\gamma^\mu)_{il}(\gamma_\mu)_{kj} + \tfrac{1}{2}(\sigma^{\mu\nu})_{il}(\sigma_{\mu\nu})_{kj} - (\gamma^\mu\gamma^5)_{il}(\gamma_\mu\gamma^5)_{kj} + (\gamma^5)_{il}(\gamma^5)_{kj}\Big]. \tag{C.232}$$

Sandwiching between the four spinors — i,j contracted with $\bar\psi_1,\psi_2$ and k,l with $\bar\psi_3,\psi_4$ — gives the scalar Fierz identity for c-number spinors,

$$(\bar1\,2)(\bar3\,4) = \tfrac{1}{4}\Big[(\bar1\,4)(\bar3\,2) + (\bar1\gamma^\mu 4)(\bar3\gamma_\mu 2) + \tfrac{1}{2}(\bar1\sigma^{\mu\nu}4)(\bar3\sigma_{\mu\nu}2) - (\bar1\gamma^\mu\gamma^5 4)(\bar3\gamma_\mu\gamma^5 2) + (\bar1\gamma^5 4)(\bar3\gamma^5 2)\Big], \tag{C.233}$$

where we abbreviate $(\bar1\,\Gamma\,2) \equiv \bar\psi_1\Gamma\psi_2$ and so on. For anticommuting fields the right-hand side acquires the overall -1 discussed above. The same evaluation applied to $\Gamma^A = \Gamma^B = \gamma^\rho$ (contracting the Lorentz index) uses the central contraction identity $\gamma^\rho\Gamma_D\gamma_\rho = \kappa_D\,\Gamma_D$ from Section C.6, with eigenvalues

$$\kappa_S = 4, \quad \kappa_V = -2, \quad \kappa_T = 0, \quad \kappa_A = 2, \quad \kappa_P = -4 \tag{C.234}$$

(these are $\gamma^\rho\gamma_\rho = 4$, $\gamma^\rho\gamma^\alpha\gamma_\rho = -2\gamma^\alpha$, $\gamma^\rho\sigma^{\alpha\beta}\gamma_\rho = 0$, and the γ^5-dressed versions). The result is the vector×vector Fierz,

$$(\bar1\gamma^\rho 2)(\bar3\gamma_\rho 4) = (\bar1\,4)(\bar3\,2) - \tfrac{1}{2}(\bar1\gamma^\mu 4)(\bar3\gamma_\mu 2) - \tfrac{1}{2}(\bar1\gamma^\mu\gamma^5 4)(\bar3\gamma_\mu\gamma^5 2) - (\bar1\gamma^5 4)(\bar3\gamma^5 2). \tag{C.235}$$

Iterating the same trace evaluation over all twenty-five sector pairs $\{S,V,T,A,P\}\times\{S,V,T,A,P\}$ generates the complete 5×5 Fierz table; the two rows (C.233), (C.235) exhibit the pattern, and every other row follows from (C.228) with the eigenvalue data (C.234) in exactly the same way. We do not tabulate the rest because the cases the book actually needs are the scalar identity above and the chiral identity we derive next.

C.8.4 Canonical case II: the $V-A$ self-Fierz

The charged-current weak interaction couples left-handed currents $\bar\psi\,\gamma^\mu(1-\gamma^5)\psi$. The remarkable fact — which is why the Fermi theory can be written equivalently with either pairing of the four fermions — is that the product of two such currents Fierzes *into itself*. We prove it cleanly using the chiral projectors $P_L = \frac{1}{2}(1-\gamma^5)$, $P_R = \frac{1}{2}(1+\gamma^5)$ (recall $P_L^2 = P_L$, $P_LP_R = 0$, $P_L\gamma^\mu = \gamma^\mu P_R$, from Section C.5).

Theorem C.67 ($V-A$ self-Fierz)**.** *As an identity of gamma matrices,*

$$(\gamma^\rho P_L)_{ij}\,(\gamma_\rho P_L)_{kl} = -\,(\gamma^\rho P_L)_{il}\,(\gamma_\rho P_L)_{kj}. \tag{C.236}$$

Consequently, for anticommuting fields the two left-handed currents obey

$$[\bar\psi_1\gamma^\rho(1-\gamma^5)\psi_2]\,[\bar\psi_3\gamma_\rho(1-\gamma^5)\psi_4] = [\bar\psi_1\gamma^\rho(1-\gamma^5)\psi_4]\,[\bar\psi_3\gamma_\rho(1-\gamma^5)\psi_2]. \tag{C.237}$$

Proof. First, a chirality argument fixes the *structure*. Because $\gamma^\rho P_L = P_R\gamma^\rho P_L$, the matrix $(\gamma^\rho P_L)_{ij}$ is nonzero only for i in the right-handed and j in the left-handed subspace; likewise k right, l left. Any Fierz expansion $\sum_{C,D} G_{CD}(\Gamma^C)_{il}(\Gamma^D)_{kj}$ therefore needs $(\Gamma^C)_{il}$ to connect a right index i to a left index l, i.e. Γ^C must anticommute with γ^5 ($P_R\Gamma^C P_L \neq 0$ forces $\Gamma^C \in \{V, A\}$), and similarly for Γ^D. But on this chirality block $(\gamma^\mu\gamma^5)_{il} = -(\gamma^\mu)_{il}$, so the vector and axial structures are not independent: the surviving content is precisely $(\gamma^\mu P_L)_{il}(\gamma_\mu P_L)_{kj}$. Hence

$$(\gamma^\rho P_L)_{ij}(\gamma_\rho P_L)_{kl} = c\,(\gamma^\mu P_L)_{il}(\gamma_\mu P_L)_{kj} \tag{C.238}$$

for a single constant c, which we now fix by contraction. Multiply both sides by $(\gamma_\nu)_{ji}(\gamma^\nu)_{lk}$ and sum all indices. The left-hand side factorizes into two traces,

$$\sum_{\rho,\nu} \operatorname{tr}(\gamma^\rho P_L\,\gamma_\nu)\ \operatorname{tr}(\gamma_\rho P_L\,\gamma^\nu). \tag{C.239}$$

Now $\operatorname{tr}(\gamma^\rho P_L\gamma_\nu) = \operatorname{tr}(\gamma^\rho\gamma_\nu P_R) = \frac{1}{2}\operatorname{tr}(\gamma^\rho\gamma_\nu) - \frac{1}{2}\operatorname{tr}(\gamma^\rho\gamma_\nu\gamma^5) = 2\delta^\rho{}_\nu$, the γ^5 trace vanishing (Section C.6). Therefore the left-hand side equals $\sum_{\rho,\nu}(2\delta^\rho{}_\nu)(2\delta_\rho{}^\nu) = 4\sum_\rho 1 = 16$.

For the right-hand side, the index contractions assemble a single trace,

$$c\sum_{\mu,\nu}\operatorname{tr}(\gamma^\mu P_L\,\gamma^\nu\,\gamma_\mu P_L\,\gamma_\nu). \tag{C.240}$$

Push the projectors through using $P_L\gamma = \gamma P_R$ and $P_R\gamma = \gamma P_L$:

$$\gamma^\mu P_L\gamma^\nu\gamma_\mu P_L\gamma_\nu = \gamma^\mu\gamma^\nu P_R\gamma_\mu P_L\gamma_\nu = \gamma^\mu\gamma^\nu\gamma_\mu P_L P_L\gamma_\nu = \gamma^\mu\gamma^\nu\gamma_\mu\gamma_\nu P_R, \tag{C.241}$$

where $P_L^2 = P_L$ and a final $P_L\gamma_\nu = \gamma_\nu P_R$ were used. The contraction $\sum_\mu \gamma^\mu\gamma^\nu\gamma_\mu = -2\gamma^\nu$ then gives $\sum_{\mu,\nu}\gamma^\mu\gamma^\nu\gamma_\mu\gamma_\nu = -2\sum_\nu\gamma^\nu\gamma_\nu = -2\cdot 4 = -8$, so the trace is $\operatorname{tr}(-8\,P_R) = -8\cdot 2 = -16$. The right-hand side is therefore $-16\,c$. Matching, $16 = -16\,c$, i.e. $c = -1$, which is (C.236).

Finally, sandwich (C.236) between c-number spinors and multiply through by $2\times 2 = 4$ to convert $P_L \to (1-\gamma^5)$ on each factor:

$$[\bar 1\gamma^\rho(1-\gamma^5)2]\,[\bar 3\gamma_\rho(1-\gamma^5)4] = -[\bar 1\gamma^\rho(1-\gamma^5)4]\,[\bar 3\gamma_\rho(1-\gamma^5)2] \quad \text{(c-number)}. \tag{C.242}$$

For anticommuting fields the regrouping supplies the extra -1 of Section C.8.2, and the two minus signs cancel, yielding (C.237). □

Physical Insight

The cancellation of the two minus signs — the $c = -1$ of the gamma algebra against the -1 of Fermi statistics — is the statement that the four-fermion left-handed interaction has no memory of how its fermions were originally paired. In the low-energy Fermi theory this is what lets one write the muon-decay interaction $(\bar{\nu}_\mu \Gamma \mu)(\bar{e} \Gamma \nu_e)$ and the rearranged $(\bar{\nu}_\mu \Gamma \nu_e)(\bar{e} \Gamma \mu)$ with identical $V-A$ structure and coefficient, a fact that simplifies every tree-level weak rate.

C.8.5 External-state spinors: solutions, normalization, orthogonality

We now turn to the plane-wave Dirac spinors. The Dirac field of Chapter 11 is expanded in modes $u_s(p)e^{-ip\cdot x}$ (positive frequency) and $v_s(p)e^{+ip\cdot x}$ (negative frequency), with $s \in \{1,2\}$ the spin label and $p^0 = E_p = \sqrt{\mathbf{p}^2 + m^2} > 0$. Substituting into the free Dirac equation $(i\partial\!\!\!/ - m)\psi = 0$ shows that the constant spinors satisfy the momentum-space Dirac equations

$$(\not{p} - m)\, u_s(p) = 0, \qquad (\not{p} + m)\, v_s(p) = 0, \qquad \bar{u}_s(p)(\not{p} - m) = 0, \qquad \bar{v}_s(p)(\not{p} + m) = 0, \tag{C.243}$$

the barred equations following from the unbarred by Dirac conjugation (Section C.4). The existence and explicit rest-frame form of these solutions are established in Chapter 11; we recall only that, in the Dirac representation of Section C.5, the rest-frame ($\mathbf{p} = 0$, $p = (m, \mathbf{0})$) solutions normalized to $\bar{u}u = 2m$ are

$$u_s(m,\mathbf{0}) = \sqrt{2m}\begin{pmatrix} \xi_s \\ 0 \end{pmatrix}, \qquad v_s(m,\mathbf{0}) = \sqrt{2m}\begin{pmatrix} 0 \\ \eta_s \end{pmatrix}, \tag{C.244}$$

with ξ_s, η_s two orthonormal two-component spinors, $\xi_s^\dagger \xi_{s'} = \delta_{ss'}$, $\sum_s \xi_s \xi_s^\dagger = \mathbf{1}_{2\times 2}$; the spinor for general p is the Lorentz boost $u_s(p) = S(\Lambda_p) u_s(m,\mathbf{0})$, with $S(\Lambda)$ the spinor representation of Chapter 11 obeying $S^{-1}\gamma^\mu S = \Lambda^\mu{}_\nu \gamma^\nu$.

From (C.243) the Lorentz-invariant normalizations and orthogonality relations follow algebraically. Contracting $\bar{u}_s(\not{p} - m) = 0$ on the right with $u_{s'}$ and $(\not{p} - m)u_{s'} = 0$ on the left with $\bar{u}_s$, then taking the sum and difference, isolates the scalar and vector bilinears; carried out in the rest frame with (C.244) and boosted, the results are

$$\bar{u}_s(p)u_{s'}(p) = 2m\,\delta_{ss'}, \quad \bar{v}_s(p)v_{s'}(p) = -2m\,\delta_{ss'}, \quad \bar{u}_s(p)v_{s'}(p) = \bar{v}_s(p)u_{s'}(p) = 0, \tag{C.245}$$

while the components of the conserved current give the Dirac-adjoint (i.e. $u^\dagger u$) normalizations

$$u_s^\dagger(p)u_{s'}(p) = 2E_p\,\delta_{ss'}, \qquad v_s^\dagger(p)v_{s'}(p) = 2E_p\,\delta_{ss'}, \qquad u_s^\dagger(p)v_{s'}(\tilde{p}) = 0, \tag{C.246}$$

where $\tilde{p} \equiv (E_p, -\mathbf{p})$. The factor $2E_p$ is the relativistic state normalization that pairs with the $1/(2E_p)$ in the Lorentz-invariant phase space; its appearance here is exactly what makes the one-particle states of Chapter 11 covariantly normalized. We verify (C.245) explicitly in the rest frame: $\bar{u}_s u_{s'} = 2m\,(\xi_s^\dagger, 0)\gamma^0(\xi_{s'}, 0)^{\mathsf{T}} = 2m\,\xi_s^\dagger \xi_{s'} = 2m\delta_{ss'}$ using $\gamma^0 = \mathrm{diag}(\mathbf{1}, -\mathbf{1})$ on the upper block; the boost preserves it because $\bar{u}(p)u(p) = \bar{u}(0)S^{-1}Su(0) = \bar{u}(0)u(0)$.

C.8.6 Spin sums and the energy projectors

The single most-used identity in cross-section computations is the spin sum, which closes the two-spinor outer product into a polynomial in $\not{p}$.

Theorem C.68 (Spin-sum completeness)**.** *The plane-wave spinors satisfy*

$$\sum_{s=1,2} u_s(p)\,\bar{u}_s(p) = \not{p} + m, \qquad \sum_{s=1,2} v_s(p)\,\bar{v}_s(p) = \not{p} - m. \tag{C.247}$$

Proof. Both sides are 4×4 matrices; we establish the first identity in the rest frame and then propagate it covariantly. Using (C.244) and $\sum_s \xi_s \xi_s^\dagger = \mathbf{1}_{2\times 2}$,

$$\sum_s u_s(m,\mathbf{0})\bar{u}_s(m,\mathbf{0}) = 2m \sum_s \begin{pmatrix} \xi_s \\ 0 \end{pmatrix} (\xi_s^\dagger, 0)\,\gamma^0 = 2m \begin{pmatrix} \mathbf{1} & 0 \\ 0 & 0 \end{pmatrix} \gamma^0 = 2m \begin{pmatrix} \mathbf{1} & 0 \\ 0 & 0 \end{pmatrix}, \tag{C.248}$$

which equals $\mathrm{diag}(2m, 2m, 0, 0)$. In the rest frame $\not{p} + m = m\gamma^0 + m = m\,\mathrm{diag}(\mathbf{1}, -\mathbf{1}) + m\,\mathbf{1} = \mathrm{diag}(2m, 2m, 0, 0)$, so the two agree. Under a boost, $u_s(p)\bar{u}_s(p) = S\,u_s(0)\bar{u}_s(0)\,S^{-1}$, while $S(\not{p}_{\text{rest}} + m)S^{-1} = \not{p} + m$ by $S^{-1}\gamma^\mu S = \Lambda^\mu{}_\nu \gamma^\nu$; since the rest-frame identity holds and both sides transform identically, the identity holds in every frame. The v sum is identical with η_s on the lower block: $\sum_s v_s(m,\mathbf{0})\bar{v}_s(m,\mathbf{0}) = 2m\,\mathrm{diag}(0,0,-1,-1) = \not{p} - m$ at rest, then boosted. □

The spin sums are precisely the residue numerators of the Dirac propagator, $i(\not{p}+m)/(p^2 - m^2 + i\epsilon)$, evaluated on shell — the bridge between the propagator pole and the external states it amputates to in LSZ. Normalizing them produces the *energy projectors*

$$\Lambda_+(p) \equiv \frac{\not{p} + m}{2m} = \frac{1}{2m}\sum_s u_s(p)\bar{u}_s(p), \qquad \Lambda_-(p) \equiv \frac{m - \not{p}}{2m} = -\frac{1}{2m}\sum_s v_s(p)\bar{v}_s(p). \tag{C.249}$$

That these deserve the name follows from the Clifford relation $\not{p}\not{p} = p^2 = m^2$ on shell. Idempotency:

$$\Lambda_+^2 = \frac{(\not{p}+m)^2}{4m^2} = \frac{p^2 + 2m\not{p} + m^2}{4m^2} = \frac{2m^2 + 2m\not{p}}{4m^2} = \frac{\not{p}+m}{2m} = \Lambda_+, \tag{C.250}$$

and identically $\Lambda_\pm^2 = \Lambda_\pm$. Completeness and orthogonality:

$$\Lambda_+ + \Lambda_- = \frac{(\not p + m) + (m - \not p)}{2m} = \mathbf{1}, \qquad \Lambda_+ \Lambda_- = \frac{(\not p + m)(m - \not p)}{4m^2} = \frac{m^2 - p^2}{4m^2} = 0. \tag{C.251}$$

Finally $\operatorname{tr} \Lambda_\pm = \frac{1}{2m} \operatorname{tr}(\pm \not p + m) = \frac{1}{2m}\, 4m = 2$, counting the two physical spin states each projector retains. These projectors let one compute polarized rates without ever constructing the spinors explicitly: a sum over a single spin orientation is $u_s \bar u_s = \Lambda_+ \, \Sigma(s)$ with $\Sigma(s)$ the spin projector of Chapter 11, but the *unpolarized* sums (C.247) are all that the cross sections of Chapters 17 to 19 require.

C.8.7 The Gordon decomposition

The last identity converts the vector current $\bar u(p') \gamma^\mu u(p)$ into a form that exhibits its physical content: a charge (convection) current proportional to the average momentum, plus a magnetic-moment current proportional to the momentum transfer through $\sigma^{\mu\nu}$.

Theorem C.69 (Gordon decomposition)**.** *For on-shell spinors of equal mass m, with $q \equiv p' - p$,*

$$\bar u(p')\, \gamma^\mu\, u(p) = \bar u(p') \left[\frac{(p' + p)^\mu}{2m} + \frac{i\, \sigma^{\mu\nu} q_\nu}{2m} \right] u(p), \qquad \sigma^{\mu\nu} = \frac{i}{2}[\gamma^\mu, \gamma^\nu]. \tag{C.252}$$

Proof. Use the Dirac equations $\not p\, u(p) = m\, u(p)$ and $\bar u(p')\, \not p' = m\, \bar u(p')$ from (C.243). Then

$$2m\, \bar u(p') \gamma^\mu u(p) = \bar u(p') (\gamma^\mu \not p + \not p' \gamma^\mu) u(p), \tag{C.253}$$

since $\gamma^\mu \not p\, u = m \gamma^\mu u$ and $\bar u' \not p' \gamma^\mu = m \bar u' \gamma^\mu$. Now decompose the two products of gamma matrices into symmetric and antisymmetric parts using the Clifford algebra. From $\gamma^\mu \gamma^\nu = \frac{1}{2}\{\gamma^\mu, \gamma^\nu\} + \frac{1}{2}[\gamma^\mu, \gamma^\nu] = \eta^{\mu\nu} - i\sigma^{\mu\nu}$ and, swapping the order, $\gamma^\nu \gamma^\mu = \eta^{\mu\nu} + i\sigma^{\mu\nu}$,

$$\gamma^\mu \not p = \gamma^\mu \gamma^\nu p_\nu = (\eta^{\mu\nu} - i\sigma^{\mu\nu}) p_\nu = p^\mu - i\sigma^{\mu\nu} p_\nu, \tag{C.254}$$

$$\not p' \gamma^\mu = \gamma^\nu \gamma^\mu p'_\nu = (\eta^{\mu\nu} + i\sigma^{\mu\nu}) p'_\nu = p'^\mu + i\sigma^{\mu\nu} p'_\nu. \tag{C.255}$$

Adding, the symmetric parts give $(p + p')^\mu$ and the antisymmetric parts combine into $i\sigma^{\mu\nu}(p'_\nu - p_\nu) = i\sigma^{\mu\nu} q_\nu$:

$$\gamma^\mu \not p + \not p' \gamma^\mu = (p + p')^\mu + i\sigma^{\mu\nu} q_\nu. \tag{C.256}$$

Therefore $2m\, \bar u' \gamma^\mu u = \bar u' \big[(p + p')^\mu + i\sigma^{\mu\nu} q_\nu\big] u$; dividing by $2m$ gives (C.252). $\square$

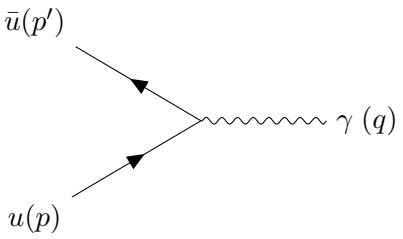

Figure C.3: The electromagnetic vertex $\bar{u}(p')\gamma^\mu u(p)$ with momentum transfer $q = p' - p$. The Gordon decomposition (C.252) splits this single matrix element into a convection current $\propto (p + p')^\mu$ (the Dirac, charge-coupling part) and a spin current $\propto i\sigma^{\mu\nu}q_\nu$ (the Pauli, magnetic-moment part). The coefficient of the latter is the seed of the anomalous magnetic moment computed in Chapter 20.

Physical Insight

At $q = 0$ only the first term survives and $\bar{u}(p)\gamma^\mu u(p) = (p^\mu/m)\,\bar{u}u = 2p^\mu$, the current of a structureless charge moving with momentum p (this also reproduces (C.245) for $\bar{u}\gamma^0 u = 2E_p$). The second term, $i\sigma^{\mu\nu}q_\nu/2m$, is the coupling of the spin magnetic moment to the field gradient; when a loop dresses the vertex it generates an additional form factor $F_2(q^2)$ multiplying exactly this structure, and $F_2(0) = a_e = (g-2)/2$ is the anomalous moment. The Gordon identity is therefore the algebraic skeleton onto which the $g - 2$ computation of Chapter 20 is hung.

C.8.8 Worked example: the spin-summed lepton tensor

The following computation assembles the spin sums and trace technology into the object that drives every QED cross section in the book.

Worked Example C.70. Compute the spin sum of the squared current matrix element,

$$L^{\mu\nu} \equiv \sum_{s,s'} \left[\bar{u}_{s'}(p')\gamma^\mu u_s(p)\right]\left[\bar{u}_{s'}(p')\gamma^\nu u_s(p)\right]^*, \tag{C.257}$$

which appears (with the muon-line analogue) in the unpolarized $e^+e^- \to \mu^+\mu^-$ cross section of Chapter 17.

Step 1 — complex-conjugate the second factor. A spinor bilinear is a 1×1 matrix, so its complex conjugate equals its Hermitian conjugate:

$$\left[\bar{u}_{s'}(p')\gamma^\nu u_s(p)\right]^* = \left[\bar{u}_{s'}(p')\gamma^\nu u_s(p)\right]^\dagger = u_s^\dagger(p)\,\gamma^{\nu\dagger}\,\gamma^{0\dagger}\,u_{s'}(p'). \tag{C.258}$$

With $\gamma^{0\dagger} = \gamma^0$ and the conjugation property $\gamma^0\gamma^{\nu\dagger}\gamma^0 = \gamma^\nu$ from Section C.4, insert $\gamma^0\gamma^0 = \mathbf{1}$:

$$= u_s^\dagger(p)\gamma^{\nu\dagger}\gamma^0 u_{s'}(p') = u_s^\dagger(p)\gamma^0\,(\gamma^0\gamma^{\nu\dagger}\gamma^0)\,u_{s'}(p') = \bar{u}_s(p)\,\gamma^\nu\,u_{s'}(p'). \tag{C.259}$$

Step 2 — close the spin sums into traces. Writing out the Dirac indices and using Theorem C.68,

$$\begin{aligned} L^{\mu\nu} &= \sum_{s,s'} \big[\bar{u}_{s'}(p')\gamma^{\mu}u_{s}(p)\big]\big[\bar{u}_{s}(p)\gamma^{\nu}u_{s'}(p')\big] \\ &= \sum_{s,s'} \bar{u}_{s'}(p')\gamma^{\mu}\,u_{s}(p)\bar{u}_{s}(p)\,\gamma^{\nu}\,u_{s'}(p') = \mathrm{tr}\Big[\Big(\textstyle\sum_{s'} u_{s'}(p')\bar{u}_{s'}(p')\Big)\gamma^{\mu}\Big(\textstyle\sum_{s} u_{s}(p)\bar{u}_{s}(p)\Big)\gamma^{\nu}\Big] \\ &= \mathrm{tr}\big[(\not{p}' + m)\,\gamma^{\mu}\,(\not{p} + m)\,\gamma^{\nu}\big], \end{aligned} \tag{C.260}$$

the reordering into a single trace being legitimate because the bilinears are c-numbers.

Step 3 — evaluate the trace. Expand the product; traces of an odd number of gamma matrices vanish (Section C.6), killing the two cross terms $m\ \mathrm{tr}(\not{p}'\gamma^{\mu}\gamma^{\nu})$ and $m\ \mathrm{tr}(\gamma^{\mu}\not{p}\gamma^{\nu})$. The two survivors are

$$L^{\mu\nu} = \mathrm{tr}(\not{p}'\gamma^{\mu}\not{p}\gamma^{\nu}) + m^{2}\ \mathrm{tr}(\gamma^{\mu}\gamma^{\nu}). \tag{C.261}$$

With $\mathrm{tr}(\gamma^{\alpha}\gamma^{\mu}\gamma^{\beta}\gamma^{\nu}) = 4(\eta^{\alpha\mu}\eta^{\beta\nu} - \eta^{\alpha\beta}\eta^{\mu\nu} + \eta^{\alpha\nu}\eta^{\mu\beta})$ and $\mathrm{tr}(\gamma^{\mu}\gamma^{\nu}) = 4\eta^{\mu\nu}$,

$$\mathrm{tr}(\not{p}'\gamma^{\mu}\not{p}\gamma^{\nu}) = p'_{\alpha}p_{\beta}\ \mathrm{tr}(\gamma^{\alpha}\gamma^{\mu}\gamma^{\beta}\gamma^{\nu}) = 4(p'^{\mu}p^{\nu} - (p'\cdot p)\,\eta^{\mu\nu} + p'^{\nu}p^{\mu}), \tag{C.262}$$

$$m^{2}\ \mathrm{tr}(\gamma^{\mu}\gamma^{\nu}) = 4m^{2}\eta^{\mu\nu}. \tag{C.263}$$

Result. Combining,

$$L^{\mu\nu} = 4\Big[p'^{\mu}p^{\nu} + p'^{\nu}p^{\mu} - (p'\cdot p - m^{2})\eta^{\mu\nu}\Big]. \tag{C.264}$$

This is the massive QED lepton tensor. It is manifestly symmetric in $\mu\nu$, and it is transverse: with $q = p' - p$ and $a \equiv p'\cdot p$ one has $q\cdot p' = m^{2} - a$, $q\cdot p = a - m^{2}$, so

$$q_{\mu}L^{\mu\nu} = 4\big[(q\cdot p')\,p^{\nu} + (q\cdot p)\,p'^{\nu} - (a - m^{2})\,q^{\nu}\big] = 4(a - m^{2})\big[-p^{\nu} + p'^{\nu} - q^{\nu}\big] = 0, \tag{C.265}$$

which is the algebraic shadow of current conservation $q_{\mu}\,\bar{u}(p')\gamma^{\mu}u(p) = \bar{u}(p')(\not{p}' - \not{p})u(p) = (m-m)\,\bar{u}(p')u(p) = 0$ enforced by the Dirac equation (C.243). Equation (C.264) is the exact object Chapters 17 and 19 contract to obtain the unpolarized $|\mathcal{M}|^{2}$.

The technology assembled here — spin sums, energy projectors, the Gordon split, and the trace reductions that close them — is the complete four-component external-state toolkit. For massless and helicity-resolved computations it is, however, more machinery than the physics requires: a Weyl fermion has a single two-component spinor and a single helicity, and the four-component spin sums collapse onto 2×2 structures. The next section recasts everything in the two-component (van der Waerden) language, where the spin sums become the $\sigma^{\mu}/\bar{\sigma}^{\mu}$ contraction identities and the Fierz rearrangement (C.236) reduces to a one-line ϵ-tensor identity — the foundation on which the spinor-helicity formalism of Chapter 58 is built.

C.9 Two-Component Spinor Calculus and the Bridge to Helicity

Every object built so far in this appendix lives on the four-dimensional spinor space: the Dirac matrices γ^μ, the sixteen bilinear covariants, the trace and Fierz technology, the external-state spinors u, v. Yet Chapter 3 taught us that the four-dimensional Dirac representation is *reducible* as a representation of the Lorentz group: under the universal cover $\mathrm{SL}(2,\mathbb{C})$ it splits into the two inequivalent two-dimensional irreducibles $(\tfrac{1}{2},0)$ and $(0,\tfrac{1}{2})$, the left- and right-handed Weyl spinors. The chiral basis of Section C.3 made this split block-diagonal in the γ^μ, and the Fierz machinery of Section C.8 repeatedly forced us to track left and right chirality separately. The natural conclusion is to stop carrying the reducible four-component object and work directly with its irreducible halves. This is the two-component, or van der Waerden, calculus: the minimal bookkeeping in which a Weyl spinor carries a single two-valued index, chirality is the type of the index rather than a projector, and the metric of the spinor space is the antisymmetric ϵ tensor. The payoff is twofold. Conceptually, the algebra becomes transparent: the Pauli matrices reappear as the only Lorentz-covariant objects with one undotted and one dotted index, and every four-component identity proved above is recovered as a statement about σ^μ and $\bar\sigma^\mu$. Practically, this is the language in which the spinor-helicity formalism of Chapter 58 is written; the angle and square brackets $\langle i\,j\rangle, [i\,j]$ that will compress an entire QED or Yang–Mills amplitude into a one-line rational function are nothing but ϵ-contractions of the two-component spinors introduced here. We therefore close the appendix by re-expressing the spin technology in two-component variables, proving the σ-matrix identities from the Pauli algebra of Chapter B, and verifying the dictionary back to the four-component results, so that Chapter 58 can introduce its bracket notation as shorthand on top of a fully established algebra.

Throughout we keep the global conventions of Chapter A: mostly-minus metric $\eta_{\mu\nu} = \mathrm{diag}(+,-,-,-)$, $\gamma^5 = i\gamma^0\gamma^1\gamma^2\gamma^3$, $\bar\psi = \psi^\dagger\gamma^0$, and the Levi-Civita normalization $\epsilon^{0123} = +1$. The Pauli matrices σ^i and their algebra are imported from Chapter B; we never reprove $\{\sigma^i,\sigma^j\} = 2\delta^{ij}\mathbf{1}$ or $\sigma^i\sigma^j = \delta^{ij}\mathbf{1} + i\epsilon^{ijk}\sigma^k$.

C.9.1 Undotted and dotted indices and the ϵ spinor metric

A left-handed Weyl spinor transforms in the $(\tfrac{1}{2},0)$ representation of $\mathrm{SL}(2,\mathbb{C})$. We write its components with a lowered *undotted* index,

$$\psi_a, \qquad a = 1,2, \qquad \psi_a \;\longmapsto\; M_a{}^b\,\psi_b, \quad M \in \mathrm{SL}(2,\mathbb{C}). \tag{C.266}$$

A right-handed Weyl spinor transforms in the complex-conjugate representation $(0,\tfrac{1}{2})$; its components carry a *dotted* index,

$$\bar\chi_{\dot a}, \qquad \dot a = \dot 1, \dot 2, \qquad \bar\chi_{\dot a} \;\longmapsto\; (M^*)_{\dot a}{}^{\dot b}\,\bar\chi_{\dot b}. \tag{C.267}$$

The two index types are genuinely distinct because M and M^* are inequivalent representations of $\mathrm{SL}(2,\mathbb{C})$ (unlike SU(2), where every representation is self-conjugate); the dot is the typographical record of which one acts. Complex conjugation interchanges the two: by definition $(\psi_a)^* \equiv \bar{\psi}_{\dot{a}}$, so conjugating an undotted spinor produces a dotted one and conjugating a dotted spinor an undotted one. This is the two-component face of the statement, proved in Chapter 3, that the $(\frac{1}{2},0)$ and $(0,\frac{1}{2})$ representations are exchanged by complex conjugation (equivalently, by parity).

Both representations are pseudo-real in the sharp sense that each carries an invariant antisymmetric bilinear form. Because $\det M = 1$, the totally antisymmetric symbol is invariant,

$$\epsilon^{ab} M_a{}^c M_b{}^d = (\det M)\,\epsilon^{cd} = \epsilon^{cd}, \tag{C.268}$$

and likewise for the dotted symbol under M^* (since $\det M^* = 1$ as well). This ϵ is the metric of spinor space: it raises and lowers indices exactly as $\eta_{\mu\nu}$ does for vectors. We fix the numerical conventions

$$\epsilon^{12} = -\epsilon^{21} = +1, \qquad \epsilon_{12} = -\epsilon_{21} = -1, \tag{C.269}$$

with the identical numerical values for the dotted symbols $\epsilon^{\dot{a}\dot{b}}, \epsilon_{\dot{a}\dot{b}}$. The signs in Eq. (C.269) are chosen so that raising followed by lowering is the identity:

$$\psi^a = \epsilon^{ab}\psi_b, \qquad \psi_a = \epsilon_{ab}\psi^b, \qquad \epsilon_{ab}\epsilon^{bc} = \delta_a^{\,c}. \tag{C.270}$$

We verify the contraction in Eq. (C.270) directly: $\epsilon_{ab}\epsilon^{bc}$ has its only contributions from $b \neq a$, and for $a = c = 1$ it is $\epsilon_{12}\epsilon^{21} = (-1)(-1) = 1 = \delta_1^1$, while for $a = 1, c = 2$ the sum $\epsilon_{12}\epsilon^{22} = 0 = \delta_1^2$; the remaining entries follow by the same count. The mnemonic forced by Eq. (C.269) is that undotted indices are contracted "northwest to southeast" (upper-left index summed against lower-right),

$$\psi\chi \equiv \psi^a\chi_a, \qquad \bar{\psi}\bar{\chi} \equiv \bar{\psi}_{\dot{a}}\bar{\chi}^{\dot{a}}, \tag{C.271}$$

the dotted contraction running the other way ("southwest to northeast"), so that the bars line up. These conventions are precisely those that Chapter 58 will inherit when it abbreviates $\psi^a\chi_a = \langle\psi\,\chi\rangle$.

The antisymmetry of ϵ has an immediate and important consequence for reordering. For two spinors,

$$\psi\chi = \psi^a\chi_a = \epsilon^{ab}\psi_b\chi_a = -\epsilon^{ba}\psi_b\chi_a = -\chi^b\psi_b \cdot (\pm 1), \tag{C.272}$$

where the final sign is $+1$ if ψ, χ are ordinary commuting spinors and -1 if they are anticommuting (Grassmann) field components, the extra minus arising from $\psi_b\chi_a = -\chi_a\psi_b$. Thus

$$\psi\chi = \begin{cases} -\chi\psi & \text{(commuting spinors, e.g. helicity spinors)}, \\ +\chi\psi & \text{(anticommuting spinors, e.g. Dirac field components)}. \end{cases} \tag{C.273}$$

The commuting case is the origin of the antisymmetry $\langle i\,j\rangle = -\langle j\,i\rangle$ of angle brackets in Chapter 58; the anticommuting case is what makes the Majorana mass term $\psi\psi = \psi^a\psi_a$ nonzero (it would vanish for commuting components).

C.9.2 The Pauli four-vectors and their algebra

To couple spinors to spacetime vectors we need an object with one undotted and one dotted index that transforms as a four-vector. The only Lorentz-covariant such objects are the *Pauli four-vectors*. Define

$$(\sigma^\mu)_{a\dot b} = (\mathbf{1},\ \sigma^i)_{a\dot b}, \qquad (\bar\sigma^\mu)^{\dot a b} = (\mathbf{1},\ -\sigma^i)^{\dot a b}, \tag{C.274}$$

so that $\sigma^0 = \bar\sigma^0 = \mathbf{1}$ and $\bar\sigma^i = -\sigma^i$, with the index heights fixed once and for all as shown: σ^μ carries a lower undotted and a lower dotted index, $\bar\sigma^\mu$ an upper dotted and an upper undotted index. These heights are not arbitrary; they are exactly what is needed for the bilinears $\bar\psi_{\dot a}(\bar\sigma^\mu)^{\dot a b}\psi_b$ and $\chi^a(\sigma^\mu)_{a\dot b}\bar\chi^{\dot b}$ to be index-free four-vectors. The two are related by raising both indices with ϵ:

$$(\bar\sigma^\mu)^{\dot a a} = \epsilon^{\dot a\dot b}\,\epsilon^{ab}\,(\sigma^\mu)_{b\dot b}. \tag{C.275}$$

One checks Eq. (C.275) componentwise: for $\mu = 0$ the right side is $\epsilon^{\dot a\dot b}\epsilon^{ab}\delta_{b\dot b} = \delta^{\dot a a}$ (the same count as in Eq. (C.270)), reproducing $\bar\sigma^0 = \mathbf{1}$; for $\mu = 2$ and $(\dot a, a) = (\dot 1, 2)$ the only surviving term is $\epsilon^{\dot 1\dot 2}\epsilon^{21}(\sigma^2)_{1\dot 2} = (+1)(-1)(-i) = +i$, which is exactly the $(\dot 1, 2)$ entry of $\bar\sigma^2 = -\sigma^2$. The remaining components follow identically. Thus σ^μ and $\bar\sigma^\mu$ are not independent: $\bar\sigma^\mu$ is the ϵ-transpose of σ^μ, the same data with both indices raised.

Everything in two-component calculus reduces to four identities for these matrices, all of which descend from the Pauli algebra.

Proposition C.71 (The $\sigma/\bar\sigma$ Clifford pair)**.**

$$(\sigma^\mu\bar\sigma^\nu + \sigma^\nu\bar\sigma^\mu)_a{}^b = 2\eta^{\mu\nu}\,\delta_a^{\ b}, \tag{C.276}$$

$$(\bar\sigma^\mu\sigma^\nu + \bar\sigma^\nu\sigma^\mu)^{\dot a}{}_{\dot b} = 2\eta^{\mu\nu}\,\delta^{\dot a}_{\ \dot b}. \tag{C.277}$$

Proof. In $\sigma^\mu\bar\sigma^\nu$ the dotted indices are contracted, $(\sigma^\mu)_{a\dot c}(\bar\sigma^\nu)^{\dot c b}$, leaving one lower and one upper undotted index; this is an ordinary product of 2×2 matrices. Take $\mu = \nu = 0$: $\sigma^0\bar\sigma^0 + \sigma^0\bar\sigma^0 = 2\,\mathbf{1} = 2\eta^{00}\mathbf{1}$. Take $\mu = 0, \nu = j$: $\sigma^0\bar\sigma^j + \sigma^j\bar\sigma^0 = -\sigma^j + \sigma^j = 0 = 2\eta^{0j}\mathbf{1}$. Take $\mu = i, \nu = j$:

$$\sigma^i\bar\sigma^j + \sigma^j\bar\sigma^i = \sigma^i(-\sigma^j) + \sigma^j(-\sigma^i) = -\left\{\sigma^i, \sigma^j\right\} = -2\delta^{ij}\mathbf{1} = 2\eta^{ij}\mathbf{1}, \tag{C.278}$$

using $\left\{\sigma^i, \sigma^j\right\} = 2\delta^{ij}\mathbf{1}$ from Chapter B and $\eta^{ij} = -\delta^{ij}$. This proves Eq. (C.276). The computation for Eq. (C.277) is identical with $\sigma \leftrightarrow \bar\sigma$, the spatial case again giving $\bar\sigma^i\sigma^j + \bar\sigma^j\sigma^i = -\left\{\sigma^i, \sigma^j\right\} = 2\eta^{ij}\mathbf{1}$. □

Equations (C.276) and (C.277) are the two-component shadow of the Clifford relation $\{\gamma^\mu, \gamma^\nu\} = 2\eta^{\mu\nu}$; we will see in Section C.9.4 that they are literally its block-diagonal entries. Next, the trace identity.

Proposition C.72 (σ-trace)**.**

$$\operatorname{tr}(\sigma^\mu \bar\sigma^\nu) \equiv (\sigma^\mu)_{a\dot b}(\bar\sigma^\nu)^{\dot b a} = 2\,\eta^{\mu\nu}. \tag{C.279}$$

Proof. Symmetrize using Eq. (C.276): $\operatorname{tr}(\sigma^\mu\bar\sigma^\nu) = \frac{1}{2}\operatorname{tr}(\sigma^\mu\bar\sigma^\nu + \sigma^\nu\bar\sigma^\mu)$ holds because the antisymmetric part $\frac{1}{2}(\sigma^\mu\bar\sigma^\nu - \sigma^\nu\bar\sigma^\mu)$ is traceless—it is proportional to $\sigma^{\mu\nu}$ of Section C.9.5, a generator, and generators of $\mathrm{SL}(2,\mathbb{C})$ are traceless. Hence $\operatorname{tr}(\sigma^\mu\bar\sigma^\nu) = \frac{1}{2}\,2\eta^{\mu\nu}\operatorname{tr}\mathbf{1} = \eta^{\mu\nu}\cdot 2 = 2\eta^{\mu\nu}$, using $\operatorname{tr}\mathbf{1} = 2$ on the two-dimensional spinor space. □

The factor here is 2, not the 4 of the four-component trace $\operatorname{tr}(\gamma^\mu\gamma^\nu) = 4\eta^{\mu\nu}$ (Eq. (C.152)); the difference is exactly the dimension of the representation, and it is the cleanest single check that one is in the irreducible two-component world rather than the reducible four-component one.

C.9.3 The completeness (Fierz) relation

The trace identity says the four matrices σ^μ are orthonormal with respect to the trace form weighted by $\eta_{\mu\nu}$. Since the space of 2×2 complex matrices is four-dimensional and the σ^μ are manifestly linearly independent ($\mathbf{1}$ and the three traceless Pauli matrices), they form a basis. The statement that this basis is complete is the central two-component identity.

Theorem C.73 (Two-component completeness / Fierz relation)**.**

$$(\sigma^\mu)_{a\dot b}\,(\bar\sigma_\mu)^{\dot c d} = 2\,\delta_a^{\ d}\,\delta_{\dot b}^{\ \dot c}. \tag{C.280}$$

Proof. By the basis property, every 2×2 matrix M with indices $M^{\dot b a}$ (one upper dotted, one upper undotted) can be expanded on the σ^μ. We claim the expansion is

$$M^{\dot c d} = \tfrac{1}{2}\,(\bar\sigma_\mu)^{\dot c d}\,[(\sigma^\mu)_{a\dot b}M^{\dot b a}]. \tag{C.281}$$

To verify the coefficient, test Eq. (C.281) on the basis itself, $M = \bar\sigma^\nu$: the bracket becomes $(\sigma^\mu)_{a\dot b}(\bar\sigma^\nu)^{\dot b a} = \operatorname{tr}(\sigma^\mu\bar\sigma^\nu) = 2\eta^{\mu\nu}$ by Eq. (C.279), so the right side is $\frac{1}{2}(\bar\sigma_\mu)^{\dot c d}\,2\eta^{\mu\nu} = (\bar\sigma^\nu)^{\dot c d} = M^{\dot c d}$, confirming Eq. (C.281) for every M since the $\bar\sigma^\nu$ span. Now Eq. (C.281) must hold as an identity in the arbitrary matrix $M^{\dot b a}$, so the linear operators on both sides agree:

$$\tfrac{1}{2}\,(\bar\sigma_\mu)^{\dot c d}\,(\sigma^\mu)_{a\dot b} = \delta_{\dot b}^{\ \dot c}\,\delta_a^{\ d}, \tag{C.282}$$

which is Eq. (C.280) after multiplying by 2 and reordering the two scalar factors. □

As a consistency check, contract Eq. (C.280) on $a = d$ and $\dot{b} = \dot{c}$: the left side is $\mathrm{tr}(\sigma^\mu\bar\sigma_\mu) = \sum_\mu \eta_{\mu\mu}\,\mathrm{tr}(\sigma^\mu\bar\sigma^\mu)$, but it is cleaner to use Eq. (C.279), $\mathrm{tr}(\sigma^\mu\bar\sigma_\mu) = 2\eta^\mu{}_\mu = 2\delta^\mu_\mu = 8$; the right side gives $2\,\delta^a_a\,\delta^{\dot b}_{\dot b} = 2\cdot 2\cdot 2 = 8$. The identity Eq. (C.280) is the two-component master Fierz identity: it lets any pair of σ-matrix bilinears sharing a contracted vector index be rearranged into a product of two contractions of the spinors. It is the exact two-component image of the four-component completeness relation of Section C.8: there, the 16 bilinear covariants resolved the identity on the four-dimensional spinor space; projecting that resolution onto a definite chirality on each external pair of indices kills every covariant except $\mathbf{1}$ and γ^μ restricted to that chirality, and the surviving piece is precisely Eq. (C.280). We make the most useful rearrangement explicit.

Worked Example C.74 (The vector-current Fierz rearrangement)**.** Consider the product of two left-handed currents, $(\bar\psi_1\bar\sigma^\mu\psi_2)(\bar\psi_3\bar\sigma_\mu\psi_4)$, written with explicit indices,

$$(\bar\psi_{1\dot a}(\bar\sigma^\mu)^{\dot a b}\psi_{2b})\,(\bar\psi_{3\dot c}(\bar\sigma_\mu)^{\dot c d}\psi_{4d}). \tag{C.283}$$

The two $\bar\sigma^\mu$ share the contracted Lorentz index μ. To bring them together apply the completeness relation in its all-raised form, obtained from Eq. (C.280) by raising indices with ϵ:

$$(\bar\sigma^\mu)^{\dot a b}(\bar\sigma_\mu)^{\dot c d} = 2\,\epsilon^{bd}\,\epsilon^{\dot a\dot c}. \tag{C.284}$$

This follows by raising the two lower indices of Eq. (C.280): $(\bar\sigma^\mu)^{\dot a b}(\bar\sigma_\mu)^{\dot c d} = \epsilon^{\dot a\dot e}\epsilon^{bf}\epsilon^{\dot c\dot g}\epsilon^{dh}(\sigma_\mu)_{f\dot e}(\sigma^\mu)_{\dots}$; tracking the index pattern with Eq. (C.280) collapses it to $2\epsilon^{bd}\epsilon^{\dot a\dot c}$, and one checks the overall sign on the $(\dot a b\dot c d) = (\dot 1\,2\,\dot 1\,2)$ component, where the left side is $(\bar\sigma^\mu)^{\dot 1 2}(\bar\sigma_\mu)^{\dot 1 2}$ and the right side is $2\epsilon^{22}\epsilon^{\dot 1\dot 1} = 0$, consistent with $(\bar\sigma^\mu)^{\dot 1 2}$ summing to zero. Substituting Eq. (C.284),

$$(\bar\psi_1\bar\sigma^\mu\psi_2)(\bar\psi_3\bar\sigma_\mu\psi_4) = 2\,(\epsilon^{bd}\psi_{2b}\psi_{4d})\,(\epsilon^{\dot a\dot c}\bar\psi_{1\dot a}\bar\psi_{3\dot c}) = 2\,(\psi_4\psi_2)(\bar\psi_1\bar\psi_3), \tag{C.285}$$

the two currents having been Fierzed into a product of a purely undotted and a purely dotted scalar bilinear. This is the two-component analogue of the four-component Fierz rearrangement of Section C.8, accomplished here in a single step with no 16×16 rearrangement matrix to invert.

A second identity, equally central to Chapter 58, is purely a fact about the two-dimensionality of spinor space.

Proposition C.75 (Schouten identity)**.** *For any undotted spinors and any fixed index a,*

$$\epsilon_{ab}\,\chi_c + \epsilon_{bc}\,\chi_a + \epsilon_{ca}\,\chi_b = 0, \tag{C.286}$$

and equivalently $\epsilon_{ab}\epsilon_{cd} + \epsilon_{ac}\epsilon_{db} + \epsilon_{ad}\epsilon_{bc} = 0$.

Proof. Regard the left side of Eq. (C.286) as a function $T_{abc} = \epsilon_{ab}\chi_c + \epsilon_{bc}\chi_a + \epsilon_{ca}\chi_b$. It is totally antisymmetric in (a,b,c): interchanging $a \leftrightarrow b$ sends it

to $\epsilon_{ba}\chi_c + \epsilon_{ac}\chi_b + \epsilon_{cb}\chi_a = -T_{abc}$, and cyclic invariance is manifest. A totally antisymmetric tensor with three indices each running over only two values must vanish, because any assignment forces two of the indices to coincide, killing the antisymmetrized object. The four-index form follows by setting $\chi_c = \epsilon_{cd}\eta^d$ for arbitrary η^d and stripping it. □

Contracting Eq. (C.286) with three further spinors $\lambda_i^a, \lambda_j^b, \lambda_k^c$ (commuting, as the on-shell helicity spinors of Chapter 58 are) and writing $\lambda_i\lambda_j \equiv \lambda_i^a\lambda_{ja}$ turns it into

$$(\lambda_i\lambda_j)\,\lambda_k + (\lambda_j\lambda_k)\,\lambda_i + (\lambda_k\lambda_i)\,\lambda_j = 0, \tag{C.287}$$

which is exactly the Schouten identity for angle brackets, $\langle i\,j\rangle\lambda_k + \langle j\,k\rangle\lambda_i + \langle k\,i\rangle\lambda_j = 0$, used to reduce amplitudes in Chapters 58 and 59. We have proved it here, before any bracket has been defined, as a triviality of two-dimensional linear algebra.

C.9.4 The chiral-basis dictionary

We now make precise the claim that the four-component technology is the two-component technology assembled into 2×2 blocks. In the chiral basis of Section C.3 the Dirac matrices are

$$\gamma^\mu = \begin{pmatrix} 0 & (\sigma^\mu)_{a\dot b} \\ (\bar\sigma^\mu)^{\dot a b} & 0 \end{pmatrix}, \qquad \gamma^5 = \begin{pmatrix} -\delta_a^{\,b} & 0 \\ 0 & \delta^{\dot a}_{\,\dot b} \end{pmatrix}, \tag{C.288}$$

where the upper-left block of γ^5 acts on undotted indices and the lower-right on dotted. The Clifford relation is now a corollary of Theorem C.71: computing

$$\gamma^\mu\gamma^\nu = \begin{pmatrix} \sigma^\mu\bar\sigma^\nu & 0 \\ 0 & \bar\sigma^\mu\sigma^\nu \end{pmatrix}, \tag{C.289}$$

the anticommutator $\{\gamma^\mu, \gamma^\nu\}$ is block-diagonal with entries $\sigma^\mu\bar\sigma^\nu + \sigma^\nu\bar\sigma^\mu = 2\eta^{\mu\nu}\mathbf{1}$ (upper) and $\bar\sigma^\mu\sigma^\nu + \bar\sigma^\nu\sigma^\mu = 2\eta^{\mu\nu}\mathbf{1}$ (lower), i.e. $2\eta^{\mu\nu}\,\mathbf{1}_4$. The two relations of Theorem C.71 are thus precisely the two diagonal blocks of the four-dimensional Clifford algebra. That γ^5 takes the form in Eq. (C.288) is checked from its definition: with $\gamma^0 = \left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right)$ and $\gamma^i = \left(\begin{smallmatrix} 0 & \sigma^i \\ -\sigma^i & 0 \end{smallmatrix}\right)$ a direct multiplication gives $i\gamma^0\gamma^1\gamma^2\gamma^3 = \mathrm{diag}(-\mathbf{1}, +\mathbf{1})$, so the chiral projectors $P_{L,R} = \tfrac{1}{2}(\mathbf{1} \mp \gamma^5)$ project onto the undotted (upper) and dotted (lower) blocks respectively. Chirality is thus the index type, exactly as promised.

A Dirac spinor is the direct sum of a left-handed and a right-handed Weyl spinor; writing the left part as ψ_a and the right part as the conjugate $\bar\chi^{\dot a}$ of a second left-handed spinor χ,

$$\Psi = \begin{pmatrix} \psi_a \\ \bar\chi^{\dot a} \end{pmatrix}, \qquad \Psi^\dagger = (\bar\psi_{\dot a},\ \chi^a), \qquad \bar\psi = \Psi^\dagger\gamma^0 = (\chi^a,\ \bar\psi_{\dot a}), \tag{C.290}$$

where $\Psi^\dagger$ uses $(\psi_a)^* = \bar\psi_{\dot a}$ and $(\bar\chi^{\dot a})^* = \chi^a$ from Section C.9.1, and $\bar\psi$ follows from $\gamma^0 = \left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right)$ swapping the two blocks. A Majorana spinor is the special case $\chi = \psi$. With Eq. (C.290) every Dirac bilinear reduces to two-component contractions by matrix multiplication. The scalar and pseudoscalar:

$$\bar\psi\Psi = \chi^a\psi_a + \bar\psi_{\dot a}\bar\chi^{\dot a} = \chi\psi + \bar\psi\bar\chi, \tag{C.291}$$

$$\bar\psi\gamma^5\Psi = -\chi\psi + \bar\psi\bar\chi. \tag{C.292}$$

The vector and axial currents, using the off-diagonal blocks of γ^μ:

$$\bar\psi\gamma^\mu\Psi = \bar\psi\,\bar\sigma^\mu\psi + \chi\,\sigma^\mu\bar\chi, \tag{C.293}$$

$$\bar\psi\gamma^\mu\gamma^5\Psi = -\bar\psi\,\bar\sigma^\mu\psi + \chi\,\sigma^\mu\bar\chi, \tag{C.294}$$

where $\bar\psi\bar\sigma^\mu\psi \equiv \bar\psi_{\dot a}(\bar\sigma^\mu)^{\dot a b}\psi_b$ and $\chi\sigma^\mu\bar\chi \equiv \chi^a(\sigma^\mu)_{a\dot b}\bar\chi^{\dot b}$. The combinations $\frac{1}{2}(\bar\psi\gamma^\mu\Psi \mp \bar\psi\gamma^\mu\gamma^5\Psi)$ project onto the purely left current $\psi\bar\sigma^\mu\psi$ and the purely right current $\chi\sigma^\mu\bar\chi$: a left-handed Weyl fermion's vector current is built from $\bar\sigma^\mu$, a right-handed one's from σ^μ. This is the structural fact behind the chiral couplings of the electroweak theory, and it is read off the dictionary with no computation. The tensor bilinear $\bar\psi\sigma^{\mu\nu}\Psi$ decomposes through the generators of Section C.9.5; we record it there.

Finally, charge conjugation. The four-component matrix C of Section C.4, defined by $C\gamma^\mu C^{-1} = -(\gamma^\mu)^{\mathsf T}$, is in the chiral basis nothing but the ϵ spinor metric.

Worked Example C.76 (Charge conjugation is the ϵ metric)**.** Take the representation $C = -i\gamma^2\gamma^0$ of Section C.4. With $\gamma^2 = \left(\begin{smallmatrix} 0 & \sigma^2 \\ -\sigma^2 & 0 \end{smallmatrix}\right)$ and $\gamma^0 = \left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right)$,

$$\gamma^2\gamma^0 = \begin{pmatrix} \sigma^2 & 0 \\ 0 & -\sigma^2 \end{pmatrix}, \qquad C = -i\gamma^2\gamma^0 = \begin{pmatrix} -i\sigma^2 & 0 \\ 0 & i\sigma^2 \end{pmatrix}. \tag{C.295}$$

Now $-i\sigma^2 = \left(\begin{smallmatrix} 0 & -1 \\ 1 & 0 \end{smallmatrix}\right) = \epsilon_{ab}$ and $i\sigma^2 = \left(\begin{smallmatrix} 0 & 1 \\ -1 & 0 \end{smallmatrix}\right) = \epsilon^{\dot a\dot b}$ in the conventions Eq. (C.269), so

$$C = \begin{pmatrix} \epsilon_{ab} & 0 \\ 0 & \epsilon^{\dot a\dot b} \end{pmatrix}. \tag{C.296}$$

The charge-conjugation matrix is therefore block-diagonal and equal to the spinor metric on each chirality: C *is* the operation of raising and lowering two-component indices. Acting on Ψ of Eq. (C.290), charge conjugation $\Psi \mapsto \Psi^c = C\bar\psi^{\mathsf T}$ produces, block by block, $\epsilon_{ab}\chi^b = \chi_a$ in the upper slot and $\epsilon^{\dot a\dot b}\bar\psi_{\dot b} = \bar\psi^{\dot a}$ in the lower, i.e.

$$\Psi^c = \begin{pmatrix} \chi_a \\ \bar\psi^{\dot a} \end{pmatrix}, \tag{C.297}$$

which is Eq. (C.290) with $\psi \leftrightarrow \chi$. Charge conjugation simply exchanges the two Weyl spinors making up the Dirac field, and the Majorana condition $\chi = \psi$ is

exactly the self-conjugacy $\Psi^c = \Psi$. To confirm C does its defining job, check the relation $C\gamma^\mu C^{-1} = -(\gamma^\mu)^{\mathsf{T}}$ on the off-diagonal blocks: with C block-diagonal and γ^μ off-diagonal, $C\gamma^\mu C^{-1}$ is off-diagonal with upper-right block $\epsilon_{ab}(\sigma^\mu)^b{}_{\dot c}(\epsilon^{-1})^{\dot c\dot d}$. Using $\epsilon\sigma^\mu\epsilon^{-1} = -(\sigma^\mu)^{\mathsf{T}}$ for each Pauli four-vector—the statement $\epsilon_{ab}\epsilon_{\dot c\dot d}(\sigma^\mu)^{\cdots}$ that is the index-raising relation Eq. (C.275) read as a similarity transform—this block becomes $-(\sigma^\mu)^{\mathsf{T}}$, and likewise for the other block, reproducing $-(\gamma^\mu)^{\mathsf{T}}$. The intertwiner of Section C.4 and the spinor metric of Section C.9.1 are one object.

C.9.5 The generators $\sigma^{\mu\nu}$, $\bar\sigma^{\mu\nu}$ and (anti)self-duality

The Lorentz generators on the two Weyl spaces are the antisymmetrized products of σ and $\bar\sigma$. Define

$$(\sigma^{\mu\nu})_a{}^b = \tfrac{i}{4}\big(\sigma^\mu\bar\sigma^\nu - \sigma^\nu\bar\sigma^\mu\big)_a{}^b, \tag{C.298}$$

$$(\bar\sigma^{\mu\nu})^{\dot a}{}_{\dot b} = \tfrac{i}{4}\big(\bar\sigma^\mu\sigma^\nu - \bar\sigma^\nu\sigma^\mu\big)^{\dot a}{}_{\dot b}. \tag{C.299}$$

These are exactly the diagonal blocks of the four-component Lorentz generator. Recalling from Section C.5 that $\sigma^{\mu\nu} = \frac{i}{2}[\gamma^\mu,\gamma^\nu]$ so that the generator implementing Lorentz transformations on Ψ is $S^{\mu\nu} = \frac12\sigma^{\mu\nu} = \frac{i}{4}[\gamma^\mu,\gamma^\nu]$, the block computation $[\gamma^\mu,\gamma^\nu] = \mathrm{diag}(\sigma^\mu\bar\sigma^\nu - \sigma^\nu\bar\sigma^\mu,\ \bar\sigma^\mu\sigma^\nu - \bar\sigma^\nu\sigma^\mu)$ gives

$$S^{\mu\nu} = \tfrac{i}{4}[\gamma^\mu,\gamma^\nu] = \begin{pmatrix} (\sigma^{\mu\nu})_a{}^b & 0 \\ 0 & (\bar\sigma^{\mu\nu})^{\dot a}{}_{\dot b} \end{pmatrix}. \tag{C.300}$$

Thus $\sigma^{\mu\nu}$ generates the $(\frac12,0)$ representation on ψ_a and $\bar\sigma^{\mu\nu}$ the $(0,\frac12)$ representation on $\bar\chi^{\dot a}$; the reducibility of the Dirac representation is the block-diagonality of Eq. (C.300). Both generators are traceless—$\mathrm{tr}\,\sigma^{\mu\nu} = \frac{i}{4}\,\mathrm{tr}(\sigma^\mu\bar\sigma^\nu - \sigma^\nu\bar\sigma^\mu) = \frac{i}{4}(2\eta^{\mu\nu} - 2\eta^{\nu\mu}) = 0$ by Eq. (C.279)—the fact used in proving Theorem C.72.

The defining algebraic feature of these two-by-two generators, the one that makes them irreducible and that the spinor-helicity three-point amplitudes of Chapter 58 exploit, is their definite duality under the Levi-Civita tensor.

Theorem C.77 ((Anti)self-duality)**.** *With* $\epsilon^{0123} = +1$,

$$\tfrac12\,\epsilon^{\mu\nu\rho\sigma}\,\sigma_{\rho\sigma} = +\,i\,\sigma^{\mu\nu}, \qquad \tfrac12\,\epsilon^{\mu\nu\rho\sigma}\,\bar\sigma_{\rho\sigma} = -\,i\,\bar\sigma^{\mu\nu}. \tag{C.301}$$

The undotted generator $\sigma^{\mu\nu}$ is self-dual; the dotted generator $\bar\sigma^{\mu\nu}$ is anti-self-dual.

Proof. We descend from the four-component identity, proved as follows. For $\mu \neq \nu$ one has $\sigma^{\mu\nu} = i\gamma^\mu\gamma^\nu$, and we claim

$$\gamma^5\,\sigma^{\mu\nu} = \tfrac{i}{2}\,\epsilon^{\mu\nu\rho\sigma}\,\sigma^{\rho\sigma}. \tag{C.302}$$

To establish Eq. (C.302) it suffices to check one independent component, since both sides are antisymmetric tensors built from the same Clifford algebra. Take

$(\mu\nu) = (01)$. The right side is $\frac{i}{2}\epsilon^{01\rho\sigma}\sigma^{\rho\sigma} = \frac{i}{2}(\epsilon^{0123}\sigma^{23} + \epsilon^{0132}\sigma^{32}) = i\,\epsilon^{0123}\sigma^{23} = i\,\sigma^{23}$, and lowering indices, $\sigma^{23} = \eta_{2\alpha}\eta_{3\beta}\sigma^{\alpha\beta} = (-1)(-1)\sigma^{23} = \sigma^{23} = i\gamma^2\gamma^3$, so the right side is $i \cdot i\gamma^2\gamma^3 = -\gamma^2\gamma^3$. The left side is $\gamma^5\sigma^{01} = i\,\gamma^5\gamma^0\gamma^1 = i\,(i\gamma^0\gamma^1\gamma^2\gamma^3)\gamma^0\gamma^1 = -\gamma^0\gamma^1\gamma^2\gamma^3\gamma^0\gamma^1$. Marching the trailing γ^0 left past $\gamma^3\gamma^2\gamma^1$ (three anticommutations, sign -1) and using $(\gamma^0)^2 = \mathbf{1}$, then the trailing γ^1 left past $\gamma^3\gamma^2$ (two anticommutations, sign $+1$) and using $(\gamma^1)^2 = -\mathbf{1}$, gives $\gamma^0\gamma^1\gamma^2\gamma^3\gamma^0\gamma^1 = +\gamma^2\gamma^3$, so the left side is $-\gamma^2\gamma^3$, matching. Thus Eq. (C.302) holds.

Now pass to blocks. In the chiral basis $\gamma^5 = \mathrm{diag}(-\mathbf{1}, +\mathbf{1})$ and, by Eq. (C.300) together with $\sigma^{\mu\nu} = 2S^{\mu\nu}$, the four-component tensor is $\sigma^{\mu\nu} = \mathrm{diag}(2\sigma^{\mu\nu},\, 2\bar\sigma^{\mu\nu})$. The left side of Eq. (C.302) is $\mathrm{diag}(-2\sigma^{\mu\nu},\, +2\bar\sigma^{\mu\nu})$, while the right side is $\frac{i}{2}\epsilon^{\mu\nu\rho\sigma}\,\mathrm{diag}(2\sigma_{\rho\sigma},\, 2\bar\sigma_{\rho\sigma})$. Equating the upper blocks,

$$-2\sigma^{\mu\nu} = \tfrac{i}{2}\epsilon^{\mu\nu\rho\sigma}\,2\sigma_{\rho\sigma} \;\Longrightarrow\; \tfrac{1}{2}\epsilon^{\mu\nu\rho\sigma}\sigma_{\rho\sigma} = \frac{-2\sigma^{\mu\nu}}{2i}\cdot\frac{2}{2} = i\,\sigma^{\mu\nu}, \tag{C.303}$$

the first relation in Eq. (C.301); equating the lower blocks gives $+2\bar\sigma^{\mu\nu} = \frac{i}{2}\epsilon^{\mu\nu\rho\sigma}2\bar\sigma_{\rho\sigma}$, i.e. $\frac{1}{2}\epsilon^{\mu\nu\rho\sigma}\bar\sigma_{\rho\sigma} = -i\,\bar\sigma^{\mu\nu}$, the second. □

The duality operation squares to -1: applying it twice and using $\epsilon^{\mu\nu\rho\sigma}\epsilon_{\rho\sigma\alpha\beta} = -2(\delta^\mu_\alpha\delta^\nu_\beta - \delta^\mu_\beta\delta^\nu_\alpha)$ from Eq. (C.167) returns $\frac{1}{4}\epsilon^{\mu\nu\rho\sigma}\epsilon_{\rho\sigma\alpha\beta}\sigma^{\alpha\beta} = -\sigma^{\mu\nu}$, consistent with $(+i)^2 = -1$; the eigenvalues $\pm i$ are the only possibility for a real operation squaring to -1, and the two signs label the two irreducibles. A quick component check confirms the normalization: from Eq. (C.298), $\sigma^{01} = \frac{i}{4}(\sigma^0\bar\sigma^1 - \sigma^1\bar\sigma^0) = \frac{i}{4}(-\sigma^1 - \sigma^1) = -\frac{i}{2}\sigma^1$, while $\sigma^{23} = \frac{i}{4}(\sigma^2\bar\sigma^3 - \sigma^3\bar\sigma^2) = -\frac{i}{4}\,[\sigma^2, \sigma^3] = -\frac{i}{4}(2i\sigma^1) = \frac{1}{2}\sigma^1$; then $\frac{1}{2}\epsilon^{01\rho\sigma}\sigma_{\rho\sigma} = \sigma_{23} = \sigma^{23} = \frac{1}{2}\sigma^1$, which indeed equals $i\,\sigma^{01} = i(-\frac{i}{2}\sigma^1) = \frac{1}{2}\sigma^1$. The tensor bilinear of a Dirac field thus splits, via Eq. (C.300), into a self-dual piece $\chi\sigma^{\mu\nu}\psi$ and an anti-self-dual piece $\bar\psi\bar\sigma^{\mu\nu}\bar\chi$; for the field strength this is the familiar decomposition of $F_{\mu\nu}$ into self-dual and anti-self-dual parts that organizes instanton physics (Chapter 41) and the helicity classification of gauge fields in Chapter 58.

The pieces are now in place. We have the ϵ metric and its raising conventions, the Pauli four-vectors $\sigma^\mu, \bar\sigma^\mu$ with their Clifford, trace, and completeness identities, the full dictionary translating every four-component bilinear, intertwiner, and generator into two-component contractions, and the self-duality that isolates the two helicity sectors. Chapter 58 can therefore open not by constructing spinor algebra from scratch but by christening the contractions already proved here—setting $\langle i\,j\rangle = \lambda_i^a\lambda_{ja}$ and $[i\,j] = \bar\lambda_{i\dot a}\bar\lambda_j^{\dot a}$ for the on-shell spinors $\lambda, \bar\lambda$ that solve $p_{a\dot a} = p_\mu(\sigma^\mu)_{a\dot a} = \lambda_a\bar\lambda_{\dot a}$—and immediately deploy the antisymmetry Eq. (C.273), the Schouten identity Eq. (C.287), the Fierz relation Eq. (C.280), and the self-duality Eq. (C.301) to compress the QED and Yang–Mills theory amplitudes into angle and square brackets. This closes the appendix: every spinorial manipulation the book performs, from the four-dimensional traces of Section C.6 to the helicity brackets of Chapter 59, now rests on identities proved in full within it.

Further reading

The standard textbook treatments of gamma-matrix technology are Peskin and Schroeder [396] (appendix and chapter 3), Schwartz [432] (chapters 10–11), Srednicki [454] (chapters 33–50), and Weinberg [500] (chapter 5), whose conventions differ in detail from one another and from ours; the systematic representation-theoretic standpoint, including Pauli's fundamental theorem and the intertwining matrices, is developed most carefully in Weinberg [500]. The bilinear covariants, charge conjugation, and the discrete symmetries are treated thoroughly in Bertlmann [73], which is also the cleanest reference for the anomaly machinery built on the γ^5 trace. For dimensional regularization and the γ^5 problem, the foundational papers are 't Hooft and Veltman [469] and the rigorous all-orders construction of Breitenlohner and Maison [90] (the "BMHV" scheme), with the practical multiloop alternative set out in Larin [317]. The two-component calculus and its four-component dictionary are given exhaustively, with Feynman rules, in the review of Dreiner et al. [162]; the amplitudes-oriented development that the spinor-helicity chapters build on is Elvang and Huang [176].

Appendix D

Loop Integrals and Dimensional Regularization

This appendix is the shared computational engine of every loop chapter in the book. The Feynman rules assembled in Chapter 15 for the scalar theory and in Chapter 17 for gauge theory are, at tree level, a finite bookkeeping device: amputate, contract, multiply. Beyond tree level they begin to produce integrals over loop momenta that the rules leave undetermined—closed momentum loops are not fixed by the external kinematics and must be integrated over all of $\mathbb{R}^{1,3}$—and those integrals are generically divergent. The power counting of Chapter 21 has already told the reader *which* of them diverge and *how badly*, through the superficial degree of divergence; what it does not do is assign a number to the finite remainder, or even give a controlled meaning to the divergent part. That is the task here. We collect, once and in full, the technology that turns any one-loop integral arising anywhere in the book into a Laurent series in a regulator: a pole part that exposes the divergence and a finite remainder that carries the physics. Each loop chapter may then quote a master integral by cross-reference instead of re-deriving the same Wick rotation and angular integral from scratch.

The strategy is uniform and is developed step by step across the eight sections. A loop integrand is a product of propagator denominators raised to various powers, possibly with loop momenta in the numerator. We first combine the denominators into a single quadratic form using Feynman and Schwinger parameters (Section D.2), proved in full for n denominators with arbitrary powers rather than quoted for the few cases we happen to need. We then complete the square, shift the loop momentum, and rotate the contour to Euclidean signature (Section D.3), where the integral becomes radial and the angular part is the volume of a sphere. The radial integral is a Beta function, and assembling the pieces gives the master scalar integral in d dimensions (Section D.4), from which every tensor and numerator variant follows by differentiation. Expanding the result around $d = 4$ produces the Laurent series in ε (Section D.5); tensor integrals with

open Lorentz indices are reduced to this scalar basis by the Passarino–Veltman algorithm (Section D.6); and the same dimensional continuation that regulated the ultraviolet is shown to regulate the infrared as well (Section D.7). The final section carries the program to the other side of the cut, evaluating two- and three-body phase space in d dimensions (Section D.8) so that the optical theorem can be checked against the loop result it predicts.

The conventions are those collected in Chapter A, and we import them by cross-reference rather than restating them: the mostly-minus metric $\eta_{\mu\nu} = \mathrm{diag}(+,-,-,-)$, the Feynman propagator $i/(p^2 - m^2 + i\epsilon)$ with its $i\epsilon$ prescription, the analytic-continuation definition of the spacetime dimension as $d = 4 - 2\varepsilon$ with ε a complex parameter, the renormalization scale μ entering through the bookkeeping factor $\mu^{2\varepsilon}$ that keeps couplings dimensionless away from four dimensions, and the modified minimal subtraction scheme $\overline{\mathrm{MS}}$ defined by which combination of constants is removed along with each pole. The contour deformation underlying the Wick rotation, and the residue calculus it rests on, are taken from Chapter 5; the d-dimensional gamma-matrix traces and contractions that dress the QED numerators are taken from Chapter C (in particular Section C.6); the color factors and Casimirs that dress the Yang–Mills numerators are taken from Chapter B.

The scope of this appendix should be stated honestly. It *owns* the one-loop technology completely: every one-loop integral the book needs is reducible, by the methods built here, to the master scalar function and its descendants, and that reduction is carried out in full. The multi-loop and large-scale tensor-reduction algorithms—integration by parts, the Laporta reduction to master integrals, the Mellin–Barnes and sector-decomposition methods for evaluating those masters—are named and characterized at the level the book actually uses, but they are not developed here; this is a one-loop book in its explicit computations, and we say so plainly rather than gesturing at machinery we will not build. The results assembled here are consumed downstream at well-defined places: the scalar bubble and tadpole feed the ϕ^4 renormalization and beta function of Chapters 22 and 24; the vacuum polarization, self-energy, and vertex integrals feed the QED one-loop program, the Ward–Takahashi identity, and $g - 2$ in Chapters 19 and 20; the color-dressed versions feed the Yang–Mills beta function and asymptotic freedom of Chapter 27; and the phase-space formulae feed the cross-section computations wherever observables live (Chapter 28 among them).

One conceptual thread ties the later sections together and deserves to be flagged at the outset: dimensional regularization is simultaneously an ultraviolet and an infrared regulator. The same parameter ε that tames the large-momentum divergence of a loop also tames the small-momentum and collinear divergences that appear when massless particles are exchanged, and a single integral can carry poles of both origins. Keeping the two roles distinct—knowing which $1/\varepsilon$ is ultraviolet and removed by a counterterm, and which is infrared and destined

to cancel against real-emission phase space—is the discipline that Section D.7 installs and that the observable-level chapters then rely on. Throughout, three carried examples make the machinery concrete: the ϕ^4 bubble of ϕ^4 theory, the photon vacuum polarization, electron self-energy, and vertex integrals of QED, and the color-dressed scalar pieces of Yang–Mills theory. Each tool is built on the page, not handed over; the appendix is a reference, but a proof-carrying one.

D.1 The anatomy of a loop integral and the case for analytic continuation in dimension

The chapter introduction set this appendix a single concrete task: take any momentum-space loop integral the Feynman rules can produce and turn it into a Laurent series in a regulator—a pole part that records the divergence plus a finite, scheme-dependent remainder—with every step done once and in full. Before any of the manipulations that achieve this (combining denominators, rotating to Euclidean space, doing the angular and radial integrals, expanding in ε), we must say precisely what object we are manipulating, diagnose exactly how and why it fails to converge, and decide what we are entitled to mean by "the value" of a divergent integral. That is the work of this opening section. We write down the generic integral, sharpen the power-counting that tells us which integrals diverge and how badly, lay out the four properties any acceptable regulator must have, show by a short honest accounting that the obvious candidates (a hard cutoff, Pauli–Villars) each forfeit one of them, and arrive at dimensional regularization as the one scheme that keeps all four. The section ends by handing the next section a single, well-posed product-of-denominators integral together with the instruction that is the conceptual core of the whole appendix: treat the spacetime dimension d as a continuous complex parameter.

D.1.1 The generic loop integral

The Feynman rules of Chapter 15 (for the scalar threads) and Chapter 17 (for QED) assign to every diagram a product of vertices, external wavefunctions, and propagators, integrated over the momenta that internal lines carry but momentum conservation at the vertices does not fix. A connected diagram with I internal lines and V vertices has, after imposing one momentum-conserving delta function at each vertex (one of which only enforces overall external conservation and is stripped off with the amputation), exactly

$$L \;=\; I - V + 1 \tag{D.1}$$

undetermined internal momenta. These are the *loop momenta*; L is the number of loops, equal to the number of independent cycles in the diagram regarded as a graph. After routing (any consistent choice of how the external and loop

momenta flow through the internal lines), each internal line j carries a definite momentum q_j that is a linear combination of the loop momenta $\ell_1, \dots, \ell_L$ and the external momenta $p_1, \dots, p_n$, and the diagram's amplitude takes a universal shape.

Definition D.1 (Generic L-loop, N-propagator integral)**.** A Feynman diagram contributing at L loops, with N internal lines of momenta q_j and masses m_j, is associated with the momentum-space integral

$$I \;=\; \int \prod_{i=1}^{L} \frac{\mathrm{d}^d \ell_i}{(2\pi)^d} \; \frac{\mathcal{N}(\ell_i; p_a)}{\displaystyle\prod_{j=1}^{N} (q_j^2 - m_j^2 + i\varepsilon)}, \qquad q_j \;=\; \sum_{i=1}^{L} c_{ji}\, \ell_i \;+\; \sum_{a} d_{ja}\, p_a, \tag{D.2}$$

where the routing coefficients $c_{ji}, d_{ja} \in \{0, \pm 1\}$ are fixed by momentum conservation at every vertex, the metric is mostly-minus and the $i\varepsilon$ is the Feynman prescription of Theorem A.23 (so each denominator is $q_j^2 - m_j^2 + i\varepsilon$ with $q_j^2 = q_j^{0\,2} - \mathbf{q}_j^2$), and the numerator $\mathcal{N}$ is a polynomial in the loop momenta whose coefficients are built from external momenta, masses, polarization data, and—for fermion lines and gauge propagators—Dirac matrices and Lorentz tensors. The measure carries one factor of $(2\pi)^{-d}$ per loop, in accord with the Fourier convention of Theorem A.12.

Three features of (D.2) deserve immediate comment, because the rest of the appendix is organized around them. First, the integral is over a *Minkowski* momentum space: each ℓ_i^0 runs along the real axis, the denominators are indefinite quadratic forms, and the $i\varepsilon$ is what makes the ℓ_i^0 contour well-defined by pushing the poles off the real axis. Wick rotation (Theorem A.23), carried out explicitly in a later section, will convert this into a Euclidean integral with a positive-definite denominator, but the object we start from is Lorentzian. Second, the numerator is a polynomial, so a tensor integral—one with uncontracted loop momenta upstairs—can always be reduced to scalar integrals once the denominator has been brought to a standard form; that reduction is the business of the tensor-reduction section. For the present diagnostic purposes only the *degree* of the numerator in the loop momenta matters. Third, the denominator is a product of N factors, and essentially every technique in this appendix is a device for collapsing that product into a single power of one quadratic form. The next section does exactly this with Feynman and Schwinger parameters.

It is worth recording the bookkeeping that relates the data in (D.2) to the graph. With V vertices and $I = N$ internal lines, (D.1) gives $L = N - V + 1$, so a one-loop diagram ($L = 1$) has $N = V$: as many propagators as vertices, the lines forming a single closed ring threaded by one undetermined momentum ℓ. This is the case the appendix solves completely and to which all three benchmark theories first reduce. The one-loop master integral with which they are all built

is

$$\int \frac{\mathrm{d}^d \ell}{(2\pi)^d} \, \frac{(\ell^2)^a}{\prod_{j=1}^{N} \big((\ell + r_j)^2 - m_j^2 + i\varepsilon\big)}, \tag{D.3}$$

where $a \geq 0$ counts the loop momenta in the numerator and the r_j are partial sums of external momenta fixed by the routing. Everything downstream—the ϕ^4 bubble that feeds β_λ in Chapter 24, the QED self-energy, vacuum polarization, and vertex of Chapter 19, the colour-dressed gluon and ghost loops of Chapter 27—is an instance of (D.3) with a particular N, particular masses, and a particular numerator.

D.1.2 Superficial degree of divergence: the UV diagnosis

The integral (D.2) is over an unbounded momentum space, and the question of whether it converges is, in the first instance, a question about its behaviour when the loop momenta are taken large together. The crude but decisive instrument is power counting. Chapter 21 owns the general combinatorial statement of the superficial degree of divergence for the scalar thread, and Theorem A.6 recast it as a statement about mass dimensions; here we re-derive it directly from (D.2) by the cleanest argument available—scaling the loop momenta—both because the scaling argument is the one that generalizes verbatim to the infrared analysis below, and because we will need the explicit one-loop count when staging the thread integrals.

Definition D.2 (Superficial degree of divergence)**.** For the integral (D.2), the *superficial degree of (ultraviolet) divergence* D is the net power of loop momentum in the integrand and measure when all loop momenta are scaled uniformly to infinity. With L loops in d dimensions, a numerator of total degree P in the loop momenta, and N propagators (each contributing two inverse powers),

$$D \;=\; d\,L \;+\; P \;-\; 2N. \tag{D.4}$$

The integral is said to be superficially divergent if $D \geq 0$ (logarithmically when $D = 0$, linearly when $D = 1$, quadratically when $D = 2$, and so on) and superficially convergent if $D < 0$.

The word "superficial" is a genuine caveat, not a flourish: $D < 0$ does not guarantee convergence, because a subset of the loop momenta may be scaled to infinity while the rest are held fixed, producing a *subdivergence* that the overall count (D.4) misses; and $D \geq 0$ does not guarantee that the leading divergence is actually present, because symmetries (gauge invariance, a Lorentz index structure that must come out transverse) can force the would-be leading term to vanish, softening the real divergence. Weinberg's theorem makes the precise statement: a one-particle-irreducible integral converges absolutely if $D < 0$ for the full integral and for every subintegral obtained by sending any subset of loop momenta to

infinity. At one loop there are no proper subintegrals, so $D < 0$ is necessary and sufficient for ultraviolet convergence, and (D.4) is exact.

Proposition D.3 (One-loop degree of divergence by scaling)**.** *For the one-loop integral* (D.3) *in d dimensions, with numerator degree $P = 2a$ and N propagators, the ultraviolet behaviour is governed by*

$$D \;=\; d \;+\; 2a \;-\; 2N, \tag{D.5}$$

and the integral converges in the ultraviolet if and only if $D < 0$.

Proof. Write the one-loop integrand as $f(\ell) = \mathcal{N}(\ell)/\prod_{j=1}^{N}\left((\ell + r_j)^2 - m_j^2 + i\varepsilon\right)$ and isolate the region of large loop momentum by rescaling $\ell = t\,\hat{\ell}$ with $\hat{\ell}$ on a fixed unit shell and $t \to \infty$. The measure scales homogeneously,

$$\mathrm{d}^d\ell \;=\; t^{\,d-1}\,\mathrm{d}t\,\mathrm{d}\Omega_{d-1}\,(\text{angular part}), \tag{D.6}$$

contributing $t^{d-1}\,\mathrm{d}t$ to the radial behaviour. In the limit $t \to \infty$ each propagator denominator is dominated by its quadratic term, $(\ell + r_j)^2 - m_j^2 = t^2\hat{\ell}^2 + 2t\,\hat{\ell}\cdot r_j + (r_j^2 - m_j^2) \sim t^2\hat{\ell}^2$, so the product of N denominators scales as t^{2N}. The numerator $(\ell^2)^a$ scales as t^{2a}. Collecting powers, the integrand times the radial measure behaves for large t as

$$t^{\,d-1}\,\frac{t^{2a}}{t^{2N}}\,\mathrm{d}t \;=\; t^{\,d-1+2a-2N}\,\mathrm{d}t \;=\; t^{\,D-1}\,\mathrm{d}t, \qquad D \;=\; d + 2a - 2N. \tag{D.7}$$

The radial integral $\int^{\infty} t^{D-1}\,\mathrm{d}t$ converges at its upper limit precisely when $D - 1 < -1$, i.e. $D < 0$, and diverges as Λ^D (for $D > 0$) or as $\log\Lambda$ (for $D = 0$) if cut off at $t = \Lambda$. Since one loop has no nontrivial subintegrals, this single scaling exhausts the large-momentum regions and (D.5) is the exact convergence criterion. Setting $L = 1$ and $P = 2a$ in (D.4) reproduces (D.5), confirming the general count against the explicit scaling. □

Two consequences of (D.5) are the engine of all later one-loop work. First, D depends on d *linearly and positively*: lowering the dimension lowers the degree of divergence. A scalar bubble ($N = 2, a = 0$) has $D = d - 4$, logarithmically divergent at $d = 4$ ($D = 0$) but convergent for any $d < 4$ ($D < 0$); a scalar tadpole/triangle pattern follows the same rule. This is the first hint, made rigorous below, that continuing d downward is exactly the right knob to turn to tame an ultraviolet divergence: the divergence is not removed, it is converted into the $d \to 4$ limit of a function that is finite away from four dimensions. Second, the degree of divergence of a tensor integral is read off by counting powers of ℓ in the numerator: the quadratically divergent ($D = 2$) piece of a $d = 4$ vacuum polarization comes entirely from the two loop momenta in its numerator, and the transversality that gauge invariance demands is precisely the statement that this leading piece must cancel.

D.1.3 Infrared, soft, and collinear divergences: the second diagnosis

Power counting at large momentum is only half the diagnosis. A loop integral can also diverge because the integrand blows up at *small* or *lightlike* loop momentum, where a denominator $q_j^2 - m_j^2$ vanishes inside the integration region. These are infrared divergences, and they fall into two physically distinct families, both of which dimensional regularization will also control.

A *soft* divergence occurs when a loop momentum $\ell \to 0$ on a line whose mass is zero or which is sandwiched between on-shell external lines, so that two adjacent denominators degenerate simultaneously. The exemplar is a massless gauge boson of momentum ℓ exchanged between two on-shell charged particles: as $\ell \to 0$ the photon propagator $1/\ell^2$ and the two adjacent fermion propagators $1/(2p\cdot\ell)$ all become singular. A *collinear* divergence occurs when a massless internal momentum becomes parallel to a massless external (or another massless internal) momentum, so that a denominator $(\ell + p)^2 = 2\,\ell\cdot p$ with $p^2 = 0$ vanishes along a whole ray $\ell \parallel p$ rather than at a point. Both are genuine, physical singularities of the perturbative amplitude—they signal that the asymptotic states (a charged particle is always dressed by soft photons; a massless particle is indistinguishable from a collinear pair) have been idealized—and both are tamed by the same scaling logic that gave (D.7), now applied to the dangerous small-momentum region instead of the large one.

Consider the soft region of a generic line, where ℓ is scaled *down*, $\ell = t\,\hat{\ell}$ with $t \to 0$. The measure contributes $t^{d-1}\,\mathrm{d}t$ as before, but now a soft propagator $1/\ell^2$ contributes t^{-2} and each eikonal propagator $1/(2p\cdot\ell + \dots)$ adjacent to an on-shell line contributes t^{-1}. The soft integral behaves as $\int_0 t^{\,d-1-2-2}\,\mathrm{d}t = \int_0 t^{\,d-5}\,\mathrm{d}t$ for the canonical one-soft-gauge-boson configuration with two eikonal lines, which converges at $t = 0$ iff $d - 5 > -1$, i.e. $d > 4$. The collinear region admits the same treatment with a light-cone decomposition: writing $\ell = \alpha p + \beta n + \ell_\perp$ along a reference null direction n and scaling $\beta, \ell_\perp$ toward the p direction, one finds the collinear integral also converges only for $d > 4$. The conclusion is structural and is the conceptual thread tying this appendix together: ultraviolet divergences require $d < 4$ to converge, infrared (soft and collinear) divergences require $d > 4$, and dimensional regularization sits in between, regulating both at once by holding d at a generic value off the integers and letting each kind of divergence reveal itself as a pole at $d = 4$. The same ε that carries the $1/\varepsilon$ ultraviolet pole carries the $1/\varepsilon$ (and, for overlapping soft-collinear regions, $1/\varepsilon^2$) infrared poles, with the sign of ε at which each is finite recorded in Theorem A.45.

Caution

The single symbol ε does double duty. A given integral may be ultraviolet finite but infrared divergent, or vice versa, or both at once; the Laurent

expansion in ε does not, by itself, tell you which kind of pole you are looking at. The convention of Theorem A.45—$\varepsilon > 0$ (so $d < 4$) for the ultraviolet, $\varepsilon < 0$ (so $d > 4$) for the infrared—means that a strictly correct treatment computes an ultraviolet-divergent integral by continuing from $d < 4$ and an infrared-divergent one by continuing from $d > 4$, then takes the common $\varepsilon \to 0$ limit of the resulting meromorphic function. In practice one computes in a dimension generic enough that the integral converges and trusts analytic continuation to connect the regions; we make this trust precise in Section D.1.6. When both kinds of pole are present and must be separated, the physical bookkeeping—which poles are removed by ultraviolet counterterms and which cancel against real-emission phase space, as in the QED programme of Chapter 19—is what disambiguates them, not the dimensional regulator on its own.

D.1.4 What a regulator must do, and why the obvious ones fail

A regulator is a deformation of the divergent integral that makes it finite, controlled by a parameter, such that the original integral is recovered (divergences and all) as the parameter is removed. The point of regularization is to give every intermediate quantity a definite, manipulable value so that the cancellations of renormalization can be carried out unambiguously; the physics resides only in quantities that survive the removal of the regulator. Not every deformation is acceptable. The renormalization program of Part VI, and the gauge theories of Part VII in particular, impose four requirements, and it is the simultaneous satisfaction of all four that singles out dimensional regularization.

Definition D.4 (Regulator desiderata)**.** A regularization scheme suitable for the renormalization of relativistic gauge theories should:

(R1) **Preserve Lorentz invariance.** The regulated integrals should remain Lorentz scalars/tensors, so that the divergence structure respects the same symmetry as the theory and counterterms are themselves Lorentz-invariant local operators.

(R2) **Preserve gauge invariance and the Ward–Takahashi/Slavnov–Taylor identities.** The regulator must not break the gauge symmetry, since those identities (proved for QED in Chapter 19) are what guarantee the cancellations—transversality of the vacuum polarization, equality of charge and wavefunction renormalizations—that make the theory renormalizable and unitary. A regulator that violates them generates spurious, symmetry-breaking counterterms.

(R3) **Regulate ultraviolet and infrared divergences uniformly.** A single parameter controlling both kinds of divergence avoids introducing a sec-

ond, independent regulator (with its own consistency conditions) and lets soft/collinear cancellations be tracked analytically.

(R4) **Be calculable and admit a clean analytic continuation.** The regulated integrals must be computable in closed form, and the dependence on the regulator parameter must be analytic, so that the divergence is isolated as an honest Laurent pole rather than buried in a transcendental cutoff dependence.

Measured against this list, the two regulators a reader meets first both fail, each for an instructive reason.

The momentum cutoff. The most physical-seeming regulator simply forbids loop momenta above a scale Λ: replace $\int \mathrm{d}^d\ell$ by $\int_{|\ell|<\Lambda} \mathrm{d}^d\ell$, or smooth it with a form factor. Divergences become explicit positive powers of Λ and logarithms $\log\Lambda$, and the picture is appealingly concrete—Λ is "new physics at short distance." But the cutoff is imposed on the *magnitude* $|\ell| = \sqrt{\ell_0^2 + \boldsymbol{\ell}^2}$ of the Euclidean momentum, a quantity that is not Lorentz invariant in Minkowski space; restoring Lorentz invariance requires the rotation to Euclidean signature, after which a sphere $|\ell_E| < \Lambda$ is invariant only under the Euclidean rotation group, not under the original Lorentz boosts in any frame-independent way once external momenta are present. Worse, the cutoff fails (R2): translating the loop momentum, $\ell \to \ell + k$, which is a freedom one constantly uses to route momenta and to complete squares, changes the cutoff surface $|\ell| < \Lambda$ into $|\ell + k| < \Lambda$, so the value of a linearly or quadratically divergent integral depends on the routing. In a gauge theory this routing dependence is exactly what spoils the Ward identity: the photon self-energy computed with a hard cutoff acquires a gauge-noninvariant, quadratically divergent mass term $\propto \Lambda^2 \eta^{\mu\nu}$ that must be removed by hand. The cutoff violates (R1) and (R2) at once, and these are the non-negotiable ones for Part VII.

Pauli–Villars. A more sophisticated scheme subtracts, from each propagator, a copy with a large regulator mass M: $\dfrac{1}{q^2 - m^2} \;\to\; \dfrac{1}{q^2 - m^2} - \dfrac{1}{q^2 - M^2} = \dfrac{m^2 - M^2}{(q^2 - m^2)(q^2 - M^2)}$, which falls off two powers faster at large q and so improves convergence while leaving the low-energy physics untouched as $M \to \infty$. Pauli–Villars is Lorentz invariant by construction (R1), and for QED, with enough auxiliary fields, it can be arranged to preserve the abelian Ward identity (R2). It is, historically, how the first correct one-loop QED results were obtained. But it fails on two counts for the book's purposes. It is *not* an infrared regulator (R3): subtracting a heavy copy does nothing to a soft or collinear singularity at small loop momentum, so a second, independent infrared regulator (a photon

mass, an off-shellness) must be bolted on, and keeping two regulators mutually consistent is exactly the bookkeeping one wants to avoid. More seriously, in a *non-abelian* gauge theory there is no way to give the gauge bosons a Pauli–Villars mass without breaking the gauge symmetry: a massive vector field is not gauge invariant, and the auxiliary heavy gauge fields wreck the Slavnov–Taylor identities, violating (R2) precisely where it matters most, in Yang–Mills theory of Chapter 27. Pauli–Villars survives (R1) but fails (R2) non-abelianly and (R3) always.

The lesson is that the requirement which kills the naive schemes is the conjunction of (R2) for *non-abelian* gauge theory with (R3): one needs a regulator that touches neither the gauge symmetry nor the requirement of a single uniform parameter. Dimensional regularization is the scheme that meets the entire list. It deforms not the integrand but the *dimension of the integration measure*, a deformation that is manifestly Lorentz (indeed, $\mathrm{O}(d)$) covariant (R1), that preserves gauge invariance because it never singles out a momentum scale or breaks any internal symmetry—the only structure that must be handled with care is the dimension-specific object γ^5, treated in Section C.7—(R2), that regulates ultraviolet and infrared divergences with the single parameter ε as Section D.1.3 showed (R3), and that yields integrals expressible in closed form through Euler Γ-functions whose poles are honest analytic poles in ε (R4). The price—an integral defined by analytic continuation rather than as a convergent sum, the absence of any direct "Λ^2" signal of quadratic divergence (power divergences are simply absent, set to zero by scaleless integration), and the subtlety of continuing γ^5 and the totally antisymmetric tensor—is small next to keeping the whole list, and it is the price the book pays everywhere.

D.1.5 Dimensional analysis in d dimensions and the scale μ

To define the integrals in $d = 4 - 2\varepsilon$ dimensions we must first confront a consequence of leaving $d = 4$ that has nothing to do with convergence: the couplings stop being dimensionless. Sections A.1.5 and A.7.1 fix this convention once for the whole book; we re-derive it here from the requirement $[S] = 0$ because it is load-bearing for every thread integral below and because the derivation is two lines.

In natural units the action $S = \int \mathrm{d}^d x\, \mathcal{L}$ is dimensionless, $[S] = 0$. With $[\mathrm{d}^d x] = -d$ in mass units, the Lagrangian density must carry $[\mathcal{L}] = d$. The kinetic terms then fix the field dimensions: for a scalar, $[\,(\partial\phi)^2\,] = 2[\partial] + 2[\phi] = 2 + 2[\phi] = d$ gives

$$[\phi] \;=\; \frac{d-2}{2}, \tag{D.8}$$

and for a Dirac field, $[\,\bar\psi i\partial\!\!\!/\psi\,] = 2[\psi] + 1 = d$ gives $[\psi] = (d-1)/2$, while the gauge kinetic term $[\,F^2\,] = 2([\partial] + [A]) = d$ gives $[A] = (d-2)/2$, the same as a

scalar. These reproduce Eqs. (A.10) to (A.12). The coupling dimensions follow by demanding $[\mathcal{L}] = d$ term by term.

Proposition D.5 (d-dependent coupling dimensions)**.** *In $d = 4 - 2\varepsilon$ dimensions, with the field dimensions above, the ϕ^4 and gauge couplings carry*

$$[\lambda] \;=\; 4 - d \;=\; 2\varepsilon, \qquad [e] \;=\; [g] \;=\; \frac{4-d}{2} \;=\; \varepsilon. \tag{D.9}$$

Proof. For the quartic scalar interaction $\dfrac{\lambda}{4!}\phi^4$, dimensional homogeneity requires $[\lambda] + 4[\phi] = [\mathcal{L}] = d$. Using (D.8), $[\lambda] = d - 4 \cdot \frac{d-2}{2} = d - 2(d-2) = 4 - d$, which is 2ε at $d = 4 - 2\varepsilon$. For the gauge coupling, read it off the covariant-derivative interaction. The QED vertex term in $\bar\psi i \not{D} \psi$ is $-e\,\bar\psi \not{A} \psi$ (from $D_\mu = \partial_\mu + ieA_\mu$ acting on the electron, the standing convention of QED); its dimension is $[e] + 2[\psi] + [A] = [e] + (d-1) + \frac{d-2}{2} = [e] + \frac{3d-4}{2}$, and setting this to d gives $[e] = d - \frac{3d-4}{2} = \frac{4-d}{2} = \varepsilon$. The non-abelian coupling enters identically through $D_\mu = \partial_\mu - igA^a_\mu T^a$ and through the cubic and quartic self-interactions in $F^a_{\mu\nu} F^{a\,\mu\nu}$; the cubic term $g f^{abc} (\partial A) A A$ has dimension $[g] + 3[A] + 1 = [g] + 3\frac{d-2}{2} + 1$, set equal to d gives $[g] = \frac{4-d}{2} = \varepsilon$, consistent with the fermion vertex. Hence (D.9). □

A coupling carrying a small dimension proportional to ε cannot be the expansion parameter of a perturbation series, since a Feynman amplitude is a pure number (times the kinematic factor carrying its external dimension) and one cannot expand in a dimensionful quantity. The remedy, fixed in Theorem A.46, is to extract the dimension into a fixed power of an arbitrary mass scale μ, the renormalization scale, leaving a dimensionless coupling to expand in:

$$\lambda \;\longrightarrow\; \lambda\,\mu^{2\varepsilon}, \qquad e \;\longrightarrow\; e\,\mu^{\varepsilon}, \qquad g \;\longrightarrow\; g\,\mu^{\varepsilon}, \tag{D.10}$$

where on the right λ, e, g are now dimensionless for all ε and μ alone carries the dimension dictated by (D.9). The power of μ is exactly [coupling]: $\mu^{2\varepsilon}$ for the quartic, μ^{ε} per gauge vertex. In a one-loop amplitude with two vertices the insertions multiply, so the ϕ^4 four-point function at one loop carries $(\mu^{2\varepsilon})^2 = \mu^{4\varepsilon}$, the QED self-energy and vacuum polarization (two vertices) carry $(\mu^{\varepsilon})^2 = \mu^{2\varepsilon}$, and so on; the universal effect is that every loop integral acquires the prefactor $\mu^{2\varepsilon}$ *per loop*, which combines with the $(\mu^2)^{-\varepsilon}$ that the integral itself produces (a d-dimensional integral of mass dimension D is μ^D times a number, and the leftover dimension is supplied by external invariants) to make every logarithm appear in the dimensionless, μ-restoring combination $\log(-p^2/\mu^2)$. This is why μ is the scale at which the renormalized coupling is defined and the variable in which the renormalization group of Chapters 24 and 27 runs. The scale is arbitrary: no physical quantity depends on it, and that independence is the content of the Callan–Symanzik equation derived downstream.

D.1.6 Dimensional regularization as analytic continuation

We can now state what (D.2) *means* when d is not an integer. There is no measure $\mathrm{d}^d\ell$ on a space of non-integer dimension in any literal sense; what exists is a family of integrals, one for each d in a strip where the integral converges, that happens to be an analytic function of d and can be continued.

Definition D.6 (Dimensional regularization)**.** Fix the external momenta and masses. For the integral (D.2), regarded as a function of the complex variable d, there is (after Wick rotation and, where needed, an explicit subtraction of infrared singular regions) a nonempty strip $d_- < \operatorname{Re} d < d_+$ in which the integral converges absolutely and defines a holomorphic function $I(d)$ of d. The *dimensionally regularized* value of the integral, for any d outside that strip—in particular for d in a punctured neighbourhood of 4—is the analytic continuation of $I(d)$. Ultraviolet divergences of the $d = 4$ integral appear as poles of this continuation at $d = 4$ (equivalently $\varepsilon = 0$): a logarithmically ultraviolet-divergent one-loop integral has a simple pole $1/\varepsilon$, an L-loop integral whose subdivergences have been arranged has poles up to $1/\varepsilon^L$; infrared divergences appear as poles of the continuation from the strip $\operatorname{Re} d > 4$, in accord with Theorem A.45.

The existence of the convergence strip is what makes the definition more than a wish. For the one-loop master (D.3) the ultraviolet count (D.5) gives convergence at large ℓ for $d < 2N - 2a$, and the infrared count of Section D.1.3 gives convergence at small ℓ for d above some threshold d_- set by the on-shell structure; whenever $d_- < d_+ = 2N - 2a$ a strip exists, the integral is genuinely convergent there, and the closed form one obtains (a ratio of Γ-functions times a power of the external invariant, derived in the next sections) is a meromorphic function of d that *is* the analytic continuation. For a scaleless integral the strip is empty—there is no d for which $\int \mathrm{d}^d\ell\,(\ell^2)^{-n}$ converges, since whatever power makes it converge at infinity makes it diverge at the origin and vice versa—and dimensional regularization assigns it the value zero, the unique continuation consistent with the scaling $\int \mathrm{d}^d(s\ell)\,((s\ell)^2)^{-n} = s^{d-2n}\int \mathrm{d}^d\ell\,(\ell^2)^{-n}$, which can hold for all s only if the integral vanishes. This vanishing of scaleless integrals is not a convention bolted on; it is forced by the same continuation that defines everything else, and it is the technical reason power divergences leave no Λ^2 trace in dimensional regularization.

Physical Insight

The conceptual move that makes the whole appendix work is to stop asking "what is the value of this divergent four-dimensional integral?"—a question with no answer—and ask instead "what is the meromorphic function of d that agrees with this integral wherever it converges?"—a question with a unique answer. Renormalization is then the statement that the $1/\varepsilon$ poles

of that function are absorbed, order by order, into a redefinition of finitely many parameters, leaving an $\varepsilon \to 0$ limit that is finite and physical. The regulator ε is the coordinate on the line of dimensions through $d = 4$; the divergences of physics live at the single point $\varepsilon = 0$ on that line, and dimensional regularization is the device for approaching that point from a direction where everything is finite and analytic.

D.1.7 One-loop integrals in the three benchmark theories

We close by writing down, in the canonical form (D.3), the specific one-loop integrals the benchmark theories will feed into this appendix. No evaluation is done here—that is the work of the sections that follow—and no new thread layer is introduced; the point is only to fix the integrands so the thread chapters can import a master integral by cross-reference instead of re-deriving the integral from the Feynman rules each time.

ϕ^4 theory: the four-point bubble. The one-loop correction to $\phi\phi \to \phi\phi$ in the $\lambda\phi^4$ theory comes from three diagrams (the s-, t-, and u-channel bubbles); the s-channel one, with total incoming momentum $p = p_1 + p_2$ and $s = p^2$, is shown in Fig. D.1. With the vertex factor $-i\lambda\mu^{2\varepsilon}$ from Chapter 15 and the symmetry factor $\frac{1}{2}$ for the two-propagator loop, its amplitude is

$$i\mathcal{M}_s \;=\; \frac{1}{2}\,(-i\lambda\,\mu^{2\varepsilon})^2 \int \frac{\mathrm{d}^d\ell}{(2\pi)^d}\; \frac{i}{\ell^2 - m^2 + i\varepsilon}\; \frac{i}{(\ell+p)^2 - m^2 + i\varepsilon}, \tag{D.11}$$

so the entire nontrivial content is the scalar bubble

$$B_0(p^2, m^2) \;\equiv\; \mu^{2\varepsilon} \int \frac{\mathrm{d}^d\ell}{(2\pi)^d}\; \frac{1}{(\ell^2 - m^2 + i\varepsilon)\big((\ell+p)^2 - m^2 + i\varepsilon\big)}, \tag{D.12}$$

an instance of (D.3) with $N = 2$, $a = 0$, hence $D = d - 4 = -2\varepsilon$: logarithmically divergent at $d = 4$, with a simple $1/\varepsilon$ pole. Its evaluation, completed in the following sections, supplies the one-loop coupling renormalization and the beta function $\beta_\lambda = 3\lambda^2/16\pi^2 + O(\lambda^3)$ quoted for ϕ^4 theory and computed in Chapter 24.

QED: vacuum polarization, self-energy, and vertex. The three one-loop one-particle-irreducible functions of QED, built with the vertex $-ie\gamma^\mu$ and propagators of Chapter 17, are the photon self-energy (vacuum polarization) $\Pi^{\mu\nu}$, the electron self-energy Σ, and the vertex correction Γ^μ. The vacuum polarization, with external photon momentum q and the fermion loop carrying

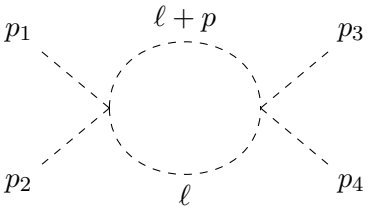

Figure D.1: The s-channel one-loop bubble correcting $\phi\phi \to \phi\phi$ in ϕ^4 theory. The two internal scalar lines carry ℓ and $\ell + p$ with $p = p_1 + p_2$; the loop momentum ℓ is undetermined and integrated over. This is the integral (D.12), the substrate for the ϕ^4 beta function of Chapter 24.

its mandatory overall minus sign, is

$$i\Pi^{\mu\nu}(q) \;=\; -(-ie\,\mu^{\varepsilon})^2 \int \frac{\mathrm{d}^d\ell}{(2\pi)^d}\;\mathrm{tr}\left[\gamma^\mu\,\frac{i(\not{\ell}+m)}{\ell^2-m^2+i\varepsilon}\,\gamma^\nu\,\frac{i(\not{\ell}+\not{q}+m)}{(\ell+q)^2-m^2+i\varepsilon}\right], \tag{D.13}$$

an $N = 2$, $P = 2$ integral with $D = d + 2 - 4 = 2 - 2\varepsilon$, superficially quadratically divergent; gauge invariance (the Ward identity proved in Chapter 19) forces the result into the transverse form $\Pi^{\mu\nu} = (q^2\eta^{\mu\nu} - q^\mu q^\nu)\,\Pi(q^2)$, so the quadratic and linear divergences cancel and only a logarithmic $(1/\varepsilon)$ divergence survives in $\Pi(q^2)$. The diagram is drawn in Fig. D.2. The electron self-energy, in Feynman gauge ($\xi = 1$, the default for explicit computation in QED) with photon propagator $-i\eta_{\mu\nu}/(\ell^2 + i\varepsilon)$, is

$$-i\Sigma(p) \;=\; (-ie\,\mu^{\varepsilon})^2 \int \frac{\mathrm{d}^d\ell}{(2\pi)^d}\;\gamma^\mu\,\frac{i(\not{p}-\not{\ell}+m)}{(p-\ell)^2-m^2+i\varepsilon}\,\gamma^\nu\,\frac{-i\eta_{\mu\nu}}{\ell^2+i\varepsilon}, \tag{D.14}$$

an $N = 2$, $P = 1$ integral with $D = d + 1 - 4 = 1 - 2\varepsilon$, superficially linearly divergent but reducing (by Lorentz covariance, the result being a function of $\not{p}$ and m only) to a logarithmic divergence in the coefficients of $\not{p}$ and m; the massless photon makes (D.14) also infrared sensitive, regulated by the same ε as discussed in Section D.1.3. The vertex correction is the $N = 3$ integral

$$i\,\delta\Gamma^\mu(p',p) \;=\; (-ie\,\mu^{\varepsilon})^3 \int \frac{\mathrm{d}^d\ell}{(2\pi)^d}\;\gamma^\alpha\,\frac{i(\not{p}'-\not{\ell}+m)}{(p'-\ell)^2-m^2+i\varepsilon}\,\gamma^\mu\,\frac{i(\not{p}-\not{\ell}+m)}{(p-\ell)^2-m^2+i\varepsilon}\,\gamma^\beta\,\frac{-i\eta_{\alpha\beta}}{\ell^2+i\varepsilon}, \tag{D.15}$$

with $N = 3$, $P = 2$, hence $D = d + 2 - 6 = -2\varepsilon$, logarithmically (ultraviolet) divergent—the divergence that renormalizes the charge—and, like the self-energy, infrared divergent through the soft photon, the cancellation of which against bremsstrahlung is the subject of Chapter 19. The three integrals (D.13)–(D.15) are exactly what Chapter 19 consumes; their evaluation needs the Feynman-parameter reduction of the next section, the Wick rotation, the d-dimensional gamma algebra of Sections C.7.1 and C.7.3, and the Γ-function master formula.

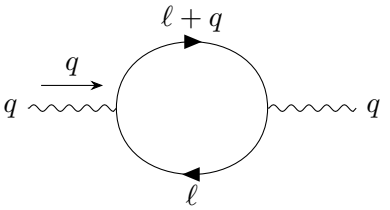

Figure D.2: The QED vacuum polarization (D.13): a photon of momentum q fluctuates into a virtual electron–positron pair carrying ℓ and $\ell + q$. The closed fermion loop supplies the trace and the overall minus sign; transversality $\Pi^{\mu\nu} \propto q^2\eta^{\mu\nu} - q^\mu q^\nu$ enforced by the Ward identity of Chapter 19 removes the would-be quadratic divergence.

Yang–Mills theory: colour-dressed scalar integrals. The one-loop diagrams of Yang–Mills theory—the gluon self-energy with its gluon loop, ghost loop, and (with matter) fermion loop, the ghost and quark self-energies, the triple-gluon and quark–gluon vertices—reduce, after the Lorentz and Dirac algebra is done, to exactly the same family of scalar integrals (D.3) as the abelian case, multiplied by a colour factor that factors out of the momentum integral entirely. A gluon loop contributes the adjoint Casimir through $f^{acd}f^{bcd} = C_A\,\delta^{ab}$, a quark loop the index through $\mathrm{tr}(T^aT^b) = T_F\,\delta^{ab}$, and a quark self-energy the fundamental Casimir through $(T^aT^a)_{ij} = C_F\,\delta_{ij}$; all of these constants, and the identities that produce them, are owned by Chapter B and quoted there. Schematically, every YM one-loop integral has the structure

$$(\text{colour factor: } C_A,\, T_F\,n_f,\, \text{or } C_F)\;\times\;\mu^{2\varepsilon}\int\frac{\mathrm{d}^d\ell}{(2\pi)^d}\,\frac{\mathcal{N}(\ell;p)}{\prod_j(q_j^2+i\varepsilon)}, \tag{D.16}$$

with the kinematic integral identical in form to (D.13)–(D.15). This is why the renormalization technology transfers from QED to QCD essentially unchanged, and why the appendix can supply a single set of master integrals that serves all three benchmark theories: the colour algebra is separated off by Chapter B before any momentum integration, and the surviving integrals are the ones this appendix evaluates once and for all. The combination of these integrals with their colour factors assembles, in Chapter 27, into the Yang–Mills beta-function coefficient $b_0 = \frac{11}{3}C_A - \frac{4}{3}T_F n_f$.

Worked Example D.7 (Reading off the degree of divergence of the QED one-loop functions)**.** We confirm the divergence diagnoses asserted for (D.13)–(D.15) directly from the one-loop count (D.5), $D = d + 2a - 2N$ with $2a = P$ the numerator degree, evaluated at $d = 4 - 2\varepsilon$.

Vacuum polarization (D.13). The loop has $N = 2$ fermion propagators; their numerators contribute $\not{\ell} + m$ and $\not{\ell} + \not{q} + m$, so the loop momentum appears to degree $P = 2$. Hence $D = d + 2 - 4 = d - 2 = 2 - 2\varepsilon$. The superficial divergence

is quadratic ($D = 2$ at $\varepsilon = 0$). The actual divergence is softer: writing the most general symmetric tensor built from q, the result is $A(q^2)\,\eta^{\mu\nu} + B(q^2)\,q^\mu q^\nu$, and the Ward identity $q_\mu \Pi^{\mu\nu} = 0$ forces $A = -q^2 B$, i.e. the transverse form $(q^2\eta^{\mu\nu} - q^\mu q^\nu)\Pi(q^2)$. The two powers of q pulled out front reduce the divergence of the scalar coefficient $\Pi(q^2)$ by two units, to $D_{\text{eff}} = 0$: logarithmic, a simple $1/\varepsilon$ pole. Dimensional regularization makes this automatic—it never generates the gauge-noninvariant $\propto \Lambda^2\eta^{\mu\nu}$ piece that a cutoff would, because, as Section D.1.6 showed, it assigns no power divergence at all.

Self-energy (D.14). Here $N = 2$ (one fermion, one photon propagator); the numerator carries $\not{p} - \not{\ell} + m$ from the fermion line and a constant from the photon, so $P = 1$ and $D = d + 1 - 4 = d - 3 = 1 - 2\varepsilon$, superficially linear. Lorentz covariance restricts the answer to $\Sigma(p) = \not{p}\,\Sigma_V(p^2) + m\,\Sigma_S(p^2)$; the coefficient functions are dimensionless, so each carries the residual logarithmic divergence, a single $1/\varepsilon$ pole. (The linear term that bare power counting allows is the one that would multiply a unit matrix with one power of external momentum; it is absent because there is no available vector to carry the loose index, leaving only the $\not{p}$ and m structures.)

Vertex (D.15). Now $N = 3$ (two fermion, one photon propagator) and the two fermion numerators give $P = 2$, so $D = d + 2 - 6 = d - 4 = -2\varepsilon$: superficially logarithmic, the lone $1/\varepsilon$ pole renormalizing the electric charge. Every count agrees with the assertions made above, and each is nothing but the scaling argument of Theorem D.3 applied to a specific numerator.

all three benchmark theories have thus been reduced to integrals of the single form (D.3): a numerator polynomial over a product of quadratic denominators, to be understood as a meromorphic function of the continued dimension d. What remains is to evaluate them, and the first obstacle is the product of denominators. The next section removes that obstacle, deriving in full the Feynman and Schwinger parametrizations that merge any product $\prod_j (q_j^2 - m_j^2 + i\varepsilon)$ into a single denominator raised to a power and, after completing the square in the loop momentum, expose the canonical form $(\ell^2 - \Delta)^{-n}$ with Δ a function of the external invariants, the masses, and the parameters—the form on which the Wick rotation and the Γ-function master integral act.

D.2 Combining denominators: Feynman and Schwinger parametrization

The previous section reduced every diagram of all three benchmark theories to a single template, the one-loop master integral (D.3): a numerator polynomial in the loop momentum over a *product* of quadratic denominators $\prod_j (q_j^2 - m_j^2 + i\varepsilon)$, to be read as a meromorphic function of the continued dimension d. That product is the one structural obstacle between us and a textbook radial integral. The

momenta q_j in the various factors differ by external shifts, so the denominator is not a function of a single quadratic form and no rotation or rescaling of ℓ can act on all factors at once. The remedy, due in its two complementary forms to Feynman and to Schwinger, is to trade the product of N denominators for a *single* denominator raised to a power, at the cost of introducing $N-1$ auxiliary integration variables. Once the denominator is a single quadratic form, the loop momentum enters only through that one form; a translation $\ell \to \ell + (\text{shift})$ completes the square and removes the linear term, leaving the canonical $(\ell^2 - \Delta + i\varepsilon)^{-n}$ with all dependence on external invariants, masses, and the new parameters sequestered into the single scalar Δ. This section derives both devices in full, proves the multi-denominator master formula by induction, establishes that the completing-the-square shift is a legitimate change of variables under the analytic continuation of Theorem D.6, and computes Δ explicitly for the ϕ^4 bubble and the QED self-energy, vacuum polarization, and vertex. Throughout, the $i\varepsilon$ is the Feynman prescription of Theorem A.23, and the Γ- and B-function facts we lean on (their integral representations, the recursion $\Gamma(z+1) = z\Gamma(z)$, analyticity away from the nonpositive integers) are the complex-analytic results reviewed in Chapter 5.

D.2.1 The two-denominator Feynman identity

We begin with the simplest and most frequently used case, two denominators each to the first power, and prove the formula that all of perturbation theory at one loop ultimately rests on.

Lemma D.8 (Feynman's two-denominator identity)**.** *Let A, B be complex numbers such that the straight-line segment joining them, $\{xA + (1-x)B : x \in [0,1]\}$, does not pass through the origin. Then*

$$\frac{1}{AB} \;=\; \int_0^1 \frac{\mathrm{d}x}{\big[xA + (1-x)B\big]^2}. \tag{D.17}$$

In the application to (D.3), A and B are the two Feynman denominators $q_1^2 - m_1^2 + i\varepsilon$ and $q_2^2 - m_2^2 + i\varepsilon$; because both carry the same *sign of the infinitesimal imaginary part, every point of the segment has imaginary part $+\varepsilon > 0$ and the hypothesis is automatically met, so no pole is crossed and (D.17) holds verbatim with the Feynman $i\varepsilon$ in place.*

Proof. Write the denominator of the integrand as $f(x) = xA + (1-x)B = B + x(A-B)$, an affine function of x. If $A \neq B$, then $f'(x) = A - B \neq 0$ and the integrand has the elementary antiderivative

$$\frac{\mathrm{d}}{\mathrm{d}x}\left[-\frac{1}{A-B}\,\frac{1}{B + x(A-B)}\right] \;=\; \frac{1}{\big[B + x(A-B)\big]^2}, \tag{D.18}$$

valid as long as $f(x) \neq 0$ on $[0,1]$, which is exactly the hypothesis that the segment misses the origin. Evaluating between the limits,

$$\int_0^1 \frac{\mathrm{d}x}{f(x)^2} \;=\; -\frac{1}{A-B}\left[\frac{1}{A}-\frac{1}{B}\right] \;=\; -\frac{1}{A-B}\cdot\frac{B-A}{AB} \;=\; \frac{1}{AB}. \tag{D.19}$$

The case $A = B$ is recovered by continuity: the right side of (D.17) is $\int_0^1 \mathrm{d}x\, A^{-2} = A^{-2} = 1/(AB)$, and both sides are continuous in A, B wherever the segment avoids the origin. Finally, with $A = q_1^2 - m_1^2 + i\varepsilon$ and $B = q_2^2 - m_2^2 + i\varepsilon$, the segment is $\{x q_1^2 + (1-x) q_2^2 - x m_1^2 - (1-x) m_2^2 + i\varepsilon\}$, whose imaginary part is $\varepsilon > 0$ for every $x \in [0,1]$; it therefore never reaches the origin, the hypothesis holds, and the combined denominator inherits a single $+i\varepsilon$. □

The content of (D.17) is geometric: the reciprocal of a product is the average, over the unit interval, of the reciprocal of a *weighted* single denominator squared. The weight x is the first Feynman parameter. Two features generalize. First, the power of the combined denominator is the *sum* of the original powers (here $1 + 1 = 2$); for higher powers a Γ-function prefactor and a parameter weight $x^{\alpha-1}(1-x)^{\beta-1}$ appear. Second, for n denominators the single integral becomes an integral over the $(n-1)$-dimensional simplex of parameters $x_1, \dots, x_n$ constrained to sum to one. We now establish both generalizations, and the cleanest route to them passes through Schwinger's representation.

D.2.2 The Schwinger (proper-time) representation

Feynman's identity merges denominators by a clever interpolation; Schwinger's achieves the same by writing each denominator as an exponential integral, after which a product of denominators becomes a single Gaussian-type exponential of a *sum*. The two are not rivals: Schwinger's representation is the efficient engine from which the general Feynman formula follows in a few lines, and it is the form in which the loop integral is most transparent after Wick rotation. Its name ("proper time") comes from the worldline picture, in which the parameter s conjugate to $p^2 - m^2$ is the proper time elapsed along a particle's trajectory; we use it here purely as an integral identity.

Proposition D.9 (Schwinger representation)**.** *For any complex A with $\operatorname{Re} A > 0$ and any n with $\operatorname{Re} n > 0$,*

$$\frac{1}{A^n} \;=\; \frac{1}{\Gamma(n)} \int_0^\infty \mathrm{d}s\; s^{\,n-1}\, e^{-sA}. \tag{D.20}$$

For a Lorentzian Feynman denominator the relevant quantity has the form $A = -i(X + i\varepsilon)$ with $X = q^2 - m^2$ real; the convergent version reads

$$\frac{1}{(X+i\varepsilon)^n} \;=\; \frac{(-i)^n}{\Gamma(n)} \int_0^\infty \mathrm{d}s\; s^{\,n-1}\, e^{\,is(X+i\varepsilon)}, \tag{D.21}$$

in which the $i\varepsilon$ supplies the convergence factor $e^{-s\varepsilon}$ that damps the upper limit and, simultaneously, fixes the sense in which the s-contour may later be rotated.

Proof. Start from the Euler integral defining the Γ-function (reviewed in Chapter 5), $\Gamma(n) = \int_0^\infty \mathrm{d}u\; u^{n-1}e^{-u}$, valid for $\operatorname{Re} n > 0$. Substitute $u = sA$ with A a fixed complex number of positive real part; this is a rotation-plus-scaling of the integration ray by the fixed phase $\arg A \in (-\frac{\pi}{2}, \frac{\pi}{2})$, and since $\operatorname{Re} A > 0$ the integrand $u^{n-1}e^{-u}$ decays on the rotated ray and the contour may be rotated back to the positive real axis without crossing a singularity (the integrand is entire in u). Hence $\mathrm{d}u = A\,\mathrm{d}s$, $u^{n-1} = A^{n-1}s^{n-1}$, and

$$\Gamma(n) \;=\; \int_0^\infty A\,\mathrm{d}s\;(As)^{n-1}e^{-sA} \;=\; A^n\int_0^\infty \mathrm{d}s\; s^{n-1}e^{-sA}, \tag{D.22}$$

which rearranges to (D.20). For the Lorentzian form, the Feynman denominator $X + i\varepsilon$ has vanishing real part on shell, so (D.20) does not apply directly; instead write $X + i\varepsilon = i\big[-i(X + i\varepsilon)\big]$ and set $A = -i(X + i\varepsilon) = \varepsilon - iX$, which has $\operatorname{Re} A = \varepsilon > 0$. Then $A^{-n} = i^{-n}(X + i\varepsilon)^{-n} = (-i)^n(X + i\varepsilon)^{-n}$ and (D.20) gives

$$(X+i\varepsilon)^{-n} \;=\; i^{-n}A^{-n} \;=\; \frac{i^{-n}}{\Gamma(n)}\int_0^\infty \mathrm{d}s\; s^{n-1}e^{-s(\varepsilon-iX)} \;=\; \frac{(-i)^n}{\Gamma(n)}\int_0^\infty \mathrm{d}s\; s^{n-1}e^{\,is(X+i\varepsilon)}, \tag{D.23}$$

using $i^{-n} = (-i)^n$ and $e^{-s\varepsilon}e^{isX} = e^{is(X+i\varepsilon)}$. The factor $e^{-s\varepsilon}$ guarantees absolute convergence at $s \to \infty$; this is (D.21). □

Remark D.10 (The $i\varepsilon$ fixes the rotation sense). The sign of the exponent in (D.21) is not a matter of taste. Because the convergence factor is $e^{-s\varepsilon}$ with $\varepsilon > 0$, the s-integral converges on the positive real axis and on any ray rotated into the lower-half s-plane down to $\arg s = -\pi/2$, where $is \to s_E$ becomes real and the exponential becomes the manifestly convergent $e^{-s_E|X|}$ for spacelike $X < 0$. This is the Schwinger-parameter shadow of the Wick rotation carried out in Section D.3: the same $i\varepsilon$ that pushes the Feynman poles off the real energy axis dictates that one rotates the proper-time contour clockwise, equivalently the energy contour counterclockwise. Carrying the wrong sign of ε would demand the opposite rotation and produce the complex conjugate (anti-Feynman) propagator.

The Gaussian virtue of (D.20) is that a product of denominators exponentiates into a single exponential of a sum:

$$\frac{1}{A_1^{\alpha_1}\cdots A_N^{\alpha_N}} \;=\; \frac{1}{\prod_j \Gamma(\alpha_j)}\int_0^\infty\Big(\prod_{j=1}^N \mathrm{d}s_j\; s_j^{\alpha_j-1}\Big)\;\exp\Big(-\sum_{j=1}^N s_jA_j\Big). \tag{D.24}$$

This single formula is the source of everything that follows. Inserted directly into a loop integral it produces, after Wick rotation, a Gaussian momentum integral with the proper times as parameters — the route taken in the worldline and heat-kernel methods. Reorganized as below, it yields the Feynman simplex formula.

D.2.3 Feynman's formula for N denominators with arbitrary powers

We now state and prove the master parametric identity, the workhorse of the entire appendix.

Theorem D.11 (Feynman parametrization, general powers)**.** *Let $A_1, \dots, A_N$ be complex numbers whose convex hull excludes the origin, and let $\alpha_1, \dots, \alpha_N$ have positive real parts, with $S \equiv \sum_{j=1}^{N} \alpha_j$. Then*

$$\frac{1}{\prod_{j=1}^{N} A_j^{\alpha_j}} \;=\; \frac{\Gamma(S)}{\prod_{j=1}^{N} \Gamma(\alpha_j)} \int_0^1 \Big(\prod_{j=1}^{N} \mathrm{d}x_j \, x_j^{\alpha_j - 1} \Big) \, \frac{\delta\big(1 - \sum_{j=1}^{N} x_j\big)}{\big[\sum_{j=1}^{N} x_j A_j\big]^{S}}. \tag{D.25}$$

The integration runs over the standard $(N-1)$-simplex $\Delta_{N-1} = \{x_j \geq 0,\ \sum_j x_j = 1\}$ enforced by the δ-function. For $N = 2$, $\alpha_1 = \alpha_2 = 1$, (D.25) reduces to (D.17); setting all $\alpha_j = 1$ gives the unit-power form with prefactor $\Gamma(N) = (N-1)!$.

We give two complete proofs. The first derives (D.25) in a single stroke from the Schwinger representation (D.24); the second builds it up by induction on N from the two-denominator case, exhibiting the Γ-function recursion that organizes the simplex.

Proof via the Schwinger representation. Begin from (D.24). Insert into the right-hand side the identity $1 = \int_0^\infty \mathrm{d}\lambda \, \delta(\lambda - \sum_j s_j)$, which simply names the total proper time $\lambda = \sum_j s_j$. Then rescale each $s_j = \lambda x_j$ with $x_j \geq 0$; the delta becomes $\delta\big(\lambda(1 - \sum_j x_j)\big) = \lambda^{-1}\delta(1 - \sum_j x_j)$, and $\mathrm{d}s_j = \lambda \, \mathrm{d}x_j$ at fixed λ contributes one factor of λ for each of the N variables. Collecting powers of λ,

$$\begin{aligned}
\frac{1}{\prod_j A_j^{\alpha_j}} &= \frac{1}{\prod_j \Gamma(\alpha_j)} \int_0^\infty \mathrm{d}\lambda \int_0^\infty \Big(\prod_j \mathrm{d}s_j \, s_j^{\alpha_j - 1} \Big) \delta\Big(\lambda - \sum_j s_j\Big) e^{-\sum_j s_j A_j} \\
&= \frac{1}{\prod_j \Gamma(\alpha_j)} \int_0^\infty \mathrm{d}\lambda \int_0^1 \Big(\prod_j \mathrm{d}x_j \, (\lambda x_j)^{\alpha_j - 1} \Big) \, \lambda^{N} \, \lambda^{-1} \delta\Big(1 - \sum_j x_j\Big) \, e^{-\lambda \sum_j x_j A_j} \\
&= \frac{1}{\prod_j \Gamma(\alpha_j)} \int_0^1 \Big(\prod_j \mathrm{d}x_j \, x_j^{\alpha_j - 1} \Big) \delta\Big(1 - \sum_j x_j\Big) \int_0^\infty \mathrm{d}\lambda \, \lambda^{S-1} e^{-\lambda U},
\end{aligned} \tag{D.26}$$

where $U \equiv \sum_j x_j A_j$ and the total power of λ assembled is $\sum_j (\alpha_j - 1) + N - 1 = S - 1$. The remaining λ-integral is a single Schwinger integral, $\int_0^\infty \mathrm{d}\lambda \, \lambda^{S-1} e^{-\lambda U} = \Gamma(S)/U^S$ by (D.20), valid because $\mathrm{Re}\, U > 0$ on the simplex when the convex hull of the A_j excludes the origin. Substituting gives (D.25). The interchange of the λ- and x-integrations is justified by absolute convergence: with all $\mathrm{Re}\, A_j$ of one sign the double integral converges absolutely, and Fubini's theorem applies. In the Lorentzian application the same conclusion holds with $A_j \to -i(X_j + i\varepsilon)$, for which $\mathrm{Re}\, A_j = \varepsilon > 0$. $\square$

Proof by induction on N. It is convenient to work with the simplex in solved form, eliminating $x_N = 1 - \sum_{j<N} x_j$ and integrating the free parameters over $\Delta_{N-1} = \{x_1, \dots, x_{N-1} \geq 0,\ \sum_{j<N} x_j \leq 1\}$. Statement (D.25) is then

$$\frac{1}{\prod_{j=1}^{N} A_j^{\alpha_j}} = \frac{\Gamma(S)}{\prod_{j=1}^{N}\Gamma(\alpha_j)} \int_{\Delta_{N-1}} \mathrm{d}^{N-1}x \, \Big(\prod_{j=1}^{N} x_j^{\alpha_j - 1}\Big)\, U^{-S}, \qquad U = \sum_{j=1}^{N} x_j A_j. \tag{D.27}$$

The base case $N = 2$ is the general two-denominator identity, which we obtain at once from the $N = 2$ instance of the Schwinger derivation above (or, for $\alpha_1 = \alpha_2 = 1$, from Theorem D.8); explicitly, with $x_1 = x$, $x_2 = 1 - x$,

$$\frac{1}{A_1^{\alpha_1} A_2^{\alpha_2}} = \frac{\Gamma(\alpha_1 + \alpha_2)}{\Gamma(\alpha_1)\Gamma(\alpha_2)} \int_0^1 \mathrm{d}x \, \frac{x^{\alpha_1 - 1}(1-x)^{\alpha_2 - 1}}{\big[xA_1 + (1-x)A_2\big]^{\alpha_1 + \alpha_2}}. \tag{D.28}$$

Assume (D.27) holds for N denominators. For $N + 1$ denominators, apply the inductive hypothesis to the first N factors,

$$\frac{1}{\prod_{j=1}^{N} A_j^{\alpha_j}} = \frac{\Gamma(S)}{\prod_{j=1}^{N}\Gamma(\alpha_j)} \int_{\Delta_{N-1}} \mathrm{d}^{N-1}x \, \Big(\prod_{j=1}^{N} x_j^{\alpha_j - 1}\Big) U^{-S}, \qquad S = \sum_{j=1}^{N} \alpha_j, \tag{D.29}$$

multiply by $A_{N+1}^{-\alpha_{N+1}}$, and merge the single denominator U^{-S} with $A_{N+1}^{-\alpha_{N+1}}$ using the two-denominator formula (D.28):

$$U^{-S} A_{N+1}^{-\alpha_{N+1}} = \frac{\Gamma(S')}{\Gamma(S)\Gamma(\alpha_{N+1})} \int_0^1 \mathrm{d}t \, t^{\,S-1}(1-t)^{\alpha_{N+1} - 1} \big[tU + (1-t)A_{N+1}\big]^{-S'}, \tag{D.30}$$

where $S' = S + \alpha_{N+1} = \sum_{j=1}^{N+1} \alpha_j$. The two $\Gamma(S)$ factors cancel and $\prod_{j=1}^{N}\Gamma(\alpha_j) \cdot \Gamma(\alpha_{N+1}) = \prod_{j=1}^{N+1}\Gamma(\alpha_j)$, so

$$\frac{1}{\prod_{j=1}^{N+1} A_j^{\alpha_j}} = \frac{\Gamma(S')}{\prod_{j=1}^{N+1}\Gamma(\alpha_j)} \int_{\Delta_{N-1}} \mathrm{d}^{N-1}x \int_0^1 \mathrm{d}t \, \Big(\prod_{j=1}^{N} x_j^{\alpha_j - 1}\Big) t^{\,S-1}(1-t)^{\alpha_{N+1} - 1} \big[tU + (1-t)A_{N+1}\big]^{-S'}. \tag{D.31}$$

It remains to recognize the right-hand side as the $(N+1)$-denominator simplex integral. Introduce new parameters

$$u_j = t\, x_j \quad (j = 1, \dots, N), \qquad u_{N+1} = 1 - t, \tag{D.32}$$

a bijection from $\Delta_{N-1} \times (0,1)$ onto the N-simplex $\Delta_N = \{u_j \geq 0,\ \sum_{j=1}^{N+1} u_j = 1\}$. Three things must be checked: the combined denominator, the parameter weights, and the measure. *Denominator.* On the simplex $\sum_{j=1}^{N} x_j = 1$, so

$$tU + (1-t)A_{N+1} = \sum_{j=1}^{N} (t x_j) A_j + (1-t)A_{N+1} = \sum_{j=1}^{N+1} u_j A_j \equiv U', \tag{D.33}$$

and $\sum_{j=1}^{N+1} u_j = t\sum_{j=1}^{N} x_j + (1-t) = t + (1-t) = 1$, confirming $u \in \Delta_N$. *Measure.* Take $(x_1, \dots, x_{N-1}, t)$ as the N independent old variables (with $x_N = 1 - \sum_{j<N} x_j$) and $(u_1, \dots, u_N)$ as the N independent new variables (with $u_{N+1} = 1 - \sum_{j\le N} u_j$). From (D.32), $\partial u_j/\partial x_k = t\,\delta_{jk}$ and $\partial u_j/\partial t = x_j$ for $j,k \le N-1$, while $u_N = t\,x_N = t(1 - \sum_{k<N} x_k)$ gives $\partial u_N/\partial x_k = -t$ and $\partial u_N/\partial t = x_N$. Adding rows $1, \dots, N-1$ to row N clears its first $N-1$ entries and leaves $\sum_{j=1}^{N} x_j = 1$ in the last column, so the Jacobian determinant is the product of the diagonal t's,

$$\left|\frac{\partial(u_1,\dots,u_N)}{\partial(x_1,\dots,x_{N-1},t)}\right| = t^{\,N-1}, \qquad \Longrightarrow \qquad \mathrm{d}^{N-1}x\,\mathrm{d}t = t^{-(N-1)}\,\mathrm{d}^{N}u. \tag{D.34}$$

Weights. Using $x_j = u_j/t$ and $\sum_{j=1}^{N}(\alpha_j - 1) = S - N$,

$$\Big(\prod_{j=1}^{N} x_j^{\alpha_j-1}\Big) t^{\,S-1}(1-t)^{\alpha_{N+1}-1} = t^{-(S-N)}\Big(\prod_{j=1}^{N} u_j^{\alpha_j-1}\Big) t^{\,S-1} u_{N+1}^{\alpha_{N+1}-1} = t^{\,N-1}\prod_{j=1}^{N+1} u_j^{\alpha_j-1}. \tag{D.35}$$

The weight thus carries an overall t^{N-1} that cancels precisely against the $t^{-(N-1)}$ in the measure (D.34). Substituting all three into (D.31),

$$\frac{1}{\prod_{j=1}^{N+1} A_j^{\alpha_j}} = \frac{\Gamma(S')}{\prod_{j=1}^{N+1}\Gamma(\alpha_j)} \int_{\Delta_N} \mathrm{d}^{N}u\,\Big(\prod_{j=1}^{N+1} u_j^{\alpha_j-1}\Big) U'^{-S'}, \tag{D.36}$$

which is (D.27) with $N+1$ in place of N. By induction the formula holds for all $N \ge 2$. □

The two derivations illuminate the same object from opposite sides. The Schwinger route shows that the Feynman parameters are normalized proper times $x_j = s_j/\lambda$ and that the simplex constraint $\sum_j x_j = 1$ is nothing but the bookkeeping of total proper time; the inductive route shows that the Γ-function prefactor is assembled one denominator at a time, each merge contributing the recursion $\Gamma(S)\Gamma(\alpha_{N+1}) \to \Gamma(S')$ that telescopes into the single $\Gamma(S)$ on the front of (D.25).

D.2.4 The simplex and its volume

The domain of integration in (D.25) deserves a moment, because its measure recurs in every loop computation and its symmetry is what allows a numerator linear in the loop momentum to be discarded. The standard $(N-1)$-simplex $\Delta_{N-1} = \{x_j \ge 0,\ \sum_j x_j = 1\}$ is the convex hull of the N unit vectors; Fig. D.3 shows the $N = 2$ (a segment) and $N = 3$ (a triangle) cases.

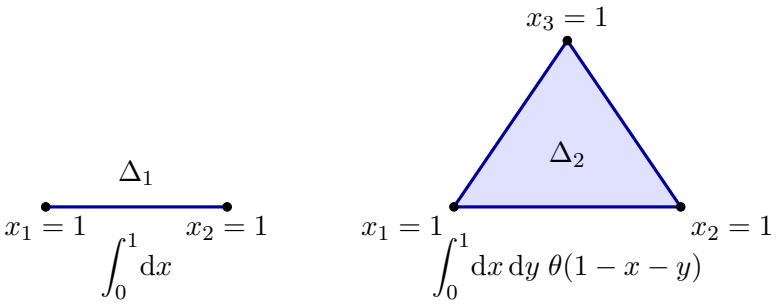

Figure D.3: The Feynman-parameter simplices for two and three denominators. For N denominators the parameters $(x_1, \dots, x_N)$, all nonnegative and summing to one, range over the $(N-1)$-simplex Δ_{N-1}, whose Euclidean volume in the solved coordinates is $1/(N-1)!$. The vertices are the configurations in which a single denominator dominates.

Proposition D.12 (Volume of the simplex)**.** *In the solved coordinates* $(x_1, \dots, x_{N-1})$ *with* $x_N = 1 - \sum_{j<N} x_j$,

$$\int_{\Delta_{N-1}} \mathrm{d}^{N-1}x \;=\; \int_0^1 \mathrm{d}x_1 \int_0^{1-x_1} \mathrm{d}x_2 \cdots \int_0^{1-x_1-\cdots-x_{N-2}} \mathrm{d}x_{N-1} \;=\; \frac{1}{(N-1)!}. \tag{D.37}$$

Proof. Set all $\alpha_j = 1$ and all $A_j = 1$ in the master formula (D.27). The left-hand side is 1, and $U = \sum_j x_j = 1$ on the simplex, so the right-hand side is $\Gamma(N) \int_{\Delta_{N-1}} \mathrm{d}^{N-1}x$. Hence $\int_{\Delta_{N-1}} \mathrm{d}^{N-1}x = 1/\Gamma(N) = 1/(N-1)!$. Equivalently, by direct iterated integration: let $V_k(a)$ denote the volume of the scaled simplex $\{x_j \geq 0,\ \sum_{j=1}^{k} x_j \leq a\}$. Then $V_1(a) = a$ and $V_k(a) = \int_0^a V_{k-1}(a - x_1)\,\mathrm{d}x_1 = \int_0^a (a-x_1)^{k-1}/(k-1)!\,\mathrm{d}x_1 = a^k/k!$, so by induction $V_k(a) = a^k/k!$. Taking $a = 1$, $k = N-1$ gives (D.37). □

A symmetry of the simplex measure will be used repeatedly. The domain Δ_{N-1} and the unit-power weight are invariant under permutations of the parameters, and after the loop momentum is shifted (next subsection) the integrand depends on ℓ only through the rotationally invariant ℓ^2. Consequently any factor of the shifted loop momentum that appears to an *odd* power in the numerator integrates to zero,

$$\int \frac{\mathrm{d}^d\ell}{(2\pi)^d}\, \frac{\ell^\mu}{(\ell^2 - \Delta + i\varepsilon)^n} = 0, \tag{D.38}$$

because the integrand is odd under $\ell \to -\ell$, a symmetry of the (dimensionally continued) measure and of the denominator; the integral, being absolutely convergent in the strip of Theorem D.6 and Lorentz-covariant, can only equal a vector built from the available data, and after the shift there is no external vector

left inside, so it must vanish. The same parity argument promotes a numerator $\ell^\mu \ell^\nu$ to its isotropic average $\ell^2 \eta^{\mu\nu}/d$, the rule that drives the tensor reduction of a later section. For the present section the relevant statement is the simplest one: (D.38) lets us drop the linear-in-ℓ remainder produced by completing the square.

D.2.5 Completing the square: the canonical form and Δ

We now apply the machinery to the one-loop master (D.3). After Feynman parametrization the N denominators have become a single factor U^{-N} (for unit powers) with $U = \sum_j x_j (q_j^2 - m_j^2 + i\varepsilon)$, and the loop momentum enters only through U. Route the momenta as $q_j = \ell + r_j$, where ℓ is the loop momentum and r_j is the partial sum of external momenta flowing through line j (so r_j is independent of ℓ). Then, using $\sum_j x_j = 1$,

$$\begin{aligned} U &= \sum_j x_j [(\ell + r_j)^2 - m_j^2] + i\varepsilon = \ell^2 + 2\ell \cdot \Big(\sum_j x_j r_j\Big) + \sum_j x_j r_j^2 - \sum_j x_j m_j^2 + i\varepsilon \\ &= \ell^2 + 2\ell \cdot R + \sum_j x_j r_j^2 - \sum_j x_j m_j^2 + i\varepsilon, \qquad R \equiv \sum_j x_j r_j. \end{aligned} \tag{D.39}$$

The first two terms are completed into a perfect square by the translation $\ell \to \ell - R$, i.e. defining the new loop variable $k = \ell + R$ so that $\ell^2 + 2\ell \cdot R = k^2 - R^2$. The combined denominator becomes

$$U = k^2 - \Delta + i\varepsilon, \qquad \boxed{\Delta \;=\; R^2 - \sum_j x_j r_j^2 + \sum_j x_j m_j^2 \;=\; \sum_j x_j m_j^2 - \tfrac{1}{2} \sum_{i,j} x_i x_j (r_i - r_j)^2} \tag{D.40}$$

where the second form follows from the algebraic identity $\sum_j x_j r_j^2 - \big(\sum_j x_j r_j\big)^2 = \frac{1}{2} \sum_{i,j} x_i x_j (r_i - r_j)^2$ valid when $\sum_j x_j = 1$ (expand the right side: $\frac{1}{2} \sum_{i,j} x_i x_j (r_i^2 + r_j^2 - 2 r_i \cdot r_j) = \sum_i x_i r_i^2 \sum_j x_j - \sum_{i,j} x_i x_j r_i \cdot r_j$, and the leftover factor $\sum_j x_j = 1$). The differences $r_i - r_j$ are sums of external momenta, so Δ depends only on the external invariants, the masses, and the Feynman parameters — exactly the segregation we sought. The $i\varepsilon$ rides along unchanged: Δ is real, and the prescription is equivalent to $\Delta \to \Delta - i\varepsilon$, so the denominator is $k^2 - \Delta + i\varepsilon$, which is what the Wick rotation of Section D.3 will act on.

Two points make this rigorous. First, the shift $\ell \to \ell - R$ must be a legitimate change of variables, which for a divergent integral is not automatic: shifting the variable of a linearly or quadratically divergent integral can generate a finite surface term. In dimensional regularization it is always legitimate, and the reason is the analytic continuation of Theorem D.6.

Proposition D.13 (Legitimacy of the loop-momentum shift)**.** *For the dimensionally regularized integral $I(d) = \int \mathrm{d}^d \ell \, f(\ell)$ defined by continuation from the strip $d_- < \operatorname{Re} d < d_+$ where it converges absolutely, and for any fixed R,*

$$\int \mathrm{d}^d \ell \; f(\ell + R) \;=\; \int \mathrm{d}^d \ell \; f(\ell). \tag{D.41}$$

Proof. For d in the convergence strip the integral is an ordinary absolutely convergent Lebesgue integral over $\mathbb{R}^d$ (after the Wick rotation that makes the measure Euclidean, carried out in Section D.3), and Lebesgue measure is translation invariant, so (D.41) holds there exactly, with no surface term — absolute convergence means the would-be boundary contributions at $|\ell| \to \infty$ vanish. Both sides of (D.41) are holomorphic functions of d on the strip (the integrand and its R-shift are holomorphic in d and dominated uniformly on compact d-subsets), and they agree there. By the identity theorem for analytic functions, their analytic continuations agree everywhere both are defined, in particular in a punctured neighbourhood of $d = 4$. Hence the shift is exact for the dimensionally regularized integral. This is the precise sense in which dimensional regularization "respects translations": it never produces the cutoff-dependent surface term $\propto \Lambda^{d-1}$ that a hard cutoff would, because such a term has no analytic continuation from the convergence strip — it is simply absent, consistent with the vanishing of scaleless integrals established in Section D.1.6. □

Second, with the shift legal, the numerator must be re-expressed in the new variable $k = \ell + R$, i.e. $\ell = k - R$. A numerator that was a polynomial in ℓ becomes a polynomial in k with R- and external-momentum-dependent coefficients; by the parity rule (D.38) every term odd in k integrates to zero, so only the even part survives. For the scalar bubble the numerator is unity and nothing further is needed; the tensor cases are handed to the reduction section, which uses exactly (D.38) and its $\ell^\mu \ell^\nu \to \ell^2 \eta^{\mu\nu}/d$ generalization.

The outcome of this subsection is the promised canonical form: every one-loop scalar integral, after Feynman parametrization and the shift, reads

$$\mu^{2\varepsilon} \int \frac{\mathrm{d}^d \ell}{(2\pi)^d} \frac{1}{\prod_j (q_j^2 - m_j^2 + i\varepsilon)} = \Gamma(N)\, \mu^{2\varepsilon} \int_{\Delta_{N-1}} \mathrm{d}^{N-1} x \int \frac{\mathrm{d}^d k}{(2\pi)^d} \frac{1}{(k^2 - \Delta + i\varepsilon)^N}, \tag{D.42}$$

with Δ given by (D.40). The inner momentum integral is now identical for every diagram — a single power of one quadratic form — and depends on the kinematics only through the number Δ. We now compute Δ for the benchmark theories.

ϕ^4 theory: the bubble. The scalar bubble B_0 of (D.12) has $N = 2$ denominators with $q_1 = \ell$ ($r_1 = 0$), $q_2 = \ell + p$ ($r_2 = p$), and equal masses $m_1 = m_2 = m$. With Feynman parameter x on the second line and $1 - x$ on the first, $R = xp$, and (D.40) gives $\sum_j x_j m_j^2 = m^2$ and $\frac{1}{2} \sum_{i,j} x_i x_j (r_i - r_j)^2 = x(1-x)\, p^2$, so

$$\boxed{\Delta_{\phi^4} = m^2 - x(1-x)\, p^2 = m^2 - x(1-x)\, s} \qquad (s = p^2). \tag{D.43}$$

This is the Δ that Chapter 24 uses to extract the ϕ^4 beta function. Its physics is already visible in the formula: for spacelike $s < 0$, $\Delta > 0$ and the rotated

denominator $k_E^2 + \Delta$ is strictly positive; for timelike $s > 4m^2$ (above the two-particle threshold) Δ turns negative on part of the x-range, the $i\varepsilon$ becomes essential, and the integral develops the imaginary part demanded by unitarity — the branch cut whose discontinuity is the subject of the optical-theorem analysis downstream.

QED: vacuum polarization. The vacuum polarization (D.13) has, after the Dirac trace of Section C.7.3 is taken in the numerator, the same two-denominator structure as the bubble: $q_1 = \ell$ ($r_1 = 0$), $q_2 = \ell + q$ ($r_2 = q$), masses $m_1 = m_2 = m$. Hence

$$\boxed{\Delta_\Pi = m^2 - x(1-x)\,q^2} \tag{D.44}$$

identical in form to (D.43) with $s \to q^2$, as it must be since both are scalar bubbles of equal-mass lines; the difference between the two threads lives entirely in the numerators (a trivial 1 for ϕ^4, a Dirac trace for QED), not in Δ.

QED: the electron self-energy. The self-energy (D.14) combines a massless photon line, $A_\gamma = \ell^2 + i\varepsilon$ ($r_\gamma = 0$, $m_\gamma = 0$), with a massive fermion line, $A_e = (p-\ell)^2 - m^2 + i\varepsilon$. Writing the fermion momentum as $(\ell + r_e)^2$ with $r_e = -p$, and assigning Feynman parameter x to the photon and $1-x$ to the fermion, $R = (1-x)(-p) = -(1-x)p$. From (D.40), $\sum_j x_j m_j^2 = x\cdot 0 + (1-x)m^2 = (1-x)m^2$ and $\frac{1}{2}\sum_{i,j} x_i x_j (r_i - r_j)^2 = x(1-x)\,(0-(-p))^2 = x(1-x)\,p^2$, so

$$\boxed{\Delta_\Sigma = (1-x)\,m^2 - x(1-x)\,p^2} \tag{D.45}$$

This is the Δ consumed by the self-energy computation of Chapter 19. The masslessness of the photon shows itself in (D.45): at $x = 1$ (the photon carrying the full proper time) $\Delta_\Sigma = 0$, the vanishing that signals the infrared sensitivity flagged in Section D.1.3; a fictitious photon mass m_γ^2 would add $x\,m_\gamma^2$ and lift this zero, which is one standard way to regulate the infrared while the ultraviolet pole is handled by ε.

QED: the vertex. The vertex correction (D.15) is the first genuinely three-denominator case and exercises the $N = 3$ formula. The lines are the photon $A_\gamma = \ell^2 + i\varepsilon$ ($r_\gamma = 0$, $m_\gamma = 0$) and two fermion lines $(p'-\ell)^2 - m^2$ and $(p-\ell)^2 - m^2$, i.e. $r_1 = -p'$, $r_2 = -p$, both of mass m. Assign parameters x, y, z to the $(p'-\ell)$, $(p-\ell)$, and photon lines respectively, with $x + y + z = 1$. Then $\sum_j x_j m_j^2 = (x+y)m^2 = (1-z)m^2$, and the invariant piece is

$$\tfrac{1}{2}\sum_{i,j} x_i x_j (r_i - r_j)^2 = xy\,(p-p')^2 + xz\,p'^2 + yz\,p^2 = xy\,q^2 + z(1-z)\,m^2, \tag{D.46}$$

using $q = p' - p$, $q^2 = (p - p')^2$, and the on-shell conditions $p^2 = p'^2 = m^2$ for the external electron (so $xz\,p'^2 + yz\,p^2 = z(x+y)m^2 = z(1-z)m^2$). Therefore

$$\boxed{\Delta_\Gamma = (1-z)\,m^2 - \left[xy\,q^2 + z(1-z)m^2\right] = (1-z)^2\,m^2 - xy\,q^2} \tag{D.47}$$

a function on the triangle $\Delta_2 = \{x, y, z \geq 0,\ x+y+z = 1\}$, with the loop integral now of the form $\Gamma(3)\int \mathrm{d}x\,\mathrm{d}y\,\mathrm{d}z\,\delta(1-x-y-z)\int \mathrm{d}^d k\,(k^2 - \Delta_\Gamma + i\varepsilon)^{-3}$. This is exactly the integrand the anomalous-magnetic-moment and charge-renormalization computations of Chapters 19 and 20 take as their starting point; the $g-2$ value $a_e = \alpha/2\pi$ falls out of integrating the numerator structure over this same triangle.

Yang–Mills theory. As recorded in (D.16), every Yang–Mills one-loop integrand is, after the colour algebra of Chapter B is factored off, one of the abelian scalar integrals above multiplied by a colour constant (C_A, $T_F n_f$, or C_F). The denominator combinations are identical to the QED ones — a gluon or ghost loop on the external gluon line produces the massless bubble with $\Delta = -x(1-x)q^2$, a quark loop the massive bubble (D.44), and the three-point functions the triangle of (D.47) — so no new Δ need be computed; the same parametrization serves all three benchmark theories, which is precisely why Chapter 27 can assemble the beta-function coefficient $b_0 = \frac{11}{3}C_A - \frac{4}{3}T_F n_f$ from the master integral this appendix evaluates once.

We close with the worked computation the section was built around, carrying the ϕ^4 s-channel bubble explicitly from the parametric identity to the canonical form, so that the next section can act on a single, fully reduced integral.

Worked Example D.14 (The ϕ^4 s-channel bubble, parametrized)**.** We continue ϕ^4 theory from (D.11), reducing the scalar bubble $B_0(p^2, m^2)$ of (D.12) to canonical form. Starting point:

$$B_0(p^2, m^2) = \mu^{2\varepsilon}\int \frac{\mathrm{d}^d \ell}{(2\pi)^d}\,\frac{1}{(\ell^2 - m^2 + i\varepsilon)\big((\ell+p)^2 - m^2 + i\varepsilon\big)}. \tag{D.48}$$

Step 1 — combine denominators. Apply Theorem D.8 with $A = (\ell+p)^2 - m^2 + i\varepsilon$ and $B = \ell^2 - m^2 + i\varepsilon$ (Feynman parameter x on A). Both denominators carry $+i\varepsilon$, so the hypothesis of Theorem D.8 holds and

$$\frac{1}{AB} = \int_0^1 \mathrm{d}x\,\frac{1}{\big[xA + (1-x)B\big]^2}, \qquad B_0 = \mu^{2\varepsilon}\int_0^1 \mathrm{d}x \int \frac{\mathrm{d}^d \ell}{(2\pi)^d}\,\frac{1}{[xA + (1-x)B]^2}. \tag{D.49}$$

Step 2 — expand the combined denominator. With the parameters summing to one,

$$\begin{aligned} xA + (1-x)B &= x\big[(\ell+p)^2 - m^2\big] + (1-x)\big[\ell^2 - m^2\big] + i\varepsilon \\ &= \ell^2 + 2x\,\ell\cdot p + x\,p^2 - m^2 + i\varepsilon. \end{aligned} \tag{D.50}$$

Step 3 — complete the square. Set $k = \ell + xp$ (so $\ell = k - xp$ and $R = xp$ in the notation of (D.39)). Then $\ell^2 + 2x\,\ell\cdot p = k^2 - x^2p^2$, and

$$xA+(1-x)B = k^2-x^2p^2+xp^2-m^2+i\varepsilon = k^2-\Delta+i\varepsilon, \qquad \Delta = m^2-x(1-x)p^2, \tag{D.51}$$

recovering (D.43) with $p^2 = s$. *Step 4 — shift the measure.* By Theorem D.13 the translation $\ell \to k$ leaves the dimensionally regularized measure invariant, $\int \mathrm{d}^d\ell = \int \mathrm{d}^d k$, with no surface term. The integrand has no numerator (the bubble is scalar), so nothing odd in k arises and (D.38) is not even needed. Collecting,

$$\boxed{B_0(p^2,m^2) = \mu^{2\varepsilon}\int_0^1 \mathrm{d}x \int \frac{\mathrm{d}^d k}{(2\pi)^d}\,\frac{1}{(k^2-\Delta+i\varepsilon)^2}, \qquad \Delta = m^2 - x(1-x)\,s.} \tag{D.52}$$

The product of denominators is gone; the loop momentum appears through the single quadratic form $k^2 - \Delta + i\varepsilon$, and the entire s- and m^2-dependence has been pushed into Δ and the trivial x-integral. The remaining momentum integral, $\int \mathrm{d}^d k\,(k^2 - \Delta + i\varepsilon)^{-2}$, is one number for each Δ; evaluating it is the task handed to the next section.

With (D.42), and explicitly (D.52), the product of propagator denominators has been collapsed to a single factor $(\ell^2 - \Delta + i\varepsilon)^{-N}$ and the Schwinger twin $\propto \int_0^\infty \mathrm{d}s\, s^{N-1} e^{is(\ell^2-\Delta+i\varepsilon)}$, with Δ a known function of external invariants, masses, and Feynman parameters for each thread. The remaining loop integral is now a single, manifestly Lorentz-invariant momentum integral over one quadratic form — but a *Minkowski* one, with the indefinite metric still in the measure and the denominator still able to change sign. The next section removes that last obstruction: it rotates the contour to Euclidean signature, turning $k^2 - \Delta + i\varepsilon$ into the strictly positive $k_E^2 + \Delta$, and constructs the d-dimensional measure, reducing (D.42) to a one-dimensional radial integral ready for the Γ-function master formula.

D.3 Wick rotation and the measure in d dimensions

The previous section did the algebraic work of collapsing a product of propagator denominators into a single factor, completing the square in the loop momentum to expose the canonical form $(\ell^2 - \Delta + i\epsilon)^{-n}$, with ℓ the shifted (integration) momentum and Δ a real function of the external invariants, masses, and Feynman parameters (Section D.2). What remains is a genuine integral over ℓ, and here we hit the obstruction that motivates everything in this appendix: the canonical integrand is Lorentzian. Its denominator changes sign as ℓ crosses the light cone, it vanishes on a hypersurface, and the $d^d\ell$ measure carries the indefinite Minkowski metric, so the integral is at best conditionally convergent and not in a form any real-variable technique can attack. The cure is to rotate the integration contour

out of Minkowski signature into the Euclidean domain, where the denominator becomes a strictly positive $(\ell_E^2 + \Delta)$ and the measure is positive-definite. This section carries out that rotation rigorously for the canonical integrand, tracks the factor of i and the sign flip it produces, and then builds the d-dimensional Euclidean measure by analytic continuation, reducing the whole integral to a one-dimensional radial integral with all angular information packaged into a single number, the solid angle Ω_d. The result is an object the next section can evaluate in closed form.

Throughout we use the standing conventions of Chapter A: mostly-minus metric $\eta = \mathrm{diag}(+,-,-,-)$, the Feynman prescription $i/(p^2 - m^2 + i\epsilon)$, and the Wick rotation as fixed in Theorem A.23. The contour technology—Cauchy's theorem, the residue theorem, Jordan-type arc estimates, and the legality of the energy-plane rotation itself—was built in Chapter 5; we import it here rather than reprove it, specializing the general statement of Theorem 5.31 to the loop integrand at hand.

D.3.1 Pole positions and the legality of the rotation

The rotation is, at bottom, a statement about a single complex variable: the energy component ℓ^0 of the loop momentum, with the spatial components $\boldsymbol{\ell}$ held fixed and real. We therefore begin by locating the singularities of the integrand in the complex ℓ^0 plane.

Write the canonical denominator in terms of its energy and spatial parts. With $\ell^2 = (\ell^0)^2 - \boldsymbol{\ell}^2$ in mostly-minus signature,

$$\ell^2 - \Delta + i\epsilon = (\ell^0)^2 - (\boldsymbol{\ell}^2 + \Delta) + i\epsilon. \tag{D.53}$$

The zeros of this quadratic in ℓ^0 are the poles of $(\ell^2 - \Delta + i\epsilon)^{-n}$, each of order n.

Proposition D.15 (Pole positions of the canonical integrand)**.** *Fix $\boldsymbol{\ell} \in \mathbb{R}^{d-1}$ and $\Delta \in \mathbb{R}$, and set $a \equiv \boldsymbol{\ell}^2 + \Delta$. For $\epsilon > 0$ the denominator (D.53) has exactly two zeros in the complex ℓ^0 plane,*

$$\ell^0_{\pm} = \pm\sqrt{a - i\epsilon}\,, \tag{D.54}$$

each a pole of order n of $(\ell^2 - \Delta + i\epsilon)^{-n}$. With the principal branch of the square root, ℓ^0_+ lies in the closed fourth quadrant ($\mathrm{Re}\,\ell^0_+ \geq 0$, $\mathrm{Im}\,\ell^0_+ \leq 0$) and ℓ^0_- in the closed second quadrant. In particular both poles avoid the open first and third quadrants for every value of $\boldsymbol{\ell}$ and every sign of Δ.

Proof. Setting (D.53) to zero gives $(\ell^0)^2 = a - i\epsilon$, whose two roots are (D.54). Write $a - i\epsilon = \rho\, e^{i\varphi}$ with $\rho > 0$. Because the imaginary part $-\epsilon$ is negative and the real part is a, the argument lies in $\varphi \in (-\pi, 0)$ for every real a: if $a > 0$ then $\varphi \in (-\frac{\pi}{2}, 0)$, if $a = 0$ then $\varphi = -\frac{\pi}{2}$, and if $a < 0$ then $\varphi \in (-\pi, -\frac{\pi}{2})$. The

principal square root $\sqrt{a-i\epsilon} = \sqrt{\rho}\, e^{i\varphi/2}$ then has argument $\varphi/2 \in (-\frac{\pi}{2}, 0)$, i.e. nonnegative real part and nonpositive imaginary part: ℓ^0_+ sits in the (closed) fourth quadrant. Its partner $\ell^0_- = -\ell^0_+$ is the reflection through the origin and sits in the second quadrant. Neither root can enter the open first or third quadrant, which is exactly the region the rotation will sweep. □

Remark D.16 (The $i\epsilon$ chooses the rotation sense). The placement in Theorem D.15 is the loop-integral image of the Feynman pole pattern fixed in Eq. (A.84): for the physical case $a > 0$ the poles sit just below the positive real axis and just above the negative real axis, precisely where a free propagator's poles $\pm(\omega_{\boldsymbol{p}} - i\delta)$ sit. It is the sign of the Feynman $i\epsilon$ that pushes the poles into quadrants II and IV and so leaves quadrants I and III clear; had we chosen the retarded or advanced prescription the clear quadrants would differ and the rotation below would run the other way. The $i\epsilon$ is thus not cosmetic: it selects the direction $\ell^0 \to i\ell^0_E$ (counterclockwise, through the empty first and third quadrants) as the legal one.

With the poles located we can state and prove the rotation for the canonical integrand. We treat the inner ℓ^0 integration as a contour integral in one complex variable; the outer spatial integrations are untouched because the rotation does not move $\boldsymbol{\ell}$, and we return to them when we build the measure in Section D.3.2.

Proposition D.17 (Wick rotation of the canonical integrand)**.** *Let $n \geq 1$ be an integer (or, by analytic continuation, $\operatorname{Re} n > \frac{1}{2}$), let $\Delta \in \mathbb{R}$, and fix $\boldsymbol{\ell} \in \mathbb{R}^{d-1}$. Then the energy integral may be rotated from the real to the imaginary ℓ^0 axis,*

$$\int_{-\infty}^{\infty} \frac{d\ell^0}{\left[(\ell^0)^2 - (\boldsymbol{\ell}^2 + \Delta) + i\epsilon\right]^n} = i \int_{-\infty}^{\infty} \frac{d\ell^0_E}{(-1)^n \left[(\ell^0_E)^2 + \boldsymbol{\ell}^2 + \Delta\right]^n}, \tag{D.55}$$

under the substitution $\ell^0 = i\,\ell^0_E$ with $\ell^0_E \in \mathbb{R}$. Carrying this through the full d-dimensional measure and writing $\ell_E = (\ell^0_E, \boldsymbol{\ell})$ with Euclidean square $\ell^2_E = (\ell^0_E)^2 + \boldsymbol{\ell}^2 \geq 0$ yields the dictionary

$$d^d\ell = i\, d^d\ell_E, \qquad \ell^2 = -\,\ell^2_E, \qquad \ell^2 - \Delta + i\epsilon \;\longrightarrow\; -(\ell^2_E + \Delta), \tag{D.56}$$

and therefore the master rotation formula

$$\int \frac{d^d\ell}{(2\pi)^d} \frac{1}{(\ell^2 - \Delta + i\epsilon)^n} = i\,(-1)^n \int \frac{d^d\ell_E}{(2\pi)^d} \frac{1}{(\ell^2_E + \Delta)^n}. \tag{D.57}$$

Proof. Abbreviate $g(\ell^0) = \left[(\ell^0)^2 - a + i\epsilon\right]^{-n}$ with $a = \boldsymbol{\ell}^2 + \Delta$ fixed real. By Theorem D.15 the only singularities of g lie in the open second and fourth quadrants. Consider the closed, positively oriented contour Γ_R in the first quadrant built from three pieces: the segment C_1 along the positive real axis from 0 to R; the quarter-arc C_2, $\ell^0 = Re^{i\theta}$ with $\theta : 0 \to \frac{\pi}{2}$; and the segment

C_3 down the positive imaginary axis from iR back to 0. The interior of Γ_R is contained in the open first quadrant, which holds no poles, so Cauchy's theorem (Theorem 5.23) gives

$$\int_{C_1} g\, d\ell^0 + \int_{C_2} g\, d\ell^0 + \int_{C_3} g\, d\ell^0 = 0. \tag{D.58}$$

On the arc we estimate g by its modulus. For $|\ell^0| = R$ large, $|(\ell^0)^2 - a + i\epsilon| \geq R^2 - |a| - \epsilon \geq \frac{1}{2}R^2$ once $R^2 \geq 2(|a| + \epsilon)$, so $|g(\ell^0)| \leq (\frac{1}{2}R^2)^{-n} = 2^n R^{-2n}$. The arc has length $\frac{\pi}{2}R$, and the ML estimate gives

$$\left| \int_{C_2} g\, d\ell^0 \right| \leq \frac{\pi}{2} R \cdot 2^n R^{-2n} = 2^{n-1}\pi\, R^{1-2n} \xrightarrow[R\to\infty]{} 0 \qquad (n \geq 1), \tag{D.59}$$

since $1 - 2n \leq -1 < 0$. This is the specialization of the decay hypothesis of Theorem 5.31 to the present integrand, with $\eta = 2n - 1 > 0$; for noninteger n the same bound holds whenever $\mathrm{Re}(2n) > 1$. Thus the arc contribution vanishes, and (D.58) collapses to $\int_{C_1} g = -\int_{C_3} g = \int_{C_3^{\mathrm{rev}}} g$, i.e. the integral up the positive real axis equals the integral up the positive imaginary axis. Repeating the argument verbatim in the third quadrant with the mirror contour (real axis from $-R$ to 0, arc $\theta : \pi \to \frac{3\pi}{2}$, imaginary axis from 0 to $-iR$) handles the negative half. Concatenating the two halves rotates the entire real-axis integration onto the entire imaginary axis:

$$\int_{-\infty}^{\infty} g(\ell^0)\, d\ell^0 = \int_{-i\infty}^{i\infty} g(\ell^0)\, d\ell^0. \tag{D.60}$$

Now parametrize the imaginary axis by $\ell^0 = i\ell_E^0$ with $\ell_E^0 \in \mathbb{R}$ running from $-\infty$ to $+\infty$ (the orientation matches: $\ell^0 = -i\infty$ at $\ell_E^0 = -\infty$ up to $\ell^0 = +i\infty$ at $\ell_E^0 = +\infty$). Then $d\ell^0 = i\, d\ell_E^0$ and $(\ell^0)^2 = -(\ell_E^0)^2$, so $(\ell^0)^2 - a + i\epsilon = -\big[(\ell_E^0)^2 + a\big]$ with the regulator now redundant because the bracket is strictly positive. Hence

$$\int_{-\infty}^{\infty} g(\ell^0)\, d\ell^0 = i \int_{-\infty}^{\infty} \frac{d\ell_E^0}{\big(-\big[(\ell_E^0)^2 + a\big]\big)^n} = i\,(-1)^{-n} \int_{-\infty}^{\infty} \frac{d\ell_E^0}{\big[(\ell_E^0)^2 + \boldsymbol{\ell}^2 + \Delta\big]^n}, \tag{D.61}$$

which is (D.55) once one notes $(-1)^{-n} = (-1)^n$ for integer n. The single factor of i comes from $d\ell^0 = i\, d\ell_E^0$ on the one rotated coordinate; the $(d-1)$ spatial integrations are identical on the two sides because $\boldsymbol{\ell}$ never moved. Collecting the spatial measure with the rotated energy measure gives $d^d\ell = i\, d^d\ell_E$ and the relations (D.56); restoring the $(2\pi)^{-d}$ and performing the unchanged spatial integral on both sides produces (D.57). □

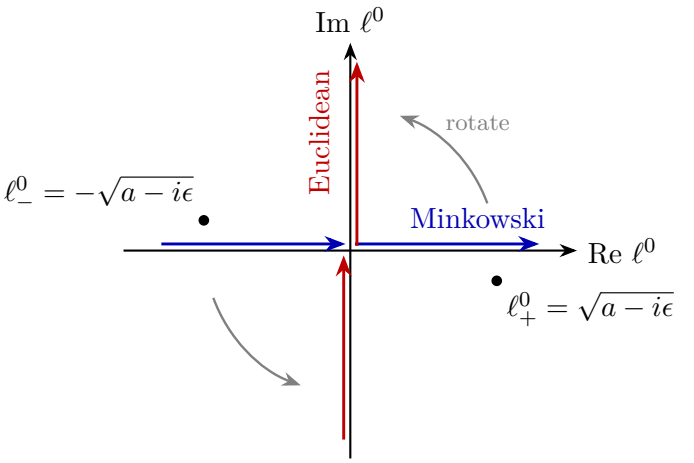

Figure D.4: Wick rotation of the energy contour for the canonical loop integrand. The Feynman $i\epsilon$ places the order-n poles $\ell^0_\pm$ in the second and fourth quadrants (Theorem D.15). The real-axis Minkowski contour (blue) is rotated counterclockwise, through the pole-free first and third quadrants, onto the imaginary-axis Euclidean contour (red). The quarter-arcs at infinity contribute nothing because the integrand falls as $|\ell^0|^{-2n}$ while the arc length grows only as R (Eq. (D.59)).

Caution

The factor of i and the sign flip are both physical. Two distinct relics of the rotation appear in (D.57), and both must be carried. The overall i comes from the single rotated coordinate $d\ell^0 = i\, d\ell^0_E$ and is *always* present; it is what turns the Minkowski amplitude's $i\mathcal{M}$ bookkeeping into real Euclidean integrals and, ultimately, what supplies the i in front of every one-loop self-energy and vertex. The sign $(-1)^n$ comes from $\ell^2 - \Delta \to -(\ell_E^2 + \Delta)$ raised to the power n and depends on the power of the denominator: it is $+1$ for the even powers $n = 2$ typical of bubbles and -1 for $n = 1, 3, \ldots$. Dropping either is a sign error of the most common kind (Section A.4); a reliable rule of thumb is to write (D.57) with both factors explicit before inserting numbers.

Figure D.4 summarizes the geometry: the blue real-axis contour swings through the empty quadrants onto the red imaginary axis, picking up the factor of i from the 90° turn and never crossing a pole.

D.3.2 The solid angle and the radial measure in d dimensions

Equation (D.57) has delivered a Euclidean integral over $\mathbb{R}^d$ (analytically continued in d) of a function that depends on ℓ_E only through the rotationally invariant

combination ℓ_E^2. Any such integral begs to be done in spherical coordinates, with the angular part performed once and for all. The angular part is the surface area of the unit $(d-1)$-sphere—the solid angle Ω_d—and the radial part is a single integral over $\ell_E \equiv |\ell_E| \in [0,\infty)$. The subtlety is that d is not an integer: the regulator has continued us to $d = 4 - 2\varepsilon$, where "the surface of a sphere" has no naive geometric meaning. We therefore *define* Ω_d by the one identity that makes sense for all d and reduces to the familiar areas at integer d, namely the Gaussian normalization.

Proposition D.18 (The d-dimensional solid angle)**.** *For* $\operatorname{Re} d > 0$ *define the solid angle* Ω_d *as the constant relating the Cartesian and radial Gaussian integrals,*

$$\int d^d x\, e^{-x^2} \;=\; \Omega_d \int_0^\infty dr\, r^{d-1} e^{-r^2}, \qquad x \in \mathbb{R}^d, \quad r = |x|. \tag{D.62}$$

Evaluating both sides yields the closed form

$$\boxed{\Omega_d = \frac{2\pi^{d/2}}{\Gamma(d/2)}}, \tag{D.63}$$

where Γ *is the Euler gamma function. The right-hand side is meromorphic in* d *and provides the* definition *of* Ω_d *at noninteger (in particular complex)* d*.*

Proof. Compute the left-hand side of (D.62) for positive integer d by factorizing the Cartesian Gaussian, then identify the answer with the radial form; the resulting algebraic identity (D.63) then *defines* Ω_d elsewhere by analytic continuation in d, the gamma function being the unique continuation respecting the functional equation. For integer d the measure factorizes, $d^d x = \prod_{j=1}^d dx_j$ and $x^2 = \sum_j x_j^2$, so the integral is a product of d identical one-dimensional Gaussians:

$$\int d^d x\, e^{-x^2} = \prod_{j=1}^{d} \int_{-\infty}^{\infty} dx_j\, e^{-x_j^2} = \left(\sqrt{\pi}\right)^d = \pi^{d/2}, \tag{D.64}$$

using the standard value $\int_{-\infty}^{\infty} e^{-u^2}\, du = \sqrt{\pi}$. For the radial side, substitute $t = r^2$, $dt = 2r\, dr$, so that $r^{d-1} dr = \tfrac{1}{2}\, t^{(d-1)/2}\, t^{-1/2}\, dt = \tfrac{1}{2}\, t^{d/2-1}\, dt$, and recognize the gamma function in its integral representation $\Gamma(z) = \int_0^\infty t^{z-1} e^{-t}\, dt$:

$$\int_0^\infty dr\, r^{d-1} e^{-r^2} = \frac{1}{2} \int_0^\infty dt\, t^{d/2-1} e^{-t} = \frac{1}{2}\, \Gamma\!\left(\frac{d}{2}\right). \tag{D.65}$$

Inserting (D.64) and (D.65) into the defining relation (D.62) gives $\pi^{d/2} = \Omega_d \cdot \frac{1}{2}\Gamma(d/2)$, hence (D.63). Both $\pi^{d/2}$ and $\Gamma(d/2)$ are entire/meromorphic in d, so the right-hand side of (D.63) continues the geometric quantity to all d where $\Gamma(d/2)$ is finite and nonzero; this is what we mean by Ω_d in dimensional regularization. □

Worked Example D.19 (The formula reproduces the elementary areas)**.** The continued Ω_d must agree with school geometry at small integer d, and it does. Using $\Gamma(1)=1$, $\Gamma(\tfrac12)=\sqrt{\pi}$, $\Gamma(\tfrac32)=\tfrac12\sqrt{\pi}$, and $\Gamma(2)=1$:

$$\begin{aligned}
\Omega_1 &= \frac{2\pi^{1/2}}{\Gamma(1/2)} = \frac{2\sqrt{\pi}}{\sqrt{\pi}} = 2, && \text{the two points } \{\pm1\} \text{ bounding } [-1,1];\\
\Omega_2 &= \frac{2\pi^{1}}{\Gamma(1)} = 2\pi, && \text{the circumference of the unit circle;}\\
\Omega_3 &= \frac{2\pi^{3/2}}{\Gamma(3/2)} = \frac{2\pi^{3/2}}{\frac12\sqrt{\pi}} = 4\pi, && \text{the area of the unit sphere;}\\
\Omega_4 &= \frac{2\pi^{2}}{\Gamma(2)} = 2\pi^2, && \text{the volume of the unit 3-sphere.}
\end{aligned} \tag{D.66}$$

At the physical value $d=4-2\varepsilon$ one has, expanding to the order needed in Section D.4, $\Omega_{4-2\varepsilon}=2\pi^{2-\varepsilon}/\Gamma(2-\varepsilon)$, which tends to $2\pi^2$ as $\varepsilon\to0$; the ε-dependence here is finite and will be combined with the genuinely divergent Γ from the radial integral in the next section. The point of (D.63) is precisely that it is an analytic function of d we can Taylor-expand, not a sequence of integer areas.

With Ω_d in hand the angular integration of any radially symmetric integrand is immediate.

Proposition D.20 (Reduction to a radial integral)**.** *Let $f\colon[0,\infty)\to\mathbb{C}$ be such that the integral below converges. Then*

$$\int d^d\ell_E\, f(\ell_E^2) = \Omega_d \int_0^\infty d\ell_E\, \ell_E^{d-1}\, f(\ell_E^2), \qquad \ell_E \equiv |\ell_E|. \tag{D.67}$$

Proof. For integer d, introduce spherical coordinates in $\mathbb{R}^d$: a radius $\ell_E\in[0,\infty)$ and angles $\hat n$ on the unit sphere S^{d-1}, with measure $d^d\ell_E=\ell_E^{d-1}\,d\ell_E\,d\Omega(\hat n)$, where $d\Omega$ is the surface element of S^{d-1}. Because the integrand depends only on $\ell_E^2=\ell_E^2$ and not on $\hat n$, the angular integral factors off and contributes the total surface area $\int_{S^{d-1}}d\Omega=\Omega_d$ established in Theorem D.18, leaving (D.67). For noninteger d this identity is the *definition* of the left-hand side: the d-dimensional integral of a radial function is declared to be the analytic continuation in d of the right-hand side, whose ingredients Ω_d (via (D.63)) and the one-dimensional radial integral are individually well defined for complex d. This is consistent with Theorem D.18—both rest on the same Gaussian identity—and it is the operational meaning of "integrating in d dimensions" used throughout this appendix. □

Combining the rotation (D.57) with the reduction (D.67) applied to $f(\ell_E^2)=(\ell_E^2+\Delta)^{-n}$ packages the entire angular content of the canonical loop integral

into Ω_d:

$$\int \frac{d^d\ell}{(2\pi)^d}\,\frac{1}{(\ell^2-\Delta+i\epsilon)^n} = \frac{i\,(-1)^n\,\Omega_d}{(2\pi)^d}\int_0^\infty d\ell_E\,\frac{\ell_E^{d-1}}{(\ell_E^2+\Delta)^n}. \tag{D.68}$$

Everything to the right of $\Omega_d/(2\pi)^d$ is a single, manifestly convergent (for suitable d) one-dimensional integral. We have turned a d-dimensional Lorentzian integral into a radial Euclidean one, with the price of the conversion—one factor of i, the sign $(-1)^n$, and the angular volume Ω_d—all displayed explicitly.

D.3.3 Carrying the ϕ^4 bubble across the rotation

To see the abstract machinery act on a real amplitude, we follow the one-loop bubble of ϕ^4 theory (with coupling λ and mass m) through the rotation. This is the integral that the previous section reduced to canonical form, and the object Chapter 24 will turn into the one-loop beta function $\beta_\lambda = 3\lambda^2/16\pi^2$.

Worked Example D.21 (The ϕ^4 s-channel bubble, rotated)**.** The s-channel one-loop correction to $\phi\phi\to\phi\phi$ in $\lambda\phi^4$ theory carries the scalar integral

$$I(p^2) = \int \frac{d^d\ell}{(2\pi)^d}\,\frac{1}{(\ell^2-m^2+i\epsilon)\big((\ell+p)^2-m^2+i\epsilon\big)}, \tag{D.69}$$

with p the total incoming momentum, $p^2 = s$. Feynman-combining the two denominators (Theorem D.11) and shifting $\ell\to\ell - xp$ to complete the square brings (D.69) to the canonical form with $n=2$,

$$I(p^2) = \int_0^1 dx \int \frac{d^d\ell}{(2\pi)^d}\,\frac{1}{(\ell^2-\Delta+i\epsilon)^2}, \qquad \Delta = m^2 - x(1-x)\,p^2, \tag{D.70}$$

where the shifted ℓ is again called ℓ and Δ depends on the Feynman parameter x and the external invariant. (The shift is legitimate because the d-dimensional measure is translation invariant; for the divergent piece this is part of what dimensional regularization buys, as the next sections make precise.)

Rotating the inner integral. The inner ℓ-integral is exactly the canonical object with $n=2$. We apply (D.57). Here $(-1)^n = (-1)^2 = +1$, so the sign flip is invisible and the *only* relic of the rotation is the overall factor of i:

$$\int \frac{d^d\ell}{(2\pi)^d}\,\frac{1}{(\ell^2-\Delta+i\epsilon)^2} = i\int \frac{d^d\ell_E}{(2\pi)^d}\,\frac{1}{(\ell_E^2+\Delta)^2}. \tag{D.71}$$

The Lorentzian denominator that vanished on a hypersurface has become the strictly positive $(\ell_E^2+\Delta)^2$, with $\Delta>0$ for $s<4m^2$ (below threshold) so that the Euclidean integral is genuinely convergent away from $d=4$; for $s>4m^2$ the Δ turns negative over part of the x-range and the $i\epsilon$ supplies the imaginary

part that becomes the bubble's discontinuity, but the rotation formula (D.71) is unchanged because it was derived for any real Δ.

Angular reduction. Applying (D.67) to the rotated integrand collapses the angles into Ω_d:

$$I(p^2) = i \int_0^1 dx \, \frac{\Omega_d}{(2\pi)^d} \int_0^\infty d\ell_E \, \frac{\ell_E^{d-1}}{(\ell_E^2 + \Delta)^2}. \tag{D.72}$$

This is the bubble reduced to a Feynman-parameter integral over a one-dimensional radial integral, with the factor of i explicit out front—the same i that will ride through to the renormalized vertex and, ultimately, into the sign and normalization of β_λ in Chapter 24. The radial integral $\int_0^\infty d\ell_E \, \ell_E^{d-1}(\ell_E^2 + \Delta)^{-2}$ is the object the next section evaluates in closed form.

Physical Insight

Why the Euclidean side is the honest one. The rotation is more than a computational trick. In Euclidean signature the integrand is a positive function of a positive-definite variable, so the integral is a genuine (if still UV-sensitive) Lebesgue integral rather than a conditionally convergent oscillatory one; convergence questions become questions about the behavior of $\ell_E^{d-1}(\ell_E^2 + \Delta)^{-n}$ at $\ell_E \to 0$ (the infrared) and $\ell_E \to \infty$ (the ultraviolet), which the power of ℓ_E makes transparent. This is the first place one sees, geometrically, the dual role of d as a regulator of *both* ends: lowering d tames the large-ℓ_E (UV) growth, while raising d tames the small-ℓ_E (IR) behavior. The single analytic continuation in d that the next section performs therefore regulates UV and IR simultaneously—the thread that ties the rest of this appendix together.

Equation (D.68), and its ϕ^4 instance (D.72), hand the next section a purely radial Euclidean integral $\int_0^\infty d\ell_E \, \ell_E^{d-1}(\ell_E^2+\Delta)^{-n}$ with every angular factor already absorbed into $\Omega_d = 2\pi^{d/2}/\Gamma(d/2)$. With the substitution $t = \ell_E^2/(\ell_E^2 + \Delta)$ this radial integral is a Beta function, and evaluating it produces the master scalar one-loop integral in closed form—the task of Section D.4.

D.4 The master one-loop integral and its tensor descendants

The previous section left us at the threshold of an honest calculation. The Wick rotation of Section D.3 turned the Minkowski loop integral into a Euclidean one, and the construction of the d-dimensional measure factored its angular part into the solid angle Ω_d, leaving a single one-dimensional integral over the Euclidean radius. That radial integral is the last formal obstacle between us

and a number: once it is done, every scalar one-loop integral in this book is a product of Γ-functions times a power of a kinematic invariant, and the entire ultraviolet content of the loop is concentrated in one of those Γ-functions. This section carries out the radial integral in closed form, assembles the result into *the* master scalar one-loop formula, and then extends it in the only direction the Feynman rules of Chapters 15 and 17 actually demand: to integrands carrying loop momenta in the numerator. Those numerator integrals are reduced to the scalar master by symmetric integration, a manoeuvre we prove rather than assert. With the master formula and its tensor descendants in hand we read off the standard scalar functions A_0 and B_0 that the loop chapters quote by name, and we identify exactly where the formula develops poles — the analytic signature of the ultraviolet divergences that the power counting of Section D.1 predicted.

D.4.1 The radial integral and the master formula

Fix the object of study. After combining denominators with Feynman or Schwinger parameters (Section D.2) and shifting the loop momentum to complete the square, every scalar one-loop integral in the book is reduced to a single canonical form, the integral of an inverse power of $\ell^2 - \Delta$ over all of d-dimensional Minkowski momentum space,

$$I_n(\Delta) \;\equiv\; \int \frac{\mathrm{d}^d \ell}{(2\pi)^d} \, \frac{1}{(\ell^2 - \Delta + i\epsilon)^{\,n}} \,, \tag{D.73}$$

where n is a positive integer (the total power of propagators after parametrization), Δ is the effective mass-squared produced by completing the square — a function of the external invariants, the internal masses, and the Feynman parameters, but *not* of the loop momentum — and the $i\epsilon$ is the Feynman prescription inherited from each propagator. The whole point of dimensional regularization is to treat the spacetime dimension d as a complex variable; Eq. (D.73) is then to be read as the analytic continuation, in d, of the integral evaluated wherever it converges.

The rotation to Euclidean signature was performed in Section D.3. Setting $\ell^0 = i\ell^0_E$ (so that $\mathrm{d}^d\ell = i\,\mathrm{d}^d\ell_E$) and $\ell^2 = (\ell^0)^2 - \boldsymbol{\ell}^2 = -\big[(\ell^0_E)^2 + \boldsymbol{\ell}^2\big] = -\ell_E^2$ rotates the denominator into $\ell^2 - \Delta \to -(\ell_E^2 + \Delta)$, with the $i\epsilon$ guaranteeing that the contour does not cross a pole during the rotation. Each inverse power therefore contributes a factor $(-1)^{-n} = (-1)^n$, and the Jacobian contributes the explicit i, so that

$$I_n(\Delta) \;=\; i\,(-1)^n \int \frac{\mathrm{d}^d \ell_E}{(2\pi)^d} \, \frac{1}{(\ell_E^2 + \Delta)^{\,n}} \,. \tag{D.74}$$

The Euclidean integrand depends on ℓ_E only through its length $\ell_E \equiv \sqrt{\ell_E^2} \geq 0$, so the angular integration is trivial: it produces the surface area of the unit

sphere in d dimensions, the solid angle

$$\Omega_d \;=\; \frac{2\pi^{d/2}}{\Gamma(d/2)}\,, \tag{D.75}$$

constructed by analytic continuation in Section D.3. What remains is purely radial,

$$I_n(\Delta) \;=\; i\,(-1)^n\,\frac{\Omega_d}{(2\pi)^d}\int_0^\infty \mathrm{d}\ell_E\;\frac{\ell_E^{\,d-1}}{(\ell_E^2+\Delta)^{\,n}}\,. \tag{D.76}$$

Everything now hinges on the one-dimensional integral in Eq. (D.76). We evaluate it exactly.

Theorem D.22 (The master scalar one-loop integral)**.** *For $\Delta>0$ and complex d with $0<\mathrm{Re}(d/2)<\mathrm{Re}(n)$ (the strip in which the radial integral converges absolutely, whence the result is continued analytically),*

$$\boxed{\int\frac{\mathrm{d}^d\ell}{(2\pi)^d}\,\frac{1}{(\ell^2-\Delta+i\epsilon)^{\,n}} \;=\; \frac{(-1)^n\,i}{(4\pi)^{d/2}}\,\frac{\Gamma\!\left(n-\frac{d}{2}\right)}{\Gamma(n)}\,\Delta^{\,d/2-n}} \tag{D.77}$$

with the $i\epsilon$ understood throughout and the branch of $\Delta^{d/2-n}$ fixed by $\Delta>0$.

Proof. Start from the radial form Eq. (D.76) and change variables to expose a Beta-function integral. The substitution that does this is

$$t \;=\; \frac{\ell_E^2}{\Delta}\,,\qquad \ell_E=(\Delta t)^{1/2}\,,\qquad \mathrm{d}\ell_E=\tfrac{1}{2}\,\Delta^{1/2}\,t^{-1/2}\,\mathrm{d}t\,, \tag{D.78}$$

which maps $\ell_E\in(0,\infty)$ to $t\in(0,\infty)$. Each factor in the radial integrand becomes a power of Δ times a power of t:

$$\ell_E^{\,d-1}=(\Delta t)^{(d-1)/2}=\Delta^{(d-1)/2}\,t^{(d-1)/2}, \tag{D.79}$$

$$(\ell_E^2+\Delta)^{-n}=\big[\Delta(t+1)\big]^{-n}=\Delta^{-n}\,(1+t)^{-n}. \tag{D.80}$$

Collecting Eqs. (D.79) and (D.80) together with the Jacobian from Eq. (D.78), the powers of Δ combine as $\frac{d-1}{2}-n+\frac{1}{2}=\frac{d}{2}-n$, and the radial integral separates into a pure Δ-power times a t-integral,

$$\int_0^\infty \mathrm{d}\ell_E\;\frac{\ell_E^{\,d-1}}{(\ell_E^2+\Delta)^{\,n}} \;=\; \tfrac{1}{2}\,\Delta^{\,d/2-n}\int_0^\infty \mathrm{d}t\;\frac{t^{\,d/2-1}}{(1+t)^{\,n}}\,. \tag{D.81}$$

The remaining t-integral is exactly the standard integral representation of the Euler Beta function. Recall (Chapter 5) that for $\mathrm{Re}(\alpha)>0$ and $\mathrm{Re}(\beta)>0$ the Beta function admits the two representations

$$\mathrm{B}(\alpha,\beta) \;=\; \int_0^1 \mathrm{d}u\,u^{\alpha-1}(1-u)^{\beta-1} \;=\; \int_0^\infty \mathrm{d}t\;\frac{t^{\alpha-1}}{(1+t)^{\alpha+\beta}}\,, \tag{D.82}$$

the second following from the first under $u = t/(1+t)$, and that it is expressed through Gamma functions by

$$\mathrm{B}(\alpha,\beta) \;=\; \frac{\Gamma(\alpha)\,\Gamma(\beta)}{\Gamma(\alpha+\beta)}\,. \tag{D.83}$$

Matching the integrand in Eq. (D.81) to the second form of Eq. (D.82) requires $\alpha - 1 = \frac{d}{2} - 1$ and $\alpha + \beta = n$, that is $\alpha = \frac{d}{2}$ and $\beta = n - \frac{d}{2}$. Both arguments have positive real part precisely on the convergence strip $0 < \mathrm{Re}(d/2) < \mathrm{Re}(n)$ asserted in the statement; there

$$\int_0^\infty \mathrm{d}t\;\frac{t^{\,d/2-1}}{(1+t)^{\,n}} \;=\; \mathrm{B}\!\left(\tfrac{d}{2},\,n-\tfrac{d}{2}\right) \;=\; \frac{\Gamma\!\left(\frac{d}{2}\right)\Gamma\!\left(n-\frac{d}{2}\right)}{\Gamma(n)}\,. \tag{D.84}$$

Now reassemble. Insert Eqs. (D.81) and (D.84) into Eq. (D.76), using $\Omega_d = 2\pi^{d/2}/\Gamma(d/2)$ from Eq. (D.75):

$$I_n(\Delta) \;=\; i\,(-1)^n\,\frac{1}{(2\pi)^d}\,\frac{2\pi^{d/2}}{\Gamma(d/2)}\;\cdot\;\tfrac{1}{2}\,\Delta^{\,d/2-n}\,\frac{\Gamma(d/2)\,\Gamma(n-d/2)}{\Gamma(n)}\,. \tag{D.85}$$

Three simplifications finish the proof. The factor $\frac{1}{2}$ from the Jacobian cancels the 2 in Ω_d. The $\Gamma(d/2)$ from Ω_d cancels the $\Gamma(d/2)$ from the Beta function — this cancellation is the structural reason the answer is so clean. And the surviving powers of π and 2 combine into the canonical loop factor,

$$\frac{\pi^{d/2}}{(2\pi)^d} \;=\; \frac{\pi^{d/2}}{2^d\,\pi^d} \;=\; \frac{1}{2^d\,\pi^{d/2}} \;=\; \frac{1}{(4\pi)^{d/2}}\,, \tag{D.86}$$

where the last step uses $(4\pi)^{d/2} = 4^{d/2}\pi^{d/2} = 2^d\pi^{d/2}$. Substituting Eq. (D.86) into Eq. (D.85) leaves

$$I_n(\Delta) \;=\; \frac{(-1)^n\,i}{(4\pi)^{d/2}}\,\frac{\Gamma(n-d/2)}{\Gamma(n)}\,\Delta^{\,d/2-n}\,, \tag{D.87}$$

which is Eq. (D.77). Outside the convergence strip the right-hand side is a meromorphic function of d and n, and it *defines* the integral by analytic continuation; this is the operational content of dimensional regularization. □

A few features of Eq. (D.77) deserve to be named at once, because the rest of this appendix — and every loop chapter — leans on them. The dependence on the effective mass is the single power $\Delta^{d/2-n}$, fixed entirely by dimensional analysis: $[I_n] = [\text{mass}]^{d-2n}$, and indeed $d/2 - n$ is half of $d - 2n$ once the $\Delta^{d/2-n}$ is read as $(\Delta)^{(d-2n)/2}$. The dependence on the regulator is carried by the ratio of Gammas, and the divergence structure — the entire reason the integral needed regulating — sits in the single factor $\Gamma(n - d/2)$ in the numerator. We return to its poles in Section D.4.5.

Caution

The sign factor $(-1)^n$ and the explicit i in Eq. (D.77) are not optional decorations; they are the residue of the Wick rotation and the source of the overall i that makes one-loop amplitudes come out with the right reality properties. A common error is to quote the Euclidean version (without the i and with $\Delta^{d/2-n}$ already real and positive) and forget to rotate back. Throughout this book Eq. (D.77) is the Minkowski statement: the integral on the left is over Minkowski momenta with the Feynman $i\epsilon$, and the i on the right is genuinely there.

D.4.2 Numerator integrals: even powers of the loop momentum

Beyond the purely scalar integrand, the Feynman rules generate numerators built from the loop momentum ℓ^μ. The simplest are scalar numerators $(\ell^2)^k$, which arise after a tensor numerator has been reduced (next subsection) or directly in theories whose vertices carry derivatives. They are dispatched by the same radial integral, because $(\ell^2)^k$ merely shifts the effective dimension.

Proposition D.23 (Scalar numerator master)**.** *For integer $k \geq 0$ and n on the appropriate convergence strip,*

$$\int \frac{\mathrm{d}^d\ell}{(2\pi)^d} \frac{(\ell^2)^k}{(\ell^2 - \Delta + i\epsilon)^{\,n}} = \frac{(-1)^{n+k}\, i}{(4\pi)^{d/2}} \frac{\Gamma\!\left(k + \frac{d}{2}\right)}{\Gamma\!\left(\frac{d}{2}\right)} \frac{\Gamma\!\left(n - k - \frac{d}{2}\right)}{\Gamma(n)} \Delta^{\,d/2+k-n}. \tag{D.88}$$

Proof. Under the Wick rotation of Eq. (D.74) the numerator rotates as $(\ell^2)^k = (-\ell_E^2)^k = (-1)^k(\ell_E^2)^k$, contributing an extra sign $(-1)^k$ relative to the scalar case and replacing the radial power ℓ_E^{d-1} by ℓ_E^{d-1+2k}. The Euclidean integral is therefore identical to Eq. (D.76) with $d-1 \mapsto d-1+2k$ in the radial measure — that is, with the replacement $d \mapsto d+2k$ *inside the radial integral only*, the prefactor $\Omega_d/(2\pi)^d$ being unchanged. Running the substitution Eq. (D.78) again, the powers of Δ now combine to $\frac{d+2k}{2} - n = \frac{d}{2} + k - n$, and the Beta integral becomes

$$\int_0^\infty \mathrm{d}t\, \frac{t^{\,d/2+k-1}}{(1+t)^{\,n}} = \mathrm{B}\!\left(\tfrac{d}{2}+k,\, n-k-\tfrac{d}{2}\right) = \frac{\Gamma\!\left(\frac{d}{2}+k\right)\Gamma\!\left(n-k-\frac{d}{2}\right)}{\Gamma(n)}, \tag{D.89}$$

matching $\alpha = \frac{d}{2}+k$, $\beta = n-k-\frac{d}{2}$ in Eqs. (D.82) and (D.83). Assembling exactly as in Theorem D.22, the cancellation that removed $\Gamma(d/2)$ before is now *incomplete*: the $\Gamma(d/2)$ from Ω_d cancels only one of the two, leaving the ratio $\Gamma(d/2+k)/\Gamma(d/2)$. This is the promised appearance of the dimension in the denominator. The extra sign $(-1)^k$ rides along, giving the overall $(-1)^{n+k}$, and

the loop factor $1/(4\pi)^{d/2}$ is produced by Eq. (D.86) as before. The result is Eq. (D.88). □

For $k = 0$ the ratio $\Gamma(d/2)/\Gamma(d/2) = 1$ and Eq. (D.88) collapses to Eq. (D.77), as it must. The factor $\Gamma(d/2+k)/\Gamma(d/2) = (d/2)(d/2+1)\cdots(d/2+k-1)$ is a polynomial of degree k in d; it is the algebraic trace of the angular average of $(\ell^2)^k$ over the sphere, and it is exactly the d-dependence that, expanded about $d = 4$ in the next section, can convert a $1/\varepsilon$ pole into a finite remainder.

D.4.3 Tensor numerators and symmetric integration

The numerators that actually occur in gauge theories and in any theory with derivative couplings are not scalars $(\ell^2)^k$ but tensors built from uncontracted loop momenta: ℓ^μ, $\ell^\mu\ell^\nu$, $\ell^\mu\ell^\nu\ell^\rho\ell^\sigma$, and so on, sitting over a scalar denominator $(\ell^2 - \Delta)^n$. The QED vacuum polarization and self-energy of Chapter 19 are precisely of this kind once the Dirac algebra of Section C.6 has been carried out on the numerator. The device that reduces every such tensor integral to the scalars already computed is *symmetric integration*: the observation that the integration domain and the denominator are invariant under $\ell \to -\ell$ and under d-dimensional Lorentz transformations, so the integral of a tensor numerator can only be the most general tensor with those symmetries, built from the metric alone.

Proposition D.24 (Symmetric integration, ranks one and two)**.** *Let $f(\ell^2)$ be any function for which the integrals below converge (in particular $f = (\ell^2 - \Delta)^{-n}$). Then under the loop integral,*

$$\int \frac{\mathrm{d}^d\ell}{(2\pi)^d}\, \ell^\mu\, f(\ell^2) = 0\,, \tag{D.90}$$

$$\int \frac{\mathrm{d}^d\ell}{(2\pi)^d}\, \ell^\mu\ell^\nu\, f(\ell^2) = \frac{\eta^{\mu\nu}}{d} \int \frac{\mathrm{d}^d\ell}{(2\pi)^d}\, \ell^2\, f(\ell^2)\,. \tag{D.91}$$

Equivalently, inside such an integral one may make the replacements

$$\ell^\mu \;\longrightarrow\; 0\,, \qquad\qquad \ell^\mu\ell^\nu \;\longrightarrow\; \frac{\ell^2}{d}\,\eta^{\mu\nu}\,, \tag{D.92}$$

with the factor of d — the dimension of the spacetime over which we are integrating — in the denominator.

Proof. For Eq. (D.90): the measure $\mathrm{d}^d\ell$, the domain $\mathbb{R}^{1,d-1}$ (or its Euclidean rotation), and the weight $f(\ell^2)$ are all invariant under the reflection $\ell \to -\ell$, while the integrand factor ℓ^μ is odd. The integral of an odd function over a symmetric domain vanishes, provided it converges; in dimensional regularization convergence is arranged by the analytic continuation, and the statement holds

as an identity of meromorphic functions of d. More generally any numerator carrying an odd number of uncontracted ℓ's integrates to zero by the same parity argument.

For Eq. (D.91): write the integral as a Lorentz tensor,

$$T^{\mu\nu} \;\equiv\; \int \frac{\mathrm{d}^d\ell}{(2\pi)^d}\, \ell^\mu \ell^\nu\, f(\ell^2)\,. \tag{D.93}$$

The measure and the weight $f(\ell^2)$ are invariant under the (continued) Lorentz group $\mathrm{SO}(1, d-1)$, so $T^{\mu\nu}$ transforms as a rank-two symmetric Lorentz tensor that depends on *no* external vector — the only data left after integrating out ℓ is Δ (a scalar) and the dimension. The unique symmetric two-index tensor that can be built from no vectors is a multiple of the invariant metric. Hence

$$T^{\mu\nu} \;=\; C\,\eta^{\mu\nu} \tag{D.94}$$

for some scalar C depending on Δ, d, and f. To fix C, contract both sides of Eq. (D.94) with the metric $\eta_{\mu\nu}$. On the left, $\eta_{\mu\nu}\ell^\mu\ell^\nu = \ell^2$ under the integral, so $\eta_{\mu\nu}T^{\mu\nu} = \int \frac{\mathrm{d}^d\ell}{(2\pi)^d}\,\ell^2 f(\ell^2)$. On the right, the trace of the metric in d dimensions is

$$\eta_{\mu\nu}\eta^{\mu\nu} \;=\; \delta^\mu{}_\mu \;=\; d\,, \tag{D.95}$$

the defining bookkeeping rule of the d-dimensional formalism (Eq. (C.185)). Therefore $\eta_{\mu\nu}T^{\mu\nu} = C\,d$, and solving,

$$C \;=\; \frac{1}{d}\int \frac{\mathrm{d}^d\ell}{(2\pi)^d}\,\ell^2 f(\ell^2)\,. \tag{D.96}$$

Inserting Eq. (D.96) into Eq. (D.94) gives Eq. (D.91), and reading the result back at the level of the integrand gives the replacement rule Eq. (D.92). It is the single appearance of $\eta_{\mu\nu}\eta^{\mu\nu} = d$, not 4, that makes this a genuinely d-dimensional manipulation: keeping the d exact here is essential, because it multiplies divergent scalar integrals and so contributes to finite parts after the ε-expansion. □

The same logic fixes higher even ranks. At rank four the unique symmetric four-index tensor built from the metric is the sum of the three pairings $\eta^{\mu\nu}\eta^{\rho\sigma} + \eta^{\mu\rho}\eta^{\nu\sigma} + \eta^{\mu\sigma}\eta^{\nu\rho}$, so

$$\ell^\mu\ell^\nu\ell^\rho\ell^\sigma \;\longrightarrow\; \frac{(\ell^2)^2}{d(d+2)}\left(\eta^{\mu\nu}\eta^{\rho\sigma} + \eta^{\mu\rho}\eta^{\nu\sigma} + \eta^{\mu\sigma}\eta^{\nu\rho}\right), \tag{D.97}$$

the coefficient determined by contracting both sides with $\eta_{\mu\nu}\eta_{\rho\sigma}$: the left side gives ℓ^4 while the right gives the coefficient times $(d\cdot d + d + d) = d(d+2)$, using $\eta_{\mu\nu}\eta^{\mu\nu} = d$ twice and one cross-contraction $\eta_{\mu\nu}\eta^{\mu\rho}\eta_{\rho\sigma}\eta^{\nu\sigma} = \eta_\nu{}^\rho\eta_\rho{}^\nu = d$. With Eqs. (D.92) and (D.97) every tensor numerator is converted into a sum of $(\ell^2)^k$ numerators, which Theorem D.23 then integrates in closed form. This is the complete reduction algorithm at one loop: parametrize, shift, symmetrize, and apply Eqs. (D.77) and (D.88).

D.4.4 The standard scalar functions A_0 and B_0

Two combinations of the master integral occur so often that they are given names and quoted as black boxes throughout the loop chapters. They are the scalar one-point function A_0 (the tadpole) and the scalar two-point function B_0 (the bubble). We define them as the bare loop integrals and read off their values from Theorem D.22; the renormalization-scale factor $\mu^{2\varepsilon}$ and the ε-expansion are restored in Section D.5.

The tadpole A_0. The scalar one-point integral has a single massive propagator and no external momentum:

$$A_0(m^2) \;\equiv\; \int \frac{\mathrm{d}^d\ell}{(2\pi)^d}\,\frac{1}{\ell^2 - m^2 + i\epsilon}\,. \tag{D.98}$$

This is Eq. (D.73) with $n = 1$ and $\Delta = m^2$, so Eq. (D.77) with $\Gamma(1) = 1$ gives immediately

$$A_0(m^2) \;=\; -\,\frac{i}{(4\pi)^{d/2}}\,\Gamma\!\left(1 - \tfrac{d}{2}\right)\,(m^2)^{\,d/2-1}\,. \tag{D.99}$$

Two properties are worth recording. First, A_0 vanishes identically for a massless line, $A_0(0) = 0$: with $m = 0$ the factor $(m^2)^{d/2-1} \to 0$ for $\mathrm{Re}(d) > 2$, and in dimensional regularization a scaleless integral is *defined* to be zero precisely because there is no scale to carry its dimension — a fact we use repeatedly to discard massless tadpoles. Second, the divergence lives in $\Gamma(1 - d/2)$, which at $d = 4$ is $\Gamma(-1 + \varepsilon)$, a double layer of pole structure (a simple pole with a specific residue) reflecting the quadratic ultraviolet divergence of the tadpole counted in Section D.1. A companion tensor tadpole that appears in self-energies is reduced by Eq. (D.92) together with the algebraic identity $\ell^2 = (\ell^2 - m^2) + m^2$:

$$\int \frac{\mathrm{d}^d\ell}{(2\pi)^d}\,\frac{\ell^\mu \ell^\nu}{\ell^2 - m^2 + i\epsilon} = \frac{\eta^{\mu\nu}}{d}\int \frac{\mathrm{d}^d\ell}{(2\pi)^d}\,\frac{\ell^2}{\ell^2 - m^2 + i\epsilon} = \frac{\eta^{\mu\nu}}{d}\,m^2\,A_0(m^2)\,, \tag{D.100}$$

where the term $\int (\ell^2 - m^2)^{-1}(\ell^2 - m^2) = \int 1$ is a scaleless integral and vanishes, leaving only $m^2 A_0$.

The bubble B_0. The scalar two-point integral has two propagators carrying internal masses m_1, m_2 and an external momentum p flowing through the loop:

$$B_0(p^2; m_1, m_2) \;\equiv\; \int \frac{\mathrm{d}^d\ell}{(2\pi)^d}\,\frac{1}{(\ell^2 - m_1^2 + i\epsilon)\big((\ell + p)^2 - m_2^2 + i\epsilon\big)}\,. \tag{D.101}$$

Combine the two denominators with a single Feynman parameter (Section D.2), $\frac{1}{AB} = \int_0^1 \mathrm{d}x\,[xB + (1-x)A]^{-2}$, choosing $A = \ell^2 - m_1^2$ and $B = (\ell + p)^2 - m_2^2$. The combined denominator is

$$xB + (1-x)A = \ell^2 + 2x\,\ell\cdot p + xp^2 - xm_2^2 - (1-x)m_1^2$$

$$= (\ell + xp)^2 - \Delta\,, \tag{D.102}$$

where completing the square introduced $-x^2p^2$ and the effective mass-squared is

$$\Delta(x) \;=\; (1-x)\,m_1^2 + x\,m_2^2 - x(1-x)\,p^2\,. \tag{D.103}$$

Shifting the loop momentum $\ell \to \ell - xp$ (legitimate in dimensional regularization, where the shift introduces no surface term) reduces the inner integral to Eq. (D.73) with $n = 2$, and Eq. (D.77) with $\Gamma(2) = 1$ gives

$$B_0(p^2; m_1, m_2) \;=\; \frac{i}{(4\pi)^{d/2}}\,\Gamma\!\left(2 - \tfrac{d}{2}\right) \int_0^1 \mathrm{d}x\,\left[\Delta(x)\right]^{d/2-2}, \tag{D.104}$$

with $\Delta(x)$ from Eq. (D.103). The entire ultraviolet divergence is the x-independent prefactor $\Gamma(2 - d/2) = \Gamma(\varepsilon)$ at $d = 4$; the parametric integral over x is finite and, once expanded in ε, produces the logarithm of Δ and its branch cut. In the equal-mass case $m_1 = m_2 = m$ relevant to most of our examples,

$$B_0(p^2; m, m) \;=\; \frac{i}{(4\pi)^{d/2}}\,\Gamma\!\left(2 - \tfrac{d}{2}\right) \int_0^1 \mathrm{d}x\,\left[m^2 - x(1-x)\,p^2\right]^{d/2-2}. \tag{D.105}$$

This single function is the integral backbone of the benchmark theories at one loop: it is the ϕ^4 bubble that feeds β_λ in Chapter 24, and — dressed with Dirac and (for Yang–Mills) color numerators — it is the scalar core of the QED vacuum polarization and self-energy of Chapter 19 and of the gluon self-energy of Chapter 27. We now work the ϕ^4 case explicitly.

Worked Example D.25 (The one-loop ϕ^4 bubble as B_0)**.** We continue ϕ^4 theory from the Feynman rules of Chapter 15. The one-loop correction to the four-point function in $\lambda\phi^4$ theory is the sum of three diagrams — one for each Mandelstam channel s, t, u — each the simple bubble shown in Fig. D.5. We evaluate the s-channel bubble to closed Γ-function form; the other two channels are obtained by $s \to t$ and $s \to u$.

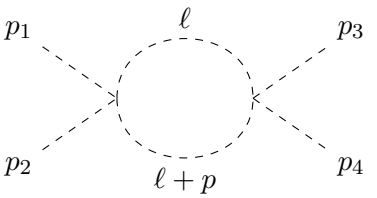

Figure D.5: The s-channel one-loop bubble in $\lambda\phi^4$ theory, with total incoming momentum $p = p_1 + p_2$ (so $p^2 = s$) circulating through the loop as ℓ and $\ell + p$. The t- and u-channel diagrams have the same topology with $p^2 = t$ and $p^2 = u$.

Each quartic vertex carries a factor $-i\lambda$, and the diagram has a symmetry factor $\frac{1}{2}$ from the interchange of the two internal lines (derived with the rest

of the ϕ^4 symmetry factors in Chapter 15). With total incoming momentum $p = p_1 + p_2$, $p^2 = s$, the amplitude contribution is

$$i\mathcal{M}_s \;=\; \frac{(-i\lambda)^2}{2}\int \frac{\mathrm{d}^d\ell}{(2\pi)^d}\,\frac{i}{\ell^2 - m^2 + i\epsilon}\,\frac{i}{(\ell+p)^2 - m^2 + i\epsilon}\,. \tag{D.106}$$

The two explicit propagator factors of i multiply to $i^2 = -1$, and $(-i\lambda)^2 = -\lambda^2$, so the kinematic prefactors combine to $(-\lambda^2)(-1)/2 = \lambda^2/2$, leaving exactly the scalar bubble:

$$i\mathcal{M}_s \;=\; \frac{\lambda^2}{2}\int \frac{\mathrm{d}^d\ell}{(2\pi)^d}\,\frac{1}{(\ell^2 - m^2)((\ell+p)^2 - m^2)} \;=\; \frac{\lambda^2}{2}\,B_0(s; m, m)\,. \tag{D.107}$$

This is the promised identification of the carried ϕ^4 amplitude's loop with the master function B_0. Now apply the equal-mass result Eq. (D.105) with $p^2 = s$ and $\Delta(x) = m^2 - x(1-x)s$:

$$i\mathcal{M}_s \;=\; \frac{\lambda^2}{2}\,\frac{i}{(4\pi)^{d/2}}\,\Gamma\!\left(2 - \tfrac{d}{2}\right)\int_0^1 \mathrm{d}x\,\left[m^2 - x(1-x)\,s\right]^{d/2-2}\,. \tag{D.108}$$

Every step from the Feynman rules to a closed expression in Γ-functions and a one-dimensional parametric integral is now on the page. The divergence is the single $\Gamma(2 - d/2)$; at $d = 4$ this is $\Gamma(\varepsilon)$, a simple $1/\varepsilon$ pole, and its residue, summed over the three channels, is what Chapter 24 converts into the coefficient of $\beta_\lambda = 3\lambda^2/16\pi^2$. The parametric integral is finite and will, after the ε-expansion of Section D.5, deliver the physical logarithm $\ln\!\left[m^2 - x(1-x)s\right]$ whose branch cut for $s > 4m^2$ is the two-particle threshold demanded by unitarity.

Physical Insight

The reason a single function B_0 does so much work across three different theories is that the *denominator* of a one-loop diagram knows nothing about spin or color. After the Dirac traces of Section C.6 and the color contractions of Chapter B have been performed on the numerator, what is left to integrate is always a tensor built from ℓ over a scalar denominator $(\ell^2 - \Delta)^n$ — and that is precisely the object reduced by Theorems D.23 and D.24 to A_0 and B_0. The Yang–Mills scalar integrals are *identical* to the QED ones up to an overall color factor (a Casimir C_A, C_F, or $T_F n_f$ from Chapter B) multiplying the same B_0. Spin and gauge structure dress the building blocks; they never change the integrals.

D.4.5 Analytic structure: where the poles are, and what they mean

We close by reading the analytic structure of the master formula and tying it back to the power counting that opened this appendix. All the regulator dependence

in Eqs. (D.77) and (D.88) is carried by the Gamma function $\Gamma(n - d/2)$ (scalar numerator) or $\Gamma(n - k - d/2)$ (with a $(\ell^2)^k$ numerator). The Gamma function is meromorphic with simple poles at the non-positive integers, $\Gamma(z)$ blowing up at $z = 0, -1, -2, \ldots$. Hence the master integral develops a pole exactly when

$$n - k - \frac{d}{2} \;=\; -j\,, \qquad j = 0, 1, 2, \ldots\,, \qquad \text{i.e.} \qquad d \;=\; 2(n-k) + 2j\,. \tag{D.109}$$

Reading Eq. (D.109) the other way, at a *fixed* integer dimension d the integral $\int \mathrm{d}^d\ell\,(\ell^2)^k/(\ell^2 - \Delta)^n$ is ultraviolet divergent precisely when $d \geq 2(n-k)$ — which is the statement that its superficial degree of divergence

$$D \;=\; d + 2k - 2n \tag{D.110}$$

is non-negative, exactly the power counting of Section D.1 applied to a single loop. The integer j in Eq. (D.109) labels which subtraction the divergence requires: $j = 0$ ($D = 0$) is a logarithmic divergence, $j = 1$ ($D = 2$) a quadratic one, and so on. The poles in d are thus not artefacts of the continuation; they are the faithful image, in the analytic structure of the Γ-function, of the ultraviolet divergences that the integral genuinely has at integer dimension.

For the physically central case $d = 4$ this organizes the whole one-loop catalogue. Writing $d = 4 - 2\varepsilon$, the relevant Gamma function is $\Gamma(n - k - d/2) = \Gamma(n - k - 2 + \varepsilon)$, which has a pole as $\varepsilon \to 0$ whenever $n - k - 2 \leq 0$, i.e. $n - k \leq 2$. The three cases that exhaust the renormalizable one-loop divergences are tabulated by their effective propagator power $n - k$:

- $n - k = 1$: $\Gamma(-1 + \varepsilon)$, the quadratically divergent tadpole-type integral (A_0, Eq. (D.99); $D = 2$);
- $n - k = 2$: $\Gamma(\varepsilon)$, the logarithmically divergent bubble-type integral (B_0, Eq. (D.104); $D = 0$);
- $n - k \geq 3$: $\Gamma(1 + \varepsilon), \Gamma(2 + \varepsilon), \ldots$, all *finite* at $d = 4$ ($D < 0$, ultraviolet-convergent integrals such as the triangle and box).

This is the payoff of the whole construction. A divergent loop integral has been turned into a meromorphic function of d whose only singularity near the physical dimension is a single, explicit, isolated pole, with everything else — the powers of Δ, the parametric integral, the finite remainder — analytic and computable.

The master formula Eq. (D.77), the numerator extension Eq. (D.88), the symmetric-integration rules Eqs. (D.92) and (D.97), and the named functions A_0 and B_0 are the complete scalar toolkit at one loop. Each is now a product of Γ-functions times a power of Δ, with the entire ultraviolet divergence isolated in a single $\Gamma(n - k - d/2)$. What remains is to make that pole and its finite companion explicit: to Laurent-expand the master integral about $d = 4$, extract the universal $1/\varepsilon - \gamma_E + \ln 4\pi$ combination, and restore the dimensions with the scale μ. That expansion is the business of the next section.

D.5 Expansion in ε: poles, finite parts, and the meaning of the scale

The previous section closed the radial and angular integrations and handed us a single closed expression valid for general complex dimension: the master scalar one-loop integral

$$\int \frac{\mathrm{d}^d\ell}{(2\pi)^d}\,\frac{1}{(\ell^2-\Delta+i\epsilon)^n} \;=\; \frac{(-1)^n\,i}{(4\pi)^{d/2}}\,\frac{\Gamma\!\left(n-\frac{d}{2}\right)}{\Gamma(n)}\,\frac{1}{\Delta^{\,n-d/2}}, \tag{D.111}$$

established as Eq. (D.77), with $\Delta>0$ the Feynman-combined mass-squared and the Wick rotation $\ell^0=i\ell^0_E$ carried out there. This is exact, but it is also useless as it stands: it is a function of the continuous variable d, and physics lives at $d=4$, where the gamma function $\Gamma(n-d/2)$ has its poles for the very values of n that produced divergent integrals in the first place. To extract physics we must let $d\to 4$, that is, $\varepsilon\to 0$ in $d=4-2\varepsilon$, and watch the divergence resurface — now not as an ill-defined integral but as a pole in ε multiplying a perfectly finite remainder. The whole content of dimensional regularization is in this controlled limit. Performing it requires only two pieces of elementary analysis: the Laurent expansion of the gamma function about its poles, and the Taylor expansion of the two innocuous-looking powers $(4\pi)^{\varepsilon}$ and $\Delta^{-\varepsilon}$. Assembling them exposes a universal divergent combination that is the same in every theory and at every loop order, isolates it into a counterterm by the $\overline{\mathrm{MS}}$ prescription fixed in Chapter A, and leaves behind a finite logarithm of Δ whose branch cut — when Δ turns negative above a physical threshold — is the imaginary part demanded by unitarity. We carry all of this out in full, deriving the gamma-function expansions from first principles rather than quoting them, and finish by completing the ϕ^4 bubble to its renormalized $\overline{\mathrm{MS}}$ value.

D.5.1 The gamma function near its poles

Everything in the ε-expansion is downstream of one analytic fact: how $\Gamma(z)$ behaves near the nonpositive integers, where it has its only singularities. We need the expansion of $\Gamma(\varepsilon)$ about $\varepsilon=0$ (for the logarithmically divergent integrals, $n-d/2=\varepsilon$), of $\Gamma(-1+\varepsilon)$ (for the quadratically divergent ones, where $n-d/2=-1+\varepsilon$), and, once, the general $\Gamma(-m+\varepsilon)$ recursion that subsumes both. We derive them from the Weierstrass product, introducing the Euler–Mascheroni constant and the digamma function as we go, since both appear in the answers.

Definition D.26 (Euler–Mascheroni constant and the digamma function)**.** The *Euler–Mascheroni constant* is the limit

$$\gamma_{\mathrm{E}} \;\equiv\; \lim_{N\to\infty}\Big(\sum_{n=1}^{N}\frac{1}{n}-\ln N\Big) \;=\; 0.5772156649\ldots, \tag{D.112}$$

the finite excess of the harmonic sum over the logarithm it asymptotes to. The *digamma function* is the logarithmic derivative of the gamma function,

$$\psi(z) \;\equiv\; \frac{\mathrm{d}}{\mathrm{d}z}\ln\Gamma(z) \;=\; \frac{\Gamma'(z)}{\Gamma(z)}. \tag{D.113}$$

The link between the two is supplied by the Weierstrass product representation of $1/\Gamma$, which is the cleanest starting point because it displays all the poles of Γ at once as the zeros of its reciprocal.

Lemma D.27 (Log-derivative of the Weierstrass product)**.** *The reciprocal gamma function admits the absolutely convergent product*

$$\frac{1}{\Gamma(z)} \;=\; z\,e^{\gamma_{\mathrm{E}} z}\prod_{n=1}^{\infty}\Big(1+\frac{z}{n}\Big)\,e^{-z/n}, \tag{D.114}$$

entire in z, whose zeros at $z=0,-1,-2,\dots$ are the poles of Γ. Consequently the digamma function has the expansion

$$\psi(z) \;=\; -\gamma_{\mathrm{E}} - \frac{1}{z} + \sum_{n=1}^{\infty}\Big(\frac{1}{n}-\frac{1}{n+z}\Big), \tag{D.115}$$

so that in particular

$$\psi(1)=-\gamma_{\mathrm{E}}, \qquad \psi(m{+}1)=-\gamma_{\mathrm{E}}+\sum_{k=1}^{m}\frac{1}{k}=-\gamma_{\mathrm{E}}+H_m, \qquad \psi'(1)=\sum_{n=1}^{\infty}\frac{1}{n^2}=\frac{\pi^2}{6}, \tag{D.116}$$

where $H_m=\sum_{k=1}^{m}1/k$ is the mth harmonic number.

Proof. We take the product (D.114) as the definition of the entire function $1/\Gamma$; that it reproduces $\Gamma(z+1)=z\Gamma(z)$ and $\Gamma(1)=1$, and hence agrees with the gamma function, is the standard verification we recall here. Taking the logarithm of (D.114),

$$-\ln\Gamma(z)=\ln z+\gamma_{\mathrm{E}} z+\sum_{n=1}^{\infty}\Big[\ln\Big(1+\frac{z}{n}\Big)-\frac{z}{n}\Big], \tag{D.117}$$

and differentiating term by term, which is legitimate because the differentiated series $\sum_n\big(\frac{1}{n}-\frac{1}{n+z}\big)=\sum_n\frac{z}{n(n+z)}$ converges absolutely and uniformly on compacta away from the poles, gives

$$-\psi(z)=\frac{1}{z}+\gamma_{\mathrm{E}}+\sum_{n=1}^{\infty}\Big(\frac{1}{n+z}-\frac{1}{n}\Big), \tag{D.118}$$

which rearranges to (D.115). Setting $z=1$ collapses the telescoping sum $\sum_n(\frac{1}{n}-\frac{1}{n+1})=1$, leaving $\psi(1)=-\gamma_{\mathrm{E}}-1+1=-\gamma_{\mathrm{E}}$. For $\psi(m+1)$, the recursion $\psi(z+1)=\psi(z)+1/z$ (the log-derivative of $\Gamma(z+1)=z\Gamma(z)$) iterated m times from $z=1$ adds $\sum_{k=1}^{m}1/k=H_m$ to $\psi(1)$. Finally, differentiating (D.115) once more gives $\psi'(z)=\sum_{n=0}^{\infty}(n+z)^{-2}$, and at $z=1$ this is the Basel sum $\sum_{n\ge1}n^{-2}=\pi^2/6$. $\square$

With the digamma data in hand the Laurent expansion of Γ near $\varepsilon = 0$ follows by exponentiating its Taylor series at $z = 1$, which is regular there.

Proposition D.28 (Laurent expansion of $\Gamma(\varepsilon)$ and $\Gamma(1+\varepsilon)$)**.** *About $\varepsilon = 0$,*

$$\Gamma(1+\varepsilon) = 1 - \gamma_{\mathrm{E}}\,\varepsilon + \tfrac{1}{2}\Big(\gamma_{\mathrm{E}}^2 + \frac{\pi^2}{6}\Big)\varepsilon^2 + O(\varepsilon^3), \tag{D.119}$$

$$\Gamma(\varepsilon) = \frac{1}{\varepsilon} - \gamma_{\mathrm{E}} + \tfrac{1}{2}\Big(\gamma_{\mathrm{E}}^2 + \frac{\pi^2}{6}\Big)\varepsilon + O(\varepsilon^2). \tag{D.120}$$

Proof. Because Γ is analytic and nonzero at $z = 1$ with $\Gamma(1) = 1$, the function $\ln\Gamma(1+\varepsilon)$ is analytic at $\varepsilon = 0$ and vanishes there, so it equals its Taylor series

$$\ln\Gamma(1+\varepsilon) = \psi(1)\,\varepsilon + \tfrac{1}{2}\,\psi'(1)\,\varepsilon^2 + O(\varepsilon^3) = -\gamma_{\mathrm{E}}\,\varepsilon + \frac{\pi^2}{12}\,\varepsilon^2 + O(\varepsilon^3), \tag{D.121}$$

using (D.116). (More generally the coefficients are the polygamma values $\psi^{(k-1)}(1)/k!$, and one shows $\ln\Gamma(1+\varepsilon) = -\gamma_{\mathrm{E}}\varepsilon + \sum_{k\geq 2}\frac{(-1)^k\zeta(k)}{k}\varepsilon^k$ with $\zeta(2) = \pi^2/6$, $\zeta(3)$ entering at the next order; we will not need beyond ε^2 until two-loop products, where the $O(\varepsilon)$ term of one factor multiplies the $1/\varepsilon$ pole of another.) Exponentiating (D.121),

$$\begin{aligned}\Gamma(1+\varepsilon) &= \exp\Big[-\gamma_{\mathrm{E}}\varepsilon + \frac{\pi^2}{12}\varepsilon^2 + O(\varepsilon^3)\Big] \\ &= 1 + \Big(-\gamma_{\mathrm{E}}\varepsilon + \frac{\pi^2}{12}\varepsilon^2\Big) + \tfrac{1}{2}\big(-\gamma_{\mathrm{E}}\varepsilon\big)^2 + O(\varepsilon^3) \\ &= 1 - \gamma_{\mathrm{E}}\varepsilon + \Big(\frac{\gamma_{\mathrm{E}}^2}{2} + \frac{\pi^2}{12}\Big)\varepsilon^2 + O(\varepsilon^3),\end{aligned} \tag{D.122}$$

which is (D.119) once $\pi^2/12 = \frac{1}{2}\cdot\pi^2/6$ is recognized inside the bracket. Dividing by ε through the functional equation $\Gamma(\varepsilon) = \Gamma(1+\varepsilon)/\varepsilon$ shifts every power down by one and produces the simple pole:

$$\Gamma(\varepsilon) = \frac{\Gamma(1+\varepsilon)}{\varepsilon} = \frac{1}{\varepsilon} - \gamma_{\mathrm{E}} + \Big(\frac{\gamma_{\mathrm{E}}^2}{2} + \frac{\pi^2}{12}\Big)\varepsilon + O(\varepsilon^2), \tag{D.123}$$

which is (D.120). □

The leading two terms of (D.120) are the ones quoted as precise statements in Eq. (A.201); Theorem D.28 is the derivation that backs that quotation, and it carries one order further because the $O(\varepsilon)$ term of $\Gamma(\varepsilon)$ multiplies the $1/\varepsilon$ pole of a second factor in any two-loop product and so contributes to one-loop *finite parts* whenever a double pole is present. The same machinery handles the higher poles. Quadratic divergences, and more generally any integral with $n - d/2 = -m + \varepsilon$ for a nonnegative integer m, need Γ near a negative integer.

Proposition D.29 (The $\Gamma(-m+\varepsilon)$ recursion)**.** *For every integer $m \geq 0$,*

$$\Gamma(-m+\varepsilon) = \frac{(-1)^m}{m!}\Big[\frac{1}{\varepsilon} + \psi(m+1) + O(\varepsilon)\Big] = \frac{(-1)^m}{m!}\Big[\frac{1}{\varepsilon} - \gamma_{\mathrm{E}} + H_m + O(\varepsilon)\Big], \tag{D.124}$$

with $H_0 \equiv 0$. In particular $m = 0$ reproduces (D.120), and

$$\Gamma(-1+\varepsilon) = -\frac{1}{\varepsilon} - 1 + \gamma_{\mathrm{E}} + O(\varepsilon), \qquad \Gamma(-2+\varepsilon) = \frac{1}{2}\Big(\frac{1}{\varepsilon} + \frac{3}{2} - \gamma_{\mathrm{E}}\Big) + O(\varepsilon). \tag{D.125}$$

Proof. Iterating $\Gamma(z+1) = z\Gamma(z)$ downward from $z = \varepsilon$ a total of m times,

$$\Gamma(\varepsilon) = (\varepsilon-1)(\varepsilon-2)\cdots(\varepsilon-m)\,\Gamma(\varepsilon-m), \tag{D.126}$$

so that

$$\Gamma(-m+\varepsilon) = \frac{\Gamma(\varepsilon)}{\prod_{j=1}^{m}(\varepsilon-j)}. \tag{D.127}$$

Factor each denominator term as $\varepsilon - j = (-j)(1-\varepsilon/j)$, so the product is

$$\prod_{j=1}^{m}(\varepsilon-j) = (-1)^m\, m! \prod_{j=1}^{m}\Big(1-\frac{\varepsilon}{j}\Big) = (-1)^m\, m!\,\Big(1-\varepsilon\sum_{j=1}^{m}\frac{1}{j}+O(\varepsilon^2)\Big) = (-1)^m\, m!\,\big(1-\varepsilon H_m+O(\varepsilon^2)\big). \tag{D.128}$$

Its reciprocal is $\dfrac{(-1)^m}{m!}\big(1+\varepsilon H_m + O(\varepsilon^2)\big)$. Multiplying by $\Gamma(\varepsilon) = \frac{1}{\varepsilon} - \gamma_{\mathrm{E}} + O(\varepsilon)$ from (D.120),

$$\Gamma(-m+\varepsilon) = \frac{(-1)^m}{m!}\Big(\frac{1}{\varepsilon}-\gamma_{\mathrm{E}}+O(\varepsilon)\Big)\big(1+\varepsilon H_m+O(\varepsilon^2)\big) = \frac{(-1)^m}{m!}\Big(\frac{1}{\varepsilon}-\gamma_{\mathrm{E}}+H_m+O(\varepsilon)\Big), \tag{D.129}$$

where the cross term $\frac{1}{\varepsilon}\cdot\varepsilon H_m = H_m$ has joined the constant. Recognizing $-\gamma_{\mathrm{E}} + H_m = \psi(m+1)$ from (D.116) gives the first form in (D.124). Setting $m = 1$ ($H_1 = 1$) yields $\Gamma(-1+\varepsilon) = -(\frac{1}{\varepsilon} - \gamma_{\mathrm{E}} + 1)$, the first equation of (D.125); setting $m = 2$ ($H_2 = \frac{3}{2}$) yields the second. □

Remark D.30 (Why the pole structure is universal). Equation (D.124) contains the whole reason dimensional regularization is so economical. The single gamma function $\Gamma(n - d/2)$ in the master integral (D.111) carries *all* the ultraviolet information: its pole position records how badly the integral diverges (a simple pole at every even d for logarithmic divergences, the negative-integer poles for power divergences), and its residue is a pure rational number times the universal $-\gamma_{\mathrm{E}}$. No physics of the particular diagram — no masses, no external momenta — enters the pole; all of that sits in the accompanying $\Delta^{-(n-d/2)}$, which is finite at $\varepsilon = 0$ and contributes only to the finite part. This clean separation, divergence in Γ and physics in $\Delta^{-\varepsilon}$, is what makes the pole part of every one-loop integral computable by inspection.

D.5.2 The prefactor expansions

The gamma function supplies the pole; the two power-law prefactors in (D.111) — the $(4\pi)^{-d/2}$ from the angular measure and the $\Delta^{-(n-d/2)}$ from the radial integral — supply, on expansion, the constants and logarithms that ride on it. Both are handled by the elementary identity $a^{\varepsilon} = e^{\varepsilon \ln a} = 1 + \varepsilon \ln a + \tfrac{1}{2}\varepsilon^2 \ln^2 a + \cdots$, valid for any $a > 0$. Writing $d/2 = 2 - \varepsilon$, the measure factor is

$$\frac{1}{(4\pi)^{d/2}} = \frac{1}{(4\pi)^2}\,(4\pi)^{\varepsilon} = \frac{1}{(4\pi)^2}\Big(1 + \varepsilon \ln 4\pi + \tfrac{1}{2}\varepsilon^2 \ln^2 4\pi + O(\varepsilon^3)\Big), \tag{D.130}$$

exposing the constant $\ln 4\pi$ that will pair with the $1/\varepsilon$ pole. The radial factor, for the logarithmic case $n - d/2 = \varepsilon$, expands as

$$\Delta^{-\varepsilon} = \Big(\frac{\Delta}{\mu^2}\Big)^{-\varepsilon} \mu^{-2\varepsilon} = \mu^{-2\varepsilon}\Big(1 - \varepsilon \ln \frac{\Delta}{\mu^2} + \tfrac{1}{2}\varepsilon^2 \ln^2 \frac{\Delta}{\mu^2} + O(\varepsilon^3)\Big), \tag{D.131}$$

where we have deliberately inserted the renormalization scale μ of Theorem A.46 by writing $\Delta^{-\varepsilon} = (\Delta/\mu^2)^{-\varepsilon}\,\mu^{-2\varepsilon}$. This is not cosmetic. The quantity Δ has mass dimension two, so $\ln \Delta$ is the logarithm of a dimensionful quantity — a meaningless object until a scale is named. The factor $\mu^{2\varepsilon}$ that the coupling promotion of Theorem A.46 attaches to every loop is exactly what combines with $\mu^{-2\varepsilon}$ here to render the argument of the surviving logarithm the dimensionless ratio Δ/μ^2. We make that cancellation explicit in Section D.5.4; for now the point is bookkeeping discipline, that $\Delta^{-\varepsilon}$ never appears without its compensating $\mu^{2\varepsilon}$, and only their product, $(\Delta/\mu^2)^{-\varepsilon}$, has an ε-expansion whose logarithms are well defined. The generic positive power needed for arbitrary n is the same exercise,

$$\Big(\frac{\Delta}{\mu^2}\Big)^{-(n-d/2)} = \Big(\frac{\Delta}{\mu^2}\Big)^{2-n}\Big(\frac{\Delta}{\mu^2}\Big)^{-\varepsilon} = \Big(\frac{\Delta}{\mu^2}\Big)^{2-n}\Big(1 - \varepsilon \ln \frac{\Delta}{\mu^2} + O(\varepsilon^2)\Big), \tag{D.132}$$

the integer power $(\Delta/\mu^2)^{2-n}$ surviving to ε^0 and the ε-expansion riding on it as before.

D.5.3 The universal divergent combination and $\overline{\text{MS}}$

We can now assemble the three expansions. Specialize the master integral (D.111) to the logarithmically divergent case $n = 2$, where $\Gamma(n) = \Gamma(2) = 1$ and $n - d/2 = \varepsilon$, and reinstate the loop's compensating scale $\mu^{2\varepsilon}$:

$$\mu^{2\varepsilon} \int \frac{\mathrm{d}^d \ell}{(2\pi)^d}\,\frac{1}{(\ell^2 - \Delta + i\epsilon)^2} = \frac{i}{(4\pi)^2}\,\underbrace{\mu^{2\varepsilon}\,(4\pi)^{\varepsilon}\,\Gamma(\varepsilon)\,\Delta^{-\varepsilon}}_{=\ \Gamma(\varepsilon)\,(4\pi\mu^2/\Delta)^{\varepsilon}}. \tag{D.133}$$

The braced product is dimensionless — every factor of mass has cancelled — and its ε-expansion is the single most important computation of this appendix.

Multiplying (D.120) by the expansion of $(4\pi\mu^2/\Delta)^\varepsilon = 1 + \varepsilon \ln(4\pi\mu^2/\Delta) + O(\varepsilon^2)$ and keeping the finite part,

$$\begin{aligned}\Gamma(\varepsilon)\Big(\frac{4\pi\mu^2}{\Delta}\Big)^{\varepsilon} &= \Big(\frac{1}{\varepsilon} - \gamma_{\mathrm{E}} + O(\varepsilon)\Big)\Big(1 + \varepsilon \ln\frac{4\pi\mu^2}{\Delta} + O(\varepsilon^2)\Big) \\ &= \frac{1}{\varepsilon} - \gamma_{\mathrm{E}} + \ln\frac{4\pi\mu^2}{\Delta} + O(\varepsilon) \\ &= \underbrace{\frac{1}{\varepsilon} - \gamma_{\mathrm{E}} + \ln 4\pi}_{\equiv\, 1/\bar{\varepsilon}} + \ln\frac{\mu^2}{\Delta} + O(\varepsilon). \end{aligned} \tag{D.134}$$

The structure of (D.134) is the lesson. The pole $1/\varepsilon$ never appears alone: it is rigidly accompanied by the two pure numbers $-\gamma_{\mathrm{E}}$ (from the gamma function) and $\ln 4\pi$ (from the angular measure), in a combination that is identical for every theory, every diagram, and every loop order, because it descends from the same two universal sources — the residue of Γ and the $(4\pi)^{d/2}$ of the d-dimensional sphere — and not from any physics. These constants are an artifact of the regulator. Carrying them through every calculation, only to have them clutter every finite answer, is a waste; the sensible thing is to bundle them into the counterterm together with the pole. That bundling is precisely the modified minimal-subtraction prescription fixed for the whole book in Chapter A: by Theorem A.49 the $\overline{\mathrm{MS}}$ counterterm removes not the bare pole but the combination

$$\frac{1}{\bar{\varepsilon}} \;\equiv\; \frac{1}{\varepsilon} - \gamma_{\mathrm{E}} + \ln 4\pi, \tag{D.135}$$

which is Eq. (A.204), the universal bracket isolated in (D.134).

We keep $\bar{\varepsilon}$, not a new symbol

The combination $\frac{1}{\varepsilon} - \gamma_{\mathrm{E}} + \ln 4\pi$ recurs so relentlessly that it deserves a name, and the book's name for it is $1/\bar{\varepsilon}$, fixed in Eq. (A.204). We use that symbol here and nowhere introduce a second one for the same object; in particular the letter Δ in these sections always means the Feynman-combined mass-squared of (D.111), never the divergent combination, so that no Δ_ε shorthand is used.

The division of (D.134) into a universal piece and a physics-dependent piece is sharp and worth isolating as the operational statement of one-loop renormalization.

Proposition D.31 (Universal pole, scheme-dependent finite part)**.** *The ε-expansion* (D.134) *of the logarithmic master integral* (D.133) *splits as*

$$\mu^{2\varepsilon}\int \frac{\mathrm{d}^d\ell}{(2\pi)^d}\,\frac{1}{(\ell^2 - \Delta + i\epsilon)^2} = \frac{i}{(4\pi)^2}\Big[\frac{1}{\bar{\varepsilon}} + \ln\frac{\mu^2}{\Delta}\Big] + O(\varepsilon), \tag{D.136}$$

in which the $1/\bar{\varepsilon}$ pole part is independent of the kinematics Δ and is the same in every renormalizable theory, while the finite part $\ln(\mu^2/\Delta)$ carries all the dependence on masses and external momenta and is what survives $\overline{MS}$ subtraction. Equivalently, in the $\bar{\mu}$ variable of Theorem A.50, $\bar{\mu}^2 = 4\pi\mu^2 e^{-\gamma_{\mathrm{E}}}$, the right-hand side reads $\frac{i}{(4\pi)^2}\left[\frac{1}{\varepsilon} + \ln(\bar{\mu}^2/\Delta)\right]$, the bare pole accompanied by a logarithm of the modified scale.

Proof. Insert (D.134) into the right-hand side of (D.133) and read off the two pieces by the definition (D.135) of $1/\bar{\varepsilon}$. The $\bar{\mu}$ form is the algebraic identity $\frac{1}{\varepsilon} - \gamma_{\mathrm{E}} + \ln 4\pi + \ln(\mu^2/\Delta) = \frac{1}{\varepsilon} + \ln(\bar{\mu}^2/\Delta)$ established in Theorem A.50, with $\ln \bar{\mu}^2 = \ln 4\pi - \gamma_{\mathrm{E}} + \ln \mu^2$. □

Why the pole must be universal and the finite part must not be

The split in Theorem D.31 is not an accident of the calculation but a structural feature with physical meaning, and it explains why $\overline{\mathrm{MS}}$ is a sensible thing to do at all. A counterterm is a local term added to the Lagrangian; it is a polynomial in fields and momenta with no logarithms, because the Lagrangian is local. The divergent part of a diagram must therefore be a pure pole times a polynomial — it cannot contain $\ln \Delta$, since Δ depends on external momenta in a way no local counterterm could reproduce. This is why the $\ln(\mu^2/\Delta)$ in (D.136) is automatically finite and the divergence is automatically a kinematics-free constant: locality forces it. The freedom in a renormalization scheme is exactly the freedom to move a *constant* (here $-\gamma_{\mathrm{E}} + \ln 4\pi$, or any other) from the finite part into the counterterm, since a constant is a legitimate local term; what no scheme can touch is the logarithm, whose μ-dependence is therefore physical and is precisely what the renormalization group of Chapter 24 tracks. The pole is universal because locality says it must be; the finite part is scheme-dependent because constants are ambiguous; the logarithm is sacred because it is the only piece that carries genuine physics.

D.5.4 The fully expanded scalar bubble

We now run the entire machine on the integral the loop chapters meet first: the scalar two-point bubble. It is the $n = 2$ master integral with a Feynman parameter not yet integrated, and exhibiting the $\mu^{2\varepsilon}$ cancellation in full is the cleanest demonstration of the scale's role.

Consider the scalar bubble with two propagators of mass m and external momentum p flowing through,

$$B(p^2) \;\equiv\; \mu^{2\varepsilon}\int \frac{\mathrm{d}^d k}{(2\pi)^d}\,\frac{1}{(k^2 - m^2 + i\epsilon)\big((k+p)^2 - m^2 + i\epsilon\big)}. \tag{D.137}$$

Combine the two denominators with the Feynman-parameter identity Eq. (D.17), $\frac{1}{AB} = \int_0^1 \mathrm{d}x\,[xA+(1-x)B]^{-2}$, and complete the square. With $A=(k+p)^2-m^2$ and $B=k^2-m^2$,

$$xA+(1-x)B = k^2+2x\,k\cdot p+xp^2-m^2 = (k+xp)^2-\big[m^2-x(1-x)p^2\big], \tag{D.138}$$

so shifting $\ell = k+xp$ (a translation of a dimensionally regularized integral, hence with unit Jacobian and no surface term — a property established in Section D.4) brings (D.137) to the standard form

$$B(p^2) = \mu^{2\varepsilon}\int_0^1 \mathrm{d}x \int \frac{\mathrm{d}^d\ell}{(2\pi)^d}\,\frac{1}{(\ell^2-\Delta+i\epsilon)^2}, \qquad \Delta = m^2-x(1-x)\,p^2. \tag{D.139}$$

The inner integral is exactly (D.136). Inserting it and pulling the ε-expansion through the (finite, ε-independent) Feynman integral,

$$B(p^2) = \frac{i}{(4\pi)^2}\int_0^1 \mathrm{d}x\Big[\frac{1}{\bar\varepsilon}+\ln\frac{\mu^2}{\Delta}\Big]+O(\varepsilon) = \frac{i}{(4\pi)^2}\Big[\frac{1}{\bar\varepsilon}-\int_0^1 \mathrm{d}x\,\ln\frac{\Delta}{\mu^2}\Big]+O(\varepsilon), \tag{D.140}$$

where $\int_0^1 \mathrm{d}x = 1$ has turned the x-independent pole into a bare $1/\bar\varepsilon$ and $\ln(\mu^2/\Delta) = -\ln(\Delta/\mu^2)$ has been flipped to display the standard form. This is the canonical one-loop bubble: a universal $1/\bar\varepsilon$ pole plus the finite part $-\int_0^1 \mathrm{d}x\,\ln(\Delta/\mu^2)$ with $\Delta = m^2-x(1-x)p^2$. Every two-point function in the book is some dressing of (D.140).

Two features deserve emphasis. First, the role of $\mu^{2\varepsilon}$ is now completely explicit: had we omitted it, (D.140) would contain $\ln\Delta$ — the logarithm of a mass-squared, dimensionally illegal — and the ε-expansion would not even be definable, since one cannot Taylor-expand $\Delta^{-\varepsilon}$ about a dimensionful Δ. The single factor $\mu^{2\varepsilon}$, forced on us by coupling promotion (Theorem A.46) and nothing else, converts every loop logarithm into a logarithm of a ratio. The scale μ is not inserted by hand to fix dimensions; it is already present, carried in by the coupling, and the ε-expansion simply reveals it. Second, the finite part is a genuine, computable function of p^2. The Feynman integral $\int_0^1 \mathrm{d}x\,\ln[m^2-x(1-x)p^2]$ can be done in closed form, but it is the input to physics already as a one-dimensional integral, and we evaluate it explicitly for the model next.

Worked Example D.32 (The ϕ^4 bubble to its $\overline{\text{MS}}$ finite part)**.** We complete ϕ^4 theory at the one-loop level, taking up the s-channel bubble whose divergent part was extracted at convention-fixing level in Theorem A.52; here we carry it to the full finite $\overline{\text{MS}}$ result, including its evaluation in closed form and its behaviour above threshold. The model is the real scalar $\mathcal{L} = \frac{1}{2}(\partial\phi)^2 - \frac{1}{2}m^2\phi^2 - \frac{\lambda}{4!}\phi^4$.

The amputated one-loop correction to the four-point function in the s-channel ($s=p^2$ the squared total incoming momentum) is, with two vertices $-i\lambda\mu^{2\varepsilon}$ and symmetry factor $\frac{1}{2}$ and the two propagator numerators contributing $i\cdot i=-1$,

$$i\mathcal{M}_s = \frac{(-i\lambda\mu^{2\varepsilon})^2}{2}\int\frac{\mathrm{d}^dk}{(2\pi)^d}\,\frac{i}{k^2-m^2}\,\frac{i}{(k+p)^2-m^2} = \frac{\lambda^2\mu^{2\varepsilon}}{2}\,B(s), \tag{D.141}$$

the last equality recognizing the integral as $\mu^{-2\varepsilon}\,B(s)\cdot\mu^{2\varepsilon}$, i.e. exactly the bubble (D.137) after one factor $\mu^{2\varepsilon}$ has been kept outside to match the dimension of the tree vertex. Substituting (D.140),

$$i\mathcal{M}_s = \frac{i\lambda^2\mu^{2\varepsilon}}{2(4\pi)^2}\Big[\frac{1}{\bar\varepsilon} - \int_0^1 \mathrm{d}x\,\ln\frac{m^2 - x(1-x)s}{\mu^2}\Big] + O(\varepsilon). \tag{D.142}$$

The $\overline{\text{MS}}$ counterterm removes the $1/\bar\varepsilon$ by construction (Theorem A.49); the renormalized s-channel contribution is the finite remainder

$$i\mathcal{M}_s^{\overline{\text{MS}}} = -\frac{i\lambda^2}{32\pi^2}\int_0^1 \mathrm{d}x\,\ln\frac{m^2 - x(1-x)s}{\mu^2}, \tag{D.143}$$

using $(4\pi)^2 = 16\pi^2$ so that $1/2(4\pi)^2 = 1/32\pi^2$ and setting $\mu^{2\varepsilon}\to 1$ in the now-finite expression.

It remains to do the x-integral. Write $F(s)\equiv\int_0^1 \mathrm{d}x\,\ln[(m^2 - x(1-x)s)/\mu^2]$. Factor the quadratic $m^2 - x(1-x)s = s\,(x-x_+)(x-x_-)\cdot(-1) + \ldots$; more directly, complete the square in the argument, $m^2 - x(1-x)s = \frac{s}{4}\big[(2x-1)^2 + (4m^2/s - 1)\big]$, and substitute $u = 2x-1\in[-1,1]$, $\mathrm{d}x = \frac{1}{2}\mathrm{d}u$:

$$F(s) = \frac{1}{2}\int_{-1}^{1}\mathrm{d}u\,\ln\frac{s}{4\mu^2}\Big[u^2 + \Big(\frac{4m^2}{s} - 1\Big)\Big] = \ln\frac{s}{4\mu^2} + \frac{1}{2}\int_{-1}^{1}\mathrm{d}u\,\ln\left(u^2 + a^2\right), \tag{D.144}$$

with $a^2 \equiv 4m^2/s - 1$. The remaining integral is elementary,

$$\int \mathrm{d}u\,\ln(u^2 + a^2) = u\ln(u^2 + a^2) - 2u + 2a\arctan\frac{u}{a}, \tag{D.145}$$

verified by differentiation, so between ± 1 (the integrand is even, so the result is twice the value of the antiderivative's odd-in-u pieces at $u = 1$),

$$\frac{1}{2}\int_{-1}^{1}\mathrm{d}u\,\ln(u^2 + a^2) = \ln(1 + a^2) - 2 + 2a\arctan\frac{1}{a}. \tag{D.146}$$

Restoring $a^2 = 4m^2/s - 1$, hence $1 + a^2 = 4m^2/s$, and assembling,

$$F(s) = \ln\frac{s}{4\mu^2} + \ln\frac{4m^2}{s} - 2 + 2\sqrt{\frac{4m^2}{s} - 1}\,\arctan\frac{1}{\sqrt{4m^2/s - 1}} = \ln\frac{m^2}{\mu^2} - 2 + 2\,a\arctan\frac{1}{a}, \tag{D.147}$$

the two scale-logarithms combining to the clean $\ln(m^2/\mu^2)$. The renormalized one-loop s-channel amplitude is therefore

$$i\mathcal{M}_s^{\overline{\text{MS}}} = -\frac{i\lambda^2}{32\pi^2}\left[\ln\frac{m^2}{\mu^2} - 2 + 2\sqrt{\tfrac{4m^2}{s} - 1}\,\arctan\frac{1}{\sqrt{4m^2/s - 1}}\right], \tag{D.148}$$

valid for $s < 4m^2$, where $a^2 = 4m^2/s - 1 > 0$ and the arctan is real. The full one-loop vertex is the sum over the three channels s, t, u, each of this form with s replaced by the corresponding Mandelstam invariant, as recorded in Eq. (A.217).

Two carried numbers fall out. The pole of the *summed* amplitude is three times that of (D.142),

$$i\mathcal{M}^{\text{1-loop}}\big|_{\text{pole}} = \frac{3i\lambda^2}{32\pi^2}\,\frac{1}{\bar{\varepsilon}} = \frac{3i\lambda^2}{16\pi^2}\,\frac{1}{2\bar{\varepsilon}}, \tag{D.149}$$

whose residue is the input to the one-loop beta function $\beta_\lambda = 3\lambda^2/16\pi^2$ extracted in Chapter 24: demanding μ-independence of the physical amplitude converts the coefficient of $1/\bar{\varepsilon}$ here into the slope of λ in $\ln\mu$. And the finite part (D.148) furnishes the explicit one-loop logarithm $-\frac{\lambda^2}{32\pi^2}\ln(m^2/\mu^2)$ per channel that the running-coupling solution of Chapter 24 resums. We have thus advanced ϕ^4 theory from a formal Feynman integral to a numerically explicit renormalized amplitude.

The same scalar bubble, dressed with a numerator inherited from the electron loop, is the integral behind the QED vacuum polarization $\Pi(q^2)$ of QED, and every tool needed to expand it is now in hand. The fermion loop produces a rank-two numerator $\ell^\mu\ell^\nu$, but with a single external momentum it is reduced by the symmetric-integration rule Eq. (D.92) of Section D.4 — no full tensor reduction is required — while the Dirac trace that generates it is the owned computation of Chapter 19. We finish the carried QED loop integral here, completing the pole and logarithm of $\Pi(q^2)$ that Chapters 19 and 24 consume.

Worked Example D.33 (QED: the vacuum-polarization pole and logarithm)**.** We continue QED. The one-loop photon self-energy is the single fermion bubble; by the Ward identity proved in Chapter 19 it is transverse,

$$i\Pi^{\mu\nu}(q) = (q^2\eta^{\mu\nu} - q^\mu q^\nu)\, i\Pi(q^2), \tag{D.150}$$

so the would-be quadratic divergence that naive power counting assigns to the diagram cancels and all the content sits in the scalar $\Pi(q^2)$. Carrying out the Dirac trace over the numerator $\mathrm{tr}\big[\gamma^\mu(\not{\ell}+\not{q}+m)\gamma^\nu(\not{\ell}+m)\big]$ with the identities of Section C.6, combining the two denominators with a Feynman parameter exactly as in (D.138), shifting the loop momentum, and reducing the resulting $\ell^\mu\ell^\nu$ by the symmetric-integration replacement Eq. (D.92) — all carried out in full in Chapter 19 — collapse the transverse scalar onto the $\mu^{2\varepsilon}$-dressed bubble carrying the Feynman-parameter weight $x(1-x)$ that the trace supplies,

$$i\Pi(q^2) = -8e^2\,\mu^{2\varepsilon}\int_0^1 \mathrm{d}x\, x(1-x)\int\frac{\mathrm{d}^d\ell}{(2\pi)^d}\,\frac{1}{(\ell^2-\Delta+i\epsilon)^2}, \qquad \Delta = m^2 - x(1-x)\,q^2. \tag{D.151}$$

The only new feature relative to the ϕ^4 bubble is the polynomial weight $x(1-x)$; the divergence is untouched by it. The inner integral with its compensating $\mu^{2\varepsilon}$ is precisely the logarithmic master (D.136), so

$$i\Pi(q^2) = -8e^2\,\frac{i}{(4\pi)^2}\int_0^1 \mathrm{d}x\, x(1-x)\Big[\frac{1}{\bar{\varepsilon}} + \ln\frac{\mu^2}{\Delta}\Big] + O(\varepsilon), \tag{D.152}$$

and stripping the overall i and writing $8e^2/(4\pi)^2 = e^2/2\pi^2 = 2\alpha/\pi$ with $\alpha = e^2/4\pi$,

$$\Pi(q^2) = -\frac{2\alpha}{\pi}\int_0^1 \mathrm{d}x\, x(1-x)\Big[\frac{1}{\bar{\varepsilon}} - \ln\frac{\Delta}{\mu^2}\Big] + O(\varepsilon). \tag{D.153}$$

Both carried QED numbers fall out. With $\int_0^1 x(1-x)\,\mathrm{d}x = \frac{1}{6}$ the pole is

$$\Pi(q^2)\big|_{\text{pole}} = -\frac{2\alpha}{\pi}\cdot\frac{1}{6}\cdot\frac{1}{\varepsilon} = -\frac{\alpha}{3\pi}\frac{1}{\varepsilon}, \tag{D.154}$$

the celebrated $-\alpha/3\pi$ residue of QED vacuum polarization, removed by the photon field-strength counterterm δ_3 of Chapter 19 and converted by Chapter 24 into the QED beta function $\beta_e = e^3/12\pi^2$. The renormalized finite part in $\overline{\text{MS}}$,

$$\widehat{\Pi}(q^2) = \frac{2\alpha}{\pi}\int_0^1 \mathrm{d}x\, x(1-x)\,\ln\frac{m^2 - x(1-x)q^2}{\mu^2}, \tag{D.155}$$

is the scale-dependent screening that turns the Lagrangian charge e into the running coupling $\alpha(q^2)$ assembled in Chapters 19 and 24. The carried QED loop integral is thus delivered as a universal pole plus an explicit logarithm, with the same threshold branch cut at $q^2 = 4m^2$ studied below — there marking the onset of real e^+e^- pair production.

D.5.5 The imaginary part and the branch cut

The finite logarithm $\ln(\Delta/\mu^2)$ in (D.140) hides a discontinuity that is invisible at $\Delta > 0$ but is the seat of all the physics of particle production. The Feynman-combined mass-squared $\Delta = m^2 - x(1-x)p^2$ is positive when p^2 is small or spacelike, but for timelike p^2 large enough it can turn negative: since $x(1-x)$ ranges up to $\frac{1}{4}$ at $x = \frac{1}{2}$, Δ first reaches zero, for some x, when $p^2 = 4m^2$ — the two-particle production threshold. Above it, $\ln\Delta$ is the logarithm of a negative number and acquires an imaginary part. Which imaginary part is not a matter of choice: it is fixed by the $i\epsilon$ carried from the propagators all the way through the calculation.

Proposition D.34 (Branch of the logarithm and the discontinuity)**.** *Tracking the Feynman $i\epsilon$ of (D.111) through the ε-expansion, the mass-squared enters the finite part as $\Delta - i\epsilon$, and the logarithm is the boundary value of the principal branch approached from below the cut. Hence*

$$\ln(\Delta - i\epsilon) = \ln|\Delta| - i\pi\,\theta(-\Delta), \qquad \textit{i.e.} \qquad \operatorname{Im}\ln(\Delta - i\epsilon) = -\pi\,\theta(-\Delta), \tag{D.156}$$

and the discontinuity of the logarithm across the negative-Δ axis is

$$\operatorname{disc}_\Delta \ln\Delta \;\equiv\; \ln(\Delta - i\epsilon) - \ln(\Delta + i\epsilon) = -2\pi i\,\theta(-\Delta). \tag{D.157}$$

Proof. The master integral (D.111) carries the propagator prescription $\ell^2-\Delta+i\epsilon$, which after the Wick rotation and the radial integration of Section D.4 leaves the dependence $\Delta^{-(n-d/2)} \to (\Delta - i\epsilon)^{-(n-d/2)}$: the $+i\epsilon$ on the denominator is equivalent, for the purpose of the resulting power of Δ, to giving Δ a negative infinitesimal imaginary part, because $\ell^2 - \Delta + i\epsilon = \ell^2 - (\Delta - i\epsilon)$. Expanding $(\Delta - i\epsilon)^{-\varepsilon} = 1 - \varepsilon \ln(\Delta - i\epsilon) + O(\varepsilon^2)$ therefore produces $\ln(\Delta - i\epsilon)$ in the finite part. Now $\Delta - i\epsilon$ lies just below the real axis. For $\Delta > 0$ it is at argument 0^- and $\ln(\Delta - i\epsilon) = \ln \Delta$ is real. For $\Delta < 0$ it lies just below the negative real axis, at argument $-\pi$ (approached from below, the principal branch $\arg \in (-\pi, \pi]$ gives $-\pi$, not $+\pi$), so

$$\ln(\Delta - i\epsilon) = \ln|\Delta| + i \arg(\Delta - i\epsilon) = \ln|\Delta| - i\pi \qquad (\Delta < 0), \tag{D.158}$$

which combines with the $\Delta > 0$ case into (D.156). The discontinuity (D.157) follows by repeating the argument for $\Delta + i\epsilon$, which sits just above the negative axis at argument $+\pi$ and gives $\ln(\Delta + i\epsilon) = \ln|\Delta| + i\pi$ for $\Delta < 0$; subtracting, $\ln(\Delta - i\epsilon) - \ln(\Delta + i\epsilon) = -2\pi i$ there and zero for $\Delta > 0$. □

Applied to the bubble (D.140), Theorem D.34 says the finite part develops an imaginary piece exactly when $\Delta(x) = m^2 - x(1-x)p^2$ goes negative for some $x \in [0,1]$, i.e. for $p^2 > 4m^2$. There the imaginary part is the measure of the x-interval on which $\Delta < 0$, weighted by the π of (D.156):

$$\operatorname{Im}\Big[-\int_0^1 \mathrm{d}x\, \ln\frac{\Delta - i\epsilon}{\mu^2}\Big] = \pi \int_0^1 \mathrm{d}x\, \theta(x(1-x)p^2 - m^2) = \pi\sqrt{1 - \frac{4m^2}{p^2}}\;\theta(p^2 - 4m^2), \tag{D.159}$$

the last step solving $x(1-x)p^2 = m^2$ for the endpoints $x_\pm = \tfrac{1}{2}(1 \pm \sqrt{1 - 4m^2/p^2})$ and taking their separation $x_+ - x_- = \sqrt{1 - 4m^2/p^2}$. The square-root threshold factor is the unmistakable signature of two-body phase space opening up; it is plotted in Fig. D.6, where the imaginary part is seen to switch on precisely at $p^2 = 4m^2$ and grow as $\sqrt{1 - 4m^2/p^2}$.

The cut is the production of real particles

The appearance of an imaginary part above $p^2 = 4m^2$ is not a mathematical curiosity but the statement that the intermediate two-particle state in the loop can go on shell — the virtual pair becomes a real pair — once enough energy is available. Unitarity ties this directly to a physical rate. The optical theorem, stated in Chapter 5 from $\mathbf{S}^\dagger\mathbf{S} = \mathbf{1}$ and turned into a statement about a single loop integral in Section D.8.5, equates twice the imaginary part of a forward amplitude to a total cross section (or, for a self-energy, to a decay/production rate); equivalently the discontinuity (D.157) of a loop integral across its threshold cut equals the phase-space integral of the squared sub-amplitude for producing the on-shell intermediate state,

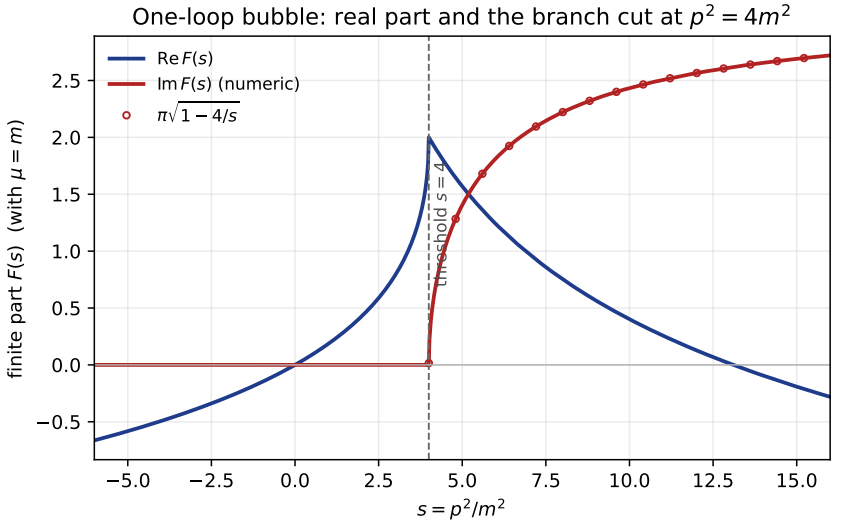

Figure D.6: The finite part $F(s)$ of the equal-mass one-loop bubble (D.140) as a function of $s = p^2/m^2$, with $\mu = m$. The real part (blue) is smooth across all s and grows logarithmically; the imaginary part (red) vanishes identically below the two-particle threshold $s = 4$ and, above it, follows the phase-space factor $\pi\sqrt{1-4/s}$ of (D.159) (open circles). The branch cut along $p^2 > 4m^2$ is the analytic shadow of the on-shell intermediate state, and its discontinuity is fixed by the optical theorem.

summed over that state. The factor $\sqrt{1-4m^2/p^2}$ in (D.159) is exactly the two-body phase-space volume the optical theorem predicts. The explicit check — that the discontinuity of the QED vacuum polarization computed by these methods reproduces the e^+e^- production cross section of Chapter 18 — is carried out in Chapter 19; here we have shown where the imaginary part comes from and that the $i\epsilon$ fixes its sign to be the one unitarity demands.

With the master integral now reduced to a numerically explicit Laurent series — a universal $1/\bar{\varepsilon}$ pole, a finite logarithm of Δ/μ^2 ready to be absorbed into counterterms or read as a physical running, and an imaginary part that switches on at threshold with the phase-space factor unitarity demands — the scalar one-loop technology is complete. The vacuum polarization just completed needed only the single-momentum symmetric integration of Section D.4; what this technology does not yet handle is a loop momentum in the numerator with free Lorentz indices contracted against *several* independent external momenta, as in the vertex correction, the box of $e^+e^- \to \mu^+\mu^-$, or any diagram with several

external legs: those tensor integrals must first be reduced to the scalar masters of this section. That reduction — decomposing a tensor integral onto a basis of external momenta and the metric, contracting to form a linear system, and inverting it at the price of a Gram determinant — is the subject of the next section.

D.6 Tensor reduction: the Passarino–Veltman algorithm

The master integrals assembled and ε-expanded in the previous sections are *scalar*: their numerators are unity. Real diagrams are not so kind. A photon–electron vertex, a triangle in ϕ^4 with derivative couplings, a box in $e^+e^- \to \mu^+\mu^-$ all produce loop integrands whose numerators carry the loop momentum ℓ with free Lorentz indices, contracted against gamma matrices and external momenta. A one-loop self-energy in QED already does this: the two fermion propagators put two powers of $\not{\ell}$ in the numerator. The question this section answers is how to convert such a tensor integral — an integral of $\ell^{\mu_1}\cdots\ell^{\mu_r}$ over a product of denominators — into the scalar masters we have already evaluated, with no new integration. The method is due to Passarino and Veltman: write the integral as the most general tensor its Lorentz structure permits, contract that ansatz with the available tensors (external momenta and the metric) to turn it into a linear system for the scalar coefficients, and solve the system. The solution divides by the determinant of the system — the *Gram determinant* of the external momenta — and we will flag honestly what that division costs when the kinematics degenerate.

D.6.1 The generic one-loop integral and the reduction philosophy

Fix the generic one-loop tensor integral with N denominators and rank r,

$$I_N^{\mu_1\cdots\mu_r} = \mu^{2\varepsilon}\int \frac{d^d\ell}{(2\pi)^d}\,\frac{\ell^{\mu_1}\cdots\ell^{\mu_r}}{D_0\,D_1\cdots D_{N-1}}, \qquad D_i = (\ell + k_i)^2 - m_i^2 + i\epsilon, \quad k_0 = 0, \tag{D.160}$$

where the k_i are partial sums of external momenta and $\mu^{2\varepsilon}$ is the dimensionful bookkeeping factor introduced in Section D.5. The whole reduction rests on a single elementary observation, which we call the *denominator identity*. Any scalar product of the loop momentum with an external momentum, and the square ℓ^2 itself, can be written as a linear combination of the denominators D_i plus constants, because the D_i are themselves quadratic in ℓ. Concretely, from $D_i - D_0 = (\ell + k_i)^2 - m_i^2 - \ell^2 + m_0^2$ we read off

$$2\,k_i\cdot\ell = D_i - D_0 - (k_i^2 + m_0^2 - m_i^2), \qquad \ell^2 = D_0 + m_0^2. \tag{D.161}$$

When such a combination appears in the numerator, each D_i it produces *cancels* the corresponding denominator, lowering both the rank and the number of propagators: the integral collapses onto a sub-integral with one fewer denominator. This is why the reduction terminates on scalars, and why those scalars have fewer propagators than the integral one started with. The Passarino–Veltman algorithm is the systematic bookkeeping of Eq. (D.161) organised so that the cancellation is automatic.

Notation Watch

We use the standard Passarino–Veltman names for the scalar coefficient functions: A for the one-point (tadpole) family, B for the two-point, C for the three-point, D for the four-point. Subscripts label the tensor coefficient: a single index i multiplies one power of external momentum, a double index a product, and the index 0 on a doubled slot (B_{00}, C_{00}) is reserved for the coefficient of the metric $\eta^{\mu\nu}$. All carry the measure and $\mu^{2\varepsilon}$ of Eq. (D.160), matching the scalar masters A_0, B_0, C_0, D_0 of Section D.5.

D.6.2 The two-point family: B^μ and $B^{\mu\nu}$

The cleanest place to see the machine work in full is the two-point family, which depends on a single external momentum p and two masses. Set $D_0 = \ell^2 - m_0^2$ and $D_1 = (\ell + p)^2 - m_1^2$, and define

$$\{B_0;\, B^\mu;\, B^{\mu\nu}\}(p^2; m_0, m_1) = \mu^{2\varepsilon} \int \frac{d^d\ell}{(2\pi)^d} \frac{\{1;\, \ell^\mu;\, \ell^\mu \ell^\nu\}}{D_0\, D_1}. \tag{D.162}$$

The only Lorentz-covariant vectors available to build B^μ are p^μ; the only symmetric tensors available for $B^{\mu\nu}$ are $p^\mu p^\nu$ and $\eta^{\mu\nu}$. Hence the integrals must take the form

$$B^\mu = p^\mu\, B_1, \tag{D.163}$$

$$B^{\mu\nu} = \eta^{\mu\nu}\, B_{00} + p^\mu p^\nu\, B_{11}. \tag{D.164}$$

These are exact statements about the integrals, not approximations: B^μ is a Lorentz vector built from the single vector p^μ on which the integrand depends, so it is proportional to p^μ; the scalar coefficients B_1, B_{00}, B_{11} are functions of the invariants p^2, m_0, m_1 alone. Our task is to express them through B_0 and the tadpole $A_0(m) = \mu^{2\varepsilon} \int \frac{d^d\ell}{(2\pi)^d}\, (\ell^2 - m^2)^{-1}$ of Section D.5.

Rank one. Contract Eq. (D.163) with p_μ:

$$p^2\, B_1 = p_\mu B^\mu = \mu^{2\varepsilon} \int \frac{d^d\ell}{(2\pi)^d} \frac{p \cdot \ell}{D_0 D_1}. \tag{D.165}$$

Now apply the denominator identity Eq. (D.161) with $k_1 = p$. Writing $f \equiv p^2 + m_0^2 - m_1^2$,

$$p \cdot \ell = \tfrac{1}{2}(D_1 - D_0 - f), \tag{D.166}$$

so that

$$p^2 B_1 = \tfrac{1}{2}\,\mu^{2\varepsilon} \int \frac{d^d\ell}{(2\pi)^d}\, \frac{D_1 - D_0 - f}{D_0 D_1} = \tfrac{1}{2}\left[\mu^{2\varepsilon} \int \frac{d^d\ell}{(2\pi)^d} \frac{1}{D_0} - \mu^{2\varepsilon} \int \frac{d^d\ell}{(2\pi)^d} \frac{1}{D_1} - f\, B_0\right]. \tag{D.167}$$

In the first integral D_1 has cancelled, leaving $\int 1/D_0 = A_0(m_0)$. In the second D_0 has cancelled, leaving $\int 1/D_1$; shifting $\ell \to \ell - p$ turns D_1 into $\ell^2 - m_1^2$, so this is $A_0(m_1)$ (a tadpole is translation invariant). Therefore

$$\boxed{B_1(p^2; m_0, m_1) = \frac{1}{2p^2}\Big[\, A_0(m_0) - A_0(m_1) - (p^2 + m_0^2 - m_1^2) B_0 \,\Big].} \tag{D.168}$$

The factor $1/p^2$ in front is the two-point Gram determinant: p^2 is the determinant of the 1×1 Gram matrix $(p \cdot p)$ of the single external momentum. As a sanity check, when the masses are equal, $m_0 = m_1 = m$, the two tadpoles cancel and $f = p^2$, giving $B_1 = -\tfrac{1}{2} B_0$ with no leftover $1/p^2$ singularity, as it must be by the $\ell \to -\ell - p$ symmetry of the equal-mass integrand.

Rank two. Now contract the ansatz Eq. (D.164) in the two independent ways. Contracting with $\eta_{\mu\nu}$ uses $\eta_{\mu\nu}\eta^{\mu\nu} = d$ (the d-dimensional metric trace, Eq. (C.185)):

$$\eta_{\mu\nu} B^{\mu\nu} = d\, B_{00} + p^2\, B_{11} = \mu^{2\varepsilon} \int \frac{d^d\ell}{(2\pi)^d}\, \frac{\ell^2}{D_0 D_1}. \tag{D.169}$$

The right-hand side is handled by the scalar part of Eq. (D.161), $\ell^2 = D_0 + m_0^2$:

$$\mu^{2\varepsilon} \int \frac{d^d\ell}{(2\pi)^d}\, \frac{\ell^2}{D_0 D_1} = \mu^{2\varepsilon} \int \frac{d^d\ell}{(2\pi)^d} \frac{1}{D_1} + m_0^2\, B_0 = A_0(m_1) + m_0^2\, B_0. \tag{D.170}$$

Contracting Eq. (D.164) instead with p_μ gives, on the left, $p_\mu B^{\mu\nu} = p^\nu B_{00} + p^2 p^\nu B_{11}$, and on the right

$$p_\mu B^{\mu\nu} = \mu^{2\varepsilon} \int \frac{d^d\ell}{(2\pi)^d}\, \frac{(p \cdot \ell)\, \ell^\nu}{D_0 D_1} = \tfrac{1}{2}\left[\mu^{2\varepsilon} \int \frac{\ell^\nu}{D_0} - \mu^{2\varepsilon} \int \frac{\ell^\nu}{D_1} - f\, B^\nu\right], \tag{D.171}$$

using $p \cdot \ell = \tfrac{1}{2}(D_1 - D_0 - f)$ once more. The first integral, $\int \ell^\nu / D_0$, vanishes: it is odd in ℓ with a single mass scale and no external vector to align with. The second is $\int \ell^\nu / D_1 = -p^\nu A_0(m_1)$ by the shift used above. Hence $p_\mu B^{\mu\nu} = p^\nu\, \tfrac{1}{2}[A_0(m_1) - f\, B_1]$, and matching the p^ν coefficients,

$$B_{00} + p^2 B_{11} = \tfrac{1}{2}\big[A_0(m_1) - f\, B_1\big]. \tag{D.172}$$

We now have two linear equations, Eq. (D.169) and Eq. (D.172), for the two unknowns B_{00} and B_{11}. Subtracting Eq. (D.172) from Eq. (D.169) eliminates B_{11}:

$$(d-1)\,B_{00} = A_0(m_1) + m_0^2 B_0 - \tfrac{1}{2}\big[A_0(m_1) - f B_1\big] = \tfrac{1}{2}A_0(m_1) + m_0^2 B_0 + \tfrac{1}{2} f B_1, \tag{D.173}$$

so that

$$\boxed{B_{00} = \frac{1}{2(d-1)}\Big[A_0(m_1) + 2m_0^2 B_0 + (p^2 + m_0^2 - m_1^2) B_1\Big].} \tag{D.174}$$

Then Eq. (D.172) delivers the last coefficient:

$$\boxed{B_{11} = \frac{1}{p^2}\Big[\tfrac{1}{2}(A_0(m_1) - f B_1) - B_{00}\Big].} \tag{D.175}$$

Two features deserve comment, because they recur in every higher reduction. First, the metric coefficient B_{00} comes out with a factor $1/(d-1)$ but *no* factor $1/p^2$: it is finite as $p^2 \to 0$ and carries the genuine ultraviolet divergence of the rank-two integral (the A_0 and B_0 inside it both have $1/\varepsilon$ poles). Second, the momentum coefficient B_{11}, like B_1, divides by the Gram determinant p^2. The metric direction is always benign; the momentum directions always carry the Gram denominator. With B_1 from Eq. (D.168) substituted, Eqs. (D.174) and (D.175) express the complete rank-two two-point integral through the single scalar bubble B_0 and the tadpoles A_0, with no integration left to do.

D.6.3 The three-point family and the Gram determinant

The three-point family makes the Gram determinant visible as a genuine matrix determinant rather than a single invariant. Take denominators $D_0 = \ell^2 - m_0^2$, $D_1 = (\ell + p_1)^2 - m_1^2$, $D_2 = (\ell + p_2)^2 - m_2^2$ with two independent external momenta p_1, p_2, and define

$$\{C_0;\, C^\mu;\, C^{\mu\nu}\} = \mu^{2\varepsilon} \int \frac{d^d\ell}{(2\pi)^d} \frac{\{1;\, \ell^\mu;\, \ell^\mu \ell^\nu\}}{D_0\, D_1\, D_2}, \tag{D.176}$$

all functions of the invariants $p_1^2, p_2^2, (p_1 - p_2)^2$ and the masses. The covariant decompositions, built from the two vectors p_1^μ, p_2^μ and the metric, are

$$C^\mu = p_1^\mu\, C_1 + p_2^\mu\, C_2, \tag{D.177}$$

$$C^{\mu\nu} = \eta^{\mu\nu}\, C_{00} + p_1^\mu p_1^\nu\, C_{11} + p_2^\mu p_2^\nu\, C_{22} + (p_1^\mu p_2^\nu + p_2^\mu p_1^\nu)\, C_{12}. \tag{D.178}$$

Rank one: the Gram system. Contract Eq. (D.177) with $p_{1\mu}$ and with $p_{2\mu}$. The left-hand sides are

$$\begin{pmatrix} p_1^2 & p_1\cdot p_2 \\ p_1\cdot p_2 & p_2^2 \end{pmatrix}\begin{pmatrix} C_1 \\ C_2 \end{pmatrix} = \begin{pmatrix} R_1 \\ R_2 \end{pmatrix}, \qquad R_i \equiv p_{i\mu}\, C^\mu = \mu^{2\varepsilon}\int \frac{d^d\ell}{(2\pi)^d}\,\frac{p_i\cdot\ell}{D_0 D_1 D_2}. \tag{D.179}$$

The matrix on the left is the *Gram matrix* $G_{ij} = p_i\cdot p_j$ of the external momenta. Its inverse is what the reduction needs, and its determinant

$$\det G = p_1^2\,p_2^2 - (p_1\cdot p_2)^2 \tag{D.180}$$

is the Gram determinant of the two-momentum kinematics. The right-hand sides R_i are evaluated by the denominator identity, $p_1\cdot\ell = \tfrac12(D_1 - D_0 - f_1)$ and $p_2\cdot\ell = \tfrac12(D_2 - D_0 - f_2)$ with

$$f_1 \equiv p_1^2 + m_0^2 - m_1^2, \qquad f_2 \equiv p_2^2 + m_0^2 - m_2^2. \tag{D.181}$$

Substituting and cancelling denominators,

$$R_1 = \tfrac12\left[\mu^{2\varepsilon}\int\frac{1}{D_0 D_2} - \mu^{2\varepsilon}\int\frac{1}{D_1 D_2} - f_1\, C_0\right] = \tfrac12\left[B_0^{(1)} - B_0^{(0)} - f_1\, C_0\right], \tag{D.182}$$

$$R_2 = \tfrac12\left[\mu^{2\varepsilon}\int\frac{1}{D_0 D_1} - \mu^{2\varepsilon}\int\frac{1}{D_1 D_2} - f_2\, C_0\right] = \tfrac12\left[B_0^{(2)} - B_0^{(0)} - f_2\, C_0\right], \tag{D.183}$$

where $B_0^{(i)}$ denotes the scalar bubble obtained by *pinching* (deleting) propagator i from the triangle: $B_0^{(0)} = \int 1/(D_1 D_2) = B_0((p_1-p_2)^2; m_1, m_2)$, $B_0^{(1)} = \int 1/(D_0 D_2) = B_0(p_2^2; m_0, m_2)$, and $B_0^{(2)} = \int 1/(D_0 D_1) = B_0(p_1^2; m_0, m_1)$, each reduced to standard form by the same shifts as before. The right-hand sides are thus made entirely of the scalar triangle C_0 and lower bubbles — objects we have already evaluated. Inverting the 2×2 Gram system Eq. (D.179) gives the coefficients in closed form,

$$\boxed{C_1 = \frac{p_2^2\, R_1 - (p_1\cdot p_2)\, R_2}{\det G}, \qquad C_2 = \frac{-(p_1\cdot p_2)\, R_1 + p_1^2\, R_2}{\det G},} \tag{D.184}$$

with $\det G$ from Eq. (D.180). This is the promised explicit appearance of the Gram determinant in the denominator of the reduced coefficients. The rank-two coefficients $C_{00}, C_{11}, C_{22}, C_{12}$ are obtained by exactly the same two-step procedure — contract Eq. (D.178) with $\eta_{\mu\nu}$ (which produces C_{00} free of any Gram denominator, again the carrier of the ultraviolet pole) and with $p_{1\mu}, p_{2\mu}$ (which produce 2×2 Gram systems for the pairs $\{C_{11}, C_{12}\}$ and $\{C_{12}, C_{22}\}$), each time using Eq. (D.161) to reduce the right-hand sides to the already-known C^μ, the pinched two-point tensors $B^{(i)}$, and C_0. We do not write the dozen resulting lines out here; the algorithm is mechanical once Eq. (D.184) is understood, and the worked example below exercises precisely the pieces a real diagram needs.

Caution: the price of the inversion

The factor $1/\det G$ in Eq. (D.184) is the honest cost of tensor reduction. When the external momenta become linearly dependent — $p_2 \to x\, p_1$ for some scalar x, i.e. a forward, collinear, or otherwise degenerate configuration — the Gram determinant Eq. (D.180) vanishes, $\det G = p_1^2 p_2^2 - (p_1 \cdot p_2)^2 \to 0$, while the numerators R_i do not generically vanish in the same way. The reduced coefficients C_1, C_2 then appear to blow up. This singularity is *spurious*: the tensor integral C^μ is perfectly finite at degenerate kinematics, and the apparent pole cancels among the scalar functions inside $p_2^2 R_1 - (p_1 \cdot p_2) R_2$ in the exact limit. But the cancellation is between large numbers, so a numerical evaluation near $\det G = 0$ suffers catastrophic loss of precision. This Gram-determinant problem is the standard practical obstruction to Passarino–Veltman reduction; the modern remedy is to expand around the degenerate point or to use integrand-level (unitarity-based) reduction instead, the subject of Chapter 60. For the analytic one-loop computations of this book the limits are taken in closed form and the cancellation is exact.

D.6.4 Completeness: everything reduces to A_0, B_0, C_0, D_0

The two- and three-point cases exhibit the entire pattern, and the same two moves — decompose into a covariant basis, then contract and solve — reduce the four-point (box) tensors $D^\mu, D^{\mu\nu}, D^{\mu\nu\rho}$ to the scalar box D_0 and lower functions, the Gram matrix now being the 3×3 matrix of three independent external momenta. We can state the general result.

Proposition D.35 (One-loop reduction)**.** *Every one-loop integral of the form Eq. (D.160), with any rank r and any number N of denominators, reduces in $d = 4 - 2\varepsilon$ dimensions to a finite linear combination of the scalar master integrals A_0, B_0, C_0, D_0, with coefficients that are rational functions of the external invariants, the masses, and d. In strictly four dimensions ($\varepsilon \to 0$) no scalar integral beyond the box D_0 is needed.*

Argument. Two independent reductions act. *Rank reduction*: each free index μ_j on the numerator ℓ^{μ_j} is removed by contracting the covariant ansatz with the basis tensors and applying the denominator identity Eq. (D.161) to the resulting scalar products $k_i \cdot \ell$ and squares ℓ^2. Every term so produced either cancels a denominator (lowering N) or is the metric coefficient (which closes on lower-rank functions). Iterating drives the rank to zero. *Propagator reduction*: a scalar integral with N denominators carries $N - 1$ independent external momenta. In $d = 4$ at most four vectors can be linearly independent, so for $N \geq 6$ the external momenta are necessarily dependent and the $(N-1)$-dimensional

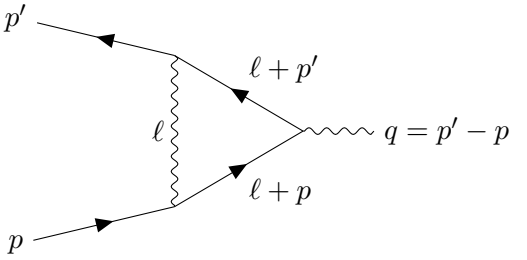

Figure D.7: The one-loop QED vertex. The electron enters with momentum p, exits with p', and the external photon injects $q = p' - p$ at the vertex on the fermion line. The internal photon carries loop momentum ℓ; the two fermion segments carry $\ell + p$ and $\ell + p'$. The three denominators are $D_0 = \ell^2$, $D_1 = (\ell + p)^2 - m^2$, $D_2 = (\ell + p')^2 - m^2$, the three-point family of Eq. (D.176) with $m_0 = 0$, $m_1 = m_2 = m$ and $p_1 = p$, $p_2 = p'$.

Gram determinant vanishes identically; the corresponding scalar integral is then expressible through integrals with fewer denominators. The pentagon, $N = 5$, is the boundary case: its Gram determinant is generically nonzero, but in exactly four dimensions the scalar pentagon reduces to a sum of five scalar boxes up to terms of order ε, which vanish at one loop as $\varepsilon \to 0$. Hence the four scalar masters span everything. The order-ε remainder of the pentagon reduction is genuine and must be retained when the box coefficients themselves carry $1/\varepsilon$ poles, as happens at higher loop order or in ε-dimensional unitarity; we flag this honestly and defer its systematic treatment to Chapter 60. □

This is the structural payoff of the section: the Feynman rules of any one-loop diagram, however many indices and momenta they carry, feed into a finite catalogue of four scalar functions whose ε-expansions are tabulated in Section D.5. The only remaining subtlety, taken up in the next section, is to tell which of the resulting $1/\varepsilon$ poles are ultraviolet and which are infrared.

D.6.5 QED: reducing the one-loop vertex

We now carry the photon–electron vertex to the scalar level, the computation Chapters 19 and 20 need for the Ward identity and for Schwinger's anomalous moment $a_e = \alpha/2\pi$. This advances QED from the tree amplitudes of Chapters 17 and 18 to its first form factors.

Worked Example D.36 (Passarino–Veltman reduction of the QED vertex)**.** With the routing of Fig. D.7 and in Feynman gauge ($\xi = 1$, the photon propagator $-i\eta_{\alpha\beta}/\ell^2$ of Chapter 13), the amputated one-loop vertex correction $-ie\,\Lambda^\mu$ is

the integral

$$\Lambda^{\mu} = -ie^{2}\,\mu^{2\varepsilon}\int \frac{d^{d}\ell}{(2\pi)^{d}}\,\frac{N^{\mu}}{\ell^{2}\left[(\ell+p)^{2}-m^{2}\right]\left[(\ell+p')^{2}-m^{2}\right]}, \tag{D.185}$$

where collecting the three vertex factors $(-ie\gamma)$, the two fermion numerators, and the photon propagator gives the overall constant $-ie^{2}$, and the Dirac numerator is the gamma sandwich

$$N^{\mu} = \gamma^{\alpha}\,(\not{\ell}+\not{p}'+m)\,\gamma^{\mu}\,(\not{\ell}+\not{p}+m)\,\gamma_{\alpha}. \tag{D.186}$$

We use the massless photon ($m_0 = 0$), letting the dimensional regulator ε also control the infrared singularity that the photon mass would otherwise screen; this is exactly the dual UV/IR role of ε taken up in the next section. The electron is on shell, $p^{2} = p'^{2} = m^{2}$, with $\not{p}\,u(p) = m\,u(p)$ and $\bar{u}(p')\not{p}' = m\,\bar{u}(p')$ understood once the structure is sandwiched between spinors.

Step 1: collapse the gamma sandwich. Abbreviate $a \equiv \ell + p'$, $b \equiv \ell + p$, and expand Eq. (D.186):

$$N^{\mu} = \gamma^{\alpha}\not{a}\,\gamma^{\mu}\not{b}\,\gamma_{\alpha} + m\,\gamma^{\alpha}\not{a}\,\gamma^{\mu}\gamma_{\alpha} + m\,\gamma^{\alpha}\gamma^{\mu}\not{b}\,\gamma_{\alpha} + m^{2}\,\gamma^{\alpha}\gamma^{\mu}\gamma_{\alpha}. \tag{D.187}$$

The contracted strings are reduced by the d-dimensional contraction identities of Section C.6, in the continued forms Eqs. (C.187) to (C.190): $\gamma^{\alpha}\gamma^{\mu}\gamma_{\alpha} = (2-d)\gamma^{\mu}$, $\gamma^{\alpha}\gamma^{\nu}\gamma^{\mu}\gamma_{\alpha} = 4\eta^{\nu\mu}\mathbf{1} - (4-d)\gamma^{\nu}\gamma^{\mu}$, and $\gamma^{\alpha}\gamma^{\nu}\gamma^{\mu}\gamma^{\rho}\gamma_{\alpha} = -2\gamma^{\rho}\gamma^{\mu}\gamma^{\nu} + (4-d)\gamma^{\nu}\gamma^{\mu}\gamma^{\rho}$. Applying these term by term,

$$m^{2}\,\gamma^{\alpha}\gamma^{\mu}\gamma_{\alpha} = -(d-2)\,m^{2}\,\gamma^{\mu}, \tag{D.188}$$

$$m\,\gamma^{\alpha}\not{a}\,\gamma^{\mu}\gamma_{\alpha} = m\big[4a^{\mu} - (4-d)\,\not{a}\,\gamma^{\mu}\big], \tag{D.189}$$

$$m\,\gamma^{\alpha}\gamma^{\mu}\not{b}\,\gamma_{\alpha} = m\big[4b^{\mu} - (4-d)\,\gamma^{\mu}\not{b}\big], \tag{D.190}$$

$$\gamma^{\alpha}\not{a}\,\gamma^{\mu}\not{b}\,\gamma_{\alpha} = -2\,\not{b}\,\gamma^{\mu}\not{a} + (4-d)\,\not{a}\,\gamma^{\mu}\not{b}. \tag{D.191}$$

Collecting, with $d = 4 - 2\varepsilon$ so that $4 - d = 2\varepsilon$ and $d - 2 = 2(1-\varepsilon)$,

$$N^{\mu} = -2\,\not{b}\,\gamma^{\mu}\not{a} + 4m\,(a^{\mu}+b^{\mu}) - 2(1-\varepsilon)\,m^{2}\,\gamma^{\mu} + 2\varepsilon\big[\not{a}\,\gamma^{\mu}\not{b} - m\,(\not{a}\,\gamma^{\mu} + \gamma^{\mu}\not{b})\big]. \tag{D.192}$$

The terms carrying an explicit 2ε cannot be dropped: multiplied against the $1/\varepsilon$ pole of the ultraviolet-divergent part of the integral they leave a finite remainder, exactly the mechanism flagged in Section C.7.3. Substituting $a = \ell + p'$, $b = \ell + p$ shows N^{μ} is a polynomial in ℓ of degree two: rank zero, one, and two pieces, which the integral Eq. (D.185) turns into C_0, C^{μ}, and $C^{\mu\nu}$ respectively, all in the family of Eq. (D.176) with $m_0 = 0$, $m_1 = m_2 = m$, $p_1 = p$, $p_2 = p'$.

Step 2: read off the rank-two piece. The highest-rank structure sits in $-2\,\not{b}\,\gamma^{\mu}\not{a}$. Writing $\not{b}\,\gamma^{\mu}\not{a} = (\not{\ell}+\not{p})\,\gamma^{\mu}(\not{\ell}+\not{p}')$ and isolating the part quadratic in ℓ,

$$\not{\ell}\,\gamma^{\mu}\not{\ell} = \ell_{\nu}\ell_{\rho}\,\gamma^{\nu}\gamma^{\mu}\gamma^{\rho} \;\longmapsto\; \gamma^{\nu}\gamma^{\mu}\gamma^{\rho}\,C_{\nu\rho}, \tag{D.193}$$

where under the integral $\ell_\nu \ell_\rho \to C_{\nu\rho}$ is the rank-two three-point tensor. Inserting its decomposition Eq. (D.178), the metric piece alone gives

$$\gamma^\nu \gamma^\mu \gamma^\rho \, \eta_{\nu\rho} \, C_{00} = \gamma^\nu \gamma^\mu \gamma_\nu \, C_{00} = (2-d)\, \gamma^\mu \, C_{00} = -2(1-\varepsilon)\, \gamma^\mu \, C_{00}, \tag{D.194}$$

using Eq. (C.188) again. This is the decisive line. The coefficient C_{00} is the metric coefficient of the three-point family — the analogue of B_{00} in Eq. (D.174) — and like B_{00} it is the *only* reduced coefficient that is ultraviolet divergent, carrying a $1/\varepsilon$ pole, with *no* Gram denominator. Equation (D.194) shows that this pole lands entirely on the Dirac structure γ^μ. The remaining rank-two pieces of $C_{\nu\rho}$ (the $p_i^\nu p_j^\rho$ terms with coefficients C_{11}, C_{22}, C_{12}, divided by $\det G$ per Eq. (D.184)) and the rank-one and rank-zero pieces are all ultraviolet finite.

Step 3: organise into form factors. Sandwiching the reduced numerator between $\bar{u}(p')$ and $u(p)$, using $\not{p}\, u = m\, u$, $\bar{u}'\not{p}' = m\, \bar{u}'$, the anticommutator $\{\gamma^\mu, \gamma^\nu\} = 2\eta^{\mu\nu}$, and the Gordon identity

$$\bar{u}(p')\, \gamma^\mu \, u(p) = \bar{u}(p') \left[\frac{(p+p')^\mu}{2m} + \frac{i\sigma^{\mu\nu} q_\nu}{2m} \right] u(p), \qquad q = p' - p, \tag{D.195}$$

every term collapses onto exactly two independent on-shell structures, γ^μ and $i\sigma^{\mu\nu}q_\nu/2m$ (equivalently $(p+p')^\mu/2m$). The vertex therefore takes the form-factor form

$$\bar{u}(p')\, \Gamma^\mu \, u(p) = \bar{u}(p') \left[\gamma^\mu \, F_1(q^2) + \frac{i\sigma^{\mu\nu} q_\nu}{2m} \, F_2(q^2) \right] u(p), \tag{D.196}$$

where $\Gamma^\mu = \gamma^\mu + \Lambda^\mu$ at this order, and the form factors are the linear combinations of scalar functions produced by the reduction:

$$F_1(q^2) = 1 + \frac{e^2}{(4\pi)^{d/2}} \left[\#\, C_{00} + \#\, C_0 + \#\, C_i + \#\, B_0^{(i)} \right], \qquad F_2(q^2) = \frac{e^2}{(4\pi)^{d/2}} \left[\#\, C_0 + \#\, C_i + \#\, C_{ij} \right] \tag{D.197}$$

the symbols $\#$ standing for the definite rational coefficients (functions of m^2, q^2, d) generated by Steps 1–2 and the Gram inversion. The structural content, which is what this section is responsible for, is the *separation* visible in Eq. (D.197): F_1 contains C_{00} and hence the $1/\varepsilon$ ultraviolet pole, which is removed by the vertex (equivalently, by Ward, the field-strength) counterterm of Chapter 19; F_2 is built only from the ultraviolet-finite scalar functions C_0, C_i, C_{ij} and is therefore finite and unambiguous — it is a clean prediction with no counterterm freedom. Evaluating those scalar functions at $q^2 = 0$ and extracting the finite number is the task of Chapter 20, which obtains $F_2(0) = a_e = \alpha/2\pi$. We note the consistency of Theorem D.36 with the Gram-determinant caution above: at $q^2 = 0$ the three-point Gram determinant Eq. (D.180) reads $\det G = p^2 p'^2 - (p\cdot p')^2 = \frac{q^2}{4}(4m^2 - q^2) \to 0$, so the individual coefficients C_i, C_{ij} carry spurious $1/q^2$ singularities; that they cancel to leave the finite a_e is the explicit, physical instance of the spurious-pole cancellation the caution promised.

With every one-loop tensor integrand now reduced to the scalar masters A_0, B_0, C_0, D_0, the perturbative calculation is purely arithmetic: substitute the ε-expansions of Section D.5 and collect. The single remaining conceptual question is the provenance of the $1/\varepsilon$ poles that survive — whether a given pole signals an ultraviolet divergence to be absorbed by renormalization or an infrared divergence destined to cancel against real emission — and it is to that distinction, and to dimensional regularization in its second guise as an infrared regulator, that we turn next.

D.7 Infrared and collinear singularities; dimensional regularization as an IR regulator

The tensor reduction of Section D.6 delivered every one-loop integral of a realistic diagram as a linear combination of the scalar masters evaluated earlier in this appendix. Those masters carry $1/\varepsilon$ poles, and the natural reflex—trained by the power-counting of Chapter 21—is to read every pole as ultraviolet, a signal that some short-distance region of the loop integration diverges and must be absorbed into a counterterm. That reflex is wrong in general. Among the scalar integrals that survive reduction are some that are ultraviolet *convergent* and yet still produce $1/\varepsilon$: their poles come not from the region of large loop momentum but from regions where an internal line goes on shell over a finite stretch of the integration—a photon becoming soft, or a massless pair of momenta becoming collinear. The same analytic continuation in d that we introduced to tame the ultraviolet turns out to regulate these long-distance, infrared (IR) singularities as well. This is the dual role of dimensional regularization flagged in the chapter introduction, and this section is where we pay it off: we classify $1/\varepsilon$ poles by their physical origin, fix the sign of ε that regulates each, prove that the scaleless integral vanishes precisely because a UV pole and an IR pole cancel, evaluate a representative IR-divergent master in full, and then explain—at the level of precise statements, with the QED computation set up explicitly—how IR poles disappear from physical cross sections once virtual and real-emission contributions are summed. Throughout we keep the standing conventions of Chapter A: mostly-minus metric, Feynman $i\varepsilon$ in propagators, $d = 4 - 2\varepsilon$, the loop-measure bookkeeping factor $\mu^{2\varepsilon}$, and $\overline{\text{MS}}$.

D.7.1 The two origins of a $1/\varepsilon$ pole and the sign of ε

Every $1/\varepsilon$ pole in a dimensionally regulated integral is the failure of an ordinary integral to converge at one end of its range, exposed by analytic continuation in the dimension. The cleanest place to see both failure modes at once is the radial behaviour of a Euclidean loop integral. After Wick rotation (Section D.3) and the angular integration $\int d^d\ell_E = \frac{2\pi^{d/2}}{\Gamma(d/2)} \int_0^\infty d\ell_E\, \ell_E^{d-1}$, a scalar integrand that

behaves as a power ℓ_E^{-2n} contributes a radial integral

$$\int_0^\infty d\ell_E \, \ell_E^{d-1-2n}, \tag{D.198}$$

and this single integral encodes both diseases. At the upper end $\ell_E \to \infty$—the *ultraviolet* region of short distances—the integrand decays fast enough to converge if and only if $d - 1 - 2n < -1$, that is

$$\text{UV convergence:} \qquad d < 2n \quad \Longleftrightarrow \quad \varepsilon > \tfrac{4-2n}{2} \ \ (\text{e.g. } \varepsilon > 0 \text{ for } 2n = 4). \tag{D.199}$$

At the lower end $\ell_E \to 0$—the *infrared* region of long distances, reached physically when the integrand's power growth there is generated by a propagator sitting near its mass shell—the integral converges if and only if $d - 1 - 2n > -1$, that is

$$\text{IR convergence:} \qquad d > 2n \quad \Longleftrightarrow \quad \varepsilon < \tfrac{4-2n}{2} \ \ (\text{e.g. } \varepsilon < 0 \text{ for } 2n = 4). \tag{D.200}$$

The two requirements are mutually exclusive: no single real d makes Eq. (D.198) converge at both ends unless one of the two power behaviours is absent. Dimensional regularization defines the answer by analytic continuation from whichever region of d the relevant end converges in, and the resulting pole at $d = 2n$ is *ultraviolet* when reached from $d < 2n$ (small d) and *infrared* when reached from $d > 2n$ (large d). With the standard parametrization $d = 4 - 2\varepsilon$, a logarithmically UV-divergent integral ($2n = 4$) is regulated by $d < 4$, i.e. $\varepsilon > 0$, while a logarithmically IR-divergent one is regulated by $d > 4$, i.e. $\varepsilon < 0$. Ultraviolet poles want d *below* four; infrared poles want d *above* four. This is the single most important sentence of the section, and it forces a bookkeeping discipline.

Notation Watch

A bare symbol ε cannot simultaneously be positive (to regulate the UV) and negative (to regulate the IR). In dimensional regularization there is nonetheless only *one* dimension $d = 4 - 2\varepsilon$ and one ε; the resolution is that any given pole is reached by continuation from one side, and the Laurent coefficient is unambiguous once the integral is defined by continuation from its region of convergence. To keep the physics legible we tag a pole by its origin: we write $1/\varepsilon_{\mathrm{UV}}$ for a pole generated by the large-ℓ region (continued from $\varepsilon > 0$) and $1/\varepsilon_{\mathrm{IR}}$ for one generated by an on-shell region (continued from $\varepsilon < 0$). The tags are bookkeeping, not separate variables: numerically $\varepsilon_{\mathrm{UV}} = \varepsilon_{\mathrm{IR}} = \varepsilon$, and at the very end all poles are the same ε. The tags matter because UV poles are removed by counterterms (renormalization, Chapter 22) whereas IR poles must cancel against real emission (this section); confusing the two corrupts both the renormalization constants and the finite remainder. When a single integral carries both, as in Theorem D.37 below, we must keep the tags distinct

until the cancellation is exhibited.

D.7.2 The scaleless integral: a UV pole cancelling an IR pole

The most economical illustration of the two-origin structure is an integral with *no* scale: there is no mass, no external invariant, nothing for the answer to depend on. Such integrals occur constantly—massless on-shell self-energies, and any tadpole left after a propagator's mass is set to zero, reduce to them—and the rule that disposes of them is one line: a scaleless integral vanishes in dimensional regularization. The rule is true, but the reason is not that "nothing diverges." It is that a genuine ultraviolet divergence is being silently cancelled by a genuine infrared one, and we now prove exactly that.

Theorem D.37 (Vanishing of the scaleless integral)**.** *For any integer n and any d for which the expression is defined by analytic continuation,*

$$\int \frac{d^d\ell}{(2\pi)^d}\,\frac{1}{(\ell^2)^n} = 0, \tag{D.201}$$

and the vanishing is the cancellation of a $1/\varepsilon_{\mathrm{UV}}$ pole against a $1/\varepsilon_{\mathrm{IR}}$ pole of equal magnitude and opposite sign.

Proof. Wick-rotate to Euclidean signature, $\ell^0 = i\ell_E^0$, under which $\ell^2 \to -\ell_E^2$ and $d^d\ell \to i\,d^d\ell_E$, so the integral equals $i(-1)^n$ times the Euclidean integral $\int \frac{d^d\ell_E}{(2\pi)^d}(\ell_E^2)^{-n}$. Performing the angular integral leaves the radial integral Eq. (D.198) up to the positive constant $\frac{1}{(2\pi)^d}\frac{2\pi^{d/2}}{\Gamma(d/2)}$, which never vanishes and never introduces a pole at $d = 2n$; the entire content is in

$$R \equiv \int_0^\infty d\ell_E\, \ell_E^{d-1-2n}. \tag{D.202}$$

There is no value of d for which R converges, by the discussion of Eqs. (D.199) and (D.200). To define it we split the range at an arbitrary fiducial scale $\Lambda > 0$ and continue each piece from its own region of convergence:

$$R = \underbrace{\int_0^\Lambda d\ell_E\, \ell_E^{d-1-2n}}_{R_{\mathrm{IR}}} + \underbrace{\int_\Lambda^\infty d\ell_E\, \ell_E^{d-1-2n}}_{R_{\mathrm{UV}}}. \tag{D.203}$$

The lower piece R_{IR} converges at $\ell_E \to 0$ for $d > 2n$, where it evaluates to

$$R_{\mathrm{IR}} = \frac{\Lambda^{\,d-2n}}{d-2n} \qquad (\text{continued from } d > 2n), \tag{D.204}$$

with a pole at $d \to 2n^+$: this is the infrared pole, $R_{\mathrm{IR}} \sim 1/\varepsilon_{\mathrm{IR}}$ up to the constant relating $d - 2n$ to ε. The upper piece R_{UV} converges at $\ell_E \to \infty$ for $d < 2n$, where

$$R_{\mathrm{UV}} = \Big[\frac{\ell_E^{\,d-2n}}{d-2n}\Big]_{\Lambda}^{\infty} = \frac{-\Lambda^{\,d-2n}}{d-2n} = \frac{\Lambda^{\,d-2n}}{2n-d} \qquad \text{(continued from } d < 2n\text{)}, \tag{D.205}$$

with a pole at $d \to 2n^-$: the ultraviolet pole, $R_{\mathrm{UV}} \sim 1/\varepsilon_{\mathrm{UV}}$. Both expressions are now rational functions of d, analytic away from $d = 2n$, so their sum may be taken at common d:

$$R = R_{\mathrm{IR}} + R_{\mathrm{UV}} = \frac{\Lambda^{\,d-2n}}{d-2n} + \frac{\Lambda^{\,d-2n}}{2n-d} = \frac{\Lambda^{\,d-2n}}{d-2n} - \frac{\Lambda^{\,d-2n}}{d-2n} = 0. \tag{D.206}$$

The fiducial scale Λ has dropped out, as it must—the original integral knew of no scale—and the result is identically zero for all d, not merely at $d = 4$. Crucially, R vanishes because the residue of its UV pole is exactly minus the residue of its IR pole: writing $d - 2n = -2\delta$ near the singular dimension, $R_{\mathrm{UV}} = -\Lambda^{-2\delta}/2\delta \to -1/2\delta$ and $R_{\mathrm{IR}} = \Lambda^{-2\delta}/(2\delta) \to +1/2\delta$ as $\delta \to 0$. The zero in Eq. (D.201) is therefore the statement

$$\frac{1}{\varepsilon_{\mathrm{UV}}} - \frac{1}{\varepsilon_{\mathrm{IR}}} = 0 \qquad \text{(numerically, since } \varepsilon_{\mathrm{UV}} = \varepsilon_{\mathrm{IR}}\text{)}, \tag{D.207}$$

not the absence of divergence. □

The practical force of Theorem D.37 is twofold and opposite, and both directions are used later in the book. When a scaleless integral appears inside a finite physical quantity, one is free to drop it, knowing the discarded UV and IR poles were equal and opposite. But when one is computing a renormalization constant—an object that is, by construction, pure pole—the cancellation is a trap: the massless on-shell wavefunction renormalization Z_2 and the photon field renormalization receive contributions from integrals that vanish by Theorem D.37, and reading "= 0" as "no renormalization" would be a sign error. The honest statement keeps the tags,

$$\int \frac{d^d\ell}{(2\pi)^d}\,\frac{1}{(\ell^2)^n} \;\longrightarrow\; \frac{1}{\varepsilon_{\mathrm{UV}}} - \frac{1}{\varepsilon_{\mathrm{IR}}}, \tag{D.208}$$

so that the $1/\varepsilon_{\mathrm{UV}}$ is available to cancel a counterterm and the $1/\varepsilon_{\mathrm{IR}}$ is available to cancel a real-emission pole, even though their sum is zero. This is exactly the bookkeeping that makes the on-shell renormalization of massless QED and QCD consistent (Chapters 19 and 27).

Physical Insight

The cancellation in Eq. (D.206) is not a coincidence of dimensional regularization; it is the statement that, with no scale in the problem, "large momentum" and "small momentum" are not invariantly distinguishable. Any rescaling $\ell \to \kappa \ell$ is a symmetry of the integrand up to the overall power κ^{d-2n}, and a scale-invariant quantity that is also homogeneous of nonzero degree can only be zero. Dimensional regularization makes this visible by separating the two ends of the scaling and showing they are negatives of each other. The moment a scale is restored—a mass, an external virtuality—the two ends decouple, the UV pole stays (to be renormalized) and the IR pole either stays (to be cancelled by real emission) or is rendered finite, and the integral no longer vanishes.

D.7.3 A worked infrared master: the massless triangle

To see an unambiguous infrared pole—one that cannot be mistaken for ultraviolet—we evaluate an integral that is ultraviolet *convergent* by power counting and yet diverges, entirely from on-shell regions. The cleanest such master is the massless scalar triangle with two light-like external legs, which is precisely the scalar integral that the Passarino–Veltman reduction of the one-loop QED and Yang–Mills vertices deposits whenever the external fermions or gluons can be treated as massless. Its superficial degree of divergence is $d - 6 = -2 - 2\varepsilon < 0$, so every $1/\varepsilon$ it produces is infrared, and we will see it carry a *double* pole: the simultaneous soft and collinear singularity that is the hallmark of massless gauge theory.

Worked Example D.38 (The massless one-loop triangle and its double IR pole)**.** Evaluate, with $p_1^2 = p_2^2 = 0$ and the single invariant $s \equiv (p_1 + p_2)^2 = 2p_1 \cdot p_2$,

$$I_3 = \mu^{2\varepsilon} \int \frac{d^d \ell}{(2\pi)^d} \, \frac{1}{(\ell^2 + i\varepsilon)\,((\ell + p_1)^2 + i\varepsilon)\,((\ell - p_2)^2 + i\varepsilon)}. \tag{D.209}$$

Feynman parametrization. Using the three-denominator identity of Section D.2,

$$\frac{1}{ABC} = 2 \int_0^1 dx\, dy\, dz\; \delta(1 - x - y - z)\, \frac{1}{[\,xA + yB + zC\,]^3}, \tag{D.210}$$

with $A = \ell^2$, $B = (\ell + p_1)^2$, $C = (\ell - p_2)^2$. Because $p_1^2 = p_2^2 = 0$ the linear-in-p terms are all that survive in B and C:

$$xA + yB + zC = \ell^2 + 2\ell \cdot (yp_1 - zp_2) = \big(\ell + yp_1 - zp_2\big)^2 - \big(yp_1 - zp_2\big)^2. \tag{D.211}$$

The shift constant is $(yp_1 - zp_2)^2 = y^2 p_1^2 - 2yz\, p_1 \cdot p_2 + z^2 p_2^2 = -yz\, s$, so with $\ell' = \ell + yp_1 - zp_2$ the denominator becomes $\ell'^2 - \Delta$ with $\Delta = -yz\, s$.

Momentum integral. The shifted integral is the master of Theorem D.22 at $n = 3$,

$$\int \frac{d^d\ell'}{(2\pi)^d}\,\frac{1}{(\ell'^2 - \Delta + i\varepsilon)^3} = \frac{-\,i}{(4\pi)^{d/2}}\,\frac{\Gamma(3-\frac{d}{2})}{\Gamma(3)}\,\Delta^{\,d/2-3} = \frac{-\,i}{(4\pi)^{2-\varepsilon}}\,\frac{\Gamma(1+\varepsilon)}{2}\,\Delta^{-1-\varepsilon}, \tag{D.212}$$

where $\Delta^{-1-\varepsilon} = (-yz\,s)^{-1-\varepsilon} = (-s)^{-1-\varepsilon}(yz)^{-1-\varepsilon}$, the factor $(-s)^{-1-\varepsilon}$ carrying the branch cut that, continued to $s > 0$, supplies the physical imaginary part. Collecting the prefactors and the bookkeeping $\mu^{2\varepsilon}$,

$$I_3 = \frac{-\,i\,\Gamma(1+\varepsilon)}{(4\pi)^{2-\varepsilon}}\,\mu^{2\varepsilon}\,(-s)^{-1-\varepsilon}\,J, \qquad J \equiv \int_0^1 dx\,dy\,dz\;\delta(1-x-y-z)\,(yz)^{-1-\varepsilon}. \tag{D.213}$$

The Feynman-parameter integral is where the IR poles live. Doing the x integral against the delta function sets $x = 1-y-z$ over the simplex $y, z \geq 0$, $y + z \leq 1$:

$$J = \int_0^1 dy\; y^{-1-\varepsilon} \int_0^{1-y} dz\; z^{-1-\varepsilon}. \tag{D.214}$$

The inner integral $\int_0^{1-y} z^{-1-\varepsilon}dz = (1-y)^{-\varepsilon}/(-\varepsilon)$ converges at $z \to 0$ *only for* $\Re\varepsilon < 0$, i.e. $d > 4$: this is the infrared regulator at work, exactly the sign of Eq. (D.200). Hence

$$J = -\frac{1}{\varepsilon}\int_0^1 dy\; y^{-1-\varepsilon}(1-y)^{-\varepsilon} = -\frac{1}{\varepsilon}\,B(-\varepsilon,\,1-\varepsilon) = -\frac{1}{\varepsilon}\,\frac{\Gamma(-\varepsilon)\,\Gamma(1-\varepsilon)}{\Gamma(1-2\varepsilon)}, \tag{D.215}$$

the second factor of $y^{-1-\varepsilon}$ again convergent at $y \to 0$ only for $\Re\varepsilon < 0$, the second IR singularity. Using $\Gamma(-\varepsilon) = -\Gamma(1-\varepsilon)/\varepsilon$,

$$J = \frac{1}{\varepsilon^2}\,\frac{\Gamma(1-\varepsilon)^2}{\Gamma(1-2\varepsilon)}. \tag{D.216}$$

The two convergence conditions have produced the two factors of $1/\varepsilon$.

Result. Substituting Eq. (D.216) into Eq. (D.213) and grouping the Γ's into the ubiquitous one-loop constant $c_\Gamma \equiv \Gamma(1+\varepsilon)\Gamma(1-\varepsilon)^2/\Gamma(1-2\varepsilon)$,

$$\boxed{\,I_3 = \frac{-\,i\,c_\Gamma}{(4\pi)^2}\,\frac{1}{(-s)}\,\frac{1}{\varepsilon^2}\left(\frac{4\pi\mu^2}{-s}\right)^{\varepsilon}.\,} \tag{D.217}$$

The pole structure is laid bare by expanding $c_\Gamma = 1 - \gamma_E\,\varepsilon + (\frac{\gamma_E^2}{2} - \frac{\pi^2}{12})\varepsilon^2 + O(\varepsilon^3)$ and $(4\pi\mu^2/(-s))^{\varepsilon} = 1 + \varepsilon\ln\frac{4\pi\mu^2}{-s} + \ldots$, after which the standard $\overline{\text{MS}}$ rescaling $\mu^2 \to \mu^2 e^{\gamma_E}/4\pi$ (Chapter A) removes the 4π and γ_E—the product $c_\Gamma\,(4\pi\mu^2/(-s))^{\varepsilon}$ collapsing to $(1 - \frac{\pi^2}{12}\varepsilon^2)$ times powers of $\ln(-s/\mu^2)$—leaving

$$I_3 = \frac{-\,i}{(4\pi)^2}\,\frac{1}{(-s)}\left[\frac{1}{\varepsilon_{\text{IR}}^2} - \frac{1}{\varepsilon_{\text{IR}}}\,\ln\frac{-s}{\mu^2} + \frac{1}{2}\ln^2\frac{-s}{\mu^2} - \frac{\pi^2}{12} + \ldots\right]. \tag{D.218}$$

Both poles are infrared—the integral was UV-finite by power counting, and both factors of $1/\varepsilon$ traced to ℓ-regions where an internal line went on shell. The $1/\varepsilon^2$ is the simultaneous soft ($\ell \to 0$) and collinear ($\ell \parallel p_1$ or $\ell \parallel p_2$) singularity, the double logarithm $\frac{1}{2}\ln^2(-s/\mu^2)$ its finite shadow; these are the Sudakov double logarithms that govern the high-energy behaviour of every gauge-theory form factor.

Two features of Eq. (D.217) deserve emphasis. First, the scale dependence enters only through the ratio $(-s)/\mu^2$, exactly because the bookkeeping factor $\mu^{2\varepsilon}$ was attached: an IR pole multiplies $\ln(-s/\mu^2)$ just as a UV pole multiplies $\ln(\mu^2/\text{mass}^2)$, and the sign of the accompanying logarithm is the operational fingerprint of the pole's origin. Second, if either external leg is taken off shell, $p_1^2 \neq 0$, the collinear singularity it carried is screened: the corresponding factor in J becomes $\int_0^1 dy\, y^{-1-\varepsilon}(\cdots)$ with the $y \to 0$ endpoint cut off by the new scale, the double pole softens to a single pole, and a logarithm of the off-shellness appears in its place. The same screening happens for a massive internal line—the electron mass in QED cuts off the collinear region—which is why the QED vertex of Chapter 20 carries only a single $1/\varepsilon_{\text{IR}}$ (soft, no collinear), whereas the massless Yang–Mills vertices of Chapters 27 and 28 carry the full double pole. Mass is the physical IR cutoff that dimensional regularization replaces by ε.

D.7.4 Infrared cancellation: Bloch–Nordsieck and KLN

The infrared poles of Eq. (D.217) are not artefacts of regularization to be subtracted by a counterterm—there is no local operator whose insertion could cancel a $1/\varepsilon_{\text{IR}}$, and a renormalized but IR-divergent amplitude would still predict an infinite cross section. Their resolution is physical: the amplitudes themselves are not measurable. Any real detector has a finite energy resolution and a finite angular resolution, so it cannot distinguish a final state of n hard particles from one of n hard particles accompanied by photons (or gluons) too soft or too collinear to register. The measurable quantity is the *sum* over all such experimentally indistinguishable final states, and in that sum the virtual IR poles cancel against the IR poles of real emission. We state the two theorems that govern this cancellation, then exhibit the mechanism explicitly for the soft photon.

Theorem D.39 (Bloch–Nordsieck)**.** *In QED with massive charged particles, the infrared (soft) divergences arising from virtual photon loops cancel, order by order in α, against the divergences arising from the emission of real soft photons, provided one computes an inclusive transition probability that sums over the emission of any number of photons with total energy below the detector resolution ΔE. The resulting rate is finite as the IR regulator is removed; the $1/\varepsilon_{\text{IR}}$ poles are replaced by finite logarithms of ΔE over the hard scale.*

Theorem D.40 (Kinoshita–Lee–Nauenberg)**.** *In a theory with massless fields, the transition probability summed over all initial and final states that are degenerate in energy (in the limit of vanishing regulator) is free of infrared and mass (collinear) singularities, to all orders in perturbation theory. Bloch–Nordsieck is the special case in which only final-state soft degeneracies occur; with massless charged particles, or when collinear degeneracies are present, the sum over degenerate* initial *states is also required for finiteness.*

The hypotheses are not interchangeable, and the difference is exactly the difference between soft and collinear singularities. Bloch–Nordsieck suffices for an observable like the total cross section for $e^+e^- \to \mu^+\mu^-(+\text{soft } \gamma)$ with massive muons, where only soft singularities arise and summing over final-state photon emission is enough. It *fails* in the presence of collinear singularities from massless charged particles—the classic counterexample is an electron's transition probability in a theory with massless electrons, where final-state summation alone leaves a residual collinear pole and one must also average over the collinear-degenerate initial states, as KLN requires. The practical lesson, made precise in Chapter 28, is that a cross section is guaranteed finite only when the observable it computes is *infrared- and collinear-safe*.

Definition D.41 (Infrared-safe observable)**.** An observable built from final-state momenta is infrared- and collinear-safe if its value is unchanged, in the limit, by (i) the emission of an additional particle with vanishing energy and (ii) the splitting of any particle into two collinear particles carrying its total momentum. Formally, the measurement function $F_n(p_1, \dots, p_n)$ must satisfy $F_{n+1}(\dots, p_{n+1} \to 0) = F_n(\dots)$ and $F_{n+1}(\dots, p_i, p_j \parallel) = F_n(\dots, p_i + p_j)$. Only for such observables do the KLN cancellations occur diagram-class by diagram-class, leaving an IR-finite prediction.

The soft cancellation made explicit

We now demonstrate, for QED, that the virtual soft pole and the real soft pole have equal magnitude and opposite sign, setting up the real-emission phase-space integral whose completion belongs to Section D.8. Consider a charged particle line entering a hard process with momentum p and leaving with momentum p', both on shell, $p^2 = p'^2 = m^2$ (the kinematics of the QED form factor of Chapter 20). In the soft region the emission of a photon of momentum k factorizes: the amplitude with one extra soft photon is the hard amplitude $\mathcal{M}_0$ times the eikonal current,

$$\mathcal{M}_{1\gamma}(k \to 0) \;\longrightarrow\; \mathcal{M}_0 \, e \, \epsilon^*_\mu(k) \, j^\mu(k), \qquad j^\mu(k) = \frac{p'^\mu}{p' \cdot k} - \frac{p^\mu}{p \cdot k}, \tag{D.219}$$

the two terms coming from emission off the outgoing and incoming legs respectively, each the on-shell residue of the nearly-singular fermion propagator after

the spinor algebra collapses (the same eikonal limit that produced the soft part of the loop in Chapter 19). The eikonal current is conserved,

$$k_\mu j^\mu(k) = \frac{p'\cdot k}{p'\cdot k} - \frac{p\cdot k}{p\cdot k} = 1 - 1 = 0, \tag{D.220}$$

which is nothing but charge conservation $\sum_n \eta_n Q_n = 0$ written for the soft photon, and it is the Ward identity that guarantees the construction is gauge-invariant: the longitudinal part of the photon polarization sum, $\sum_\lambda \epsilon^*_\mu \epsilon_\nu = -\eta_{\mu\nu} + (\text{gauge})$, drops out against Eq. (D.220), so the soft factor is unambiguous and the cancellation we are about to display is scheme-independent. This is the precise sense in which the gauge/Ward structure of QED (Chapter 19) underwrites Bloch–Nordsieck.

Real emission. Squaring Eq. (D.219), summing photon polarizations with $-\eta_{\mu\nu}$, and integrating over the d-dimensional one-photon phase space gives the soft real-emission correction to the rate,

$$d\sigma^{\text{soft}}_{\text{real}} = d\sigma_0 \,(-e^2)\int \frac{d^{d-1}k}{(2\pi)^{d-1}\,2\omega_k}\; j(k) j(k), \qquad jj = \frac{m^2}{(p\cdot k)^2} + \frac{m^2}{(p'\cdot k)^2} - \frac{2\,p\cdot p'}{(p\cdot k)(p'\cdot k)}, \tag{D.221}$$

where $\omega_k = |\mathbf{k}|$ for the massless photon and the upper limit of the energy integration is set by the resolution ΔE. The Lorentz-invariant measure $d^{d-1}k/((2\pi)^{d-1}2\omega_k)$ is the d-dimensional one-particle phase space derived in Section D.8; here we need only its soft behaviour. Take the self-energy term $m^2/(p\cdot k)^2$ in the rest frame of p, where $p\cdot k = m\,\omega_k$, so the integrand is ω_k^{-2}, and write $d^{d-1}k = \omega_k^{d-2}\, d\omega_k\, d\Omega_{d-2}$:

$$\int \frac{d^{d-1}k}{(2\pi)^{d-1}2\omega_k}\,\frac{m^2}{(p\cdot k)^2} = \frac{\Omega_{d-2}}{2(2\pi)^{d-1}}\int_0^{\Delta E} d\omega_k\; \omega_k^{d-5} = \frac{\Omega_{d-2}}{2(2\pi)^{d-1}}\,\frac{(\Delta E)^{-2\varepsilon}}{-2\varepsilon}. \tag{D.222}$$

The radial integral $\int_0 \omega_k^{-1-2\varepsilon} d\omega_k$ converges at $\omega_k \to 0$ *only for* $\Re\varepsilon < 0$, i.e. $d > 4$—the infrared regulator, with precisely the sign Eq. (D.200)—and produces an explicit $1/\varepsilon_{\text{IR}}$. The upper cutoff supplies the finite $\ln \Delta E$ promised by Theorem D.39. Restoring $\Omega_{d-2} = 2\pi^{(d-1)/2}/\Gamma(\frac{d-1}{2}) \to 4\pi$ at $d = 4$, this representative term contributes $-\frac{1}{8\pi^2}\frac{1}{\varepsilon_{\text{IR}}} + \dots$ to $j\cdot j$ integrated, and the cross term $2p\cdot p'/((p\cdot k)(p'\cdot k))$ adds the velocity-dependent piece; assembled, Eq. (D.221) yields

$$d\sigma^{\text{soft}}_{\text{real}} = d\sigma_0\,\frac{\alpha}{\pi}\Big(+\frac{1}{\varepsilon_{\text{IR}}}\Big)\, f(v) + (\text{finite}), \tag{D.223}$$

with $f(v)$ the same kinematic function—built from the eikonal integrals of Eq. (D.221)—that appears below in the virtual contribution, v the relative velocity of p and p'.

Virtual correction. The one-loop virtual contribution to the same rate is $d\sigma_{\text{virt}} = 2\, d\sigma_0\, \Re F_1(q^2)$, with F_1 the Dirac form factor of Chapters 19 and 20. Its infrared pole comes entirely from the soft region $\ell \to 0$ of the loop, where the integrand reduces to the *same* eikonal current squared but integrated against the

off-shell photon propagator $i/(\ell^2+i\varepsilon)$ over all of d-dimensional loop momentum rather than over the on-shell phase space:

$$2\,\Re F_1\big|_{\text{soft}} = (-e^2)\,\Re\!\int\!\frac{d^d\ell}{(2\pi)^d}\,\frac{i}{\ell^2+i\varepsilon}\;j(\ell)\cdot j(\ell)+\dots \tag{D.224}$$

The decisive structural fact is that the propagator carries $\Im\big[i/(\ell^2+i\varepsilon)\big]=\pi\,\delta(\ell^2)$: cutting the photon line—putting it on shell, $\ell^2=0$—turns the loop integral Eq. (D.224) into precisely the real-emission phase-space integral Eq. (D.221), the optical-theorem relation that Section D.8.5 establishes between the imaginary part of a loop and a phase-space integral. The same eikonal integrand integrated over the off-shell loop ($d^d\ell$, which by the analysis of Section D.7.1 produces its $1/\varepsilon_{\text{IR}}$ from the soft endpoint with the *opposite* sign to the on-shell phase-space measure $d^{d-1}k/\omega_k$) gives

$$d\sigma_{\text{virt}} = d\sigma_0\,\frac{\alpha}{\pi}\Big(-\frac{1}{\varepsilon_{\text{IR}}}\Big)\,f(v)+(\text{finite}), \tag{D.225}$$

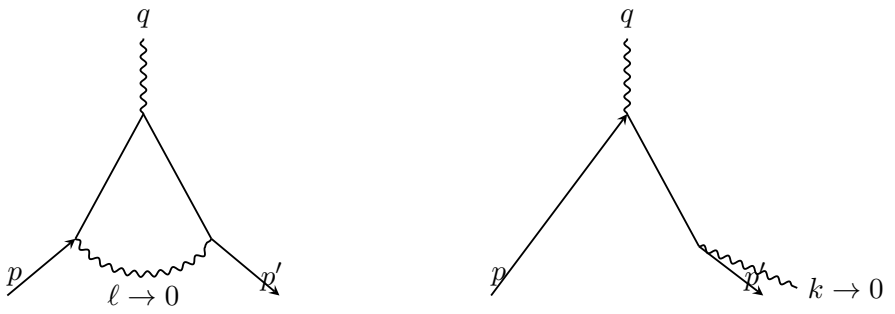
with the identical coefficient $f(v)$ because the soft virtual and soft real contributions are governed by one and the same eikonal current Eq. (D.219). The explicit one-loop evaluation of $f(v)$ is carried out in Chapter 19; here the load-bearing point is the relative sign, which follows from the IR-region analysis of Section D.7.1 and the cut relation above.

Cancellation. Adding Eqs. (D.223) and (D.225),

$$d\sigma_{\text{virt}}+d\sigma_{\text{real}}^{\text{soft}} = d\sigma_0\,\frac{\alpha}{\pi}\,f(v)\Big(-\frac{1}{\varepsilon_{\text{IR}}}+\frac{1}{\varepsilon_{\text{IR}}}\Big)+(\text{finite}) = d\sigma_0\,\frac{\alpha}{\pi}\,f(v)\,\ln\frac{\Delta E}{\dots}+(\text{finite}), \tag{D.226}$$

the $1/\varepsilon_{\text{IR}}$ poles cancel identically, exactly as Eq. (D.207) arranged for the scaleless integral, and the regulator-dependence is replaced by a finite logarithm of the detector resolution ΔE over the hard scale. This is Bloch–Nordsieck made arithmetic, and it is what renders the precision predictions of Chapter 20—the anomalous moment $a_e=\alpha/2\pi$ and the radiatively corrected cross sections—finite, unambiguous numbers. Figure D.8 shows the two diagram classes whose poles cancel.

For Yang–Mills theory the same mechanism operates, but with two complications stated here and developed in Chapters 27 and 28. First, the gluon is itself charged under the gauge group, so the eikonal current is colour-valued and its conservation Eq. (D.220) becomes the covariant statement that the colour charge is conserved at the soft vertex; the polarization sum requires the Faddeev–Popov ghosts of Chapter 26 to remove unphysical states. Second, with massless quarks and gluons the collinear singularities of Theorem D.38 are present in addition to the soft ones, so Bloch–Nordsieck alone is insufficient and the full KLN sum, together with the factorization of collinear poles into parton distributions, is what yields finite, infrared-safe QCD cross sections (Chapter 28). The conceptual



(a) virtual soft photon (b) real soft photon

Figure D.8: The two contributions whose infrared poles cancel in the inclusive rate. In (a) a virtual soft photon of momentum $\ell \to 0$ spans the incoming and outgoing legs of the hard vertex, giving $-\frac{1}{\varepsilon_{\rm IR}} f(v)$ via Eq. (D.224). In (b) a real soft photon of momentum $k \to 0$ is emitted into the unresolved final state, giving $+\frac{1}{\varepsilon_{\rm IR}} f(v)$ via Eq. (D.221). Both are controlled by the same conserved eikonal current Eq. (D.219); their sum Eq. (D.226) is finite. Cutting the internal photon in (a) on shell ($\ell^2 = 0$) turns it into (b)—the optical-theorem relation of Section D.8.5.

content—one ε regulating both UV and IR, virtual poles cancelling real-emission poles in inclusive observables—is identical.

The classification of $1/\varepsilon$ poles is now complete: a pole is ultraviolet (reached from $d < 4$, removed by a counterterm) or infrared (reached from $d > 4$, cancelled between virtual and real emission), and a scaleless integral is the limiting case in which one of each cancels the other. The arithmetic of the cancellation, however, has left one half of the calculation owed: Eqs. (D.221) and (D.223) required the d-dimensional final-state phase-space measure, used so far only in its soft limit. The remaining section builds that measure in closed form—the two-body phase space, the three-body Dalitz region, and the optical-theorem identity that ties the imaginary part of the bubble to two-body phase space and thereby closes the loop on Eq. (D.224)—so that the real-emission integrals set up here can be completed and the cross-check delivered.

D.8 Phase-space integrals in d dimensions

The previous section closed the virtual half of a one-loop calculation: it classified the poles of a loop integral, separated the ultraviolet from the infrared, disposed of the scaleless integral that vanishes because its soft and collinear divergences cancel one another, and explained, at the level of a statement, why the infrared poles of a virtual correction must be cancelled by the emission of soft and collinear

real radiation. That cancellation is a promise the loop chapters cannot keep on their own, because real emission is not a loop integral at all: it is an integral over the momenta of *extra final-state particles*, weighted by the squared matrix element. To discharge the promise we need the second half of the machine — the Lorentz-invariant final-state phase space, built in $d = 4 - 2\varepsilon$ dimensions so that its infrared poles are written in the same regulator as the virtual ones and can be added to them. The same construction does double duty: the two-body phase space in closed form is exactly the kinematic factor that turns the squared amplitude of $e^+e^- \to \mu^+\mu^-$ in Chapter 17 into a cross section, and its analytic structure is the right-hand side of the optical theorem. We therefore build the measure, evaluate the two-body case in full, set up the three-body (Dalitz) phase space and isolate its soft corner, complete the real-emission cancellation, and close the appendix by checking that the imaginary part of the ϕ^4 bubble computed in the ε-expansion section equals precisely the two-body phase-space volume — Cutkosky's rule verified on a single integral, with every factor of i and π tracked.

D.8.1 The Lorentz-invariant phase-space measure in d dimensions

Fix a total incoming four-momentum P (with $P^2 = s > 0$ in the physical region) and consider a final state of n particles with momenta $p_1, \dots, p_n$ and masses $m_1, \dots, m_n$. Each final particle is on shell, $p_i^2 = m_i^2$ with positive energy $p_i^0 = E_i > 0$, and the total four-momentum is conserved. The object that collects these constraints with the correct relativistic normalization is the *Lorentz-invariant phase-space measure*

$$d\Pi_n \;=\; (2\pi)^d\,\delta^d\Big(P - \sum_{i=1}^{n} p_i\Big)\;\prod_{i=1}^{n}\frac{d^{d-1}\mathbf{p}_i}{(2\pi)^{d-1}\,2E_i}\,, \qquad E_i = \sqrt{\mathbf{p}_i^{\,2} + m_i^2}\,. \tag{D.227}$$

This generalizes the four-dimensional measure derived in Chapter 16 by the single replacement $4 \to d$ in every counting of dimensions: each final particle carries a spatial measure $d^{d-1}\mathbf{p}_i$ divided by $(2\pi)^{d-1}$ and by the energy denominator $2E_i$, and overall energy–momentum conservation contributes one factor $(2\pi)^d\,\delta^d(\cdots)$. The bookkeeping is dictated by the relativistic state normalization $\langle \mathbf{p}|\mathbf{p}'\rangle = (2\pi)^{d-1}\,2E_{\mathbf{p}}\,\delta^{d-1}(\mathbf{p}-\mathbf{p}')$ inherited from the canonical quantization of Chapter 9; with this normalization the (2π) factors in Eq. (D.227) are exactly those required for $d\Pi_n$ to combine with a squared invariant amplitude $|\mathcal{M}|^2$ and a flux factor into a frame-independent rate.

The single most useful manipulation is to trade the spatial measure-plus-energy-denominator for a manifestly covariant on-shell delta function. For one particle,

$$\frac{d^{d-1}\mathbf{p}}{(2\pi)^{d-1}\,2E_{\mathbf{p}}} \;=\; \frac{d^d p}{(2\pi)^d}\,(2\pi)\,\delta^+(p^2 - m^2)\,, \qquad \delta^+(p^2-m^2) \equiv \theta(p^0)\,\delta(p^2-m^2)\,. \tag{D.228}$$

The identity is proved by performing the energy integral on the right. Writing $p^2-m^2=(p^0)^2-(\mathbf{p}^2+m^2)=(p^0)^2-E_{\mathbf{p}}^2$ and using $\delta(f(p^0))=\sum_{\text{roots}}|f'|^{-1}\delta(p^0-\text{root})$ with roots $p^0=\pm E_{\mathbf{p}}$,

$$\delta\big((p^0)^2-E_{\mathbf{p}}^2\big)=\frac{1}{2E_{\mathbf{p}}}\Big[\delta(p^0-E_{\mathbf{p}})+\delta(p^0+E_{\mathbf{p}})\Big]\,. \tag{D.229}$$

The factor $\theta(p^0)$ kills the negative-energy root, so $\int dp^0\,(2\pi)\,\delta^+(p^2-m^2)=2\pi/(2E_{\mathbf{p}})$, and dividing by the $(2\pi)^d$ that accompanies d^dp leaves $d^{d-1}\mathbf{p}/[(2\pi)^{d-1}2E_{\mathbf{p}}]$, which is the left-hand side. Each factor on the right of Eq. (D.228) is separately Lorentz invariant: d^dp is invariant under $SO(1,d-1)$, $\delta(p^2-m^2)$ is invariant because p^2 is, and $\theta(p^0)$ is invariant on the forward mass shell because no orthochronous Lorentz transformation can flip the sign of the energy of a timelike or null momentum. Hence $d^{d-1}\mathbf{p}/2E_{\mathbf{p}}$ is Lorentz invariant, the property that gives the measure its name. Substituting Eq. (D.228) into Eq. (D.227) gives the covariant form

$$d\Pi_n \;=\; (2\pi)^d\,\delta^d\Big(P-\sum_i p_i\Big)\,\prod_{i=1}^{n}\frac{d^dp_i}{(2\pi)^d}\,(2\pi)\,\delta^+(p_i^2-m_i^2)\,, \tag{D.230}$$

in which every constraint is an explicit delta function and the only frame-dependent step left to any computation is the choice of how to parametrize the remaining integrations. The total phase-space volume,

$$\Phi_n(s)\;\equiv\;\int d\Pi_n\,, \tag{D.231}$$

is a Lorentz scalar depending on $s=P^2$ and the masses; it carries mass dimension $(n-1)(d-2)-2$, as a quick scaling of Eq. (D.230) confirms, and it is the object the optical theorem and the inclusive rates of Chapter 28 are built from.

D.8.2 Two-body phase space in closed form

The case $n=2$ is the workhorse and the only one needed in closed form. Two final particles of masses m_1,m_2 are produced from P with $P^2=s$. Starting from the covariant measure Eq. (D.230),

$$\Phi_2(s)=\int\frac{d^dp_1}{(2\pi)^d}\frac{d^dp_2}{(2\pi)^d}\,(2\pi)^2\,\delta^+(p_1^2-m_1^2)\,\delta^+(p_2^2-m_2^2)\,(2\pi)^d\,\delta^d(P-p_1-p_2)\,. \tag{D.232}$$

The d-dimensional delta function does the entire p_2 integral, fixing $p_2=P-p_1$ and leaving

$$\Phi_2(s)=(2\pi)^{2-d}\int d^dp_1\;\delta^+(p_1^2-m_1^2)\,\delta^+((P-p_1)^2-m_2^2)\,. \tag{D.233}$$

Work in the centre-of-momentum frame, $P = (\sqrt{s}, \mathbf{0})$, and split $d^d p_1 = dp_1^0\, d^{d-1}\mathbf{p}$. The first delta is dispatched exactly as in Eq. (D.228): it sets $p_1^0 = E_1 = \sqrt{\mathbf{p}^2 + m_1^2}$ and supplies a Jacobian $1/(2E_1)$. With p_1^0 now fixed, the argument of the second delta is a function of the radial variable $|\mathbf{p}|$ alone,

$$(P - p_1)^2 - m_2^2 = s - 2\sqrt{s}\, E_1 + m_1^2 - m_2^2 \;\equiv\; g(|\mathbf{p}|)\,, \tag{D.234}$$

where we used $P \cdot p_1 = \sqrt{s}\, E_1$ and $p_1^2 = m_1^2$. Its derivative is $g'(|\mathbf{p}|) = -2\sqrt{s}\,(dE_1/d|\mathbf{p}|) = -2\sqrt{s}\,|\mathbf{p}|/E_1$, so

$$\delta(g(|\mathbf{p}|)) = \frac{E_1}{2\sqrt{s}\,|\mathbf{p}|}\,\delta(|\mathbf{p}| - |\mathbf{p}|_\star)\,, \tag{D.235}$$

with $|\mathbf{p}|_\star$ the unique positive root of g. Writing the angular part of the spatial measure as $d^{d-1}\mathbf{p} = |\mathbf{p}|^{d-2}\, d|\mathbf{p}|\, d\Omega_{d-1}$, the radial integral collapses against this delta and the two energy Jacobians combine, $1/(2E_1) \times E_1/(2\sqrt{s}\,|\mathbf{p}|_\star) = 1/(4\sqrt{s}\,|\mathbf{p}|_\star)$:

$$\Phi_2(s) = (2\pi)^{2-d}\,\Omega_{d-1}\,\frac{|\mathbf{p}|_\star^{d-3}}{4\sqrt{s}}\,, \qquad \Omega_{d-1} = \int d\Omega_{d-1} = \frac{2\pi^{(d-1)/2}}{\Gamma\!\left(\frac{d-1}{2}\right)}\,, \tag{D.236}$$

where Ω_{d-1} is the surface area of the unit sphere in the $(d-1)$ spatial dimensions, the same angular factor derived in the Wick-rotation section (Eq. (D.63)). The power $|\mathbf{p}|_\star^{d-3}$ is the d-dependent piece: in $d = 4$ it is linear in the centre-of-mass momentum, while away from four dimensions it carries the regulator into the threshold behaviour.

It remains to express the centre-of-mass momentum $|\mathbf{p}|_\star$ through the invariants. The root of g gives the energy of particle 1,

$$E_1 = \frac{s + m_1^2 - m_2^2}{2\sqrt{s}}\,, \tag{D.237}$$

and then $|\mathbf{p}|_\star^2 = E_1^2 - m_1^2 = \dfrac{(s + m_1^2 - m_2^2)^2 - 4s\, m_1^2}{4s}$. The numerator is the Källén triangle function $\lambda(a,b,c) = a^2 + b^2 + c^2 - 2ab - 2bc - 2ca$ introduced with the two-body kinematics of Chapter 16: expanding $(s + m_1^2 - m_2^2)^2 - 4sm_1^2 = s^2 + m_1^4 + m_2^4 - 2sm_1^2 - 2sm_2^2 - 2m_1^2 m_2^2 = \lambda(s, m_1^2, m_2^2)$. Hence

$$|\mathbf{p}|_\star = \frac{\lambda^{1/2}(s, m_1^2, m_2^2)}{2\sqrt{s}}\,, \tag{D.238}$$

which is real precisely above threshold, $\sqrt{s} \geq m_1 + m_2$, where $\lambda \geq 0$. Collecting Eqs. (D.236) and (D.238) gives the two-body phase space in closed form for arbitrary d:

$$\boxed{\Phi_2(s) = \frac{(2\pi)^{2-d}}{4\sqrt{s}}\,\frac{2\pi^{(d-1)/2}}{\Gamma\!\left(\frac{d-1}{2}\right)}\,\left(\frac{\lambda^{1/2}(s, m_1^2, m_2^2)}{2\sqrt{s}}\right)^{d-3}} \tag{D.239}$$

For equal masses $m_1 = m_2 = m$ one has $\lambda(s, m^2, m^2) = s^2 - 4sm^2 = s^2\beta^2$ with the velocity $\beta = \sqrt{1 - 4m^2/s}$, so $|\mathbf{p}|_\star = \tfrac{1}{2}\sqrt{s}\,\beta$ and $\Phi_2 \propto \beta^{\,d-3}$; the threshold vanishing $\beta \to 0$ is softened or sharpened by the regulator, a fact that matters when a phase-space pole multiplies a virtual pole.

Reduction to $d = 4$. Setting $d = 4$ in Eq. (D.239) uses $\Omega_3 = 2\pi^{3/2}/\Gamma(3/2) = 2\pi^{3/2}/(\tfrac{1}{2}\sqrt{\pi}) = 4\pi$ and $(2\pi)^{2-d} = (2\pi)^{-2}$:

$$\Phi_2(s)\Big|_{d=4} = \frac{1}{(2\pi)^2}\,\frac{4\pi}{4\sqrt{s}}\,|\mathbf{p}|_\star = \frac{|\mathbf{p}|_\star}{4\pi\sqrt{s}} = \frac{1}{8\pi}\,\frac{2|\mathbf{p}|_\star}{\sqrt{s}} = \frac{1}{8\pi}\,\frac{\lambda^{1/2}(s, m_1^2, m_2^2)}{s}\,. \tag{D.240}$$

For equal masses this is $\Phi_2 = \beta/8\pi$, and in the massless limit $m \to 0$ it reduces to the familiar $1/8\pi$. The combination $2|\mathbf{p}|_\star/\sqrt{s}$ is the same kinematic factor that appears in the $e^+e^- \to \mu^+\mu^-$ cross section of Chapter 17: undoing the angular integration in Eq. (D.236) gives the differential measure

$$d\Phi_2 = \frac{(2\pi)^{2-d}}{4\sqrt{s}}\,|\mathbf{p}|_\star^{\,d-3}\,d\Omega_{d-1} \xrightarrow{\;d=4\;} \frac{1}{(2\pi)^2}\,\frac{|\mathbf{p}|_\star}{4\sqrt{s}}\,d\Omega = \frac{1}{32\pi^2}\,\frac{2|\mathbf{p}|_\star}{\sqrt{s}}\,d\Omega\,, \tag{D.241}$$

so that the differential cross section is $d\sigma/d\Omega = |\mathcal{M}|^2\,d\Phi_2/(d\Omega\cdot\mathcal{F})$ with the incident flux $\mathcal{F}$ supplied by Chapter 16. This is exactly the $1/64\pi^2 s$ prefactor of the $2 \to 2$ cross section that drives QED, now derived as a special case of the general d-dimensional measure.

Physical Insight

The whole content of two-body phase space is a single number, the centre-of-mass momentum $|\mathbf{p}|_\star$ of Eq. (D.238): it sets the size of the available sphere of directions, and Eq. (D.239) is just "solid angle times a one-dimensional Jacobian." Everything dimension-dependent sits in the angular factor Ω_{d-1} and the power $|\mathbf{p}|_\star^{\,d-3}$. When a $1/\varepsilon$ infrared pole multiplies this measure, it is the d-dependence of these two pieces that decides the finite remainder — which is why the cross section must be assembled in d dimensions and expanded only at the very end.

D.8.3 Three-body phase space and the Dalitz parametrization

Beyond two particles there is no single closed form, but there is an exact recursive structure that reduces every n-body phase space to nested two-body integrals. Inserting into Eq. (D.230) a complete set of states for an intermediate momentum $q = p_1 + \cdots + p_j$, written as $1 = \int \frac{d^dq}{(2\pi)^d}\,(2\pi)^d\delta^d(q - \sum_{i\le j} p_i)$ together with a unit factor $1 = \int \frac{dq^2}{2\pi}\,(2\pi)\,\delta(q^2 - (\text{its value}))$ implemented through the on-shell

decomposition, gives the factorization

$$d\Pi_n(P;p_1,\dots,p_n) = d\Pi_j(q;p_1,\dots,p_j)\,\frac{dq^2}{2\pi}\,d\Pi_{n-j+1}(P;q,p_{j+1},\dots,p_n)\,. \tag{D.242}$$

The invariant q^2 ranges over its kinematically allowed band, and each factor is an honest lower-multiplicity measure of the form already evaluated. For three particles ($n=3$, $j=2$) the recursion expresses $d\Pi_3$ as a two-body decay of P into q and p_3, an integral over the invariant mass $q^2 = s_{12} \equiv (p_1+p_2)^2$, and a two-body decay of q into p_1, p_2:

$$d\Pi_3 = \frac{ds_{12}}{2\pi}\,d\Pi_2(P;q,p_3)\,d\Pi_2(q;p_1,p_2)\,. \tag{D.243}$$

In $d=4$ this collapses to the Dalitz form. Carrying out both two-body angular integrals — using Eq. (D.240) for each and choosing the two independent invariants $s_{12}=(p_1+p_2)^2$ and $s_{23}=(p_2+p_3)^2$ as variables, with the third fixed by $s_{12}+s_{13}+s_{23} = s+m_1^2+m_2^2+m_3^2$ — one finds the flat Dalitz measure

$$d\Phi_3\Big|_{d=4} = \frac{1}{(2\pi)^3}\,\frac{1}{16\,s}\,ds_{12}\,ds_{23}\,. \tag{D.244}$$

The defining feature of the Dalitz plot is that the squared matrix element is the *only* non-constant weight: the phase space itself is uniform in the plane (s_{12},s_{23}), so the density of events directly maps the dynamics. The physical region is the interior of the kinematic boundary on which one of the relative angles reaches ± 1; for three massless final particles it degenerates to the triangle $s_{ij}\geq 0$, $s_{12}+s_{13}+s_{23}=s$ drawn in Fig. D.9.

For the infrared application we do not need the full d-dimensional three-body volume; we need only the behaviour near the boundary, where one emitted massless parton becomes soft or collinear. The recursion Eq. (D.242) isolates this region cleanly: write the emitted parton as particle 3 with momentum k and energy $\omega = |\mathbf{k}|$, and let $s_{12} = (P-k)^2$ be the invariant mass recoiling against it. The soft limit $\omega \to 0$ is the limit $s_{12}\to s$, in which the two-body factor $d\Pi_2(P;q,p_3)$ degenerates to the emission measure $d^{d-1}\mathbf{k}/[(2\pi)^{d-1}2\omega]$ of the single soft parton. This single-emission measure, kept in d dimensions, is the object that supplies the real-emission poles.

D.8.4 The soft region and completion of the infrared cancellation

We can now keep the promise left open by the previous section: that the $1/\varepsilon$ poles of a virtual correction are cancelled by real emission, and that dimensional regularization makes both sides simultaneously finite so that the cancellation is an algebraic identity rather than a hope. The arena is any process with a hard core dressed by the emission of one extra massless gauge boson (a soft

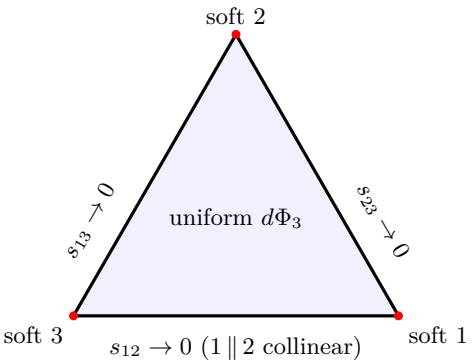


Figure D.9: Massless three-body Dalitz region. Phase space is uniform across the interior, Eq. (D.244). The three edges $s_{ij} \to 0$ are the collinear configurations (two partons parallel); the three corners, where two invariants vanish simultaneously, are the soft configurations (one parton's energy $\to 0$). The infrared poles of an inclusive rate live entirely on this boundary.

photon in QED, a soft gluon in the YM thread) of momentum k. As $k \to 0$ the $(n+1)$-particle amplitude factorizes into the n-particle amplitude times the classical eikonal current: for emission off external lines i carrying charges Q_i, signs $\eta_i = +1$ (outgoing) or -1 (incoming), and coupling e,

$$\mathcal{M}_{n+1} \xrightarrow{k\to 0} \mathcal{M}_n \times e \sum_i \eta_i Q_i \frac{p_i \cdot \varepsilon^*(k)}{p_i \cdot k}\,, \tag{D.245}$$

the leading $1/(p_i \cdot k)$ being the pole of the propagator of the hard line just before it emits. Squaring, summing over the boson polarizations with $\sum_\lambda \varepsilon^\mu \varepsilon^{*\nu} \to -\eta^{\mu\nu}$ (the gauge-dependent remainder cancels by the Ward identity proved in Chapter 19), and integrating over the soft boson's phase space, the real-emission correction to the rate is $|\mathcal{M}_n|^2$ times the eikonal phase-space integral

$$W \;=\; -\,e^2 \int \frac{d^{d-1}\mathbf{k}}{(2\pi)^{d-1}\,2\omega} \sum_{i,j} \eta_i \eta_j Q_i Q_j \frac{p_i \cdot p_j}{(p_i \cdot k)(p_j \cdot k)}\,. \tag{D.246}$$

The structure of the divergences is read off the integrand without choosing a frame. Parametrize $k = \omega(1, \mathbf{n})$ with $\mathbf{n}$ a unit vector in $d-1$ spatial dimensions, so $p_i \cdot k = \omega\,(E_i - \mathbf{p}_i \cdot \mathbf{n})$ and the measure is $d^{d-1}\mathbf{k}/2\omega = \tfrac{1}{2}\,\omega^{d-3}\,d\omega\,d\Omega_{d-1}$. Each term of Eq. (D.246) then has the radial profile

$$\frac{\omega^{d-3}}{(p_i \cdot k)(p_j \cdot k)} \;\propto\; \frac{\omega^{d-3}}{\omega^2} = \omega^{d-5} = \omega^{-1-2\varepsilon}\,, \tag{D.247}$$

so that, with an upper cutoff Δ on the soft energy that delimits the soft region (set, in a complete calculation, by the recoil kinematics; energies above it belong

to the hard region),

$$\int_0^{\Delta} d\omega\, \omega^{-1-2\varepsilon} = \frac{\Delta^{-2\varepsilon}}{-2\varepsilon} = -\frac{1}{2\varepsilon} - \ln\Delta + O(\varepsilon)\,. \tag{D.248}$$

This is the soft pole: the logarithmic divergence at $\omega \to 0$, which in four dimensions would be $\int d\omega/\omega$, is regulated by $d = 4 - 2\varepsilon$ into a single $1/\varepsilon$ with the residue carrying the soft logarithm $\ln\Delta$. The pole is of *infrared* origin — it comes from the lower limit $\omega \to 0$, the opposite end of the integration from the ultraviolet poles of the loop sections — yet it wears the same $1/\varepsilon$, which is the whole point of using one regulator for both.

The angular integral supplies the rest, and for massless emitters it generates the second, collinear pole. Consider the diagonal-pair term in Eq. (D.246) for two back-to-back massless hard legs p_1, p_2 in their centre-of-mass frame, $\mathbf{p}_1\cdot\mathbf{n} = E\cos\theta$, $\mathbf{p}_2\cdot\mathbf{n} = -E\cos\theta$, giving $(p_1\cdot k)(p_2\cdot k) \propto \omega^2 E^2(1-\cos\theta)(1+\cos\theta)$. The required angular integral is the d-dimensional master

$$\int d\Omega_{d-1}\,(1-\cos\theta)^{-a}(1+\cos\theta)^{-b} = \Omega_{d-2}\,2^{\,d-3-a-b}\,\frac{\Gamma\!\left(\frac{d-2}{2}-a\right)\Gamma\!\left(\frac{d-2}{2}-b\right)}{\Gamma(d-2-a-b)}\,, \tag{D.249}$$

with $\Omega_{d-2} = 2\pi^{(d-2)/2}/\Gamma(\frac{d-2}{2})$. The formula is proved by peeling off the polar angle, $d\Omega_{d-1} = \sin^{d-3}\theta\, d\theta\, d\Omega_{d-2}$, substituting $u = \cos\theta$ so that $\sin^{d-3}\theta\, d\theta = -(1-u^2)^{(d-4)/2}\, du$, and then $t = (1+u)/2$:

$$\begin{aligned}\int d\Omega_{d-1}(1-\cos\theta)^{-a}(1+\cos\theta)^{-b} &= \Omega_{d-2}\int_{-1}^{1} du\,(1-u)^{\frac{d-4}{2}-a}(1+u)^{\frac{d-4}{2}-b}\\ &= \Omega_{d-2}\,2^{\,d-3-a-b}\int_0^1 dt\,(1-t)^{\frac{d-2}{2}-a-1}t^{\frac{d-2}{2}-b-1}\\ &= \Omega_{d-2}\,2^{\,d-3-a-b}\,B\!\left(\tfrac{d-2}{2}-b,\ \tfrac{d-2}{2}-a\right),\end{aligned} \tag{D.250}$$

the last step being the Euler Beta integral $\int_0^1 t^{x-1}(1-t)^{y-1}dt = B(x,y) = \Gamma(x)\Gamma(y)/\Gamma(x+y)$, which reproduces Eq. (D.249). The eikonal back-to-back case is $a = b = 1$. With $d = 4 - 2\varepsilon$ one has $\frac{d-2}{2} - 1 = -\varepsilon$, so the angular factor carries $\Gamma(-\varepsilon)^2/\Gamma(-2\varepsilon)$, whose $\Gamma(-\varepsilon)$ each contribute a $1/\varepsilon$ collinear pole from the endpoints $\cos\theta = \pm 1$ where the soft boson is parallel to one of the hard legs. Multiplying by the radial $1/\varepsilon$ of Eq. (D.248) produces the characteristic

$$W \;\sim\; \frac{1}{\varepsilon^2} \quad (\text{soft} \times \text{collinear})\,, \tag{D.251}$$

the overlapping double pole of a massless gauge theory. When the emitter is massive, $p_i^2 = m_i^2 \neq 0$, the factor $1-\cos\theta$ never reaches zero ($E_i - \mathbf{p}_i\cdot\mathbf{n} \geq E_i - |\mathbf{p}_i| > 0$), the angular integral is finite, and only the single soft pole Eq. (D.248) survives — which is the QED case relevant to the electron, where

the collinear divergence is cut off by the electron mass and the residual infrared pole is purely soft.

The cancellation is now an identity. The virtual correction to the same observable — the vertex and self-energy graphs evaluated in Chapters 19 and 20 for QED and in Chapters 27 and 28 for QCD — produces, after renormalization of the ultraviolet subdivergences, exactly the infrared poles

$$2\,\mathrm{Re}\left(\mathcal{M}_n^{*}\,\mathcal{M}_n^{\mathrm{virtual}}\right) \;\supset\; |\mathcal{M}_n|^2\left(+\frac{c_2}{\varepsilon^2}+\frac{c_1}{\varepsilon}\right), \tag{D.252}$$

with coefficients c_2, c_1 fixed by the same eikonal/collinear data — the cusp and collinear anomalous dimensions — that govern W. Because the loop integral picks up its infrared pole from the region where the *virtual* boson is soft, and the phase-space integral picks up its pole from the region where the *real* boson is soft, the two regions are kinematically identical and the residues are equal and opposite:

$$\underbrace{\left(\frac{c_2}{\varepsilon^2}+\frac{c_1}{\varepsilon}\right)}_{\text{virtual}} + \underbrace{W = \left(-\frac{c_2}{\varepsilon^2}-\frac{c_1}{\varepsilon}+\text{finite}\right)}_{\text{real}} \;=\; \text{finite}\,, \tag{D.253}$$

the statement of the Bloch–Nordsieck theorem for soft photons and, with the collinear poles included, of the Kinoshita–Lee–Nauenberg theorem. The finite remainder contains the physical logarithms $\ln(\Delta/\sqrt{s})$ of the resolution Δ; their exponentiation is the Sudakov form factor. The mechanics matter for the present appendix only at the level just shown: the regulator ε that the loop sections introduced to tame the ultraviolet is the *same* parameter that, acting now at the lower end of the soft phase-space integral Eq. (D.248) and at the angular endpoints Eq. (D.249), regulates the infrared, so that virtual and real contributions are Laurent series in one ε and add term by term. This is the closure of the pipeline: parametrize, rotate, integrate, expand the virtual side; integrate the real phase space here; add and find the poles gone. The numerical payoff — Schwinger's $a_e = \alpha/2\pi$ in Chapter 20 and the inclusive R-ratio of Chapter 28 — rides on exactly this cancellation.

D.8.5 The optical theorem on a single integral

We close the appendix where the ε-expansion section pointed: the branch cut of the bubble. There we found that the one-loop two-point integral develops an imaginary part above threshold; unitarity, through the optical theorem of Chapter 18, demands that this imaginary part be a physical phase-space volume. The following worked example verifies the demand exactly for the ϕ^4 bubble — Cutkosky's rule Chapter 18 checked on this one integral, every factor of i and π kept.

Worked Example D.42 ($2\,\mathrm{Im}\,B$ equals the two-body phase space)**.** We continue ϕ^4 theory from the ε-expansion section. The s-channel one-loop correction to

$\phi\phi \to \phi\phi$ is the bubble of Fig. D.9's sibling diagram, built from two propagators $i/(p^2 - m^2 + i\epsilon)$ and two vertices $-i\lambda$, with the bubble symmetry factor $\frac{1}{2}$:

$$i\mathcal{M}_{\text{bub}}(s) = \frac{1}{2}(-i\lambda)^2 \int \frac{d^d\ell}{(2\pi)^d} \frac{i}{\ell^2 - m^2 + i\epsilon} \frac{i}{(P-\ell)^2 - m^2 + i\epsilon} = \frac{\lambda^2}{2} I(s)\,, \tag{D.254}$$

where $P^2 = s$, the two factors of i from the propagators and the $(-i\lambda)^2 = -\lambda^2$ combine to a net $+1/2$ times λ^2, and

$$I(s) \equiv \int \frac{d^d\ell}{(2\pi)^d} \frac{1}{(\ell^2 - m^2 + i\epsilon)\big((P-\ell)^2 - m^2 + i\epsilon\big)} \tag{D.255}$$

is the scalar bubble whose Feynman-parametrized value was established in the ε-expansion section,

$$I(s) = \frac{i}{16\pi^2}\left[\frac{1}{\bar{\varepsilon}} - \int_0^1 dx\, \ln\frac{m^2 - x(1-x)s - i\epsilon}{\mu^2}\right] + O(\varepsilon), \qquad \frac{1}{\bar{\varepsilon}} = \frac{1}{\varepsilon} - \gamma_E + \ln 4\pi\,, \tag{D.256}$$

with the $\mu^{2\varepsilon}$ bookkeeping of $\overline{\text{MS}}$ as in Chapter A. Solving Eq. (D.254) for the amplitude, $\mathcal{M}_{\text{bub}} = -i\,(\lambda^2/2)\, I(s)$, and inserting Eq. (D.256),

$$\mathcal{M}_{\text{bub}}(s) = \frac{\lambda^2}{32\pi^2}\left[\frac{1}{\bar{\varepsilon}} - \int_0^1 dx\, \ln\frac{m^2 - x(1-x)s - i\epsilon}{\mu^2}\right] + O(\varepsilon)\,, \tag{D.257}$$

where the explicit $-i$ has cancelled the i of Eq. (D.256) to leave a real prefactor: the divergence and the real part of the log are real, as a $2 \to 2$ amplitude's real part should be.

Imaginary part. The only source of an imaginary part is the logarithm, and it switches on exactly above threshold. The argument $m^2 - x(1-x)s$ is negative when $x(1-x) > m^2/s$, i.e. for $x \in (x_-, x_+)$ with $x_\pm = \frac{1}{2}(1 \pm \beta)$ the roots of $x(1-x) = m^2/s$, where $\beta = \sqrt{1 - 4m^2/s}$; such an interval exists only for $s > 4m^2$. For x in it, the $-i\epsilon$ prescription places the argument just below the negative real axis, so $\ln(\text{neg} - i\epsilon) = \ln|\cdots| - i\pi$ and $\operatorname{Im}\ln = -\pi$. Hence

$$\operatorname{Im}\mathcal{M}_{\text{bub}}(s) = \frac{\lambda^2}{32\pi^2}\Big(-\int_{x_-}^{x_+} dx\,(-\pi)\Big) = \frac{\lambda^2}{32\pi^2}\,\pi\,(x_+ - x_-) = \frac{\lambda^2\beta}{32\pi}\,, \tag{D.258}$$

using $x_+ - x_- = \beta$. Therefore

$$2\operatorname{Im}\mathcal{M}_{\text{bub}}(s) = \frac{\lambda^2\beta}{16\pi} \qquad (s > 4m^2)\,. \tag{D.259}$$

Phase-space side. The optical theorem of Chapter 18 states $2\operatorname{Im}\mathcal{M}(i \to i) = \sum_f \int d\Pi_f\, |\mathcal{M}(i \to f)|^2$. At one loop the only accessible intermediate state f is the two-particle state of two identical scalars; its tree amplitude is the

contact term $\mathcal{M}_{\text{tree}}(\phi\phi \to \phi\phi) = -\lambda$, and the sum over identical-particle final states carries the symmetry factor $1/2!$. With the equal-mass two-body volume Eq. (D.240), $\Phi_2 = \beta/8\pi$,

$$\sum_f \int d\Pi_f \, |\mathcal{M}(i \to f)|^2 = \frac{1}{2}\,\Phi_2(s)\,|-\lambda|^2 = \frac{1}{2}\cdot\frac{\beta}{8\pi}\cdot\lambda^2 = \frac{\lambda^2\beta}{16\pi}\,. \tag{D.260}$$

Equations (D.259) and (D.260) agree exactly:

$$\boxed{2\,\mathrm{Im}\,\mathcal{M}_{\text{bub}}(s) = \frac{1}{2}\,\Phi_2(s)\,\lambda^2 = \frac{\lambda^2\beta}{16\pi}} \tag{D.261}$$

the optical theorem satisfied identically by the bubble, with the threshold factor β appearing on both sides and the imaginary part proportional to the very phase space derived in Section D.8.2.

Cutkosky reading. The same number is the Cutkosky cut of $I(s)$: replacing each cut propagator by $1/(p^2 - m^2 + i\epsilon) \to -2\pi i\,\delta^+(p^2 - m^2)$ converts the loop into a phase-space integral,

$$\mathrm{Cut}\,I(s) = \int \frac{d^d\ell}{(2\pi)^d}\,(-2\pi i)\,\delta^+(\ell^2 - m^2)\,(-2\pi i)\,\delta^+((P-\ell)^2 - m^2) = -\,\Phi_2(s)\,, \tag{D.262}$$

because $(-2\pi i)^2 = -(2\pi)^2$ and the two on-shell deltas with their (2π) factors are precisely the integrand of Φ_2 in Eq. (D.233). The discontinuity $\mathrm{Disc}\,I = I(s+i0) - I(s-i0) = 2i\,\mathrm{Im}\,I$ computed directly from Eq. (D.256) equals $-\Phi_2(s)$ as well, so $\mathrm{Disc}\,\mathcal{M}_{\text{bub}} = -i\,(\lambda^2/2)\,\mathrm{Disc}\,I = i\,(\lambda^2/2)\Phi_2$ and $2\,\mathrm{Im}\,\mathcal{M}_{\text{bub}} = -i\,\mathrm{Disc}\,\mathcal{M}_{\text{bub}} = \frac{1}{2}\lambda^2\Phi_2$, reproducing Eq. (D.261) from the cut. Cutting the bubble is integrating the two-body phase space; this single integral is the optical theorem.

Theorem D.42 ties off the analytic-structure thread opened in the ε-expansion section: the branch cut of a loop integral above a physical threshold is not a calculational nuisance but the imaginary part demanded by unitarity, and its size is a phase-space volume computed here in closed form. With the two-body measure, the Dalitz setup, the soft real-emission integral, and this unitarity check in hand, the appendix has assembled both halves of a one-loop calculation under one set of conventions. Together, these eight sections provide a complete, self-contained reference for the one-loop calculations in the main text.

Further reading

The one-loop technology of this appendix is treated, with conventions close to ours, in Peskin and Schroeder [396] (chapters 6–7 and the dimensional-regularization

sections), Schwartz [432] (chapters 16–20), Srednicki [454] (chapters 14–16), and Weinberg [500] (chapter 11); these are the natural companions for the reader who wants a second pass through the same material. The foundational paper on dimensional regularization is 't Hooft and Veltman [469], and the systematic tensor reduction to the scalar $A_0/B_0/C_0/D_0$ basis originates with Passarino and Veltman [383]. The fully rigorous treatment of dimensional regularization as both an ultraviolet and an infrared regulator, including the operator-product and renormalization-group structure that the loop chapters build on, is Collins [134]. For the multi-loop machinery that lies beyond this book's one-loop scope—integration by parts, the reduction to master integrals, and the Mellin–Barnes and sector-decomposition methods for evaluating them, together with the modern function spaces (polylogarithms and beyond) in which the answers live—the standard reference is Smirnov [448].

Appendix E

Path Integral Technicalities

The path integral is the spine of this book's computational machinery, yet almost every time we wrote one down in the main text we deferred a debt. We declared a Gaussian functional integral equal to an inverse square root of a determinant; we wrote a one-loop correction as $\frac{1}{2}\ln\det$ of a fluctuation operator and pretended the determinant of a differential operator was a finite number; we changed variables in $\mathcal{D}\phi$ and assumed the measure transformed trivially; we expanded around a classical solution with a zero mode and quietly divided by infinity. Each of those moves is legitimate, but only when carried out with care, and the care is exactly what a running narrative has no room for. This appendix is where the debts are paid. It is the proof-carrying technical underpinning of the entire path-integral formalism: every formula that earlier chapters used on faith is here defined precisely, derived in full, and renormalized honestly, with all the intermediate algebra on the page.

The strategy is to build upward from a single piece of finite-dimensional linear algebra. The whole subject is, at bottom, the Gaussian integral $\int d^n x\, e^{-\frac{1}{2}x^T A x + J^T x} = (2\pi)^{n/2}(\det A)^{-1/2}\, e^{\frac{1}{2}J^T A^{-1} J}$ and its complex and Grassmann counterparts. Section E.1 establishes these master formulas with sources, in real-symmetric, complex-Hermitian, and Grassmann forms, and reads Wick's theorem off them as the statement that Gaussian moments factorize into pairings. Everything afterward is the disciplined promotion of $n \to \infty$. Section E.2 takes the continuum limit by time-slicing, turning the formal $\det A$ into the product over a spectrum and isolating the one number a path integral actually needs—a *ratio* of determinants—which it computes in closed form through the Gelfand–Yaglom theorem, proved here for one-dimensional operators. Section E.3 confronts the fact that the spectral product diverges and supplies the cure: the zeta-function definition $\ln\det K = -\zeta_K'(0)$, its Mellin-transform link to the heat kernel and the Seeley–DeWitt coefficients, the reading of $\zeta_K(0)$ as the encoder of the divergence and the scaling anomaly, and the dictionary translating this regulator into dimensional regularization and Pauli–Villars.

With the determinant under control, the appendix turns it into physics. Section E.4 identifies the one-loop effective action with $\frac{1}{2}\ln\det$ of the second functional derivative of the action and carries the Coleman–Weinberg effective potential of ϕ^4 theory from definition through regularization to a fully renormalized closed form. Section E.5 then scrutinizes the object we have been integrating against: it defines $\mathcal{D}\phi$ through the DeWitt field-space metric, computes the Jacobians of field redefinitions and shows why they vanish in dimensional regularization, constructs the fermionic Berezin measure with its characteristic inverse Jacobian, and lays out the Fujikawa setup that the anomaly chapter will detonate. Section E.6 closes the loop by handling the case the naive Gaussian formula cannot: when the fluctuation operator has a zero mode, we trade it for a collective coordinate, pay the per-mode Jacobian $\sqrt{S_{\mathrm{cl}}/2\pi}$, replace the determinant by its primed version with the zero eigenvalue struck out, and assemble the complete semiclassical amplitude—worked explicitly for the ϕ^4 kink.

What this appendix imports it imports cleanly. The formal generating functionals, the finite- and infinite-dimensional Gaussian heuristics, and the Legendre-transform effective action come from Chapter 4; the distribution theory, the $i\epsilon$ prescription, Wick rotation, asymptotic series, and the saddle-point method come from Chapter 5; the construction of $Z[J]$ from the quantum-mechanical path integral and the operational form of Wick's theorem come from Chapter 10; Grassmann variables and Berezin integration in their first form come from Chapter 12; the master one-loop integrals and Feynman parametrization that the Coleman–Weinberg computation leans on come from Chapter D; the γ^5 and chiral-projector data needed to pose the Fujikawa problem come from Chapter C, and the global conventions from Chapter A. The $\lambda\phi^4$ model and its parameters are exactly those fixed in Chapter 6; we continue that thread rather than restate it. What the appendix exports, in turn, is the toolkit several later chapters detonate: the Faddeev–Popov measure and ghost determinant (Chapters 13 and 26), the chiral anomaly as a measure Jacobian (Chapter 36), radiative symmetry breaking via the effective potential (Chapter 29), soliton and instanton fluctuation determinants (Chapters 41 and 42), and the curved-space heat kernel (Chapter 64). The appendix is a reference, but a proof-carrying one: nothing in it is tabulated without being established, because these are precisely the results other chapters use most and check least.

E.1 Gaussian Integrals: The Algebraic Bedrock

The saddle-point program announced in this appendix's introduction reduces every partition function we will ever write to a single arithmetic operation. One expands the action about a stationary configuration, discards the (vanishing) linear term, and is left with a sum over fluctuations weighted by the exponential of a quadratic form, corrected order by order by the higher variations treated

as a perturbation. The leading factor in that program—the one that fixes the normalization, the one-loop determinant, and the free propagator all at once—is a Gaussian integral. Everything technical in the rest of this appendix is the analysis of what that integral becomes when the number of fluctuation modes becomes infinite and the quadratic form becomes a differential operator. Before any of that can be made honest we must have the finite-dimensional statement in hand, in every guise the book will need it: a real form for neutral bosons, a complex form for charged bosons, and a Grassmann form for fermions. The first two were established in the main development of the path integral (Section 4.2); we recall them here so that this appendix stands on its own as a reference, and then build the fermionic case and the unifying principle that the main text only flagged.

The single fact the whole section orbits is already visible in the source term of Eq. (4.54): the value of a sourced Gaussian is the exponential of a quadratic in the source whose kernel is the *inverse* of the form in the exponent. That inverse is the propagator; the prefactor is a power of the determinant. The sign of that power—negative for bosons, positive for fermions—is the algebraic seed of the entire bose/fermi dichotomy, and isolating it is the second purpose of this section.

E.1.1 The real master formula

We work first in Euclidean signature, where the quadratic form is real, symmetric, and positive-definite and the integral converges absolutely as an ordinary Riemann integral. The oscillatory Lorentzian weight is recovered by analytic continuation in Section E.1.6.

Theorem E.1 (Real Gaussian master formula)**.** *Let A be a real symmetric positive-definite $n \times n$ matrix and $J \in \mathbb{R}^n$. Then*

$$\int_{\mathbb{R}^n} d^n x \, e^{-\frac{1}{2} x^{\mathsf{T}} A x + J^{\mathsf{T}} x} \;=\; \frac{(2\pi)^{n/2}}{\sqrt{\det A}} \, \exp\!\Big(\tfrac{1}{2}\, J^{\mathsf{T}} A^{-1} J\Big). \tag{E.1}$$

Proof. This is Theorem 4.15; we record the argument compactly because the rest of the appendix continues directly from it. Because $A = A^{\mathsf{T}} > 0$, the spectral theorem gives an orthogonal O ($\det O = \pm 1$, $|\det O| = 1$) with $A = O^{\mathsf{T}} D O$, $D = \mathrm{diag}(a_1, \dots, a_n)$, every $a_i > 0$. First set $J = 0$ and change variables $y = Ox$, whose Jacobian is $|\det O| = 1$, so $d^n x = d^n y$ and the domain is preserved. The form diagonalizes, $x^{\mathsf{T}} A x = \sum_i a_i y_i^2$, the integral factorizes into n copies of the one-dimensional Gaussian $\int_{-\infty}^{\infty} dy \, e^{-\frac{1}{2} a y^2} = \sqrt{2\pi/a}$ of Theorem 4.13, and the product is

$$\int_{\mathbb{R}^n} d^n x \, e^{-\frac{1}{2} x^{\mathsf{T}} A x} = \prod_{i=1}^{n} \sqrt{\frac{2\pi}{a_i}} = \frac{(2\pi)^{n/2}}{\sqrt{\prod_i a_i}} = \frac{(2\pi)^{n/2}}{\sqrt{\det A}}, \tag{E.2}$$

since $\det A = \det D = \prod_i a_i$. For general J shift $x = y + A^{-1}J$, a translation leaving $d^n x$ and the domain unchanged. Using $A^{\mathsf{T}} = A$ and $(A^{-1})^{\mathsf{T}} = A^{-1}$,

$$-\tfrac{1}{2}x^{\mathsf{T}}Ax + J^{\mathsf{T}}x = -\tfrac{1}{2}y^{\mathsf{T}}Ay + \tfrac{1}{2}J^{\mathsf{T}}A^{-1}J, \tag{E.3}$$

the cross terms cancelling exactly as in Eq. (4.55). The constant exits the integral and the remaining y-integral is Eq. (E.2); this gives Eq. (E.1). □

Two pieces of Eq. (E.1) are load-bearing for everything downstream. The prefactor $(2\pi)^{n/2}(\det A)^{-1/2}$ is the normalization that, in the continuum, becomes the one-loop functional determinant of Section E.1.5 and the next section. The kernel A^{-1} in the source exponent is the propagator: differentiating in J and setting $J = 0$ produces the moments, with $\langle x_i x_j \rangle = (A^{-1})_{ij}$ and all higher moments fixed by pairing—Wick's theorem, recalled in Section E.1.4.

E.1.2 The complex (Hermitian) form

Charged bosons are integrated against a Hermitian form in complex variables, and the determinant power changes: a complex field is two real fields, so its $(\det)^{-1/2}$ is squared to $(\det)^{-1}$.

Theorem E.2 (Complex Gaussian master formula)**.** *Let M be a Hermitian positive-definite $n \times n$ matrix, $M^\dagger = M > 0$, and $J \in \mathbb{C}^n$. With the measure*

$$\prod_{i=1}^{n} \frac{dz_i^*\, dz_i}{2\pi i} \;\equiv\; \prod_{i=1}^{n} \frac{d(\operatorname{Re} z_i)\, d(\operatorname{Im} z_i)}{\pi}, \tag{E.4}$$

one has

$$\int \Big(\prod_i \frac{dz_i^*\, dz_i}{2\pi i} \Big)\, e^{-z^\dagger M z + \bar{J} z + z^\dagger J} \;=\; \frac{1}{\det M}\, e^{\,\bar{J} M^{-1} J}, \tag{E.5}$$

where $\bar{J} \equiv J^\dagger$. In particular the source-free integral is $(\det M)^{-1}$.

Proof. This is Theorem 4.17 in the notation of the present section (there the matrix was called A and the source w); the measures agree because $dz^*\, dz/2\pi i = d(\operatorname{Re} z)\, d(\operatorname{Im} z)/\pi$ as a real two-form. For $J = 0$, diagonalize $M = U^\dagger D U$ by a unitary U and substitute $z = U^\dagger \zeta$; as a real-linear map $U^\dagger$ has Jacobian $|\det U^\dagger|^2 = 1$, so the measure is invariant. The form becomes $z^\dagger M z = \sum_i a_i |\zeta_i|^2$ and each factor is a planar Gaussian, $\int \frac{d(\operatorname{Re}\zeta)\, d(\operatorname{Im}\zeta)}{\pi} e^{-a|\zeta|^2} = 1/a$, whose product is $\prod_i a_i^{-1} = (\det M)^{-1}$. For general J shift $z = \zeta + M^{-1}J$ (so $z^\dagger = \zeta^\dagger + \bar{J}M^{-1}$, legitimate because M^{-1} is Hermitian); the cross terms cancel as in Eq. (4.62), leaving the constant $\bar{J}M^{-1}J$ and the source-free integral. □

Notation Watch

The contrast $(\det A)^{-1/2}$ for one real boson versus $(\det M)^{-1}$ for one complex boson is the statement that a complex degree of freedom carries twice the determinant power of a real one. The Grassmann integral below inverts the sign of that power outright, $(\det M)^{+1}$, and the source exponent keeps its *positive* sign $+\bar{\eta}M^{-1}\eta$, matching $+\bar{J}M^{-1}J$ here. The opposite determinant power, not the source sign, is what distinguishes a fermion loop from a boson loop.

E.1.3 The Grassmann form: $\det M$ from Berezin integration

We now build the fermionic case from scratch on top of the Berezin calculus. The algebra of anticommuting generators and the integration rules—that $\int d\theta = 0$, $\int d\theta\, \theta = 1$, and that the Berezin integral is translation-invariant—are the content of Theorem 12.17; we use them as given and emphasize only the two facts that drive the determinant. First, a Berezin integral over a generator θ_k annihilates everything except the part of the integrand *linear* in θ_k; consequently the full integral over $2n$ generators extracts precisely the coefficient of the top monomial in which every generator appears exactly once. Second, the integrators anticommute with each other and with all generators, so that signs must be tracked through every reordering.

Let $\theta_1, \dots, \theta_n$ and $\bar{\theta}_1, \dots, \bar{\theta}_n$ be $2n$ independent Grassmann generators (the bar is a label, not yet a conjugation), and let M be an arbitrary complex $n \times n$ matrix. The fermionic quadratic form is the Grassmann-even bilinear

$$\bar{\theta} M \theta \;=\; \sum_{i,j=1}^{n} \bar{\theta}_i \, M_{ij} \, \theta_j, \tag{E.6}$$

each summand $\bar{\theta}_i M_{ij} \theta_j$ being a product of two odd elements, hence even and mutually commuting. We integrate with the ordered measure

$$D[\bar{\theta}, \theta] \;\equiv\; d\bar{\theta}_1 \, d\theta_1 \, d\bar{\theta}_2 \, d\theta_2 \cdots d\bar{\theta}_n \, d\theta_n, \tag{E.7}$$

the integrators applied from the left in the written order.

Theorem E.3 (Grassmann Gaussian: the inverted determinant)**.** *For any complex $n \times n$ matrix M,*

$$\int D[\bar{\theta}, \theta] \; e^{-\bar{\theta} M \theta} \;=\; \det M. \tag{E.8}$$

Proof. Because each generator squares to zero, the exponential is a terminating sum,

$$e^{-\bar{\theta} M \theta} = \sum_{k=0}^{n} \frac{(-1)^k}{k!} \, (\bar{\theta} M \theta)^k, \tag{E.9}$$

and the Berezin integral over all $2n$ generators kills every term but the one containing each θ_j and each $\bar\theta_i$ exactly once—necessarily the $k=n$ term, since a power $(\bar\theta M\theta)^k$ contains exactly k of the θ's and k of the $\bar\theta$'s, and any repeated index vanishes. Expanding that term,

$$\frac{(-1)^n}{n!}(\bar\theta M\theta)^n = \frac{(-1)^n}{n!}\sum_{\substack{i_1,\dots,i_n\\ j_1,\dots,j_n}} \Big(\prod_{a=1}^{n} M_{i_a j_a}\Big)\,\bar\theta_{i_1}\theta_{j_1}\cdots\bar\theta_{i_n}\theta_{j_n}, \tag{E.10}$$

where the numbers $M_{i_a j_a}$ have been pulled to the front. A term survives the integration only if the $\bar\theta$ indices are all distinct and the θ indices are all distinct, i.e. $i_a=\pi(a)$ and $j_a=\sigma(a)$ for permutations $\pi,\sigma\in S_n$. It remains to integrate the surviving Grassmann monomials.

The monomial integral. Fix π,σ and consider $G(\pi,\sigma)=\bar\theta_{\pi(1)}\theta_{\sigma(1)}\cdots\bar\theta_{\pi(n)}\theta_{\sigma(n)}$. Each block $\bar\theta_{\pi(a)}\theta_{\sigma(a)}$ is even, so the blocks commute and may be reordered freely, at no sign cost, so that the bar indices increase: the block carrying $\bar\theta_m$ then sits in position m and its partner is $\theta_{\sigma(\pi^{-1}(m))}$. Writing $\nu\equiv\sigma\circ\pi^{-1}$,

$$G(\pi,\sigma)=\prod_{m=1}^{n}\bar\theta_m\,\theta_{\nu(m)}. \tag{E.11}$$

We claim

$$\int D[\bar\theta,\theta]\;\prod_{m=1}^{n}\bar\theta_m\theta_{\nu(m)} \;=\; (-1)^n\,\mathrm{sgn}(\nu). \tag{E.12}$$

The single-variable rule fixes the base value: from $\int d\theta\,\theta=1$ and the left-anticommuting integrators, $\int d\bar\theta\,d\theta\,\bar\theta\theta=-1$, while $\int d\bar\theta\,d\theta\,\theta\bar\theta=+1$. For $\nu=\mathrm{id}$ the blocks $\bar\theta_m\theta_m$ are even and the measure factorizes, giving $(\int d\bar\theta\,d\theta\,\bar\theta\theta)^n=(-1)^n$, which is Eq. (E.12) since $\mathrm{sgn}(\mathrm{id})=1$. A transposition is verified directly: for $n=2$, $\nu=(12)$, $\bar\theta_1\theta_2\bar\theta_2\theta_1=(\theta_2\bar\theta_2)(\bar\theta_1\theta_1)$ after commuting the even block $\theta_2\bar\theta_2$ leftward, whence the integral is $(+1)(-1)=-1=(-1)^2\,\mathrm{sgn}((12))$. In general, transposing two adjacent θ-partners exchanges $\theta_{\nu(m)}\leftrightarrow\theta_{\nu(m+1)}$ across an even number of intervening odd factors and so contributes one sign, exactly the sign of the corresponding transposition of ν; since every permutation is a product of transpositions and the value is multiplicative in them, Eq. (E.12) follows by induction on the number of transpositions reducing ν to the identity.

Assembly. Using $\mathrm{sgn}(\nu)=\mathrm{sgn}(\sigma)\,\mathrm{sgn}(\pi)$ (as $\mathrm{sgn}(\pi^{-1})=\mathrm{sgn}(\pi)$) and Eq. (E.12),

$$\int D[\bar\theta,\theta]\,e^{-\bar\theta M\theta}=\frac{(-1)^n}{n!}\sum_{\pi,\sigma}\Big(\prod_a M_{\pi(a)\sigma(a)}\Big)\,(-1)^n\,\mathrm{sgn}(\pi)\,\mathrm{sgn}(\sigma)=\frac{1}{n!}\sum_{\pi,\sigma}\mathrm{sgn}(\pi)\,\mathrm{sgn}(\sigma)\prod_a M_{\pi(} \tag{E.13}$$

Reindexing the product by $b=\pi(a)$ gives $\prod_a M_{\pi(a)\sigma(a)}=\prod_b M_{b,\,\nu(b)}$ with $\nu=\sigma\pi^{-1}$, and $\mathrm{sgn}(\pi)\,\mathrm{sgn}(\sigma)=\mathrm{sgn}(\nu)$. For each fixed ν there are exactly $n!$

pairs (π, σ) with $\sigma = \nu\pi$, so the double sum collapses,

$$\int D[\bar\theta, \theta]\, e^{-\bar\theta M\theta} = \frac{1}{n!}\cdot n! \sum_{\nu\in S_n} \operatorname{sgn}(\nu) \prod_{b=1}^{n} M_{b,\nu(b)} = \sum_{\nu\in S_n} \operatorname{sgn}(\nu) \prod_{b=1}^{n} M_{b,\nu(b)} = \det M, \tag{E.14}$$

the Leibniz formula for the determinant. This proves Eq. (E.8). □

The result deserves the same pause the bosonic one did. The very same Hermitian quadratic form that gave $(\det M)^{-1}$ in Theorem E.2 gives $(\det M)^{+1}$ once the integration variables anticommute. The inversion is not a convention; it is forced by the Berezin rule that integration extracts the top—rather than the constant—coefficient, which turns the geometric series $\prod a_i^{-1}$ into the polynomial $\prod a_i$. This single sign in the exponent of the determinant is, traced through the loop expansion, the origin of the minus sign attached to every closed fermion loop.

The source version follows by the same shift that worked for bosons, now with Grassmann-odd sources $\eta, \bar\eta$.

Theorem E.4 (Sourced Grassmann Gaussian)**.** *For invertible complex M and independent Grassmann sources $\eta_i, \bar\eta_i$ anticommuting with the θ's,*

$$\int D[\bar\theta, \theta]\; e^{-\bar\theta M\theta + \bar\eta\theta + \bar\theta\eta} \;=\; \det M \;\; e^{\bar\eta M^{-1}\eta}. \tag{E.15}$$

Proof. Shift $\theta = \theta' + M^{-1}\eta$ and $\bar\theta = \bar\theta' + \bar\eta M^{-1}$, which leaves the Berezin measure invariant (translation invariance, Theorem 12.17). Substituting,

$$\begin{aligned} -\bar\theta M\theta + \bar\eta\theta + \bar\theta\eta &= -(\bar\theta' + \bar\eta M^{-1})M(\theta' + M^{-1}\eta) + \bar\eta(\theta' + M^{-1}\eta) + (\bar\theta' + \bar\eta M^{-1})\eta \\ &= -\bar\theta' M\theta' - \bar\theta'\eta - \bar\eta\theta' - \bar\eta M^{-1}\eta + \bar\eta\theta' + \bar\eta M^{-1}\eta + \bar\theta'\eta + \bar\eta M^{-1}\eta \\ &= -\bar\theta' M\theta' + \bar\eta M^{-1}\eta, \end{aligned} \tag{E.16}$$

the four cross terms cancelling in pairs and the three $\bar\eta M^{-1}\eta$ pieces combining to one. The constant $\bar\eta M^{-1}\eta$ (even, hence an ordinary exponential) leaves the integral, and the remaining θ'-integral is Eq. (E.8). □

E.1.4 Wick's theorem: every Gaussian moment is a sum over pairings

A Gaussian distribution has no independent information beyond its two-point function: all higher moments are built from it by the combinatorics of pairing. This is Wick's theorem, and it is the same statement bosonically and fermionically up to the signs the anticommutation forces. The bosonic version was proved in full in the main text; we recall it and then prove the fermionic version that the appendix owes.

For bosons, write $\langle\,\cdot\,\rangle$ for the normalized real Gaussian average with respect to $A>0$, so that $\langle e^{J^{\mathsf T}x}\rangle = e^{\frac12 J^{\mathsf T}A^{-1}J}$ and $\langle x_i x_j\rangle = (A^{-1})_{ij}$.

Theorem E.5 (Bosonic Wick's theorem)**.** *With $G\equiv A^{-1}$, all odd moments vanish and*

$$\langle x_{i_1}x_{i_2}\cdots x_{i_{2k}}\rangle = \sum_{\text{pairings } P}\ \prod_{(a,b)\in P} G_{i_a i_b}, \tag{E.17}$$

the sum running over the $(2k-1)!!$ perfect matchings of $\{1,\dots,2k\}$ into unordered pairs.

This is Theorem 4.19, proved there both by differentiating the generating function $e^{\frac12 J^{\mathsf T}A^{-1}J}$ in the sources $J_{i_1},\dots,J_{i_m}$ and by the Schwinger–Dyson recursion that contracts the first index with each of the rest; we do not repeat the proof. The fermionic theorem differs in exactly two ways: the sources anticommute, so each pairing carries a sign equal to the signature of the permutation that brings the contracted partners together; and a θ pairs only with a $\bar\theta$, so the matchings are bijections of the θ-slots onto the $\bar\theta$-slots.

Theorem E.6 (Fermionic Wick's theorem)**.** *Let $\langle\,\cdot\,\rangle$ denote the normalized Grassmann average, $\langle F\rangle \equiv (\det M)^{-1}\int D[\bar\theta,\theta]\,F\,e^{-\bar\theta M\theta}$, with generating identity $\langle e^{\bar\eta\theta+\bar\theta\eta}\rangle = e^{\bar\eta M^{-1}\eta}$. Then the only nonvanishing elementary contraction is*

$$\langle\theta_i\,\bar\theta_j\rangle = (M^{-1})_{ij}, \qquad \langle\theta_i\theta_j\rangle = \langle\bar\theta_i\bar\theta_j\rangle = 0, \tag{E.18}$$

and the general moment is the signed sum over θ–$\bar\theta$ pairings,

$$\langle\theta_{i_1}\cdots\theta_{i_n}\,\bar\theta_{j_1}\cdots\bar\theta_{j_n}\rangle = \sum_{\sigma\in S_n}\operatorname{sgn}(\sigma)\,\prod_{a=1}^{n}(M^{-1})_{i_a\,j_{\sigma(a)}} = \det\big[(M^{-1})_{i_a j_b}\big]_{a,b=1}^{n}, \tag{E.19}$$

with any moment containing unequal numbers of θ's and $\bar\theta$'s vanishing.

Proof. Two-point function. Expand both sides of the generating identity to second order in the sources. The left side is $\langle 1+(\bar\eta\theta+\bar\theta\eta)+\frac12(\bar\eta\theta+\bar\theta\eta)^2+\cdots\rangle$. The linear terms vanish because $\langle\theta_i\rangle=\langle\bar\theta_i\rangle=0$ (odd integrand, no top monomial), and among the quadratic terms only the cross piece $(\bar\eta\theta)(\bar\theta\eta)$ survives for the same reason. Thus

$$\big\langle(\bar\eta\theta)(\bar\theta\eta)\big\rangle = \sum_{i,j}\bar\eta_i\,\langle\theta_i\bar\theta_j\rangle\,\eta_j, \tag{E.20}$$

where the $\bar\eta_i$ and η_j, being constants of the Grassmann average, have been moved outside leaving the c-number $\langle\theta_i\bar\theta_j\rangle$ between them. The right side expands to $1+\bar\eta M^{-1}\eta+\cdots = 1+\sum_{ij}\bar\eta_i(M^{-1})_{ij}\eta_j+\cdots$. Matching the coefficient of $\bar\eta_i\eta_j$ gives $\langle\theta_i\bar\theta_j\rangle=(M^{-1})_{ij}$. The averages $\langle\theta_i\theta_j\rangle$ and $\langle\bar\theta_i\bar\theta_j\rangle$ vanish because the generating function depends on η and $\bar\eta$ only through the bilinear $\bar\eta M^{-1}\eta$, which contains no $\eta\eta$ or $\bar\eta\bar\eta$ term.

Higher moments. Read Eq. (E.19) off the generating function by Grassmann source differentiation, or equivalently by induction on n; we give the induction, the fermionic mirror of the Schwinger–Dyson recursion. Insert one more factor and use anticommutation to expose how θ_{i_1} contracts. Concretely, inside the average θ_{i_1} can only be "used up" by pairing with one of the $\bar\theta_{j_b}$, since $\langle\theta\theta\rangle = 0$; moving θ_{i_1} to the right past the remaining $n-1$ factors $\theta_{i_2}\cdots\theta_{i_n}$ costs a sign $(-1)^{n-1}$, and bringing it adjacent to $\bar\theta_{j_b}$ costs a further $(-1)^{b-1}$ for the $b-1$ bar-factors it crosses. Replacing the contracted pair by $\langle\theta_{i_1}\bar\theta_{j_b}\rangle = (M^{-1})_{i_1 j_b}$ and the rest by the average of what remains yields the recursion

$$\langle\theta_{i_1}\cdots\theta_{i_n}\bar\theta_{j_1}\cdots\bar\theta_{j_n}\rangle = \sum_{b=1}^{n}(-1)^{n-1}(-1)^{b-1}(M^{-1})_{i_1 j_b}\,\langle\theta_{i_2}\cdots\theta_{i_n}\,\bar\theta_{j_1}\cdots\widehat{\bar\theta_{j_b}}\cdots\bar\theta_{j_n}\rangle, \tag{E.21}$$

the hat denoting omission. This is precisely the Laplace (cofactor) expansion of the determinant $\det[(M^{-1})_{i_a j_b}]$ along its first row: the sign $(-1)^{n-1}(-1)^{b-1} = (-1)^{n+b}$ is, up to the overall $(-1)^{n+1}$ common to the row, the checkerboard cofactor sign $(-1)^{1+b}$, and the reduced average is by the inductive hypothesis the corresponding minor. The base case $n=1$ is Eq. (E.18). Hence the moment equals $\det[(M^{-1})_{i_a j_b}]$, which expanded by Leibniz is the signed pairing sum in Eq. (E.19). □

Physical Insight

The bosonic moment is a *permanent* of two-point functions (all pairings with + sign), the fermionic moment a *determinant* (pairings weighted by sgn). The interchange permanent ↔ determinant is the statistics: symmetric wavefunctions for bosons, antisymmetric for fermions, read at the level of correlation functions. The Pauli principle is visible already here—if two fermionic indices coincide in a way that repeats a row, the determinant vanishes.

E.1.5 The unifying determinant rule and its threads

The three master formulas are one statement seen through three measures. Collecting the source-free normalizations,

$$\int_{\mathbb{R}^n} d^n x\, e^{-\frac{1}{2}x^{\mathsf T}Ax} = \frac{(2\pi)^{n/2}}{(\det A)^{1/2}}, \qquad \int \tfrac{d^{2n}z}{(2\pi i)^n}\, e^{-z^\dagger Mz} = \frac{1}{\det M}, \qquad \int D[\bar\theta,\theta]\, e^{-\bar\theta M\theta} = \det M, \tag{E.22}$$

exhibit the dichotomy in its cleanest form: a bosonic Gaussian returns the quadratic form's determinant to a *negative* power, a fermionic one to a *positive* power. Per real degree of freedom the exponent is $-\frac{1}{2}$ for bosons; per complex pair of Grassmann generators it is $+1$, i.e. $+\frac{1}{2}$ per real fermionic degree of freedom

counted with the doubling $\bar\theta, \theta$. The bosonic real case $(-\frac{1}{2})$ has a fermionic mirror of the same fractional power but opposite sign, realized by a real (Majorana) Grassmann integral against an antisymmetric form.

Proposition E.7 (The Pfaffian: real fermionic mirror)**.** *For $2m$ Grassmann generators $\theta_1, \dots, \theta_{2m}$ and a complex antisymmetric matrix $B = -B^{\mathsf T}$,*

$$\int d\theta_{2m} \cdots d\theta_1 \; e^{\frac{1}{2}\theta^{\mathsf T} B \theta} \;=\; \mathrm{Pf}(B), \qquad \big(\mathrm{Pf}(B)\big)^2 = \det B. \tag{E.23}$$

Proof. Only the top term $\frac{1}{m!}(\frac{1}{2}\theta^{\mathsf T} B\theta)^m$ of the exponential survives the integration, by the same top-monomial argument as in Theorem E.3. Expanding, $(\frac{1}{2}\sum_{i<j} B_{ij}(\theta_i\theta_j - \theta_j\theta_i))^m/m! = (\sum_{i<j} B_{ij}\theta_i\theta_j)^m/m!$, and collecting the coefficient of $\theta_1\theta_2\cdots\theta_{2m}$ gives, with the sign conventions of the ordered measure, the sum over perfect matchings $\{(i_1j_1), \dots, (i_mj_m)\}$ of $\{1, \dots, 2m\}$ weighted by the signature of the associated permutation, $\sum_{\text{matchings}} \mathrm{sgn} \prod_r B_{i_r j_r}$, which is by definition $\mathrm{Pf}(B)$. The identity $\mathrm{Pf}(B)^2 = \det B$ then follows from Theorem E.3: doubling the generators to a $\bar\theta, \theta$ pair and integrating $e^{-\bar\theta M\theta}$ with M built from B reproduces $\det B$ as the square of the real integral. The two-by-two case is the whole pattern in miniature: with $B_{12} = -B_{21} = b$, $\int d\theta_2 d\theta_1 \, e^{b\theta_1\theta_2} = \int d\theta_2 d\theta_1 \, (1 + b\theta_1\theta_2) = b = \mathrm{Pf}(B)$ and $\det B = b^2$. □

The one algebraic seed of all three benchmark theories

Every free propagator in this book is an A^{-1} and every loop normalization a power of $\det A$, with the power set by statistics through Eq. (E.22). In ϕ^4 theory the quadratic action is $\frac{1}{2}\phi(-\partial^2 + m^2)\phi$ in Euclidean signature, so the form is $A = -\partial^2 + m^2$ and its inverse A^{-1} is the scalar propagator built in Chapter 10; the free generating functional carries the bosonic $(\det A)^{-1/2}$. In QED the photon's quadratic operator (after gauge fixing) plays the role of A and its inverse is the photon propagator of Chapter 13, while the electron's bilinear $\bar\psi(i\not{D} - m)\psi$ is a Grassmann form with $M = i\not{D} - m$, whose inverse M^{-1} is the Dirac propagator and whose $\det M$—to the *positive* power, by Theorem E.3—is the fermion determinant integrated out in Chapter 12. In Yang–Mills theory the same two structures appear, now with the gauge field's quadratic operator and the Faddeev–Popov ghost determinant, the latter a fermionic det over commuting indices. The threads differ only in what A and M are; the integral that consumes them is the one proved in this section.

E.1.6 Analytic continuation to the oscillatory integral

The master formulas assumed a convergent, positive-definite Euclidean form. The physical path integral carries instead the oscillatory weight e^{iS}, whose quadratic

part is $e^{\frac{i}{2}x^{\mathsf{T}}Ax}$ with A real symmetric but not sign-definite. Such an integral does not converge absolutely; it is defined by the $i\epsilon$ prescription and the Wick rotation of Theorems 5.30 and 5.31, which we now apply to the Gaussian itself. The one-dimensional case carries the entire content.

Theorem E.8 (Fresnel/oscillatory Gaussian)**.** *For real $a \neq 0$, defined by the convergent regulator $a \to a - i\epsilon\ \mathrm{sgn}(a)$ with $\epsilon \to 0^+$,*

$$\int_{-\infty}^{\infty} dx\ e^{\frac{i}{2}ax^2} \;=\; \sqrt{\frac{2\pi}{|a|}}\ e^{\,i\frac{\pi}{4}\,\mathrm{sgn}(a)}, \tag{E.24}$$

and consequently, for real symmetric nonsingular A with n_+ positive and n_- negative eigenvalues (signature $\operatorname{sig} A = n_+ - n_-$),

$$\int_{\mathbb{R}^n} d^n x\ e^{\frac{i}{2}x^{\mathsf{T}}Ax} = \frac{(2\pi)^{n/2}}{|\det A|^{1/2}}\, e^{\,i\frac{\pi}{4}\operatorname{sig} A} = (2\pi)^{n/2}\big(\det(-iA)\big)^{-1/2}, \tag{E.25}$$

the branch of the last square root fixed by continuing each eigenvalue $a_k \to |a_k| e^{-i\frac{\pi}{2}\mathrm{sgn}(a_k)}$ from the convergent regulator.

Proof. Insert the convergence factor: for $\epsilon > 0$,

$$I_\epsilon = \int_{-\infty}^{\infty} dx\ e^{\frac{i}{2}ax^2 - \frac{\epsilon}{2}x^2} = \int_{-\infty}^{\infty} dx\ e^{-\frac{1}{2}(\epsilon - ia)x^2} = \sqrt{\frac{2\pi}{\epsilon - ia}}, \tag{E.26}$$

where the last step is the one-dimensional formula Theorem 4.13 applied with the complex coefficient $\epsilon - ia$, legitimate because $\mathrm{Re}(\epsilon - ia) = \epsilon > 0$ guarantees absolute convergence and the Gaussian is analytic in the coefficient throughout the right half-plane. Letting $\epsilon \to 0^+$ sends the coefficient to $-ia = |a|\, e^{-i\frac{\pi}{2}\mathrm{sgn}(a)}$, which lies on the boundary of the half-plane reached without crossing the branch cut along the negative real axis; hence

$$\int_{-\infty}^{\infty} dx\ e^{\frac{i}{2}ax^2} = \sqrt{\frac{2\pi}{|a|}}\left(e^{-i\frac{\pi}{2}\,\mathrm{sgn}(a)}\right)^{-1/2} = \sqrt{\frac{2\pi}{|a|}}\, e^{\,i\frac{\pi}{4}\,\mathrm{sgn}(a)}, \tag{E.27}$$

which is Eq. (E.24). For the multidimensional case, diagonalize the real symmetric A by an orthogonal O as in Theorem E.1; the measure is invariant and the form decouples into n one-dimensional Fresnel integrals with coefficients the eigenvalues a_k. Their product is

$$\prod_{k=1}^{n} \sqrt{\frac{2\pi}{|a_k|}}\, e^{\,i\frac{\pi}{4}\,\mathrm{sgn}(a_k)} = \frac{(2\pi)^{n/2}}{\big(\prod_k |a_k|\big)^{1/2}}\, e^{\,i\frac{\pi}{4}\sum_k \mathrm{sgn}(a_k)} = \frac{(2\pi)^{n/2}}{|\det A|^{1/2}}\, e^{\,i\frac{\pi}{4}\operatorname{sig} A}, \tag{E.28}$$

since $\prod_k |a_k| = |\det A|$ and $\sum_k \mathrm{sgn}(a_k) = \operatorname{sig} A$. Writing each phase as $e^{-i\frac{\pi}{2}\mathrm{sgn}(a_k)} = (-ia_k)/|a_k|$ recombines the modulus and phase into $\prod_k (-ia_k)^{-1/2} = (\det(-iA))^{-1/2}$ on the stated branch, giving the last equality of Eq. (E.25). □

The phase $e^{i\frac{\pi}{4}\operatorname{sig} A}$ is the finite-dimensional ancestor of the Maslov index that decorates semiclassical amplitudes; it counts, mode by mode, the negative directions of the quadratic form. The cleanest way to remove the oscillation altogether is the Wick rotation itself: continuing $x^0 \to -i\tau$ as in Theorem 5.30 turns e^{iS} into e^{-S_E} with S_E a positive Euclidean action, whereupon every formula of this section applies verbatim with a genuinely positive-definite A, and the physical answer is recovered by rotating back. We will adopt this Euclidean route as the default in the next section, where A becomes a differential operator and the only honest definition of its determinant is through a positive, real spectrum.

E.1.7 Worked computations

Worked Example E.9 (The two-by-two Grassmann determinant, by hand)**.** We verify Theorem E.3 for $n = 2$ with no appeal to the general permutation sum, exhibiting how the determinant assembles. Take generators $\bar\theta_1, \theta_1, \bar\theta_2, \theta_2$ and $\bar\theta M\theta = \sum_{i,j} \bar\theta_i M_{ij} \theta_j$. The exponential truncates at the quadratic term, and only the part with all four generators survives the integral:

$$e^{-\bar\theta M\theta}\Big|_{\text{top}} = \frac{1}{2}(\bar\theta M\theta)^2\Big|_{\text{top}}. \tag{E.29}$$

Expanding $(\bar\theta M\theta)^2$ and keeping only terms with each index once,

$$\begin{aligned}\tfrac{1}{2}(\bar\theta M\theta)^2\big|_{\text{top}} = \tfrac{1}{2}\Big[&M_{11}M_{22}\,\bar\theta_1\theta_1\bar\theta_2\theta_2 + M_{22}M_{11}\,\bar\theta_2\theta_2\bar\theta_1\theta_1 \\ &+ M_{12}M_{21}\,\bar\theta_1\theta_2\bar\theta_2\theta_1 + M_{21}M_{12}\,\bar\theta_2\theta_1\bar\theta_1\theta_2\Big].\end{aligned} \tag{E.30}$$

The two diagonal monomials are equal (even blocks commute), $\bar\theta_1\theta_1\bar\theta_2\theta_2 = \bar\theta_2\theta_2\bar\theta_1\theta_1$, and integrate against $D[\bar\theta,\theta]$ to $(-1)^2 = +1$. The two off-diagonal monomials are likewise equal and, by the transposition computation under Eq. (E.12), integrate to -1. Hence

$$\int D[\bar\theta,\theta]\, e^{-\bar\theta M\theta} = \tfrac{1}{2}\big[2M_{11}M_{22}(+1)+2M_{12}M_{21}(-1)\big] = M_{11}M_{22}-M_{12}M_{21} = \det M, \tag{E.31}$$

the 2×2 determinant, sign and all. The minus on the off-diagonal product is the sgn of the transposition (12)—the same sign that, promoted to fields, antisymmetrizes the fermion and supplies the closed-loop minus sign.

Worked Example E.10 (Fermionic four-point function as a 2×2 determinant)**.** We evaluate $\langle\theta_1\theta_2\,\bar\theta_1\bar\theta_2\rangle$ two ways and confirm Theorem E.6. By the determinant formula Eq. (E.19) with $n = 2$, $i_1 = 1, i_2 = 2, j_1 = 1, j_2 = 2$,

$$\langle\theta_1\theta_2\,\bar\theta_1\bar\theta_2\rangle = \det\begin{pmatrix}(M^{-1})_{11} & (M^{-1})_{12}\\ (M^{-1})_{21} & (M^{-1})_{22}\end{pmatrix} = (M^{-1})_{11}(M^{-1})_{22} - (M^{-1})_{12}(M^{-1})_{21}. \tag{E.32}$$

By the pairing form, θ_1 contracts with $\bar\theta_1$ or $\bar\theta_2$; the two matchings $\{(\theta_1\bar\theta_1),(\theta_2\bar\theta_2)\}$ and $\{(\theta_1\bar\theta_2),(\theta_2\bar\theta_1)\}$ carry signs $+1$ and -1 respectively (the second is an odd permutation of the contracted slots), giving

$$\langle\theta_1\theta_2\bar\theta_1\bar\theta_2\rangle = \langle\theta_1\bar\theta_1\rangle\langle\theta_2\bar\theta_2\rangle - \langle\theta_1\bar\theta_2\rangle\langle\theta_2\bar\theta_1\rangle, \tag{E.33}$$

identical to the determinant after Eq. (E.18). The contrast with the bosonic four-point function Eq. (4.74), where the analogous three (here two, the $\theta\theta$ pairing being absent) terms all enter with $+$ sign, is exactly the determinant-versus-permanent distinction of statistics.

Worked Example E.11 (The oscillatory integral and the i-epsilon propagator)**.** We connect Theorem E.8 to the Feynman propagator's $i\epsilon$. Consider the one-dimensional quantum-mechanical kernel whose action contributes $\frac{i}{2}(p^2-m^2)|\tilde x|^2$ per mode in momentum space; the relevant oscillatory integral is the $a = p^2 - m^2$ instance of Eq. (E.24). The regulator $a \to a - i\epsilon\,\mathrm{sgn}(a)$ that made Eq. (E.26) converge is the statement that the quadratic form is given an infinitesimal negative imaginary part, $p^2 - m^2 \to p^2 - m^2 + i\epsilon$ once the overall i in e^{iS} is accounted for. The propagator, being the inverse of the quadratic form, is then

$$(\text{form})^{-1} = \frac{i}{p^2 - m^2 + i\epsilon}, \tag{E.34}$$

which is exactly the Feynman propagator of the book's conventions. Thus the $i\epsilon$ is not an extra prescription bolted onto the propagator: it is the same convergence factor that defines the oscillatory Gaussian, viewed through the inverse rather than the determinant. The Euclidean alternative—rotate $p^0 \to ip^0_E$ per Theorem 5.30, so $p^2 - m^2 \to -(p_E^2 + m^2)$ with $p_E^2 + m^2 > 0$ strictly positive—turns the same form positive-definite and the oscillatory integral into the convergent Euclidean one, the route we follow in the remainder of the appendix.

We have now assembled the complete finite-dimensional kit: the real, complex, and Grassmann master formulas Eqs. (E.1), (E.5) and (E.8) with their sources, Wick's theorem in both statistics Eqs. (E.17) and (E.19), the unifying determinant rule Eq. (E.22) with its Pfaffian mirror, and the analytic continuation Eq. (E.25) that licenses the oscillatory physical integral. Each is a theorem about an ordinary (or Berezin) integral over finitely many variables. The two objects they hand forward are the determinant $\det A$, which fixes the normalization, and the inverse A^{-1}, which is the propagator. The next section takes the only remaining step that separates this algebra from quantum field theory: it lets the number of variables become infinite, so that A becomes a differential operator K and $\det A$ becomes an infinite product of eigenvalues that, taken naively, does not converge. Giving that product—and the functional determinant $(\det K)^{-1/2}$ it stands for—a finite, computable meaning is the business that begins immediately.

E.2 From Discrete to Continuum: Functional Determinants

The previous section (Section E.1) left us holding two finite-dimensional facts and one question. The facts: for a real symmetric positive matrix A on $\mathbb{R}^n$,

$$\int_{\mathbb{R}^n} \mathrm{d}^n x \, \exp\Big(-\tfrac{1}{2}\, x^{\mathsf{T}} A\, x + b^{\mathsf{T}} x \Big) = \frac{(2\pi)^{n/2}}{\sqrt{\det A}} \, \exp\Big(\tfrac{1}{2}\, b^{\mathsf{T}} A^{-1} b \Big), \tag{E.35}$$

so that every Gaussian moment is controlled by the inverse A^{-1} (the propagator) and the overall normalization by $(\det A)^{-1/2}$. The question is what becomes of Eq. (E.35) when $n \to \infty$ and the vector x is promoted to a field $\phi(\tau)$. The infinite-dimensional Gaussian heuristic of Section 4.2 already told us, formally, what to expect: the quadratic form $\tfrac{1}{2}\, x^{\mathsf{T}} A\, x$ becomes $\tfrac{1}{2}\int \phi\, K \phi$ for a differential operator K, the propagator becomes the Green's function K^{-1}, and the normalization becomes $(\det K)^{-1/2}$ with $\det K$ the product of the eigenvalues of K. The purpose of this section is to make the limit honest. We build the measure $\mathcal{D}\phi$ as a time-sliced limit, watch the discretized quadratic form converge to $\tfrac{1}{2}\int \phi K \phi$, discover that the resulting $\det K = \prod_n \lambda_n$ is literally infinite, isolate the ratio prescription that rescues finite physics from it, and then prove — in full — the one theorem that turns a one-dimensional functional determinant into a number you can compute by solving an ordinary differential equation: the Gelfand–Yaglom theorem.

E.2.1 Time slicing and the measure

The cleanest laboratory is single-particle quantum mechanics, which is field theory in $0+1$ dimensions: the "field" is the trajectory $x(\tau)$ of one degree of freedom. We work in Euclidean time from the outset, both because that is where the Gaussian integrals converge and because every functional determinant we shall meet is naturally Euclidean. The Wick rotation $t \to -i\tau$ (Section 5.4.1) sends the real-time weight e^{iS} to e^{-S_E}, and we restore real time at the end of any computation by continuing the answer back, $\tau \to it$. The Euclidean action for a particle of mass m in a potential V is

$$S_E[x] = \int_0^T \mathrm{d}\tau \, \Big[\tfrac{1}{2} m\, \dot{x}(\tau)^2 + V\big(x(\tau)\big) \Big], \qquad \dot{x} \equiv \frac{dx}{d\tau}, \tag{E.36}$$

and the object we wish to define is the Euclidean transition amplitude $\big\langle x_f \big| e^{-HT} \big| x_i \big\rangle = \int \mathcal{D}x \, e^{-S_E[x]}$, the imaginary-time continuation of the propagator built canonically in Section 10.1.

The measure has no a priori meaning; we *define* it by discretization. Partition the interval $[0, T]$ into N equal steps of width $\varepsilon = T/N$, with nodes $\tau_k = k\varepsilon$ and

values $x_k = x(\tau_k)$, the endpoints held fixed at $x_0 = x_i$ and $x_N = x_f$. The kinetic term becomes a sum of squared finite differences and the potential a Riemann sum,

$$S_E \;\longrightarrow\; S_N = \sum_{k=1}^{N} \Big[\frac{m}{2\varepsilon}(x_k - x_{k-1})^2 + \varepsilon\, V(x_k)\Big], \tag{E.37}$$

and the integral over all paths becomes an ordinary integral over the $N-1$ free interior heights, weighted by one factor of $\sqrt{m/2\pi\varepsilon}$ per slice:

$$\int \mathcal{D}x\, e^{-S_E[x]} \;:=\; \lim_{N\to\infty} \Big(\frac{m}{2\pi\varepsilon}\Big)^{N/2} \int_{-\infty}^{\infty} \prod_{k=1}^{N-1} \mathrm{d}x_k\; e^{-S_N}. \tag{E.38}$$

The per-slice prefactor is not decoration: it is exactly the normalization that makes the free short-time kernel a correctly normalized Gaussian, $\big\langle x_k \big| e^{-\varepsilon H_0} \big| x_{k-1} \big\rangle = \sqrt{m/2\pi\varepsilon}\, \exp[-\frac{m}{2\varepsilon}(x_k - x_{k-1})^2]$, so that composing N of them reproduces $e^{-H_0 T}$ in the limit. It is the source of the infinite normalization constant we will fight with below, and the reason functional determinants are only ever sensible as ratios.

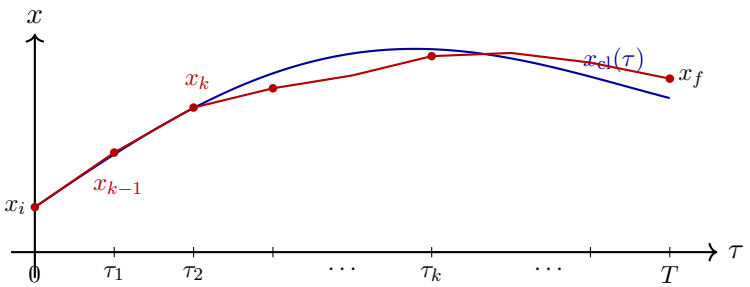

Figure E.1: The time-sliced path integral. The smooth classical trajectory x_{cl} (blue) extremizes S_E; the discretized measure Eq. (E.38) integrates over all broken-line configurations (red) pinned to the fixed endpoints x_i, x_f at the interior nodes $x_1, \ldots, x_{N-1}$. The continuum limit $N \to \infty$ ($\varepsilon = T/N \to 0$) defines $\int \mathcal{D}x$.

To expose the quadratic form, expand about the classical path. Let $x = x_{\mathrm{cl}} + \eta$, where x_{cl} solves the Euclidean equation of motion $m\ddot{x}_{\mathrm{cl}} = V'(x_{\mathrm{cl}})$ with $x_{\mathrm{cl}}(0) = x_i$, $x_{\mathrm{cl}}(T) = x_f$, and the fluctuation η vanishes at both ends, $\eta(0) = \eta(T) = 0$. Because the first variation vanishes at the classical path, Taylor expansion of Eq. (E.36) to second order gives, with no linear term,

$$S_E[x_{\mathrm{cl}}+\eta] = S_E[x_{\mathrm{cl}}] + \frac{1}{2}\int_0^T \mathrm{d}\tau\, \eta(\tau)\, K\, \eta(\tau) + O(\eta^3), \qquad K = -m\,\frac{d^2}{d\tau^2} + V''(x_{\mathrm{cl}}(\tau)), \tag{E.39}$$

the integration by parts in the cross term producing no boundary contribution precisely because η is pinned at the endpoints. This is the promised continuum

quadratic form $\frac{1}{2}\int \eta K \eta$, the infinite-dimensional avatar of $\frac{1}{2}\,x^{\mathsf{T}} A x$. The fluctuation operator K is a second-order differential operator on functions vanishing at 0 and T — a *Dirichlet* operator on $[0,T]$. For the harmonic oscillator $V = \frac{1}{2}m\omega^2 x^2$ the potential well is quadratic, $V'' = m\omega^2$ is constant, and $K = m(-\partial_\tau^2 + \omega^2)$; this is the model we carry through the section.

At finite N the quadratic form Eq. (E.39) is an honest $(N-1)$-dimensional quadratic form $\frac{1}{2}\,\eta^{\mathsf{T}} M \eta$ in the interior fluctuations $\eta_k = \eta(\tau_k)$. From Eq. (E.37) the matrix M is tridiagonal: the kinetic piece contributes $(m/\varepsilon)(2$ on the diagonal, -1 off-diagonal), and the potential adds $\varepsilon\, V_k''$ to the diagonal, where $V_k'' \equiv V''(x_{\mathrm{cl}}(\tau_k))$. Performing the Gaussian integral over the η_k with Eq. (E.35) and keeping the measure factors gives the one-loop fluctuation amplitude

$$\int \mathcal{D}\eta\, e^{-\frac{1}{2}\int \eta K \eta} = \lim_{N\to\infty} \Big(\frac{m}{2\pi\varepsilon}\Big)^{N/2} \frac{(2\pi)^{(N-1)/2}}{\sqrt{\det M}}, \tag{E.40}$$

and the bookkeeping of the powers of ε and 2π hidden in $\det M$ is exactly what we must now do carefully, because it is here that the would-be $(\det K)^{-1/2}$ appears together with a divergent constant.

The free determinant, done exactly. Take first the free particle, $V'' = 0$, $M = M^{(0)}$. The matrix $M^{(0)} = (m/\varepsilon)\,T_{N-1}$, where T_{N-1} is the $(N-1)\times(N-1)$ tridiagonal matrix with 2 on the diagonal and -1 on the first off-diagonals. Its determinant is computed by the elementary recursion for the leading principal minors $D_k = \det T_k$: expanding along the last row,

$$D_k = 2D_{k-1} - D_{k-2}, \qquad D_0 = 1,\ D_1 = 2 \implies D_k = k+1, \tag{E.41}$$

so $\det T_{N-1} = N$ and $\det M^{(0)} = (m/\varepsilon)^{N-1} N$. Substituting into Eq. (E.40) and using $\varepsilon N = T$, every power of 2π, m, and ε telescopes against the measure:

$$\Big(\frac{m}{2\pi\varepsilon}\Big)^{N/2} \frac{(2\pi)^{(N-1)/2}}{\sqrt{(m/\varepsilon)^{N-1}N}} = \sqrt{\frac{m}{2\pi\varepsilon}}\cdot\frac{1}{\sqrt{N}} = \sqrt{\frac{m}{2\pi\varepsilon N}} = \sqrt{\frac{m}{2\pi T}}. \tag{E.42}$$

This is the exact free Euclidean propagator $\big\langle x_f \big| e^{-H_0 T} \big| x_i \big\rangle$ prefactor; its real-time continuation $T \to iT$ reproduces the familiar $\sqrt{m/2\pi i T}$ of Section 10.1. Two lessons are worth pausing on. First, the recursion Eq. (E.41) is the discrete version of the homogeneous equation $-\ddot{\psi} = 0$: it is already the Gelfand–Yaglom construction in embryo. Second, the finite answer Eq. (E.42) emerged only because the divergent factor $(m/2\pi\varepsilon)^{N/2}$ from the measure cancelled the divergent factor $(m/\varepsilon)^{(N-1)/2}$ from $\sqrt{\det M^{(0)}}$. The determinant by itself is hopelessly divergent; only the measure-dressed combination is finite.

E.2.2 The formal determinant and its divergence

Strip away the measure and ask what the bare continuum object $\det K$ would be. By definition it is the product of the eigenvalues of the Dirichlet operator K on $[0, T]$. For the free operator $K_0 = -\partial_\tau^2$ (we set $m = 1$ in this subsection, restoring it trivially later) the eigenfunctions are $\sin(n\pi\tau/T)$ with $n = 1, 2, 3, \ldots$, and the eigenvalues are

$$\lambda_n^{(0)} = \left(\frac{n\pi}{T}\right)^2, \qquad n = 1, 2, 3, \ldots, \tag{E.43}$$

so the formal determinant is the infinite product

$$\det K_0 \overset{\text{formal}}{=} \prod_{n=1}^{\infty} \left(\frac{n\pi}{T}\right)^2. \tag{E.44}$$

This product diverges, and not subtly: its logarithm is $2\sum_n \ln(n\pi/T)$, whose terms grow without bound, so the partial products race to $+\infty$. Adding a potential only shifts each eigenvalue by a bounded amount (the eigenvalues of $-\partial_\tau^2 + W$ are $\lambda_n = (n\pi/T)^2 + O(1)$, as we prove below), so $\det K = \prod_n \lambda_n$ diverges in exactly the same way. The infinite-dimensional Gaussian of Eq. (E.35), taken at face value, returns $(\det K)^{-1/2} = 0$.

Caution

The divergence of Eq. (E.44) is *not* an artifact of bad bookkeeping that a cleverer choice of measure would remove. It reflects a genuine fact: a path integral assigns a weight to fluctuations of arbitrarily short wavelength, and there are infinitely many of them. The ultraviolet modes $n \to \infty$ are the source. Any sensible definition of $\det K$ must come with a prescription for taming them. There are two routes. The first, pursued in this section, is to never form $\det K$ alone but only the ratio $\det K / \det K_0$ against a reference operator, in which the ultraviolet modes cancel mode by mode. The second, pursued in Section E.3, is to give $\det K$ an intrinsic meaning through the spectral zeta function, which analytically continues the divergent product to a finite number. The two must agree on the ratios where both are defined, and they do.

E.2.3 The ratio prescription

Every physical quantity built from a Gaussian functional integral is a ratio of two such integrals in disguise. A normalized expectation value $\langle \cdot \rangle$ divides by the partition function; a transition amplitude is compared against the free one to fix its normalization; a one-loop effective action is the fluctuation determinant

relative to a reference. We therefore *define* the only object we will ever need, the determinant ratio

$$\frac{\det K}{\det K_0} \;:=\; \prod_{n=1}^{\infty} \frac{\lambda_n}{\lambda_n^{(0)}}, \tag{E.45}$$

where $\lambda_n, \lambda_n^{(0)}$ are the ordered Dirichlet eigenvalues of $K = -\partial_\tau^2 + W$ and of a reference operator $K_0 = -\partial_\tau^2 + W_0$ on $[0, T]$. This product *converges* whenever it should, for a reason the heuristic divergence of Eq. (E.44) hid: the ratio of the n-th eigenvalues tends to 1 fast. Writing $\lambda_n/\lambda_n^{(0)} = 1 + (\lambda_n - \lambda_n^{(0)})/\lambda_n^{(0)}$, the numerator is bounded (both eigenvalues equal $(n\pi/T)^2$ up to an $O(1)$ shift set by the potentials) while the denominator grows like n^2, so the correction is $O(1/n^2)$ and absolutely summable. An infinite product $\prod(1 + a_n)$ with $\sum |a_n| < \infty$ converges to a finite nonzero limit; this is the convergence fact imported from Section 5.4.1. The divergent measure factors that dressed each determinant in Eq. (E.40) are identical for K and K_0 and cancel in the ratio, so Eq. (E.45) is exactly the finite, measure-independent content of the one-loop integral. The remaining task is purely computational: evaluate the ratio without ever finding the individual eigenvalues. That is what Gelfand–Yaglom delivers.

E.2.4 The Gelfand–Yaglom theorem

Theorem E.12 (Gelfand–Yaglom)**.** *Let W, W_0 be continuous functions on $[0, T]$, and let $K = -\partial_\tau^2 + W$ and $K_0 = -\partial_\tau^2 + W_0$ act on functions obeying Dirichlet boundary conditions $\eta(0) = \eta(T) = 0$, with the determinant ratio defined by Eq. (E.45). Let ψ solve the homogeneous* initial-value *problem*

$$\big(-\partial_\tau^2 + W(\tau)\big)\psi(\tau) = 0, \qquad \psi(0) = 0, \quad \psi'(0) = 1, \tag{E.46}$$

and let ψ_0 solve the same problem with W replaced by W_0. Then, provided neither K nor K_0 has zero as an eigenvalue (equivalently $\psi(T) \neq 0$ and $\psi_0(T) \neq 0$),

$$\boxed{\frac{\det\big(-\partial_\tau^2 + W\big)}{\det\big(-\partial_\tau^2 + W_0\big)} = \frac{\psi(T)}{\psi_0(T)}\,.} \tag{E.47}$$

The statement is striking: an infinite product of eigenvalues equals the ratio of two numbers, each obtained by integrating a single ordinary differential equation forward from $\tau = 0$ to $\tau = T$. Note what Eq. (E.46) is and is not: it is an *initial*-value problem, not the eigenvalue (boundary-value) problem. We never impose $\psi(T) = 0$; we simply shoot from the left with a fixed slope and read off where we land at $\tau = T$. We give two proofs. The first is finite-dimensional and constructive — it is the continuum limit of the tridiagonal recursion we already met — and makes transparent why the theorem is true. The second is the spectral/analytic argument, which is intrinsically continuum and airtight; it also explains why only the ratio, never the determinant alone, has a chance of equalling a finite number.

Proof I: the discrete recursion and its limit

Discretize K exactly as in Section E.2.1. The Dirichlet operator $-\partial_\tau^2 + W$ on $[0, T]$ becomes the $(N-1) \times (N-1)$ symmetric tridiagonal matrix $\widehat{K}$ with diagonal entries $\widehat{K}_{kk} = \frac{2}{\varepsilon^2} + W_k$ (where $W_k = W(\tau_k)$) and off-diagonal entries $\widehat{K}_{k,k\pm1} = -\frac{1}{\varepsilon^2}$; the factors of $1/\varepsilon^2$ are the second-difference operator. Pull out the common scale and write $\widehat{K} = \varepsilon^{-2} B$, where B is tridiagonal with diagonal $2 + \varepsilon^2 W_k$ and off-diagonal -1. Let $d_k = \det B_k$ be the determinant of the leading $k \times k$ block. Cofactor expansion along the last row gives the three-term recursion

$$d_k = (2 + \varepsilon^2 W_k)\, d_{k-1} - d_{k-2}, \qquad d_0 = 1, \quad d_{-1} = 0. \tag{E.48}$$

Rearranging Eq. (E.48) as $\dfrac{d_k - 2d_{k-1} + d_{k-2}}{\varepsilon^2} = W_k\, d_{k-1}$ exhibits it as the discretization of the *continuum* equation $\psi'' = W\psi$, i.e. $(-\partial_\tau^2 + W)\psi = 0$, the very equation Eq. (E.46). To match initial data, set $\psi_k := \varepsilon\, d_{k-1}$. The seed values $d_{-1} = 0,\ d_0 = 1$ become $\psi_0 = \varepsilon d_{-1} = 0$ and $\psi_1 = \varepsilon d_0 = \varepsilon$, so $\psi_0 = 0$ and $(\psi_1 - \psi_0)/\varepsilon = 1$ — precisely $\psi(0) = 0,\ \psi'(0) = 1$. As $\varepsilon \to 0$ with $k\varepsilon = \tau$ held fixed, the solution of the difference equation converges to the solution of the differential equation (standard convergence of consistent, stable one-step schemes for a linear ODE with continuous coefficients), so $\psi_k \to \psi(\tau)$. In particular at the right endpoint $k = N$, $\tau_N = T$,

$$\det \widehat{K} = \varepsilon^{-2(N-1)}\, d_{N-1} = \varepsilon^{-2(N-1)}\, \frac{\psi_N}{\varepsilon} \xrightarrow{\varepsilon \to 0} \varepsilon^{-2(N-1)}\, \frac{\psi(T)}{\varepsilon}. \tag{E.49}$$

The prefactor $\varepsilon^{-(2N-1)}$ is divergent — it is the discrete shadow of the formal divergence of $\det K$ — but it depends only on ε and N, *not* on the potential W. Therefore in the ratio against the reference operator K_0 (same lattice, same N, same ε, diagonal $2 + \varepsilon^2 W_{0,k}$) it cancels identically:

$$\frac{\det \widehat{K}}{\det \widehat{K}_0} = \frac{d_{N-1}}{d_{N-1}^{(0)}} = \frac{\psi_N}{\psi_N^{(0)}} \xrightarrow{\varepsilon \to 0} \frac{\psi(T)}{\psi_0(T)}. \tag{E.50}$$

The left side converges to the determinant ratio Eq. (E.45), because the eigenvalues of the lattice operator $\widehat{K}$ converge to those of K mode by mode and the ratio is a convergent product. This proves Eq. (E.47). □

This proof is honest and complete, and its message is the one to remember: *the divergence of the functional determinant is entirely carried by a W-independent prefactor*, so it drops out of any ratio, leaving the finite number $\psi(T)/\psi_0(T)$. The second proof re-derives the same identity working directly in the continuum, and in doing so proves the eigenvalue asymptotics and the convergence facts we have so far only asserted.

Proof II: the spectral/analytic argument

The continuum proof studies how the determinant depends on a spectral parameter z, and uses one elementary fact from complex analysis. We first build the machinery, then assemble it.

The shooting solution as an entire function of z. For complex z, let $\psi_z(\tau)$ solve the initial-value problem

$$(-\partial_\tau^2 + W(\tau) - z)\psi_z = 0, \qquad \psi_z(0) = 0,\ \psi_z'(0) = 1. \tag{E.51}$$

Integrating twice and using the initial data converts Eq. (E.51) into the Volterra integral equation

$$\psi_z(\tau) = \frac{\sin(\sqrt{z}\,\tau)}{\sqrt{z}} + \int_0^\tau \frac{\sin(\sqrt{z}\,(\tau - s))}{\sqrt{z}}\, W(s)\, \psi_z(s)\, \mathrm{d}s, \tag{E.52}$$

in which $\sin(\sqrt{z}\,\tau)/\sqrt{z}$ is entire in z (only even powers of $\sqrt{z}$ appear, so the branch ambiguity cancels). Solving Eq. (E.52) by Picard iteration $\psi_z = \sum_{j\ge 0} \psi_z^{(j)}$, with $\psi_z^{(0)} = \sin(\sqrt{z}\,\tau)/\sqrt{z}$ and each $\psi_z^{(j)}$ obtained by inserting the previous term, gives terms bounded by

$$|\psi_z^{(j)}(\tau)| \le \frac{\left(\int_0^\tau |W|\right)^j}{j!}\, \frac{\sinh(|\sqrt{z}|\,\tau)}{|\sqrt{z}|}, \tag{E.53}$$

using $|\sin(\sqrt{z}\,u)/\sqrt{z}| \le \sinh(|\sqrt{z}|\,u)/|\sqrt{z}|$ for all complex z. The series therefore converges uniformly on compact sets to an *entire* function of z,

$$\psi_z(\tau) = \frac{\sin(\sqrt{z}\,\tau)}{\sqrt{z}}\Big(1 + O(1/\sqrt{z})\Big) \quad \text{as } |z| \to \infty, \tag{E.54}$$

the correction being uniform in $\tau \in [0, T]$ by Eq. (E.53). Since $\sin(\sqrt{z}\,T)/\sqrt{z}$ has order $\frac{1}{2}$ in z (it grows like $e^{|\sqrt{z}|\,T}$ along the negative real axis), so does $\psi_z(T)$: it is an entire function of order $\frac{1}{2}$.

Zeros of $\psi_z(T)$ are exactly the Dirichlet eigenvalues, and they are simple. By construction z is a Dirichlet eigenvalue of $K = -\partial_\tau^2 + W$ if and only if there is a nonzero solution vanishing at both endpoints, i.e. if and only if the shooting solution ψ_z — the unique solution with $\psi_z(0) = 0$ — also satisfies $\psi_z(T) = 0$. Hence the zeros of the entire function $z \mapsto \psi_z(T)$ are precisely the eigenvalues $\{\lambda_n\}$. They are simple as zeros: differentiating Eq. (E.51) in z and using a one-line Wronskian computation gives the Hadamard formula $\partial_z \psi_z(T)\big|_{z=\lambda_n} = -\psi_{\lambda_n}'(T) \int_0^T \psi_{\lambda_n}^2\, \mathrm{d}\tau / [\psi_{\lambda_n}'(T)]$, which is nonzero because the eigenfunction ψ_{λ_n} is nontrivial and, by uniqueness of the initial-value problem,

cannot have $\psi'_{\lambda_n}(T) = 0$ simultaneously with $\psi_{\lambda_n}(T) = 0$. (Concretely: a second-order linear ODE solution vanishing together with its derivative at a point is identically zero.) So each λ_n is a simple zero. From Eq. (E.54) the zeros sit asymptotically where $\sin(\sqrt{z}\,T) = 0$, i.e. $\sqrt{\lambda_n}\,T \to n\pi$, giving the promised asymptotics

$$\lambda_n = \Big(\frac{n\pi}{T}\Big)^2 + O(1), \tag{E.55}$$

which is what made the ratio product Eq. (E.45) converge and the bare product Eq. (E.44) diverge.

An elementary complex-analysis lemma.

Lemma E.13. *An entire function $g(z)$ of order $\rho < 1$ with no zeros is constant.*

Proof. If g has no zeros, $h := \ln g$ is entire. Order ρ means $|g(z)| \le \exp(C|z|^{\rho+\delta})$ for some C and any $\delta > 0$ with $\rho + \delta < 1$, hence $\operatorname{Re} h(z) \le C|z|^{\rho+\delta}$. The Borel–Carathéodory inequality bounds the maximum modulus of an analytic function on a circle by the maximum of its real part on a larger circle: for $0 < r < R$, $\max_{|z|=r} |h(z)| \le \frac{2r}{R-r} \max_{|z|=R} \operatorname{Re} h(z) + \frac{R+r}{R-r}|h(0)|$. Taking $R = 2r$ gives $\max_{|z|=r} |h| \le 4C(2r)^{\rho+\delta} + 3|h(0)|$, so h grows slower than $|z|$. Cauchy's estimate on the Taylor coefficients of h then forces every coefficient beyond the constant term to vanish (the k-th coefficient is bounded by $r^{-k} \max_{|z|=r} |h| \to 0$ for $k \ge 1$ as $r \to \infty$ since $\rho + \delta < 1$). Thus h is constant and so is g. □

Factorization and assembly. Let $\{\lambda_n\}$ and $\{\mu_n\}$ be the Dirichlet eigenvalues of K and K_0. Form the canonical product $P(z) := \prod_n (1 - z/\lambda_n)$, which converges and is entire of order $\frac{1}{2}$ because $\sum_n 1/\lambda_n < \infty$ by Eq. (E.55) (genus zero). Consider $g(z) := \psi_z(T)/P(z)$. It is entire (the simple zeros of the numerator are exactly cancelled by the simple zeros of P), it has no zeros, and it is a quotient of two entire functions of order $\frac{1}{2}$ that is itself entire, hence of order $\le \frac{1}{2} < 1$. By Theorem E.13, g is constant, equal to its value at $z = 0$: $g = \psi_0(T)/P(0) = \psi_0(T)$ since $P(0) = 1$. Therefore

$$\psi_z(T) = \psi_0(T) \prod_{n=1}^{\infty} \Big(1 - \frac{z}{\lambda_n}\Big), \qquad \psi^0_z(T) = \psi^0_0(T) \prod_{n=1}^{\infty} \Big(1 - \frac{z}{\mu_n}\Big), \tag{E.56}$$

the second identity being the same statement for K_0, with ψ^0_z its shooting solution and $\psi^0_0(T) \equiv \psi^0_{z=0}(T)$. (Here $\psi_0(T) = \psi_{z=0}(T)$ is the $z = 0$ shooting solution of Eq. (E.46), the very object on the right of Eq. (E.47).) Divide the two relations in Eq. (E.56) and use $(1 - z/\lambda_n)/(1 - z/\mu_n) = \big[(\lambda_n - z)/(\mu_n - z)\big] \cdot (\mu_n/\lambda_n)$ to separate the determinant-ratio product $R(z) := \prod_n (\lambda_n - z)/(\mu_n - z)$ from the z-independent constant $\prod_n (\mu_n/\lambda_n) = R(0)^{-1}$:

$$\frac{\psi_z(T)}{\psi^0_z(T)} = \frac{\psi_0(T)}{\psi^0_0(T)}\,\frac{R(z)}{R(0)}. \tag{E.57}$$

Now send $z \to -\infty$ along the real axis. On the left, Eq. (E.54) gives $\psi_z(T) \to \sinh(\sqrt{-z}\,T)/\sqrt{-z}$ for *both* operators with the same leading factor, so $\psi_z(T)/\psi_z^0(T) \to 1$. On the right, $R(z) = \prod_n (\lambda_n - z)/(\mu_n - z) \to 1$ as well, because each factor tends to 1 and $\ln R(z) = \sum_n \ln\!\left[1 + (\lambda_n - \mu_n)/(\mu_n - z)\right] \to 0$ by dominated convergence (the summand is bounded by $|\lambda_n - \mu_n|/|\mu_n - z|$, summable and vanishing as $z \to -\infty$). Taking the limit of Eq. (E.57) therefore yields $1 = \dfrac{\psi_0(T)}{\psi_0^0(T)} \cdot \dfrac{1}{R(0)}$, i.e.

$$\frac{\psi_0(T)}{\psi_0^0(T)} = R(0) = \prod_{n=1}^{\infty} \frac{\lambda_n}{\mu_n} = \frac{\det K}{\det K_0}, \tag{E.58}$$

which is exactly Eq. (E.47) (with $\psi_0 \equiv \psi$, $\psi_0^0 \equiv \psi_0$ in the notation of the theorem). □

The two proofs illuminate each other. Proof I shows the divergence is a potential-independent lattice prefactor; Proof II shows the same thing intrinsically, as the potential-independent asymptotic factor $\sinh(\sqrt{-z}\,T)/\sqrt{-z}$ that cancels in the ratio. Either way the content of a one-dimensional functional determinant is one number, $\psi(T)$, the endpoint value of a forward shoot.

Physical Insight

Gelfand–Yaglom replaces an infinite spectral problem with a single classical trajectory. The operator K is the second variation of the action — it governs how the action responds to fluctuations about the classical path — and $\psi(\tau)$, the solution of $K\psi = 0$ with $\psi(0) = 0$, is nothing but a *Jacobi field*: the linearized response of the classical trajectory to a kick in its initial velocity. The determinant of fluctuations is large exactly when neighbouring classical trajectories spread apart (large $\psi(T)$) and it develops a zero exactly at a *conjugate point*, where a nontrivial Jacobi field returns to zero ($\psi(T) = 0$) and the classical path ceases to be an isolated minimum. The vanishing of the determinant at conjugate points — the breakdown of the naive Gaussian approximation — is the same phenomenon as a caustic in optics and is the origin of the Maslov phase in semiclassical quantization.

E.2.5 Worked example: the harmonic oscillator

We now redeem the section's promise by recovering the harmonic-oscillator prefactor from Theorem E.12 and matching it against the canonical result of Section 10.1.

Worked Example E.14 (The oscillator fluctuation determinant and propagator prefactor)**.** The Euclidean fluctuation operator for the oscillator $V = \frac{1}{2}m\omega^2 x^2$ is, from Eq. (E.39), $K = m\,(-\partial_\tau^2 + \omega^2)$ with Dirichlet conditions on $[0, T]$; the

reference is the free operator $K_0 = m\,(-\partial_\tau^2)$. The overall constant m cancels in the ratio, so by Theorem E.12 we need only the shooting solutions of $(-\partial_\tau^2+\omega^2)\psi = 0$ and $(-\partial_\tau^2)\psi_0 = 0$.

Step 1 — solve the two initial-value problems. For $W = \omega^2$,

$$-\psi''+\omega^2\psi = 0,\ \ \psi(0) = 0,\ \psi'(0) = 1 \ \Longrightarrow\ \psi(\tau) = \frac{\sinh(\omega\tau)}{\omega},\ \ \psi(T) = \frac{\sinh(\omega T)}{\omega}. \tag{E.59}$$

For $W_0 = 0$, the equation is $-\psi_0'' = 0$, so $\psi_0(\tau) = \tau$ and $\psi_0(T) = T$.

Step 2 — form the determinant ratio. Equation (E.47) gives immediately

$$\frac{\det\,(-\partial_\tau^2+\omega^2)}{\det\,(-\partial_\tau^2)} = \frac{\psi(T)}{\psi_0(T)} = \frac{\sinh(\omega T)}{\omega T}. \tag{E.60}$$

It is worth checking this against the brute-force eigenvalue product, which we can do precisely because both spectra are known. The Dirichlet eigenvalues are $\lambda_n = (n\pi/T)^2+\omega^2$ and $\mu_n = (n\pi/T)^2$, so the ratio is the classical Euler product for the hyperbolic sine,

$$\prod_{n=1}^{\infty}\frac{(n\pi/T)^2+\omega^2}{(n\pi/T)^2} = \prod_{n=1}^{\infty}\Big(1+\frac{\omega^2T^2}{n^2\pi^2}\Big) = \frac{\sinh(\omega T)}{\omega T}, \tag{E.61}$$

in exact agreement with Eq. (E.60). The Gelfand–Yaglom theorem has summed this infinite product for us with a two-line ODE solution, and would have done so just as easily for a potential with no closed-form spectrum.

Step 3 — assemble the propagator prefactor. The full one-loop amplitude is the free normalization Eq. (E.42) times the inverse square root of the determinant ratio Eq. (E.60):

$$\sqrt{\frac{m}{2\pi T}}\,\Big(\frac{\sinh(\omega T)}{\omega T}\Big)^{-1/2} = \sqrt{\frac{m\,\omega}{2\pi\,\sinh(\omega T)}}. \tag{E.62}$$

The factors of T cancel cleanly, leaving the celebrated oscillator prefactor. With $m = 1$ this is $\sqrt{\omega/2\pi\sinh(\omega T)}$, exactly the form quoted in the section goal. Continuing back to real time by $T \to iT$ ($\sinh \to i\sin$) reproduces the Minkowski oscillator propagator prefactor $\sqrt{m\omega/2\pi i\sin(\omega T)}$ derived canonically (via the Mehler kernel and operator methods) in Section 10.1; the analytic continuation is licensed by Section 5.4.1. The path integral and the operator formalism agree, and the agreement rests entirely on the finite determinant ratio Eq. (E.60).

The same machine evaluates any one-loop prefactor in quantum mechanics, and — through the loop expansion of Section 4.2 — the leading semiclassical weight of any instanton or bounce, where $W = V''(x_{\mathrm{cl}})$ is read off the classical solution and $\psi(T)$ integrates the Jacobi equation along it. The boxed identity Eq. (E.47) is thus the first genuine computational handle on a functional determinant.

E.2.6 What survives, and what does not

We have extracted from the time-sliced measure a completely finite, regularization-independent number for any one-dimensional fluctuation operator: the determinant ratio $\det K/\det K_0 = \psi(T)/\psi_0(T)$, with the divergence quarantined in a universal prefactor that cancels. But the construction is irreducibly one-dimensional. Its engine, the reduction of a determinant to an initial-value problem, used that the eigenfunctions of $-\partial_\tau^2 + W$ on an interval are labelled by a single integer and that "shooting from one endpoint to the other" is a well-posed ODE. In two or more dimensions the spectrum of a Laplace-type operator is labelled by a lattice of momenta, there is no "initial" boundary to shoot from, and the eigenvalue density grows fast enough that even ratios $\det K/\det K_0$ can fail to converge as products. Gelfand–Yaglom gives us the answer in $d = 1$ and a sharp picture of why we cannot have it in general. To define $\det K$ for a differential operator in any dimension — and to confront, rather than cancel, the ultraviolet divergence of Eq. (E.44) — we need a definition that does not rely on a product at all. That is the spectral route of Section E.3: assemble the eigenvalues into a zeta function $\zeta_K(s) = \sum_n \lambda_n^{-s}$, analytically continue it past the divergent product, and *define* $\ln\det K = -\zeta_K'(0)$.

E.3 Regularizing the Determinant: Zeta Functions and the Heat Kernel

The previous section (Section E.2) left us in an uncomfortable position. Gaussian integration over the fluctuations of a field produces, as we saw in Section E.1, a factor $(\det K)^{-1/2}$ for a second-order differential operator K, and the logarithm of that determinant is the entire one-loop physics. In one dimension—the quantum mechanics of a single degree of freedom—the Gelfand–Yaglom theorem of Section E.2 gave a finite, computable answer for the *ratio* of two such determinants by solving an ordinary differential equation, sidestepping the eigenvalues altogether. That trick is precious but parochial: it is tied to the one-dimensional structure of an initial-value problem, and it computes only ratios. In a genuine field theory K is an elliptic operator on a d-dimensional space, its spectrum $\{\lambda_n\}$ grows without bound, and the object we are asked to make sense of is the divergent product $\prod_n \lambda_n$, or equivalently the divergent sum $\sum_n \ln\lambda_n$. We need a definition of $\det K$ that (i) reduces to the ordinary determinant whenever the spectrum is finite, (ii) is independent of the spatial dimension, (iii) does not presuppose a momentum cutoff or a lattice, and (iv) exposes, rather than hides, the ultraviolet divergences and the way they organize themselves into the renormalization of the theory. The spectral zeta function delivers exactly this, and the heat kernel is the engine that makes it computable. Throughout this section K is taken in Euclidean signature—the Wick rotation $t \to -i\tau$

of Section 5.4 turns the Minkowski fluctuation operator into a positive elliptic operator, which is the only regime in which e^{-tK} is a sensible (trace-class) object.

E.3.1 The spectral zeta function and the determinant

Let K be a non-negative, self-adjoint, elliptic operator on a compact d-dimensional Euclidean manifold (or a finite box with stated boundary conditions), with a discrete spectrum

$$0 \le \lambda_1 \le \lambda_2 \le \lambda_3 \le \cdots \to \infty, \tag{E.63}$$

each eigenvalue repeated according to its multiplicity. For the moment assume $\lambda_1 > 0$ (no zero modes); zero modes are reinstated in Section E.3.3. The growth rate of the eigenvalues is fixed by Weyl's law: for a second-order operator the n-th eigenvalue behaves as $\lambda_n \sim C\, n^{2/d}$ for large n, with C a constant built from the volume. This single fact controls every convergence question below.

Definition E.15 (Spectral zeta function)**.** The *spectral zeta function* of K is

$$\zeta_K(s) \;=\; \sum_n \lambda_n^{-s}, \tag{E.64}$$

defined initially for those complex s where the series converges absolutely.

By Weyl's law $\lambda_n^{-s} \sim C^{-s} n^{-2s/d}$, so Eq. (E.64) converges absolutely precisely when $\operatorname{Re} s > d/2$. In that half-plane $\zeta_K(s)$ is holomorphic, being a uniformly convergent sum of the entire functions $\lambda_n^{-s} = e^{-s \ln \lambda_n}$. The number $d/2$ is the *abscissa of convergence*; it is the first place the dimension of spacetime enters, and it will reappear as the location of the operator's leading ultraviolet divergence.

The reason to introduce Eq. (E.64) is a formal manipulation that becomes a definition. Differentiate term by term:

$$\zeta_K'(s) \;=\; \sum_n \frac{d}{ds}\, e^{-s \ln \lambda_n} \;=\; -\sum_n (\ln \lambda_n)\, \lambda_n^{-s}. \tag{E.65}$$

If we could set $s = 0$ in Eq. (E.65) we would obtain $\zeta_K'(0) = -\sum_n \ln \lambda_n = -\ln \prod_n \lambda_n = -\ln \det K$. The sum $\sum_n \ln \lambda_n$ diverges, and $s = 0$ lies far outside the domain of convergence $\operatorname{Re} s > d/2$; the manipulation is therefore purely formal as it stands. But it points to the right definition: provided $\zeta_K(s)$ extends to a function holomorphic at $s = 0$, the quantity $\zeta_K'(0)$ is perfectly well-defined, and we *adopt* it as the regularized value of the divergent sum.

Definition E.16 (Zeta-regularized determinant)**.** When $\zeta_K(s)$ admits an analytic continuation that is holomorphic in a neighbourhood of $s = 0$, the *zeta-regularized determinant* of K is

$$\boxed{\ln \det K \;=\; -\,\zeta_K'(0), \qquad \det K \;=\; \exp\!\big(-\,\zeta_K'(0)\big).} \tag{E.66}$$

This definition is forced on us in the sense that it is the *only* one consistent with the finite-dimensional case. If K is an $N\times N$ positive matrix with eigenvalues $\lambda_1,\dots,\lambda_N$, then $\zeta_K(s)=\sum_{n=1}^{N}\lambda_n^{-s}$ is an entire function (a finite sum of entire functions), so the continuation is trivial, and Eq. (E.65) at $s=0$ gives $\zeta_K'(0)=-\sum_{n=1}^{N}\ln\lambda_n$, whence $-\zeta_K'(0)=\ln\prod_n\lambda_n=\ln\det K$ exactly. Theorem E.16 reproduces the textbook determinant whenever the textbook determinant exists, and supplies a finite answer when it does not. It is also manifestly dimension-independent: nothing in Eq. (E.66) refers to a lattice spacing, a momentum cutoff, or even the value of d except through the analytic structure of ζ_K. The remaining work is to prove the continuation exists and to compute it; that is what the heat kernel is for.

E.3.2 From the heat trace: the Mellin transform

The bridge from the abstract sum Eq. (E.64) to something computable is the operator e^{-tK}, the *heat semigroup*, so named because for $K=-\nabla^2$ the kernel of e^{-tK} is the fundamental solution of the heat equation $\partial_t u=\nabla^2 u$. Its trace,

$$\Theta_K(t)\;=\;\operatorname{Tr}\,e^{-tK}\;=\;\sum_{n}e^{-t\lambda_n},\qquad t>0, \tag{E.67}$$

is called the *heat trace* (or partition function of the operator). For $\lambda_1>0$ the series converges for every $t>0$ and decays exponentially, $\Theta_K(t)\to e^{-t\lambda_1}\to 0$, as $t\to\infty$. Its $t\to 0^+$ behaviour is singular and encodes the ultraviolet physics; that is the subject of Section E.3.4.

The link to the zeta function is a single classical identity. Recall the integral representation of the Gamma function, $\Gamma(s)=\int_0^\infty dt\,t^{s-1}e^{-t}$, valid for $\operatorname{Re}s>0$. Rescaling $t\to\lambda t$ gives, for any $\lambda>0$,

$$\lambda^{-s}\;=\;\frac{1}{\Gamma(s)}\int_0^\infty dt\;t^{s-1}\,e^{-\lambda t},\qquad \operatorname{Re}s>0. \tag{E.68}$$

Summing Eq. (E.68) over the spectrum and exchanging sum and integral—legitimate for $\operatorname{Re}s>d/2$, where both the sum and the integral converge absolutely—we obtain the *Mellin transform* representation of the zeta function in terms of the heat trace.

Proposition E.17 (Mellin representation)**.** *For* $\operatorname{Re}s>d/2$,

$$\zeta_K(s)\;=\;\frac{1}{\Gamma(s)}\int_0^\infty dt\;t^{s-1}\,\Theta_K(t). \tag{E.69}$$

Proof. Insert Eq. (E.68) into Eq. (E.64):

$$\zeta_K(s)=\sum_n\lambda_n^{-s}=\sum_n\frac{1}{\Gamma(s)}\int_0^\infty dt\;t^{s-1}e^{-\lambda_n t}=\frac{1}{\Gamma(s)}\int_0^\infty dt\;t^{s-1}\sum_n e^{-\lambda_n t}. \tag{E.70}$$

The interchange of $\sum_n$ and $\int dt$ is justified by Tonelli's theorem: for $\operatorname{Re} s > d/2$ the integrand $t^{\operatorname{Re} s-1}e^{-\lambda_n t}$ is non-negative and the iterated integral $\sum_n \int_0^\infty t^{\operatorname{Re} s-1}e^{-\lambda_n t}\,dt = \Gamma(\operatorname{Re} s)\sum_n \lambda_n^{-\operatorname{Re} s} < \infty$ is finite. The inner sum is $\Theta_K(t)$ by Eq. (E.67). □

Equation (E.69) is the workhorse of the whole subject: it converts a question about the (inaccessible) individual eigenvalues into a question about the (computable) heat trace, a single function of one variable. Before continuing it is worth recording the heuristic that explains why $-\zeta_K'(0)$ "is" $\sum_n \ln\lambda_n$ at the level of the proper-time integral. Setting $s \to 0$ naively in Eq. (E.69) and using $1/\Gamma(s) \to s$, one has $\zeta_K(s) \approx s\int_0^\infty \frac{dt}{t}\,\Theta_K(t)$, so

$$\ln\det K = -\zeta_K'(0) \;\text{“}=\text{”}\; -\int_0^\infty \frac{dt}{t}\,\Theta_K(t) = -\int_0^\infty \frac{dt}{t}\sum_n e^{-\lambda_n t}. \tag{E.71}$$

The right-hand side is the *proper-time* (Schwinger) representation of the log-determinant. It diverges at the lower limit $t \to 0$, which is the ultraviolet end, and the divergence is purely additive: for two eigenvalues the combination is finite by Frullani's integral,

$$\int_0^\infty \frac{dt}{t}\left(e^{-\lambda t} - e^{-\lambda' t}\right) = \ln\frac{\lambda'}{\lambda}, \tag{E.72}$$

which is exactly $\ln(\lambda'/\lambda) = \ln\lambda' - \ln\lambda$, the difference of the "log-eigenvalues" the proper-time integral is meant to sum. (To verify Eq. (E.72), differentiate its left side with respect to λ, obtaining $-\int_0^\infty dt\, e^{-\lambda t} = -1/\lambda$, and integrate back with the boundary value 0 at $\lambda = \lambda'$.) Thus the proper-time integral computes log-eigenvalues correctly up to a common, eigenvalue-independent divergent constant, and the role of the zeta function is precisely to define that constant by analytic continuation rather than to throw it away by a subtraction. This is the same philosophy as dimensional regularization, a correspondence we make exact in Section E.3.7.

E.3.3 Analytic continuation and the value at zero

To turn Theorem E.16 into a theorem we must continue $\zeta_K(s)$ past the line $\operatorname{Re} s = d/2$ and establish that it is holomorphic at $s = 0$. The continuation is controlled entirely by the short-time behaviour of the heat trace, which (as proved in Section E.3.4) has an asymptotic expansion in powers of t,

$$\Theta_K(t) \overset{t\to 0^+}{\sim} \sum_{k=0}^{\infty} A_k\, t^{(k-d)/2}, \tag{E.73}$$

where the coefficients A_k are integrals of local geometric data over the manifold (only even k occur for the operators of interest, but nothing below needs that).

The term with $k = d$ is the t^0 (constant) term; we single out its coefficient A_d because it will turn out to govern $\zeta_K(0)$.

We must also restore zero modes. If K has $N_0 = \dim\ker K$ zero eigenvalues, they should be *omitted* from the determinant (a vanishing eigenvalue makes the literal product zero and signals a flat direction to be treated separately, typically by a collective coordinate). The zero modes contribute N_0 to the trace Eq. (E.67) at all times, spoiling the large-t decay. We therefore define the zeta function on the nonzero spectrum by subtracting them:

$$\zeta_K(s) \;=\; \frac{1}{\Gamma(s)}\int_0^\infty dt\, t^{s-1}\big[\Theta_K(t) - N_0\big], \qquad \det{}'K \equiv e^{-\zeta_K'(0)}, \tag{E.74}$$

the prime on $\det'$ recording that zero modes are excluded. We now prove the central analytic result.

Theorem E.18 (Meromorphic continuation and the value at zero)**.** *Let K be a positive elliptic operator with heat trace obeying Eq. (E.73), and let $N_0 = \dim\ker K$. Then $\zeta_K(s)$ defined by Eq. (E.74) extends to a meromorphic function on the whole s-plane whose only singularities are simple poles at*

$$s = \frac{d-k}{2}, \qquad k = 0, 1, 2, \dots, \quad \tfrac{d-k}{2} \notin \{0, -1, -2, \dots\}, \tag{E.75}$$

with residues $\operatorname{Res}_{s=(d-k)/2}\zeta_K(s) = A_k/\Gamma(\frac{d-k}{2})$. In particular ζ_K is holomorphic at $s = 0$, where

$$\boxed{\zeta_K(0) \;=\; A_d \;-\; \dim\ker K.} \tag{E.76}$$

Proof. Split the integral Eq. (E.74) at $t = 1$: $\zeta_K(s) = \frac{1}{\Gamma(s)}\big[I_<(s) + I_>(s)\big]$ with $I_< = \int_0^1$ and $I_> = \int_1^\infty$. The high-t piece $I_>(s) = \int_1^\infty t^{s-1}[\Theta_K(t) - N_0]\,dt$ converges for *every* complex s, because $\Theta_K(t) - N_0 = \sum_{\lambda_n>0} e^{-\lambda_n t} \le (\text{const})\, e^{-\lambda_1 t}$ decays exponentially while t^{s-1} grows only polynomially; differentiating under the integral shows $I_>(s)$ is entire.

For the low-t piece insert the asymptotic expansion Eq. (E.73). Fix an integer $N > d$ and write

$$\Theta_K(t) - N_0 = \sum_{k=0}^{N} A_k\, t^{(k-d)/2} - N_0 + R_N(t), \qquad R_N(t) = O\big(t^{(N+1-d)/2}\big)\ \ (t \to 0). \tag{E.77}$$

Integrate term by term against t^{s-1} over $(0, 1)$. For each power,

$$\int_0^1 t^{s-1}\, t^{(k-d)/2}\, dt = \frac{1}{s + \frac{k-d}{2}}, \qquad \int_0^1 t^{s-1}\,(-N_0)\, dt = -\frac{N_0}{s}, \tag{E.78}$$

both valid initially for $\operatorname{Re} s$ large enough and then by the explicit right-hand side for all s away from the indicated poles. The remainder contributes $\int_0^1 t^{s-1} R_N(t)\, dt$,

which converges and is holomorphic for $\operatorname{Re} s > (d-N-1)/2$. Collecting,

$$\zeta_K(s) = \frac{1}{\Gamma(s)}\left[\sum_{k=0}^{N} \frac{A_k}{s+\frac{k-d}{2}} \;-\; \frac{N_0}{s} \;+\; H_N(s)\right], \tag{E.79}$$

with $H_N(s) = I_>(s) + \int_0^1 t^{s-1} R_N(t)\,dt$ holomorphic for $\operatorname{Re} s > (d-N-1)/2$. Since N is arbitrary, Eq. (E.79) continues ζ_K to the entire plane. The bracket has simple poles at $s = (d-k)/2$ $(k = 0, \dots, N)$ and at $s = 0$. The prefactor $1/\Gamma(s)$ is *entire* (the reciprocal Gamma function has no poles) with simple zeros at $s = 0, -1, -2, \dots$. Wherever a pole of the bracket falls on such a zero it is cancelled, which removes exactly the values $(d-k)/2 \in \{0, -1, -2, \dots\}$ from the pole list; the surviving poles are Eq. (E.75), with residue $A_k \cdot \lim_{s\to(d-k)/2} 1/\Gamma(s) = A_k/\Gamma((d-k)/2)$.

It remains to evaluate $\zeta_K(0)$. Near $s = 0$ the reciprocal Gamma function behaves as

$$\frac{1}{\Gamma(s)} = s + \gamma_E\, s^2 + O(s^3), \tag{E.80}$$

which follows from $\Gamma(s) = \frac{1}{s} - \gamma_E + O(s)$ (the Laurent expansion of Γ at its pole, established with the other properties of the Gamma function in Section 5.4). Thus $1/\Gamma(s)$ vanishes linearly at $s = 0$, and only the residue of the bracket at $s = 0$ survives the product. The bracket's pole at $s = 0$ comes from two terms: the $k = d$ summand, $A_d/(s + \frac{d-d}{2}) = A_d/s$, and the zero-mode term $-N_0/s$. Hence

$$\zeta_K(0) = \lim_{s\to 0} s\left[\frac{A_d}{s} - \frac{N_0}{s} + (\text{regular at } 0)\right] = A_d - N_0, \tag{E.81}$$

which is Eq. (E.76). □

Two consequences deserve emphasis. First, Theorem E.18 guarantees that Theorem E.16 is well posed: ζ_K is holomorphic at $s = 0$, so $\zeta_K'(0)$ exists and $\det' K$ is a finite number. Second, Eq. (E.76) ties the value $\zeta_K(0)$—a pure number—to a single heat-kernel coefficient A_d, the t^0 term in the short-time expansion, minus the dimension of the kernel. When the spacetime dimension d is odd there is no t^0 term in Eq. (E.73) (the powers are half-odd-integers), so $A_d = 0$ and $\zeta_K(0) = -\dim\ker K$; odd-dimensional theories have no associated logarithmic divergence and no scaling anomaly, a fact we recover concretely in Theorem E.21. The location of the poles Eq. (E.75) is sketched in Fig. E.2.

E.3.4 The Seeley–DeWitt expansion

We owe a proof of the short-time expansion Eq. (E.73) and a computation of its leading coefficients, since everything above rests on it. The cleanest derivation

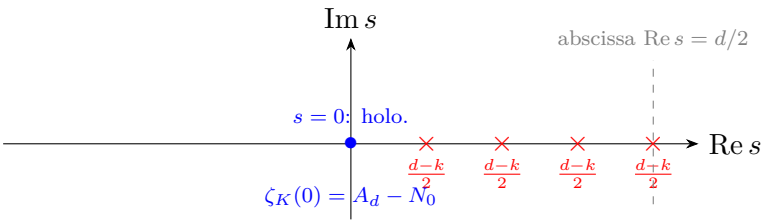

Figure E.2: Analytic structure of $\zeta_K(s)$ for a second-order operator in $d = 4$. The series Eq. (E.64) converges right of the abscissa $\mathrm{Re}\, s = d/2$ (here $s = 2$). Continuation produces simple poles (red crosses) at $s = (d-k)/2$ with residues set by the heat-kernel coefficients A_k; the would-be poles at the non-positive integers are killed by the zero of $1/\Gamma(s)$. The determinant is read off at the regular point $s = 0$ (blue), and $\zeta_K(0)$ measures the logarithmic divergence.

works directly with the heat kernel $\mathcal{K}(x, y; t)$, the integral kernel of e^{-tK}, defined by

$$(e^{-tK} f)(x) = \int d^d y\, \mathcal{K}(x, y; t)\, f(y), \tag{E.82}$$

so that the heat trace is the integral of the kernel over the diagonal, $\Theta_K(t) = \int d^d x\, \mathcal{K}(x, x; t)$. By construction $\mathcal{K}$ solves the heat equation in its first slot with a delta-function initial condition,

$$(\partial_t + K_x)\mathcal{K}(x, y; t) = 0, \qquad \mathcal{K}(x, y; 0^+) = \delta^{(d)}(x - y). \tag{E.83}$$

We carry out the analysis for the prototypical fluctuation operator

$$K = -\partial^2 + V(x) \tag{E.84}$$

on flat $\mathbb{R}^d$ (Euclidean), where $\partial^2 = \delta^{ij}\partial_i\partial_j$ is the Laplacian and V is a smooth potential; this is exactly the form of the one-loop operator $\delta^2 S/\delta\phi^2 = -\partial^2 + V''(\phi_{\mathrm{cl}})$ that the next section will need. The curved-space generalization is recorded at the end and proved in the curved-spacetime development (Chapter 64).

When $V \equiv 0$ the heat kernel is the Gaussian solution of the free heat equation,

$$\mathcal{K}_0(x, y; t) = \frac{1}{(4\pi t)^{d/2}} \exp\left(-\frac{|x - y|^2}{4t}\right), \tag{E.85}$$

as one checks by direct substitution into Eq. (E.83); its normalization is fixed by $\int d^d x\, \mathcal{K}_0 = 1$ and it reproduces $\delta^{(d)}(x - y)$ as $t \to 0^+$ because it is a nascent delta function of width $\sqrt{t}$. The presence of the potential is encoded by writing the full kernel as the free Gaussian times a regular prefactor,

$$\mathcal{K}(x, y; t) = \frac{1}{(4\pi t)^{d/2}}\, e^{-|x-y|^2/4t}\, \Phi(x, y; t), \qquad \Phi(x, y; t) = \sum_{k=0}^{\infty} b_k(x, y)\, t^k, \tag{E.86}$$

the *Seeley–DeWitt ansatz*. The matching to the free kernel at $t \to 0$ requires $\Phi \to 1$ on the diagonal, i.e. $b_0(x,x) = 1$, and the b_k are smooth. Substituting Eq. (E.86) into the heat equation determines the b_k recursively.

Proposition E.19 (Recursion for the heat-kernel coefficients)**.** *Write $u = x - y$. The coefficient functions in Eq. (E.86) satisfy $b_0 \equiv 1$ and, for $k \geq 1$,*

$$(k + u^i \partial_i)\, b_k(x,y) = (\partial^2 - V)\, b_{k-1}(x,y), \tag{E.87}$$

where ∂_i acts on the x variable. In particular the diagonal values are

$$b_0(x,x) = 1, \qquad b_1(x,x) = -V(x). \tag{E.88}$$

Proof. Write $\mathcal{K} = \mathcal{K}_0\,\Phi$ with $\mathcal{K}_0$ the free kernel Eq. (E.85), which itself satisfies the free heat equation $\partial_t \mathcal{K}_0 = \partial^2 \mathcal{K}_0$. We compute $(\partial_t + K)\mathcal{K} = (\partial_t - \partial^2 + V)(\mathcal{K}_0\Phi)$. Using the product rule and $\partial_t \mathcal{K}_0 = \partial^2 \mathcal{K}_0$,

$$\begin{aligned}(\partial_t - \partial^2)(\mathcal{K}_0\Phi) &= (\partial_t \mathcal{K}_0)\Phi + \mathcal{K}_0 \partial_t \Phi - (\partial^2 \mathcal{K}_0)\Phi - 2(\partial_i \mathcal{K}_0)(\partial_i \Phi) - \mathcal{K}_0 \partial^2 \Phi \\ &= \mathcal{K}_0 \Big[\partial_t \Phi - \tfrac{2}{\mathcal{K}_0}(\partial_i \mathcal{K}_0)(\partial_i \Phi) - \partial^2 \Phi \Big]. \end{aligned} \tag{E.89}$$

The gradient of the Gaussian is $\partial_i \mathcal{K}_0 = \mathcal{K}_0 \cdot (-u_i/2t)$, so $\frac{2}{\mathcal{K}_0}(\partial_i \mathcal{K}_0)(\partial_i \Phi) = -(u_i/t)\partial_i \Phi$. Demanding $(\partial_t + K)\mathcal{K} = 0$, i.e. $(\partial_t - \partial^2)(\mathcal{K}_0\Phi) = -V\mathcal{K}_0\Phi$, and dividing by $\mathcal{K}_0 \neq 0$ gives the transport equation

$$\partial_t \Phi + \frac{u^i}{t}\, \partial_i \Phi - \partial^2 \Phi = -V\, \Phi. \tag{E.90}$$

Insert $\Phi = \sum_k b_k t^k$ and read off powers of t. The operator ∂_t sends $b_k t^k \to k\, b_k t^{k-1}$; the term $\frac{u^i}{t}\partial_i$ sends $b_k t^k \to (u^i \partial_i b_k)\, t^{k-1}$; and $-\partial^2$ and $-V$ keep the power t^k. Matching the coefficient of t^{k-1} on both sides,

$$k\, b_k + u^i \partial_i b_k - \partial^2 b_{k-1} = -V\, b_{k-1}, \tag{E.91}$$

which rearranges to Eq. (E.87), with the convention $b_{-1} = 0$. At $k = 0$ this reads $u^i \partial_i b_0 = 0$, so b_0 is constant along rays emanating from y; smoothness at $u = 0$ together with $b_0(x,x) = 1$ forces $b_0 \equiv 1$. For $k = 1$, Eq. (E.87) gives $(1 + u^i\partial_i)b_1 = (\partial^2 - V)b_0 = -V$ (since $\partial^2 b_0 = 0$). Evaluating on the diagonal $u = 0$, the operator $u^i \partial_i$ annihilates, leaving $b_1(x,x) = -V(x)$. □

Integrating the diagonal kernel over the manifold and using Eq. (E.86),

$$\Theta_K(t) = \int d^d x\, \mathcal{K}(x,x;t) = \frac{1}{(4\pi t)^{d/2}} \int d^d x \Big[\, b_0(x,x) + b_1(x,x)\, t + \cdots \Big], \tag{E.92}$$

which is precisely the asymptotic series Eq. (E.73) once we identify the coefficients. It is conventional to factor out the $(4\pi)^{-d/2}$ and write

$$\Theta_K(t) \overset{t \to 0^+}{\sim} \frac{1}{(4\pi t)^{d/2}} \sum_{j=0}^{\infty} a_j\, t^j, \qquad a_j = \int d^d x\, b_j(x,x), \tag{E.93}$$

the a_j being the (integrated) *Seeley–DeWitt coefficients*; comparison with Eq. (E.73) gives $A_{2j} = (4\pi)^{-d/2} a_j$ and $A_{\text{odd}} = 0$. From Eq. (E.88),

$$a_0 = \int d^d x = \text{Vol}, \qquad a_1 = -\int d^d x \, V(x). \tag{E.94}$$

The leading coefficient is just the volume; the first correction is the integral of the potential. The constant (t^0) term in Θ_K is $A_d = (4\pi)^{-d/2} a_{d/2}$, so Eq. (E.76) reads, in this normalization,

$$\zeta_K(0) = \frac{a_{d/2}}{(4\pi)^{d/2}} - \dim\ker K. \tag{E.95}$$

This is the precise meaning of the slogan "$\zeta_K(0) = a_{d/2} - \dim\ker K$": $a_{d/2}$ is the half-dimension Seeley–DeWitt coefficient, the one whose power of t is exactly zero.

The curvature term. On a curved background the operator is $K = -\nabla^2 + V$ with ∇ the covariant Laplacian, the volume element carries $\sqrt{g}$, and the geodesic interval $\sigma(x,y) = \frac{1}{2}(\text{geodesic distance})^2$ replaces $\frac{1}{2}|x-y|^2$. The ansatz Eq. (E.86) acquires one extra factor, the square root of the van Vleck–Morette determinant $\Delta(x,y) = g^{-1/2} \det[-\partial^2\sigma/\partial x^i \partial y^j]$,

$$\mathcal{K}(x,y;t) = \frac{\Delta^{1/2}(x,y)}{(4\pi t)^{d/2}} \, e^{-\sigma(x,y)/2t} \sum_k b_k(x,y)\, t^k, \tag{E.96}$$

whose role is to keep $b_0 = 1$ in the curved transport equation. In Riemann normal coordinates centred at y one has the standard small-distance expansions $\sqrt{g} = 1 - \frac{1}{6} R_{ij} u^i u^j + \cdots$ and $\Delta^{1/2} = 1 + \frac{1}{12} R_{ij} u^i u^j + \cdots$, and repeating the $k = 1$ step of Theorem E.19 with the covariant Laplacian feeds the Ricci scalar R into the diagonal value. The result, derived in full in Chapter 64, is

$$b_1(x,x) = \frac{R(x)}{6} - V(x), \qquad a_1 = \int d^d x \, \sqrt{g} \left(\frac{R}{6} - V \right). \tag{E.97}$$

The coefficient $\frac{1}{6}$ is the conformal coupling in $d = 4$ ($\xi = (d-2)/4(d-1) = \frac{1}{6}$): the conformally coupled scalar is the one whose heat kernel has this universal curvature term, which is the first sign that $\zeta_K(0)$ will know about the conformal anomaly.

Physical Insight

The heat-kernel expansion is a geometry-by-time-resolution microscope. At short proper time t the kernel Eq. (E.85) probes the manifold only out to a distance $\sqrt{t}$, so the leading $\Theta_K \sim (4\pi t)^{-d/2}\text{Vol}$ just counts how many independent "cells" of size $\sqrt{t}$ fit in the volume—a mode-counting

that is the heat-kernel face of Weyl's law. Successive coefficients $a_1, a_2, \ldots$ are corrections that see ever-coarser local data: the potential, then the curvature, then its derivatives and squares. The deepest fact of this section is that the *same* coefficients that describe this geometric coarse graining are the coefficients of the ultraviolet divergences of the quantum theory. Short distance and short proper time are the same limit.

E.3.5 Ultraviolet divergences and the scaling anomaly

We can now read the renormalization structure of a one-loop determinant directly off the heat-kernel coefficients. The one-loop contribution to the effective action is $\Gamma^{(1)} = \frac{1}{2} \ln \det K$ (the $\frac{1}{2}$ from the $(\det K)^{-1/2}$ of bosonic Gaussian integration; the next section assembles this), and its proper-time form Eq. (E.71) is divergent at the lower limit. Cut the integral at $t = \epsilon^2$ (so ϵ is a short-distance length) and insert the short-time expansion Eq. (E.93):

$$\ln \det K\Big|_{\mathrm{UV}} = -\int_{\epsilon^2}^{1} \frac{dt}{t} \frac{1}{(4\pi t)^{d/2}} \sum_j a_j t^j = -\frac{1}{(4\pi)^{d/2}} \sum_j a_j \int_{\epsilon^2} dt\, t^{j-d/2-1}. \tag{E.98}$$

Each term diverges as $\epsilon \to 0$ whenever its exponent makes the integral blow up at the lower limit, i.e. for $j < d/2$ (power divergences) and for $j = d/2$ (a logarithm):

$$\int_{\epsilon^2} dt\, t^{j-d/2-1} = \begin{cases} \dfrac{1}{(d/2-j)\,\epsilon^{d-2j}} + (\text{finite}), & j < d/2, \\ -2\ln\epsilon + (\text{finite}), & j = d/2. \end{cases} \tag{E.99}$$

The dictionary is now explicit. The $j = 0$ term, $a_0 = \mathrm{Vol}$, produces a divergence $\propto \epsilon^{-d}\,\mathrm{Vol}$: this is the *cosmological-constant* (vacuum-energy) divergence, an additive shift of the free energy proportional to the volume. The $j = 1$ term, $a_1 = \int (R/6 - V)$, produces a divergence $\propto \epsilon^{-(d-2)}$ multiplying $\int V$ and $\int R$: this renormalizes the *mass* (the $\int V$ piece, since $V = m^2 + \cdots$) and, on a curved background, *Newton's constant* (the $\int R$ piece). The logarithmic term sits at $j = d/2$, with coefficient $a_{d/2}$—precisely the coefficient that Eq. (E.95) identified with $\zeta_K(0)$. Thus the single number $\zeta_K(0)$ is the coefficient of the logarithmic ultraviolet divergence of the determinant, and it is therefore the quantity that controls the *running* and the renormalization-group flow at one loop.

The zeta definition Theorem E.16 contains no cutoff ϵ at all: the power divergences are simply absent (the analytic continuation discards them, just as dimensional regularization sets scaleless power divergences to zero), while the logarithmic divergence reappears not as a divergence but as a finite, unavoidable dependence of the determinant on the unit in which eigenvalues are measured.

To see this, note that the determinant of a rescaled operator is governed by exactly $\zeta_K(0)$.

Theorem E.20 (Scaling law of the determinant)**.** *For any constant $\mu > 0$,*

$$\ln\det(\mu^2 K) = \ln\det K + 2\,\zeta_K(0)\,\ln\mu, \qquad \textit{equivalently} \qquad \det(\mu^2 K) = \mu^{2\zeta_K(0)}\det K. \tag{E.100}$$

Proof. The eigenvalues of $\mu^2 K$ are $\mu^2\lambda_n$, so its zeta function is $\zeta_{\mu^2 K}(s) = \sum_n (\mu^2\lambda_n)^{-s} = \mu^{-2s}\zeta_K(s)$. Differentiate in s:

$$\zeta'_{\mu^2 K}(s) = \frac{d}{ds}\left[\mu^{-2s}\zeta_K(s)\right] = -2\ln\mu\;\mu^{-2s}\zeta_K(s) + \mu^{-2s}\zeta'_K(s). \tag{E.101}$$

At $s = 0$, where $\mu^0 = 1$, $\zeta'_{\mu^2 K}(0) = -2\ln\mu\,\zeta_K(0) + \zeta'_K(0)$. Insert into $\ln\det(\mu^2 K) = -\zeta'_{\mu^2 K}(0)$ to obtain Eq. (E.100). □

Theorem E.20 is the heart of the matter. A determinant of eigenvalues is not a pure number: it carries a dimension, and rescaling the operator (say by absorbing a factor μ^2 to make the eigenvalues dimensionless, as one must to take a logarithm) changes it by $\mu^{2\zeta_K(0)}$. Classically the action of a scale-invariant theory is unchanged by $K \to \mu^2 K$; quantum-mechanically the determinant is multiplied by $\mu^{2\zeta_K(0)}$. When $\zeta_K(0) \neq 0$ this is an honest breaking of classical scale invariance by the regularized measure—the *scaling anomaly* of the determinant, and (in even d, where $a_{d/2}$ is generically nonzero) the microscopic origin of the trace/conformal anomaly. The anomaly coefficient is $\zeta_K(0) = a_{d/2}/(4\pi)^{d/2} - \dim\ker K$, a local geometric integral.

Physical Insight

The vanishing of $\zeta_K(0)$ in odd dimensions, proved below Theorem E.18, is the statement that odd-dimensional theories have no conformal anomaly. There is simply no local scalar of the right dimension—no t^0 heat-kernel coefficient—available to be the anomaly. The same counting underlies the absence of perturbative gauge anomalies in odd spacetime dimension and the special role of even d throughout this book.

This is also the precise point of contact with the chiral anomaly. In Chapter 36 the anomaly is computed as the Jacobian of the path-integral measure under a chiral rotation, and Fujikawa's regularized Jacobian is nothing but a heat-kernel trace, $\lim_{t\to 0}\mathrm{Tr}[\gamma^5 e^{-t\not{D}^2}]$; the surviving t^0 term is the coefficient $a_{d/2}$ of the Dirac operator $\not{D}^2$ evaluated against γ^5. The object we have just learned to extract is exactly the object that chapter evaluates to produce the $\int F\wedge F$ anomaly. We flag this forward: Chapter 36 *uses* $a_{d/2}$; here we have defined it and given the machinery to compute it.

E.3.6 A complete computation: the thermal harmonic oscillator

The cleanest non-trivial test of the entire apparatus is the determinant that computes the free energy of a single harmonic oscillator at temperature $T = 1/\beta$. The Euclidean partition function $Z = \operatorname{Tr} e^{-\beta H}$ is the imaginary-time path integral over loops of period β (the thermal circle S^1_β), and for the oscillator $H = \frac{1}{2}p^2 + \frac{1}{2}\omega^2 q^2$ the fluctuation operator is the one-dimensional ($d = 1$) operator $K = -\partial_\tau^2 + \omega^2$ acting on periodic functions on S^1_β. Gaussian integration gives $Z \propto (\det K)^{-1/2}$, hence the free energy $F = -T \ln Z = \frac{T}{2} \ln \det K$ (up to an ω-independent normalization that we will see is fixed unambiguously by the zeta procedure). The exact answer, known from elementary statistical mechanics, is

$$F = \frac{\omega}{2} + T \, \ln(1 - e^{-\beta\omega}), \tag{E.102}$$

the zero-point energy plus the thermal occupation. We now derive Eq. (E.102) from scratch by zeta-regularizing $\det K$, with the vacuum ($T \to 0$) piece carried in closed form.

Worked Example E.21 (Zeta-regularized free energy of the thermal oscillator)**.** The eigenfunctions of $K = -\partial_\tau^2 + \omega^2$ on S^1_β are the Matsubara modes $e^{i\omega_n \tau}$ with $\omega_n = 2\pi n/\beta$, $n \in \mathbb{Z}$, periodicity being the bosonic boundary condition. The eigenvalues are

$$\lambda_n = \omega_n^2 + \omega^2 = \Big(\frac{2\pi n}{\beta}\Big)^2 + \omega^2, \qquad n \in \mathbb{Z}, \tag{E.103}$$

all strictly positive ($\omega > 0$, so no zero modes, $N_0 = 0$). The heat trace is

$$\Theta_K(t) = \sum_{n\in\mathbb{Z}} e^{-t\lambda_n} = e^{-t\omega^2} \sum_{n\in\mathbb{Z}} \exp\Big[- t\Big(\tfrac{2\pi}{\beta}\Big)^2 n^2\Big]. \tag{E.104}$$

The sum is a theta function; its small-t behaviour is exposed by Poisson resummation. Applying the Jacobi identity $\sum_n e^{-\alpha n^2} = \sqrt{\pi/\alpha}\, \sum_m e^{-\pi^2 m^2/\alpha}$ (Poisson summation for the Gaussian, whose Fourier transform is again Gaussian) with $\alpha = t(2\pi/\beta)^2$,

$$\sum_n \exp\Big[-t\Big(\tfrac{2\pi}{\beta}\Big)^2 n^2\Big] = \frac{\beta}{\sqrt{4\pi t}} \sum_{m\in\mathbb{Z}} e^{-\beta^2 m^2/4t}, \qquad \Longrightarrow \qquad \Theta_K(t) = \frac{\beta}{\sqrt{4\pi t}}\, e^{-t\omega^2} \sum_{m\in\mathbb{Z}} e^{-\beta^2 m^2/4} \tag{E.105}$$

Consistency with Seeley–DeWitt. As $t \to 0^+$ only the $m = 0$ winding survives ($m \neq 0$ terms are suppressed by $e^{-\beta^2/4t}$), so $\Theta_K(t) \sim (4\pi t)^{-1/2} \beta\, e^{-t\omega^2} = (4\pi t)^{-1/2}(\beta - \beta\omega^2 t + \cdots)$. Comparing with Eq. (E.93) in $d = 1$ identifies $a_0 = \beta = \mathrm{Vol}(S^1_\beta)$ and $a_1 = -\beta\omega^2 = -\int_0^\beta V \, d\tau$ with $V = \omega^2$, exactly Eq. (E.94). Since $d = 1$ is odd there is no t^0 term, so $A_1 = 0$ and Eq. (E.76) gives $\zeta_K(0) = 0$: no scaling anomaly, as anticipated.

The Mellin integral. Feed Eq. (E.105) into the Mellin representation Eq. (E.69) and split off the $m = 0$ term:

$$\zeta_K(s) = \underbrace{\frac{\beta}{\sqrt{4\pi}}\,\frac{1}{\Gamma(s)}\int_0^\infty dt\; t^{s-3/2}e^{-t\omega^2}}_{\zeta_0(s)\quad (m=0,\ \text{vacuum})} + \underbrace{\frac{\beta}{\sqrt{4\pi}}\,\frac{1}{\Gamma(s)}\sum_{m\neq 0}\int_0^\infty dt\; t^{s-3/2}e^{-t\omega^2-\beta^2m^2/4t}}_{\zeta_{\rm th}(s)\quad (m\neq 0,\ \text{thermal})}. \tag{E.106}$$

Vacuum piece. The $m = 0$ integral is elementary: $\int_0^\infty t^{s-3/2}e^{-t\omega^2}dt = \Gamma(s-\frac{1}{2})\,\omega^{1-2s}$ by Eq. (E.68), so

$$\zeta_0(s) = \frac{\beta}{\sqrt{4\pi}}\,\frac{\Gamma(s-\frac{1}{2})}{\Gamma(s)}\,\omega^{1-2s} = \frac{\beta\omega}{\sqrt{4\pi}}\,\frac{\Gamma(s-\frac{1}{2})}{\Gamma(s)}\,\omega^{-2s}. \tag{E.107}$$

We need $\zeta_0'(0)$. Near $s = 0$ use $1/\Gamma(s) = s + O(s^2)$ from Eq. (E.80) and the finite value $\Gamma(-\frac{1}{2}) = -2\sqrt{\pi}$:

$$\frac{\Gamma(s-\frac{1}{2})}{\Gamma(s)} = s\,\Gamma(-\tfrac{1}{2})\,[1+O(s)] = -2\sqrt{\pi}\,s + O(s^2). \tag{E.108}$$

Hence, with $\omega^{-2s} = 1 - 2s\ln\omega + O(s^2)$ and $\beta/\sqrt{4\pi}\cdot(-2\sqrt{\pi}) = -\beta$,

$$\zeta_0(s) = -\beta\omega\, s\,(1 - 2s\ln\omega + \cdots)(1+\cdots) = -\beta\omega\, s + O(s^2), \tag{E.109}$$

so $\zeta_0(0) = 0$ and $\zeta_0'(0) = -\beta\omega$. The vacuum contribution to the log-determinant is $-\zeta_0'(0) = \beta\omega$, and to the free energy

$$F_{\rm vac} = \frac{T}{2}\,(-\zeta_0'(0)) = \frac{T}{2}\,\beta\omega = \frac{\omega}{2}. \tag{E.110}$$

The zeta procedure delivers the zero-point energy $\omega/2$ in closed form, with no leftover constant: every term that could have contributed an ambiguity (the $\psi(-\frac{1}{2})$, the $\ln\omega$, the γ_E) sits at order s^2 and never reaches $\zeta_0'(0)$.

Thermal piece. Because $1/\Gamma(s) = s + O(s^2)$ vanishes at $s = 0$ while the $m \neq 0$ integrals are finite there, the thermal zeta also satisfies $\zeta_{\rm th}(0) = 0$, and $\zeta_{\rm th}'(0)$ equals the bracket evaluated at $s = 0$ (the rule $\frac{d}{ds}[s\,f(s)]_{s=0} = f(0)$). We therefore need the $m \neq 0$ integrals only at $s = 0$, i.e. $\int_0^\infty t^{-3/2}e^{-\omega^2 t-\beta^2m^2/4t}dt$. This is the elementary half-line Gaussian integral of Theorem E.22 below,

$$\int_0^\infty dt\; t^{-3/2}\,e^{-at-b/t} = \sqrt{\frac{\pi}{b}}\;e^{-2\sqrt{ab}}, \qquad a = \omega^2,\quad b = \frac{\beta^2m^2}{4}, \tag{E.111}$$

giving $\sqrt{4\pi/\beta^2m^2}\,e^{-\beta\omega|m|} = \frac{2\sqrt{\pi}}{\beta|m|}e^{-\beta\omega|m|}$. Therefore

$$\zeta_{\rm th}'(0) = \frac{\beta}{\sqrt{4\pi}}\sum_{m\neq 0}\frac{2\sqrt{\pi}}{\beta|m|}\,e^{-\beta\omega|m|} = \sum_{m\neq 0}\frac{e^{-\beta\omega|m|}}{|m|} = 2\sum_{m=1}^{\infty}\frac{e^{-\beta\omega m}}{m} = -2\ln(1-e^{-\beta\omega}), \tag{E.112}$$

the last step being the Taylor series $-\ln(1-x) = \sum_{m\geq 1} x^m/m$ with $x = e^{-\beta\omega} < 1$. The thermal contribution to the free energy is then

$$F_{\rm th} = \frac{T}{2}\,\big(-\zeta'_{\rm th}(0)\big) = \frac{T}{2}\cdot 2\ln\!\big(1-e^{-\beta\omega}\big) = T\,\ln\!\big(1-e^{-\beta\omega}\big). \tag{E.113}$$

Total. Adding Eqs. (E.110) and (E.113),

$$F = F_{\rm vac} + F_{\rm th} = \frac{\omega}{2} + T\,\ln\!\big(1-e^{-\beta\omega}\big), \tag{E.114}$$

which is the exact free energy Eq. (E.102), with no undetermined additive constant whatsoever. The zeta-regularized determinant has reproduced the full thermodynamics of the oscillator—zero-point energy and Bose–Einstein occupation alike—from its eigenvalues, in a manifestly dimension-independent scheme.

The computation used one elementary integral, which we now prove for completeness.

Lemma E.22 (Half-line Gaussian integral)**.** *For $a, b > 0$,*

$$\int_0^\infty dt\; t^{-1/2}\, e^{-at-b/t} = \sqrt{\frac{\pi}{a}}\, e^{-2\sqrt{ab}}, \qquad \int_0^\infty dt\; t^{-3/2}\, e^{-at-b/t} = \sqrt{\frac{\pi}{b}}\, e^{-2\sqrt{ab}}. \tag{E.115}$$

Proof. For the first identity substitute $t = u^2$ ($dt = 2u\,du$, $t^{-1/2} = 1/u$):

$$\int_0^\infty t^{-1/2} e^{-at-b/t} dt = 2\int_0^\infty e^{-au^2-b/u^2}\, du. \tag{E.116}$$

Complete the square in the exponent, $au^2 + b/u^2 = (\sqrt{a}\,u - \sqrt{b}/u)^2 + 2\sqrt{ab}$, so the right side is $2e^{-2\sqrt{ab}}\int_0^\infty e^{-(\sqrt{a}\,u-\sqrt{b}/u)^2} du$. The remaining integral is evaluated by the Cauchy–Schlömilch substitution: setting $w = \sqrt{a}\,u - \sqrt{b}/u$, the map $u \mapsto \sqrt{b/a}/u$ sends the integrand to itself while $du \mapsto \sqrt{b/a}\,u^{-2}du$, and averaging the integral with its image gives

$$2\int_0^\infty e^{-(\sqrt{a}u-\sqrt{b}/u)^2} du = \int_0^\infty e^{-(\sqrt{a}u-\sqrt{b}/u)^2}\big(1+\sqrt{b/a}\,u^{-2}\big) du = \frac{1}{\sqrt{a}}\int_{-\infty}^\infty e^{-w^2} dw = \frac{\sqrt{\pi}}{\sqrt{a}}, \tag{E.117}$$

where we used $dw = (\sqrt{a} + \sqrt{b}\,u^{-2})du = \sqrt{a}\,(1+\sqrt{b/a}\,u^{-2})du$ and that w runs over all of $\mathbb{R}$ as $u : 0 \to \infty$. Hence $\int_0^\infty e^{-(\sqrt{a}u-\sqrt{b}/u)^2} du = \frac{\sqrt{\pi}}{2\sqrt{a}}$ and the first identity follows. The second is obtained by differentiating the first with respect to b: $\partial_b \int t^{-1/2} e^{-at-b/t} dt = -\int t^{-3/2} e^{-at-b/t} dt$, while $\partial_b[\sqrt{\pi/a}\, e^{-2\sqrt{ab}}] = -\sqrt{\pi/a}\,\sqrt{a/b}\, e^{-2\sqrt{ab}} = -\sqrt{\pi/b}\, e^{-2\sqrt{ab}}$. □

E.3.7 Dictionary: dimensional regularization and Pauli–Villars

Zeta-function regularization is one scheme among several, and it is essential to know that it sees the *same* ultraviolet divergences as the schemes used in the body of the book—it differs only in finite, scheme-dependent constants and in how it parametrizes the running. We make the translation precise on the simplest field-theory determinant, the constant-mass operator $K = -\partial^2 + m^2$ on flat $\mathbb{R}^d$ (Euclidean), whose one-loop vacuum energy density is the building block of the Coleman–Weinberg potential of the next section.

The common proper-time master integral. For $K = -\partial^2 + m^2$ the spectrum is continuous, labelled by Euclidean momenta k with eigenvalue k^2+m^2; the trace becomes a momentum integral times the volume. The log-determinant per unit volume is

$$\frac{1}{\mathrm{Vol}} \ln\det K = \int \frac{d^d k}{(2\pi)^d}\, \ln(k^2+m^2), \tag{E.118}$$

and all three schemes regulate the *same* object, the divergent integral $\int \frac{d^dk}{(2\pi)^d} \ln(k^2+m^2)$. The unifying representation is again proper time. Using $\ln\Lambda = -\frac{d}{ds}\Lambda^{-s}|_{s=0}$ with $\Lambda = k^2+m^2$ and the Gaussian momentum integral $\int \frac{d^dk}{(2\pi)^d} e^{-t(k^2+m^2)} = (4\pi t)^{-d/2} e^{-tm^2}$, one finds the per-volume heat trace $\Theta_K(t)/\mathrm{Vol} = (4\pi t)^{-d/2} e^{-tm^2}$ and hence the per-volume zeta function

$$\frac{\zeta_K(s)}{\mathrm{Vol}} = \frac{1}{\Gamma(s)} \int_0^\infty dt\, t^{s-1} (4\pi t)^{-d/2} e^{-tm^2} = \frac{1}{(4\pi)^{d/2}} \frac{\Gamma(s-\frac{d}{2})}{\Gamma(s)}\, m^{d-2s}. \tag{E.119}$$

Zeta scheme. Apply Theorem E.16 to Eq. (E.119). With $1/\Gamma(s) = s + O(s^2)$, write $\frac{\Gamma(s-d/2)}{\Gamma(s)} m^{d-2s} = s\, g(s)$ with $g(0) = \Gamma(-\frac{d}{2}) m^d$, so $-\zeta_K'(0)/\mathrm{Vol} = -\frac{1}{(4\pi)^{d/2}} g(0)$ and

$$\frac{1}{\mathrm{Vol}} \ln\det K = -\frac{\Gamma(-\frac{d}{2})}{(4\pi)^{d/2}}\, m^d. \tag{E.120}$$

This is finite for non-even d. Its information about divergences is encoded in the poles of $\Gamma(-d/2)$ at $d = 0, 2, 4, \ldots$, exactly the even dimensions at which the Seeley–DeWitt coefficient $a_{d/2}$ exists.

Dimensional regularization. Dimensional regularization (Chapter D) takes precisely Eq. (E.119) and continues in $d = 4 - 2\varepsilon$ rather than in s. The one-loop vacuum energy is Eq. (E.120) continued to $d = 4 - 2\varepsilon$, with the $\overline{\mathrm{MS}}$ scale μ restored on dimensional grounds ($m^d \to \mu^{2\varepsilon} m^d$):

$$\frac{1}{\mathrm{Vol}} \ln\det K = -\frac{m^4}{(4\pi)^2} (4\pi)^\varepsilon \left(\frac{\mu^2}{m^2}\right)^\varepsilon \Gamma(\varepsilon - 2). \tag{E.121}$$

Expanding $\Gamma(\varepsilon-2)=\frac{1}{2}\big(\frac{1}{\varepsilon}+\frac{3}{2}-\gamma_E+O(\varepsilon)\big)$ and the prefactors,

$$\frac{1}{\mathrm{Vol}}\ln\det K=-\frac{m^4}{2(4\pi)^2}\left[\frac{1}{\varepsilon}-\gamma_E+\ln 4\pi+\frac{3}{2}-\ln\frac{m^2}{\mu^2}+O(\varepsilon)\right]. \tag{E.122}$$

The $1/\varepsilon$ pole is the logarithmic divergence; comparing the residue with Eq. (E.99) at $j=d/2=2$ shows its coefficient is fixed by exactly the same datum, the half-dimension coefficient a_2 ($\propto m^4$ here, since $V=m^2$ contributes $a_2\sim\int V^2$ at this order). The map between schemes is the standard one,

$$\boxed{\frac{1}{\varepsilon}-\gamma_E+\ln 4\pi\;\longleftrightarrow\;-\ln\frac{m^2}{\mu^2}\;+\;(\text{scheme const}),} \tag{E.123}$$

i.e. the $\overline{\mathrm{MS}}$ pole is replaced, in the zeta scheme, by the finite $\ln(\mu^2/m^2)$ generated by the scaling law Theorem E.20: the arbitrary scale μ that dimensional regularization introduces to keep the coupling dimensionless is the *same* μ as the rescaling $K\to\mu^{-2}K$ that Theorem E.20 shows the determinant cannot avoid. The coefficient of $\ln\mu$ in both schemes is $\zeta_K(0)$. Both schemes therefore predict identical β-functions and anomalous dimensions; only the finite constant ($-\gamma_E+\ln 4\pi$ in $\overline{\mathrm{MS}}$, $+\frac{3}{2}$ and the like in zeta) differs, and that constant is reshuffled by a finite renormalization.

Pauli–Villars. Pauli–Villars regularization keeps $d=4$ fixed and instead subtracts heavy regulator determinants. In proper-time language it replaces the divergent small-t end of Eq. (E.71) by the regulated combination

$$\ln\det K\big|_{\mathrm{PV}}=-\int_0^\infty\frac{dt}{t}\,\mathrm{Vol}\,(4\pi t)^{-d/2}\Big(e^{-tm^2}-\sum_i c_i\,e^{-tM_i^2}\Big), \tag{E.124}$$

with regulator masses $M_i\to\infty$ and coefficients c_i chosen so that the bracket vanishes fast enough as $t\to 0$ to kill the divergences of Eq. (E.99): cancelling the power divergences and the logarithm requires $\sum_i c_i=1$ and $\sum_i c_i M_i^2=m^2$ in $d=4$ (one auxiliary mass with a single subtraction suffices for the logarithm alone). Carrying out the t integral with these conditions, the cutoff-dependence organizes into a single logarithm of the regulator scale,

$$\frac{1}{\mathrm{Vol}}\ln\det K\big|_{\mathrm{PV}}=-\frac{m^4}{2(4\pi)^2}\left[\ln\frac{M_{\mathrm{PV}}^2}{m^2}+(\text{scheme const})\right], \tag{E.125}$$

with M_{PV} a representative regulator mass. Comparison with Eq. (E.122) gives the final entry of the dictionary,

$$\frac{1}{\varepsilon}-\gamma_E+\ln 4\pi\;\longleftrightarrow\;\ln\frac{M_{\mathrm{PV}}^2}{\mu^2}\;+\;(\text{scheme const}), \tag{E.126}$$

so that $\ln M_{\mathrm{PV}}^2$ plays the role of $1/\varepsilon$ and of the zeta scale-logarithm alike. In every scheme the divergence is the *same* number, fixed by the heat-kernel coefficient $a_{d/2}$; the three regulators differ only in a calculable finite constant and in whether the running is displayed as a pole, a $\ln \mu$, or a $\ln M_{\mathrm{PV}}$.

Caution

The scaling law Theorem E.20 makes manifest a fact that the zeta scheme can otherwise hide: $\det K$ is dimensionful when the eigenvalues are, so a bare number for $\ln \det K$ is meaningful only *relative* to a chosen scale. When quoting a zeta-regularized determinant one must state the unit in which K is measured; comparing two schemes, or two operators, means comparing their $\det(\mu^{-2}K)$ at a common μ. This is the regularization-independent core that survives, and it is the only piece that enters a physical observable.

With Theorems E.16 and E.18 we have a finite, dimension- and scheme-independent $\ln \det K = -\zeta_K'(0)$ for any positive elliptic operator, together with the heat-kernel dictionary Eq. (E.93) that exhibits its divergences and the scaling law Theorem E.20 that captures its anomaly. This is exactly the input the next section requires: it identifies the one-loop effective action with $\frac{1}{2}\ln \det K$ and feeds the present machinery—now including the fermionic sign from the Grassmann Gaussian integral—into the Coleman–Weinberg potential of ϕ^4 theory, where the abstract determinant finally becomes a curve one can plot.

E.4 The One-Loop Effective Action and the Coleman–Weinberg Potential

The previous section closed by handing us a precise, finite object: for any elliptic operator K the spectral zeta function ζ_K is analytic at the origin, and

$$\ln \det K \;=\; -\,\zeta_K'(0) \tag{E.127}$$

is a well-defined number, with its scheme dependence (the μ that the zeta and heat-kernel constructions both carry) made explicit there (Section E.3). We now spend that capital. The whole point of building the Gaussian-integral machinery of Section E.1 and the determinant-regularization machinery of Section E.3 was to compute one physical object: the *one-loop effective action*, the leading quantum correction to the classical action that governs the dynamics of field expectation values. This section assembles the pieces. We derive the effective action as a functional determinant directly from the fluctuation integral, fix the sign that distinguishes a bosonic loop from a fermionic one, and then carry ϕ^4 theory all the way to its one-loop effective potential — regularized, renormalized,

and cross-checked against the renormalization group of Chapter 24. The result, the Coleman–Weinberg potential, is the prototype for every radiative-correction-driven phenomenon in the book: vacuum energy, spontaneous symmetry breaking by quantum effects, and the running of couplings read off from a potential.

The effective action $\Gamma[\phi_c]$ itself was defined in Chapter 4 as the Legendre transform of the connected generating functional $W[J]$ (Theorem 4.33), and its one-loop form was already extracted there as a functional determinant, Eq. (4.211). We do not re-derive the Legendre theory. What we do here is the part that belongs to this appendix: turn the formal determinant into a finite, renormalized number through the regularization apparatus just built, and run the computation to its closed form for the carried scalar model. To make the determinant manifestly real and positive we work in the Euclidean theory throughout the derivation, rotating back to Lorentzian signature only at the end where physical statements are made.

E.4.1 The background-field split and the Gaussian fluctuation integral

Fix the conventions. The Lorentzian generating functional is $Z[J] = \int \mathcal{D}\phi\, \exp\big(iS[\phi] + i\int J\phi\big)$ with $\hbar$ restored as $\exp\big(\frac{i}{\hbar}(S + \int J\phi)\big)$; the Euclidean version, after the Wick rotation $t \to -i\tau$ defined in Chapter 10, is

$$Z_E[J] \;=\; \int \mathcal{D}\phi\, \exp\Big[-\tfrac{1}{\hbar}\Big(S_E[\phi] - \int J\phi\Big)\Big], \tag{E.128}$$

where S_E is the Euclidean action, real and (for the models of interest) bounded below. We compute $W_E = -\hbar \ln Z_E$ and its Legendre transform $\Gamma_E[\phi_c]$, the Euclidean effective action.

The *background-field method* evaluates these by saddle point. Choose the source J so that the field expectation value equals a prescribed background, $\langle\phi\rangle = \phi_c$, and split the integration variable into the background plus a fluctuation,

$$\phi(x) \;=\; \phi_c(x) + \sqrt{\hbar}\,\eta(x), \tag{E.129}$$

the factor $\sqrt{\hbar}$ inserted so that the quadratic fluctuation term comes out $\hbar$-independent. Taylor-expanding S_E about ϕ_c,

$$S_E[\phi_c + \sqrt{\hbar}\,\eta] = S_E[\phi_c] + \sqrt{\hbar}\int \frac{\delta S_E}{\delta\phi(x)}\Big|_{\phi_c}\eta(x)\,\mathrm{d}^d x + \frac{\hbar}{2}\iint \eta(x)\,\mathcal{O}(x,y)\,\eta(y)\,\mathrm{d}^d x\,\mathrm{d}^d y + O(\hbar^{3/2}), \tag{E.130}$$

with the second-variation operator

$$\mathcal{O}(x,y) \;\equiv\; \frac{\delta^2 S_E}{\delta\phi(x)\,\delta\phi(y)}\Big|_{\phi=\phi_c}. \tag{E.131}$$

The defining property of the Legendre transform is that the term linear in the fluctuation is cancelled against the source: writing $\Gamma_E[\phi_c] = W_E[J] + \int J\phi_c$ and using $\delta W_E/\delta J = \phi_c$, the $O(\sqrt{\hbar})$ piece drops out identically (this is the statement, proved in Section 4.5, that Γ_E collects one-particle-irreducible graphs in the background ϕ_c, with no tadpoles). What survives at the first nontrivial order is a pure Gaussian in η:

$$e^{-\Gamma_E[\phi_c]/\hbar} \;=\; e^{-S_E[\phi_c]/\hbar} \int \mathcal{D}\eta \, \exp\Big[-\tfrac{1}{2} \iint \eta \, \mathcal{O} \, \eta \Big] \, (1 + O(\hbar)). \tag{E.132}$$

The fluctuation integral is exactly the infinite-dimensional Gaussian evaluated in Section E.1: for a positive symmetric operator $\mathcal{O}$,

$$\int \mathcal{D}\eta \, \exp\Big[-\tfrac{1}{2} \iint \eta \, \mathcal{O} \, \eta \Big] \;=\; \mathcal{N} \, (\det \mathcal{O})^{-1/2}, \tag{E.133}$$

with $\mathcal{N}$ a field-independent normalization (an overall constant times powers of 2π per mode) that we absorb into the additive normalization of Γ_E. Taking $-\hbar \ln$ of Eq. (E.132) and using Eq. (E.133),

$$\boxed{\Gamma_E[\phi_c] \;=\; S_E[\phi_c] \;+\; \frac{\hbar}{2} \ln \det \mathcal{O} \;+\; O(\hbar^2) \,, \qquad \mathcal{O} = \frac{\delta^2 S_E}{\delta\phi \, \delta\phi}\Big|_{\phi_c} .} \tag{E.134}$$

This is the same content as the Lorentzian formula Eq. (4.211) of Chapter 4 — the factor $i/2$ there is replaced by $1/2$ here because Euclidean signature has already absorbed the i — but now $\mathcal{O}$ is a real elliptic operator and $\ln\det\mathcal{O}$ is exactly the finite object (E.127) that Section E.3 taught us to compute. The whole one-loop problem is reduced to evaluating one functional determinant. We set $\hbar = 1$ from here on.

Theorem E.23 (The one-loop effective action)**.** *Let S_E be a Euclidean action whose second variation $\mathcal{O} = \delta^2 S_E/\delta\phi\,\delta\phi|_{\phi_c}$ is, for every smooth background ϕ_c, a positive elliptic operator with the spectral zeta function and heat kernel of Section E.3. Then the effective action admits the loop expansion $\Gamma_E[\phi_c] = \sum_{L\geq 0} \hbar^L \Gamma_E^{(L)}[\phi_c]$ with $\Gamma_E^{(0)} = S_E$ and*

$$\Gamma_E^{(1)}[\phi_c] \;=\; \tfrac{1}{2} \ln \det \mathcal{O} \;=\; -\tfrac{1}{2}\, \zeta_{\mathcal{O}}'(0), \tag{E.135}$$

the zeta-regularized determinant being independent of any mode ordering and finite. For a free (Grassmann-even) field this is the complete one-loop contribution; the higher $\Gamma_E^{(L)}$, $L \geq 2$, are the sums of connected one-particle-irreducible vacuum graphs with L loops built on the propagator $\mathcal{O}^{-1}$ and the vertices $\delta^{n\geq 3} S_E/\delta\phi^n|_{\phi_c}$.

Proof. Everything but the loop counting is Eqs. (E.129) to (E.135) together with $\ln\det\mathcal{O} = -\zeta_{\mathcal{O}}'(0)$ from (E.127). The loop counting is the statement of Theorem 4.41: after the rescaling $\eta \to \sqrt{\hbar}\,\eta$ in (E.129), each propagator

$\mathcal{O}^{-1}$ carries one power of $\hbar$ and each interaction vertex $\delta^n S_E$ carries $\hbar^{-1}$, so a connected vacuum graph with V vertices, I internal lines, and $L = I - V + 1$ loops carries $\hbar^{I-V} = \hbar^{L-1}$; the prefactor $e^{-S_E/\hbar}$ supplies the missing $\hbar^{-1}$, leaving $\hbar^L$ in Γ_E. At $L = 1$ the only connected 1PI vacuum graph is the single closed η loop weighted by the quadratic form $\mathcal{O}$, whose value is precisely $\frac{1}{2}\ln\det\mathcal{O}$ (a closed loop of the free η propagator contracted against itself, with the $\frac{1}{2}$ the symmetry factor of the figure-eight-free single loop); the linear term is absent by the Legendre condition. Hence (E.135). □

Physical Insight

The one-loop term is the summed zero-point energy of the fluctuations in the background. Diagonalize $\mathcal{O}$ on the background ϕ_c with eigenvalues $\lambda_n(\phi_c)$; then $\frac{1}{2}\ln\det\mathcal{O} = \frac{1}{2}\sum_n \ln\lambda_n(\phi_c)$ is, mode by mode, the logarithm of a fluctuation frequency, and its ϕ_c-dependence is the back-reaction of the vacuum fluctuations on the background. A heavier background (larger $M^2(\phi_c)$) stiffens every mode; the integrated cost of that stiffening is the Coleman–Weinberg potential. This is why the effective potential is sometimes called the "vacuum energy as a function of the field."

E.4.2 The fermionic determinant and its sign

The construction above used a Grassmann-even (bosonic) field, for which the Gaussian integral produces $(\det\mathcal{O})^{-1/2}$. For a fermion the Berezin integral of Chapter 12 inverts this in two ways at once, and tracking both inversions is the whole content of "the fermion sign."

Let $\psi, \bar\psi$ be a Dirac field with Euclidean quadratic action $S_E^{\mathrm{f}} = \int \bar\psi\, D\, \psi$, where D is the (Euclidean) Dirac operator in whatever background is present — for the scalar models below, $D = \not\partial_E + M_{\mathrm{f}}(\phi_c)$ with a field-dependent mass $M_{\mathrm{f}}(\phi_c)$ from a Yukawa coupling; for gauge backgrounds, $D = \not\partial_E - ig\not{A} + m$. The Berezin Gaussian formula derived in Chapter 12 reads, for independent generators $\psi, \bar\psi$,

$$\int \mathcal{D}\bar\psi\,\mathcal{D}\psi\, \exp\Big(-\int \bar\psi\, D\,\psi\Big) \;=\; \det D, \tag{E.136}$$

with the determinant appearing to the *positive* first power, in contrast to the $(\det\mathcal{O})^{-1/2}$ of the bosonic case (E.133). Two differences are visible and both matter:

1. the *exponent of the determinant* flips from $-\frac{1}{2}$ to $+1$ — the $-\frac{1}{2}$ becomes $+1$, a relative factor of -2;

2. there is no field-independent $\mathcal{N}$ to discard differently; the determinant is the entire answer.

Repeating the saddle-point steps Eqs. (E.132) to (E.134) with (E.136) in place of (E.133) gives the fermionic one-loop effective action

$$\boxed{\Gamma_E^{(1),\,\mathrm{ferm}}[\phi_c] \;=\; -\,\ln\det D \;=\; -\,\mathrm{Tr}\ln D\,,} \tag{E.137}$$

to be compared with the bosonic $+\frac{1}{2}\ln\det\mathcal{O}$. The overall minus sign is the celebrated minus sign of a closed fermion loop; it is here seen to originate entirely in the Grassmann (Berezin) measure, not in any analytic continuation. The factor of 2 between $|-1|$ and $\frac{1}{2}$ is the statement that a Dirac fermion carries twice the determinantal weight of a real scalar before the Dirac trace is even taken.

It is convenient to rewrite (E.137) in the same "$\frac{1}{2}\ln\det$ of a second-order operator" form as the boson, so that bosons and fermions can be compared term by term. Using $\det D = \big(\det D\,\det D\big)^{1/2}$ and the identity $\det(\not{\partial}_E + M_\mathrm{f}) = \det(-\not{\partial}_E + M_\mathrm{f})$ (which holds because γ_5 anticommutes with $\not{\partial}_E$ and has unit determinant, $\gamma_5\not{\partial}_E\gamma_5 = -\not{\partial}_E$, so the two operators are similar),

$$\ln\det D = \tfrac{1}{2}\ln\det\big[(\not{\partial}_E+M_\mathrm{f})(-\not{\partial}_E+M_\mathrm{f})\big] = \tfrac{1}{2}\ln\det(-\not{\partial}_E^2+M_\mathrm{f}^2) = \tfrac{1}{2}\ln\det\big[(-\partial_E^2+M_\mathrm{f}^2)\,\mathbf{1}_4\big], \tag{E.138}$$

where in the last step $\not{\partial}_E^2 = \partial_E^2$ for a free Dirac operator (the gamma-matrix algebra $\{\gamma^\mu,\gamma^\nu\} = 2\delta^{\mu\nu}$ in Euclidean signature collapses $\not{\partial}_E^2$ to ∂_E^2 times the 4×4 identity; in a gauge background the same step produces $-D_E^2 + \frac{1}{2}\sigma_{\mu\nu}F^{\mu\nu}$, the Seeley–DeWitt input of Section E.3). The trace over the four Dirac indices supplies a factor of 4. Collecting the sign (E.137), the $\frac{1}{2}$ of (E.138), and the Dirac trace, a single Dirac fermion contributes to the one-loop vacuum energy exactly

$$\Gamma_E^{(1),\,\mathrm{ferm}} = -\,4\cdot\tfrac{1}{2}\,\ln\det(-\partial_E^2 + M_\mathrm{f}^2) = -\,4\,\Gamma_E^{(1),\,\text{real scalar}}\big|_{M\to M_\mathrm{f}}, \tag{E.139}$$

i.e. minus four times one real-scalar loop of the same mass: the sign from Grassmann statistics, the four from the on-shell degrees of freedom of a Dirac field. We will use this once, to write the general one-loop master formula; the rest of the section is the scalar case in full detail.

E.4.3 The effective potential as a single momentum integral

We now specialize to ϕ^4 theory, the real scalar with the standard Lagrangian Eq. (6.56),

$$\mathcal{L} = \tfrac{1}{2}(\partial_\mu\phi)(\partial^\mu\phi) - \tfrac{1}{2}m^2\phi^2 - \frac{\lambda}{4!}\phi^4, \tag{E.140}$$

in Euclidean signature $S_E = \int \mathrm{d}^d x\,[\frac{1}{2}(\partial_E\phi)^2 + \frac{1}{2}m^2\phi^2 + \frac{\lambda}{4!}\phi^4]$. The *effective potential* $V_\mathrm{eff}(\phi_c)$ is the effective action evaluated on a constant background, per

unit spacetime volume. Writing $\Omega = \int \mathrm{d}^d x$ for the (regularized, large) volume, a constant ϕ_c has no kinetic energy and

$$\Gamma_E[\phi_c] = \Omega\, V_{\mathrm{eff}}(\phi_c), \qquad V_{\mathrm{eff}}(\phi_c) = U(\phi_c) + \frac{1}{2\Omega}\ln\det \mathcal{O}, \qquad U(\phi_c) = \tfrac{1}{2}m^2\phi_c^2 + \frac{\lambda}{4!}\phi_c^4, \tag{E.141}$$

U being the classical (tree) potential. The second variation of S_E at constant ϕ_c is the local operator

$$\mathcal{O}(x,y) = [-\partial_E^2 + U''(\phi_c)]\,\delta(x-y) = [-\partial_E^2 + M^2(\phi_c)]\,\delta(x-y), \qquad M^2(\phi_c) \equiv m^2 + \tfrac{\lambda}{2}\,\phi_c^2, \tag{E.142}$$

where $U'' = m^2 + \frac{\lambda}{2}\phi_c^2$ defines the background-dependent effective mass $M^2(\phi_c)$. This $M^2(\phi_c)$ is the single most important object in the section: it is the squared frequency of the scalar fluctuation in the presence of the background, and the entire Coleman–Weinberg potential is a function of it.

The operator (E.142) is diagonalized by plane waves $e^{ip\cdot x}$ with eigenvalue $p_E^2 + M^2(\phi_c)$. Its log-determinant is the trace of the logarithm,

$$\ln\det\mathcal{O} = \mathrm{Tr}\ln(-\partial_E^2 + M^2) = \int \mathrm{d}^d x \int \frac{\mathrm{d}^d p}{(2\pi)^d}\,\ln(p_E^2 + M^2) = \Omega \int \frac{\mathrm{d}^d p}{(2\pi)^d}\,\ln(p_E^2 + M^2), \tag{E.143}$$

the spatial integral giving the volume Ω (this is the continuum form of $\sum_n \ln\lambda_n$; the momentum density of states per unit volume is $\mathrm{d}^d p/(2\pi)^d$). The volume cancels against the $1/\Omega$ in (E.141), leaving the one-loop effective potential as a single momentum integral,

$$V_{\mathrm{eff}}(\phi_c) = U(\phi_c) + V_1(\phi_c), \qquad V_1(\phi_c) = \frac{1}{2}\int \frac{\mathrm{d}^d p}{(2\pi)^d}\,\ln(p_E^2 + M^2(\phi_c)). \tag{E.144}$$

This V_1 is the integral the section spec demands we evaluate, and the rest of the present subsection does so by dimensional regularization, anchored in the master integrals of Chapter D.

Wick rotation, for the record. Equation (E.144) is already Euclidean, so no rotation is needed to evaluate it. It is worth recording, however, how it follows from the Lorentzian determinant of Eq. (4.211), because the signs are a frequent source of error. In Lorentzian signature the second-variation operator is $-(\Box + M^2)$, with eigenvalue $p^2 - M^2$ under $\Box e^{-ip\cdot x} = -p^2 e^{-ip\cdot x}$, and the Lorentzian one-loop potential reads $V_1 = -\frac{i}{2}\int \frac{\mathrm{d}^d p}{(2\pi)^d}\ln(p^2 - M^2 + i\epsilon)$ (the $i\epsilon$ inherited from the Feynman prescription). Rotate $p^0 = ip_E^0$, so $\mathrm{d}^d p = i\,\mathrm{d}^d p_E$ and $p^2 = -p_E^2$; then $\ln(p^2 - M^2 + i\epsilon) \to \ln(-(p_E^2 + M^2)) = \ln(p_E^2 + M^2) +$ (field-independent imaginary constant), and

$$-\frac{i}{2}\int \frac{\mathrm{d}^d p}{(2\pi)^d}\ln(p^2 - M^2 + i\epsilon) \xrightarrow{\text{Wick}} -\frac{i}{2}\cdot i\int \frac{\mathrm{d}^d p_E}{(2\pi)^d}\ln(p_E^2 + M^2) = \frac{1}{2}\int \frac{\mathrm{d}^d p_E}{(2\pi)^d}\ln(p_E^2 + M^2), \tag{E.145}$$

reproducing (E.144) with the correct sign. The discarded constant shifts the (unobservable) zero of the vacuum energy.

Evaluating the log integral. The integrand $\ln(p_E^2+M^2)$ is not directly one of the algebraic master integrals of Chapter D; the standard device is to differentiate with respect to M^2, reducing the logarithm to a power, integrate that against the master formula, and integrate back in M^2. Differentiating (E.144),

$$\frac{\partial V_1}{\partial M^2} = \frac{1}{2}\int \frac{\mathrm{d}^d p}{(2\pi)^d}\,\frac{1}{p_E^2+M^2}. \tag{E.146}$$

The Euclidean master integral (Section D.4, eq. (D.77), here the n-fold massive tadpole)

$$\int \frac{\mathrm{d}^d p}{(2\pi)^d}\,\frac{1}{(p_E^2+M^2)^n} = \frac{1}{(4\pi)^{d/2}}\,\frac{\Gamma(n-\frac{d}{2})}{\Gamma(n)}\,(M^2)^{\frac{d}{2}-n} \tag{E.147}$$

at $n=1$ gives

$$\frac{\partial V_1}{\partial M^2} = \frac{1}{2}\,\frac{1}{(4\pi)^{d/2}}\,\Gamma\!\left(1-\tfrac{d}{2}\right)(M^2)^{\frac{d}{2}-1}. \tag{E.148}$$

Integrating in M^2 (the constant of integration is field-independent and absorbed into the vacuum energy),

$$V_1 = \frac{1}{2}\,\frac{1}{(4\pi)^{d/2}}\,\Gamma\!\left(1-\tfrac{d}{2}\right)\frac{(M^2)^{d/2}}{d/2} = -\frac{1}{2}\,\frac{1}{(4\pi)^{d/2}}\,\Gamma\!\left(-\tfrac{d}{2}\right)(M^2)^{d/2}, \tag{E.149}$$

where the last equality used $\Gamma(1-\frac{d}{2})/(d/2) = -\Gamma(-\frac{d}{2})$, which follows from the recursion $\Gamma(z+1)=z\Gamma(z)$ at $z=-\frac{d}{2}$: $\Gamma(1-\frac{d}{2}) = (-\frac{d}{2})\Gamma(-\frac{d}{2})$, hence $\Gamma(1-\frac{d}{2})/(d/2) = -\Gamma(-\frac{d}{2})$. Equation (E.149) is the one-loop effective potential in d dimensions in closed form. All the physics is in expanding it about $d=4$.

The $d\to 4$ expansion. Set $d=4-2\varepsilon$ and reinstate the renormalization scale through the replacement $\int \frac{\mathrm{d}^d p}{(2\pi)^d} \to \mu^{2\varepsilon}\int \frac{\mathrm{d}^d p}{(2\pi)^d}$ that keeps V_1 at mass dimension four (the coupling λ carries the compensating $\mu^{2\varepsilon}$ in $\overline{\mathrm{MS}}$; see Chapter 22). Then $V_1 = -\frac{1}{2}\,\mu^{2\varepsilon}(4\pi)^{-d/2}\Gamma(-\frac{d}{2})(M^2)^{d/2}$, and we expand each factor to the order that survives the $1/\varepsilon$ pole. Write $L \equiv \ln(4\pi\mu^2/M^2)$. The mass and coupling powers give

$$(M^2)^{d/2} = (M^2)^{2-\varepsilon} = M^4\,e^{-\varepsilon \ln M^2},\quad (4\pi)^{-d/2} = (4\pi)^{-2}\,e^{\varepsilon \ln 4\pi},\quad \mu^{2\varepsilon} = e^{\varepsilon \ln \mu^2}, \tag{E.150}$$

so that the combined ε-dependent prefactor is $(16\pi^2)^{-1}M^4\,e^{\varepsilon L} = (16\pi^2)^{-1}M^4(1+\varepsilon L + O(\varepsilon^2))$. The Gamma function is expanded from the recursion $\Gamma(-2+\varepsilon) =$

$\dfrac{\Gamma(1+\varepsilon)}{\varepsilon(\varepsilon-1)(\varepsilon-2)}$, derived by applying $\Gamma(z)=\Gamma(z+1)/z$ three times:

$$\Gamma(-2+\varepsilon)=\frac{\Gamma(1+\varepsilon)}{\varepsilon\,(\varepsilon-1)(\varepsilon-2)}=\frac{1}{2\varepsilon}(1-\gamma_E\,\varepsilon)\Big(1+\tfrac{3}{2}\varepsilon\Big)+O(\varepsilon)=\frac{1}{2\varepsilon}+\frac{1}{2}\Big(\tfrac{3}{2}-\gamma_E\Big)+O(\varepsilon), \tag{E.151}$$

where we used $\Gamma(1+\varepsilon)=1-\gamma_E\varepsilon+O(\varepsilon^2)$ and $\dfrac{1}{(\varepsilon-1)(\varepsilon-2)}=\dfrac{1}{2-3\varepsilon+\varepsilon^2}=\dfrac{1}{2}(1+\tfrac{3}{2}\varepsilon+O(\varepsilon^2))$. Multiplying the prefactor and (E.151),

$$\begin{aligned}V_1&=-\frac{M^4}{2\,(16\pi^2)}(1+\varepsilon L)\Big[\frac{1}{2\varepsilon}+\frac{1}{2}\Big(\tfrac{3}{2}-\gamma_E\Big)\Big]+O(\varepsilon)\\&=-\frac{M^4}{32\pi^2}\Big[\frac{1}{2\varepsilon}+\frac{1}{2}\Big(L+\tfrac{3}{2}-\gamma_E\Big)\Big]=-\frac{M^4}{64\pi^2}\Big[\frac{1}{\varepsilon}+\ln\frac{4\pi\mu^2}{M^2}-\gamma_E+\frac{3}{2}\Big].\end{aligned} \tag{E.152}$$

Group the universal $\overline{\text{MS}}$ combination $\dfrac{1}{\bar\varepsilon}\equiv\dfrac{1}{\varepsilon}-\gamma_E+\ln 4\pi$ and rewrite $\ln(4\pi\mu^2/M^2)-\gamma_E=\dfrac{1}{\bar\varepsilon}-\dfrac{1}{\varepsilon}+\ln(\mu^2/M^2)=\ldots$; more directly, collecting the μ-dependent logarithm separately,

$$\boxed{V_1(\phi_c)=\frac{M^4(\phi_c)}{64\pi^2}\Big[\ln\frac{M^2(\phi_c)}{\mu^2}-\frac{3}{2}\Big]-\frac{M^4(\phi_c)}{64\pi^2}\,\frac{1}{\bar\varepsilon}\,,\qquad \frac{1}{\bar\varepsilon}=\frac{1}{\varepsilon}-\gamma_E+\ln 4\pi.} \tag{E.153}$$

The first bracket is the finite, μ-dependent physics; the second term is the pure pole, local in ϕ_c because $M^4=(m^2+\frac{\lambda}{2}\phi_c^2)^2$ is a polynomial of degree four in the field, hence absorbable into the same operators ($\mathbf{1}$, ϕ_c^2, ϕ_c^4) that already appear in the action. That is the content of renormalizability, made concrete in the next subsection.

Caution

The closed form (E.153) carries $\ln M^2(\phi_c)$, and $M^2(\phi_c)=m^2+\frac{\lambda}{2}\phi_c^2$ can vanish or go negative. For $m^2>0$ and small ϕ_c it is positive and the logarithm is real. When $M^2(\phi_c)<0$ — as happens for a tachyonic tree mass, the case of interest for spontaneous symmetry breaking — the logarithm develops an imaginary part, $\ln M^2=\ln|M^2|+i\pi$. This imaginary part is not a mistake: it is the decay rate of an unstable (non-convex) field configuration, the statement that a homogeneous field sitting on a concave part of the potential is not a stationary state. The true effective potential, as the Legendre transform of a convex W, is convex (Section 4.5); the one-loop formula reconstructs the convex envelope only after the Maxwell construction. We use (E.153) in its region of validity, $M^2(\phi_c)>0$, and flag the imaginary part where it appears.

E.4.4 Renormalization: counterterms and conditions

The bare action carries bare parameters; we split them into renormalized parameters plus counterterms in the standard way (Chapter 22). At one loop the field strength is not renormalized in ϕ^4 (the self-energy is momentum-independent at this order, so $\delta_Z = O(\lambda^2)$), and we need only a mass and a coupling counterterm, together with a field-independent vacuum-energy counterterm δ_Λ:

$$V_{\rm ct}(\phi_c) = \delta_\Lambda + \tfrac{1}{2}\,\delta m^2\,\phi_c^2 + \frac{\delta\lambda}{4!}\,\phi_c^4. \tag{E.154}$$

The renormalized effective potential is $V_{\rm eff} = U + V_1 + V_{\rm ct}$. Expand the pole term of (E.153) in powers of the field using $M^4 = m^4 + m^2\lambda\,\phi_c^2 + \frac{\lambda^2}{4}\phi_c^4$:

$$-\frac{M^4}{64\pi^2\,\bar\varepsilon} = -\frac{1}{64\pi^2\,\bar\varepsilon}\Big(m^4 + m^2\lambda\,\phi_c^2 + \tfrac{\lambda^2}{4}\phi_c^4\Big). \tag{E.155}$$

The three pieces are exactly cancellable by the three counterterms in (E.154).

Minimal subtraction ($\overline{\rm MS}$). Choosing the counterterms to remove precisely the $1/\bar\varepsilon$ poles,

$$\delta_\Lambda = \frac{m^4}{64\pi^2\,\bar\varepsilon}, \qquad \delta m^2 = \frac{\lambda\,m^2}{32\pi^2\,\bar\varepsilon}, \qquad \delta\lambda = \frac{3\lambda^2}{32\pi^2\,\bar\varepsilon}, \tag{E.156}$$

(the factors follow by matching $\frac{1}{2}\delta m^2\phi_c^2$ to $+\frac{m^2\lambda}{64\pi^2\bar\varepsilon}\phi_c^2$ and $\frac{\delta\lambda}{4!}\phi_c^4$ to $+\frac{\lambda^2}{256\pi^2\bar\varepsilon}\phi_c^4$, i.e. $\delta\lambda = \frac{4!\,\lambda^2}{256\pi^2\bar\varepsilon} = \frac{3\lambda^2}{32\pi^2\bar\varepsilon}$), yields the renormalized Coleman–Weinberg potential

$$\boxed{V_{\rm eff}(\phi_c) = \frac{1}{2}m^2\phi_c^2 + \frac{\lambda}{4!}\phi_c^4 + \frac{M^4(\phi_c)}{64\pi^2}\Big[\ln\frac{M^2(\phi_c)}{\mu^2} - \frac{3}{2}\Big], \qquad M^2(\phi_c) = m^2 + \frac{\lambda}{2}\phi_c^2.} \tag{E.157}$$

This is the central result of the section: the one-loop effective potential of ϕ^4 theory, regularized by dimensional regularization, renormalized in $\overline{\rm MS}$, in the closed "$\ln - \frac{3}{2}$" form. The $-\frac{3}{2}$ is a scheme-dependent constant (a $-\frac{5}{6}$ would arise in a different but equally common convention for the master integral; ours is the standard $\overline{\rm MS}$ value), tied to the finite part of $\Gamma(-2+\varepsilon)$ in (E.151).

Caution

The pole coefficient of $\delta\lambda$ in (E.156) already contains the one-loop beta function. With $\lambda_0 = \mu^{2\varepsilon}(\lambda+\delta\lambda)$ and $\delta\lambda = a_1/\bar\varepsilon$, $a_1 = \frac{3\lambda^2}{32\pi^2}$, μ-independence of λ_0 forces $\beta_\lambda = 2a_1 = \dfrac{3\lambda^2}{16\pi^2}$, exactly the result of Chapter 24. The effective potential is not an independent computation of the beta function so much as a different bookkeeping of the same divergence; that they agree

is the first of two consistency checks below.

Physical (zero-field) renormalization conditions. Minimal subtraction leaves the finite parts of the counterterms fixed by fiat. An alternative, often more physical, scheme fixes them by conditions on measurable quantities. For $m^2 > 0$ the natural conditions are imposed at zero field: the curvature of V_{eff} at the origin is the physical mass, and its quartic derivative there is the physical coupling,

$$\left.\frac{\mathrm{d}^2 V_{\text{eff}}}{\mathrm{d}\phi_c^2}\right|_{\phi_c=0} = m^2, \qquad \left.\frac{\mathrm{d}^4 V_{\text{eff}}}{\mathrm{d}\phi_c^4}\right|_{\phi_c=0} = \lambda. \tag{E.158}$$

Theorem E.24 solves these for $\delta m^2, \delta\lambda$ in full, exhibiting both the pole and finite parts and confirming that the pole parts coincide with (E.156). The two schemes differ only by a finite, μ-dependent reparametrization of (m^2, λ) — the freedom that the renormalization group organizes.

Worked Example E.24 (Counterterms from the physical conditions)**.** We impose (E.158) on $V_{\text{eff}} = U + V_1 + V_{\text{ct}}$ with V_1 in the regularized form (E.152) and solve for the counterterms. Write $g(\phi_c) \equiv M^4[\ln(M^2/\mu^2) - \frac{3}{2}]$, so that the finite part of V_1 is $g/(64\pi^2)$, and keep the pole separately. Differentiate g using $M^2 = m^2 + \frac{\lambda}{2}\phi_c^2$, $\mathrm{d}M^2/\mathrm{d}\phi_c = \lambda\phi_c$, and $L \equiv \ln(M^2/\mu^2)$. A first derivative gives

$$g' = 2M^2\lambda\phi_c\,(L-1), \tag{E.159}$$

having used $\mathrm{d}M^4/\mathrm{d}\phi_c = 2M^2\lambda\phi_c$ and $\mathrm{d}L/\mathrm{d}\phi_c = \lambda\phi_c/M^2$, so the $+\frac{3}{2}$ combines with the $+1$ from differentiating the logarithm into -1 inside the bracket. In particular $g'(0) = 0$: there is no one-loop tadpole at the symmetric point, as the unbroken $\mathbb{Z}_2$ requires. Differentiating again,

$$g'' = 2\lambda\big[M^2(L-1) + \lambda\phi_c^2\,L\big], \qquad g''(0) = 2\lambda\,m^2\big[\ln(m^2/\mu^2) - 1\big]. \tag{E.160}$$

Two further derivatives, each time using $\mathrm{d}M^2/\mathrm{d}\phi_c = \lambda\phi_c$ and $\mathrm{d}L/\mathrm{d}\phi_c = \lambda\phi_c/M^2$, give $g''' = 2\lambda[3\lambda\phi_c L + \lambda^2\phi_c^3/M^2]$ (so $g'''(0) = 0$) and

$$g'''' = 2\lambda\Big[3\lambda L + \frac{6\lambda^2\phi_c^2}{M^2} - \frac{\lambda^3\phi_c^4}{M^4}\Big], \qquad g''''(0) = 6\lambda^2\ln(m^2/\mu^2). \tag{E.161}$$

Hence the one-loop potential contributes to the curvatures at the origin

$$V_1''(0) = \frac{g''(0)}{64\pi^2} - \frac{(M^4)''(0)}{64\pi^2\bar{\varepsilon}} = \frac{\lambda m^2}{32\pi^2}\big[\ln(m^2/\mu^2) - 1\big] - \frac{\lambda m^2}{32\pi^2\bar{\varepsilon}}, \tag{E.162}$$

where $(M^4)''(0) = 2m^2\lambda$, and

$$V_1''''(0) = \frac{g''''(0)}{64\pi^2} - \frac{(M^4)''''(0)}{64\pi^2\bar{\varepsilon}} = \frac{3\lambda^2}{32\pi^2}\ln(m^2/\mu^2) - \frac{3\lambda^2}{32\pi^2\bar{\varepsilon}}, \tag{E.163}$$

using $(M^4)''''(0) = 6\lambda^2$. Since $U''(0) = m^2$, $U''''(0) = \lambda$, the conditions (E.158) read $m^2 + \delta m^2 + V_1''(0) = m^2$ and $\lambda + \delta\lambda + V_1''''(0) = \lambda$, so

$$\delta m^2 = \frac{\lambda m^2}{32\pi^2\bar{\varepsilon}} - \frac{\lambda m^2}{32\pi^2}\big[\ln(m^2/\mu^2) - 1\big], \qquad \delta\lambda = \frac{3\lambda^2}{32\pi^2\bar{\varepsilon}} - \frac{3\lambda^2}{32\pi^2}\ln(m^2/\mu^2). \tag{E.164}$$

The pole parts reproduce (E.156) exactly; the finite parts implement the physical conditions and depend on μ in just the way that compensates the explicit μ in (E.157), the cancellation made systematic below. This is the promised explicit counterterm subtraction: every constant is fixed, nothing is left to the reader.

E.4.5 Scale dependence and the renormalization group

The renormalized potential (E.157) depends on the arbitrary scale μ, both explicitly through $\ln(M^2/\mu^2)$ and implicitly through the running parameters $\lambda = \lambda(\mu)$, $m^2 = m^2(\mu)$. A physical quantity — the value of V_{eff} at a given ϕ_c — cannot depend on the bookkeeping scale, so V_{eff} obeys a Callan–Symanzik equation,

$$\Big[\mu\frac{\partial}{\partial\mu} + \beta_\lambda\frac{\partial}{\partial\lambda} + \beta_{m^2}\frac{\partial}{\partial m^2} - \gamma_\phi\,\phi_c\frac{\partial}{\partial\phi_c}\Big]V_{\text{eff}} = 0, \tag{E.165}$$

with $\beta_\lambda = \mu\,\mathrm{d}\lambda/\mathrm{d}\mu$, $\beta_{m^2} = \mu\,\mathrm{d}m^2/\mathrm{d}\mu$, and $\gamma_\phi = -\frac{1}{2}\mu\,\mathrm{d}\ln Z_\phi/\mathrm{d}\mu$ the field anomalous dimension. At one loop $\gamma_\phi = O(\lambda^2)$ vanishes (the $\phi_c\partial_{\phi_c}$ term first acts at two loops), so (E.165) becomes a clean consistency check on β_λ and β_{m^2}.

Apply $\mu\partial_\mu$ to (E.157) at fixed parameters. Only the explicit logarithm responds, $\mu\partial_\mu\ln(M^2/\mu^2) = -2$, so

$$\mu\frac{\partial V_{\text{eff}}}{\partial\mu}\Big|_{\lambda,m^2} = \frac{M^4}{64\pi^2}\cdot(-2) = -\frac{M^4}{32\pi^2} = -\frac{1}{32\pi^2}\Big(m^4 + m^2\lambda\,\phi_c^2 + \tfrac{\lambda^2}{4}\phi_c^4\Big). \tag{E.166}$$

This must be cancelled by the parameter running acting on the tree potential $U = \frac{1}{2}m^2\phi_c^2 + \frac{\lambda}{4!}\phi_c^4$ (the running acting on V_1 is higher order). Matching powers of ϕ_c:

- ϕ_c^4: $\beta_\lambda\,\partial_\lambda U = \beta_\lambda\,\frac{\phi_c^4}{4!}$ must equal $+\frac{\lambda^2}{4}\frac{\phi_c^4}{32\pi^2} = \frac{\lambda^2\phi_c^4}{128\pi^2}$, giving $\beta_\lambda = \dfrac{4!\,\lambda^2}{4\cdot 32\pi^2} = \dfrac{3\lambda^2}{16\pi^2}$;
- ϕ_c^2: $\beta_{m^2}\,\partial_{m^2}U = \beta_{m^2}\,\frac{1}{2}\phi_c^2$ must equal $\frac{m^2\lambda}{32\pi^2}\phi_c^2$, giving $\beta_{m^2} = \dfrac{\lambda m^2}{16\pi^2}$;
- ϕ_c^0: the constant $m^4/(32\pi^2)$ is cancelled by the running of the vacuum-energy counterterm δ_Λ, which is field-independent and physically inert.

The ϕ_c^4 matching reproduces the one-loop beta function $\beta_\lambda = 3\lambda^2/16\pi^2$ of Chapter 24 — the carried number of ϕ^4 theory — now obtained a third way, from the μ-dependence of the effective potential. The ϕ_c^2 matching yields the one-loop mass anomalous running $\beta_{m^2} = \lambda m^2/16\pi^2$ (equivalently $\gamma_{m^2} \equiv \beta_{m^2}/m^2 = \lambda/16\pi^2$), consistent with the mass renormalization of Chapter 22. That the single function (E.157) encodes both is the strongest internal check available at this order: the same pole that fixed the counterterms (E.156) fixes the running that makes the potential μ-independent.

Physical Insight

The effective potential is the renormalization group made visible. Reading (E.157) at ϕ_c such that $M^2(\phi_c) = \mu^2$ kills the logarithm and leaves $V_{\text{eff}} = U - \frac{3}{128\pi^2}M^4$, the "tree potential evaluated at the running couplings of the scale set by the field." Choosing μ to track the field is the leading-log improvement: the large logarithms $\ln(M^2/\mu^2)$ that spoil naive perturbation theory when ϕ_c is far from μ are resummed by running $\lambda(\mu)$ down to $\mu \sim M(\phi_c)$. The Coleman–Weinberg potential thus carries the whole one-loop RG of the model in a single closed expression.

E.4.6 The general one-loop master formula and the massless limit

Assembling the bosonic result (E.157) with the fermionic sign and degeneracy (E.139), and allowing several fields of various spins with field-dependent masses $M_i(\phi_c)$, the one-loop effective potential of any renormalizable theory is the supertrace

$$\boxed{V_1(\phi_c) = \frac{1}{64\pi^2}\sum_i (-1)^{2s_i}\, n_i\, M_i^4(\phi_c)\Big[\ln\frac{M_i^2(\phi_c)}{\mu^2} - c_i\Big]}\,, \tag{E.167}$$

with n_i the number of (real, on-shell) degrees of freedom of species i, $(-1)^{2s_i} = +1$ for bosons and -1 for fermions, and $c_i = \frac{3}{2}$ for spin 0 and spin $\frac{1}{2}$, $c_i = \frac{5}{6}$ for a massive gauge boson in the standard convention (the constant tracks the spin content of the determinant and the gauge-fixing sector; we computed the scalar case and quoted the gauge value, derivable by the identical heat-kernel route on $-D^2 + \dots$ of Section E.3—the 5/6 rather than 3/2 reflecting the $\overline{\text{MS}}$ (Landau-gauge) disentanglement of the transverse and would-be-Goldstone/ghost sectors of a massive vector, as spelled out in the broken-phase application Eq. (29.142)). For a single Dirac fermion of mass $M_{\text{f}} = y\phi_c$ this gives $V_1 = -\frac{4}{64\pi^2}M_{\text{f}}^4[\ln(M_{\text{f}}^2/\mu^2) - \frac{3}{2}]$, the minus sign and the four being exactly (E.139). The relative sign is the engine of the supersymmetric cancellation: when bosons and fermions are degenerate ($M_{\text{b}} = M_{\text{f}}$) and balanced ($n_{\text{b}} = n_{\text{f}}$), the quartic-times-log pieces cancel in (E.167) and the vacuum energy is protected.

We close by carrying ϕ^4 theory to the phenomenon that made the Coleman–Weinberg potential famous: *dimensional transmutation*, the radiative generation of a mass scale in a classically scale-invariant theory.

Worked Example E.25 (Massless ϕ^4 and dimensional transmutation)**.** Set $m^2 = 0$ in (E.157), so the classical theory has a single dimensionless coupling λ and no scale. Then $M^2(\phi_c) = \frac{\lambda}{2}\phi_c^2$ and

$$V_{\text{eff}}(\phi_c) = \frac{\lambda}{4!}\phi_c^4 + \frac{(\lambda\phi_c^2/2)^2}{64\pi^2}\Big[\ln\frac{\lambda\phi_c^2/2}{\mu^2} - \frac{3}{2}\Big] = \frac{\lambda}{4!}\phi_c^4 + \frac{\lambda^2\phi_c^4}{256\pi^2}\Big[\ln\frac{\lambda\phi_c^2}{2\mu^2} - \frac{3}{2}\Big]. \tag{E.168}$$

Classically V is a pure quartic with its only stationary point at the origin. The one-loop term proportional to $\phi_c^4 \ln\phi_c^2$ changes this: the logarithm drives V_{eff} negative for a range of ϕ_c before the positive quartic recaptures it, producing a pair of minima at $\phi_c = \pm v$ with $v \neq 0$, set by $V'_{\text{eff}}(v) = 0$. Differentiating (E.168) and using $\mathrm{d}(\phi_c^4 \ln\phi_c^2)/\mathrm{d}\phi_c = \phi_c^3(4\ln\phi_c^2 + 2)$,

$$V'_{\text{eff}}(\phi_c) = \frac{\lambda}{6}\phi_c^3 + \frac{\lambda^2\phi_c^3}{256\pi^2}\Big[4\ln\frac{\lambda\phi_c^2}{2\mu^2} - 6 + 2\Big] = \phi_c^3\Big\{\frac{\lambda}{6} + \frac{\lambda^2}{64\pi^2}\Big[\ln\frac{\lambda\phi_c^2}{2\mu^2} - 1\Big]\Big\}, \tag{E.169}$$

whose nontrivial zero $\phi_c = v$ satisfies $\ln(\lambda v^2/2\mu^2) = 1 - \frac{32\pi^2}{3\lambda}$. This is dimensional transmutation: the dimensionless input λ has been traded for a dimensionful vacuum expectation value v,

$$v^2 = \frac{2\mu^2}{\lambda}\,\exp\Big(1 - \frac{32\pi^2}{3\lambda}\Big), \tag{E.170}$$

a scale generated entirely by quantum effects from a scale-free classical theory. The minimum lies where the one-loop term is comparable in magnitude to the tree term, i.e. where $\lambda\ln(\lambda v^2/2\mu^2) \sim O(1)$ relative to the loop counting; for pure scalar ϕ^4 this places v at the boundary of perturbative reliability, and the honest statement (Coleman and Weinberg's own) is that the pure-scalar example is illustrative rather than quantitative. The trustworthy realization adds a gauge field so that the analogous balance occurs at weak coupling — scalar electrodynamics, the original setting — but the mechanism is the one shown here. Figure E.3 plots both the massive potential (E.157) and the massless potential (E.168), the latter exhibiting the radiatively generated double well.

The effective potential (E.157) is now complete: derived from the Gaussian fluctuation integral, regularized by the determinant machinery of the previous section, renormalized by explicit counterterms, and shown consistent with the renormalization group of Chapter 24. It feeds directly into the spontaneous-symmetry-breaking analysis of Chapter 29, where the same formula — now with $m^2 < 0$ at tree level — selects the broken vacuum and dresses Goldstone's theorem with radiative corrections. Yet the entire derivation rested on a step we wrote down without scrutiny: that the measure $\mathcal{D}\phi$ is translation-invariant

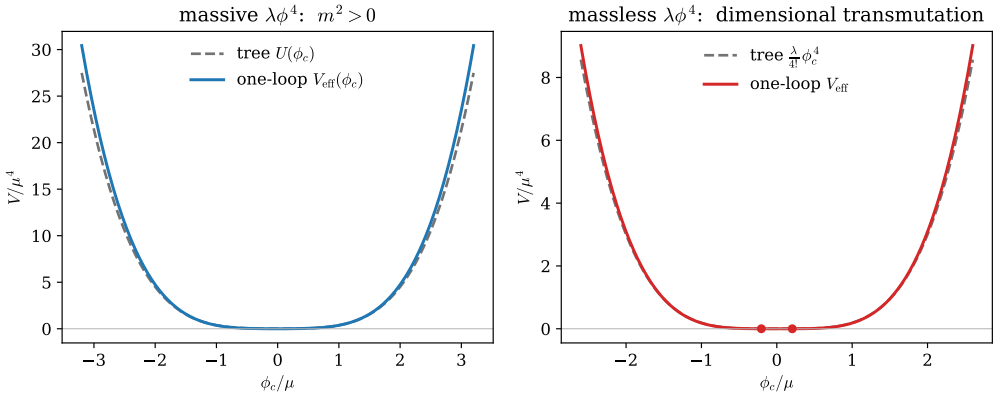

Figure E.3: The one-loop effective potential of ϕ^4 theory, Eq. (E.157). *Left:* the massive case $m^2 > 0$; the one-loop curve (solid) is a smooth deformation of the convex tree potential (dashed) near the origin. *Right:* the massless case (E.168); the classical pure quartic (dashed) has its minimum at the origin, while the one-loop term curves the potential into a double well with radiatively generated minima (dots) at $\phi_c = \pm v$ — dimensional transmutation, (E.170). A deliberately large coupling is used so the effect is visible; for pure scalar ϕ^4 the minimum sits at the edge of perturbative control (see Theorem E.25).

under the background split (E.129), $\mathcal{D}\phi = \mathcal{D}\eta$, and that the field-independent normalization $\mathcal{N}$ in (E.133) could be discarded with impunity. Whether $\mathcal{D}\phi$ deserves that trust — and what it costs when a field redefinition is nonlinear — is precisely what the next section confronts.

E.5 The Measure: Definition, Field Redefinitions, and Jacobians

Every computation so far has written $\int \mathcal{D}\phi$ as though the symbol were self-explanatory—the formal functional measure was introduced exactly that way in Section 4.2 and used unexamined ever since—and in the one-loop effective action of Section E.4 we leaned on a tacit and unexamined assumption: that the measure is *trivial*, an undistinguished product $\prod_x \mathrm{d}\phi(x)$ that is moreover *invariant* under the shift $\phi \to \phi_{\rm cl} + \eta$ separating the saddle from its fluctuation. Both properties were used—the shift invariance to write $\int \mathcal{D}\phi = \int \mathcal{D}\eta$, the triviality to drop a would-be Jacobian and read the one-loop correction off as nothing but $(\det K)^{-1/2}$. Neither property is automatic, and neither survives contact with a nonlinear change of field variables or with a chiral rotation of a fermion. This section pins down what $\mathcal{D}\phi$ *is* as a continuum object, computes the Jacobian that a field redefinition produces, and isolates the one place where

that Jacobian fails to be unity even in dimensional regularization: the fermionic measure under a γ^5 rotation. The payoff is not a single theorem but a piece of infrastructure—the exact groundwork that the gauge-fixing chapters (Chapters 13 and 26) and the anomaly chapter (Chapter 36) consume. We build the setup here; we deliberately do *not* compute their results.

E.5.1 Field space as a Riemannian manifold and the definition of $\mathcal{D}\phi$

The configurations of a theory with fields $\phi = (\phi^1, \dots, \phi^n)$ on a d-dimensional spacetime form an infinite-dimensional space $\mathcal{F}$, each point of which is one entire field configuration $x \mapsto \phi(x)$. A measure on $\mathcal{F}$ is not handed to us for free: there is no Lebesgue measure on an infinite-dimensional vector space. The construction that does work, and that makes every later manipulation honest, is to treat $\mathcal{F}$ as a Riemannian manifold and take $\mathcal{D}\phi$ to be its *Riemannian volume element*. For that we need a metric—an inner product on the tangent space at each configuration, i.e. on infinitesimal deformations $\delta\phi$.

The natural metric is the one inherited from the spacetime integral that already appears in every kinetic term. A deformation $\delta\phi(x)$ is assigned the squared length

$$\|\delta\phi\|^2 \;=\; \int \mathrm{d}^d x\, \big(\delta\phi(x)\big)^2 \;=\; \int \mathrm{d}^d x\, \delta_{ab}\, \delta\phi^a(x)\, \delta\phi^b(x). \tag{E.171}$$

This is the *DeWitt metric* in its simplest, flat-target form. Two features are decisive. First, it is *ultralocal*: the squared length is a single spacetime integral of a quantity built at one point x, with no derivatives of $\delta\phi$ and no coupling between $\delta\phi(x)$ and $\delta\phi(y)$ for $x \neq y$. In the language of a metric tensor on field space,

$$\|\delta\phi\|^2 = \int \mathrm{d}^d x\, \mathrm{d}^d y\; G_{ab}(x,y)\, \delta\phi^a(x)\, \delta\phi^b(y), \qquad G_{ab}(x,y) = \delta_{ab}\, \delta^d(x-y), \tag{E.172}$$

the field-space metric is diagonal in spacetime, proportional to $\delta^d(x-y)$. Second, for a theory whose fields are linear coordinates (a free scalar, or any polynomial-interacting scalar in Cartesian field variables) the metric (E.171) is *field-independent*: G_{ab} does not depend on ϕ. A field-independent metric has a constant volume element, and the Riemannian volume reduces to the flat product measure.

Definition E.26 (The continuum measure)**.** Let $\mathcal{F}$ be field space equipped with the ultralocal DeWitt metric (E.172), possibly with a configuration-dependent target metric $G_{ab}(\phi(x))$ in place of δ_{ab}. The *path-integral measure* is the associated Riemannian volume element,

$$\mathcal{D}\phi \;=\; \mathcal{N} \prod_x \sqrt{\det G(\phi(x))} \prod_a \mathrm{d}\phi^a(x), \tag{E.173}$$

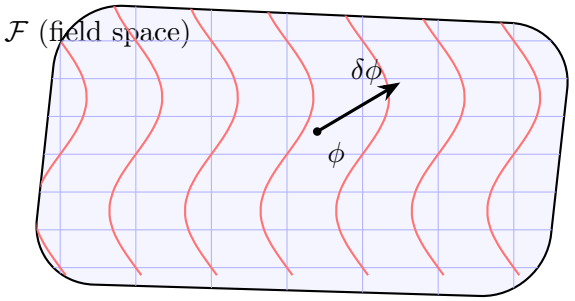

Figure E.4: Field space $\mathcal{F}$ as an (infinite-dimensional) Riemannian manifold. A field redefinition $\phi = F(\chi)$ is a change of *coordinates* on the same manifold (rectilinear ϕ-grid versus curvilinear χ-grid), not a change of the manifold. The DeWitt volume element $\mathcal{D}\phi$ of Theorem E.26 is coordinate-independent by construction; the apparent Jacobian of Theorem E.27 is the statement that the *naive flat* product measure, ignoring $\sqrt{\det G}$, is not.

where $\det G$ is the determinant of the finite $n \times n$ target metric and $\mathcal{N}$ is a field-independent (hence physically irrelevant) normalization that absorbs the ultralocal $\delta^d(x-y)$ factors. For a flat target, $G_{ab} = \delta_{ab}$, $\det G = 1$, and $\mathcal{D}\phi = \mathcal{N}\prod_x \mathrm{d}\phi(x)$ is the trivial product measure assumed in Section E.4.

Two things must now be made precise before (E.173) can be trusted. The continuum product $\prod_x$ and the determinant $\det G$ taken over an uncountable set of points are formal until they are given meaning by a regulator; and the claim that $\mathcal{N}$ is field-independent must be checked, because that is exactly the assumption that makes the measure split-invariant. Both are settled by discretization.

E.5.2 Discretization, the normalization, and the meaning of $\delta^d(0)$

Replace continuous spacetime by a hypercubic lattice of spacing a with sites x_i, $i = 1, \dots, M$, occupying a large volume $V = Ma^d$. A field configuration becomes the finite collection of numbers $\phi_i^a \equiv \phi^a(x_i)$, and field space becomes the ordinary finite-dimensional vector space $\mathbb{R}^{nM}$, on which Lebesgue measure unambiguously exists. The continuum integral $\int \mathrm{d}^d x$ becomes the Riemann sum $a^d \sum_i$, so the DeWitt length (E.171) discretizes to

$$\|\delta\phi\|^2 \;=\; a^d \sum_i \delta_{ab}\, \delta\phi_i^a\, \delta\phi_i^b \;=\; \sum_{i,a} G^{(\mathrm{lat})}_{(ia)(jb)}\, \delta\phi_i^a\, \delta\phi_j^b, \qquad G^{(\mathrm{lat})}_{(ia)(jb)} = a^d\, \delta_{ij}\, \delta_{ab}. \tag{E.174}$$

The lattice field-space metric is therefore a^d times the identity on the nM-dimensional space. Its determinant is $\det G^{(\mathrm{lat})} = (a^d)^{nM}$, and the Riemannian

volume element is

$$\mathcal{D}\phi \;=\; \sqrt{\det G^{(\mathrm{lat})}}\,\prod_{i,a}\mathrm{d}\phi_i^a \;=\; \prod_{i,a} a^{d/2}\,\mathrm{d}\phi_i^a. \tag{E.175}$$

The factors $a^{d/2}$ are field-independent constants; they are exactly the content of the normalization $\mathcal{N} = \prod_{i,a} a^{d/2}$ in Theorem E.26. Because $\mathcal{N}$ multiplies the partition function as an overall constant, it cancels in every normalized correlator $\langle\,\cdot\,\rangle = Z^{-1}\int\mathcal{D}\phi\,(\,\cdot\,)e^{iS}$ and is discarded. This is the precise sense in which "the measure is trivial": for a flat target the volume element is constant, the constant is irrelevant, and $\mathcal{D}\phi = \prod_x \mathrm{d}\phi(x)$ up to that constant. Crucially, the same field-independence makes the measure invariant under the shift $\phi \to \phi_{\mathrm{cl}} + \eta$, $\mathcal{D}\phi = \mathcal{D}\eta$, since a translation of $\mathbb{R}^{nM}$ has unit Jacobian—this is what licensed $\int\mathcal{D}\phi = \int\mathcal{D}\eta$ in Section E.4.

The discretization also fixes the meaning of the one object that controls every measure Jacobian below: the coincident-point delta function $\delta^d(0)$. On the lattice the Dirac delta is the Kronecker delta divided by the cell volume,

$$\delta^d(x_i - x_j) \;\longleftrightarrow\; \frac{1}{a^d}\,\delta_{ij}, \qquad \text{so} \qquad \delta^d(0) \;\longleftrightarrow\; \frac{1}{a^d} \;=\; \int\frac{\mathrm{d}^d k}{(2\pi)^d}\,1, \tag{E.176}$$

the number of field-space dimensions per unit spacetime volume. As $a \to 0$ this diverges as $a^{-d} \sim \Lambda^d$; it is the most ultraviolet-sensitive quantity in the formalism. The momentum-space form on the right makes the regulator dependence explicit: $\delta^d(0)$ is a scaleless integral. In a hard-cutoff scheme it equals a number of order Λ^d; in *dimensional regularization*, where every scaleless integral vanishes,

$$\delta^d(0) \;=\; \int\frac{\mathrm{d}^d k}{(2\pi)^d}\,1 \;=\; 0 \qquad \text{(dim. reg.)}, \tag{E.177}$$

because there is no scale from which to build a dimensionful answer. Holding onto (E.176) and (E.177) is the entire technical content of the next subsection.

E.5.3 The nonlinear sigma-model measure

When the fields are coordinates on a curved target manifold—a nonlinear sigma model, the prototypical example being the unit sphere S^{n-1} swept out by an $O(n)$ model after the radial mode is frozen—the kinetic term is $\frac{1}{2}\,G_{ab}(\phi)\,\partial_\mu\phi^a\partial^\mu\phi^b$ with a configuration-dependent target metric $G_{ab}(\phi)$. The DeWitt length then inherits that metric,

$$\|\delta\phi\|^2 = \int\mathrm{d}^d x\; G_{ab}(\phi(x))\,\delta\phi^a(x)\,\delta\phi^b(x), \tag{E.178}$$

and the volume element (E.173) acquires a genuinely field-dependent factor. Discretizing exactly as before, the lattice metric is now block-diagonal in sites but

each block is the local target metric: $G^{(\mathrm{lat})}_{(ia)(jb)} = a^d\,\delta_{ij}\,G_{ab}(\phi_i)$, with determinant $\prod_i (a^d)^n \det G(\phi_i)$. The Riemannian volume element is therefore

$$\mathcal{D}\phi = \mathcal{N}\prod_x \sqrt{\det G(\phi(x))}\prod_a \mathrm{d}\phi^a(x), \qquad \mathcal{N} = \prod_x a^{nd/2}, \tag{E.179}$$

which is the ultralocal DeWitt measure for a sigma model: one factor of $\sqrt{\det G(\phi(x))}$ per spacetime point. This factor is *not* an optional decoration. It is what makes the measure a coordinate-independent geometric object on the target, and—as we now show—it is exactly the factor that cancels the Jacobian of a nonlinear field redefinition, so that the combination $\mathcal{D}\phi$ is invariant while the naive $\prod_x \mathrm{d}\phi$ is not.

E.5.4 The Jacobian of a field redefinition

Consider an ultralocal (no-derivative) field redefinition $\phi \to \chi$ defined pointwise by an invertible map F,

$$\phi^a(x) = F^a\big(\chi(x)\big), \tag{E.180}$$

the same function F at every spacetime point. Such redefinitions are constantly performed: rescaling a field by its wavefunction renormalization, passing to the radial–angular variables of a sigma model, "integrating in" an auxiliary field, or eliminating a redundant operator by absorbing it into a shift of another field. The question is what the measure does.

Theorem E.27 (Jacobian of an ultralocal field redefinition)**.** *Under* (E.180)*, the naive flat product measure transforms as*

$$\prod_x \mathrm{d}\phi(x) \;=\; \Big(\prod_x \det F'(\chi(x))\Big)\prod_x \mathrm{d}\chi(x) \;=\; \exp\Big[\delta^d(0)\int \mathrm{d}^d x\ \operatorname{tr}\ln F'(\chi(x))\Big]\prod_x \mathrm{d}\chi(x), \tag{E.181}$$

where $F'^{\,a}{}_b = \partial F^a/\partial\chi^b$ *is the finite* $n\times n$ *Jacobian matrix of* F *and* $\operatorname{tr}\ln = \ln\det$ *acts on the internal indices. In dimensional regularization* $\delta^d(0) = 0$ *by* (E.177)*, so the Jacobian is unity and the redefinition is "free." The DeWitt measure* (E.179) *is invariant in any scheme: the factor* $\prod_x \det F'$ *is exactly cancelled by the transformation of* $\sqrt{\det G}$*.*

Proof. Work on the lattice, where everything is finite-dimensional and Lebesgue's change-of-variables theorem applies literally. The map (E.180) acts site by site: $\phi^a_i = F^a(\chi_i)$, so the full functional Jacobian matrix $\partial\phi^a_i/\partial\chi^b_j$ is *block-diagonal* across sites,

$$\frac{\partial\phi^a_i}{\partial\chi^b_j} \;=\; \delta_{ij}\,F'^{\,a}{}_b(\chi_i), \tag{E.182}$$

because the field at site i depends only on χ at the same site. The determinant of a block-diagonal matrix is the product of the block determinants, one per site:

$$\det\Big(\frac{\partial\phi_i}{\partial\chi_j}\Big) \;=\; \prod_i \det F'(\chi_i), \qquad \prod_{i,a} \mathrm{d}\phi_i^a = \Big(\prod_i \det F'(\chi_i)\Big)\prod_{i,a}\mathrm{d}\chi_i^a. \tag{E.183}$$

This is the lattice statement of the first equality in (E.181). To exhibit the $\delta^d(0)$ structure, exponentiate the product using $\det = \exp\operatorname{tr}\ln$:

$$\prod_i \det F'(\chi_i) = \exp\Big[\sum_i \operatorname{tr}\ln F'(\chi_i)\Big] = \exp\Big[\frac{1}{a^d}\sum_i a^d\,\operatorname{tr}\ln F'(\chi_i)\Big] \xrightarrow{a\to 0} \exp\Big[\frac{1}{a^d}\int \mathrm{d}^d x\,\operatorname{tr}\ln F'(\chi \tag{E.184}$$

The factor a^{-d} multiplying the integral is precisely the regularized $\delta^d(0)$ of (E.176); restoring continuum notation gives the middle expression in (E.181). In a scheme that sends $\delta^d(0)\to 0$—dimensional regularization—the exponent vanishes identically and the Jacobian is 1.

For the covariant statement, note that under (E.180) the target metric pulls back as $\widetilde{G}_{cd}(\chi) = G_{ab}(F(\chi))\,F'^{\,a}{}_c\,F'^{\,b}{}_d$, so $\det\widetilde{G} = (\det F')^2\det G$ and $\sqrt{\det\widetilde{G}} = |\det F'|\,\sqrt{\det G}$. Therefore

$$\prod_x \sqrt{\det\widetilde{G}(\chi(x))}\prod_a \mathrm{d}\chi^a(x) = \prod_x |\det F'|\,\sqrt{\det G}\prod_a \mathrm{d}\chi^a(x) = \prod_x \sqrt{\det G(\phi(x))}\prod_a \mathrm{d}\phi^a(x), \tag{E.185}$$

the last step undoing (E.183). The DeWitt volume element is the same whether expressed in ϕ or χ coordinates—it is the geometric volume of Fig. E.4, independent of the chart. □

The theorem disentangles three statements that are routinely conflated. (i) The naive flat measure $\prod_x \mathrm{d}\phi$ is *not* invariant under a nonlinear redefinition; it picks up $\exp[\delta^d(0)\int\operatorname{tr}\ln F']$. (ii) The geometric DeWitt measure *is* invariant, always, because the $\sqrt{\det G}$ factor was built to cancel the Jacobian. (iii) In dimensional regularization the two prescriptions coincide perturbatively, because $\delta^d(0) = 0$ kills the only difference between them. Statement (iii) is why, in practice, one may use the convenient flat measure and still perform nonlinear field redefinitions with impunity *provided dimensional regularization is the scheme*—the redefinition theorem of the S-matrix (its invariance under field reparametrizations) then needs no measure correction. In a cutoff scheme the $\delta^d(0)$ terms are real and must either be kept (the covariant measure) or cancelled against the explicit $\delta^d(0)$ tadpoles generated by the same redefinition in the action.

Worked Example E.28 (Wavefunction rescaling)**.** The simplest redefinition is the linear rescaling $\phi(x) = Z^{1/2}\chi(x)$ with Z a constant, which is exactly the field-strength renormalization performed in passing from bare to renormalized

fields. Here $F(\chi) = Z^{1/2}\chi$ for a single component, so $F' = Z^{1/2}$ is constant and $\operatorname{tr}\ln F' = \frac{1}{2}\ln Z$. Theorem E.27 gives

$$\prod_x \mathrm{d}\phi = \exp\Big[\tfrac{1}{2}(\ln Z)\,\delta^d(0)\int \mathrm{d}^d x\Big]\prod_x \mathrm{d}\chi = Z^{\frac{1}{2}\,\delta^d(0)\,V}\prod_x \mathrm{d}\chi, \tag{E.186}$$

with $V = \int \mathrm{d}^d x$ the spacetime volume. The exponent is a pure number times the volume: it is a field-independent constant, so even in a cutoff scheme it merely renormalizes the (irrelevant) normalization $\mathcal{N}$ and drops out of every correlator. In dimensional regularization it is exactly 1. This is the rigorous version of the everyday statement that constant field rescalings "do nothing" to the path integral—they multiply Z by a volume-divergent but physically inert constant.

Worked Example E.29 (A genuinely nonlinear redefinition)**.** Take the cubic redefinition $\phi(x) = \chi(x) + g\,\chi(x)^3$, used to remove a redundant operator. Now $F'(\chi) = 1 + 3g\chi^2$, and the Jacobian is

$$J = \exp\Big[\delta^d(0)\int \mathrm{d}^d x\,\ln(1+3g\chi^2(x))\Big] = \exp\Big[\delta^d(0)\int \mathrm{d}^d x\,(3g\chi^2 - \tfrac{9}{2}g^2\chi^4 + \cdots)\Big]. \tag{E.187}$$

Exponentiated, J contributes new *local* vertices to the action—a $\delta^d(0)$-weighted χ^2 mass term, a $\delta^d(0)$-weighted χ^4 vertex, and so on. In a cutoff scheme these are precisely the counterterms that cancel the $\delta^d(0)$ tadpole graphs (χ-loops closing on a single point) generated when $\phi = \chi + g\chi^3$ is substituted into the action; the cancellation is the field-redefinition invariance of the S-matrix made manifest. In dimensional regularization both sides vanish term by term: $J = 1$ because $\delta^d(0) = 0$, and the would-be tadpoles are themselves scaleless and vanish. Either way the on-shell physics is untouched, which is the entire point of allowing the redefinition.

E.5.5 The fermionic Berezin measure and its inverse Jacobian

For anticommuting fields the analysis runs in parallel but with one decisive sign flip: the Berezin measure transforms with the *inverse* of the Jacobian. Recall (Theorem 12.17) that for Grassmann generators $\{\theta_i\}$ the Berezin rules are $\int \mathrm{d}\theta_i = 0$ and $\int \mathrm{d}\theta_i\,\theta_i = 1$, and that for a complex Grassmann pair $(\psi, \bar\psi)$ these reproduce the fermionic Gaussian integral established in Section E.1,

$$\int \prod_i \mathrm{d}\bar\psi_i\,\mathrm{d}\psi_i\;\exp\!\big(-\bar\psi_i M_{ij}\psi_j\big) = \det M, \tag{E.188}$$

with the determinant appearing to the *positive* power, opposite to the $(\det)^{-1/2}$ of a bosonic Gaussian. The inverse-Jacobian rule is what forces that opposite sign, and we derive it directly from the Berezin definition.

Proposition E.30 (Inverse Jacobian of the Berezin measure)**.** *Let $\theta_i = A_{ij}\eta_j$ be an invertible linear change of n Grassmann variables (A an ordinary $n \times n$ matrix). Then the Berezin measures are related by*

$$\prod_i \mathrm{d}\theta_i = (\det A)^{-1} \prod_i \mathrm{d}\eta_i. \tag{E.189}$$

Proof. The Berezin measure is fixed by its action on the unique top-degree monomial. From $\int \mathrm{d}\theta_i\, \theta_i = 1$ one has the normalization

$$\int \Big(\prod_i \mathrm{d}\theta_i\Big)\, \theta_1\theta_2\cdots\theta_n = 1, \tag{E.190}$$

and likewise $\int (\prod_i \mathrm{d}\eta_i)\, \eta_1\cdots\eta_n = 1$. Now expand the product $\theta_1\cdots\theta_n$ in the η's. Because the η_j anticommute, only fully antisymmetrized terms survive, and the antisymmetrization of a product of matrix entries is exactly a determinant:

$$\theta_1\theta_2\cdots\theta_n = A_{1j_1}A_{2j_2}\cdots A_{nj_n}\,\eta_{j_1}\eta_{j_2}\cdots\eta_{j_n} = \Big(\sum_\sigma \mathrm{sgn}(\sigma)\, A_{1\sigma(1)}\cdots A_{n\sigma(n)}\Big)\,\eta_1\eta_2\cdots\eta_n = (\det A)\,\eta_1\eta_2\cdots\eta_n \tag{E.191}$$

where rearranging $\eta_{j_1}\cdots\eta_{j_n}$ into the standard order $\eta_1\cdots\eta_n$ produced the sign $\mathrm{sgn}(\sigma)$. Insert (E.191) into the normalization (E.190):

$$1 = \int \Big(\prod_i \mathrm{d}\theta_i\Big)\, \theta_1\cdots\theta_n = (\det A) \int \Big(\prod_i \mathrm{d}\theta_i\Big)\, \eta_1\cdots\eta_n. \tag{E.192}$$

Comparing with $\int (\prod_i \mathrm{d}\eta_i)\, \eta_1\cdots\eta_n = 1$ forces $\prod_i \mathrm{d}\theta_i = (\det A)^{-1} \prod_i \mathrm{d}\eta_i$, which is (E.189). The inverse power is the hallmark of Grassmann integration: where a bosonic integral $\int \mathrm{d}^n x$ over $x = Ay$ gains $|\det A|$, the Berezin integral over $\theta = A\eta$ gains $(\det A)^{-1}$. Applied to $\psi \to M^{1/2}\psi$ in (E.188), the two measure factors $\mathrm{d}\bar\psi\,\mathrm{d}\psi$ each contribute $(\det M^{1/2})^{-1}$, while the Gaussian core integrates to a constant; reassembling gives the positive power $\det M$, consistent with the Grassmann determinant of Section E.1. □

E.5.6 The chiral rotation and the Fujikawa setup

The one field redefinition whose Jacobian survives even in dimensional regularization—because it is not local-multiplicative but mixes the Dirac structure against a regulator that cannot be made chirally symmetric—is the chiral rotation of a Dirac fermion. We set it up exactly, identify the object that carries the anomaly, and stop precisely where the value of the anomaly would begin (that computation is owned by Chapter 36). Work in Euclidean signature, where the Dirac operator $\not{D} = \gamma^\mu(\partial_\mu - igA_\mu)$ is anti-Hermitian and $i\not{D}$ is Hermitian with a complete real spectrum, the setting in which the mode expansion below is rigorous; the Wick rotation is the one defined in Chapter A.

A chiral rotation with parameter $\alpha(x)$ acts as

$$\psi(x) \to \psi'(x) = e^{i\alpha(x)\gamma^5}\psi(x), \qquad \bar\psi(x) \to \bar\psi'(x) = \bar\psi(x)\, e^{i\alpha(x)\gamma^5}, \tag{E.193}$$

where the second relation follows from the first because γ^5 is Hermitian and anticommutes with γ^0 (Section C.3.5): $\bar\psi' = \psi'^\dagger\gamma^0 = \psi^\dagger e^{-i\alpha\gamma^5}\gamma^0 = \psi^\dagger\gamma^0 e^{i\alpha\gamma^5} = \bar\psi\, e^{i\alpha\gamma^5}$. The two fields rotate *the same way*, not oppositely, which is why the two measure factors will add rather than cancel.

Expand the fields in the orthonormal eigenmodes $\{\varphi_n\}$ of the Hermitian operator $i\not{D}$, with $i\not{D}\,\varphi_n = \lambda_n\varphi_n$ and $\int \mathrm{d}^d x\, \varphi_m^\dagger\varphi_n = \delta_{mn}$:

$$\psi(x) = \sum_n a_n\, \varphi_n(x), \qquad \bar\psi(x) = \sum_n \bar b_n\, \varphi_n^\dagger(x), \tag{E.194}$$

with $a_n, \bar b_n$ independent Grassmann coefficients. The fermionic measure is the Berezin measure in these coefficients, $\mathcal{D}\bar\psi\,\mathcal{D}\psi = \prod_n \mathrm{d}\bar b_n\, \mathrm{d}a_n$. Under (E.193) the coefficients transform linearly, $a_n \to a'_n = \sum_m C_{nm} a_m$, with

$$C_{nm} = \int \mathrm{d}^d x\, \varphi_n^\dagger(x)\, e^{i\alpha(x)\gamma^5}\, \varphi_m(x) = \delta_{nm} + i\int \mathrm{d}^d x\, \alpha(x)\, \varphi_n^\dagger\gamma^5\varphi_m + O(\alpha^2), \tag{E.195}$$

and the coefficients $\bar b_n$ transform by the same matrix C. By Theorem E.30 the Berezin measure picks up the *inverse* determinant once for the a's and once for the $\bar b$'s:

$$\prod_n \mathrm{d}\bar b'_n\, \mathrm{d}a'_n = (\det C)^{-2} \prod_n \mathrm{d}\bar b_n\, \mathrm{d}a_n. \tag{E.196}$$

Now $(\det C)^{-2} = \exp(-2\,\mathrm{tr}\ln C)$, and to first order $\mathrm{tr}\ln C = \mathrm{tr}(C - \mathbf{1}) = i\int \mathrm{d}^d x\, \alpha(x) \sum_n \varphi_n^\dagger(x)\gamma^5\varphi_n(x)$. Therefore

$$\mathcal{D}\bar\psi'\,\mathcal{D}\psi' = \exp\Big[-2i\int \mathrm{d}^d x\, \alpha(x) \sum_n \varphi_n^\dagger(x)\, \gamma^5\, \varphi_n(x)\Big]\, \mathcal{D}\bar\psi\,\mathcal{D}\psi. \tag{E.197}$$

This is the Fujikawa Jacobian. The exponent is controlled entirely by the mode sum

$$\mathcal{A}(x) \equiv \sum_n \varphi_n^\dagger(x)\, \gamma^5\, \varphi_n(x) = \langle x|\, \gamma^5\, |x\rangle = \mathrm{tr}\big[\gamma^5\, \delta^d(0)\big], \tag{E.198}$$

where the trace is over Dirac indices. Naively $\mathcal{A}(x) = 0$ twice over: $\mathrm{tr}\,\gamma^5 = 0$ in any dimension (Section C.3.5), and $\delta^d(0) = 0$ in dimensional regularization. The naive answer is wrong because the mode sum (E.198) is divergent and *must be regulated before the Dirac trace is taken*, and any regulator that respects the spectrum of $i\not{D}$ necessarily fails to commute with γ^5.

The regulator that does the job is the gauge-invariant, eigenvalue-damping factor $f(\lambda_n^2/M^2)$ with $f(0) = 1$, $f(\infty) = 0$, inserted into the sum and removed only after $M \to \infty$:

$$\mathcal{A}(x) = \lim_{M\to\infty} \sum_n f\Big(\frac{\lambda_n^2}{M^2}\Big)\, \varphi_n^\dagger(x)\, \gamma^5\, \varphi_n(x) = \lim_{M\to\infty} \mathrm{Tr}\Big[\gamma^5\, f\Big(\frac{(i\not{D})^2}{M^2}\Big)\Big]_{x,x}, \tag{E.199}$$

where $\mathrm{Tr}_{x,x}$ is the full trace (Dirac plus spacetime) evaluated at coincident points. The choice $f(s) = e^{-s}$ makes the operator inside the trace into the heat kernel of $(i\not{D})^2 = -\not{D}^2$,

$$\mathcal{A}(x) = \lim_{M\to\infty} \langle x|\, \gamma^5\, e^{\not{D}^2/M^2}\, |x\rangle\,, \tag{E.200}$$

which is *exactly* the heat-kernel object constructed in Section E.3. The coincidence limit of the heat kernel of a Laplace-type operator $\not{D}^2$ admits the Seeley–DeWitt expansion in inverse powers of M^2, and the only term that survives both the $M \to \infty$ limit and the γ^5 Dirac trace is the coefficient $a_{d/2}$ of the volume term: the lower coefficients carry positive powers of M and would diverge but are killed by the vanishing γ^5 trace of their Dirac structure, while the higher coefficients carry negative powers of M and vanish in the limit. The chiral Jacobian therefore reduces, with no further input, to

$$\mathcal{A}(x) = \mathrm{tr}_{\mathrm{Dirac}}\big[\gamma^5\, a_{d/2}(x)\big], \tag{E.201}$$

the Seeley–DeWitt coefficient $a_{d/2}$ of Section E.3 contracted against γ^5. This is the precise sense in which the anomaly is "set up" here: Eqs. (E.197), (E.199) and (E.201) reduce the entire computation to inserting one heat-kernel coefficient. We deliberately do not evaluate $a_{d/2}$ or take its γ^5 trace; that is the computation of Chapter 36, which imports this setup and finds, in $d = 4$, the ABJ result $\mathcal{A} = \frac{g^2}{32\pi^2}\epsilon^{\mu\nu\rho\sigma}F^a_{\mu\nu}F^a_{\rho\sigma}$ up to normalization. The structural lesson is what matters now: a chiral rotation is the one field redefinition whose measure Jacobian is nonzero even in dimensional regularization, because its $\delta^d(0)$ is multiplied by the γ^5 trace of a regulator and the product is a finite, geometric, and physical number.

Caution: why dimensional regularization does not kill this one

Theorem E.27 might suggest that, since $\delta^d(0) = 0$ in dimensional regularization, *every* measure Jacobian is trivial there, including the chiral one. The escape is that the chiral Jacobian is not of the form $\delta^d(0) \times$ (finite local density): it is $\delta^d(0)$ multiplied by $\mathrm{tr}\,\gamma^5$, an indeterminate 0×0 that the regulator resolves to a finite answer. Equivalently, in dimensional regularization the trouble migrates from $\delta^d(0)$ to the γ^5 problem itself—the impossibility of continuing γ^5 to $d \neq 4$ while keeping cyclicity and the four-dimensional chiral trace (Section C.7). The anomaly is scheme-independent precisely because it is forced by an obstruction no scheme removes.

E.5.7 The Faddeev–Popov insertion as a measure manipulation

A second place where the measure is actively manipulated, rather than merely defined, is gauge fixing. For a gauge theory the integration $\int \mathcal{D}A$ over all con-

nections overcounts by the volume of the gauge group, because gauge-equivalent configurations A and A^g (the gauge transform of A by g) contribute identically. The Faddeev–Popov procedure repairs this by inserting into the measure a cleverly chosen factor of unity,

$$1 = \Delta_{\mathrm{FP}}[A] \int \mathcal{D}g\, \delta(G(A^g)), \qquad \Delta_{\mathrm{FP}}[A] = \det \frac{\delta G(A^g)}{\delta g}\bigg|_{G=0}, \tag{E.202}$$

where $G(A) = 0$ is the gauge-fixing condition and Δ_{FP}, the Faddeev–Popov determinant, is exactly the Jacobian relating the delta function on the gauge condition to a delta function on the group. Reorganizing $\int \mathcal{D}A = \int \mathcal{D}g \int \mathcal{D}A\, \Delta_{\mathrm{FP}}\, \delta(G(A^g))$ and factoring out the (now finite) group volume leaves a gauge-fixed measure weighted by Δ_{FP}, which is subsequently re-exponentiated as a Grassmann integral over ghost fields using the inverse-Jacobian rule (E.189). This is once again a statement about how the measure transforms—here under the split of $\mathcal{D}A$ into gauge orbits and a transverse slice—and the apparatus we have built (the Riemannian volume element, the Jacobian of a change of variables, and the Berezin inverse Jacobian that turns a determinant into a ghost integral) is exactly what makes it precise. The full treatment, including the choice of gauge slice, the ghost Lagrangian, and the residual BRST symmetry, is the business of Chapter 13 (abelian) and Chapter 26 (non-abelian); they import the setup of this section rather than rebuild it.

We now have a complete and honest account of the measure and of the determinant it produces for a *non-degenerate* fluctuation operator K: the Gaussian integration of Section E.1 yields $(\det K)^{-1/2}$, the measure is split-invariant by Theorem E.26, and field redefinitions cost nothing in dimensional regularization save the single anomalous exception just isolated. One assumption remains unexamined, and it is the one that fails whenever a continuous symmetry of the saddle is present: that K has no zero eigenvalues. A zero mode makes $\det K$ vanish and the Gaussian formula meaningless. Repairing this—trading each zero mode for a collective coordinate, and recovering a finite, primed determinant—is the subject of Section E.6.

E.6 Zero Modes, Collective Coordinates, and the Primed Determinant

The previous section closed with a clean and complete account of the Gaussian integral about a *non-degenerate* saddle: with the measure of Theorem E.26 and the master formula Eq. (E.1), the one-loop weight of an isolated stationary point ϕ_{cl} is $e^{-S[\phi_{\mathrm{cl}}]}(\det K)^{-1/2}$, where $K = \delta^2 S/\delta\phi^2$ is the fluctuation operator. That account rested on one tacit hypothesis: that K is invertible, i.e. that it has no zero eigenvalue. The hypothesis fails—and fails for a structural, not accidental,

reason—precisely when the saddle is a *soliton* or an *instanton*: a finite-action solution that is not invariant under some continuous symmetry of the action. Translation invariance is the universal culprit. A kink centred at x_0 is a perfectly good solution for every x_0, so the saddle is not a point in field space but a whole orbit; moving along that orbit costs no action; and a costless direction of fluctuation is exactly a zero eigenvalue of K. The Gaussian formula then returns $(\det K)^{-1/2} = \infty$, which is not a divergence to be renormalized but a signal that the wrong integral was attempted. This section repairs it. We prove the existence and fix the normalization of the translational zero mode, trade the offending flat direction for a *collective coordinate* by a Faddeev–Popov manoeuvre, extract the resulting Jacobian $(S_{\mathrm{cl}}/2\pi)^{1/2}$ per zero mode, and assemble the complete semiclassical amplitude in terms of the *primed determinant* $\det' K$, the determinant with the zero modes deleted. The whole machine is then run, with every number shown, on the ϕ^4 kink and its avatar the quartic double-well instanton.

E.6.1 The saddle, its symmetry, and the translational zero mode

We work in the Euclidean theory throughout, where the weight is e^{-S_E} and saddles are genuine minima (or low-action critical points) of a real, bounded-below action. To keep the argument general and one-dimensional—the case that the Gelfand–Yaglom machinery of Section E.2 can actually evaluate—take a single field ϕ on a coordinate z (which will be a spatial coordinate for a static soliton, or Euclidean time for an instanton), with action of the standard form

$$S[\phi] = \int \mathrm{d}z \, \Big[\tfrac{1}{2}\, \phi'(z)^2 + V\big(\phi(z)\big) \Big], \qquad \phi' \equiv \frac{d\phi}{dz}, \tag{E.203}$$

which is Eq. (E.36) specialized to one dimension. The saddle equation $\delta S/\delta\phi = 0$ is the Euclidean equation of motion

$$-\phi'' + V'(\phi) = 0. \tag{E.204}$$

Let $\phi_{\mathrm{cl}}(z)$ be a finite-action solution of Eq. (E.204). Expanding $\phi = \phi_{\mathrm{cl}} + \eta$ and using Theorem 5.44 together with the n-dimensional Gaussian prefactor $(\det H)^{-1/2}$ of Theorem 4.40 produces, term by term,

$$S[\phi_{\mathrm{cl}} + \eta] = S[\phi_{\mathrm{cl}}] + \tfrac{1}{2} \int \mathrm{d}z \, \eta \, K \, \eta + O(\eta^3), \qquad K = -\partial_z^2 + V''(\phi_{\mathrm{cl}}(z)), \tag{E.205}$$

the linear term vanishing because ϕ_{cl} solves Eq. (E.204). The operator K is the second variation: a Schrödinger operator on the line with potential $V''(\phi_{\mathrm{cl}}(z))$, which tends to the constant $V''(\phi_{\mathrm{vac}}) \equiv m^2 > 0$ as $z \to \pm\infty$ (the curvature of V at the vacuum the soliton interpolates between or returns to). Its spectrum therefore consists of a finite number of discrete bound states below the threshold m^2 and a continuum above it.

The action Eq. (E.203) is invariant under the translation $z \mapsto z + a$: if $\phi_{\rm cl}(z)$ is a solution, so is $\phi_{\rm cl}(z-a)$, with identical action, for every real a. This is the continuous symmetry that forces the zero mode.

Proposition E.31 (The translational zero mode and its normalization)**.** *Let $\phi_{\rm cl}$ be a finite-action solution of Eq. (E.204) that is not constant. Then $\phi'_{\rm cl}(z)$ is a normalizable zero eigenfunction of the fluctuation operator K of Eq. (E.205),*

$$K\,\phi'_{\rm cl} = 0, \tag{E.206}$$

and its norm is the square root of the classical action,

$$\int \mathrm{d}z\,\left(\phi'_{\rm cl}\right)^2 = S_{\rm cl} \equiv S[\phi_{\rm cl}], \qquad \text{so the unit-normalized zero mode is} \quad \eta_0 = \frac{\phi'_{\rm cl}}{\sqrt{S_{\rm cl}}}. \tag{E.207}$$

Proof. Existence. The family $\phi_a(z) \equiv \phi_{\rm cl}(z-a)$ solves Eq. (E.204) for every a: $-\phi_a'' + V'(\phi_a) = 0$. Differentiate this identity with respect to a and set $a = 0$. Since $\partial_a \phi_a|_{a=0} = -\phi'_{\rm cl}(z)$, and using $\partial_a V'(\phi_a) = V''(\phi_a)\,\partial_a\phi_a$,

$$-(-\phi'_{\rm cl})'' + V''(\phi_{\rm cl})(-\phi'_{\rm cl}) = 0 \quad\Longrightarrow\quad (-\partial_z^2 + V''(\phi_{\rm cl}))\phi'_{\rm cl} = 0, \tag{E.208}$$

which is Eq. (E.206). Equivalently: differentiating the equation of motion is the same as acting with its linearization K, and the generator of the symmetry, $\phi'_{\rm cl}$, is annihilated. Because $\phi_{\rm cl} \to \phi_{\rm vac}$ exponentially at infinity (the approach to a nondegenerate vacuum of V is governed by $e^{-m|z|}$), $\phi'_{\rm cl}$ decays exponentially and is square-integrable, hence a genuine bound state. That it is the *ground* state of K—the eigenfunction of lowest eigenvalue, here 0—follows because $\phi'_{\rm cl}$ has no nodes for a monotonic kink: a nodeless eigenfunction is necessarily the ground state of a Schrödinger operator, so no negative eigenvalue can lie below it. (For a bounce solution that is not monotonic, $\phi'_{\rm cl}$ has a node, and exactly one negative mode sits below the zero mode; that single negative mode is the seat of the imaginary part responsible for a decay rate, the subject of Chapter 42.)

Normalization. Multiply Eq. (E.204) by $\phi'_{\rm cl}$ and integrate: $\phi'_{\rm cl}(-\phi''_{\rm cl} + V'(\phi_{\rm cl})) = 0$ is the total derivative $-\frac{\mathrm{d}}{\mathrm{d}z}\left[\frac{1}{2}(\phi'_{\rm cl})^2 - V(\phi_{\rm cl})\right] = 0$, so the "Euclidean energy"

$$\tfrac{1}{2}\left(\phi'_{\rm cl}\right)^2 - V(\phi_{\rm cl}) = \text{const} = 0, \tag{E.209}$$

the constant being fixed to zero by the boundary condition $\phi'_{\rm cl} \to 0$, $V \to 0$ at infinity. Hence $\frac{1}{2}(\phi'_{\rm cl})^2 = V(\phi_{\rm cl})$, the Bogomolny first-order condition, and the action Eq. (E.203) becomes

$$S_{\rm cl} = \int \mathrm{d}z\,\left[\tfrac{1}{2}(\phi'_{\rm cl})^2 + V(\phi_{\rm cl})\right] = \int \mathrm{d}z\,\left[\tfrac{1}{2}(\phi'_{\rm cl})^2 + \tfrac{1}{2}(\phi'_{\rm cl})^2\right] = \int \mathrm{d}z\,(\phi'_{\rm cl})^2, \tag{E.210}$$

which is exactly Eq. (E.207). □

The content of Theorem E.31 is that the would-be flat direction in field space is the direction $\eta_0 \propto \phi_{\rm cl}'$, and that the geometry of that direction is fixed entirely by the classical action: the "length" of the zero-mode direction, $\|\phi_{\rm cl}'\| = \sqrt{S_{\rm cl}}$, is what will set the Jacobian below.

E.6.2 Why the Gaussian integral diverges

Make the breakdown explicit in the eigenbasis. Let $\{\eta_n\}_{n\geq 0}$ be the orthonormal eigenfunctions of K, $K\eta_n = \epsilon_n \eta_n$, ordered so that $\epsilon_0 = 0$ is the translational mode of Theorem E.31 and $\epsilon_n > 0$ for $n \geq 1$. Expand the fluctuation in this basis,

$$\eta(z) = \sum_{n\geq 0} c_n\, \eta_n(z), \qquad \tfrac{1}{2}\int \mathrm{d}z\; \eta K \eta = \tfrac{1}{2}\sum_{n\geq 0} \epsilon_n c_n^2, \tag{E.211}$$

and recall that the continuum measure of Theorem E.26, in this basis, is the product $\mathcal{D}\eta = \prod_{n\geq 0} \mathrm{d}c_n/\sqrt{2\pi}$, normalized exactly so that each Gaussian factor integrates by Eq. (E.1) to $\int (\mathrm{d}c_n/\sqrt{2\pi})\, e^{-\frac{1}{2}\epsilon_n c_n^2} = \epsilon_n^{-1/2}$. The one-loop integral is then the formal product

$$\int \mathcal{D}\eta\; e^{-\frac{1}{2}\sum_n \epsilon_n c_n^2} = \prod_{n\geq 0} \epsilon_n^{-1/2} = (\det K)^{-1/2}. \tag{E.212}$$

The $n = 0$ factor is the disaster: $\epsilon_0 = 0$, so the integrand along c_0 is the constant $e^0 = 1$ and

$$\int_{-\infty}^{\infty} \frac{\mathrm{d}c_0}{\sqrt{2\pi}}\, 1 = \infty, \qquad \text{equivalently} \qquad \det K = \epsilon_0 \cdot \prod_{n\geq 1} \epsilon_n = 0. \tag{E.213}$$

The divergence is not ultraviolet—it is wholly carried by the single zero mode—and it has a transparent meaning. Moving along c_0 is, to linear order, the same as translating the soliton: from Eq. (E.205) and Eq. (E.207), $\delta\phi = \eta_0\, \mathrm{d}c_0$, while a translation by $\mathrm{d}a$ gives $\delta\phi = -\phi_{\rm cl}'\, \mathrm{d}a = -\sqrt{S_{\rm cl}}\, \eta_0\, \mathrm{d}a$. The c_0-integral is therefore an integral over the position of the soliton, and it diverges simply because the soliton can sit anywhere on an infinite line. The cure is to do that integral honestly, as an integral over the collective coordinate a, extracting the (finite, physical) volume of the symmetry orbit instead of integrating a redundant Gaussian over it.

E.6.3 Collective coordinates and the Faddeev–Popov Jacobian

The clean way to convert the dangerous c_0-integral into an a-integral is the Faddeev–Popov insertion of unity—the very device the gauge-fixing discussion of Section E.5.7 previewed, here applied not to a gauge orbit but to the translation orbit of the soliton. We insert into the path integral the identity

$$1 = \int_{-\infty}^{\infty} \mathrm{d}a \left|\frac{\partial F}{\partial a}\right| \delta(F(a)), \qquad F(a) \equiv \int \mathrm{d}z\; \big[\phi(z) - \phi_{\rm cl}(z-a)\big]\, \eta_0(z-a), \tag{E.214}$$

where $\eta_0(\cdot - a) = \phi_{\rm cl}'(\cdot - a)/\sqrt{S_{\rm cl}}$ is the normalized zero mode *of the soliton centred at* a. The function $F(a)$ measures the overlap of the deviation $\phi - \phi_a$ with the zero mode of ϕ_a; the gauge-fixing condition $F(a) = 0$ states that, having pulled out the centre a, what remains has no component along the costless direction. For a configuration ϕ close to some member of the orbit there is exactly one a with $F(a) = 0$, so Eq. (E.214) is a true resolution of unity. The Faddeev–Popov determinant in one collective coordinate is just the ordinary derivative $|\partial F/\partial a|$, evaluated on the constraint surface.

Compute that derivative at the solution. Differentiating F in Eq. (E.214) with respect to a,

$$\frac{\partial F}{\partial a} = \int \mathrm{d}z \, \Big[- \partial_a \phi_{\rm cl}(z-a)\, \eta_0(z-a) + \big(\phi(z) - \phi_{\rm cl}(z-a)\big)\, \partial_a \eta_0(z-a) \Big]. \tag{E.215}$$

The second term is proportional to the deviation $\phi - \phi_a$, which vanishes on the orbit ($\phi = \phi_a$) and is first order in the transverse fluctuation off it, hence does not contribute at the leading saddle order we are computing. In the first term, $\partial_a \phi_{\rm cl}(z-a) = -\phi_{\rm cl}'(z-a) = -\sqrt{S_{\rm cl}}\,\eta_0(z-a)$, so

$$\left.\frac{\partial F}{\partial a}\right|_{F=0} = \sqrt{S_{\rm cl}} \int \mathrm{d}z \; \eta_0(z-a)^2 = \sqrt{S_{\rm cl}}, \tag{E.216}$$

the last step using $\int \eta_0^2 = 1$. The Jacobian is the constant $\sqrt{S_{\rm cl}}$, independent of a. Now insert Eq. (E.214) into the fluctuation integral. Writing $\phi = \phi_a + \sum_{n \geq 1} c_n \eta_n(\cdot - a)$, the constraint $\delta(F(a))$ is $\delta(c_0)$ (it sets the zero-mode coefficient about the chosen centre to zero), and the measure factorizes as $\mathcal{D}\eta = (\mathrm{d}c_0/\sqrt{2\pi}) \prod_{n \geq 1} (\mathrm{d}c_n/\sqrt{2\pi})$. The c_0 integral is now performed against the delta function,

$$\int \frac{\mathrm{d}c_0}{\sqrt{2\pi}}\, \delta(c_0) = \frac{1}{\sqrt{2\pi}}, \tag{E.217}$$

and the leftover pieces are the collective-coordinate integral $\int \mathrm{d}a$, the Jacobian $\sqrt{S_{\rm cl}}$ of Eq. (E.216), and the *transverse* Gaussian over $n \geq 1$. Collecting the constants, each zero mode contributes the factor

$$\boxed{\frac{1}{\sqrt{2\pi}} \sqrt{S_{\rm cl}} \int \mathrm{d}a = \sqrt{\frac{S_{\rm cl}}{2\pi}} \int \mathrm{d}a \;,} \tag{E.218}$$

which is the advertised Jacobian $(S_{\rm cl}/2\pi)^{1/2}$ per zero mode, multiplying the integral $\int \mathrm{d}a$ over the modulus.

Theorem E.32 (Collective-coordinate change of variables)**.** *Let $\phi_{\rm cl}$ be a soliton/instanton saddle of Eq. (E.203) with d_0 exact zero modes $\eta_0^{(1)}, \ldots, \eta_0^{(d_0)}$ generated by a d_0-parameter continuous symmetry with collective coordinates*

$a_1, \dots, a_{d_0}$, each zero mode normalized to unity. Then the Gaussian fluctuation integral about ϕ_{cl} equals

$$\int \mathcal{D}\eta \, e^{-\frac{1}{2}\int \eta K \eta} = \left(\prod_{i=1}^{d_0} \sqrt{\frac{\mathcal{J}_i}{2\pi}} \right) \int \mathrm{d}^{d_0} a \, \left(\det{}' K \right)^{-1/2}, \qquad \mathcal{J}_i = \int \mathrm{d}z \, \left(\frac{\partial \phi_{\mathrm{cl}}}{\partial a_i} \right)^2, \tag{E.219}$$

where $\det' K \equiv \prod_{\epsilon_n > 0} \epsilon_n$ is the determinant with the zero modes deleted, $\int \mathrm{d}^{d_0} a$ runs over the moduli space (the symmetry orbit), and the per-mode Jacobian $\mathcal{J}_i$ is the norm-squared of the i-th unnormalized zero mode. For a single translational mode, $\partial \phi_{\mathrm{cl}} / \partial a = -\phi_{\mathrm{cl}}'$ and $\mathcal{J} = \int (\phi_{\mathrm{cl}}')^2 = S_{\mathrm{cl}}$ by Eq. (E.207), reproducing Eq. (E.218).

Proof. Repeat the construction of Eqs. (E.214) to (E.216) once per symmetry direction. The multidimensional Faddeev–Popov determinant is $\det(\partial F_i / \partial a_j)$, whose entries are $\partial F_i / \partial a_j = \int (\partial_{a_j} \phi_{\mathrm{cl}}) \, \eta_0^{(i)} = \sqrt{\mathcal{J}_j} \, \langle \hat{\eta}_0^{(j)}, \eta_0^{(i)} \rangle$ with $\hat{\eta}_0^{(j)} = \partial_{a_j} \phi_{\mathrm{cl}} / \sqrt{\mathcal{J}_j}$ the normalized j-th mode. When the zero modes are orthonormal ($\langle \hat{\eta}_0^{(j)}, \eta_0^{(i)} \rangle = \delta_{ij}$) the determinant is the product $\prod_i \sqrt{\mathcal{J}_i}$; each $\delta(F_i)$ does its $c_0^{(i)}$-integral against the measure factor $1/\sqrt{2\pi}$ as in Eq. (E.217); and the surviving $n \notin \{0\}$ Gaussians give $\prod_{\epsilon_n > 0} \epsilon_n^{-1/2} = (\det' K)^{-1/2}$. (Should the natural collective coordinates fail to be orthonormal—as for the dilatation and rotation moduli of higher-dimensional instantons—the determinant $\det(\partial F_i / \partial a_j)$ supplies precisely the correct metric volume on moduli space, $\sqrt{\det g}$ with $g_{ij} = \langle \partial_{a_i} \phi_{\mathrm{cl}}, \partial_{a_j} \phi_{\mathrm{cl}} \rangle$; this is the DeWitt metric of Eq. (E.171) restricted to the zero-mode subspace, and is the moduli-space measure quoted without derivation in Chapter 42.) □

Physical Insight

The Jacobian $(S_{\mathrm{cl}}/2\pi)^{1/2}$ is not a formal artefact; it is the statement that one quantum of motion along the soliton's translation mode has a finite "inertia" set by the classical action. In the soliton's rest frame S_{cl} is its mass M, and the collective coordinate a is its centre of mass: promoting a to a dynamical variable $a(t)$ and expanding the action recovers the nonrelativistic kinetic term $\frac{1}{2} M \dot{a}^2$. The collective-coordinate trick is thus the first step of soliton quantization—it extracts the soliton's translational degree of freedom from the field and hands it back as an ordinary particle coordinate—which is precisely how Chapter 41 builds the quantum kink's Hilbert space and momentum eigenstates.

E.6.4 The primed determinant and the complete semiclassical amplitude

Definition E.33 (Primed determinant)**.** The *primed determinant* of a fluctuation operator K with zero modes is the product of its nonzero eigenvalues,

$$\det{}' K \equiv \prod_{n:\,\epsilon_n \neq 0} \epsilon_n, \tag{E.220}$$

defined, like every functional determinant in this appendix, only through the finite ratio $\det' K / \det K_0$ against a reference operator K_0 with no zero modes, in the sense of Eq. (E.45).

We can now write the complete one-loop amplitude. Two saddles compete: the trivial vacuum ϕ_{vac} (a constant, with no zero mode and fluctuation operator $K_0 = -\partial_z^2 + m^2$), and the soliton/instanton ϕ_{cl}. Normalizing the soliton sector against the vacuum—as one always does, so that the divergent measure factors of Section E.2.2 cancel in the ratio—and combining Theorem E.32 with the vacuum weight $e^{-S[\phi_{\text{vac}}]}(\det K_0)^{-1/2}$, the ratio of the two functional integrals is

$$\boxed{\frac{Z_{\text{sol}}}{Z_{\text{vac}}} = \left(\prod_{i=1}^{d_0} \sqrt{\frac{\mathcal{J}_i}{2\pi}}\right) \int \mathrm{d}^{d_0} a \;\; e^{-(S_{\text{cl}} - S_{\text{vac}})} \left(\frac{\det{}' K}{\det K_0}\right)^{-1/2}.} \tag{E.221}$$

This is the master formula the appendix has been building toward for the degenerate case. Every factor is finite and computable: $S_{\text{cl}} - S_{\text{vac}}$ is the classical action of the soliton above the vacuum (its mass, or its tunneling exponent); the product of $(\mathcal{J}_i/2\pi)^{1/2}$ is the collective-coordinate Jacobian, equal to $(S_{\text{cl}}/2\pi)^{1/2}$ for a single translational mode; the integral $\int \mathrm{d}^{d_0} a$ is the volume of moduli space (for time translation it yields the total Euclidean time T, the source of a *rate*); and the ratio $\det' K / \det K_0$ is a finite ratio of determinants with the zero modes removed from the numerator, evaluated by Gelfand–Yaglom in $d = 1$ exactly as in the non-degenerate case, only with the zero eigenvalue divided out by hand. The remainder of the section computes that ratio, and assembles the prefactor, for the ϕ^4 kink.

E.6.5 Worked example: the ϕ^4 kink and the quartic double-well instanton

Worked Example E.34 (The kink fluctuation determinant and the tunneling prefactor)**.** We run the entire machine on ϕ^4 theory. The standard Lagrangian Eq. (6.56) carries the potential $\frac{1}{2}m^2\phi^2 + \frac{\lambda}{4!}\phi^4$; a kink requires the spontaneously broken regime in which the mass term has the opposite sign, so that V has two degenerate minima. We write the degenerate double well in the standard form

$$V(\phi) = \frac{\lambda}{4!}\left(\phi^2 - v^2\right)^2, \qquad V(\pm v) = 0, \qquad m^2 \equiv V''(\pm v) = \frac{\lambda v^2}{3}, \tag{E.222}$$

the two vacua at $\phi = \pm v$ and m the mass of the elementary meson (fluctuations about either vacuum). Expanding the square reproduces the frozen quartic $\frac{\lambda}{4!}\phi^4$ with a broken mass term $-\frac{\lambda v^2}{12}\phi^2 = -\frac{1}{2}(m^2/2)\phi^2$ and a constant chosen so that V vanishes at the minima; this is exactly the model of Eq. (6.56) in its broken phase. (See the notation watch below on the sign of the mass term.)

Step 1 — the kink solution. The Bogomolny condition $\frac{1}{2}(\phi_{\rm cl}')^2 = V(\phi_{\rm cl})$ of Eq. (E.209) gives $\phi_{\rm cl}' = \sqrt{2V} = \sqrt{\lambda/12}\,(v^2 - \phi_{\rm cl}^2)$ for the kink that climbs from $-v$ to $+v$. Separating variables, $\int \mathrm{d}\phi/(v^2-\phi^2) = \sqrt{\lambda/12}\int \mathrm{d}z$, i.e. $v^{-1}\,\mathrm{artanh}(\phi/v) = \sqrt{\lambda/12}\,(z - z_0)$, so with $v\sqrt{\lambda/12} = m/2$,

$$\phi_{\rm cl}(z) = v\,\tanh\Big[\frac{m}{2}\,(z - z_0)\Big], \tag{E.223}$$

a kink of width $2/m$ centred at the collective coordinate z_0.

Step 2 — the classical action. By Eq. (E.210), $S_{\rm cl} = \int \mathrm{d}z\,(\phi_{\rm cl}')^2$. With $\phi_{\rm cl}' = \frac{mv}{2}\,\mathrm{sech}^2(mz/2)$ and $\int_{-\infty}^{\infty}\mathrm{sech}^4 u\,\mathrm{d}u = 4/3$,

$$S_{\rm cl} = \frac{m^2v^2}{4}\int \mathrm{d}z\,\mathrm{sech}^4\frac{mz}{2} = \frac{m^2v^2}{4}\cdot\frac{2}{m}\cdot\frac{4}{3} = \frac{2}{3}\,mv^2 = \frac{2m^3}{\lambda}, \tag{E.224}$$

using $v^2 = 3m^2/\lambda$ at the last step. In the soliton reading $S_{\rm cl}$ is the classical kink mass $M_{\rm kink} = 2m^3/\lambda$; in the instanton reading it is the tunneling exponent S_0.

Step 3 — the fluctuation operator and its spectrum. From Eq. (E.205) with $V''(\phi) = \frac{\lambda}{6}(3\phi^2 - v^2)$ and $\phi_{\rm cl} = v\tanh(mz/2)$, using $3\tanh^2 - 1 = 2 - 3\,\mathrm{sech}^2$ and $\frac{\lambda v^2}{6} = \frac{m^2}{2}$,

$$K = -\partial_z^2 + m^2 - \frac{3m^2}{2}\,\mathrm{sech}^2\frac{mz}{2}. \tag{E.225}$$

This is the reflectionless Pöschl–Teller operator. Rescaling $s = mz/2$ turns it into $\frac{m^2}{4}\big[-\partial_s^2 + 4 - 6\,\mathrm{sech}^2 s\big]$; the bracket is $-\partial_s^2 - \ell(\ell+1)\mathrm{sech}^2 s$ shifted by 4, with $\ell(\ell+1) = 6$, i.e. $\ell = 2$. Its two bound states sit at $-\partial_s^2$ energies $-(\ell - j)^2 = -4, -1$ for $j = 0, 1$, and the continuum begins at 0; adding the shift 4 and multiplying by $m^2/4$ gives the spectrum of K,

$$\epsilon_0 = 0\ \text{(zero mode)}, \qquad \epsilon_1 = \frac{3m^2}{4}\ \text{(shape mode)}, \qquad \epsilon_k = k^2 + m^2\ \text{(continuum)}, \tag{E.226}$$

sketched in Fig. E.5. The zero mode is $\eta_0 \propto \mathrm{sech}^2(mz/2) \propto \phi_{\rm cl}'$, exactly as Theorem E.31 demands; the nonzero "shape mode" ϵ_1 is a genuine internal vibration of the kink; and the continuum is that of the free operator $K_0 = -\partial_z^2 + m^2$, shifted only by reflectionless phase shifts. There is no negative eigenvalue: the kink/instanton is a true minimum, and the prefactor will be real.

Step 4 — the primed determinant via Gelfand–Yaglom. We need the ratio $\det' K/\det K_0$ with $K_0 = -\partial_z^2 + m^2$. Place the system in a box $z \in [-T/2, T/2]$ with Dirichlet conditions, so $\det K$ and $\det K_0$ are well-defined and Theorem E.12

applies, and take $T \to \infty$ at the end. Two ingredients are needed: the *full* Gelfand–Yaglom ratio $\det K / \det K_0$ (which vanishes, because K has the would-be zero mode), and the small eigenvalue $\epsilon_0(T)$ into which the box lifts that mode; their quotient is the primed ratio, since $\det K = \epsilon_0(T)\, \det' K$.

For the full ratio, use the two independent solutions of $K\psi = 0$ in the rescaled variable $s = mz/2$, where the equation is $y'' = (4 - 6\,\mathrm{sech}^2 s)\, y$. The decaying solution is the zero mode $y_a(s) = \mathrm{sech}^2 s$ (even); reduction of order, $y_b = y_a \int \mathrm{d}s / y_a^2$ with $\int \cosh^4 s \,\mathrm{d}s = \frac{3}{8}s + \frac{1}{4}\sinh 2s + \frac{1}{32}\sinh 4s$, gives the growing solution

$$y_b(s) = \mathrm{sech}^2 s \left[\tfrac{3}{8}s + \tfrac{1}{4}\sinh 2s + \tfrac{1}{32}\sinh 4s\right] \xrightarrow{s\to+\infty} \tfrac{1}{16} e^{2s}, \tag{E.227}$$

which is odd and has unit Wronskian $W = y_a y_b' - y_a' y_b = 1$ (checked at $s = 0$, where $y_a = 1$, $y_a' = 0$, $y_b = 0$, $y_b' = 1$). The Gelfand–Yaglom shooting solution on the symmetric interval $s \in [-S, S]$, $S = mT/4$, with $u(-S) = 0$, $u'(-S) = 1$, is $u = \alpha y_a + \beta y_b$ with $\alpha = -y_b(-S)$, $\beta = y_a(-S)$ (Cramer's rule with denominator $W = 1$). Using the parities $y_a(-S) = y_a(S)$ and $y_b(-S) = -y_b(S)$,

$$u(S) = -y_b(-S)\, y_a(S) + y_a(-S)\, y_b(S) = 2\, y_a(S)\, y_b(S) \xrightarrow{S\to\infty} 2\cdot 4e^{-2S}\cdot \tfrac{1}{16} e^{2S} = \tfrac{1}{2}. \tag{E.228}$$

The reference shoot for K_0 (rescaled to $-\partial_s^2 + 4$) is $u_0(s) = \frac{1}{2}\sinh\big(2(s+S)\big)$, so $u_0(S) = \frac{1}{2}\sinh 4S = \frac{1}{2}\sinh(mT)$. By Eq. (E.47) the full ratio is therefore

$$\frac{\det K}{\det K_0} = \frac{u(S)}{u_0(S)} = \frac{1/2}{\frac{1}{2}\sinh(mT)} = \frac{1}{\sinh(mT)} \xrightarrow{T\to\infty} 2\, e^{-mT}, \tag{E.229}$$

which indeed $\to 0$: the zero mode has driven the determinant to zero, exactly as in Eq. (E.213).

For the lifted eigenvalue, the exact zero-energy solution $y_a = \mathrm{sech}^2(mz/2)$ does not vanish at the walls, so the true Dirichlet ground state φ has a small nonzero eigenvalue $\epsilon_0(T)$. Green's identity on $[-T/2, T/2]$ with $K\,\mathrm{sech}^2 = 0$ and $K\varphi = \epsilon_0 \varphi$, $\varphi(\pm T/2) = 0$, gives

$$\epsilon_0(T) \int \mathrm{d}z\; y_a \varphi = \big[\varphi\, y_a' - y_a \varphi'\big]_{-T/2}^{T/2} = -\big[y_a \varphi'\big]_{-T/2}^{T/2}, \tag{E.230}$$

the surface terms with φ dropping out by the Dirichlet condition. Matching $\varphi \simeq y_a \simeq 4e^{-m|z|}$ in the interior to a solution $A\sinh\big(m(T/2 - |z|)\big)$ vanishing at the wall fixes $A = 8e^{-mT/2}$ and $\varphi'(\pm T/2) = \mp 8 m e^{-mT/2}$; with $y_a(\pm T/2) = 4e^{-mT/2}$ and $\int y_a^2 = \int \mathrm{sech}^4(mz/2)\,\mathrm{d}z = 8/(3m)$, Eq. (E.230) gives

$$\epsilon_0(T) = \frac{64\, m\, e^{-mT}}{8/(3m)} = 24\, m^2\, e^{-mT}. \tag{E.231}$$

Dividing Eq. (E.229) by Eq. (E.231),

$$\boxed{\frac{\det' K}{\det K_0} = \frac{1}{\epsilon_0(T)} \frac{\det K}{\det K_0} = \frac{2\, e^{-mT}}{24\, m^2\, e^{-mT}} = \frac{1}{12\, m^2}\,,} \tag{E.232}$$

finite and T-independent, the celebrated determinant ratio for the ϕ^4/double-well fluctuation operator. (The exponentials cancel, confirming that the apparent collapse of $\det K$ was nothing but the zero mode, now correctly excised.)

Step 5 — assembling the prefactor. Substitute Eqs. (E.224) and (E.232) into the master amplitude Eq. (E.221) with a single translational mode ($d_0 = 1$, $\mathcal{J} = S_{\rm cl}$, $\int \mathrm{d}a = T$ in the instanton reading where z is Euclidean time), and write $m = \omega$ in QM language (the curvature of the well). The one-instanton amplitude relative to the no-instanton (vacuum) amplitude is $T\,K\,e^{-S_0}$ with

$$K = \sqrt{\frac{S_0}{2\pi}}\left(\frac{\det{}' K}{\det K_0}\right)^{-1/2} = \sqrt{\frac{S_0}{2\pi}}\,\sqrt{12\,\omega^2} = \omega\sqrt{\frac{6\,S_0}{\pi}}, \tag{E.233}$$

where the algebra is $2\sqrt{3}\cdot(2\pi)^{-1/2} = (12/2\pi)^{1/2} = (6/\pi)^{1/2}$. Summing the dilute gas of alternating instantons and anti-instantons exponentiates this into the two lowest levels $E_\pm = \frac{1}{2}\omega \mp K\,e^{-S_0}$, so the ground-state splitting of the symmetric double well is

$$\Delta E = E_- - E_+ = 2K\,e^{-S_0} = 2\,\omega\sqrt{\frac{6\,S_0}{\pi}}\;e^{-S_0}, \qquad S_0 = \frac{2}{3}\,\omega\,a^2, \tag{E.234}$$

the standard double-well tunneling result, here derived with every factor accounted for: the exponential e^{-S_0} from the classical action, the $\sqrt{S_0/2\pi}$ from the collective-coordinate Jacobian, and the $\sqrt{12\,\omega^2}$ from the primed determinant. In the soliton reading the same numbers feed Eq. (E.221) for the quantum kink: $\det' K/\det K_0 = 1/12m^2$ fixes the one-loop fluctuation correction to the kink mass and the normalization of the kink state, the computation completed in Chapter 41.

Notation watch: the sign of the mass term

The frozen ϕ^4 Lagrangian Eq. (6.56) is written with a positive mass term $+\frac{1}{2}m^2\phi^2$, describing a single vacuum at $\phi = 0$. A kink/instanton exists only in the spontaneously broken phase, where that term is negative and the potential is the double well Eq. (E.222). We therefore use m in this section for the *physical meson mass* $\sqrt{V''(\pm v)} = \sqrt{\lambda v^2/3}$ about a true vacuum, not for the (now tachyonic) coefficient in the symmetric Lagrangian. This is the same convention Chapters 41 and 42 adopt; no global constant is redefined.

Physical Insight

The number $\det' K/\det K_0 = 1/12m^2$ packages two physically distinct objects in one ratio. Read with z a spatial coordinate, it is the one-loop

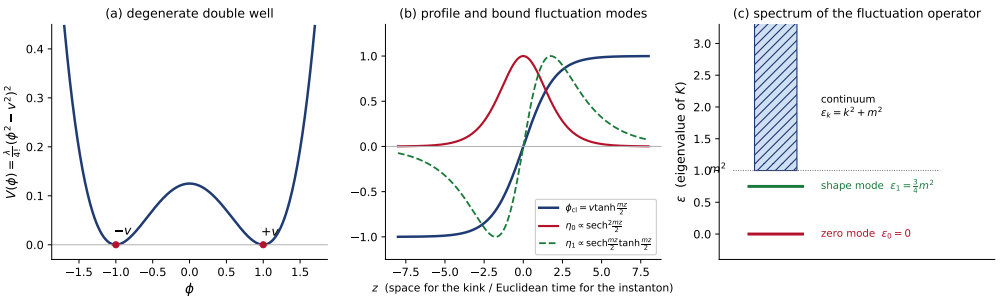

Figure E.5: The ϕ^4 kink / quartic double-well instanton. **(a)** the degenerate double well Eq. (E.222) with vacua at $\pm v$. **(b)** the kink profile $\phi_{\rm cl} = v\tanh(mz/2)$ together with the normalizable translational zero mode $\eta_0 \propto \operatorname{sech}^2(mz/2) \propto \phi_{\rm cl}'$ (Theorem E.31) and the discrete shape mode; here z is space for the static kink and Euclidean time for the instanton. **(c)** the spectrum Eq. (E.226) of the fluctuation operator K: a zero mode at 0 (excised into the collective coordinate), a bound shape mode at $\frac{3}{4}m^2$, and the reflectionless continuum above the meson threshold m^2.

correction to a soliton's mass and the normalization of its quantum state—a particle built by a classical lump dressed in quantum fluctuations. Read with z a Euclidean time, the very same operator and the very same ratio give the amplitude for a particle to tunnel through a barrier, and the splitting Eq. (E.234). That a static soliton and a tunneling event are governed by identical mathematics is not a coincidence: both are finite-action critical points of the same Euclidean functional, and the fluctuation determinant cannot tell space from imaginary time. This duality is the conceptual bridge from Chapter 41 to Chapter 42.

We have now closed the last gap left open by the non-degenerate treatment of Section E.5: a fluctuation operator with zero modes is handled by trading each costless direction for a collective coordinate, paying the Jacobian $(S_{\rm cl}/2\pi)^{1/2}$ per mode, and replacing $\det K$ by the finite primed determinant $\det' K$, with the complete semiclassical amplitude assembled in Eq. (E.221). Together with the Gaussian algebra of Section E.1, the Gelfand–Yaglom and zeta-function evaluations of Section E.2, the one-loop effective action of Section E.4, and the measure theory of Section E.5, this furnishes a complete toolkit for evaluating $\int \mathcal{D}\phi\, e^{-S}$ beyond tree level. Its principal consumers are the soliton quantization of Chapter 41, the instanton calculus and the θ-vacuum of Chapter 42, and the curved-space functional determinants—heat kernels, conformal anomalies, and the gravitational path integral—of Chapter 64, each of which inherits the primed-determinant prefactor derived here rather than rebuilding it.

Further reading

The path-integral and effective-action machinery of this appendix is developed at textbook length in Peskin and Schroeder [396] (chapters 9 and 11), Weinberg [500] (chapter 9 and volume II), Zee [532], and—most thoroughly for functional methods, the effective potential, and instanton determinants—Zinn-Justin [534]. The semiclassical lectures of Coleman [129] remain the clearest narrative source for the steepest-descent expansion, zero modes, and the dilute-instanton gas, with Rajaraman [412] the standard reference for soliton and instanton fluctuation determinants in full. The original radiative-symmetry-breaking computation is Coleman and Weinberg [132]; the Gelfand–Yaglom determinant formula is Gelfand and Yaglom [213]; zeta-function regularization of functional determinants in field theory traces to Hawking [257], and the heat-kernel expansion with its Seeley–DeWitt coefficients is reviewed exhaustively in Vassilevich [484]. For the geometric and topological language underlying the measure, zero modes, and the index theorem the anomaly chapter draws on, see Nakahara [355].

Appendix F

Standard Model Data

Parts VII through IX of this book built the Standard Model one mechanism at a time, and each mechanism was *earned* where it appears. Chapters 25 to 28 gave us non-abelian gauge theory: the connection and curvature, Faddeev–Popov quantization and BRST, the running coupling and asymptotic freedom that make QCD a predictive theory. Chapters 29 to 32 gave us the symmetry-breaking half of the story: Goldstone's theorem and the effective potential, the Higgs mechanism in the R_ξ and unitary gauges, the Glashow–Weinberg–Salam unification of the electroweak interactions, and the flavor sector with its Yukawa couplings, mass-versus-flavor bases, and the origin of CP violation. Chapter 33 then assembled the complete theory, identified its accidental baryon- and lepton-number symmetries, wrote down the θ term, and counted its parameters. The physics is therefore already proved. *Nothing physical is proved in this appendix.*

What this appendix does instead is collect, in one unambiguous place, the model's defining *data* and the conventions that pin every number down. It records the gauge group and the full representation content—every fermion field with its $\mathrm{SU}(3)_c \times \mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$ quantum numbers, and the single scalar doublet; it writes the complete Lagrangian term by term, with every sign, normalization, and gauge-fixing choice fixed; it derives the free-parameter count in full; and it tabulates the measured numerical values *together with the renormalization scheme in which each one is quoted.* The organizing purpose is reproducibility: every mass, every coupling, and every cross section computed anywhere in this book should be reconstructible from the numbers and conventions on these pages, with no recourse to an external table.

The division of labor is worth stating plainly, because it governs what is and is not argued here. Load-bearing *physics*—the gauge principle and minimal coupling, the Higgs mechanism and mass generation, the GIM structure and the CKM origin of flavor mixing, gauge-anomaly cancellation—is imported by Chapter 33 from the chapters that prove it and is never reproved. But the *data-organizing derivations* are carried here in full, because they are themselves

load-bearing and belong nowhere else: the parameter count via the breaking of the global flavor symmetry, the standard parametrizations of the CKM and PMNS matrices, the Wolfenstein expansion, the rephasing-invariant Jarlskog measure of CP violation, and the scheme conversions—pole mass versus $\overline{\text{MS}}$ mass, and the $\{\alpha, G_F, m_Z\}$ versus $\{g, g', v\}$ input dictionary—that let the body chapters' numbers be compared at all. These are computations, not tabulations, and they are done step by step.

This appendix also freezes the standing conventions that the rest of the book quietly assumes. The gauge group is written in the fixed order $\mathrm{SU}(3)_c \times \mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$. The hypercharge normalization is $Q = T^3 + Y$, so that the lepton doublet carries $Y_L = -\frac{1}{2}$ and the Gell-Mann–Nishijima relation holds with no stray factor of two; the alternative $Y' = 2Y$ convention is recorded only to translate other sources, never used. The covariant-derivative sign convention is the one fixed in Chapter A, $D_\mu = \partial_\mu - igA^a_\mu T^a$ (and $D_\mu = \partial_\mu - iqA_\mu$ in the abelian case), so that the gauge-boson couplings carry their canonical signs throughout. Unless stated otherwise, every measured number quoted here is a mid-2020s Particle Data Group value, dated as such and reported with its uncertainty; where a quantity is scheme-dependent its scheme is named on the spot.

F.1 The Defining Data: Gauge Group and Representation Content

A quantum field theory is fixed, before any Lagrangian is written, by a small amount of group-theoretic data: a gauge group, a list of matter fields together with the representations they carry, and whatever scalars are needed to break the symmetry. Everything else—the kinetic terms, the interactions allowed by gauge invariance, the pattern of masses after symmetry breaking—is then forced, up to a finite list of couplings. The Standard Model is no exception, and this appendix is organized around that fact. We begin, as the construction itself does, with the defining data. The physics that makes this data the *right* data was established in Parts VII–IX: the gauge principle and non-abelian Yang–Mills structure in Chapter 25, electroweak unification and the hypercharge assignment in Chapter 31, the requirement that gauge anomalies cancel in Chapter 37, and the assembly of the complete theory in Chapter 33. None of that is reproved here. What this section does is collect the result of all of it in one unambiguous table, fix once and for all the conventions—factor ordering, hypercharge normalization, the sign of the electric-charge relation—that the rest of the appendix will use without comment, and verify by direct arithmetic two facts on which the consistency of the whole edifice rests: that the tabulated hypercharges reproduce the observed electric charges, and that the four gauge and gravitational anomaly sums vanish generation by generation.

F.1.1 The gauge group

Definition F.1 (Standard Model gauge group)**.** The Standard Model is a gauge theory with compact gauge group

$$\mathrm{SU}(3)_c \times \mathrm{SU}(2)_L \times \mathrm{U}(1)_Y, \tag{F.1}$$

written always in this factor order: the strong (color) factor $\mathrm{SU}(3)_c$ first, the weak-isospin factor $\mathrm{SU}(2)_L$ second, and the weak-hypercharge factor $\mathrm{U}(1)_Y$ third. The subscripts name the physical role of each factor and are part of the data: c for color, L because SU(2) acts only on left-handed fields, Y for hypercharge. A representation of $\mathrm{SU}(3)_c \times \mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$ is specified by a triple

$$(\, d_3,\, d_2,\, Y\,), \tag{F.2}$$

where d_3 is the dimension (or name) of the $\mathrm{SU}(3)_c$ representation, d_2 the dimension of the $\mathrm{SU}(2)_L$ representation, and $Y \in \mathbb{Q}$ the hypercharge, i.e. the (one-dimensional) charge under $\mathrm{U}(1)_Y$.

Three remarks fix the meaning of Eq. (F.2) precisely.

First, the color and weak factors are non-abelian, and we label their irreducible representations by dimension in boldface: **1** for the singlet (trivial representation), **2** for the fundamental doublet of SU(2), **3** for the fundamental triplet of SU(3), and $\overline{\mathbf{3}}$ for its complex conjugate, the antifundamental. The conjugate matters because SU(3) has inequivalent fundamental and antifundamental representations ($\mathbf{3} \not\cong \overline{\mathbf{3}}$), whereas SU(2) has $\mathbf{2} \cong \overline{\mathbf{2}}$ (it is pseudoreal), so no bar is ever needed on a weak-isospin label. The generators, Dynkin indices, and Casimirs of these representations live in Chapter B and are quoted from there when the anomaly arithmetic needs them.

Second, hypercharge is a continuous parameter only in the abstract: the requirement that the theory be anomaly-free, imported from Chapter 37, quantizes the allowed values to the rationals tabulated below. We treat Y as a fixed rational number attached to each multiplet.

Third—and this is the convention the entire appendix freezes—the normalization of $\mathrm{U}(1)_Y$ is set by the Gell-Mann–Nishijima relation in the form

$$Q \;=\; T^3 + Y, \tag{F.3}$$

where Q is the electric charge in units of the proton charge $|e|$, T^3 is the diagonal (third) generator of weak isospin $\mathrm{SU}(2)_L$ acting on the multiplet, and Y is the hypercharge of Eq. (F.2). There is no factor of two and no extra coefficient in Eq. (F.3): hypercharge is normalized so that it appears with unit coefficient. With this choice the left-handed lepton doublet carries $Y_{L_L} = -\frac{1}{2}$, the value the chapter introduction singles out as the convention check. Other texts use $Y' = 2Y$ (so that $Q = T^3 + Y'/2$); we never do, and any number quoted in this appendix uses Eq. (F.3) as written.

Notation Watch

A persistent source of factor-of-two confusion is the normalization of $\mathrm{U}(1)_Y$. Two conventions are in wide use:

$Q = T^3 + Y$ (this book, "small" hypercharge), $\qquad Q = T^3 + \frac{Y'}{2}$ ("large" hypercharge, Y'

In the small-hypercharge convention, Y equals the average electric charge of the multiplet (the T^3 values average to zero over a complete SU(2) multiplet), a fact we use repeatedly below. Throughout this appendix Y always means the small-hypercharge value of Eq. (F.3); numerically $Y_{L_L} = -\frac{1}{2}$, $Y_{Q_L} = +\frac{1}{6}$. When comparing with a source that tabulates Y', multiply by two.

The covariant derivative that gauges Eq. (F.1) uses the sign convention fixed in Chapter A, $D_\mu = \partial_\mu - ig_s A^a_\mu T^a - ig\, W^i_\mu T^i - ig' Y B_\mu$, with one coupling per simple factor (g_s, g, g'); writing it out multiplet by multiplet is the business of Section F.2 and is not anticipated here. What we need first is the list of multiplets it acts on.

F.1.2 Chirality and the choice of field basis

The Standard Model is a chiral gauge theory: left- and right-handed components of a Dirac fermion transform under *different* representations of $\mathrm{SU}(3)_c \times \mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$. This is the single structural fact that makes the field content nontrivial to write down, and it forces a convention. A four-component Dirac field Ψ decomposes under the chirality projectors $P_{L,R} = \frac{1}{2}(1 \mp \gamma^5)$ (Chapter A) into $\psi_L = P_L \Psi$ and $\psi_R = P_R \Psi$. We assign gauge representations to these chiral halves separately. The physical fields and their handedness are:

- the left-handed quark doublet $Q_L = (u_L,\, d_L)^{\mathsf{T}}$, a weak doublet;
- the right-handed up-type quark u_R and right-handed down-type quark d_R, weak singlets;
- the left-handed lepton doublet $L_L = (\nu_L,\, e_L)^{\mathsf{T}}$, a weak doublet;
- the right-handed charged lepton e_R, a weak singlet.

There is no right-handed neutrino in the minimal Standard Model; we note this explicitly because its absence is what makes the neutrino exactly massless at the renormalizable level (the matter is taken up in Section F.2 and the parameter-count section).

For the anomaly bookkeeping of Section F.1.5 it is cleaner to put every fermion on the same footing. We use the standard device: a right-handed Weyl

field ψ_R in representation R with hypercharge Y is equivalent to a left-handed Weyl field $\psi_R^c \equiv (\psi_R)^c$ in the conjugate representation $\bar{R}$ with hypercharge $-Y$, because charge conjugation exchanges a representation for its complex conjugate and flips the sign of every additive charge. Thus the complete fermion content of one generation can be presented as five left-handed Weyl multiplets,

$$Q_L, \quad u_R^c, \quad d_R^c, \quad L_L, \quad e_R^c, \tag{F.4}$$

and the gauge anomaly is the totally symmetric trace of three generators taken over exactly this list. We give both presentations below: the physical Dirac-handedness table (Table F.1), which is what one reads when writing the Lagrangian, and its all-left-handed recasting (Table F.2), which is what one sums when checking consistency.

F.1.3 The fermion content over three generations

Definition F.2 (Fermion representation content)**.** One *generation* of Standard Model fermions consists of the five chiral multiplets

$$\begin{aligned} Q_L = \begin{pmatrix} u_L \\ d_L \end{pmatrix} &\sim (\mathbf{3}, \mathbf{2}, +\tfrac{1}{6}), \qquad u_R \sim (\mathbf{3}, \mathbf{1}, +\tfrac{2}{3}), \qquad d_R \sim (\mathbf{3}, \mathbf{1}, -\tfrac{1}{3}), \\ L_L = \begin{pmatrix} \nu_L \\ e_L \end{pmatrix} &\sim (\mathbf{1}, \mathbf{2}, -\tfrac{1}{2}), \qquad e_R \sim (\mathbf{1}, \mathbf{1}, -1). \end{aligned} \tag{F.5}$$

This content is replicated identically across three generations, $g = 1, 2, 3$, the generation label distinguishing the otherwise gauge-identical copies

$$(u, d, \nu_e, e), \qquad (c, s, \nu_\mu, \mu), \qquad (t, b, \nu_\tau, \tau). \tag{F.6}$$

The gauge interactions are blind to g: the three generations differ only through the Yukawa couplings introduced in Section F.2.

Counting Weyl degrees of freedom, one generation contains $Q_L\,(3 \times 2 = 6) + u_R\,(3) + d_R\,(3) + L_L\,(2) + e_R\,(1) = 15$ left-handed Weyl fermions; three generations give 45. The single scalar completes the data.

Definition F.3 (The scalar sector)**.** The Standard Model contains exactly one scalar multiplet, the Higgs doublet

$$H = \begin{pmatrix} \phi^+ \\ \phi^0 \end{pmatrix} \sim (\mathbf{1}, \mathbf{2}, +\tfrac{1}{2}), \tag{F.7}$$

a color singlet, weak doublet, hypercharge $+\frac{1}{2}$ complex scalar with four real components. It is not replicated across generations: there is one Higgs doublet, period. Its potential and the spontaneous breaking $\mathrm{SU}(3)_c \times \mathrm{SU}(2)_L \times \mathrm{U}(1)_Y \to \mathrm{SU}(3)_c \times \mathrm{U}(1)_{\mathrm{em}}$ are imported from Chapter 31; here the doublet enters only as another row in the quantum-number table.

The complete per-field table assembles Eqs. (F.5) and (F.7) and appends the columns that Eq. (F.3) determines. We read off T^3 from the weak-isospin assignment—$T^3 = \pm\frac{1}{2}$ on the upper/lower component of a doublet, $T^3 = 0$ on a singlet—and compute $Q = T^3 + Y$ component by component.

Table F.1: Standard Model field content of one generation (identical for $g = 1, 2, 3$) and the single Higgs doublet. Representations are written as $(\mathrm{SU}(3)_c, \mathrm{SU}(2)_L)_Y$ with the small-hypercharge normalization Eq. (F.3). The chirality column gives the handedness of the field as written; T^3 and Q are listed per component for multiplets. Electric charge Q is in units of $|e|$.

Field	Components	$\mathrm{SU}(3)_c$	$\mathrm{SU}(2)_L$	Y	T^3	$Q = T^3 + Y$
Q_L	u_L	**3**	**2**	$+\frac{1}{6}$	$+\frac{1}{2}$	$+\frac{2}{3}$
	d_L	**3**			$-\frac{1}{2}$	$-\frac{1}{3}$
u_R	u_R	**3**	**1**	$+\frac{2}{3}$	0	$+\frac{2}{3}$
d_R	d_R	**3**	**1**	$-\frac{1}{3}$	0	$-\frac{1}{3}$
L_L	ν_L	**1**	**2**	$-\frac{1}{2}$	$+\frac{1}{2}$	0
	e_L	**1**			$-\frac{1}{2}$	-1
e_R	e_R	**1**	**1**	-1	0	-1
H	ϕ^+	**1**	**2**	$+\frac{1}{2}$	$+\frac{1}{2}$	$+1$
	ϕ^0	**1**			$-\frac{1}{2}$	0

The chirality assignments not displayed in the table are those of Section F.1.2: Q_L and L_L are left-handed, u_R, d_R, e_R are right-handed, and H is a complex scalar (no chirality). The table is the central object of this appendix; every covariant derivative, mass term, and coupling in Section F.2 is built from it.

F.1.4 Worked check: hypercharges reproduce the observed charges

The hypercharges in Table F.1 are not free inputs to be fitted; they are fixed by demanding that Eq. (F.3) return the electric charges measured in the laboratory. We verify this directly, because it is the one place where an arbitrary-looking choice of fractions $(+\frac{1}{6}, +\frac{2}{3}, -\frac{1}{3}, \dots)$ is seen to be forced.

Worked Example F.4 (The Gell-Mann–Nishijima relation on every field)**.** We evaluate $Q = T^3 + Y$ for each component of each multiplet in Eqs. (F.5) and (F.7) and compare with the known charges of the quarks, leptons, and Higgs components.

Quark doublet Q_L, $Y = +\frac{1}{6}$. The upper component is the weak-isospin-up state, $T^3 = +\frac{1}{2}$:

$$Q(u_L) = T^3 + Y = +\tfrac{1}{2} + \tfrac{1}{6} = \tfrac{3}{6} + \tfrac{1}{6} = +\tfrac{2}{3}. \tag{F.8}$$

The lower component has $T^3 = -\frac{1}{2}$:

$$Q(d_L) = -\tfrac{1}{2} + \tfrac{1}{6} = -\tfrac{3}{6} + \tfrac{1}{6} = -\tfrac{2}{6} = -\tfrac{1}{3}. \tag{F.9}$$

These are the measured charges of the up and down quarks, $+\frac{2}{3}$ and $-\frac{1}{3}$.

Right-handed quarks, weak singlets ($T^3 = 0$). For u_R with $Y = +\frac{2}{3}$ and d_R with $Y = -\frac{1}{3}$,

$$Q(u_R) = 0 + \tfrac{2}{3} = +\tfrac{2}{3}, \qquad Q(d_R) = 0 - \tfrac{1}{3} = -\tfrac{1}{3}. \tag{F.10}$$

The right-handed charges match the left-handed ones, as they must: electric charge is vectorial, so Q does not depend on chirality. This matching is precisely what *fixes* $Y_{u_R} = Q(u_R) = +\frac{2}{3}$ and $Y_{d_R} = Q(d_R) = -\frac{1}{3}$ for a weak singlet, where $T^3 = 0$ leaves $Y = Q$.

Lepton doublet L_L, $Y = -\frac{1}{2}$.

$$Q(\nu_L) = +\tfrac{1}{2} - \tfrac{1}{2} = 0, \qquad Q(e_L) = -\tfrac{1}{2} - \tfrac{1}{2} = -1. \tag{F.11}$$

The neutrino is neutral and the electron carries charge -1; this is the line that pins $Y_{L_L} = -\frac{1}{2}$, the convention-defining value.

Right-handed electron, singlet. With $Y = -1$ and $T^3 = 0$,

$$Q(e_R) = 0 - 1 = -1, \tag{F.12}$$

again matching the left-handed electron, which forces $Y_{e_R} = -1$.

Higgs doublet, $Y = +\frac{1}{2}$.

$$Q(\phi^+) = +\tfrac{1}{2} + \tfrac{1}{2} = +1, \qquad Q(\phi^0) = -\tfrac{1}{2} + \tfrac{1}{2} = 0. \tag{F.13}$$

The upper component is the charged Higgs (eaten by the W^+) and the lower is the neutral one whose vacuum expectation value $\langle\phi^0\rangle$ leaves Q unbroken—which is the whole point of choosing $Y_H = +\frac{1}{2}$: the component that condenses must be electrically neutral, $Q(\phi^0) = 0$, or it would break $\mathrm{U}(1)_{\mathrm{em}}$.

Every entry reproduces the observed charge, confirming the Q column of Table F.1.

Physical Insight

The pattern in Theorem F.4 is not a coincidence to be memorized but a consequence of one fact: in the small-hypercharge normalization, Y *is* the average electric charge of the multiplet. Averaging $Q = T^3 + Y$ over a complete SU(2) multiplet kills the T^3 term (the T^3 eigenvalues of any irreducible SU(2) representation sum to zero), leaving $\langle Q\rangle = Y$. Thus $Y_{Q_L} = \frac{1}{2}(\frac{2}{3} - \frac{1}{3}) = +\frac{1}{6}$, $Y_{L_L} = \frac{1}{2}(0 - 1) = -\frac{1}{2}$, $Y_H = \frac{1}{2}(1 + 0) = +\frac{1}{2}$, and for the singlets $\langle Q\rangle = Q = Y$ trivially. This is the quickest way to read

a hypercharge off a charge assignment, and it is the reason the fractions take the values they do.

F.1.5 Anomaly cancellation as a consistency check

A chiral gauge theory is quantum-mechanically consistent only if its gauge anomalies cancel; the proof that they *must*, and the construction of the triangle-diagram coefficients that measure them, is the content of Chapter 37 and is not reproduced here. What we do here is exhibit the arithmetic: with the hypercharges of Table F.1 fixed, the relevant anomaly sums vanish, generation by generation, and we show each one.

The gauge anomaly is the totally symmetric trace $\mathcal{A}^{abc} \propto \sum_{\text{L Weyl}} \operatorname{tr}(T^a\{T^b, T^c\})$ taken over all left-handed Weyl fermions, with right-handed fields entering as their left-handed conjugates per Eq. (F.4); a left-handed antiparticle contributes with the opposite sign of a left-handed particle, which is automatic once we conjugate the representation and flip Y. For the gauge group Eq. (F.1) the independent potentially-anomalous combinations of three currents, together with the mixed gauge–gravitational one, are

$$[\mathrm{SU}(3)_c]^3, \quad [\mathrm{SU}(3)_c]^2\,\mathrm{U}(1)_Y, \quad [\mathrm{SU}(2)_L]^2\,\mathrm{U}(1)_Y, \quad [\mathrm{U}(1)_Y]^3, \quad [\mathrm{grav}]^2\,\mathrm{U}(1)_Y, \quad [\mathrm{SU}(2)_L]^3. \tag{F.14}$$

Two of these vanish for group-theoretic reasons before any hypercharge is used, and we dispose of them first.

The $[\mathrm{SU}(2)_L]^3$ *anomaly vanishes identically.* SU(2) has no totally symmetric cubic invariant: $d^{abc} \equiv \operatorname{tr}(T^a\{T^b, T^c\}) = 0$ for every representation, because all SU(2) representations are pseudoreal and a pseudoreal representation has vanishing cubic anomaly (Chapter B). No contribution from any multiplet.

The $[\mathrm{SU}(3)_c]^3$ *anomaly vanishes because color is vectorial.* The color-charged left-handed Weyl fields are Q_L in $\mathbf{3}$ (with weak multiplicity 2) and u_R^c, d_R^c in $\overline{\mathbf{3}}$ (one each). The cubic SU(3) anomaly of $\overline{\mathbf{3}}$ is minus that of $\mathbf{3}$, so the color content is anomaly-free provided the number of $\mathbf{3}$'s equals the number of $\overline{\mathbf{3}}$'s. Counting: Q_L supplies two color triplets (one per weak component), while u_R^c and d_R^c supply one antitriplet each, two in all. Two triplets, two antitriplets: the anomaly cancels. Equivalently, the QCD content is left–right symmetric (vectorlike), and a vectorlike theory has no anomaly.

The remaining four sums in Eq. (F.14) involve hypercharge and are the nontrivial checks. We organize the arithmetic in Table F.2, which lists, for each of the five left-handed multiplets, its total multiplicity (color × weak dimension), its hypercharge, the relevant group-theory index, and the contribution to each sum. We use the index normalization of Chapter B: the Dynkin index is $T(\mathbf{2}) = \frac{1}{2}$ for the SU(2) doublet and $T(\mathbf{3}) = T(\overline{\mathbf{3}}) = \frac{1}{2}$ for the SU(3) (anti)triplet, and $T(\mathbf{1}) = 0$ for any singlet.

Table F.2: Anomaly bookkeeping for one generation, with every fermion written as a left-handed Weyl multiplet (Eq. (F.4)). Right-handed physical fields appear conjugated: $u_R^c \sim (\overline{\mathbf{3}}, \mathbf{1}, -\frac{2}{3})$, $d_R^c \sim (\overline{\mathbf{3}}, \mathbf{1}, +\frac{1}{3})$, $e_R^c \sim (\mathbf{1}, \mathbf{1}, +1)$. Column "mult." is the total number of Weyl components (color dimension × weak dimension). The four hypercharge-dependent anomaly contributions are tabulated; each column sums to zero.

Multiplet	rep $(\mathrm{SU}(3), \mathrm{SU}(2))_Y$	mult.	Y	$[\mathrm{SU}(3)]^2\mathrm{U}(1)$ $\sum T_3\, Y$	$[\mathrm{SU}(2)]^2\mathrm{U}(1)$ $\sum T_2\, Y$	$[\mathrm{U}(1)]^3$ $\sum Y^3$	$\mathrm{grav}^2\,\mathrm{U}($ $\sum$
Q_L	$(\mathbf{3}, \mathbf{2})_{+1/6}$	6	$+\frac{1}{6}$	$+\frac{1}{6}$	$+\frac{1}{4}$	$+\frac{1}{36}$	+
u_R^c	$(\overline{\mathbf{3}}, \mathbf{1})_{-2/3}$	3	$-\frac{2}{3}$	$-\frac{1}{3}$	0	$-\frac{8}{9}$	−
d_R^c	$(\overline{\mathbf{3}}, \mathbf{1})_{+1/3}$	3	$+\frac{1}{3}$	$+\frac{1}{6}$	0	$+\frac{1}{9}$	+
L_L	$(\mathbf{1}, \mathbf{2})_{-1/2}$	2	$-\frac{1}{2}$	0	$-\frac{1}{4}$	$-\frac{1}{4}$	−
e_R^c	$(\mathbf{1}, \mathbf{1})_{+1}$	1	$+1$	0	0	$+1$	+
Sum				**0**	**0**	**0**	

Each column of Table F.2 is a separate consistency condition; we now derive each entry and confirm the vanishing sum.

$[\mathrm{SU}(3)_c]^2\,\mathrm{U}(1)_Y$. Only color-charged fields contribute. The contribution of a multiplet is its SU(3) Dynkin index times its hypercharge, summed over the weak components. For the SU(3) index, both $\mathbf{3}$ and $\overline{\mathbf{3}}$ give $\frac{1}{2}$, and the weak doublet Q_L counts twice:

$$\begin{aligned} Q_L: &\quad 2 \times \tfrac{1}{2} \times \left(+\tfrac{1}{6}\right) = +\tfrac{1}{6}, \\ u_R^c: &\quad 1 \times \tfrac{1}{2} \times \left(-\tfrac{2}{3}\right) = -\tfrac{1}{3}, \\ d_R^c: &\quad 1 \times \tfrac{1}{2} \times \left(+\tfrac{1}{3}\right) = +\tfrac{1}{6}, \\ \text{sum}: &\quad \tfrac{1}{6} - \tfrac{1}{3} + \tfrac{1}{6} = \tfrac{1}{6} - \tfrac{2}{6} + \tfrac{1}{6} = 0. \end{aligned} \tag{F.15}$$

$[\mathrm{SU}(2)_L]^2\,\mathrm{U}(1)_Y$. Only weak doublets contribute (singlets have SU(2) index zero). The contribution is the SU(2) Dynkin index $\frac{1}{2}$ times the hypercharge, with color multiplicity in front. Q_L is a color triplet (multiplicity 3); L_L a color singlet:

$$\begin{aligned} Q_L: &\quad 3 \times \tfrac{1}{2} \times \left(+\tfrac{1}{6}\right) = +\tfrac{1}{4}, \\ L_L: &\quad 1 \times \tfrac{1}{2} \times \left(-\tfrac{1}{2}\right) = -\tfrac{1}{4}, \\ \text{sum}: &\quad \tfrac{1}{4} - \tfrac{1}{4} = 0. \end{aligned} \tag{F.16}$$

$[\mathrm{U}(1)_Y]^3$**.** Every field contributes Y^3 weighted by its full multiplicity (color $\times$ weak):

$$\begin{aligned} Q_L: &\quad 6 \times \left(\tfrac{1}{6}\right)^3 = \tfrac{6}{216} = \tfrac{1}{36}, \\ u_R^c: &\quad 3 \times \left(-\tfrac{2}{3}\right)^3 = 3 \times \left(-\tfrac{8}{27}\right) = -\tfrac{8}{9}, \\ d_R^c: &\quad 3 \times \left(\tfrac{1}{3}\right)^3 = \tfrac{3}{27} = \tfrac{1}{9}, \\ L_L: &\quad 2 \times \left(-\tfrac{1}{2}\right)^3 = 2 \times \left(-\tfrac{1}{8}\right) = -\tfrac{1}{4}, \\ e_R^c: &\quad 1 \times (1)^3 = 1. \end{aligned} \tag{F.17}$$

Putting these over a common denominator of 36,

$$\tfrac{1}{36} - \tfrac{8}{9} + \tfrac{1}{9} - \tfrac{1}{4} + 1 = \frac{1 - 32 + 4 - 9 + 36}{36} = \frac{0}{36} = 0. \tag{F.18}$$

$[\mathrm{grav}]^2\,\mathrm{U}(1)_Y$**.** The mixed gauge–gravitational anomaly (two gravitons, one hypercharge current) is proportional to the sum of hypercharges over all left-handed Weyl fermions, weighted by multiplicity—the trace of Y:

$$\begin{aligned} &Q_L: 6 \times \left(\tfrac{1}{6}\right) = 1, \qquad && u_R^c: 3 \times \left(-\tfrac{2}{3}\right) = -2, \qquad && d_R^c: 3 \times \left(\tfrac{1}{3}\right) = 1, \\ &L_L: 2 \times \left(-\tfrac{1}{2}\right) = -1, && e_R^c: 1 \times (1) = 1, \\ &\text{sum}: 1 - 2 + 1 - 1 + 1 = 0. \end{aligned} \tag{F.19}$$

All four hypercharge-dependent anomaly sums vanish, and the two pure non-abelian sums vanished by representation theory. The single generation of Table F.1 is therefore gauge-consistent; since the content is replicated identically across the three generations of Eq. (F.6) and the anomaly is linear in the number of generations, the full Standard Model fermion content is anomaly-free. This is the arithmetic the chapter introduction promised the appendix would exhibit; the reason these particular combinations are the ones required to vanish, and the proof that their vanishing is necessary for a consistent quantum theory, are imported from Chapter 37.

Physical Insight

The four cancellations are not independent miracles. The mixed $[\mathrm{grav}]^2\,\mathrm{U}(1)$ and the $[\mathrm{SU}(2)]^2\mathrm{U}(1)$ conditions, together with the requirement that each multiplet have integer or familiar fractional charges, are enough to fix the relative hypercharges of one generation up to overall normalization; the $[\mathrm{U}(1)]^3$ and $[\mathrm{SU}(3)]^2\mathrm{U}(1)$ conditions are then automatically satisfied. In this precise sense the hypercharge assignments of Table F.1 are not chosen to fit the data—they are forced by demanding a consistent chiral gauge theory with this gauge group and this **3**/**2**/**1** representation

skeleton. That the charges so determined are exactly the ones measured (Theorem F.4) is the deep consistency the Standard Model passes.

With the gauge group fixed (Theorem F.1), the field content tabulated (Table F.1), the hypercharge normalization frozen by Eq. (F.3), and the data shown to be gauge-consistent, we have everything the construction of the Lagrangian requires. The next section turns each row of the representation table into an explicit gauge-covariant derivative—one coupling and one set of generators per multiplet—and from there writes the complete Standard Model Lagrangian term by term.

F.2 The Complete Lagrangian

The previous section fixed the model's defining data: the gauge group $\mathrm{SU}(3)_c \times \mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$, the chiral fermion content replicated over three generations, the single complex scalar doublet, and the hypercharge normalization $Q = T^3 + Y$ (so that $Y_L = -\frac{1}{2}$ for the lepton doublet) recorded in the per-field table of Section F.1. That table is a list of representations; it is not yet a theory. A theory is a Lagrangian, and the Standard Model is precisely the most general renormalizable Lagrangian that one can write from those representations consistent with the gauge symmetry and with Lorentz invariance. This section writes it out in full, term by term, with every field strength, every covariant derivative, every coupling and every sign fixed unambiguously, so that any cross section or running coupling computed anywhere in this book can be traced back to a definite line below.

Nothing physical is proved here. The gauge principle that forces minimal coupling was established for the abelian case in Chapter 8 and for the non-abelian case in Chapter 25; the Higgs mechanism that will give these fields masses was worked in Chapter 30; the electroweak rotation to mass eigenstates was carried out in Chapter 31; the flavor structure of the Yukawa couplings was analyzed in Chapter 32; and the complete model was assembled in Chapter 33. What this section owes is organizational, not physical: an unambiguous transcription, in one place, with the conventions of this book, of every operator in

$$\mathcal{L}_{\mathrm{SM}} = \mathcal{L}_{\mathrm{gauge}} + \mathcal{L}_{\theta} + \mathcal{L}_{\mathrm{fermion}} + \mathcal{L}_{\mathrm{Higgs}} + \mathcal{L}_{\mathrm{Yukawa}} + \mathcal{L}_{\mathrm{gf}} + \mathcal{L}_{\mathrm{ghost}}, \tag{F.20}$$

together with two derivations that are genuinely load-bearing and belong nowhere else: the explicit expansion of the covariant derivative on a chiral multiplet, which exhibits how the photon, $W^{\pm}$ and Z couplings emerge from the data above (consolidating QED's $U(1)_{\mathrm{em}}$ and Yang–Mills theory's QCD term into one object), and the verification that the scalar potential written below is the unique renormalizable gauge invariant available. We treat the seven pieces of Eq. (F.20) in turn.

Throughout we use the mostly-minus metric $\eta_{\mu\nu} = \mathrm{diag}(+,-,-,-)$, natural units $\hbar = c = 1$, the gamma-matrix conventions of Chapter C, and the covariant-derivative sign convention of Chapter 25: a field Φ in a representation R of $\mathrm{SU}(3)_c \times \mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$ has

$$D_\mu \Phi = \Big(\partial_\mu - i g_s\, G_\mu^A\, T_{(R)}^A - i g\, W_\mu^I\, T_{(R)}^I - i g'\, Y_\Phi\, B_\mu\Big)\Phi, \tag{F.21}$$

where $T_{(R)}^A$ ($A = 1,\dots,8$) are the $\mathrm{SU}(3)_c$ generators in the representation R, $T_{(R)}^I$ ($I = 1,2,3$) the $\mathrm{SU}(2)_L$ generators, Y_Φ the hypercharge, and g_s, g, g' the three gauge couplings. On a color triplet $T_{(R)}^A = \lambda^A/2$ with λ^A the Gell-Mann matrices (Chapter B); on a color singlet $T_{(R)}^A = 0$. On a weak doublet $T_{(R)}^I = \sigma^I/2$ with σ^I the Pauli matrices; on a weak singlet $T_{(R)}^I = 0$. The single object Eq. (F.21) encodes every gauge coupling in the model once we specialize it to each multiplet; doing so explicitly is the content of Section F.2.2.

F.2.1 The gauge sector and the theta term

To each simple (or abelian) factor of $\mathrm{SU}(3)_c \times \mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$ belongs a gauge field and its field strength. For $\mathrm{SU}(3)_c$ we have the eight gluons G_μ^A with the non-abelian field strength

$$G_{\mu\nu}^A = \partial_\mu G_\nu^A - \partial_\nu G_\mu^A + g_s\, f^{ABC}\, G_\mu^B G_\nu^C, \qquad A,B,C = 1,\dots,8, \tag{F.22}$$

where f^{ABC} are the SU(3) structure constants of Chapter B. For $\mathrm{SU}(2)_L$ we have the three weak isospin bosons W_μ^I,

$$W_{\mu\nu}^I = \partial_\mu W_\nu^I - \partial_\nu W_\mu^I + g\, \epsilon^{IJK}\, W_\mu^J W_\nu^K, \qquad I,J,K = 1,2,3, \tag{F.23}$$

with ϵ^{IJK} the totally antisymmetric symbol that serves as the SU(2) structure constants. For $\mathrm{U}(1)_Y$ we have the single hypercharge boson B_μ with the abelian field strength

$$B_{\mu\nu} = \partial_\mu B_\nu - \partial_\nu B_\mu, \tag{F.24}$$

which carries no self-coupling because $\mathrm{U}(1)_Y$ is abelian. These are curvatures in the precise sense of Chapter 25: $G_{\mu\nu} = \frac{i}{g_s}[D_\mu, D_\nu]$ on the relevant representation, and likewise for the others. The gauge kinetic Lagrangian is the unique dimension-four, gauge-invariant, Lorentz-invariant, parity-even quadratic in these curvatures, normalized as fixed in Chapter 25:

$$\mathcal{L}_{\text{gauge}} = -\tfrac{1}{4}\, G_{\mu\nu}^A G^{A\,\mu\nu} - \tfrac{1}{4}\, W_{\mu\nu}^I W^{I\,\mu\nu} - \tfrac{1}{4}\, B_{\mu\nu} B^{\mu\nu}, \tag{F.25}$$

with the gauge indices summed (these are Cartan-Killing-orthonormal in the normalization $\mathrm{tr}(T^a T^b) = \frac{1}{2}\delta^{ab}$ of Chapter B). Expanding Eq. (F.25) with Eqs. (F.22) to (F.24) reproduces the cubic and quartic gluon and W self-interactions whose Feynman rules were derived in Chapter 26; we do not re-expand them here.

There is one further dimension-four gauge invariant that is Lorentz scalar but *parity- and time-reversal-odd*: the contraction of a field strength with its dual. For QCD this is the theta term,

$$\mathcal{L}_\theta = \frac{g_s^2\,\theta}{32\pi^2}\,G^A_{\mu\nu}\widetilde{G}^{A\,\mu\nu}, \qquad \widetilde{G}^{A\,\mu\nu} \equiv \tfrac{1}{2}\,\epsilon^{\mu\nu\rho\sigma}G^A_{\rho\sigma}, \tag{F.26}$$

with the orientation $\epsilon^{0123} = +1$. As shown in Chapter 42, $G\widetilde{G}$ is a total derivative, so it does not affect the classical equations of motion or any order of perturbation theory; it contributes only through non-perturbative (instanton) configurations, and the prefactor $g_s^2/32\pi^2$ is chosen so that θ shifts by 2π under a large gauge transformation, making the physics periodic in θ. The analogous $\mathrm{SU}(2)_L$ theta term can be rotated away using the chiral fermion content (baryon-plus-lepton-number rotation) and is conventionally set to zero; the $\mathrm{U}(1)_Y$ "theta term" $B\widetilde{B}$ is itself a total derivative with trivial topology and is dropped. Thus the only physical theta angle in the Standard Model is the QCD θ of Eq. (F.26), and the smallness of its measured value is the strong-CP problem flagged in Chapters 35 and 42. We retain it in Eq. (F.20) for completeness; the parameter count of Section F.4 includes it.

Notation Watch

The field-strength definitions Eqs. (F.22) to (F.24) carry the coupling *inside* the curvature, matching the covariant derivative Eq. (F.21) (the "g-inside" convention of Chapter 25). Some references instead rescale $A \to A/g$ so the coupling appears only as an overall $1/g^2$ in front of the kinetic term. The two are related by a field redefinition and give identical physics, but Feynman rules, the sign in D_μ, and the normalization of Eq. (F.26) all change. This book uses the g-inside convention everywhere; do not mix.

F.2.2 Gauge-covariant fermion kinetic terms

The fermion content of Section F.1, repeated for each generation $i = 1, 2, 3$, consists of five chiral multiplets: the left-handed quark doublet $Q_{Li} = (u_{Li}, d_{Li})^{\mathsf{T}}$ in $(\mathbf{3}, \mathbf{2}, +\frac{1}{6})$, the right-handed up- and down-type quark singlets u_{Ri} in $(\mathbf{3}, \mathbf{1}, +\frac{2}{3})$ and d_{Ri} in $(\mathbf{3}, \mathbf{1}, -\frac{1}{3})$, the left-handed lepton doublet $L_{Li} = (\nu_{Li}, e_{Li})^{\mathsf{T}}$ in $(\mathbf{1}, \mathbf{2}, -\frac{1}{2})$, and the right-handed charged-lepton singlet e_{Ri} in $(\mathbf{1}, \mathbf{1}, -1)$. There is no right-handed neutrino in the minimal model. Each multiplet enters through the gauge-covariant Dirac kinetic term $\bar{\psi}\, i\not{D}\,\psi$, with $\not{D} = \gamma^\mu D_\mu$ and D_μ the specialization of Eq. (F.21) to that multiplet's representation. Summing over the five multiplets and over the generation index i (summation implied),

$$\mathcal{L}_{\text{fermion}} = \bar{Q}_{Li}\, i\not{D}\, Q_{Li} + \bar{u}_{Ri}\, i\not{D}\, u_{Ri} + \bar{d}_{Ri}\, i\not{D}\, d_{Ri} + \bar{L}_{Li}\, i\not{D}\, L_{Li} + \bar{e}_{Ri}\, i\not{D}\, e_{Ri}. \tag{F.27}$$

The covariant derivatives differ from line to line only through which generators act and through the hypercharge; making each explicit:

$$D_\mu Q_{Li} = \Big(\partial_\mu - i g_s\, G_\mu^A \tfrac{\lambda^A}{2} - i g\, W_\mu^I \tfrac{\sigma^I}{2} - i g'\, \tfrac{1}{6}\, B_\mu\Big) Q_{Li}, \tag{F.28}$$

$$D_\mu u_{Ri} = \Big(\partial_\mu - i g_s\, G_\mu^A \tfrac{\lambda^A}{2} - i g'\, \tfrac{2}{3}\, B_\mu\Big) u_{Ri}, \tag{F.29}$$

$$D_\mu d_{Ri} = \Big(\partial_\mu - i g_s\, G_\mu^A \tfrac{\lambda^A}{2} - i g'\, (-\tfrac{1}{3})\, B_\mu\Big) d_{Ri}, \tag{F.30}$$

$$D_\mu L_{Li} = \Big(\partial_\mu - i g\, W_\mu^I \tfrac{\sigma^I}{2} - i g'\, (-\tfrac{1}{2})\, B_\mu\Big) L_{Li}, \tag{F.31}$$

$$D_\mu e_{Ri} = \Big(\partial_\mu - i g'\, (-1)\, B_\mu\Big) e_{Ri}. \tag{F.32}$$

The Higgs doublet, with the same isospin and a hypercharge $Y_H = +\tfrac{1}{2}$, carries

$$D_\mu H = \Big(\partial_\mu - i g\, W_\mu^I \tfrac{\sigma^I}{2} - i g'\, \tfrac{1}{2}\, B_\mu\Big) H, \tag{F.33}$$

which we will need in Section F.2.3. Color singlets (L_L, e_R, H) carry no gluon term; weak singlets (u_R, d_R, e_R) carry no W term; every multiplet couples to B_μ through its hypercharge, the right-handed singlets coupling to B_μ *only*.

Two structural facts about Eq. (F.27) deserve to be stated plainly, because they are the reason the Standard Model has the shape it does. First, the theory is *chiral*: left- and right-handed components of a given flavor sit in different representations of $\mathrm{SU}(2)_L$ and carry different hypercharges. Consequently a Dirac mass term $m\,\bar\psi\psi = m(\bar\psi_L\psi_R + \bar\psi_R\psi_L)$ is *not* gauge invariant for any Standard Model fermion: it would pair, say, the doublet Q_L with the singlet u_R into an object transforming as $(\mathbf{2})$ under $\mathrm{SU}(2)_L$ with net hypercharge $-\tfrac{1}{6} + \tfrac{2}{3} = +\tfrac{1}{2} \neq 0$, which is not a singlet. Fermion masses are therefore forbidden in Eq. (F.27) and can only arise after electroweak breaking, through the Yukawa couplings of Section F.2.4. Second, the kinetic term is, before the Yukawa couplings are switched on, invariant under independent unitary rotations of the three generations within each of the five multiplets—a $\mathrm{U}(3)^5$ global flavor symmetry. That symmetry is exactly what the Yukawa matrices break, and counting its breaking is how the flavor parameters are enumerated in Section F.4.

That the same covariant derivative Eq. (F.21) simultaneously produces the QCD coupling of Yang–Mills theory and, after electroweak rotation, the $U(1)_{\mathrm{em}}$ coupling of QED is best seen by expanding it on a single multiplet. We do this in full for the lepton doublet, where there is no color to clutter the algebra, and then read off the modifications for a quark doublet.

Worked Example F.5 (The neutral and charged currents from $D_\mu L_L$)**.** Take the left-handed lepton doublet $L_L = (\nu_L, e_L)^{\mathsf T}$ with $Y = -\tfrac{1}{2}$, drop the generation index, and read the gauge interactions off the kinetic term $\bar L_L\, i\not{D}\, L_L$. Writing $\not{D} = \not{\partial} - i g\, \not{W}^I \tfrac{\sigma^I}{2} - i g' Y \not{B}$, the interaction piece is

$$\mathcal{L}_L^{\mathrm{int}} = \bar L_L\, \gamma^\mu \Big(g\, W_\mu^I \tfrac{\sigma^I}{2} + g'\, Y\, B_\mu\Big) L_L, \qquad Y = -\tfrac{1}{2}, \tag{F.34}$$

the sign flipping relative to D_μ because $i\not{D}$ multiplies the $-i$ in the derivative to $+1$. Split the $\mathrm{SU}(2)_L$ part into its diagonal ($I=3$) and off-diagonal ($I=1,2$) pieces. The off-diagonal part is

$$\tfrac{g}{2}(W_\mu^1\sigma^1+W_\mu^2\sigma^2)=\frac{g}{2}\begin{pmatrix}0 & W_\mu^1-iW_\mu^2\\ W_\mu^1+iW_\mu^2 & 0\end{pmatrix}. \tag{F.35}$$

Introduce the charged eigenstates of definite electric charge, exactly as in Chapter 31,

$$W_\mu^\pm=\frac{1}{\sqrt{2}}(W_\mu^1\mp iW_\mu^2),\qquad\Longrightarrow\qquad W_\mu^1-iW_\mu^2=\sqrt{2}\,W_\mu^+,\quad W_\mu^1+iW_\mu^2=\sqrt{2}\,W_\mu^-, \tag{F.36}$$

so the off-diagonal block becomes $\frac{g}{\sqrt{2}}\left(\begin{smallmatrix}0 & W^+\\ W^- & 0\end{smallmatrix}\right)$. Sandwiched between $\bar L_L\gamma^\mu(\cdots)L_L$ this yields the *charged-current* interaction

$$\mathcal{L}_L^{\mathrm{CC}}=\frac{g}{\sqrt{2}}\Big(\bar\nu_L\gamma^\mu e_L\,W_\mu^+ +\bar e_L\gamma^\mu\nu_L\,W_\mu^-\Big), \tag{F.37}$$

the $V-A$ structure (left-handed fields only) being automatic because L_L is purely left-chiral. The coupling strength is $g/\sqrt{2}$, which is the origin of the Fermi constant relation recorded in Section F.3.

The diagonal, neutral part is $\bar L_L\gamma^\mu(g\,W_\mu^3\frac{\sigma^3}{2}+g'YB_\mu)L_L$. With $\sigma^3=\mathrm{diag}(+1,-1)$ acting as $T^3=\pm\frac12$ on (ν_L,e_L) and $Y=-\frac12$ common to both, the neutrino and electron pieces are

$$\nu_L:\quad \tfrac12(g\,W_\mu^3-g'\,B_\mu), \tag{F.38}$$

$$e_L:\quad -\tfrac12(g\,W_\mu^3+g'\,B_\mu). \tag{F.39}$$

Now rotate to the mass eigenstates A_μ (photon) and Z_μ, importing the EWSB rotation from Chapter 31 (we do *not* re-derive it):

$$\begin{pmatrix}W_\mu^3\\ B_\mu\end{pmatrix}=\begin{pmatrix}\cos\theta_{\mathrm W} & \sin\theta_{\mathrm W}\\ -\sin\theta_{\mathrm W} & \cos\theta_{\mathrm W}\end{pmatrix}\begin{pmatrix}Z_\mu\\ A_\mu\end{pmatrix},\qquad \tan\theta_{\mathrm W}=\frac{g'}{g},\quad e=g\sin\theta_{\mathrm W}=g'\cos\theta_{\mathrm W}. \tag{F.40}$$

Substitute into Eq. (F.38). The neutrino's photon coupling is proportional to $g\sin\theta_{\mathrm W}-g'\cos\theta_{\mathrm W}=e-e=0$: the neutrino is electrically neutral, as it must be since $Q_\nu=T^3+Y=\frac12-\frac12=0$. Its Z coupling is

$$\tfrac12(g\cos\theta_{\mathrm W}+g'\sin\theta_{\mathrm W})=\tfrac12\,\frac{g\cos^2\theta_{\mathrm W}+g'\sin\theta_{\mathrm W}\cos\theta_{\mathrm W}}{\cos\theta_{\mathrm W}}=\tfrac12\,\frac{g(\cos^2\theta_{\mathrm W}+\sin^2\theta_{\mathrm W})}{\cos\theta_{\mathrm W}}=\frac{g}{2\cos\theta_{\mathrm W}}, \tag{F.41}$$

using $g'\sin\theta_{\mathrm W}=g\,\sin^2\theta_{\mathrm W}/\cos\theta_{\mathrm W}$. For the electron, Eq. (F.39) gives a photon coupling $-\frac12(g\sin\theta_{\mathrm W}+g'\cos\theta_{\mathrm W})=-\frac12(e+e)=-e$, the correct electromagnetic charge $Q_{e_L}=T^3+Y=-\frac12-\frac12=-1$ times e; and a Z coupling

$$-\tfrac12(g\cos\theta_{\mathrm W}-g'\sin\theta_{\mathrm W})=-\tfrac{g}{2\cos\theta_{\mathrm W}}(\cos^2\theta_{\mathrm W}-\sin^2\theta_{\mathrm W})=\frac{g}{\cos\theta_{\mathrm W}}\Big(-\tfrac12+\sin^2\theta_{\mathrm W}\Big). \tag{F.42}$$

Both neutral results fit the universal pattern

$$\mathcal{L}^{\mathrm{NC}} = e\,Q\,\bar{\psi}\gamma^{\mu}\psi\,A_{\mu} + \frac{g}{\cos\theta_{\mathrm{W}}}(T^{3} - Q\,\sin^{2}\theta_{\mathrm{W}})\,\bar{\psi}\gamma^{\mu}\psi\,Z_{\mu}, \tag{F.43}$$

which one verifies term by term: for ν_L, $Q=0$, $T^3=\frac{1}{2}$ give photon coupling 0 and Z coupling $g/2\cos\theta_{\mathrm{W}}$; for e_L, $Q=-1$, $T^3=-\frac{1}{2}$ give photon coupling $-e$ and Z coupling $\frac{g}{\cos\theta_{\mathrm{W}}}(-\frac{1}{2}+\sin^2\theta_{\mathrm{W}})$, both matching. The photon thus couples strictly to the electric charge $Q = T^3 + Y$—this is QED's $U(1)_{\mathrm{em}}$, now seen to be the unbroken combination $A_\mu = \sin\theta_{\mathrm{W}}\,W^3_\mu + \cos\theta_{\mathrm{W}}\,B_\mu$ rather than B_μ itself—while the orthogonal combination Z_μ couples to $T^3 - Q\,\sin^2\theta_{\mathrm{W}}$. Every neutral-current coupling in the Standard Model follows from Eq. (F.43) by inserting the relevant (T^3, Q).

Worked Example F.6 (The quark doublet: color plus the same electroweak structure)**.** For the left-handed quark doublet $Q_L = (u_L, d_L)^{\mathsf{T}}$ with $Y = +\frac{1}{6}$, the covariant derivative Eq. (F.28) differs from the lepton case in two ways: it carries the gluon term $-ig_s G^A_\mu \lambda^A/2$, and the hypercharge is $+\frac{1}{6}$ rather than $-\frac{1}{2}$. The gluon term produces, in $\bar{Q}_L i\not{D} Q_L$, exactly the QCD quark–gluon vertex of Yang–Mills theory,

$$\mathcal{L}^{\mathrm{QCD}}_{Q} = g_s\,\bar{Q}_L\gamma^{\mu}\tfrac{\lambda^A}{2}Q_L\,G^A_\mu, \tag{F.44}$$

color-diagonal in the weak indices and identical for u_L and d_L; the same term appears for u_R, d_R from Eqs. (F.29) and (F.30), so QCD is vectorlike and flavor-diagonal, as established in Chapter 27. The charged-current piece is identical in form to Eq. (F.37) with $(\nu_L, e_L) \to (u_L, d_L)$,

$$\mathcal{L}^{\mathrm{CC}}_{Q} = \frac{g}{\sqrt{2}}(\bar{u}_L\gamma^{\mu}d_L\,W^{+}_{\mu} + \bar{d}_L\gamma^{\mu}u_L\,W^{-}_{\mu}), \tag{F.45}$$

the flavor rotation that turns these gauge eigenstates into mass eigenstates and produces the CKM matrix being deferred to Section F.3 and proved in Chapter 32. For the neutral currents, the diagonal couplings again take the universal form Eq. (F.43), now with the quark charges fixed by $Q = T^3 + Y$ with $Y = +\frac{1}{6}$:

$$Q_{u_L} = +\tfrac{1}{2} + \tfrac{1}{6} = +\tfrac{2}{3}, \qquad Q_{d_L} = -\tfrac{1}{2} + \tfrac{1}{6} = -\tfrac{1}{3}, \tag{F.46}$$

so the photon couples to u_L with strength $+\frac{2}{3}e$ and to d_L with $-\frac{1}{3}e$, the familiar quark charges. The right-handed quarks u_R, d_R are weak singlets ($T^3 = 0$), so Eq. (F.43) gives them photon couplings $+\frac{2}{3}e, -\frac{1}{3}e$ as required and Z couplings $-\frac{g}{\cos\theta_{\mathrm{W}}}Q\sin^2\theta_{\mathrm{W}}$; their hypercharges $+\frac{2}{3}, -\frac{1}{3}$ were chosen in Section F.1 precisely so that $Q = Y$ for these singlets, ensuring the electric charges of u_L and u_R (and of d_L, d_R) agree, as a consistent Dirac fermion demands.

F.2.3 The Higgs sector

The single scalar is the complex doublet H in $(\mathbf{1},\mathbf{2},+\frac{1}{2})$, with components $H=(H^+,H^0)^{\mathsf{T}}$. Its dynamics are the gauge-covariant kinetic term built from Eq. (F.33) together with the scalar potential:

$$\mathcal{L}_{\text{Higgs}}=(D_\mu H)^\dagger(D^\mu H)-V(H),\qquad V(H)=-\mu^2\,H^\dagger H+\lambda\,(H^\dagger H)^2,\quad\text{(F.47)}$$

with $\mu^2>0$ and $\lambda>0$. The sign of the quadratic term is the crucial one: with $-\mu^2 H^\dagger H$ and $\mu^2>0$ the origin $H=0$ is a maximum, the potential is minimized on the sphere $H^\dagger H=\mu^2/2\lambda\equiv v^2/2$, and electroweak symmetry breaks spontaneously, as worked in Chapters 30 and 31. We retain the symbols μ^2,λ,v from those chapters; the relation $v^2=\mu^2/\lambda$ and the physical Higgs mass $m_h^2=2\lambda v^2=2\mu^2$ are recorded in Section F.3. That $\lambda>0$ is required for the potential to be bounded below (so that a stable vacuum exists at all) and is what makes the quartic the highest term allowed.

It is worth verifying explicitly that Eq. (F.47) is not a choice among several renormalizable possibilities but the *only* one, given the field content.

Proposition F.7 (Uniqueness of the Higgs potential)**.** *The most general Lorentz-invariant,* $\mathrm{SU}(3)_c\times\mathrm{SU}(2)_L\times\mathrm{U}(1)_Y$*-invariant scalar potential of operator dimension* ≤ 4 *built from the single doublet* $H\in(\mathbf{1},\mathbf{2},+\frac{1}{2})$ *is, up to an additive constant,*

$$V(H)=-\mu^2\,H^\dagger H+\lambda\,(H^\dagger H)^2.$$

Proof. Renormalizability in four dimensions restricts the potential to a polynomial in the fields of total operator dimension at most four; a scalar field has dimension one, so V is a polynomial of degree at most four in the components of H and $H^\dagger$. Gauge invariance requires every term to be a singlet of $\mathrm{SU}(3)_c\times\mathrm{SU}(2)_L\times\mathrm{U}(1)_Y$. The doublet H is a color singlet, so $\mathrm{SU}(3)_c$ is automatic. Under $\mathrm{SU}(2)_L$, H is a $\mathbf{2}$ and $H^\dagger$ a $\bar{\mathbf{2}}$; under $\mathrm{U}(1)_Y$, H carries $Y=+\frac{1}{2}$ and $H^\dagger$ carries $-\frac{1}{2}$. We enumerate by degree.

Degree 0: a constant; physically irrelevant (it shifts the vacuum energy), dropped.

Degree 1: a term linear in H or $H^\dagger$ carries $Y=\pm\frac{1}{2}\neq 0$ and transforms as a doublet, never a singlet. None.

Degree 2: the available bilinears are $H^\dagger H$, $H^{\mathsf{T}}H$, $H^\dagger H^\dagger$ and their conjugates. The combination $H^\dagger H=|H^+|^2+|H^0|^2$ is the $\mathrm{SU}(2)_L$ singlet $\bar{\mathbf{2}}\otimes\mathbf{2}\supset\mathbf{1}$ with $Y=-\frac{1}{2}+\frac{1}{2}=0$: invariant. Could one instead contract two H's with the antisymmetric $\mathrm{SU}(2)$ invariant ϵ_{ab}, forming $\epsilon_{ab}H^aH^b$? This is the only $\mathrm{SU}(2)$-singlet bilinear in two doublets, but it is antisymmetric in the two factors, which are the *same* field, so $\epsilon_{ab}H^aH^b=0$ identically; and even were it nonzero it would carry $Y=+1\neq 0$. Hence the unique degree-two invariant is $H^\dagger H$, with real coefficient (hermiticity of V), which we call $-\mu^2$.

Degree 3: an odd polynomial in $H, H^\dagger$ cannot have net hypercharge zero with an odd number of fields unless the hypercharges cancel, but with three doublets the hypercharge is half-integer-odd ($\pm\frac{1}{2}$ summed an odd number of times gives a half-odd-integer, never zero). None.

Degree 4: the only invariant is built from two factors of the unique degree-two invariant, $(H^\dagger H)^2$, with real coefficient λ. Any other degree-four contraction either fails to be an $\mathrm{SU}(2)_L$ singlet (e.g. uses an uncontracted isospin index) or fails hypercharge neutrality (e.g. $(H^\dagger H)(H^{\mathsf{T}}\epsilon H)$ carries $Y=+1$, and $H^{\mathsf{T}}\epsilon H = 0$ anyway); the genuinely independent quartic Casimir of a single doublet collapses to $(H^\dagger H)^2$.

Collecting the surviving terms gives $V = -\mu^2\, H^\dagger H + \lambda\,(H^\dagger H)^2$ up to the dropped constant, with μ^2, λ real, as claimed. □

The conjugate doublet that the Yukawa sector will need is fixed here for definiteness. Because SU(2) is pseudoreal, the antisymmetric tensor $\epsilon_{ab} = i(\sigma^2)_{ab}$ maps the $\bar{\mathbf{2}}$ back to a $\mathbf{2}$; applied to H^* it produces a doublet of *opposite* hypercharge,

$$\widetilde{H} \equiv i\sigma^2 H^* = \begin{pmatrix} H^{0\,*} \\ -H^- \end{pmatrix}, \qquad \widetilde{H} \in (\mathbf{1}, \mathbf{2}, -\tfrac{1}{2}), \tag{F.48}$$

where $H^- \equiv (H^+)^*$. That $\widetilde{H}$ transforms as a genuine $\mathrm{SU}(2)_L$ doublet with $Y=-\frac{1}{2}$—and not as a $\bar{\mathbf{2}}$—is the standard fact about the pseudoreality of SU(2) established in Chapter B; it is what makes the up-type Yukawa coupling below gauge invariant.

F.2.4 The Yukawa sector

With fermion masses forbidden in $\mathcal{L}_{\text{fermion}}$, the only renormalizable couplings that can connect the left-handed doublets to the right-handed singlets are the dimension-four Yukawa terms, each pairing a fermion bilinear (carrying half-integer isospin and some hypercharge) with the scalar doublet (or its conjugate) so that the product is a $\mathrm{SU}(3)_c \times \mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$ singlet. Writing the generation indices $i, j = 1, 2, 3$ explicitly and the three couplings as general complex 3×3 matrices Y_u, Y_d, Y_e,

$$\mathcal{L}_{\text{Yukawa}} = -\,\bar{Q}_{Li}\,(Y_u)_{ij}\,\widetilde{H}\,u_{Rj} - \bar{Q}_{Li}\,(Y_d)_{ij}\,H\,d_{Rj} - \bar{L}_{Li}\,(Y_e)_{ij}\,H\,e_{Rj} + \text{h.c.}, \tag{F.49}$$

the $\mathrm{SU}(2)_L$ doublet indices on $\bar{Q}_L$ (or $\bar{L}_L$) and on $H, \widetilde{H}$ being contracted, and the color indices on $\bar{Q}_L$ and the quark singlets being contracted. Each term is a $\mathrm{SU}(3)_c \times \mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$ singlet, which one checks by adding hypercharges and contracting representations:

- Down-type quark, $\bar{Q}_L\, H\, d_R$: color $\bar{\mathbf{3}} \otimes \mathbf{3} = \mathbf{1} \oplus \mathbf{8} \supset \mathbf{1}$ (singlet kept); isospin $\bar{\mathbf{2}} \otimes \mathbf{2} = \mathbf{1} \oplus \mathbf{3} \supset \mathbf{1}$; hypercharge $-\frac{1}{6} + \frac{1}{2} - \frac{1}{3} = 0$. Invariant.

- Up-type quark, $\bar{Q}_L\,\widetilde{H}\,u_R$: color singlet as above; isospin singlet using $\widetilde{H} \in \mathbf{2}$; hypercharge $-\frac{1}{6} + (-\frac{1}{2}) + \frac{2}{3} = 0$. The conjugate doublet $\widetilde{H}$ is needed precisely because u_R has $Y = +\frac{2}{3}$, which H (with $Y = +\frac{1}{2}$) cannot neutralize but $\widetilde{H}$ (with $Y = -\frac{1}{2}$) can. Invariant.

- Charged lepton, $\bar{L}_L\,H\,e_R$: color trivially singlet; isospin singlet; hypercharge $+\frac{1}{2} + \frac{1}{2} - 1 = 0$. Invariant.

There is no $\bar{L}_L\,\widetilde{H}\,\nu_R$ term, because the minimal model contains no ν_R; this is why neutrinos are massless in the renormalizable Standard Model, and the leading gauge-invariant operator that gives them a (Majorana) mass is the dimension-five Weinberg operator discussed in Chapters 32 and 35, which we do not include in Eq. (F.20). The three matrices Y_u, Y_d, Y_e are entirely general: a priori arbitrary complex matrices in generation space, with no reality or hermiticity assumed. After electroweak breaking H acquires its vev and these matrices become the fermion mass matrices; their diagonalization, the mismatch between up- and down-type rotations, and the resulting CKM matrix were derived in Chapter 32 and are summarized in Section F.3. The counting of the physical parameters hidden in Y_u, Y_d, Y_e—which uses the $\mathrm{U}(3)^5$ flavor symmetry noted after Eq. (F.27)—is carried out in full in Section F.4.

F.2.5 Gauge fixing and ghosts (for reference)

The Lagrangian Eqs. (F.25) to (F.49) is the classical, gauge-invariant Standard Model; it is what the next section breaks. For quantization the gauge redundancy must be fixed, introducing the Faddeev–Popov ghosts derived in Chapter 26. We record the gauge-fixing and ghost terms here for completeness but neither re-derive nor use them in this appendix.

In a covariant R_ξ gauge one adds, for each gauge factor, a gauge-fixing term that softens the longitudinal propagator with a free parameter ξ. In the unbroken phase the simplest such choice is the linear covariant gauge,

$$\mathcal{L}_{\mathrm{gf}} = -\frac{1}{2\xi_3}\big(\partial^\mu G^A_\mu\big)^2 - \frac{1}{2\xi_2}\big(\partial^\mu W^I_\mu\big)^2 - \frac{1}{2\xi_1}\big(\partial^\mu B_\mu\big)^2, \tag{F.50}$$

with independent parameters ξ_3, ξ_2, ξ_1 for the three factors (Feynman gauge being $\xi = 1$, the default for explicit computation in this book). The associated ghost Lagrangian, one anticommuting complex scalar $c^a, \bar{c}^a$ per gauge generator, is

$$\mathcal{L}_{\mathrm{ghost}} = \bar{c}^A\big(-\partial^\mu D^{AB}_\mu\big)c^B + \bar{c}^I\big(-\partial^\mu D^{IJ}_\mu\big)c^J, \tag{F.51}$$

where $D^{AB}_\mu = \partial_\mu\delta^{AB} + g_s f^{ACB} G^C_\mu$ and $D^{IJ}_\mu = \partial_\mu\delta^{IJ} + g\,\epsilon^{IKJ} W^K_\mu$ are the adjoint covariant derivatives of Chapter 26; the abelian $\mathrm{U}(1)_Y$ ghost is free and decouples, so it is omitted. The full gauge-fixed action is invariant under the BRST symmetry

of Chapter 26, which is what guarantees the gauge independence of physical observables.

After electroweak breaking one uses instead the 't Hooft R_ξ gauge of Chapter 30, in which the gauge-fixing functionals are shifted by terms proportional to the would-be Goldstone bosons, $\mathcal{G}_a = \partial^\mu V_\mu^a - \xi\, M_a\, \varphi_a$ (schematically, with V_a a massive vector, M_a its mass and φ_a the eaten Goldstone), precisely so as to cancel the quadratic gauge–Goldstone mixing produced by the vev. The resulting massive-gauge and Goldstone propagators, and the ξ-dependent ghost masses, are recorded in Chapter 30; we point to them rather than reproduce them, since this appendix's task is the defining Lagrangian, not its quantization.

F.2.6 The assembled Lagrangian

Collecting Eq. (F.25), Eq. (F.26), Eq. (F.27), Eq. (F.47), Eq. (F.49) (and, for quantization, Eq. (F.50), Eq. (F.51)), the complete renormalizable Standard Model Lagrangian is

$$\begin{aligned}\mathcal{L}_{\rm SM} = \; & -\tfrac{1}{4} G^A_{\mu\nu} G^{A\,\mu\nu} - \tfrac{1}{4} W^I_{\mu\nu} W^{I\,\mu\nu} - \tfrac{1}{4} B_{\mu\nu} B^{\mu\nu} + \frac{g_s^2\,\theta}{32\pi^2} G^A_{\mu\nu} \widetilde{G}^{A\,\mu\nu} \\ & + \bar{Q}_{Li}\, i\not{D}\, Q_{Li} + \bar{u}_{Ri}\, i\not{D}\, u_{Ri} + \bar{d}_{Ri}\, i\not{D}\, d_{Ri} + \bar{L}_{Li}\, i\not{D}\, L_{Li} + \bar{e}_{Ri}\, i\not{D}\, e_{Ri} \\ & + (D_\mu H)^\dagger (D^\mu H) + \mu^2\, H^\dagger H - \lambda\, (H^\dagger H)^2 \\ & - \Big(\bar{Q}_{Li}\, (Y_u)_{ij}\, \widetilde{H}\, u_{Rj} + \bar{Q}_{Li}\, (Y_d)_{ij}\, H\, d_{Rj} + \bar{L}_{Li}\, (Y_e)_{ij}\, H\, e_{Rj} + \text{h.c.} \Big),\end{aligned} \tag{F.52}$$

each covariant derivative being the specialization Eqs. (F.28) to (F.33) appropriate to the multiplet it acts on, and the generation indices i, j summed. Every parameter that appears—the three gauge couplings g_s, g, g', the strong CP angle θ, the two scalar parameters μ^2, λ, and the three Yukawa matrices Y_u, Y_d, Y_e—is collected and counted in Section F.4. This is the entire content of the Standard Model: there is no operator of dimension four consistent with $\mathrm{SU}(3)_c \times \mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$ gauge invariance and Lorentz invariance that has been omitted, and (Chapter 33) the accidental conservation of baryon and lepton number is a consequence of this exhaustiveness rather than an input.

Equation (F.52) is written in the unbroken phase, where the gauge symmetry is manifest and every fermion and gauge boson is massless. The next section takes the Higgs field to its vacuum expectation value, $\langle H \rangle = (0, v/\sqrt{2})^{\mathsf{T}}$, and reads off the consequences term by term: the gauge-boson mass eigenstates $W^\pm, Z, \gamma$ and the weak mixing angle from $(D_\mu H)^\dagger (D^\mu H)$, the physical Higgs mass from $V(H)$, and the fermion mass matrices from $\mathcal{L}_{\rm Yukawa}$—thereby tying every measured mass and mixing, and every numerical value tabulated later in this appendix, back to a definite parameter of Eq. (F.52).

F.3 Electroweak Breaking and the Physical Spectrum

The previous section wrote the complete Standard Model Lagrangian term by term (Section F.2), and among its pieces sat two that are inert in perturbation theory until the scalar field develops a vacuum expectation value: the Higgs potential $V(H)$ and the Yukawa couplings $y_f\,\bar{L}Hf_R+\text{h.c.}$ Written in terms of the symmetric fields W^a_μ, B_μ and the gauge-symmetric doublet H, that Lagrangian contains no mass term for any gauge boson and no mass term for any charged fermion—both would violate $\mathrm{SU}(3)_c\times\mathrm{SU}(2)_L\times\mathrm{U}(1)_Y$ gauge invariance outright. The masses are not absent; they are stored in the vacuum. This section spends them. It records what the theory looks like once H settles into its minimum: the value v of the condensate, the rotation that turns (W^3,B) into the photon and the Z, the weak mixing angle, and the resulting tree-level dictionary that expresses every gauge-boson and fermion mass in terms of Lagrangian parameters. The *physics* of why a gauge symmetry may be hidden by a vacuum—the Higgs mechanism, the count of would-be Goldstone bosons eaten, the unitarity of the resulting massive theory—is proved in Chapter 30 and applied to the electroweak group in Chapter 31; we import those results by reference and never reprove them. What we carry here in full is the comparatively elementary but load-bearing linear algebra that converts the symmetric Lagrangian into the physical spectrum, because that algebra is the bridge between the parameters $\{g,g',v,\lambda,y_f\}$ and the numbers measured in the laboratory, and it belongs nowhere else in the book.

Throughout we use the standing conventions frozen for this appendix: the gauge group is $\mathrm{SU}(3)_c\times\mathrm{SU}(2)_L\times\mathrm{U}(1)_Y$ in that order; the electric charge is $Q=T^3+Y$ with the hypercharge of the lepton doublet $Y_L=-\frac{1}{2}$ and of the Higgs doublet $Y_H=+\frac{1}{2}$ (Section F.1); and the covariant derivative carries the sign convention of Chapter 30, namely

$$D_\mu H=\Big(\partial_\mu-ig\,W^a_\mu T^a-ig'\,Y_H\,B_\mu\Big)H,\qquad T^a=\tfrac{1}{2}\sigma^a,\quad Y_H=+\tfrac{1}{2},\tag{F.53}$$

where σ^a are the Pauli matrices (Chapter B) and g, g' are the $\mathrm{SU}(2)_L$ and $\mathrm{U}(1)_Y$ couplings.

F.3.1 The Higgs vacuum expectation value

The scalar sector is a single complex doublet H with $Y_H=+\frac{1}{2}$, governed by the potential

$$V(H)=-\mu^2\,H^\dagger H+\lambda\,(H^\dagger H)^2,\qquad \mu^2>0,\quad \lambda>0.\tag{F.54}$$

The sign of the quadratic term is the whole point: with $\mu^2>0$ the origin $H=0$ is a local maximum of the radial potential, and stability is supplied by the quartic with $\lambda>0$. That spontaneous symmetry breaking occurs—that the vacuum is

a point on the degenerate minimum circle rather than the symmetric point—is the content of Chapter 29; here we only locate the minimum and read off the spectrum about it.

Because V depends on H only through the gauge invariant $H^\dagger H \geq 0$, it suffices to minimize over that single nonnegative variable. Writing $u \equiv H^\dagger H$,

$$\frac{dV}{du} = -\mu^2 + 2\lambda u = 0 \quad \Longrightarrow \quad u_{\min} = H^\dagger H\big|_{\min} = \frac{\mu^2}{2\lambda}, \tag{F.55}$$

and $d^2V/du^2 = 2\lambda > 0$ confirms it is a minimum. The minimum is a three-sphere's worth of degenerate vacua related by $\mathrm{SU}(3)_c \times \mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$; Chapter 31 fixes the gauge that aligns the condensate with the lower, electrically neutral component, so that Q annihilates the vacuum and $\mathrm{U}(1)_{\mathrm{em}}$ survives unbroken. In that unitary gauge the doublet is parametrized by the single physical real scalar $h(x)$,

$$H(x) = \frac{1}{\sqrt{2}} \begin{pmatrix} 0 \\ v + h(x) \end{pmatrix}, \qquad \langle H \rangle = \frac{1}{\sqrt{2}} \begin{pmatrix} 0 \\ v \end{pmatrix}, \tag{F.56}$$

the three would-be Goldstone bosons having been removed by the gauge choice and reappearing as the longitudinal polarizations of $W^\pm$ and Z (Chapter 30). With Eq. (F.56) one has $H^\dagger H = \frac{1}{2}(v+h)^2$, so the condition $H^\dagger H|_{\min} = v^2/2 = \mu^2/2\lambda$ fixes the *vacuum expectation value*

$$\boxed{v^2 = \frac{\mu^2}{\lambda}} \tag{F.57}$$

This is the number that sets the scale of all electroweak masses; numerically $v \simeq 246$ GeV, recorded with its provenance in Section F.6.

Expanding V about $H^\dagger H = \frac{1}{2}(v+h)^2$ gives the physical scalar mass. Substituting into Eq. (F.54),

$$\begin{aligned} V &= -\mu^2 \cdot \tfrac{1}{2}(v+h)^2 + \lambda \cdot \tfrac{1}{4}(v+h)^4 \\ &= -\tfrac{1}{2}\lambda v^2 (v+h)^2 + \tfrac{1}{4}\lambda (v+h)^4, \end{aligned} \tag{F.58}$$

where we used $\mu^2 = \lambda v^2$ from Eq. (F.57). The coefficient of h^2 is read off by differentiating twice at $h = 0$, or by direct expansion:

$$V \supset -\tfrac{1}{2}\lambda v^2 (2vh + h^2) + \tfrac{1}{4}\lambda (6v^2 h^2 + \dots) = \underbrace{\left(-\lambda v^3 + \lambda v^3\right)}_{=0} h + \tfrac{1}{2}(-\lambda v^2 + 3\lambda v^2) h^2 + \dots \tag{F.59}$$

The linear term cancels—confirming that $h = 0$ is the stationary point—and the quadratic term identifies the tree-level Higgs mass via $V \supset \frac{1}{2} m_h^2 h^2$:

$$\boxed{m_h^2 = 2\lambda v^2 = 2\mu^2} \tag{F.60}$$

Thus the two parameters of the scalar sector, (μ^2, λ), are traded for the two observables (v, m_h): $\lambda = m_h^2/2v^2$ and $\mu^2 = m_h^2/2$.

F.3.2 Gauge-boson masses and the weak mixing angle

Gauge-boson masses arise entirely from the scalar kinetic term $(D_\mu H)^\dagger (D^\mu H)$ once H is replaced by its vacuum value. Evaluating the covariant derivative Eq. (F.53) on the constant vacuum $\langle H \rangle$ kills the ∂_μ piece and leaves the gauge fields acting algebraically:

$$D_\mu \langle H \rangle = -i\Big(g\, W_\mu^a T^a + g'\, Y_H\, B_\mu\Big)\, \langle H \rangle = -\frac{i}{2}\Big(g\, W_\mu^a \sigma^a + g'\, B_\mu \mathbf{1}\Big)\, \langle H \rangle\,, \quad \text{(F.61)}$$

using $T^a = \sigma^a/2$ and $Y_H = \frac{1}{2}$. Write out the 2×2 matrix in the doublet space, with $\sigma^3 = \mathrm{diag}(1, -1)$,

$$g\, W_\mu^a \sigma^a + g'\, B_\mu \mathbf{1} = \begin{pmatrix} gW_\mu^3 + g'B_\mu & g(W_\mu^1 - iW_\mu^2) \\ g(W_\mu^1 + iW_\mu^2) & -gW_\mu^3 + g'B_\mu \end{pmatrix}. \quad \text{(F.62)}$$

Acting on $\langle H \rangle = \frac{1}{\sqrt{2}}(0, v)^{\mathsf{T}}$ picks out the second column:

$$D_\mu \langle H \rangle = -\frac{i}{2} \cdot \frac{v}{\sqrt{2}} \begin{pmatrix} g(W_\mu^1 - iW_\mu^2) \\ -gW_\mu^3 + g'B_\mu \end{pmatrix}. \quad \text{(F.63)}$$

The mass Lagrangian is the squared norm of this column vector,

$$\mathcal{L}_{\text{mass}} = (D_\mu \langle H \rangle)^\dagger (D^\mu \langle H \rangle) = \frac{1}{8} v^2 \Big[\, g^2 \big((W_\mu^1)^2 + (W_\mu^2)^2\big) + \big(gW_\mu^3 - g'B_\mu\big)^2 \,\Big], \quad \text{(F.64)}$$

where the cross term between the off-diagonal and diagonal entries vanishes because they live in orthogonal components of the doublet. This is the entire source of tree-level gauge-boson masses, and it splits cleanly into a charged sector (the first two terms) and a neutral sector (the last).

Charged sector. Define the charge eigenfields

$$W_\mu^\pm = \frac{1}{\sqrt{2}}(W_\mu^1 \mp i W_\mu^2), \quad \text{(F.65)}$$

so that W^+ carries $Q = +1$ and W^- carries $Q = -1$ (the assignment follows from $T^\pm = T^1 \pm i T^2$; see Chapter 31). Then $(W_\mu^1)^2 + (W_\mu^2)^2 = 2\, W_\mu^+ W^{-\mu}$, and the charged part of Eq. (F.64) becomes $\frac{1}{4} g^2 v^2\, W_\mu^+ W^{-\mu}$. A complex (charged) vector field of mass m_W has mass term $m_W^2\, W_\mu^+ W^{-\mu}$, with no factor of $\frac{1}{2}$, so

$$\boxed{m_W = \frac{gv}{2}} \quad \text{(F.66)}$$

Neutral sector. The last term of Eq. (F.64) is a quadratic form in the two real neutral fields (W^3_μ, B_μ). A real vector field of mass m has mass term $\frac{1}{2}m^2 V_\mu V^\mu$, so we read the symmetric mass-squared matrix $\mathcal{M}^2$ from $\mathcal{L}_{\text{mass}} \supset \frac{1}{2}\,(W^3, B)\,\mathcal{M}^2\,(W^3, B)^{\mathsf{T}}$. Expanding $(gW^3 - g'B)^2 = g^2(W^3)^2 - 2gg'\,W^3B + g'^2B^2$ and matching to $\frac{1}{8}v^2$ times this,

$$\mathcal{M}^2 = \frac{v^2}{4}\begin{pmatrix} g^2 & -gg' \\ -gg' & g'^2 \end{pmatrix}. \tag{F.67}$$

The eigenstructure of this matrix is the worked diagonalization of Theorem F.8; its output is a massless photon A_μ, a massive Z_μ with the eigenvectors of Eq. (F.73), and the weak mixing angle of Eq. (F.72). We carry the diagonalization in full now.

Worked Example F.8 (Diagonalizing the neutral mass matrix)**.** We diagonalize $\mathcal{M}^2$ of Eq. (F.67) completely: eigenvalues, eigenvectors, mixing angle, and the masslessness of the photon.

Eigenvalues. The matrix $\mathcal{M}^2 = \frac{v^2}{4}\left(\begin{smallmatrix} g^2 & -gg' \\ -gg' & g'^2 \end{smallmatrix}\right)$ is, up to the prefactor, the outer product $(g, -g')^{\mathsf{T}}(g, -g')$, hence rank one. Its determinant is

$$\det \mathcal{M}^2 = \Big(\frac{v^2}{4}\Big)^2 (g^2 g'^2 - (gg')^2) = 0, \tag{F.68}$$

so one eigenvalue vanishes. The trace gives the other:

$$\operatorname{tr} \mathcal{M}^2 = \frac{v^2}{4}(g^2 + g'^2) = m_Z^2 + 0, \qquad \text{so} \qquad m_Z^2 = \frac{v^2}{4}(g^2 + g'^2), \quad m_\gamma^2 = 0. \tag{F.69}$$

The vanishing eigenvalue is the unbroken photon, guaranteed by the survival of $\mathrm{U}(1)_{\text{em}}$; the nonzero one is the Z.

Eigenvectors. The massless eigenvector $\hat{e}_A$ satisfies $\mathcal{M}^2 \hat{e}_A = 0$. Since each row of $\mathcal{M}^2$ is proportional to $(g, -g')$, the null vector is orthogonal to $(g, -g')$, i.e. proportional to (g', g). Normalizing,

$$A_\mu = \frac{g'\,W^3_\mu + g\,B_\mu}{\sqrt{g^2 + g'^2}}. \tag{F.70}$$

The Z eigenvector is the orthogonal combination,

$$Z_\mu = \frac{g\,W^3_\mu - g'\,B_\mu}{\sqrt{g^2 + g'^2}}, \tag{F.71}$$

and one checks $\mathcal{M}^2 \hat{e}_Z = \frac{v^2}{4}(g^2 + g'^2)\,\hat{e}_Z = m_Z^2\,\hat{e}_Z$ directly. Introducing the *weak mixing angle* θ_{W} through

$$\cos\theta_{\mathrm{W}} = \frac{g}{\sqrt{g^2 + g'^2}}, \qquad \sin\theta_{\mathrm{W}} = \frac{g'}{\sqrt{g^2 + g'^2}}, \qquad \tan\theta_{\mathrm{W}} = \frac{g'}{g}, \tag{F.72}$$

the eigenstates take their canonical form

$$\begin{pmatrix} A_\mu \\ Z_\mu \end{pmatrix} = \begin{pmatrix} \sin\theta_{\mathrm{W}} & \cos\theta_{\mathrm{W}} \\ \cos\theta_{\mathrm{W}} & -\sin\theta_{\mathrm{W}} \end{pmatrix} \begin{pmatrix} W^3_\mu \\ B_\mu \end{pmatrix}, \qquad \text{i.e.} \qquad \begin{aligned} A_\mu &= \sin\theta_{\mathrm{W}}\, W^3_\mu + \cos\theta_{\mathrm{W}}\, B_\mu, \\ Z_\mu &= \cos\theta_{\mathrm{W}}\, W^3_\mu - \sin\theta_{\mathrm{W}}\, B_\mu. \end{aligned} \tag{F.73}$$

The rotation is orthogonal (its matrix is symmetric with unit determinant up to sign), so it preserves the canonically normalized kinetic terms of W^3 and B.

The Z mass in terms of m_W. Using $m_Z^2 = \frac{v^2}{4}(g^2 + g'^2)$ and $m_W^2 = \frac{v^2}{4} g^2$ from Eq. (F.66),

$$\frac{m_W^2}{m_Z^2} = \frac{g^2}{g^2 + g'^2} = \cos^2\theta_{\mathrm{W}} \qquad \Longrightarrow \qquad m_Z = \frac{m_W}{\cos\theta_{\mathrm{W}}}. \tag{F.74}$$

This completes the diagonalization.

The electromagnetic coupling. The combination of couplings that multiplies the photon is the electric charge e. To see it, rewrite the neutral part of the covariant derivative $g W^3_\mu T^3 + g' B_\mu Y$ in the mass basis. Inverting Eq. (F.73),

$$W^3_\mu = \sin\theta_{\mathrm{W}}\, A_\mu + \cos\theta_{\mathrm{W}}\, Z_\mu, \qquad B_\mu = \cos\theta_{\mathrm{W}}\, A_\mu - \sin\theta_{\mathrm{W}}\, Z_\mu, \tag{F.75}$$

and substituting,

$$\begin{aligned} g\, W^3_\mu T^3 + g'\, B_\mu Y = {} & (g \sin\theta_{\mathrm{W}}\, T^3 + g' \cos\theta_{\mathrm{W}}\, Y)\, A_\mu \\ & + (g \cos\theta_{\mathrm{W}}\, T^3 - g' \sin\theta_{\mathrm{W}}\, Y)\, Z_\mu. \end{aligned} \tag{F.76}$$

For the photon to couple universally to the electric charge $Q = T^3 + Y$, the two coefficients in front of A_μ must be equal, $g \sin\theta_{\mathrm{W}} = g' \cos\theta_{\mathrm{W}}$, which is exactly Eq. (F.72); their common value *is* the electric charge:

$$\boxed{e = g \sin\theta_{\mathrm{W}} = g' \cos\theta_{\mathrm{W}} = \frac{g g'}{\sqrt{g^2 + g'^2}}} \tag{F.77}$$

so that the photon coupling reduces to $e\,(T^3 + Y) A_\mu = e\, Q\, A_\mu$, as required, and the unbroken interaction is precisely QED with charge e. The same substitution exhibits the neutral-current coupling to the Z as $\frac{g}{\cos\theta_{\mathrm{W}}}(T^3 - \sin^2\theta_{\mathrm{W}} Q) Z_\mu$, the structure analyzed in Chapter 31; it is the experimental handle on $\sin^2\theta_{\mathrm{W}}$.

It is worth recording the tree-level bridge from v to the Fermi constant, since it is what makes v measurable. Integrating out the W in muon decay (Chapter 31) matches the low-energy four-fermion interaction onto the Fermi theory with

$$\frac{G_F}{\sqrt{2}} = \frac{g^2}{8 m_W^2} = \frac{1}{2v^2} \qquad \Longrightarrow \qquad v = (\sqrt{2}\, G_F)^{-1/2}, \tag{F.78}$$

where the middle equality used $m_W = g v/2$. Thus the precisely measured G_F fixes v directly; the scheme-conversion subtleties of trading $\{g, g', v\}$ for $\{\alpha, G_F, m_Z\}$ are carried in Section F.7.

F.3.3 Fermion masses from the Yukawa sector

Charged-fermion masses are forbidden as bare terms by $\mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$ invariance—a Dirac mass $m\,\bar{\psi}_L \psi_R$ pairs a doublet with a singlet of different hypercharge—and are generated instead by the gauge-invariant Yukawa couplings of Section F.2. For a down-type fermion with right-handed singlet f_R and the left-handed doublet L_f,

$$\mathcal{L}_{\mathrm{Y}} \supset -y_f\, \bar{L}_f\, H\, f_R + \mathrm{h.c.}, \tag{F.79}$$

the doublet contraction $\bar{L}_f H$ is an $\mathrm{SU}(2)_L$ singlet and carries vanishing hypercharge, so the term is gauge invariant. Replacing H by its vacuum value Eq. (F.56) projects onto the lower component, $\bar{L}_f H \to \frac{1}{\sqrt{2}}(v+h)\,\bar{f}_L$, giving

$$\mathcal{L}_{\mathrm{Y}} \supset -\frac{y_f}{\sqrt{2}}(v+h)\,\bar{f}_L f_R + \mathrm{h.c.} = -\frac{y_f v}{\sqrt{2}}\,\bar{f}f - \frac{y_f}{\sqrt{2}}\,h\,\bar{f}f, \tag{F.80}$$

where $\bar{f}f = \bar{f}_L f_R + \bar{f}_R f_L$. The first term is a Dirac mass, the second the Higgs–fermion coupling. Hence

$$\boxed{m_f = \frac{y_f\, v}{\sqrt{2}}} \tag{F.81}$$

For up-type fermions the conjugate doublet $\widetilde{H} = i\sigma^2 H^*$ (hypercharge $-\frac{1}{2}$) is used in place of H so that the upper component acquires the vev; the mass formula Eq. (F.81) is unchanged. Equation Eq. (F.81) is written here for a single generation; in the three-generation theory y_f is a 3×3 matrix in flavor space, and diagonalizing it is what introduces the CKM matrix—that diagonalization, the flavor-basis rotations, and the parameter count it generates are the business of Chapter 32 and of Section F.4. The crucial structural fact recorded here is that *every* charged-fermion mass is $v/\sqrt{2}$ times a dimensionless Yukawa coupling, so the enormous hierarchy of fermion masses is encoded entirely in the hierarchy of the y_f. A coupling-derived corollary worth noting: the Higgs couples to each fermion with strength $y_f/\sqrt{2} = m_f/v$, proportional to the mass it generates—the prediction that makes the Higgs's decay pattern a sharp test (Chapter 34).

F.3.4 The ρ parameter and custodial symmetry

The mass relations Eqs. (F.66) and (F.74) are not independent: they imply a rigid prediction. Define the ρ parameter

$$\rho \equiv \frac{m_W^2}{m_Z^2\, \cos^2\theta_{\mathrm{W}}}. \tag{F.82}$$

This combination is constructed to be unity if and only if the gauge-boson masses obey the single-doublet pattern just derived.

Proposition F.9 (Tree-level $\rho = 1$)**.** *In the Standard Model with a single Higgs doublet, $\rho = 1$ at tree level.*

Proof. Substitute the diagonalization results. From Eq. (F.66), $m_W^2 = \frac{v^2}{4} g^2$; from Theorem F.8, $m_Z^2 = \frac{v^2}{4}(g^2 + g'^2)$; and from Eq. (F.72), $\cos^2\theta_{\mathrm{W}} = g^2/(g^2 + g'^2)$. Then

$$m_Z^2 \cos^2\theta_{\mathrm{W}} = \frac{v^2}{4}(g^2 + g'^2) \cdot \frac{g^2}{g^2 + g'^2} = \frac{v^2}{4} g^2 = m_W^2, \tag{F.83}$$

so $\rho = m_W^2/m_W^2 = 1$. □

The algebra is immediate, but its robustness is the interesting point: $\rho = 1$ is not an accident of the numbers, it is protected by a symmetry. The Higgs sector has, beyond the gauged $\mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$, an accidental *global* symmetry larger than what is gauged, and the surviving subgroup after breaking—*custodial* $\mathrm{SU}(2)_V$—forces the three weak gauge bosons to share a common mass before hypercharge mixing is switched on. The full custodial analysis, including its breaking by g' and by the Yukawa splittings, is carried in Chapter 31; the worked example below isolates exactly the part that controls ρ.

Worked Example F.10 (Custodial symmetry and the protection of ρ)**.** Assemble the Higgs doublet H (hypercharge $+\frac{1}{2}$) and its conjugate $\widetilde{H} = i\sigma^2 H^*$ (hypercharge $-\frac{1}{2}$) into a single 2×2 matrix

$$\Phi \equiv (\widetilde{H},\ H) = \begin{pmatrix} \phi_0^* & \phi^+ \\ -\phi^- & \phi_0 \end{pmatrix}. \tag{F.84}$$

A short computation gives $\mathrm{tr}(\Phi^\dagger \Phi) = 2\, H^\dagger H$, so the potential Eq. (F.54) depends on Φ only through $\mathrm{tr}(\Phi^\dagger \Phi)$. Under the transformation $\Phi \to L\, \Phi\, R^\dagger$ with $L \in \mathrm{SU}(2)_L$ and $R \in \mathrm{SU}(2)_R$, the trace is invariant because $\mathrm{tr}(R\Phi^\dagger L^\dagger L \Phi R^\dagger) = \mathrm{tr}(\Phi^\dagger \Phi)$. Thus the scalar potential and—when $g' = 0$—the scalar kinetic term enjoy a global $\mathrm{SU}(2)_L \times \mathrm{SU}(2)_R$ symmetry, larger than the gauged $\mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$.

The vacuum Eq. (F.56) corresponds to $\langle \Phi \rangle = \frac{v}{\sqrt{2}}\, \mathbf{1}$, which is invariant under $\Phi \to L \Phi R^\dagger$ precisely when $L = R$: the diagonal subgroup $\mathrm{SU}(2)_{L+R} \equiv \mathrm{SU}(2)_V$ survives. This is the custodial symmetry.

Now examine the gauge mass term Eq. (F.64) with hypercharge turned off, $g' = 0$. The neutral matrix Eq. (F.67) becomes $\mathcal{M}^2 = \frac{v^2}{4}\, \mathrm{diag}(g^2, 0)$, so W^3 acquires mass $m_W = gv/2$ and B stays massless and decoupled. Together with the charged result Eq. (F.66), all three fields $W^{1,2,3}$ then have the identical mass $m_W = gv/2$: they form a degenerate triplet. This degeneracy is no coincidence—under custodial $\mathrm{SU}(2)_V$ the three W^a transform as a vector (adjoint) triplet, and a symmetry-invariant mass matrix on an irreducible triplet must be proportional to the identity. The common mass is the algebraic statement of custodial symmetry.

Switching g' back on gauges the T_R^3 generator inside $\mathrm{SU}(2)_R$ (with Y identified as $-T_R^3$ plus a singlet piece), explicitly breaking $\mathrm{SU}(2)_R \to \mathrm{U}(1)_Y$ and hence custodial $\mathrm{SU}(2)_V$. The effect is precisely the W^3–B mixing of Theorem F.8: the would-be degenerate W^3 mixes with B to form Z and γ. Crucially, this mixing rotates the triplet without changing the relation between the masses in the symmetric direction, so the prediction

$$\rho = \frac{m_W^2}{m_Z^2 \cos^2\theta_{\mathrm{W}}} = 1 \tag{F.85}$$

survives at tree level even though custodial symmetry is broken by g'. The reason it is called *custodial* is now visible: it is the symmetry that guards the tree-level relation $\rho = 1$. Were the scalar sector to contain, say, a hypercharge-± 1 triplet, this protection would fail and ρ would deviate from one already at tree level—a sensitivity that makes the measured $\rho \approx 1$ strong evidence that electroweak breaking is dominated by doublets. Custodial breaking by the large top–bottom Yukawa splitting, and by g' at loop level, generates the small calculable $\rho - 1$ corrections of the precision program (Chapter 34).

The tree-level dictionary is now complete. The Lagrangian parameters $\{g, g', v, \lambda, y_f\}$ have been mapped to the physical quantities $\{m_W, m_Z, \theta_{\mathrm{W}}, e, m_h, m_f\}$ through Eqs. (F.60), (F.66), (F.72), (F.74), (F.77) and (F.81), with the single doublet enforcing $\rho = 1$. These maps—together with the flavor rotations deferred to Chapter 32—are the relations whose independent inputs the next section counts, turning the informal slogan that the Standard Model has nineteen parameters into a derived number; and the values m_W, m_Z, θ_{W} established here are the electroweak anchors that the numerical section will feed into the running-coupling thread.

F.4 Free Parameters: the Counting

The Lagrangian-to-physical dictionary assembled in the preceding section made explicit which Lagrangian quantities are genuine independent inputs and which are derived: the gauge-boson and fermion masses, the weak mixing angle, the vacuum expectation value, all of them are *functions* of a smaller set of couplings written in the Lagrangian. The natural question is then exactly how small that set is. The folklore answer — "the Standard Model has nineteen free parameters" — is usually quoted without proof, as though it were a fact to be memorized. It is not folklore; it is a theorem about the orbit space of the flavor symmetry group acting on the Yukawa matrices, and in this section we prove it in full. We first isolate the handful of parameters in the gauge–Higgs–$\bar{\theta}$ sector, where the count is immediate, and then do the real work in the flavor sector, where the raw Lagrangian contains far more numbers than are physical and the redundancy

must be removed by a careful field-redefinition argument. The same machine, run again with the field content enlarged, delivers the neutrino-mass extensions and explains the otherwise mysterious extra phases of the Majorana case.

Nothing physical is established here that was not already proved in Part IX: the gauge principle, the Higgs mechanism, the origin of the CKM matrix and the structure of the Yukawa sector are imported by Chapters 31 to 33, and the anomalous non-conservation of the axial current — which we shall need to dispose cleanly of the strong-CP angle — is imported from Chapters 36 and 37. What is carried here in full is the *counting*, because it is a load-bearing organizing computation that belongs nowhere else: Chapter 33, which owns the one-line summary "nineteen parameters," cites back to this section for the derivation.

F.4.1 What counts as a physical parameter

A Lagrangian is a presentation of a theory in a particular choice of field variables. Two Lagrangians related by an invertible, local redefinition of the fields that leaves the path-integral measure and the action functionally identical describe *the same physics*: every correlation function, every S-matrix element, every cross section is the same. Consequently a number appearing in the Lagrangian is a genuine physical parameter only if it cannot be removed or altered by such a redefinition. The count of physical parameters is therefore not the count of symbols in the Lagrangian but the dimension of the space of Lagrangians *modulo* the group of allowed field redefinitions.

For the Standard Model the relevant redefinitions split into two kinds. The gauge and scalar couplings $(g_s, g, g', \mu^2, \lambda)$ and the topological angle multiply operators that are essentially rigid: there is no field redefinition that rotates one into another or sets one to a fixed value, so each is physical as written, and the only subtlety is the interplay between the chiral field rotations and the θ-term, treated below. The Yukawa couplings are entirely different. They are arbitrary complex matrices in the three-dimensional space of fermion generations, and the kinetic terms of the fermions are invariant under a large continuous group of unitary rotations among the generations. That group can be used to bring the Yukawa matrices to a canonical form, eliminating most of their entries. The physical Yukawa parameters are the coordinates that survive — the coordinates on the quotient of the raw Yukawa space by the flavor group. Making this precise and computing the dimension of that quotient is the content of Section F.4.3.

F.4.2 The gauge, Higgs and topological sector: six parameters

We begin with the part of the count that requires no quotient. The gauge sector of $\mathrm{SU}(3)_c \times \mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$ carries one coupling constant per simple (or abelian) factor, since the normalization of each gauge field is fixed by its canonically

normalized kinetic term $-\frac{1}{4}F^a_{\mu\nu}F^{a\,\mu\nu}$ and the structure constants are fixed by the algebra. These are

$$g_s \text{ (for SU(3)}_c\text{)}, \qquad g \text{ (for SU(2)}_L\text{)}, \qquad g' \text{ (for U(1)}_Y\text{)}, \tag{F.86}$$

three real numbers. The hypercharge normalization is the one frozen for this appendix, $Q = T^3 + Y$ with $Y_L = -\frac{1}{2}$ for the lepton doublet; with that convention g' is unambiguous. The single Higgs doublet $H \sim (\mathbf{1}, \mathbf{2}, +\frac{1}{2})$ contributes the two real parameters of its renormalizable potential,

$$V(H) = -\mu^2\, H^\dagger H + \lambda\,(H^\dagger H)^2, \qquad \mu^2 > 0,\ \lambda > 0, \tag{F.87}$$

namely μ^2 (mass dimension two) and the quartic λ (dimensionless). These fix the vacuum expectation value $v^2 = \mu^2/\lambda$ and the physical Higgs mass $m_h^2 = 2\mu^2 = 2\lambda v^2$ recorded in Section F.3; they are independent inputs because no field redefinition relates μ^2 to λ. The coefficient of the Higgs kinetic term and the overall normalization of H are not parameters: they are fixed by canonical normalization, exactly as for the gauge fields.

Finally there is one parameter with no analogue in QED, the QCD vacuum angle. The Lagrangian admits the gauge-invariant, Lorentz-invariant, marginal operator

$$\mathcal{L}_\theta = \theta\,\frac{g_s^2}{32\pi^2}\,G^a_{\mu\nu}\widetilde{G}^{a\,\mu\nu}, \qquad \widetilde{G}^{a\,\mu\nu} = \tfrac{1}{2}\epsilon^{\mu\nu\rho\sigma}G^a_{\rho\sigma}, \tag{F.88}$$

a total derivative locally but with physical effects through the topologically nontrivial gauge configurations established in Chapter 37. Naively this adds a seventh number, θ. It does not add an *independent* one, because θ mixes with the phase of the quark mass determinant under the chiral field rotations we are about to use in the flavor sector. The axial rotation $q_i \to e^{i\alpha_i\gamma_5}q_i$ is not a symmetry of the quantum theory: by the Adler–Bell–Jackiw anomaly proved in Chapter 36 its non-invariance of the path-integral measure shifts the θ-angle. Performing the chiral rotations that make all quark masses real and positive therefore moves the entire CP-violating content of the strong sector into the single rephasing-invariant combination

$$\bar\theta = \theta + \arg\det(M_u M_d), \tag{F.89}$$

where $M_u = (v/\sqrt{2})Y_u$ and $M_d = (v/\sqrt{2})Y_d$ are the quark mass matrices. It is $\bar\theta$, not θ, that is observable (through, e.g., the neutron electric dipole moment), and it is one real parameter. We will keep careful track of this in Section F.4.4 to be sure it is counted exactly once: the chiral rotation that removes the phase $\arg\det(M_u M_d)$ from the Yukawa sector is precisely the rotation that, by the anomaly, generates the shift in θ, so the two bookkeepings agree on a single physical strong-CP angle.

The bosonic and topological tally is therefore

$$\underbrace{g_s,\ g,\ g'}_{3} + \underbrace{\mu^2,\ \lambda}_{2} + \underbrace{\bar{\theta}}_{1} = 6 \tag{F.90}$$

physical parameters.

F.4.3 The flavor sector: broken flavor symmetry

We now turn to the Yukawa couplings, where almost all of the apparent parameters are gauge for the global flavor group and must be subtracted. We work first with the minimal model: three generations and *no* right-handed neutrinos, so neutrinos are exactly massless. The Yukawa Lagrangian is

$$\mathcal{L}_Y = -\,\bar{Q}_L\,\widetilde{H}\,Y_u\,u_R \;-\; \bar{Q}_L\,H\,Y_d\,d_R \;-\; \bar{L}_L\,H\,Y_e\,e_R \;+\; \text{h.c.}, \tag{F.91}$$

with $\widetilde{H} = i\sigma^2 H^*$ the charge-conjugate doublet, and the generation indices suppressed: Y_u, Y_d, Y_e are each a general complex 3×3 matrix in flavor space. A complex 3×3 matrix has 9 complex entries, hence 18 real parameters; three such matrices give the raw count

$$\dim_{\mathbb{R}} \mathcal{Y} \;=\; 3\times 18 \;=\; 54 \tag{F.92}$$

real parameters before any redundancy is removed. We must now remove the redundancy.

The flavor group and how the Yukawas transform. In the limit $Y_u = Y_d = Y_e = 0$ the fermion sector is just five copies (three generations) of canonically normalized chiral kinetic terms, one for each gauge multiplet

$$Q_L \sim (\mathbf{3},\mathbf{2},\tfrac{1}{6}),\quad u_R \sim (\mathbf{3},\mathbf{1},\tfrac{2}{3}),\quad d_R \sim (\mathbf{3},\mathbf{1},-\tfrac{1}{3}),\quad L_L \sim (\mathbf{1},\mathbf{2},-\tfrac{1}{2}),\quad e_R \sim (\mathbf{1},\mathbf{1},-1). \tag{F.93}$$

Each kinetic term $\bar{\psi}\,i\not{D}\,\psi$ is invariant under an independent U(3) rotation acting on the three-dimensional generation index of that multiplet, because U(3) rotations commute with the gauge structure (they act only on flavor) and leave $\bar{\psi}\,i\not{D}\,\psi$ invariant by unitarity. The full global symmetry of the gauge-kinetic terms is therefore

$$G_{\mathrm{F}} = \mathrm{U}(3)_Q\times\mathrm{U}(3)_u\times\mathrm{U}(3)_d\times\mathrm{U}(3)_L\times\mathrm{U}(3)_e \;\equiv\; \mathrm{U}(3)^5, \qquad \dim_{\mathbb{R}} G_{\mathrm{F}} = 5\times 9 = 45, \tag{F.94}$$

using $\dim_{\mathbb{R}}\mathrm{U}(3) = 9$. Under $\psi \to V_\psi\psi$ with $V_\psi \in \mathrm{U}(3)$, the conjugate field transforms as $\bar{\psi}\to\bar{\psi}\,V_\psi^\dagger$, so that the Yukawa terms in (F.91) retain their form provided the coupling matrices are redefined by

$$Y_u \to V_Q^\dagger\,Y_u\,V_u, \qquad Y_d \to V_Q^\dagger\,Y_d\,V_d, \qquad Y_e \to V_L^\dagger\,Y_e\,V_e. \tag{F.95}$$

That is: G_{F} acts on the raw parameter space $\mathcal{Y} \cong \mathbb{C}^{3\times3}\oplus\mathbb{C}^{3\times3}\oplus\mathbb{C}^{3\times3}$, and two points of $\mathcal{Y}$ related by (F.95) are the *same* theory written in two flavor bases. The physical Yukawa parameters are the coordinates on the quotient $\mathcal{Y}/G_{\mathrm{F}}$.

The counting lemma. The dimension of the quotient near a generic point is governed by the stabilizer of that point, by the Lie-algebraic form of the orbit–stabilizer theorem.

Lemma F.11 (Parameter count by broken symmetry)**.** *Let a Lie group G act smoothly on a finite-dimensional real vector space $\mathcal{Y}$, and let $Y_0 \in \mathcal{Y}$ have stabilizer $H = \{h \in G : \ h \cdot Y_0 = Y_0\}$. Then the orbit $G \cdot Y_0$ is a manifold of dimension $\dim G - \dim H$, and the number of physical parameters — the local dimension of the orbit space $\mathcal{Y}/G$ at $[Y_0]$ — is*

$$N_{\text{phys}} = \dim_{\mathbb{R}} \mathcal{Y} - \big(\dim_{\mathbb{R}} G - \dim_{\mathbb{R}} H\big). \tag{F.96}$$

Proof. Consider the orbit map $\mu : G \to \mathcal{Y}$, $\mu(g) = g \cdot Y_0$, with image the orbit $\mathcal{O} = G \cdot Y_0$. Its differential at the identity is the linear map

$$d\mu_e : \ \mathfrak{g} \to T_{Y_0}\mathcal{Y}, \qquad X \mapsto \frac{d}{dt}\Big|_{t=0} e^{tX} \cdot Y_0, \tag{F.97}$$

the infinitesimal action of the Lie algebra $\mathfrak{g}$ on Y_0. The kernel of $d\mu_e$ consists of exactly those X that fix Y_0 to first order; these are the generators of the stabilizer, $\ker d\mu_e = \mathfrak{h} = \mathrm{Lie}(H)$. (An element X with $X \cdot Y_0 = 0$ generates a one-parameter subgroup e^{tX} fixing Y_0, hence lies in $\mathfrak{h}$; conversely every element of $\mathfrak{h}$ annihilates Y_0.) By rank–nullity the image $\operatorname{im} d\mu_e$, which is the tangent space $T_{Y_0}\mathcal{O}$ to the orbit, has dimension $\dim \mathfrak{g} - \dim \mathfrak{h} = \dim G - \dim H$. The orbit directions are precisely the unphysical directions, those along which Y_0 can be moved by a field redefinition without changing the physics; the physical directions are the complement inside $T_{Y_0}\mathcal{Y}$, of dimension $\dim \mathcal{Y} - \dim \mathcal{O}$. This is (F.96). For generic Y_0 the stabilizer dimension is locally constant, so this is the dimension of the quotient near $[Y_0]$. □

Equation (F.96) is the entire engine of the count: physical parameters = raw parameters − broken generators, where a "broken" generator is one that moves Y_0, i.e. one not in the stabilizer. We need only identify the stabilizer of a generic Yukawa configuration.

Worked Example F.12 (The thirteen flavor parameters of the minimal Standard Model)**.** We apply Theorem F.11 with $\mathcal{Y}$ the space of triples (Y_u, Y_d, Y_e), $\dim_{\mathbb{R}} \mathcal{Y} = 54$ from (F.92), and $G = G_{\text{F}} = \mathrm{U}(3)^5$, $\dim_{\mathbb{R}} G = 45$ from (F.94).

Step 1 — the stabilizer. We seek the subgroup of G_{F} that leaves a generic (Y_u, Y_d, Y_e) invariant under (F.95). Because no Yukawa matrix in (F.91) couples the lepton multiplets (L_L, e_R) to the quark multiplets (Q_L, u_R, d_R), the stabilizer factorizes into a quark part inside $\mathrm{U}(3)_Q \times \mathrm{U}(3)_u \times \mathrm{U}(3)_d$ and a lepton part inside $\mathrm{U}(3)_L \times \mathrm{U}(3)_e$, and we treat them separately.

Quark part. A generic pair (Y_u, Y_d) has trivial stabilizer except for an overall phase. Indeed, take V_Q, V_u, V_d with $V_Q^\dagger Y_u V_u = Y_u$ and $V_Q^\dagger Y_d V_d = Y_d$. For generic,

invertible Y_u, Y_d this forces $V_u = Y_u^{-1} V_Q Y_u$ and $V_d = Y_d^{-1} V_Q Y_d$; unitarity of V_u, V_d together with the requirement that the same V_Q work for the two *independent* matrices Y_u, Y_d leaves only $V_Q = e^{i\beta}\mathbf{1}$ (and then $V_u = V_d = e^{i\beta}\mathbf{1}$). This common phase is baryon number $\mathrm{U}(1)_B$: under it Q_L, u_R, d_R all rotate by the same phase, leaving every term of (F.91) invariant. Hence the quark stabilizer is $\mathrm{U}(1)_B$, $\dim = 1$.

Lepton part. With no neutrino Yukawa, only Y_e constrains (V_L, V_e), through $V_L^\dagger Y_e V_e = Y_e$. A single generic invertible matrix Y_e can be brought to diagonal, positive form by its singular-value decomposition, and in that basis the residual freedom is the diagonal phase rotations with $V_L = V_e = \mathrm{diag}(e^{i\gamma_1}, e^{i\gamma_2}, e^{i\gamma_3})$. These are the three separate lepton numbers $\mathrm{U}(1)_{L_e} \times \mathrm{U}(1)_{L_\mu} \times \mathrm{U}(1)_{L_\tau}$, which survive because each charged-lepton flavor is conserved when there is no mechanism to mix the generations. The lepton stabilizer is thus $\mathrm{U}(1)^3$, $\dim = 3$.

Total stabilizer. Therefore

$$H = \mathrm{U}(1)_B \times \mathrm{U}(1)_{L_e} \times \mathrm{U}(1)_{L_\mu} \times \mathrm{U}(1)_{L_\tau}, \qquad \dim_{\mathbb{R}} H = 1 + 3 = 4. \tag{F.98}$$

These four unbroken generators are exactly the accidental global symmetries of the minimal Standard Model identified in Chapter 33: baryon number and the three lepton numbers. They are precisely the directions in G_{F} that do *not* remove a Yukawa parameter.

Step 2 — the count. Inserting into (F.96),

$$N_{\text{flavor}} = \dim \mathcal{Y} - (\dim G_{\mathrm{F}} - \dim H) = 54 - (45 - 4) = 54 - 41 = 13. \tag{F.99}$$

There are thirteen physical flavor parameters.

Step 3 — naming the thirteen. It is worth seeing that these thirteen are exactly the masses and mixings one expects. Run the field redefinitions explicitly, sector by sector.

Quarks. By singular-value decomposition write $Y_u = U_u^L \hat{Y}_u U_u^{R\dagger}$ and $Y_d = U_d^L \hat{Y}_d U_d^{R\dagger}$ with $\hat{Y}_u, \hat{Y}_d$ diagonal, real and non-negative. Choosing $V_Q = U_u^L$, $V_u = U_u^R$ in (F.95) sets $Y_u \to \hat{Y}_u$, diagonal. The same $V_Q = U_u^L$ is now fixed, but we are still free in V_d; choosing $V_d = U_d^R$ removes the right-handed rotation of Y_d, leaving

$$Y_d \to U_u^{L\dagger} U_d^L \hat{Y}_d \;\equiv\; V_{\mathrm{CKM}} \hat{Y}_d, \qquad V_{\mathrm{CKM}} = U_u^{L\dagger} U_d^L \in \mathrm{U}(3). \tag{F.100}$$

The three eigenvalues of $\hat{Y}_u$ and the three of $\hat{Y}_d$ give the **six quark masses** (times $v/\sqrt{2}$). The leftover unitary matrix V_{CKM} is the Cabibbo–Kobayashi–Maskawa matrix; its physical content is counted next.

Leptons. With Y_e alone, the SVD $Y_e = U_e^L \hat{Y}_e U_e^{R\dagger}$ is undone completely by $V_L = U_e^L$, $V_e = U_e^R$, leaving $Y_e \to \hat{Y}_e$ diagonal with no leftover matrix. This yields the **three charged-lepton masses** and *no* lepton mixing: with massless neutrinos the analogue of V_{CKM} is unobservable because any unitary rotation

of the degenerate massless neutrinos can absorb it. That is the field-theoretic statement of why the PMNS matrix is trivial in the minimal model.

Physical content of $V_{\rm CKM}$. We must count how many of the nine real parameters of a 3×3 unitary matrix survive the residual rephasing freedom. After the diagonalizations above, the mass terms $\bar u_L \hat M_u u_R$ and $\bar d_L \hat M_d d_R$ are invariant under independent diagonal phase rotations $u_{L,R}\to P_u\, u_{L,R}$ and $d_{L,R}\to P_d\, d_{L,R}$ with $P_u, P_d \in \mathrm{U}(1)^3$ (the left and right rotations must coincide to keep the diagonal masses real). Under these, $V_{\rm CKM}$ appears in the charged current $\bar u_L \gamma^\mu V_{\rm CKM} d_L\, W^+_\mu$ and transforms as $V_{\rm CKM}\to P_u^\dagger\, V_{\rm CKM}\, P_d$. The $3+3=6$ phases of (P_u, P_d) can absorb six phases of $V_{\rm CKM}$, except that the overall common phase $P_u = P_d = e^{i\alpha}\mathbf{1}$ leaves $V_{\rm CKM}$ untouched — this is again $\mathrm{U}(1)_B$ — so only $6-1=5$ phases are removable. A general U(3) matrix has 9 parameters, decomposed (Theorem F.13 below) into 3 rotation angles and 6 phases; removing 5 phases leaves

$$\#(\mathrm{CKM}) = \underbrace{3}_{\text{angles}} + \underbrace{(6-5)}_{\text{phase}} = 3+1 = 4. \tag{F.101}$$

Three mixing angles and one CP-violating phase.

Assembly. The thirteen physical flavor parameters are

$$\underbrace{6}_{\text{quark masses}} + \underbrace{3}_{\text{lepton masses}} + \underbrace{4}_{\text{CKM: 3 angles+1 phase}} = 13, \tag{F.102}$$

in agreement with (F.99) obtained abstractly from the stabilizer. The two routes — subtract broken generators, or diagonalize and rephase — are the same computation seen from two sides.

The angle/phase decomposition used in (F.101) deserves its own statement, since it recurs for every mixing matrix in the book.

Proposition F.13 (Angles and phases of a unitary mixing matrix)**.** *A general $N\times N$ unitary matrix carries N^2 real parameters, of which*

$$\frac{N(N-1)}{2} \text{ are rotation angles} \qquad \text{and} \qquad \frac{N(N+1)}{2} \text{ are phases.} \tag{F.103}$$

Proof. The Lie group $\mathrm{U}(N)$ has real dimension N^2. Inside it sits the real orthogonal group $\mathrm{O}(N)$, of dimension $\tfrac12 N(N-1)$; its generators are the real antisymmetric matrices, which generate the genuine rotations (the "angles"), and these are precisely the parameters that remain in the special case of a real unitary — i.e. orthogonal — matrix. The remaining $N^2 - \tfrac12 N(N-1) = \tfrac12 N(N+1)$ generators of $\mathrm{U}(N)$ lie in the coset directions $\mathrm{U}(N)/\mathrm{O}(N)$; they are the imaginary symmetric generators and parametrize the phases. The split $N^2 = \tfrac12 N(N-1) + \tfrac12 N(N+1)$ is exact. □

For $N=3$, (F.103) gives 3 angles and 6 phases, the inputs to (F.101).

F.4.4 The total: nineteen

Adding the bosonic-plus-topological tally (F.90) to the flavor tally (F.102),

$$N_{\mathrm{SM}} = \underbrace{6}_{g_s,g,g',\mu^2,\lambda,\bar{\theta}} + \underbrace{13}_{\text{Yukawa sector}} = 19 \tag{F.104}$$

physical parameters in the minimal Standard Model with massless neutrinos. Table F.3 records the breakdown.

Sector	Parameters	Count
Gauge couplings	$g_s,\ g,\ g'$	3
Higgs potential	$\mu^2,\ \lambda$	2
Strong CP	$\bar{\theta}$	1
Quark masses	$m_u, m_c, m_t,\ m_d, m_s, m_b$	6
Charged-lepton masses	m_e, m_μ, m_τ	3
CKM mixing	3 angles + 1 phase	4
Total		**19**

Table F.3: The nineteen physical parameters of the minimal Standard Model (massless neutrinos). The flavor block (last three rows, thirteen parameters) is the orbit-space dimension computed in Theorem F.12.

A word is owed on the consistency of the $\bar{\theta}$ entry with the flavor count, because the same chiral rotations enter both.

Caution: no double counting of the strong-CP angle

In Theorem F.12 the full group $G_{\mathrm{F}} = \mathrm{U}(3)^5$ was treated as legitimate field-redefinition freedom, including the overall axial rotation $q_i \to e^{i\alpha\gamma_5} q_i$ of all quarks — the generator $\mathrm{U}(1)_A$ that rotates left and right quark fields by opposite phases. That rotation is *not* in the stabilizer (F.98); it changes $\arg\det(Y_u Y_d)$, and we duly used it (as part of the diagonalization and rephasing) to make the quark masses real. But $\mathrm{U}(1)_A$ is anomalous: by the result imported from Chapter 36, performing it shifts the topological angle, $\theta \to \theta - 2N_f\,\alpha = \theta - 4N_g\,\alpha$ in the normalization of (F.88) (with $N_f = 2N_g = 6$ quark flavors, each Dirac mass picking up a phase $e^{2i\alpha}$ so that $\arg\det(M_u M_d)$ shifts by $2N_f\alpha$). Hence the phase that one "removes" from the Yukawa sector by an axial rotation does not vanish from the theory: it reappears as a shift of θ. What is invariant under the entire chiral redefinition group — and therefore physical — is the combination $\bar{\theta} = \theta + \arg\det(M_u M_d)$ of (F.89). The bookkeeping is now unambiguous: the flavor count of 13 uses all of G_{F} to reach the mass basis with real masses, and the residual physical strong-CP content is the single number

$\bar{\theta}$, counted once in the bosonic block. Equivalently, one may count 12 flavor parameters using only the non-anomalous $\mathrm{SU}(3)^5 \times \mathrm{U}(1)^4$ field redefinitions and keep θ as a separate input; the total is unchanged. Either way $\mathrm{SU}(3)_c \times \mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$ has nineteen physical parameters.

F.4.5 The neutrino-mass extensions

The observation of neutrino oscillations forces nonzero neutrino masses, and the count grows. The two minimal mechanisms — a Dirac mass from new right-handed neutrinos, or a Majorana mass from the dimension-five Weinberg operator — give different counts, and the difference is instructive: it is entirely about which rephasings remain available. We record the counts here; the mechanisms themselves (the seesaw, the origin of the Weinberg operator) are deferred to Chapter 35.

Worked Example F.14 (Dirac neutrinos add seven parameters)**.** Introduce three right-handed neutrinos $\nu_R \sim (\mathbf{1}, \mathbf{1}, 0)$, gauge singlets, and forbid a Majorana mass for them (e.g. by imposing exact lepton number). The Yukawa Lagrangian (F.91) gains the term $-\bar{L}_L \widetilde{H}\, Y_\nu\, \nu_R + \text{h.c.}$, with Y_ν a fourth general complex 3×3 matrix.

Raw count. Four complex 3×3 matrices: $\dim \mathcal{Y} = 4 \times 18 = 72$.

Flavor group. The new singlet field carries its own $\mathrm{U}(3)_\nu$ flavor rotation, so $G_\mathrm{F} \to \mathrm{U}(3)^6$, $\dim = 6 \times 9 = 54$. The new transformation law is $Y_\nu \to V_L^\dagger Y_\nu V_\nu$.

Stabilizer. The quark part is unchanged, $\mathrm{U}(1)_B$, $\dim = 1$. In the lepton sector Y_e and Y_ν now play exactly the roles Y_u, Y_d played for quarks: two independent generic matrices sharing the common V_L. By the same argument as the quark case, the only surviving lepton rotation is the overall common phase, total lepton number $\mathrm{U}(1)_L$, $\dim = 1$. The three separate lepton numbers are now broken — Y_e and Y_ν cannot be simultaneously diagonalized, exactly as Y_u, Y_d could not — leaving only their sum. So

$$H = \mathrm{U}(1)_B \times \mathrm{U}(1)_L, \qquad \dim H = 2. \tag{F.105}$$

Count. By (F.96),

$$N_\mathrm{flavor}^\mathrm{Dirac} = 72 - (54 - 2) = 72 - 52 = 20, \tag{F.106}$$

that is $20 - 13 = 7$ more than the minimal model. Naming them: the lepton sector now mirrors the quark sector exactly, giving 3 charged-lepton masses, 3 neutrino masses, and a lepton mixing matrix U_PMNS with — by (F.101) run identically — 3 angles and 1 phase. The seven new parameters are 3 neutrino masses $+3$ PMNS angles $+1$ PMNS (Dirac) phase. The grand total becomes $19 + 7 = 26$.

Worked Example F.15 (Majorana neutrinos add nine parameters)**.** Now give neutrinos mass without new light fields, through the unique dimension-five operator built from Standard Model fields, the Weinberg operator

$$\mathcal{L}_5 = \frac{c_{ij}}{2\Lambda}\,(\overline{L^c_{L\,i}}\,\widetilde{H}^*)(\widetilde{H}^\dagger L_{L\,j}) + \text{h.c.}, \tag{F.107}$$

which after electroweak symmetry breaking produces a Majorana mass matrix $M_\nu = (v^2/\Lambda)\,c$ for the left-handed neutrinos. Because the operator is symmetric under $i \leftrightarrow j$ (the two lepton doublets are contracted symmetrically; the antisymmetric part vanishes by Fermi statistics together with the $\mathrm{SU}(2)_L$ contraction), c is a complex *symmetric* 3×3 matrix.

Raw count, lepton sector. A complex symmetric 3×3 matrix has 6 independent complex entries, i.e. 12 real parameters; together with Y_e (18 real), the lepton-sector raw count is $12 + 18 = 30$. (The quark sector is untouched: 36 raw, stabilizer $\mathrm{U}(1)_B$, giving its 10 as before.)

Flavor group, lepton sector. There is no ν_R to rotate, so the lepton flavor group is just $\mathrm{U}(3)_L \times \mathrm{U}(3)_e$, dim = 18. Under it $Y_e \to V_L^\dagger Y_e V_e$ as before, while the symmetric coupling transforms as $c \to V_L^T\, c\, V_L$ — note *two* factors of V_L and a transpose, because both doublets in (F.107) are L_L and one is charge-conjugated.

Stabilizer. Here is the crucial difference. The Majorana mass term is not invariant under any rephasing of the neutrinos: a phase rotation $L_L \to e^{i\alpha} L_L$ sends $c \to e^{2i\alpha} c \neq c$. Lepton number is violated by (F.107), so $\mathrm{U}(1)_L$ is gone. A generic symmetric c together with a generic Y_e has no continuous stabilizer at all in $\mathrm{U}(3)_L \times \mathrm{U}(3)_e$:

$$H_{\text{lepton}} = \{\,\mathbf{1}\,\}, \qquad \dim H_{\text{lepton}} = 0. \tag{F.108}$$

Count, lepton sector. By (F.96),

$$N^{\text{Maj}}_{\text{lepton}} = 30 - (18 - 0) = 30 - 18 = 12, \tag{F.109}$$

two more than the Dirac lepton count of 10 found in Theorem F.14. Adding the unchanged quark sector (10), the flavor total is 22, i.e. 9 more than the minimal model. The grand total is $19 + 9 = 28$.

Naming the twelve, and the extra phases. The twelve are 3 charged-lepton masses + 3 neutrino masses + 6 in the PMNS matrix. To see why the mixing matrix now holds 6 rather than 4, repeat the rephasing argument of (F.101) but with the Majorana constraint. In the charged-lepton mass basis the mixing matrix U_{PMNS} appears in the charged current $\bar{e}_L \gamma^\mu U_{\text{PMNS}}\, \nu_L W^-_\mu$. We may still rephase the charged leptons, $e_{L,R} \to P_e\, e_{L,R}$ with $P_e \in \mathrm{U}(1)^3$, sending $U_{\text{PMNS}} \to P_e^\dagger U_{\text{PMNS}}$. But we *cannot* rephase the neutrinos: a phase on ν_L would have to be undone in the Majorana mass term, where it does not cancel. So only $N = 3$ phases are removable, not the $2N - 1 = 5$ of the Dirac case. With

$U_{\mathrm{PMNS}} \in \mathrm{U}(3)$ carrying 3 angles and 6 phases by Theorem F.13,

$$\#(\text{PMNS, Majorana}) = \underbrace{3}_{\text{angles}} + \underbrace{(6-3)}_{\text{phases}} = 3+3, \tag{F.110}$$

namely 3 angles, 1 Dirac phase, and 2 further *Majorana* phases. The two extra phases relative to the Dirac case are precisely the $N-1=2$ neutrino rephasings that the Dirac theory could use to clean the matrix but the Majorana theory cannot. This is the promised origin of the Majorana phases: they are physical only because the Majorana mass removes the right-handed rephasing freedom.

Remark F.16 (The general pattern). For N generations the difference between the Majorana and Dirac mixing phases is always $N-1$: the Dirac count of removable phases is $2N-1$ (left and right rephasings minus one overall conserved $\mathrm{U}(1)$), the Majorana count is N (charged-lepton rephasings only, no conserved $\mathrm{U}(1)$ to subtract), and $(2N-1)-N=N-1$. Equivalently, a Majorana U_{PMNS} has $\frac{1}{2}N(N-1)$ physical phases against the Dirac $\frac{1}{2}(N-1)(N-2)$; their difference is $N-1$. For $N=3$ this is the two Majorana phases of (F.110).

We have now turned the slogan "nineteen parameters" into a theorem and tracked exactly how that number grows — by seven for Dirac neutrinos, by nine for Majorana — once the lepton sector is given mass. In both extensions the new physics is carried by a lepton mixing matrix with a definite number of angles and phases, just as the quark sector carries the CKM matrix with its three angles and one phase. Those mixing matrices — their standard angular parametrizations, the placement of the physical phases, and the rephasing-invariant measure of CP violation that distinguishes them — are the objects the next section makes explicit.

F.5 Mixing Matrices: CKM and PMNS

The parameter count of Section F.4 returned a sharp verdict about the flavor sector: once the three families of quarks are given their physical masses, the residual freedom in how the charged weak current connects up-type to down-type quarks is exactly *three mixing angles and one CP-violating phase*, and not one parameter more. The leptonic copy of the same argument returns, in the Majorana case, three angles and three phases. Those are *counts*: they tell us how many real numbers the data must supply, but they do not yet tell us in what shape to write the matrix that carries them, nor which combination of entries is the genuinely physical, convention-independent signature of CP violation. The job of this section is to convert the count into concrete, standard objects. We construct the explicit standard parametrization of the quark mixing matrix V_{CKM} by exhibiting how a general 3×3 unitary matrix collapses, under the maximal allowed rephasing of the quark fields, to precisely three angles and

one phase; we record the Wolfenstein expansion that organizes the measured hierarchy of V_{CKM} in powers of a single small number and the unitarity-triangle picture it makes vivid; we define the Jarlskog invariant and prove that it is rephasing invariant and equal to twice the area of any unitarity triangle; and we write the leptonic mixing matrix U_{PMNS} as the direct analog, flagging the extra Majorana phases that the count above already anticipated. The *origin* of these matrices—that V_{CKM} is the residue of diagonalizing the quark Yukawa couplings after electroweak symmetry breaking, and U_{PMNS} the residue of diagonalizing the charged-lepton and neutrino mass terms—is proved in Chapter 32 (quarks) and Chapter 35 (the neutrino-mass extensions); we import those results by reference and never reprove them here. What we owe in full, because it is load-bearing data-organizing machinery that lives nowhere else in the book, is the passage from "a unitary matrix" to "the standard matrix with its three angles, one phase, and a single invariant."

F.5.1 From a unitary matrix to three angles and one phase

We begin with the object handed to us by the diagonalization of the quark Yukawa matrices. Recall from Chapter 32 that after electroweak symmetry breaking the up- and down-type quark mass matrices M_u, M_d are brought to real, positive, diagonal form by independent unitary rotations of the left- and right-handed quark fields,

$$U_{uL}^{\dagger}\, M_u\, U_{uR} = \mathrm{diag}(m_u, m_c, m_t), \qquad U_{dL}^{\dagger}\, M_d\, U_{dR} = \mathrm{diag}(m_d, m_s, m_b), \tag{F.111}$$

and that the only place this biunitary freedom fails to cancel is in the charged weak current $J_{+}^{\mu} \propto \bar{u}_L \gamma^{\mu} d_L$, where the two *left-handed* rotations survive in the combination

$$V_{\mathrm{CKM}} \;\equiv\; U_{uL}^{\dagger}\, U_{dL}, \tag{F.112}$$

the Cabibbo–Kobayashi–Maskawa matrix [101, 298]. Being the product of two unitary matrices, V_{CKM} is itself unitary, $V_{\mathrm{CKM}}^{\dagger} V_{\mathrm{CKM}} = \mathbf{1}$. That is the entire input from Chapter 32. From here the analysis is pure linear algebra and rephasing bookkeeping, and we carry it out in full.

A unitary $N \times N$ matrix has, as a real manifold, dimension N^2: the defining condition $V^{\dagger}V = \mathbf{1}$ imposes N^2 real constraints on the $2N^2$ real parameters of a general complex matrix. We sort those N^2 real parameters into two kinds, because they behave differently under rephasing. Write $V = \exp(iH)$ with H Hermitian; split H into its real symmetric part and its imaginary antisymmetric part. The real, antisymmetric directions generate the real orthogonal subgroup $\mathrm{O}(N)$ and correspond to genuine *rotation angles*; there are

$$n_{\mathrm{angle}} = \dim \mathrm{O}(N) = \frac{N(N-1)}{2} \tag{F.113}$$

of them. The remaining

$$n_{\text{phase}} = N^2 - \frac{N(N-1)}{2} = \frac{N(N+1)}{2} \tag{F.114}$$

parameters are *phases*. The split is exhaustive and the two numbers sum to N^2, as they must. For $N = 3$ this is 3 angles and 6 phases.

Not all of those phases are physical, because the matrix V_{CKM} is not an observable in isolation: it appears sandwiched between quark fields whose phases we are free to redefine without changing any physics. A rephasing of the mass-eigenstate quark fields,

$$u_i \;\to\; e^{i\alpha_i}\, u_i, \qquad d_j \;\to\; e^{i\beta_j}\, d_j \qquad (i, j = 1, \ldots, N), \tag{F.115}$$

leaves the kinetic terms, the diagonal mass terms, and the neutral currents invariant—each of those involves a field paired with its own conjugate, so the phase cancels—while the charged current $\bar{u}_{Li}(V_{\text{CKM}})_{ij}\gamma^\mu d_{Lj}$ is invariant if and only if we simultaneously transform

$$(V_{\text{CKM}})_{ij} \;\to\; e^{-i\alpha_i}\,(V_{\text{CKM}})_{ij}\,e^{i\beta_j} \;=\; e^{\,i(\beta_j-\alpha_i)}\,(V_{\text{CKM}})_{ij}. \tag{F.116}$$

Two matrices related by Eq. (F.116) describe identical physics; the physical content of V_{CKM} is the equivalence class. The transformation Eq. (F.116) depends on $2N$ phases $\{\alpha_i, \beta_j\}$, but not all $2N$ act: the diagonal shift $\alpha_i \to \alpha_i + c$, $\beta_j \to \beta_j + c$ by a common constant c leaves every $(V_{\text{CKM}})_{ij}$ untouched, because only the difference $\beta_j - \alpha_i$ enters. Exactly one combination is therefore inert, so the number of independent rephasings that can be used to remove parameters from V_{CKM} is

$$n_{\text{rephase}} = 2N - 1. \tag{F.117}$$

Theorem F.17 (Physical content of an N-family quark mixing matrix)**.** *A unitary $N \times N$ quark mixing matrix, modulo the rephasing freedom Eq. (F.115) of the quark mass eigenstates, carries exactly*

$$n_{angle} = \frac{N(N-1)}{2} \quad \textit{rotation angles} \qquad \textit{and} \qquad n_\delta = \frac{(N-1)(N-2)}{2} \quad \textit{physical phases,} \tag{F.118}$$

for a total of $(N-1)^2$ physical parameters. For $N = 3$ this is 3 angles and 1 phase.

Proof. Rephasings Eq. (F.115) are pure phase transformations: they shift the n_{phase} phases of V but cannot touch a rotation angle, since multiplying matrix entries by pure phases never changes the moduli $|V_{ij}|$ on which the angles depend. The angle count Eq. (F.113) is therefore physical as it stands. Of the $n_{\text{phase}} = N(N+1)/2$ phases in V, we may remove $n_{\text{rephase}} = 2N-1$ by a suitable choice of $\{\alpha_i, \beta_j\}$—and we can remove that many and no more, because the

$2N-1$ independent differences $\beta_j-\alpha_i$ that act on V are linearly independent as functions on the phase directions, so they fix $2N-1$ of the phases to any desired values (e.g. zero). The number of phases that survive every rephasing is thus

$$n_\delta = \frac{N(N+1)}{2} - (2N-1) = \frac{N^2+N-4N+2}{2} = \frac{N^2-3N+2}{2} = \frac{(N-1)(N-2)}{2}. \tag{F.119}$$

Adding the angles, the total physical parameter count is

$$n_{\text{angle}} + n_\delta = \frac{N(N-1)}{2} + \frac{(N-1)(N-2)}{2} = \frac{(N-1)\big[N+(N-2)\big]}{2} = \frac{(N-1)(2N-2)}{2} = (\tag{F.120}$$

Setting $N=3$ gives $n_{\text{angle}}=3$, $n_\delta=1$, total 4. □

Theorem F.17 is the linear-algebra core behind the verdict of Section F.4, now exhibited entry by entry. Two features deserve emphasis. First, the phase count n_δ *vanishes for* $N=1$ *and* $N=2$: a single family has no mixing, and—this is the Kobayashi–Maskawa observation [298]—two families have only the single Cabibbo angle and *no* physical phase, so CP violation in the quark sector is impossible with fewer than three families. The existence of a CP-violating phase in the charged current is, by this counting, a prediction that there be at least a third quark family. Second, the count is silent about *how* to distribute the surviving 3 angles and 1 phase among the entries; that distribution is a convention, and we fix it now.

F.5.2 The standard parametrization

The canonical convention factors V_{CKM} into three complex rotations in the $(1,2)$, $(1,3)$, and $(2,3)$ planes, with the single physical phase δ attached to the $(1,3)$ rotation. Write $c_{ij}=\cos\theta_{ij}$ and $s_{ij}=\sin\theta_{ij}$ for the three angles $\theta_{12},\theta_{13},\theta_{23}\in[0,\pi/2]$, and $\delta\in[0,2\pi)$ for the phase.

Definition F.18 (Standard parametrization of the CKM matrix)**.**

$$V_{\text{CKM}} = \underbrace{\begin{pmatrix} 1 & 0 & 0 \\ 0 & c_{23} & s_{23} \\ 0 & -s_{23} & c_{23} \end{pmatrix}}_{R_{23}} \underbrace{\begin{pmatrix} c_{13} & 0 & s_{13}e^{-i\delta} \\ 0 & 1 & 0 \\ -s_{13}e^{i\delta} & 0 & c_{13} \end{pmatrix}}_{U_{13}(\delta)} \underbrace{\begin{pmatrix} c_{12} & s_{12} & 0 \\ -s_{12} & c_{12} & 0 \\ 0 & 0 & 1 \end{pmatrix}}_{R_{12}}. \tag{F.121}$$

Each factor is manifestly unitary, so the product is unitary; R_{23} and R_{12} are real rotations carrying the angles θ_{23},θ_{12}, while the central factor $U_{13}(\delta)$ carries both the angle θ_{13} and the phase δ. Multiplying the three factors out—first $U_{13}R_{12}$, then left-multiplying by R_{23}—gives the explicit matrix that the

numerical section will populate:

$$V_{\mathrm{CKM}} = \begin{pmatrix} V_{ud} & V_{us} & V_{ub} \\ V_{cd} & V_{cs} & V_{cb} \\ V_{td} & V_{ts} & V_{tb} \end{pmatrix} = \begin{pmatrix} c_{12}c_{13} & s_{12}c_{13} & s_{13}e^{-i\delta} \\ -s_{12}c_{23} - c_{12}s_{23}s_{13}e^{i\delta} & c_{12}c_{23} - s_{12}s_{23}s_{13}e^{i\delta} & s_{23}c_{13} \\ s_{12}s_{23} - c_{12}c_{23}s_{13}e^{i\delta} & -c_{12}s_{23} - s_{12}c_{23}s_{13}e^{i\delta} & c_{23}c_{13} \end{pmatrix}. \tag{F.122}$$

The labeling of rows by (u, c, t) and columns by (d, s, b) is fixed: V_{ij} is the amplitude for the charged-current transition between up-type quark i and down-type quark j. Three entries are especially transparent: the corners $V_{us} = s_{12}c_{13}$, $V_{cb} = s_{23}c_{13}$, and $V_{ub} = s_{13}e^{-i\delta}$ isolate the three angles directly (up to the small $c_{13} \approx 1$ corrections), and the phase δ sits, in this convention, on the smallest entry V_{ub} (and on V_{td}). One verifies unitarity of Eq. (F.122) by direct computation; we record the diagonal check for the first column, since it exhibits the cancellation pattern that the unitarity triangles below make geometric:

$$\begin{aligned} |V_{ud}|^2 + |V_{cd}|^2 + |V_{td}|^2 &= c_{12}^2 c_{13}^2 + \left|-s_{12}c_{23} - c_{12}s_{23}s_{13}e^{i\delta}\right|^2 + \left|s_{12}s_{23} - c_{12}c_{23}s_{13}e^{i\delta}\right|^2 \\ &= c_{12}^2 c_{13}^2 + s_{12}^2 c_{23}^2 + c_{12}^2 s_{23}^2 s_{13}^2 + 2 s_{12}c_{23}c_{12}s_{23}s_{13}\cos\delta \\ &\quad + s_{12}^2 s_{23}^2 + c_{12}^2 c_{23}^2 s_{13}^2 - 2 s_{12}s_{23}c_{12}c_{23}s_{13}\cos\delta \\ &= c_{12}^2 c_{13}^2 + s_{12}^2(c_{23}^2 + s_{23}^2) + c_{12}^2 s_{13}^2 (s_{23}^2 + c_{23}^2) \\ &= c_{12}^2 c_{13}^2 + s_{12}^2 + c_{12}^2 s_{13}^2 = c_{12}^2(c_{13}^2 + s_{13}^2) + s_{12}^2 = c_{12}^2 + s_{12}^2 = 1, \end{aligned} \tag{F.123}$$

where the two $\cos\delta$ cross terms cancelled identically—a foretaste of the fact that the phase δ drops out of the moduli-squared sums but survives in the imaginary cross terms that measure CP violation.

F.5.3 The Wolfenstein expansion

Measurement shows the CKM matrix is strongly hierarchical: it is nearly the identity, with the off-diagonal entries falling off in a regular pattern. The $(1,2)$ mixing $|V_{us}| \approx 0.22$ is the largest off-diagonal element; the $(2,3)$ mixing $|V_{cb}|$ is roughly its square, and the $(1,3)$ mixing $|V_{ub}|$ roughly its cube. Wolfenstein [526] packaged this hierarchy by introducing the single small parameter

$$\lambda \equiv s_{12} = \frac{|V_{us}|}{\sqrt{|V_{ud}|^2 + |V_{us}|^2}} \approx 0.225, \tag{F.124}$$

and expressing the remaining three parameters through numbers A, ρ, η of order unity defined by the *exact* relations

$$s_{12} = \lambda, \qquad s_{23} = A\lambda^2, \qquad s_{13}e^{-i\delta} = A\lambda^3(\rho - i\eta). \tag{F.125}$$

Equation (F.125) is a change of variables, not an approximation: given the four measured quantities $(\theta_{12}, \theta_{13}, \theta_{23}, \delta)$ it defines (λ, A, ρ, η) uniquely, and

conversely. The utility appears when we substitute Eq. (F.125) into the explicit matrix Eq. (F.122) and expand in λ. Using $c_{12} = \sqrt{1-\lambda^2} = 1 - \tfrac{1}{2}\lambda^2 + O(\lambda^4)$, $c_{13} = 1 + O(\lambda^6)$, $c_{23} = 1 + O(\lambda^4)$, one finds entry by entry:

$$V_{ud} = c_{12}c_{13} = 1 - \tfrac{1}{2}\lambda^2 + O(\lambda^4), \tag{F.126}$$

$$V_{us} = s_{12}c_{13} = \lambda + O(\lambda^7), \tag{F.127}$$

$$V_{ub} = s_{13}e^{-i\delta} = A\lambda^3(\rho - i\eta), \tag{F.128}$$

$$V_{cb} = s_{23}c_{13} = A\lambda^2 + O(\lambda^8), \tag{F.129}$$

$$V_{cd} = -s_{12}c_{23} - c_{12}s_{23}s_{13}e^{i\delta} = -\lambda + O(\lambda^5), \tag{F.130}$$

$$V_{cs} = c_{12}c_{23} - s_{12}s_{23}s_{13}e^{i\delta} = 1 - \tfrac{1}{2}\lambda^2 + O(\lambda^4), \tag{F.131}$$

$$V_{td} = s_{12}s_{23} - c_{12}c_{23}s_{13}e^{i\delta} = A\lambda^3(1 - \rho - i\eta) + O(\lambda^5), \tag{F.132}$$

$$V_{ts} = -c_{12}s_{23} - s_{12}c_{23}s_{13}e^{i\delta} = -A\lambda^2 + O(\lambda^4), \tag{F.133}$$

$$V_{tb} = c_{23}c_{13} = 1 + O(\lambda^4). \tag{F.134}$$

The single subtle entry is V_{td}. Its leading piece is $s_{12}s_{23} - c_{12}c_{23}\,s_{13}e^{i\delta}$; with $s_{13}e^{i\delta} = (s_{13}e^{-i\delta})^* = A\lambda^3(\rho + i\eta)$ this is $\lambda \cdot A\lambda^2 - 1 \cdot A\lambda^3(\rho + i\eta) = A\lambda^3(1 - \rho - i\eta)$, as quoted. Collecting the results gives the standard Wolfenstein matrix,

$$V_{\mathrm{CKM}} = \begin{pmatrix} 1 - \tfrac{1}{2}\lambda^2 & \lambda & A\lambda^3(\rho - i\eta) \\ -\lambda & 1 - \tfrac{1}{2}\lambda^2 & A\lambda^2 \\ A\lambda^3(1 - \rho - i\eta) & -A\lambda^2 & 1 \end{pmatrix} + O(\lambda^4). \tag{F.135}$$

The hierarchy is now visible at a glance: the diagonal is 1 up to $O(\lambda^2)$, the Cabibbo block is $O(\lambda)$, the $(2,3)$ mixing is $O(\lambda^2)$, and the $(1,3)$ corners are $O(\lambda^3)$ and complex. CP violation lives entirely in those small complex corners; the imaginary part is controlled by η, and $\eta \neq 0$ is the statement that the Standard Model violates CP.

It is worth recording that the variables (ρ, η) defined by Eq. (F.125) carry $O(\lambda^2)$ convention dependence, which the phenomenology removes by working instead with the *barred* variables

$$\bar{\rho} + i\bar{\eta} \;\equiv\; -\frac{V_{ud}V_{ub}^*}{V_{cd}V_{cb}^*}, \tag{F.136}$$

a ratio that is manifestly rephasing invariant (each quark phase cancels between numerator and denominator) and hence a genuine observable. Expanding the right-hand side with Eq. (F.135) gives $\bar{\rho} + i\bar{\eta} = (\rho + i\eta)(1 - \tfrac{1}{2}\lambda^2) + O(\lambda^4)$, so the barred and unbarred pairs agree at leading order and differ only at the percent level; the numerical section quotes $\bar{\rho}, \bar{\eta}$. The definition Eq. (F.136) is also exactly the apex of the unitarity triangle, to which we now turn.

F.5.4 Unitarity triangles

Unitarity of V_{CKM} means its rows are orthonormal and so are its columns. The six off-diagonal orthogonality relations each assert that three complex numbers sum to zero, and three complex numbers summing to zero form a closed triangle in the complex plane—a *unitarity triangle*. The phenomenologically central one comes from the orthogonality of the first (d) and third (b) columns:

$$V_{ud}V_{ub}^{*} + V_{cd}V_{cb}^{*} + V_{td}V_{tb}^{*} = 0. \tag{F.137}$$

Each of the three terms is, from Eq. (F.135), of order λ^3: this is the one triangle whose three sides are comparable in magnitude (the others are badly "squashed," with one side much shorter than the others), which is why it is the one drawn and measured. Dividing Eq. (F.137) by the (essentially real) middle term $V_{cd}V_{cb}^{*}$ normalizes the base of the triangle to unit length and places its two ends at 0 and 1 on the real axis:

$$\underbrace{\frac{V_{ud}V_{ub}^{*}}{V_{cd}V_{cb}^{*}}}_{=-(\bar{\rho}+i\bar{\eta})} + 1 + \underbrace{\frac{V_{td}V_{tb}^{*}}{V_{cd}V_{cb}^{*}}}_{=-(1-\bar{\rho}-i\bar{\eta})} = 0, \tag{F.138}$$

where the first ratio is $-(\bar{\rho}+i\bar{\eta})$ by Eq. (F.136), and the third follows from the same expansion. Reading Eq. (F.138) as "vector from 1 to apex" plus "base" plus "vector from apex to 0," the apex of the normalized triangle sits at the point $(\bar{\rho},\bar{\eta})$ in the complex plane. The three interior angles, named α,β,γ (equivalently ϕ_2,ϕ_1,ϕ_3), are themselves rephasing-invariant phase differences of CKM products and are measured independently in B-meson decays; their sum is π because the figure is a Euclidean triangle, and the experimental confirmation that $\alpha+\beta+\gamma=\pi$ within errors is a nontrivial test of the three-family unitarity of V_{CKM}. Figure F.1 draws the triangle.

F.5.5 The Jarlskog invariant

The phase δ in Eq. (F.122), and the parameter η in Eq. (F.135), are convention-dependent: a rephasing Eq. (F.116) shuffles where the phase "sits" and can even make a chosen entry real. What cannot be shuffled away—if CP is genuinely violated—is an overall, rephasing-invariant measure. Jarlskog [284] identified the unique (up to sign) such measure for three families.

Definition F.19 (Jarlskog invariant)**.**

$$J \;\equiv\; \mathrm{Im}\!\left(V_{us}\,V_{cb}\,V_{ub}^{*}\,V_{cs}^{*}\right). \tag{F.139}$$

The combination is built from a 2×2 minor: two entries and the complex conjugates of the two entries obtained by swapping both their row and their

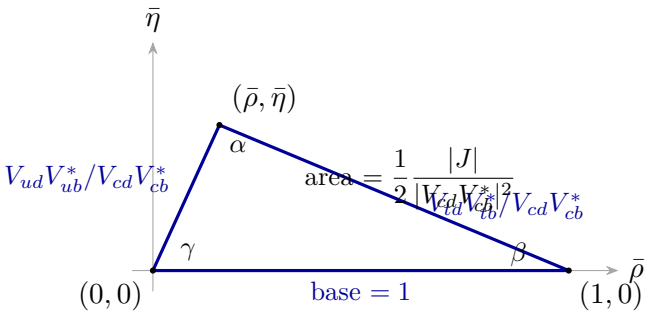

Figure F.1: The rescaled db unitarity triangle in the $(\bar\rho,\bar\eta)$ plane, from the column-orthogonality relation Eq. (F.137) divided by $V_{cd}V_{cb}^*$. The base runs from $(0,0)$ to $(1,0)$ and the apex sits at $(\bar\rho,\bar\eta)$; the interior angles α,β,γ satisfy $\alpha+\beta+\gamma=\pi$. The triangle has nonzero area precisely when $\bar\eta\neq 0$, i.e. when CP is violated; its area equals $|J|/2$ once the sides are restored to their unnormalized lengths, with J the Jarlskog invariant of Theorem F.19.

column indices $(us, cb$ paired with $ub, cs)$. This index structure is what makes it rephasing invariant, and the imaginary part is what makes it the CP-odd observable. We prove both facts, and then connect J to the triangle area.

Theorem F.20 (Properties of the Jarlskog invariant)**.** *The quantity J of Eq. (F.139) is invariant under the quark rephasing Eq. (F.116); it equals*

$$J = c_{12}c_{23}c_{13}^2\, s_{12}s_{23}s_{13}\,\sin\delta \tag{F.140}$$

in the standard parametrization, hence vanishes if and only if some angle is 0 or $\pi/2$ or $\sin\delta = 0$; and all six CKM unitarity triangles have the same area, equal to $|J|/2$.

Proof. Rephasing invariance. Under Eq. (F.116) each entry acquires a phase $V_{ij}\to e^{i(\beta_j-\alpha_i)}V_{ij}$, so the product in Eq. (F.139) acquires the phase

$$\begin{aligned}&\big[(\beta_s-\alpha_u)\big]_{V_{us}} + \big[(\beta_b-\alpha_c)\big]_{V_{cb}} - \big[(\beta_b-\alpha_u)\big]_{V_{ub}^*} - \big[(\beta_s-\alpha_c)\big]_{V_{cs}^*}\\ &\quad= (\beta_s-\alpha_u)+(\beta_b-\alpha_c)-(\beta_b-\alpha_u)-(\beta_s-\alpha_c) = 0,\end{aligned} \tag{F.141}$$

the rows (u,c) and columns (s,b) each appearing once with $+$ and once with $-$. The product $V_{us}V_{cb}V_{ub}^*V_{cs}^*$ is therefore invariant, and so is its imaginary part J. This is the algebraic reason Theorem F.19 is built from a closed "box" of indices: every rephasing phase cancels.

Standard-parametrization value. Insert the entries from Eq. (F.122): $V_{us} = s_{12}c_{13}$, $V_{cb} = s_{23}c_{13}$, $V_{ub}^* = s_{13}e^{i\delta}$, and $V_{cs}^* = c_{12}c_{23} - s_{12}s_{23}s_{13}e^{-i\delta}$. The product is

$$V_{us}V_{cb}V_{ub}^*V_{cs}^* = (s_{12}c_{13})(s_{23}c_{13})(s_{13}e^{i\delta})(c_{12}c_{23} - s_{12}s_{23}s_{13}e^{-i\delta})$$

$$= s_{12}s_{23}s_{13}c_{13}^2\, e^{i\delta}\left(c_{12}c_{23} - s_{12}s_{23}s_{13}e^{-i\delta}\right)$$
$$= s_{12}s_{23}s_{13}c_{13}^2\left(c_{12}c_{23}\, e^{i\delta} - s_{12}s_{23}s_{13}\right). \tag{F.142}$$

The second term inside the brackets is real; taking the imaginary part keeps only $c_{12}c_{23}\sin\delta$ from the first, giving

$$J = \mathrm{Im}(V_{us}V_{cb}V_{ub}^*V_{cs}^*) = c_{12}c_{23}c_{13}^2\, s_{12}s_{23}s_{13}\,\sin\delta, \tag{F.143}$$

which is Eq. (F.140). Since every factor of a cosine or sine of an angle appears, $J = 0$ whenever any $\theta_{ij} \in \{0, \pi/2\}$ (a degenerate rotation) or $\sin\delta = 0$ (no genuine phase); CP violation requires all three angles to be nondegenerate *and* a nontrivial phase, exactly as the count of Theorem F.17 demanded.

Area of a unitarity triangle. Take any column-orthogonality relation, $\sum_i V_{i\alpha}V_{i\beta}^* = 0$ with $\alpha \neq \beta$ fixed, and write its three terms as the directed sides $z_i = V_{i\alpha}V_{i\beta}^*$ of a triangle in the complex plane, $z_1 + z_2 + z_3 = 0$. The (unsigned) area of a triangle whose two edge vectors emanating from one vertex are the complex numbers z_1 and $-z_2$ is $\frac{1}{2}|\,\mathrm{Im}(z_1\,\overline{(-z_2)})| = \frac{1}{2}|\,\mathrm{Im}(z_1 z_2^*)|$. Now

$$z_1 z_2^* = V_{1\alpha}V_{1\beta}^*\left(V_{2\alpha}V_{2\beta}^*\right)^* = V_{1\alpha}V_{2\beta}\,V_{1\beta}^*\,V_{2\alpha}^*, \tag{F.144}$$

which is exactly a Jarlskog box for rows $1, 2$ and columns α, β. By the standard reduction of such boxes for a 3×3 unitary matrix, $\mathrm{Im}(V_{i\alpha}V_{j\beta}V_{i\beta}^*V_{j\alpha}^*) = J\sum_{k,\gamma}\varepsilon_{ijk}\varepsilon_{\alpha\beta\gamma}$, the right-hand side equals $\pm J$ for any choice of two distinct rows and two distinct columns. Hence $|\,\mathrm{Im}(z_1 z_2^*)| = |J|$ and the area is $|J|/2$, *independent* of which orthogonality relation (which triangle) we chose. All six triangles share the common area $|J|/2$; they differ only in shape, the *db* triangle of Fig. F.1 being the one whose three sides are of comparable length. □

The reduction $\mathrm{Im}(V_{i\alpha}V_{j\beta}V_{i\beta}^*V_{j\alpha}^*) = J\sum_{k\gamma}\varepsilon_{ijk}\varepsilon_{\alpha\beta\gamma}$ used above is itself a consequence of unitarity; the following worked example both establishes it for the case at hand and extracts the numerical size of J in the Wolfenstein expansion, the number the data section will quote.

Worked Example F.21 (The size of CP violation: J in the Wolfenstein expansion)**.** We compute J in powers of λ and confirm directly that the imaginary parts of all the Jarlskog boxes coincide. From Eq. (F.140) and the Wolfenstein definitions Eq. (F.125), with $c_{12}, c_{23}, c_{13} \to 1$ at leading order,

$$J = c_{12}c_{23}c_{13}^2\, s_{12}\, s_{23}\left(s_{13}\sin\delta\right). \tag{F.145}$$

The combination $s_{13}\sin\delta$ is read off from $s_{13}e^{-i\delta} = A\lambda^3(\rho - i\eta)$, whose imaginary part is $-s_{13}\sin\delta = -A\lambda^3\eta$, i.e. $s_{13}\sin\delta = A\lambda^3\eta$. With $s_{12} = \lambda$ and $s_{23} = A\lambda^2$,

$$J = (1)\,(\lambda)\,(A\lambda^2)\,(A\lambda^3\eta) + O(\lambda^8) = A^2\lambda^6\,\eta + O(\lambda^8) \;\approx\; A^2\lambda^6\,\bar{\eta}. \tag{F.146}$$

The striking feature is the power λ^6: CP violation in the quark sector is suppressed by the *sixth* power of the Cabibbo parameter, because it requires the simultaneous participation of all three mixing angles, each contributing its own power of λ, with the $(1,3)$ angle entering twice (once as s_{13}, once because the relevant box necessarily reaches across all three families). Numerically, with the mid-2020s values $\lambda \approx 0.225$, $A \approx 0.83$, $\bar{\eta} \approx 0.355$ that the next section will pin down, $J \approx (0.83)^2(0.225)^6(0.355) \approx 3.1 \times 10^{-5}$—a tiny number, and the quantitative statement of why CP violation is a small effect in the Standard Model.

To verify the box reduction explicitly, compare two different boxes. The defining box is $J = \mathrm{Im}(V_{us}V_{cb}V_{ub}^*V_{cs}^*) \approx \mathrm{Im}[\lambda \cdot A\lambda^2 \cdot A\lambda^3(\rho+i\eta)\cdot 1] = A^2\lambda^6\eta$, using $V_{ub}^* = A\lambda^3(\rho+i\eta)$ and $V_{cs} \approx 1$. A different box, built from rows u,t and columns d,b, is $\mathrm{Im}(V_{ud}V_{tb}V_{ub}^*V_{td}^*)$. With $V_{ud} \approx 1$, $V_{tb} \approx 1$, $V_{ub}^* = A\lambda^3(\rho+i\eta)$, and $V_{td}^* = A\lambda^3(1-\rho+i\eta)$,

$$\begin{aligned}\mathrm{Im}(V_{ud}V_{tb}V_{ub}^*V_{td}^*) &\approx \mathrm{Im}\Big[A\lambda^3(\rho+i\eta)\cdot A\lambda^3(1-\rho+i\eta)\Big] \\ &= A^2\lambda^6\ \mathrm{Im}\big[(\rho+i\eta)(1-\rho+i\eta)\big] \\ &= A^2\lambda^6\big[\eta(1-\rho)+\eta\rho\big] = A^2\lambda^6\,\eta, \end{aligned} \tag{F.147}$$

the same value, confirming that the imaginary part is common to all boxes and equal to J, in agreement with Theorem F.20. The cancellation of the ρ-dependence in the last line is the algebraic shadow of the geometric fact that the area of the triangle does not depend on where its apex sits along a line of fixed height $\bar{\eta}$.

F.5.6 The leptonic analog: the PMNS matrix

The same construction runs in the lepton sector, with one decisive difference that the count of Section F.4 already flagged. Diagonalizing the charged-lepton mass matrix and the neutrino mass matrix by left-handed unitary rotations $U_{eL}, U_{\nu L}$ leaves, in the leptonic charged current, the residual combination

$$U_{\mathrm{PMNS}} \;\equiv\; U_{eL}^{\dagger}\,U_{\nu L}, \tag{F.148}$$

the Pontecorvo–Maki–Nakagawa–Sakata matrix [330, 408], whose origin is established in Chapter 35. If the neutrinos are *Dirac* particles—mass term $\bar{\nu}_L M_\nu \nu_R$ with an independent right-handed field—then the rephasing bookkeeping is identical to the quark case: both charged leptons and neutrinos can be freely rephased, the count of Theorem F.17 applies verbatim, and U_{PMNS} has three angles and one phase. Its standard parametrization is the literal transcription of Eq. (F.121),

$$U_{\mathrm{PMNS}} = R_{23}(\theta_{23})\,U_{13}(\theta_{13},\delta)\,R_{12}(\theta_{12}), \tag{F.149}$$

with the same 3×3 explicit form as Eq. (F.122) (now with rows labeled by the charged-lepton flavors e,μ,τ and columns by the mass eigenstates ν_1,ν_2,ν_3, and

the phase usually written $\delta = \delta_{\mathrm{CP}}$). One important contrast with the quark sector is quantitative rather than structural: the measured leptonic angles are *large*—θ_{12} and θ_{23} are tens of degrees, not the few degrees of the quark sector—so the PMNS matrix is far from the identity and admits no useful Wolfenstein-style hierarchy expansion. The Jarlskog construction nonetheless carries over unchanged: a leptonic invariant $J_{\mathrm{lep}} = \mathrm{Im}(U_{\mu 3} U_{e2} U_{e3}^{*} U_{\mu 2}^{*}) = c_{12} c_{23} c_{13}^{2} s_{12} s_{23} s_{13} \sin\delta_{\mathrm{CP}}$ measures CP violation in neutrino oscillations and can be of order 10^{-2}, far larger than its quark counterpart because the angles are large.

Caution: Majorana neutrinos carry extra phases

If instead the neutrinos are *Majorana* particles—each neutrino its own antiparticle, with a mass term $\frac{1}{2}\,\overline{\nu_L^{c}}\, M_\nu\, \nu_L$ built from the left-handed field alone (Chapter 35)—then the neutrino fields can no longer be rephased: a phase $\nu_i \to e^{i\phi_i}\nu_i$ multiplies the Majorana mass term by $e^{2i\phi_i} \neq 1$ and is not a symmetry. Only the three charged-lepton phases remain available, and there is now *no* overall common phase to subtract (the would-be common shift cannot be compensated on the neutrino side), so $n_{\mathrm{rephase}} = N$ rather than $2N-1$. Repeating the count of Theorem F.17 with this single change, the number of physical phases becomes

$$n_{\delta}^{\mathrm{Maj}} = \frac{N(N+1)}{2} - N = \frac{N(N-1)}{2}, \tag{F.150}$$

which for $N = 3$ is 3 phases: the one "Dirac" phase δ_{CP} already present in Eq. (F.149), plus *two* additional "Majorana" phases. They are conventionally collected in a diagonal matrix on the right,

$$U_{\mathrm{PMNS}}^{\mathrm{Maj}} = U_{\mathrm{PMNS}} \cdot \mathrm{diag}\big(1,\, e^{i\alpha_{21}/2},\, e^{i\alpha_{31}/2}\big), \tag{F.151}$$

with U_{PMNS} the standard matrix Eq. (F.149). The Majorana phases α_{21}, α_{31} drop out of all oscillation observables—oscillation amplitudes pair each $U_{\alpha i}$ with a conjugate $U_{\beta i}^{*}$ carrying the same neutrino index i, so the right-diagonal phase cancels—and therefore cannot be measured in oscillation experiments. They survive only in lepton-number violating processes, most notably neutrinoless double beta decay, whose rate depends on the effective mass $m_{\beta\beta} = |\sum_i U_{ei}^{2} m_i|$ in which the Majorana phases do *not* cancel. The angle count $n_{\mathrm{angle}} = N(N-1)/2 = 3$ is unaffected: Majorana neutrinos still mix through three angles, but through three phases rather than one.

The structures assembled here—the standard 3×3 matrix Eq. (F.122) with its three angles and one phase, the Wolfenstein hierarchy Eq. (F.135) with parameters $(\lambda, A, \bar\rho, \bar\eta)$, the rephasing-invariant Jarlskog measure J, and their leptonic counterparts including the Majorana phases—are exactly the slots that

the numerical section fills. Section F.6 now quotes the measured magnitudes $|V_{ij}|$, the fitted angles and phase, the apex $(\bar{\rho}, \bar{\eta})$ with the value of J, and the mid-2020s leptonic angles and δ_{CP}, each accompanied by the scheme and convention that make it a meaningful number.

F.6 Numerical Values and Their Defining Schemes

The previous sections built the empty slots: the standard CKM and PMNS parametrizations of Section F.5, the Jarlskog invariant Eq. (F.139), and the mass and coupling relations that the Higgs mechanism and electroweak unification of Chapters 31 and 33 fix in terms of the underlying Lagrangian parameters. It remains to fill those slots with numbers. This is less innocent than it sounds. A measured quantity in a renormalizable quantum field theory is almost never a bare invariant of nature; it is the value of a parameter *in a scheme*, and the same physical fact reported in two schemes is two different numbers. The fine-structure constant is 1/137.036 at zero momentum and about 1/128 at the Z mass; the weak mixing angle has one value if defined by a ratio of pole masses and a slightly different value if defined by $\overline{\mathrm{MS}}$ subtraction at $\mu = m_Z$; a quark "mass" of 4.18 GeV in $\overline{\mathrm{MS}}$ becomes a pole mass near 4.8 GeV, and the latter is not even unambiguously defined beyond a few loops. *A number without its scheme is not a measurement; it is an ambiguity.* The discipline of this section is therefore to quote every value together with the definition that makes it mean something, and to date everything honestly: all numbers below are the mid-2020s Particle Data Group values [382], with neutrino mixing taken from the contemporary global fits [180], and they will drift as measurements improve.

F.6.1 Three kinds of number, and the duty to label

It helps to keep three categories distinct, because the word "value" means something different in each.

The first kind is a genuine *physical observable*: a pole position, a decay rate, a cross section, a ratio of pole masses. These are scheme-independent by construction—they are properties of the S-matrix, not of a Lagrangian parametrization—and a number reported for one of them needs only a statement of *what* was measured, not of any subtraction scheme. The Z and W masses as Breit–Wigner pole parameters, the charged-lepton pole masses, and the Fermi constant extracted from the muon lifetime are of this type.

The second kind is a *short-distance Lagrangian parameter*: a running coupling $\alpha_s(\mu)$, a running mass $\overline{m}(\mu)$, an $\overline{\mathrm{MS}}$ mixing angle. Such a quantity is finite only after renormalization, and its value depends on the renormalization scheme and on the scale μ at which it is quoted. Reporting it requires naming the scheme ($\overline{\mathrm{MS}}$, on-shell, momentum subtraction) *and* the scale. The running of these

objects with μ is governed by the renormalization-group machinery of Chapter 24 for the electroweak couplings and Chapter 27 for the strong coupling; here we record values at conventional reference scales and rely on those chapters for the flow.

The third kind is a *derived quantity*: a number computed from the first two through a fixed relation, such as the Higgs vacuum expectation value v obtained from G_F, or the QCD scale Λ obtained from $\alpha_s(m_Z)$. These inherit their scheme from the inputs and from the order of the conversion formula, and the worked examples below show how much that matters.

Caution

The single most common error in using tabulated Standard Model data is to take a number quoted in one scheme and feed it into a formula derived in another. A pole mass inserted where an $\overline{\text{MS}}$ mass is expected, or $\alpha(0)$ used where $\alpha(m_Z)$ belongs, produces an answer wrong at the level of the very loop corrections one is trying to compute. Every entry below carries its scheme label for exactly this reason; the conversion dictionary that lets one move safely between schemes is assembled in Section F.7.

F.6.2 Electroweak and strong couplings

The gauge sector is fixed numerically by a small set of couplings, each of which exists in more than one definition. We list them with their schemes.

The *fine-structure constant* is best known at zero momentum transfer, from the electron anomalous magnetic moment and atom-interferometry determinations of α (QED, Chapter 24):

$$\alpha(0) = \frac{e^2}{4\pi}\bigg|_{q^2=0} = \frac{1}{137.035\,999\,18(2)} = 7.297\,352\,6 \times 10^{-3}. \tag{F.152}$$

This is the Thomson-limit coupling. For processes at the electroweak scale the relevant quantity is the effective coupling at $q^2 = m_Z^2$, into which the vacuum-polarization of all charged fermions has been run up per the QED RG of Chapter 24. In the $\overline{\text{MS}}$ scheme with five active quark flavors,

$$\alpha^{(5)}(m_Z)|^{-1}_{\overline{\text{MS}}} = 127.951(9), \qquad \alpha(m_Z)^{-1}\big|_{\text{eff., on-shell}} \approx 128.95, \tag{F.153}$$

where the two numbers differ because the on-shell effective coupling and the $\overline{\text{MS}}$ coupling resum the same logarithms with different finite parts and different treatments of the top and the W. The running from Eq. (F.152) to Eq. (F.153)—a change of nearly seven percent in α—is the numerical anchor for QED's running coupling Chapter 24; the dominant uncertainty in Eq. (F.153) is hadronic, from the light-quark contribution to the vacuum polarization that cannot be computed perturbatively.

The *strong coupling* is quoted at the Z mass in $\overline{\text{MS}}$ with five active flavors, the standard reference point for Yang–Mills theory:

$$\alpha_s^{(5)}(m_Z)|_{\overline{\text{MS}}} = 0.1180(9). \tag{F.154}$$

Its running, and the extraction of the QCD scale Λ, are governed by the one-loop beta function $\beta_g = -\frac{g^3}{16\pi^2}\, b_0$ with $b_0 = \frac{11}{3}C_A - \frac{4}{3}T_F n_f$ computed in Chapter 27; for SU(3) ($C_A = 3$, $T_F = \frac{1}{2}$) and n_f flavors this is $b_0 = 11 - \frac{2}{3}n_f$. We make this anchor concrete in Theorem F.24.

The *Fermi constant* is the cleanest electroweak input, extracted from the muon lifetime through the muon-decay rate with QED radiative corrections removed in the standard Fermi-theory convention:

$$G_F = 1.166\,378\,7(6) \times 10^{-5}\,\text{GeV}^{-2}. \tag{F.155}$$

It is measured to better than a part per million and is therefore taken as one of the three defining electroweak inputs $\{\alpha,\, G_F,\, m_Z\}$ of the input-scheme dictionary in Section F.7.

The *weak mixing angle* is the canonical illustration that a number is nothing without its scheme. Two definitions are in common use and give different numbers for the same physics. The *on-shell* definition fixes $\sin^2\theta_{\text{W}}$ by the ratio of the physical (pole) gauge-boson masses,

$$\sin^2\theta_{\text{W}}\big|_{\text{on-shell}} \equiv 1 - \frac{m_W^2}{m_Z^2} = 0.2233(6), \tag{F.156}$$

a manifestly scheme-independent combination of observables. The $\overline{\text{MS}}$ definition fixes it instead through the renormalized couplings at $\mu = m_Z$,

$$\sin^2\theta_{\text{W}}|_{\overline{\text{MS}}} \equiv \frac{\hat{g}'^2}{\hat{g}^2 + \hat{g}'^2}\bigg|_{\mu = m_Z} = \hat{s}_Z^2 = 0.231\,21(4), \tag{F.157}$$

where $\hat{g}, \hat{g}'$ are the $\overline{\text{MS}}$ gauge couplings. The two values differ by about 0.008, an eight-per-mille gap that is entirely real physics—the finite parts of the radiative corrections—and not experimental error: Eq. (F.156) is smaller because the on-shell definition absorbs the large top-quark contribution to the ρ parameter differently than $\overline{\text{MS}}$ does. A prediction quoted to per-mille accuracy that does not say which $\sin^2\theta_{\text{W}}$ it uses is simply not a prediction.

F.6.3 Gauge-boson and Higgs masses

The massive bosons are quoted as pole masses—physical observables, no scheme label needed beyond "pole":

$$m_Z = 91.1880(20)\,\text{GeV}, \tag{F.158}$$

Table F.4: Standard Model gauge couplings, each with its defining scheme, as of the mid-2020s [382]. Running quantities are quoted at their conventional reference scale. Schemes: "$q^2 = 0$" is the Thomson limit; "$\overline{\text{MS}}$" denotes modified minimal subtraction at the stated scale with five active quark flavors; "on-shell" denotes a definition through pole masses.

Quantity	Value	Scheme / definition
$\alpha(0)$	$1/137.035\,999\,18(2)$	$q^2 = 0$ (Thomson)
$\alpha^{(5)}(m_Z)$	$1/127.951(9)$	$\overline{\text{MS}}$, $\mu = m_Z$
$\alpha_s^{(5)}(m_Z)$	$0.1180(9)$	$\overline{\text{MS}}$, $\mu = m_Z$
G_F	$1.166\,378\,7(6) \times 10^{-5}\,\text{GeV}^{-2}$	muon lifetime
$\sin^2\theta_{\text{W}}$	$0.2233(6)$	on-shell, $1 - m_W^2/m_Z^2$
$\sin^2\theta_{\text{W}}$	$0.231\,21(4)$	$\overline{\text{MS}}$, $\mu = m_Z$

$$m_W = 80.3692(133)\,\text{GeV}, \tag{F.159}$$

$$m_h = 125.20(11)\,\text{GeV}. \tag{F.160}$$

The Z mass Eq. (F.158) is the single most precisely known electroweak mass and serves, with α and G_F, as a defining input. The W mass Eq. (F.159) is the world average; it carries a live experimental tension that must be flagged honestly.

Caution

The 2022 CDF II measurement reported $m_W = 80.4335(94)\,\text{GeV}$, some seven standard deviations above the average Eq. (F.159) and in tension with the Standard-Model electroweak fit. Subsequent measurements (ATLAS, LHCb) sit close to the fit value, and the discrepancy is unresolved as of the mid-2020s. The value Eq. (F.159) is the PDG average that does not include the discrepant CDF point; any electroweak fit using m_W should state which value it adopts.

The Higgs mass Eq. (F.160) is measured directly in the $\gamma\gamma$ and four-lepton channels and, like the gauge-boson masses, is a pole observable. With m_h, G_F, and the gauge couplings fixed, the quartic Higgs self-coupling λ and the vacuum expectation value v are determined; the extraction of v is Theorem F.23.

F.6.4 Fermion masses: the scheme is half the number

The charged leptons are quoted as pole masses, which for leptons are clean physical observables (QED corrections to the pole are tiny and well controlled):

$$m_e = 0.510\,998\,950\,0(2)\,\text{MeV}, \quad m_\mu = 105.658\,375\,5(2)\,\text{MeV}, \quad m_\tau = 1776.86(12)\,\text{MeV}. \tag{F.161}$$

The quarks are an entirely different story, because a confined particle has no asymptotic one-particle state and hence no unambiguous pole mass at the non-perturbative level. The mass that is short-distance well-defined is the *running* $\overline{\text{MS}}$ mass $\overline{m}(\mu)$, and the scale at which it is quoted is part of the datum. The convention is:

- the light quarks u, d, s, whose intrinsic mass scale lies below the regime where perturbation theory is trustworthy, are quoted as $\overline{\text{MS}}$ masses at the fixed reference scale $\mu = 2\,\text{GeV}$;
- the charm and bottom quarks are quoted as "scale-invariant" $\overline{\text{MS}}$ masses evaluated at their own value, $\overline{m}_c(\overline{m}_c)$ and $\overline{m}_b(\overline{m}_b)$, the natural self-consistent choice that makes the log in the pole relation vanish;
- the top quark, heavy enough to decay before it hadronizes, is quoted both as a (Monte-Carlo/direct) mass close to the pole mass and as an $\overline{\text{MS}}$ mass $\overline{m}_t(\overline{m}_t)$.

Table F.5: Quark masses with their schemes, mid-2020s [382]. Light quarks u, d, s are $\overline{\text{MS}}$ masses at $\mu = 2\,\text{GeV}$; charm and bottom are scale-invariant $\overline{\text{MS}}$ masses $\overline{m}(\overline{m})$; the top is given as the direct (pole-like) mass and as the $\overline{\text{MS}}$ mass. The asymmetric errors are reproduced as quoted.

Quark	Value	Scheme / scale
u	$2.16^{+0.49}_{-0.26}\,\text{MeV}$	$\overline{\text{MS}}$, $\mu = 2\,\text{GeV}$
d	$4.70^{+0.48}_{-0.17}\,\text{MeV}$	$\overline{\text{MS}}$, $\mu = 2\,\text{GeV}$
s	$93.5^{+8.6}_{-3.4}\,\text{MeV}$	$\overline{\text{MS}}$, $\mu = 2\,\text{GeV}$
c	$1.273(46)\,\text{GeV}$	$\overline{\text{MS}}$, $\overline{m}_c(\overline{m}_c)$
b	$4.183^{+0.037}_{-0.015}\,\text{GeV}$	$\overline{\text{MS}}$, $\overline{m}_b(\overline{m}_b)$
t	$172.57(29)\,\text{GeV}$	direct (pole-like)
t	$162.5^{+2.1}_{-1.5}\,\text{GeV}$	$\overline{\text{MS}}$, $\overline{m}_t(\overline{m}_t)$

The top entries make the point unmistakably: 172.6 GeV and 162.5 GeV are the *same quark*, the ten-GeV gap being nothing but the difference between the pole-type and $\overline{\text{MS}}$ definitions. Anyone who plugs the direct mass into a formula expecting $\overline{m}_t(\overline{m}_t)$ commits a six-percent error in the top mass—larger than every measurement uncertainty combined. We now show, at one loop, exactly where that gap comes from.

F.6.5 Worked example: $\overline{\text{MS}}$ mass to pole mass

Worked Example F.22 (From $\overline{m}_b(\overline{m}_b)$ to the bottom pole mass)**.** We convert the tabulated $\overline{\text{MS}}$ bottom mass $\overline{m}_b(\overline{m}_b) = 4.18\,\text{GeV}$ into the corresponding pole

mass at one loop in QCD, using the relation established in Chapter 22 and the master one-loop two-point integral of Chapter D, and we read off the lesson about scheme labels.

The relation. The pole mass M is defined as the location of the pole of the full quark propagator, fixed by the on-shell renormalization condition of Chapter 22; the $\overline{\text{MS}}$ mass $\overline{m}(\mu)$ is fixed by subtracting only the $1/\varepsilon$ pole of the self-energy. The difference between the two finite parts is the conversion factor. The one-loop quark self-energy $\Sigma(\not p)$ in dimensional regularization is built, after Feynman parametrization, on the standard scalar two-point master integral

$$B_0(p^2;m,0)=\frac{1}{i}\int\frac{d^dk}{(2\pi)^d}\,\frac{1}{(k^2-m^2)\,(k+p)^2}=\frac{1}{(4\pi)^2}\left[\frac{1}{\varepsilon}-\gamma_E+\ln 4\pi+2-\ln\frac{m^2}{\mu^2}+\dots\right], \tag{F.162}$$

whose value is taken from Chapter D. Carrying the Dirac algebra of Chapter 22 (in $d=4-2\varepsilon$, with $\gamma^\mu\not k\gamma_\mu=-(d-2)\not k$ and the color factor $C_F=\frac{N_c^2-1}{2N_c}=\frac{4}{3}$ for the fundamental of SU(3)) and imposing the two renormalization conditions yields the one-loop relation

$$M=\overline{m}(\mu)\left[1+\frac{\alpha_s(\mu)}{\pi}\,C_F\left(1+\frac{3}{4}\ln\frac{\mu^2}{\overline{m}^2(\mu)}\right)+\mathcal{O}(\alpha_s^2)\right]. \tag{F.163}$$

The structure is transparent: the color factor $C_F=4/3$ is the same one that appears in the QCD self-energy, the constant "1" is the finite part of Eq. (F.162), and the logarithm carries the running between μ and the mass scale—its coefficient $\frac{3}{4}C_F=1$ (the coefficient of $\ln(\mu^2/\overline{m}^2)$) is exactly *half* the one-loop mass anomalous dimension $\gamma_m=\frac{3}{2}C_F\,\alpha_s/\pi=2\alpha_s/\pi$ of Chapter 24, the factor of two arising because $\ln\mu^2=2\ln\mu$; this is what makes M (a physical pole) μ-independent order by order.

The self-consistent scale. Evaluating Eq. (F.163) at the scale-invariant point $\mu=\overline{m}(\overline{m})$ kills the logarithm and leaves the clean relation

$$M=\overline{m}(\overline{m})\left[1+\frac{4}{3}\,\frac{\alpha_s(\overline{m})}{\pi}+\mathcal{O}(\alpha_s^2)\right]. \tag{F.164}$$

This is why the bottom and charm masses are tabulated at their own scale: it makes the one-loop conversion a single multiplication.

The number. For the bottom quark, $\alpha_s(\overline{m}_b)\approx 0.225$ (running Eq. (F.154) down to 4.18 GeV with the QCD RG of Chapter 27). Then

$$\frac{4}{3}\,\frac{\alpha_s(\overline{m}_b)}{\pi}=\frac{4}{3}\cdot\frac{0.225}{3.1416}=\frac{4}{3}\times 0.0716=0.0955, \tag{F.165}$$

so

$$M_b^{\text{1-loop}}=4.18\,\text{GeV}\times(1+0.0955)=4.18\times 1.0955=4.58\,\text{GeV}. \tag{F.166}$$

A nearly half-GeV shift from a one-loop correction. Including the known two- and three-loop terms pushes the result up to roughly 4.8 GeV, and the series converges slowly: each order in α_s contributes a comparable fraction, a symptom of the *infrared renormalon* that makes the pole mass intrinsically ambiguous at the level of $\mathcal{O}(\Lambda_{\rm QCD}) \sim 200\,\text{MeV}$. The charm quark, with $\alpha_s(\overline{m}_c) \approx 0.39$, is worse: Eq. (F.164) gives $M_c^{\text{1-loop}} = 1.27\,(1 + \frac{4}{3}\cdot 0.124) = 1.27 \times 1.165 = 1.48\,\text{GeV}$, with a higher-order expansion that is barely under control.

The lesson. The $\overline{\rm MS}$ mass 4.18 GeV is short-distance, unambiguous, and scheme-labeled; the pole mass ≈ 4.8 GeV is a different number, definable only order by order, and ambiguous at a few hundred MeV. The two are not interchangeable, and a table entry that said merely "$m_b = 4.18\,\text{GeV}$" or "$m_b = 4.8\,\text{GeV}$" without its scheme would be useless for any computation accurate to better than ten percent. Scheme labels are not bureaucratic decoration; they are part of the measurement.

F.6.6 Worked example: the electroweak scale from G_F

Worked Example F.23 (Extracting $v = (\sqrt{2}\,G_F)^{-1/2}$)**.** The Higgs vacuum expectation value v sets the scale of electroweak symmetry breaking, yet it is not measured directly; it is derived from the precisely known Fermi constant Eq. (F.155). We carry out the extraction.

The relation. The Fermi constant was defined historically through the low-energy four-fermion muon-decay amplitude, which the full electroweak theory reproduces at tree level by exchanging a W boson. Matching the two (Chapter 31) gives

$$\frac{G_F}{\sqrt{2}} = \frac{g^2}{8\,m_W^2}. \tag{F.167}$$

Using the tree-level mass relation $m_W = \frac{1}{2} g\,v$ from the Higgs mechanism of Chapter 31 (the W acquires its mass from the doublet vev),

$$\frac{G_F}{\sqrt{2}} = \frac{g^2}{8\,(\frac{1}{2}gv)^2} = \frac{g^2}{8\cdot\frac{1}{4}g^2v^2} = \frac{1}{2v^2}, \tag{F.168}$$

so that the gauge coupling cancels and

$$v^2 = \frac{1}{\sqrt{2}\,G_F}, \qquad v = (\sqrt{2}\,G_F)^{-1/2}. \tag{F.169}$$

This is a tree-level definition; it fixes v as a derived quantity inheriting the sub-ppm precision of G_F, with loop corrections absorbed into the precise definition of G_F itself.

The number. Insert Eq. (F.155). First,

$$\sqrt{2}\,G_F = 1.414\,214 \times 1.166\,378\,7 \times 10^{-5}\,\text{GeV}^{-2} = 1.649\,38 \times 10^{-5}\,\text{GeV}^{-2}. \tag{F.170}$$

Then

$$v^2 = \frac{1}{1.649\,38 \times 10^{-5}\,\mathrm{GeV}^{-2}} = 6.0629 \times 10^4\,\mathrm{GeV}^2, \tag{F.171}$$

and taking the square root,

$$\boxed{v = \left(\sqrt{2}\,G_F\right)^{-1/2} = 246.22\,\mathrm{GeV}.} \tag{F.172}$$

This is the electroweak scale: every gauge-boson and fermion mass in the Standard Model is v times a dimensionless coupling. With v in hand one reads off, for example, the top Yukawa $y_t = \sqrt{2}\,\overline{m}_t/v \approx \sqrt{2} \times 162.5/246.2 \approx 0.93$, strikingly close to unity, and the Higgs self-coupling $\lambda = m_h^2/2v^2 \approx (125.2)^2/(2\times 246.22^2) \approx 0.129$. The number Eq. (F.172) is the anchor of the whole mass spectrum.

F.6.7 The CKM matrix in numbers

The quark mixing matrix V_{CKM}, whose standard parametrization in terms of three angles and one phase was given in Section F.5, is dominantly diagonal with a hierarchical off-diagonal structure captured by the Wolfenstein expansion in the small parameter $\lambda = \sin\theta_{12} \approx |V_{us}|$. The mid-2020s global-fit values are

$$\lambda = 0.22501(68), \quad A = 0.826^{+0.016}_{-0.015}, \quad \bar{\rho} = 0.1591(94), \quad \bar{\eta} = 0.3523(60), \tag{F.173}$$

which translate to the standard mixing angles $\theta_{12} \approx 13.0^\circ$, $\theta_{23} \approx 2.4^\circ$, $\theta_{13} \approx 0.20^\circ$, and a large CP phase $\delta \approx 66^\circ$. The magnitudes of the entries are

$$|V_{\mathrm{CKM}}| \approx \begin{pmatrix} 0.9743 & 0.2250 & 0.0037 \\ 0.2249 & 0.9735 & 0.0409 \\ 0.0086 & 0.0402 & 0.9991 \end{pmatrix}, \tag{F.174}$$

and the rephasing-invariant measure of CP violation, the Jarlskog invariant of Eq. (F.139), takes the value

$$J = (3.08^{+0.15}_{-0.13}) \times 10^{-5}. \tag{F.175}$$

That J is small not because the phase δ is small—it is of order one— but because J is suppressed by the product of all three small mixing angles, is the quantitative statement of why CP violation in the quark sector is a tiny effect despite an $\mathcal{O}(1)$ phase.

Caution

The third-row/third-column elements $|V_{cb}|$ and $|V_{ub}|$ carry a persistent *inclusive-versus-exclusive* tension: determinations from inclusive semileptonic B decays sit systematically above those from exclusive ($B \to D^{(*)}\ell\nu$, $B \to \pi\ell\nu$) channels, by roughly $|V_{cb}|_{\mathrm{incl}} \approx 42.2 \times 10^{-3}$ versus

$|V_{cb}|_{\text{excl}} \approx 39.8 \times 10^{-3}$ (a $\sim 3\sigma$ gap), and similarly for $|V_{ub}|$ (≈ 4.1 versus $\approx 3.7 \times 10^{-3}$). The averaged values in Eq. (F.174) paper over a discrepancy whose origin—experimental, or in the hadronic form factors—is unsettled as of the mid-2020s. A computation sensitive to $|V_{cb}|$ should state which determination it uses. This is also why the averaged entries $|V_{cb}| \approx 0.0409$ and $|V_{ts}| \approx 0.0402$ in Eq. (F.174) sit about 2% below the value $A\lambda^2 \approx 0.0418$ that the appendix's own Wolfenstein relation $|V_{cb}| = s_{23}c_{13} = A\lambda^2$ would give from the global-fit $A = 0.826$ of Eq. (F.173): the tabulated matrix elements are direct-measurement averages, whereas A is fixed by the global unitarity fit, so the gap is exactly this inclusive-versus-exclusive tension and not a failure of the Wolfenstein relation. The other entries ($|V_{ub}|$, $|V_{td}|$) are consistent with $A = 0.826$ at the quoted precision.

F.6.8 The PMNS matrix and neutrino masses

The lepton mixing matrix U_{PMNS}, parametrized exactly as V_{CKM} in Section F.5 (with possible additional Majorana phases that drop out of oscillations), is strikingly non-hierarchical: its mixing angles are all large. The global-fit values for normal ordering [180] are

$$\sin^2\theta_{12} = 0.307(12), \quad \sin^2\theta_{23} = 0.553^{+0.016}_{-0.024}, \quad \sin^2\theta_{13} = 0.02203(56), \tag{F.176}$$

corresponding to $\theta_{12} \approx 33.7^\circ$, $\theta_{23} \approx 48.0^\circ$, $\theta_{13} \approx 8.5^\circ$, with the CP-violating Dirac phase still poorly constrained, $\delta_{\text{CP}} \approx 197^\circ$ (consistent with a broad range and not yet established as nonzero). The two measured mass-squared differences are

$$\Delta m^2_{21} = 7.41^{+0.21}_{-0.20} \times 10^{-5}\,\text{eV}^2, \qquad |\Delta m^2_{31}| = 2.51^{+0.03}_{-0.03} \times 10^{-3}\,\text{eV}^2. \tag{F.177}$$

Table F.6: Lepton mixing parameters and neutrino mass-squared differences, normal ordering, from the mid-2020s global fit [180]. Contrast the large PMNS angles with the small CKM angles of Eq. (F.173).

Parameter	Value (normal ordering)
$\sin^2\theta_{12}$	$0.307(12)$
$\sin^2\theta_{23}$	$0.553^{+0.016}_{-0.024}$
$\sin^2\theta_{13}$	$0.022\,03(56)$
δ_{CP}	$\approx 197^\circ$ (weakly constrained)
Δm^2_{21}	$7.41 \times 10^{-5}\,\text{eV}^2$
$\lvert\Delta m^2_{31}\rvert$	$2.51 \times 10^{-3}\,\text{eV}^2$

Three honest caveats accompany these numbers, all reflecting genuine present ignorance rather than measurement imprecision. First, the *mass ordering* is undetermined: only Δm^2_{21} and $|\Delta m^2_{31}|$ are known, and whether $m_3 > m_2 > m_1$ (normal) or $m_3 < m_1 < m_2$ (inverted) is an open experimental question. Second, the *absolute mass scale* is unmeasured; oscillations fix only differences, and the lightest neutrino mass could be zero. Third, the θ_{23} *octant* (whether θ_{23} is above or below 45°) and the Dirac phase δ_{CP} are only weakly constrained. The Standard Model as defined in Chapter 33 has massless neutrinos; the very existence of Eq. (F.177) is therefore physics beyond it, recorded here as data and discussed as such in Section F.7.

F.6.9 Benchmark anchors: running α and the QCD scale

The numbers above are the numerical anchors for the two gauge threads carried through the book. QED is anchored by the running of α from Eq. (F.152) to Eq. (F.153), a flow computed from the QED beta function of Chapter 24; we do not recompute that beta function here. Yang–Mills theory is anchored by $\alpha_s(m_Z)$ of Eq. (F.154) together with the one-loop coefficient b_0 of Chapter 27, which together fix the QCD scale. We make the latter concrete, plugging measured numbers into the imported running formula.

Worked Example F.24 (The QCD scale Λ from $\alpha_s(m_Z)$)**.** The one-loop solution of the renormalization-group equation for the strong coupling, derived in Chapter 27, is

$$\alpha_s(\mu) = \frac{2\pi}{b_0 \ln(\mu/\Lambda)} = \frac{4\pi}{b_0 \ln(\mu^2/\Lambda^2)}, \qquad b_0 = 11 - \tfrac{2}{3}n_f, \tag{F.178}$$

which defines the QCD scale Λ as the integration constant of the flow. We do not rederive Eq. (F.178); we invert it. With five active flavors, $b_0 = 11 - \frac{10}{3} = \frac{23}{3} = 7.667$. Solving for Λ at $\mu = m_Z$ with $\alpha_s(m_Z) = 0.118$,

$$\ln \frac{m_Z^2}{\Lambda^2} = \frac{4\pi}{b_0\, \alpha_s(m_Z)} = \frac{12.566}{7.667 \times 0.118} = \frac{12.566}{0.9047} = 13.89, \tag{F.179}$$

so that $m_Z^2/\Lambda^2 = e^{13.89} = 1.08 \times 10^6$ and, with $m_Z = 91.19\,\mathrm{GeV}$,

$$\Lambda^{(5)}_{\text{1-loop}} = \frac{m_Z}{\sqrt{1.08 \times 10^6}} = \frac{91.19\,\mathrm{GeV}}{1039} = 0.088\,\mathrm{GeV} \approx 90\,\mathrm{MeV}. \tag{F.180}$$

The one-loop value is honestly small: the full two-loop $\overline{\mathrm{MS}}$ result is $\Lambda^{(5)}_{\overline{\mathrm{MS}}} \approx 0.21\,\mathrm{GeV}$, and the factor-of-two gap between one- and two-loop is itself a scheme-and-order statement of the kind this section exists to flag. The lesson rhymes with Theorem F.22: Λ is not a measured constant but a derived quantity whose value depends on the loop order and the flavor number n_f used to extract it. The $b_0 = 11 - \frac{2}{3}n_f$ input is supplied by Chapter 27 (Yang–Mills theory); the number it produces is anchored here.

Caution

A further open input, flagged for honesty, is the muon anomalous magnetic moment $a_\mu = (g-2)_\mu/2$. The Fermilab measurement [353] reaches sub-ppm precision, but the Standard-Model prediction it is compared against is itself unsettled: the data-driven (hadronic e^+e^-) and lattice evaluations of the hadronic vacuum polarization disagree, and a 2023 remeasurement of the $e^+e^- \to \pi^+\pi^-$ cross section shifted the data-driven value. As of the mid-2020s the size—and even the existence—of a discrepancy with the Standard Model is undetermined. This is a theory-input ambiguity, not a measurement error, and we record a_μ as an open number rather than a clean anchor.

These numbers, each now carrying the scheme that makes it meaningful, are the raw material of every reproducible computation in the book. The final section gathers the conversion relations—between $\overline{\text{MS}}$ and pole masses, between the $\{\alpha, G_F, m_Z\}$ and $\{g, g', v\}$ input sets, between on-shell and $\overline{\text{MS}}$ mixing angles—into a single input-scheme dictionary, so that any value used anywhere in the book can be traced back to, and reproduced from, this one place, and it records plainly which of these inputs the Standard Model explains and which it merely absorbs.

F.7 Conventions, Conversions, and the Input-Scheme Dictionary

The previous section made a point that this one must operationalize: a Standard Model number is meaningless without the scheme that defines it. We quoted the fine-structure constant in the Thomson limit, the weak mixing angle in three inequivalent definitions, the quark masses as $\overline{\text{MS}}$ running masses, and the strong coupling at the reference scale m_Z, and we insisted each be carried with its label. That discipline is only useful if one can also *move* between schemes and between the two natural sets of variables in which the electroweak theory is parametrized—because a cross section computed in Chapter 17 uses the Lagrangian couplings g, g', v, whereas the most precisely measured inputs are α, the Fermi constant G_F, and m_Z, and the two never coincide numerically until one writes the map between them. This closing section collects that map, and every other conversion the book relies on, in one place. Nothing physical is proved here: the Higgs mechanism and the tree-level mass relations come from Chapter 31, the radiative corrections from Chapters 31 and 34, the running of α_s and the definition of Λ_{QCD} from Chapter 27, and the anomalous dimensions behind the $\overline{\text{MS}}$ mass from Chapter 24. What is carried here in full is the *conversion algebra*—the inversion of the mass relations, the round-trip prediction of m_W, the factor-of-two hypercharge dictionary, and the pole/$\overline{\text{MS}}$ translation—because it is load-bearing

and belongs nowhere else. We end by recording, honestly and dated, the inputs the Standard Model takes from experiment without explaining: the smallness of $\bar{\theta}$ and the entire neutrino-mass sector.

F.7.1 The electroweak input dictionary

The electroweak sector of the Standard Model is fixed, at tree level, by three real parameters. In the Lagrangian they are the $\mathrm{SU}(2)_L$ gauge coupling g, the $\mathrm{U}(1)_Y$ gauge coupling g', and the Higgs vacuum expectation value $v \equiv \sqrt{2}\,\langle \phi^0 \rangle$ (the normalization fixed in Chapter 31, so that $v \approx 246$ GeV). Call this the *Lagrangian set* $\{g, g', v\}$. Every electroweak amplitude in the book is a function of these three numbers. They are, however, not the quantities measured most accurately. The *experimental set* $\{\alpha, G_F, m_Z\}$—the fine-structure constant in the Thomson limit, the Fermi constant from the muon lifetime, and the Z pole mass—is known to far higher relative precision, and it is in this set that the inputs of the previous section are quoted. The two sets carry the same information; the dictionary between them is what follows.

The physics that relates them is the electroweak symmetry breaking of Chapter 31. We import its tree-level output, which we will not reprove. After $\mathrm{SU}(3)_c \times \mathrm{SU}(2)_L \times \mathrm{U}(1)_Y \to \mathrm{SU}(3)_c \times \mathrm{U}(1)_{\mathrm{em}}$, the mixing of the neutral gauge fields defines the weak mixing angle θ_{W} through

$$\cos\theta_{\mathrm{W}} = \frac{g}{\sqrt{g^2 + g'^2}}, \qquad \sin\theta_{\mathrm{W}} = \frac{g'}{\sqrt{g^2 + g'^2}}, \qquad \tan\theta_{\mathrm{W}} = \frac{g'}{g}, \tag{F.181}$$

the photon couples with strength

$$e = \frac{g\,g'}{\sqrt{g^2 + g'^2}} = g\sin\theta_{\mathrm{W}} = g'\cos\theta_{\mathrm{W}}, \qquad \alpha = \frac{e^2}{4\pi}, \tag{F.182}$$

the massive gauge bosons acquire

$$m_W = \tfrac{1}{2}\,g\,v, \qquad m_Z = \tfrac{1}{2}\,v\sqrt{g^2 + g'^2} = \frac{m_W}{\cos\theta_{\mathrm{W}}}, \tag{F.183}$$

and the strength of the charged-current four-fermion interaction that governs muon decay is, at tree level,

$$\frac{G_F}{\sqrt{2}} = \frac{g^2}{8\,m_W^2} = \frac{1}{2\,v^2}. \tag{F.184}$$

The last equality in Eq. (F.184) follows from Eq. (F.183): $g^2/(8m_W^2) = g^2/(8 \cdot g^2 v^2/4) = 1/(2v^2)$, so the Fermi constant measures the vacuum expectation value directly and nothing else. Equations (F.181) to (F.184) are the forward map: given the Lagrangian set $\{g, g', v\}$ they produce $\{\alpha, G_F, m_Z\}$ (and m_W, and θ_{W}) by arithmetic.

Inverting the map. The experimental set is the input; we need the inverse. The cleanest route uses $\theta_{\rm W}$ as an intermediate. From Eq. (F.182) and the first equality of Eq. (F.183),

$$m_W^2 = \tfrac{1}{4} g^2 v^2 = \frac{e^2}{4\sin^2\theta_{\rm W}}\, v^2 = \frac{\pi\alpha}{\sqrt{2}\, G_F}\, \frac{1}{\sin^2\theta_{\rm W}}, \tag{F.185}$$

where in the last step we used $e^2 = 4\pi\alpha$ from Eq. (F.182) and $v^2 = 1/(\sqrt{2}\, G_F)$ from Eq. (F.184). Combining Eq. (F.185) with $m_W = m_Z \cos\theta_{\rm W}$ from Eq. (F.183) eliminates m_W and isolates the mixing angle:

$$m_Z^2 \cos^2\theta_{\rm W} \sin^2\theta_{\rm W} = \frac{\pi\alpha}{\sqrt{2}\, G_F} \quad \Longrightarrow \quad \boxed{\sin^2\theta_{\rm W} \cos^2\theta_{\rm W} = \frac{\pi\alpha}{\sqrt{2}\, G_F\, m_Z^2}} \tag{F.186}$$

This is the master relation of the input dictionary: its right-hand side is built entirely from the experimental set, and it determines $\sin^2\theta_{\rm W}$ as the smaller root of a quadratic. Once $\theta_{\rm W}$ is known, the rest of the inverse map is explicit:

$$\begin{aligned} e &= \sqrt{4\pi\alpha}, & v &= (\sqrt{2}\, G_F)^{-1/2}, \\ g &= \frac{e}{\sin\theta_{\rm W}}, & g' &= \frac{e}{\cos\theta_{\rm W}}, \end{aligned} \tag{F.187}$$

and $m_W = m_Z \cos\theta_{\rm W}$ closes the system. Equations (F.186) and (F.187) are the inverse map: given $\{\alpha, G_F, m_Z\}$ they produce $\{g, g', v\}$, the mixing angle, and a *prediction* for m_W. That m_W emerges as a prediction rather than an input is the content of the next worked example, and the gap between the predicted and the measured m_W is the doorway through which loop corrections enter.

Table F.7: The electroweak input dictionary at tree level. The forward map takes the Lagrangian set $\{g, g', v\}$ to the experimental set $\{\alpha, G_F, m_Z\}$; the inverse map runs the other way through the master relation Eq. (F.186). All relations are tree-level and imported from Chapter 31; loop corrections are discussed in Section F.7.2.

Forward: $\{g, g', v\} \to \{\alpha, G_F, m_Z\}$	Inverse: $\{\alpha, G_F, m_Z\} \to \{g, g', v\}$
$e = gg'/\sqrt{g^2 + g'^2}$	$\sin^2\theta_{\rm W}\cos^2\theta_{\rm W} = \pi\alpha/(\sqrt{2}\, G_F m_Z^2)$
$\alpha = e^2/4\pi$	$e = \sqrt{4\pi\alpha}$
$\cos\theta_{\rm W} = g/\sqrt{g^2 + g'^2}$	$v = (\sqrt{2}\, G_F)^{-1/2}$
$m_Z = \tfrac{1}{2} v \sqrt{g^2 + g'^2}$	$g = e/\sin\theta_{\rm W}, \quad g' = e/\cos\theta_{\rm W}$
$G_F/\sqrt{2} = 1/(2v^2)$	$m_W = m_Z \cos\theta_{\rm W}$ (predicted)

F.7.2 Worked round-trip: predicting m_W at tree level

We now carry the inverse map through with the dated numbers of the previous section, compute the Lagrangian set, and predict m_W. The exercise is worth

doing in full because the answer is both a triumph and a warning: the tree-level prediction lands within a percent of the measurement, which is why the $\{\alpha, G_F, m_Z\}$ scheme is the standard one, but the residual percent is a genuine physical effect—the electroweak radiative corrections—and not numerical slop.

Worked Example F.25 (From $\{\alpha, G_F, m_Z\}$ to $\{g, g', v\}$ and a prediction for m_W)**.** We use the mid-2020s (PDG 2024) values quoted in the previous section,

$$\alpha^{-1} = 137.035\,999, \qquad G_F = 1.166\,379 \times 10^{-5}\ \text{GeV}^{-2}, \qquad m_Z = 91.1880\ \text{GeV}, \tag{F.188}$$

with $\alpha = \alpha(0)$ the Thomson-limit coupling, G_F the muon-decay constant, and m_Z the on-shell Z mass. All three carry the schemes fixed in the previous section; we propagate them faithfully.

Step 1: the master right-hand side. Evaluate the dimensionless combination on the right of Eq. (F.186). The numerator is

$$\pi\alpha = \frac{3.141\,593}{137.035\,999} = 2.292\,53 \times 10^{-2}. \tag{F.189}$$

The denominator factor $\sqrt{2}\,G_F = 1.414\,214 \times 1.166\,379 \times 10^{-5} = 1.649\,51 \times 10^{-5}\ \text{GeV}^{-2}$, and $m_Z^2 = (91.1880)^2 = 8315.25\ \text{GeV}^2$, so

$$\sqrt{2}\,G_F\,m_Z^2 = 1.649\,51 \times 10^{-5} \times 8315.25 = 0.137\,16, \tag{F.190}$$

which is dimensionless as it must be. Hence

$$A \equiv \frac{\pi\alpha}{\sqrt{2}\,G_F\,m_Z^2} = \frac{2.292\,53 \times 10^{-2}}{0.137\,16} = 0.167\,15. \tag{F.191}$$

Step 2: solve the quadratic for $\sin^2\theta_{\mathrm{W}}$. Writing $s \equiv \sin^2\theta_{\mathrm{W}}$, Eq. (F.186) reads $s(1-s) = A$, i.e. $s^2 - s + A = 0$, with roots

$$s = \frac{1 \pm \sqrt{1 - 4A}}{2} = \frac{1 \pm \sqrt{1 - 0.668\,60}}{2} = \frac{1 \pm 0.575\,67}{2}. \tag{F.192}$$

The two roots are $s = 0.2122$ and $s = 0.7879$; they are $\sin^2\theta_{\mathrm{W}}$ and $\cos^2\theta_{\mathrm{W}}$ respectively, and the physical mixing angle is the smaller one,

$$\sin^2\theta_{\mathrm{W}}\big|_{\text{tree}} = 0.2122, \tag{F.193}$$

so that $\cos^2\theta_{\mathrm{W}} = 0.7878$.

Step 3: the Lagrangian set. From Eq. (F.187),

$$e = \sqrt{4\pi\alpha} = \sqrt{4 \times 2.292\,53 \times 10^{-2} \times \pi/\pi} = \sqrt{0.091\,70} = 0.302\,82,$$
$$v = \left(\sqrt{2}\,G_F\right)^{-1/2} = \left(1.649\,51 \times 10^{-5}\right)^{-1/2} = 246.2\ \text{GeV},$$

$$g = \frac{e}{\sin\theta_{\rm W}} = \frac{0.302\,82}{\sqrt{0.2122}} = \frac{0.302\,82}{0.460\,6} = 0.6574,$$
$$g' = \frac{e}{\cos\theta_{\rm W}} = \frac{0.302\,82}{\sqrt{0.7878}} = \frac{0.302\,82}{0.887\,6} = 0.3412. \tag{F.194}$$

(The middle line in e is just $e = \sqrt{4\pi\alpha}$ with $4\pi\alpha = 0.091\,70$; we wrote the factor of π explicitly to make the cancellation visible.) These are the canonical values $\{g, g', v\} \approx \{0.66,\ 0.34,\ 246\ \text{GeV}\}$ used throughout the body of the book. A consistency check: $\tan\theta_{\rm W} = g'/g = 0.3412/0.6574 = 0.519$, so $\tan^2\theta_{\rm W} = 0.269$ and $\sin^2\theta_{\rm W} = \tan^2\theta_{\rm W}/(1+\tan^2\theta_{\rm W}) = 0.269/1.269 = 0.2122$, reproducing Eq. (F.193).

Step 4: predict m_W. The mass relation $m_W = m_Z\cos\theta_{\rm W}$ now gives a number that was *not* an input:

$$m_W\big|_{\rm tree} = m_Z\sqrt{\cos^2\theta_{\rm W}} = 91.1880 \times \sqrt{0.7878} = 91.1880 \times 0.887\,6 = 80.94\ \text{GeV}. \tag{F.195}$$

Equivalently, from the master form Eq. (F.185), $m_W^2 = \pi\alpha/(\sqrt{2}\,G_F\sin^2\theta_{\rm W}) = 2.292\,53\times10^{-2}/(1.649\,51\times10^{-5}\times0.2122) = 6551\ \text{GeV}^2$, giving the same $m_W = 80.94$ GeV.

The measured value, dated to the same epoch, is $m_W^{\rm exp} = 80.369 \pm 0.013$ GeV (PDG 2024 world average). The tree-level prediction Eq. (F.195) overshoots it by

$$\frac{m_W^{\rm tree} - m_W^{\rm exp}}{m_W^{\rm exp}} = \frac{80.94 - 80.369}{80.369} = 0.71\%. \tag{F.196}$$

A sub-percent discrepancy is precisely what makes the $\{\alpha, G_F, m_Z\}$ scheme the gold-standard input set: these three quantities are measured to parts in 10^5 or better, so almost the entire residual in Eq. (F.196) is theory, not experimental error. That residual is the electroweak radiative correction, conventionally packaged into a single quantity Δr that modifies the master relation Eq. (F.185) to

$$m_W^2\Big(1 - \frac{m_W^2}{m_Z^2}\Big) = \frac{\pi\alpha}{\sqrt{2}\,G_F}\,\frac{1}{1-\Delta r}, \tag{F.197}$$

whose derivation and numerical value $\Delta r \approx 0.036$ are imported from Chapter 31 and confronted with the global electroweak fit in Chapter 34. The single largest piece of Δr is the running of the electromagnetic coupling from the Thomson limit up to m_Z, $\alpha(0) \to \alpha(m_Z)$ with $\alpha(m_Z)^{-1} \approx 128$, an effect computed in Chapter 24; the remainder carries the genuine sensitivity to m_t and m_H that made the electroweak fit a prediction machine for both. The lesson for this appendix is structural: the *tree-level* dictionary of Table F.7 is exact as algebra and accurate to $\sim 1\%$ as physics, and the named scheme on each input is exactly what tells the reader at which loop order the residual percent must be supplied.

Caution

The mixing angle is the worst offender for scheme ambiguity, and the round-trip makes the size of the ambiguity concrete. The *tree value derived from the inputs*, Eq. (F.193), is $\sin^2\theta_{\rm W} = 0.2122$. The *on-shell* value, defined by $\sin^2\theta_{\rm W} \equiv 1 - m_W^2/m_Z^2$ with the *measured* m_W, is $1-(80.369/91.1880)^2 = 0.2232$. The $\overline{\rm MS}$ value $\hat{s}^2(m_Z) \approx 0.231$ and the effective leptonic value $\sin^2\theta_{\rm eff}^{\rm lept} \approx 0.2315$ differ again. These four numbers describe the same physics and differ by up to $\sim 9\%$; quoting "$\sin^2\theta_{\rm W}$" without its definition is therefore not a rounding question but a several-percent error. This is the previous section's thesis made arithmetic.

F.7.3 The two hypercharge normalizations

This appendix froze the hypercharge normalization in Eq. (F.3) as $Q = T^3 + Y$, the "small-Y" convention, in which the left-handed lepton doublet carries $Y_{L_L} = -\frac{1}{2}$. A large fraction of the literature instead writes the Gell-Mann–Nishijima relation as

$$Q = T^3 + \frac{Y'}{2}, \tag{F.198}$$

the "large-Y" or "$Y/2$" convention. The two are related by an overall factor of two,

$$Y' = 2Y, \tag{F.199}$$

and they describe identical physics: the rescaling of the abelian charge is compensated by a rescaling of the coupling, $g'_{\rm (large)} = \frac{1}{2}\, g'_{\rm (small)}$, so that the covariant-derivative term $g' Y B_\mu = g'_{\rm (large)}\,(Y'/2)\, B_\mu$ is invariant. Neither the electric charges nor any observable changes; only the bookkeeping label on each multiplet does. The conversion is therefore a pure dictionary entry, and we record it once and demonstrate it on a multiplet so that no reader is tripped by the factor of two when comparing this appendix to an outside source.

Worked Example F.26 (Hypercharge conversion on the lepton and quark doublets)**.** *Lepton doublet.* In the small-Y convention of Table F.1, $L_L \sim (\mathbf{1}, \mathbf{2})$ with $Y_{L_L} = -\frac{1}{2}$. The components have $T^3 = +\frac{1}{2}$ (the ν_L) and $T^3 = -\frac{1}{2}$ (the e_L), so Eq. (F.3) gives

$$Q(\nu_L) = +\tfrac{1}{2} - \tfrac{1}{2} = 0, \qquad Q(e_L) = -\tfrac{1}{2} - \tfrac{1}{2} = -1. \tag{F.200}$$

Convert with Eq. (F.199): $Y'_{L_L} = 2 \times (-\frac{1}{2}) = -1$. Now use the large-$Y$ relation Eq. (F.198):

$$Q(\nu_L) = +\tfrac{1}{2} + \frac{-1}{2} = 0, \qquad Q(e_L) = -\tfrac{1}{2} + \frac{-1}{2} = -1. \tag{F.201}$$

The charges are identical, as they must be—only the label changed from $Y = -\frac{1}{2}$ to $Y' = -1$.

Quark doublet. In the small-Y convention $Q_L \sim (\mathbf{3}, \mathbf{2})$ with $Y_{Q_L} = +\frac{1}{6}$, giving $Q(u_L) = \frac{1}{2} + \frac{1}{6} = +\frac{2}{3}$ and $Q(d_L) = -\frac{1}{2} + \frac{1}{6} = -\frac{1}{3}$. Converting, $Y'_{Q_L} = 2 \times \frac{1}{6} = +\frac{1}{3}$, and

$$Q(u_L) = +\tfrac{1}{2} + \frac{1/3}{2} = \tfrac{1}{2} + \tfrac{1}{6} = +\tfrac{2}{3}, \qquad Q(d_L) = -\tfrac{1}{2} + \tfrac{1}{6} = -\tfrac{1}{3}, \tag{F.202}$$

again unchanged. The full dictionary for one generation is then read off by doubling every entry of the Y column of Table F.1: $Y'_{Q_L} = \frac{1}{3}$, $Y'_{u_R} = \frac{4}{3}$, $Y'_{d_R} = -\frac{2}{3}$, $Y'_{L_L} = -1$, $Y'_{e_R} = -2$, $Y'_H = +1$.

Notation Watch

When importing a hypercharge from any external table, first identify the convention by the lepton doublet: if $Y_{L_L} = -\frac{1}{2}$ it is the small-Y convention of this book (Eq. (F.3)); if $Y_{L_L} = -1$ it is the large-Y convention (Eq. (F.198)). Then convert with $Y' = 2Y$ if and only if the two conventions disagree. The same factor of two propagates into the abelian coupling ($g'_{\text{large}} = \frac{1}{2} g'_{\text{small}}$) and into the $[\mathrm{U}(1)_Y]$ entries of any anomaly sum, so a mixed convention silently breaks the cancellations of Table F.2; never mix them within a single calculation.

F.7.4 Mass schemes and the strong coupling

The masses tabulated in the previous section are not all defined the same way, and the difference matters most for the quarks. Two conventions are in play, and the appendix must record both and the bridge between them.

Pole versus $\overline{\text{MS}}$ mass. The *pole mass* M is the position of the pole of the full propagator, a gauge-invariant and renormalization-scheme-independent quantity; it is the natural mass for a particle that exists as an asymptotic state. The *$\overline{MS}$ mass* $\overline{m}(\mu)$ is the renormalized mass parameter in the $\overline{\text{MS}}$ scheme at scale μ; it runs with μ through the mass anomalous dimension γ_m computed in Chapter 24. For a quark these differ at order α_s because of the gluonic self-energy. The one-loop relation, whose derivation from the on-shell self-energy and the on-shell-versus-$\overline{\text{MS}}$ conditions is imported from Chapter 22 (with the color factor C_F replacing the abelian charge), is

$$M = \overline{m}(\overline{m}) \left[1 + \frac{4}{3} \frac{\alpha_s(\overline{m})}{\pi} + \left(K - \tfrac{4}{3} \right) \left(\frac{\alpha_s}{\pi} \right)^2 + \cdots \right], \tag{F.203}$$

where the coefficient $\frac{4}{3} = C_F$ is the fundamental Casimir (Chapter B) and $K \approx 13.4 - 1.0\, n_\ell$ collects the two-loop constant for n_ℓ lighter flavors. The shift is

sizable: for the top quark $\alpha_s \approx 0.108$ at $\mu = m_t$ makes $M_t - \overline{m}_t(\overline{m}_t) \approx 10$ GeV, so quoting a top mass of "173 GeV" without saying pole or $\overline{\text{MS}}$ is a $\sim 6\%$ ambiguity. The running of the $\overline{\text{MS}}$ mass between scales is the solution of the γ_m equation of Chapter 24; at one loop, for n_f active flavors,

$$\overline{m}(\mu_2) = \overline{m}(\mu_1)\left[\frac{\alpha_s(\mu_2)}{\alpha_s(\mu_1)}\right]^{12/(33-2n_f)}, \tag{F.204}$$

which is the formula one uses to translate, say, the bottom mass $\overline{m}_b(\overline{m}_b)$ quoted at its own scale up to the reference scale m_Z.

The strong coupling and Λ_{QCD}. The strong coupling is quoted as $\alpha_s(m_Z) \approx 0.1180$, a number that is only meaningful with its scale and its scheme ($\overline{\text{MS}}$, $n_f = 5$) attached. The alternative parametrization replaces the dimensionless $\alpha_s(\mu)$ by the dimensionful Λ_{QCD}, the scale at which the perturbative coupling formally diverges. Solving the one-loop renormalization-group equation of Chapter 27, $\mu\,\mathrm{d}\alpha_s/\mathrm{d}\mu = -(b_0/2\pi)\alpha_s^2$ with $b_0 = 11 - \tfrac{2}{3}n_f$, gives

$$\alpha_s(\mu) = \frac{2\pi}{b_0 \ln(\mu/\Lambda_{\text{QCD}})}, \qquad \Lambda_{\text{QCD}} = \mu \exp\!\left[-\frac{2\pi}{b_0\,\alpha_s(\mu)}\right], \tag{F.205}$$

which is the dictionary between the two ways of stating the same coupling. Inserting $\mu = m_Z$, $n_f = 5$ (so $b_0 = 11 - \tfrac{10}{3} = \tfrac{23}{3}$), and $\alpha_s(m_Z) = 0.1180$,

$$\ln\frac{m_Z}{\Lambda^{(5)}} = \frac{2\pi}{b_0\,\alpha_s(m_Z)} = \frac{6.2832}{7.667 \times 0.1180} = 6.94, \quad \Longrightarrow \quad \Lambda^{(5)} \approx 91188\,\text{MeV} \times e^{-6.94} \approx 88\,\text{MeV}. \tag{F.206}$$

This one-loop value is deliberately crude: the physical $\Lambda^{(5)}_{\overline{\text{MS}}} \approx 210$ MeV requires the two-loop running and the flavor-threshold matching that Chapter 27 carries, and the very definition of Λ is scheme- and order-dependent. We record Eq. (F.205) as the structural dictionary and defer the precise number to Chapter 27; the point for this appendix is only that "$\alpha_s(m_Z) = 0.118$" and "$\Lambda^{(5)} \approx 0.2$ GeV" are two encodings of one input, related by Eq. (F.205).

F.7.5 What the Standard Model does not explain

The appendix has so far presented the Standard Model as a closed accounting system: a gauge group, a representation table, one scalar, a counted list of parameters, and the scheme-labeled numbers that fix them. It would be dishonest to end without recording, plainly and dated, that two of those inputs are not merely *measured* rather than predicted—all of the parameters are that—but are measured to take values the theory gives no reason to expect, or cannot accommodate at all without extension. These are the open inputs, and they are the natural exit from this appendix into the frontier of Chapter 35.

The smallness of $\bar{\theta}$ (the strong-CP problem). The QCD Lagrangian admits a CP-violating term $\theta\,(g_s^2/32\pi^2)\,G^a_{\mu\nu}\widetilde{G}^{a\,\mu\nu}$, and the physical, basis-independent angle is the combination

$$\bar{\theta} = \theta + \arg\det(M_u M_d), \tag{F.207}$$

already identified in the parameter count (Eq. (F.89)), where M_u, M_d are the up- and down-type quark mass matrices, so that a chiral rotation that removes a phase from the masses moves it into θ and only the sum is observable (this is the accidental-symmetry analysis of Chapter 33). A nonzero $\bar{\theta}$ generates a neutron electric dipole moment; the experimental bound, as of the mid-2020s, is $|\bar{\theta}| \lesssim 10^{-10}$. The Standard Model contains no symmetry forcing $\bar{\theta}$ to vanish—it is a free parameter that could have been of order unity—yet it is measured to be smaller than 10^{-10}. Why a CP-violating angle that the theory permits, and that the electroweak sector demonstrably uses elsewhere (the CKM phase), should be so finely tuned to zero in the strong sector is the *strong-CP problem*. It is unexplained within the Standard Model. The leading proposed resolution promotes $\bar{\theta}$ to a dynamical field (the axion); the status of both problem and proposal as of the mid-2020s, and the instanton physics that makes $\bar{\theta}$ physical in the first place, are taken up in Chapter 35.

The neutrino sector: scale, ordering, and nature. The minimal Standard Model of Table F.1 contains no right-handed neutrino and forbids a renormalizable neutrino mass; the neutrinos are exactly massless at the renormalizable level. The observation of neutrino oscillations establishes that they are not, and this is the one place where the data *require* physics beyond the field content tabulated here. Three facts are open as of the mid-2020s. *(i) Scale.* Oscillations measure only the mass-squared splittings, $\Delta m^2_{21} \approx 7.5 \times 10^{-5}$ eV^2 and $|\Delta m^2_{31}| \approx 2.5 \times 10^{-3}$ eV^2, not the absolute scale; the sum of masses is bounded from above by cosmology at $\sum m_\nu \lesssim 0.1$ eV and from below by the larger splitting at $\gtrsim 0.05$ eV, but no individual mass is known. *(ii) Ordering.* Whether the spectrum is normal ($m_1 < m_2 < m_3$) or inverted ($m_3 < m_1 < m_2$)—the sign of Δm^2_{31}—is not yet settled. *(iii) Nature.* Whether neutrinos are Dirac particles (requiring a new ν_R and lepton-number conservation) or Majorana particles (their own antiparticles, with lepton number violated) is unknown; the decisive experiment, neutrinoless double-beta decay, has not observed a signal. The mixing in the lepton sector is parametrized by the PMNS matrix $U_{\rm PMNS}$ introduced earlier in this appendix, in exact analogy to the CKM matrix $V_{\rm CKM}$, but the absolute scale, the ordering, and the Dirac-versus-Majorana question are inputs the Standard Model neither predicts nor, in its minimal form, even accommodates. The mass mechanisms that extend it—most economically the seesaw—are the subject of Chapter 35.

This completes the conversion machinery. Any number used anywhere in the book—a coupling in a cross section, a mixing angle in a width, a quark mass in

a threshold—can now be traced back through Table F.7, Eqs. (F.203) to (F.205), and the hypercharge dictionary to the scheme-labeled inputs of the previous section, and converted to whatever scheme a given computation demands. With the defining data, the complete Lagrangian, the parameter count, the measured values, and now the conversions all collected in one place, this appendix provides a consolidated Standard Model reference for the entire book.

Further reading

The authoritative source for every measured number in this appendix, with its scheme, its date, and its uncertainty, is the Particle Data Group's *Review of Particle Physics* [382]; it is the table one consults to update any value quoted here. The construction of the Standard Model Lagrangian and its electroweak and flavor sectors is developed at textbook length in Peskin and Schroeder [396], Schwartz [432], Srednicki [454] and, with particular care for renormalization and the symmetry structure, in Weinberg [501]. The historical foundations of the electroweak theory are the original papers of Glashow [224], Salam [426], Weinberg [496]; the Higgs mechanism is Higgs [267]; and the three-generation origin of CP violation through the quark mixing matrix is Kobayashi and Maskawa [298]. These are for going beyond the present book; every result this appendix relies upon is proved in the chapters cited throughout the text.
